## Biographies

**Edward H Kerns** is Associate Director, Chemical and Screening Sciences, Wyeth Research, where he leads the in vitro physicochemical and metabolic profiling group for medicinal chemistry in drug discovery. He was previously with the Bristol-Myers Squibb Pharmaceutical Research Institute in analytical research and development. His research interests include the development of methods for property assessment, the use of property data in medicinal chemistry and the application of advanced analytical technologies for research and development.

**Li Di**, PhD is Principal Research Scientist II, Chemical and Screening Sciences, Wyeth Research, where she leads the Princeton, NJ physicochemical and metabolic property profiling group. She was previously with Syntex Research in drug discovery and development. Her research interests include the development and application of methods for

physicochemical and metabolic property measurement and the selection and optimization of discovery lead compounds, and solid state chemistry. Dr Di received her PhD, Chemistry from Brandies University in 1991 and completed a postdoctoral fellowship at Boston University, School of Medicine in Biophysics in 1993.

### 5.21.1 Introduction

As a result of the advances in high-throughput technologies, it is now possible to evaluate a large number of drug candidates. Key data in the attrition of new molecules are ADME (absorption, distribution, metabolism, and excretion) data based on *in silico*, *in vitro*, and *in vivo* results. Physicochemical properties of a molecule such as its  $pK_a$ , lipophilicity, and chemical stability in solution are independent of the solid state. Most drugs are administered orally. Therefore, the absorption of the drug substance in the body can be limited by its solid-state properties such as dissolution rate and solubility.

It has been stated that most new molecules in late development and in newly marketed products are poorly soluble.<sup>1</sup> The interface between drug discovery and development is very critical to optimize the candidate selection in order to reduce considerably the number of projects rejected during development. The 'developability assessment' has become an increasingly important criteria in addition to traditional drug efficacy and toxicity evaluation.<sup>2</sup>

The physicochemical properties of acidic or basic compounds in the solid state can be modified by salt formation.<sup>3</sup> However, an organic compound can have several solid forms, crystalline or not, and its physical properties in the solid state will depend on these solid forms. Therefore, the choice of a salt form has to be done in correlation with its 'polymorphic' behavior. In addition, particle size reduction and pharmaceutical formulations can enhance dissolution and thereby absorption.

The pharmaceutical community has recognized the relevance of the polymorphic behavior of organic substances since the epoch-making papers of Halebian and McCrone in the early 1970s.<sup>4,5</sup> According to McCrone,<sup>4</sup> for a compound "the number of forms known is proportional to the time and energy put in research on that compound." The market withdrawal of ritonavir in 1998 1 year after its launch was caused by its far too slow dissolution rate due to an insoluble

stable polymorph not found during development. The high number of efficacy and safety problems has led health authorities to set guidelines for the study of polymorphism and particle size for each new active ingredient, in connection with the properties of the drug product (ICH guideline Q6A<sup>6</sup>). The number of publications, review articles, and patents on the subject is constantly increasing since solid-state behavior is a major concern for drug safety and quality. There are a number of important reviews in the literature including strategic considerations at the interface of drug discovery and development.<sup>7–39</sup> For example, a recent review lists more than 500 drug substances exhibiting polymorphism.<sup>34</sup>

It is the objective of this chapter to summarize the thermodynamic rules that are the driving force of polymorphism, pseudo-polymorphism, and apomorphism in order to optimize the selection of salt and/or crystal form and to avoid the hurdles and problems involved in ADME and toxicology studies. This chapter also points to some strategies to overcome solubility problems by modification of salt form, crystal form, particle size, complexes, co-crystals, or formulations.

## 5.21.2 Basic Considerations

To introduce this section, **Figure 1** summarizes all possible organizations of organic substances in the solid state.

### 5.21.2.1 Definitions, Polymorphs, Solvates, Hydrates, Amorphous Forms

Polymorphism is the ability of a substance to crystallize into different crystalline forms. These crystalline forms are called polymorphs or crystalline modifications. Polymorphs have the same liquid or gaseous state but they behave differently in the solid state. There are two cases, enantiotropy, where at a given pressure and depending on temperature, each form has a domain of stability, and monotropy (only one form is stable whatever the temperature).

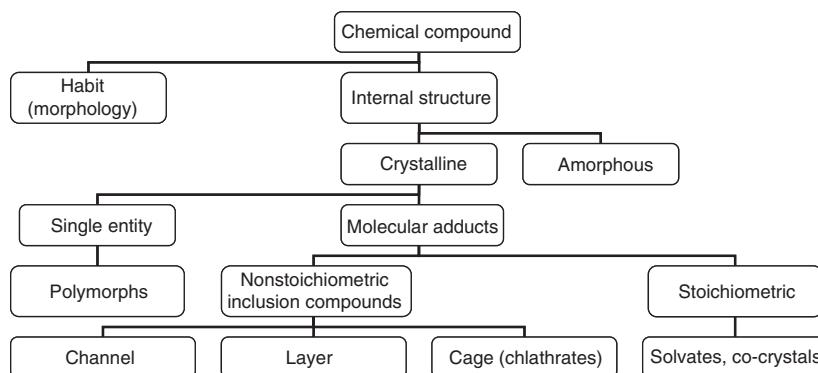

The expression pseudopolymorphism applies to hydrates and solvates. Solvent and also water may be part of the crystal lattice; a new compound is formed between a volatile phase and the drug substance. In addition solvates and hydrates of defined composition may have polymorphs.<sup>23,34</sup>

The amorphous state produced by precipitation, milling, drying, melting, lyophilization, and spray-drying is characterized by solidification in a disordered, random manner; it is structurally similar to the liquid state.

### 5.21.2.2 The Crystalline and Amorphous States: Basic Concepts

In crystalline substances atoms have defined positions and arrangements, and lattice energy plays a role in all solid-state reactions. This is not the case with amorphous substances, where it is difficult to know how and where counterions and excipients are bound. Methods used in polymer analysis may be used, e.g., thermal analysis, infrared (IR) and Raman spectroscopy, and nuclear magnetic resonance (NMR) spectroscopy.

On heating, crystalline substances undergo a first-order transition into the liquid or gaseous phase. If a physical property of a crystalline substance is plotted against temperature, a sharp discontinuity occurs at the melting point. For amorphous substances, there is no sharply defined melting point, and a change of slope occurs at the so-called glass transition temperature  $T_g$ . Below this temperature, the amorphous phase has certain properties of a crystalline solid (e.g., plastic deformation) and is termed 'glassy.' Above this temperature, the substance retains some of the properties of a liquid, e.g., molecular mobility, and is termed 'rubbery.'

**Figure 1** Possible solid phases of a chemical compound according to Haleblan. (Reprinted from Haleblan, J.; McCrone, W. *J. Pharm. Sci.* **1969**, 58, 911–929; Copyright © (1969), with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

### 5.21.2.3 Thermodynamic Background, Gibbs' Rules, and Phase Diagrams

The relationships between different phases are governed by the Gibbs' phase rule:

$$V = C + 2 - \Psi \quad [1]$$

where  $V$  is the variance,  $C$  the number of constituents, and  $\Psi$  the number of phases.

In the case of polymorphism,  $C = 1$ . If two solid phases are present and if both pressure and temperature vary, the variance is unity. If pressure is fixed, variance is zero. Phase diagrams of pressure versus temperature illustrate the different equilibrium curves for polymorphism (Figure 2).

For each solid form, there is a solid–liquid equilibrium curve and a solid–vapor equilibrium curve. In the case of enantiotropy, there is an equilibrium curve where both polymorphs are in equilibrium. In cases of 'monotropy' there is no thermodynamic transition between two phases since only one solid form is thermodynamically stable.

The ability of a system to perform work and to undergo a spontaneous change at constant pressure is measured by the Gibbs energy  $\Delta G$  (formerly called free energy).  $\Delta G$  has been defined in terms of enthalpy and entropy changes ( $\Delta H$  and  $\Delta S$ , respectively) at temperature  $T$  as:

$$\Delta G = \Delta H - T\Delta S \quad [2]$$

Gibbs energy ( $G$ ), enthalpy ( $H$ ), and entropy ( $S$ ) are state functions and the term  $\Delta$  can be omitted giving:

$$G = H - TS \quad [3]$$

At 0 K,  $G = H$ . Since the entropy  $S$  is always positive,  $G$  decreases with increasing temperature. The energy diagram  $G$  versus temperature at a given pressure reflects the transition observed between solid phases and between solid and liquid phases. If a transition between phases occurs, at this temperature both phases have the same Gibbs energy  $G$ .

In general, the thermodynamic relationship between two polymorphic phases is represented by plotting Gibbs energy as a function of temperature for each form. If the two curves intersect below the melting point of each polymorph, a reversible transition occurs at the temperature  $T_t$  of the intersection. At temperatures below  $T_t$ , polymorph A has the lower Gibbs energy and is therefore the thermodynamically stable form, while at temperatures above  $T_t$  polymorph B is stable. The transition point can be low — close to 40 °C in the case of tolbutamide or close to 100 °C in the case of propyphenazone or even higher than 200 °C.<sup>34</sup> In the case of monotropy, there is no intersection of the Gibbs energy of both forms and the higher melting form is always the thermodynamically stable form.

**Figure 2** Phase diagrams of pressure versus temperature for a single crystalline compound with two crystalline forms showing: (a) enantiotropic behavior (AB, sublimation curve of solid I; BC, sublimation curve of solid II; BF, solid I  $\leftrightarrow$  solid II equilibrium curve; CF, solid II melting curve); (b) monotropic behavior (AE, sublimation curve of solid II; EF, melting curve of solid II). Dashed lines represent metastable transformation curves.<sup>7</sup> (Reproduced with permission from Giron, D.; Grant, D. J. W. In *Handbook of Pharmaceutical Salts: Properties, Selection and Use*; Stahl, P. H., Wermuth, C. G., Eds.; IUPAC, Verlag Helvetica Chimica Acta: Zürich, Switzerland, 2002, pp 42–81.)

The relative position of the  $G$ -isobars ( $\Delta G_{A \rightarrow B}$ ) of different modifications can be determined by solubility experiments in a given solvent ( $S_A$  is the saturation solubility of the modification A and  $S_B$  the saturation solubility of the modification B):

$$\Delta G_{A \rightarrow B} = RT \ln(S_A/S_B) \quad [4]$$

Each crystal form has its own heat capacity, which is a function of the enthalpy  $H$  and the temperature. The heat capacities of solids at constant volume and constant pressure are about the same. The  $H$  isobars of two modifications are parallel. Their distance is the transition enthalpy  $\Delta H_t$ .

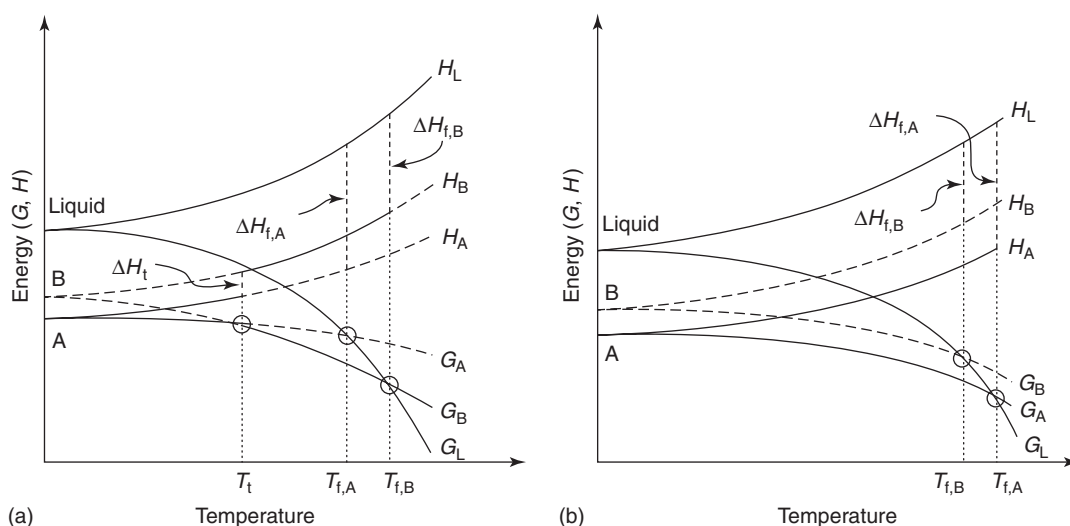

Burger<sup>35</sup> proposed that energy/temperature diagrams of the Gibbs energy and the enthalpy should be plotted, as functions of temperature. This proposal is the fundamental tool for the solution of complex polymorphic systems.<sup>36</sup> As shown in Figure 3a and b, a notable difference between enantiotropy and monotropy is the melting enthalpy of the higher melting form. In the case of enantiotropy, the higher melting form has the lower melting enthalpy. In the case of monotropy, the higher melting form has the higher melting enthalpy.

The relationship between melting enthalpies of two solid phases A and B and the heat of transition is approximately:

$$\Delta H_t = \Delta H_A^f - \Delta H_B^f \quad [5]$$

The phase diagrams of solvates and hydrates are more complex since binary mixtures are implied with different compositions. The new compound may have a congruent melting or a noncongruent melting (Figure 4). By heating, the melting of the solvate or hydrate may be observed followed by transformation to an anhydrous form, or the solvent is evolved with an endothermic transition into the anhydrous form. A series of such binary phase diagrams have to be considered if several compounds are formed. These diagrams are fundamental for the understanding of crystallization and drying steps.

The glass transition of amorphous solids is a second order transition and is characterized by a change of heat capacity. Above this temperature, the increase in molecular mobility facilitates spontaneous crystallization into the crystalline form with an exothermic enthalpy change after the glass transition. The use of amorphous forms is attractive, particularly for sparingly soluble compounds because of the enhanced solubility and dissolution rate over the crystalline state leading to increased bioavailability. Amorphous additives or excipients can give miscible phases with a new temperature of glass transition higher than the drug substance with the ability to stabilize it in the amorphous state. However, the amorphous state is thermodynamically unstable. The glass transition temperature,  $T_g$ , is lowered by water or other additives according to the Gordon–Taylor equation,<sup>40</sup> facilitating conversion to the rubbery state and hence facilitating crystallization. Moreover, uncontrolled crystallizations can occur at any time, and are accelerated by the presence of water. Figure 5 shows the changes in Gibbs energy between crystalline state, amorphous state, and liquid state.<sup>36</sup>

**Figure 3** Energy diagrams according to Burger showing the plots of Gibbs energy  $G$  and enthalpy  $H$  versus temperature for the solid and liquid phases of a single compound with two crystalline forms showing (a) enantiotropy and (b) monotropy. (Reproduced with permission from Giron, D.; Grant, D. J. W. In *Handbook of Pharmaceutical Salts: Properties, Selection and Use*; Stahl, P. H., Wermuth, C. G., Eds.; IUPAC, Verlag Helvetica Chimica Acta: Zürich, Switzerland, 2002; pp 42–81.)

**Figure 4** Phase diagrams of binary mixtures with formation of a new compound: (a) congruent melting point; and (b) incongruent melting point with dissociation of both components in liquid state (mostly occurring for solvates). (Reproduced with permission from Giron, D.; Grant, D. J. W. In *Handbook of Pharmaceutical Salts: Properties, Selection and Use*; Stahl, P. H., Wermuth, C. G., Eds.; IUPAC, Verlag Helvetica Chimica Acta: Zürich, Switzerland, 2002, pp 42–81.)

**Figure 5** Graphic plot of the changes in Gibbs energy among crystalline state, amorphous state, and liquid state. (Reproduced with permission from Giron, D.; Grant, D. J. W. In *Handbook of Pharmaceutical Salts: Properties, Selection and Use*; Stahl, P. H., Wermuth, C. G., Eds.; IUPAC, Verlag Helvetica Chimica Acta: Zürich, Switzerland, 2002, pp 42–81.)

Liquid crystals are a state of order between crystals and liquids. They have imperfect long-range orders of orientation and position. Thus, they can be fluid like a liquid and they can have anisotropic properties like crystals (e.g., cholesterol ester, phenyl benzoates, paraffins, surfactants, glycol-lipids). Thermotropic phases such as fenoprofen Na, Ca, or K with water have been reviewed.<sup>41</sup> The solid properties of chiral substances depend on phase diagrams and have been discussed elsewhere.<sup>42</sup>

When the solid phases are in contact with a solvent, the Gibbs phase rule applies. Depending on the temperature, different domains of stability of each crystal form may exist. In the case of enantiotropic polymorphism and in the case of solvates there are points where the solubility of forms is the same. An example of solubility versus temperature in the case of pseudopolymorphism is given in [Figure 6](#) for an acidic compound N existing as anhydrous, monohydrate, and trihydrate forms.

#### 5.21.2.4 Methods for Screening, Detection, Characterization, and Modeling

As demonstrated above, different solid phases can be stable in different environments. In the case of enantiotropy, for example, the low melting form is the thermodynamically stable form at temperatures below the transition point. A hydrate can crystallize from aqueous solution and an anhydrous phase from organic solutions, both crystalline forms

**Figure 6** Solubility curves (expressed as measured concentration) versus temperature. Experimental curves for compound N exhibiting an anhydrous crystalline form, a monohydrate, and a trihydrate.

being stable. An anhydrous phase can be stable at low relative humidity (RH) and a hydrate at high relative humidity. But ‘metastable’ or ‘unstable’ forms may coexist resulting from supersaturation or from desolvation or dehydration. In early development, salt selection and polymorphism screening are strongly correlated.<sup>16,17</sup>

All investigations on polymorphism should consider crystallizations and parameters such as temperature, coprecipitation, and slurry in different solvents and under different conditions in order to explore a great number of parameters.<sup>17,23,43–49</sup> Relevant high-throughput systems are now used at the drug discovery stage and a number of companies offer specialist equipment or services. These include Tessella Inc., USA; Solvias, Basel, Switzerland; RPD TOOL, Muttentz, Switzerland; Zinsser Analytic GmbH, Eschborner, Germany; Advantium Technology BV, The Netherlands; SCCI Inc, West Lafayette, USA; Ricerca Bioscience LLC, USA; Pharmaterials Ltd, London, UK; Transform Pharmaceuticals, USA; and Symix, USA. A list of preferred solvents based on electronegativity has been proposed.<sup>50</sup>

Quenching from the melt, lyophilization, and precipitation by adding cosolvent can yield the amorphous state. Heating/cooling curves produced using differential scanning calorimetry (DSC) or the combined technique DSC–spectroscopy permit forms that are not obtained from solvents to be observed.<sup>23,34</sup> Screening methods may yield the drug candidate in crystalline form via salts if feasible, detect solvate formation, manufacture ‘unstable’ or ‘metastable’ forms, study hydrate formation by water sorption–desorption experiments (hygroscopicity), consider solvate formation by including solvent atmosphere studies to the crystallizations, determine the effect of pressure and milling, grinding, or granulating, and manufacture the amorphous phase.

In crystallization systems, the thermodynamic stable form(s) depends on temperature and pH, whereas in atmosphere systems they depend on temperature and relative humidity. The analytical method here is generally x-ray diffraction followed by thermal analysis or spectroscopy. Thereafter, pure forms have to be manufactured and characterized, and thermodynamic relationships understood. For this purpose, DSC and microcalorimetry are the best techniques.<sup>23,34,51,52</sup> The thermogravimetric analysis can also detect solvates and hydrates.

Very often the differences in melting energies of the crystalline forms are too small for fair characterization; therefore, it is convenient to mix the solid phases and to equilibrate saturated solutions as slurries in different solvents and to analyze the insoluble solid. The transformation of metastable phases in the thermodynamic stable phases takes place via solvent-mediated transition.

A knowledge of the temperature of transition in cases of enantiotropy or solvates (hydrates) is often crucial. It can be determined by equilibration at different temperatures, evaluation from DSC, or calculation from DSC data. However, using the relationship of solubility to temperature is not accurate enough according to Burger.<sup>37</sup> Table 1 summarizes the data obtained for a neutral purine derivative MKS492<sup>53</sup> by using a combination of techniques.

X-ray diffraction is widely used for detection in high-throughput screening (HTS), calculation of the phase purity by calculating theoretical x-ray diffractions from the single crystal structure, and for quantification.<sup>23</sup> Modeling software allows crystal structures to be calculated from x-ray diffraction patterns.<sup>54–56</sup> The use of synchrotron is the most sophisticated technique. Polymorphism prediction software can contribute to such studies, but there are limitations.<sup>57,58</sup> The modeling of morphology can be successfully used to modify the crystal habit by changing the solvents of crystallization.

**Table 1** Example of characterization of polymorphs of the neutral purine derivative MKS492

### 5.21.3 Physicochemical Properties in the Solid State

#### 5.21.3.1 Overview of Relevant Properties for Drug Formulation

All physicochemical characteristics of the solid state are involved in polymorphism and pseudopolymorphism. The main properties affected are color,<sup>59–61</sup> morphology (crystal shape), volume, density, melting and sublimation temperatures, heat capacity, conductivity, viscosity, crystal hardness, refractive index, solubility, dissolution rate, stability, hygroscopicity, processability, and solid-state reactions. The single crystal structure of crystalline substance delivers the density and the morphology.<sup>23</sup> The density can be measured by pycnometry. According to the polymorphism rule of Burger, the higher the density, the greater the stability. Some polymorphs may have differences of melting point smaller than 1 °C or larger than 100 °C (e.g., riboflavin).<sup>62</sup> For ADME studies, solubility, dissolution in aqueous media as well as hygroscopicity and chemical stability are obviously of relevance.

#### 5.21.3.2 Solubility

It is trivial knowledge that the pH-dependent solubility of an ionizable drug depends on its p*K*<sub>a</sub>. The relation of solubility to temperature obeys the phase rule (eqn [1]). In cases of enantiotropic polymorphism and pseudopolymorphism, there is a thermodynamically fixed temperature at which the crystal forms in equilibrium have the same solubility (Figure 6). Measurements of solubility should take polymorphism into account. Immediate solubility can be different from equilibrium solubility and supersaturation can result from kinetic slow transformation into the stable form in the solvent at the temperature of measurement (see Section 5.21.4). The concentrations should be measured as a function of time when determining the solubility of the different forms because of possible transformation during the measurement. Furthermore, the temperature should be kept constant and should be accurately defined.

Solubility can be measured by phase solubility analysis,<sup>63</sup> where an excess of the solid remains in equilibrium with the saturated solution. The solution can be analyzed by gravimetry, high-performance liquid chromatography (HPLC), or spectroscopy. High-throughput methods of solubility determination have been developed by UV spectrometry or by

nephelometry based on the appearance of the solid phase. In all solubility determinations, soluble impurities can significantly influence the measured solubility.

The 'equilibrium' solubility must be studied with good knowledge of the different phases and with an analysis of the residual solid. Since several thermodynamic stable species may exist depending on the solvent, pH, temperature, and relative humidity, it is more appropriate to define the 'equilibrium solubility' of the stable forms in the medium and at the temperature considered. In the case of salts, exchange of the counterion with the buffers has to be considered.<sup>16,17</sup> A recent review<sup>67</sup> compiled solubility ratios of polymorphs of 55 compounds. The study concluded that the typical ratio of solubility is less than 2. In addition to the experimental data, the calculations of solubility based on thermal data, melting point, and melting energy showed good agreement. The solubility of solvates in water is higher than the solubility of nonsolvated forms.<sup>63</sup> This is demonstrated by the example of a compound P in Figure 7. Hydrates are less soluble (compound Q in Figure 8). The solubility of amorphous solids is generally higher than that of crystalline solids. Table 2 lists some published examples.

**Figure 7** Water solubility of solvates of compound P compared to the crystalline form A.

**Figure 8** Water solubility of compound Q as a hydrate and an anhydrous form.

**Table 2** Some examples of the impact of amorphous solid form on solubility

| Substance     | Forms                   | Solubility ratio              | Reference                           |
|---------------|-------------------------|-------------------------------|-------------------------------------|
| Glibenclamide | Amorphous/crystalline   | 14 (23 °C, buffer)            | Mosharraf and Nystrom <sup>68</sup> |

**Figure 9** Scheme of interface during dissolution ( $S_s$ , solubility at interface;  $S_b$ , solubility in solution).

### 5.21.3.3 Dissolution Rate and Intrinsic Dissolution Rate

For poorly soluble compounds, the absorption rate may be limited by the dissolution rate.<sup>64–66</sup> Dissolution rate (DR) and intrinsic dissolution rate (IDR) are defined according to the Noyes–Whitney equation:

$$\text{DR} : dM/dt = (A \cdot D/h) \cdot (S_s - S_b) \quad (6)$$

$$\text{IDR} : (dM/dt) \cdot (1/A) = k S_s \quad (7)$$

where  $A$  is the total surface area,  $D$  the diffusion coefficient,  $h$  the stagnant layer,  $S_s$  the solubility at the interface, and  $S_b$  the solubility in solution. Figure 9 illustrates the dissolution interface.

The dissolution rates of powders are often measured by the flow-cell method. Figure 10 illustrates the example of three polymorphic crystalline forms of the neutral purine derivative MKS492 (Table 1). The impact of polymorphs is not very high since the drug is dissolved within 20 min. The case of metolazone<sup>7</sup> shown in Figure 11 is quite different. The stable form is so insoluble that even after 10 h 80% dissolution is not reached.<sup>7</sup>

The dissolution rate per unit surface area (the intrinsic dissolution rate, eqn [7]) is independent of particle size and is therefore very appropriate for polymorphic studies. In the ‘disk’ method, the powder is compressed to produce a compact disk or tablet. The method is described in the US Pharmacopoeia.<sup>73</sup> Only one face of the disk is exposed to the dissolution medium and the cumulative amount dissolved per unit surface area is determined by ultraviolet spectrophotometry until 10% of the solid is dissolved. The slope of the plot of mass dissolved per unit surface area against time gives the intrinsic dissolution rate in appropriate units, e.g.,  $\text{mg min}^{-1} \text{cm}^{-2}$ . If a change in the slope is observed during the course of the experiment, this implies a change in the solid phase exposed to the solvent occurs during the experiment. Dissociation of the unionized form as well as a polymorphic change can occur.<sup>17</sup> The ratio of intrinsic dissolution of two phases is the same ratio as their solubility. According to Kaplan,<sup>74</sup> there is no problem of dissolution for a compound if the  $\text{IDR} > 1$ . IDR is considered to have good predictability for new drugs.<sup>75</sup>

The pharmaceutical significance of polymorphism is exemplified in Table 3 for poorly soluble substances. An amorphous form can improve behavior, but by a factor  $< 5$ . If different salt forms are possible with the same counterion, their IDR is also very relevant (Table 3). In the example given in the last two columns of Table 3, the monosodium salt is very soluble, the monohydrate somewhat less so, and the hemisalt is poorly soluble.

Drug solubility and dissolution rate are not constant throughout the gastrointestinal tract since  $S_s$  is pH dependent. Figure 12 illustrates the pH-dependent IDR of a monobasic compound R as base with a  $\text{pK}_a$  of  $c. 7$  in different hydrochloric acid (HCl) solutions. The effect of counterions on the IDR of this compound can be seen in Figure 13.<sup>3,17,139</sup>

**Figure 10** Dissolution rate of three crystalline forms of the neutral purine derivative MKS492.<sup>53</sup> All forms are quickly dissolved.

**Figure 11** Dissolution rate of two forms of metolazone. Both samples were micronized and had the same particle size distribution. The difference in behavior is significant. After 900 min (15h), form II had not reached 80% dissolution. (Modified from Giron, D. *Labo-Pharma-Probl. Techn.* **1981**, 307, 151–160.)

#### 5.21.3.4 Hygroscopicity and Interaction with Water Vapor Expressed by Sorption Isotherms

At a given temperature, the relative humidity (RH) is determined as the ratio of actual water vapor pressure over saturated water vapor pressure. The behavior of drugs at different temperatures and humidities for different climates is generally studied by gravimetry. The RH for gravimetric studies of water sorption and desorption can be controlled by saturated salt solutions<sup>76</sup> or by continuous humidification of a stream of air or nitrogen to which the solid sample is exposed (Dynamic Vapour Sorption (DVS), Surface Measurement Systems Ltd, UK). Solid-state hydration may occur leading to the formation of hydrates. X-ray diffractometers may be equipped with special sample cells for exposing the

G., Eds.; IUPAC, Helvetica Chimica Acta: Zürich, Switzerland, 2002; pp 42–81.)

sample to controlled temperature and humidity. **Figure 14** shows the sorption-desorption isotherms of different salt forms of a compound S.<sup>14</sup> **Figure 15** shows typical curves: (a) with a complete reversibility, a phenomenon generally observed for amorphous solids; and (b) with a typical hysteresis for a defined hydrate formation.

### 5.21.3.5 Chemical Stability

Chemical reactivity in the solid state is correlated with the nature of the crystalline modifications. Walkling<sup>77</sup> found that the two crystalline modifications of fenretinide behave quite differently. After 4 weeks at 25 °C, the stable form showed no detectable degradation, whereas the unstable form showed 8% degradation.

The amorphous state is very reactive.<sup>78</sup> **Table 4** illustrates the difference in reactivity between the two crystalline forms and the amorphous form of a very insoluble compound T (example 1). The crystalline form A is more stable than the crystalline form B and the amorphous form. Also, for a small molecule such as compound U (example 2) that is very

**Table 4** Influence of polymorphism on chemical stability in the solid state

|   | <i>Degradation (HPLC)</i>              |                              |
|---|--|------------------------------|
| <b>Example 1 (compound T, neutral, MW c. 1200, insoluble in water)</b>                        | <b>1 month at 80 °C (oxygen/water)</b> |                              |
| Crystalline form A  | No degradation                         |                              |
| Crystalline form B  | 0.5–1.5% degradation                   |                              |
| Amorphous form  | 2–3.5% degradation                     |                              |

| Amorphous form  | 5% degradation                         |                              |
| <b>Example 3 (compound V, neutral, MW c. 900)</b>   | <b>2 weeks at 50 °C</b>                | <b>Exposition 1200 klx h</b> |
| Monohydrate A   | No degradation                         | 10%                          |
| Monohydrate B   | 12%                                    | 23%                          |
| <b>Example 4 (peptide W, as base)</b>   | <b>1 week at 70 °C</b>                 | <b>Exposition 300 klx h</b>  |
| Crystalline form  | 10%                                    | 2%                           |
| Amorphous form  | 80%                                    | 38%                          |

soluble in water, the amorphous form is very unstable compared to the crystalline one. Large differences are observed for the two polymorphs, a dihydrate of compound V (example 3) with several chemical unstable functions. In the amorphous state of the peptide W (example 4), both the base and its hydrochloride were very unstable. However, the base could be obtained as a crystalline material with a substantial gain in stability.<sup>23</sup>

Polymorphs can behave differently under exposure to light as described for several drugs.<sup>23,79–82</sup> In the case of ethoxycinnamic acid, different photolytic degradation products were obtained for each form.<sup>83</sup> Generally, stability decreases as the particle size decreases.

### 5.21.4 Kinetic Aspects

The processing of drug substances and drug products involves solvent(s), temperature and pressure changes, as well as mechanical stress; different solid phases may coexist in the drug product. Organic substances show supersaturation behavior and unstable solid phases, which should not exist in defined temperature, pressure and humidity may behave like stable forms. These solid metastable phases obtained outside their domains of stability will convert to the thermodynamically stable forms at given temperatures, pressures, and relative humidities. These conversions driven by thermodynamics are governed by kinetics and are influenced by impurities, particle size, crystal defects, the presence of seeds, and temperature. An energy barrier has to be attained to start a transformation.<sup>84</sup> Many examples show that in early development metastable forms — often called ‘disappearing polymorphs’<sup>138</sup> — or amorphous solids are first obtained and then later thermodynamically stable forms can appear unexpectedly. Low purity of research samples might hinder crystallization. In the case of ritonavir, this acute problem led to the withdrawal of a marketed formulation.<sup>85</sup> Basic thermodynamic relationships may be understood by considering the phase diagrams and the stability domains: melting enthalpy rule by DSC, solvent-mediated transformation studies, dissolution, and solubility rule. **Figure 16** illustrates the decrease of solubility due to transformation in the thermodynamically stable form in water for a compound X.

**Figure 17** shows an old example of an abandoned indole derivative compound Y for which a slow transformation was initiated by the presence of seeds during storage.<sup>83</sup> Two batches of the base were manufactured as a metastable crystalline modification. Analysis of samples using formal stability studies showed transformation of the second batch while the first batch remained unchanged. The only difference between the two batches was the presence of a small amount of the insoluble stable form in the second batch.

**Figure 16** The case of compound X: (a) transformation of A into B; and (b) transformation of A and B into a monohydrate. The apparent solubility is the solubility of the metastable form. The thermodynamic solubility is the solubility of the stable form at saturation.

**Figure 17** Role of seeds in transformation during storage (compound Y). Two batches put in a stability program showed different behavior. Batch 1 did not change; however, because of the presence of seeds of the stable form B, batch 2 was transformed into form B. The higher the temperature, the faster the transformation (comparison of data after 6 months at 21 °C, 30 °C, and 50 °C).<sup>83</sup>

**Figure 18** Kinetic effect, compound Z: slow transformation of a crystalline anhydrous form into a monohydrate when stored in a nonmoisture-protecting packaging. The transformation is followed by the measurement of water in %. The transformation rate is batch dependent as demonstrated for batch 1 and batch 2 after 3 months at 40 °C/75% RH and 24 months at 30 °C/70% RH. No transformation occurred in tight packaging.

Figure 18 shows the slow transformation of an anhydrous form of a compound Z into a monohydrate during storage in nonprotective packaging for several months at 40 °C/75% RH and 30 °C/70% RH. The two batches showed different kinetics of transformation.

Mechanical stress can induce transformation in metastable or amorphous forms.<sup>86,87</sup> Amorphous solids are very difficult to stabilize, give product variability and stability.<sup>88,89</sup> Prediction of the fragility of amorphous solids can be calculated from thermal data<sup>90,91</sup> and storage condition rules proposed.<sup>91</sup> However, water greatly reduces the temperature of the glass transition<sup>92</sup> and spontaneous crystallization may occur during storage. This recrystallization is the basis of the quantitative determination of amorphous content in drug substances.<sup>93–95</sup>

Kinetic effects have to be considered for ionizable drug substances since competition with the chloride counterion can play a role in the gastric fluid.<sup>96,97</sup> For acidic salts, dissociation into the base may slowly occur.<sup>16,17</sup>

### 5.21.5 Modulation of Physicochemical Properties

According to Johnson and Wolfgang,<sup>98</sup> assessment of the potential toxicity of new pharmaceuticals is also correlated to their bioavailability in toxicology studies. They recommend a scheme for optimizing oral bioavailability in toxicology studies, which is comparable to the recommendations for developability assessment<sup>2</sup> of poorly soluble substances. This section gives some suggestions for modifying the physicochemical properties of drug substances in order to enhance their bioavailability.

#### 5.21.5.1 Effect of Salt Form

Low bioavailability is most common with oral dosage forms of poorly water-soluble, slowly absorbed drugs. More factors can affect bioavailability when absorption is slow or incomplete than when it is rapid and complete. The alteration of the pH of the formulation is the first way to solubilize acidic or basic compounds. Lin<sup>99</sup> described the example of L-735,524, a human immunodeficiency virus (HIV) protease inhibitor. When given orally as a suspension in 0.5% methylcellulose (MC, pH 6.5), its bioavailability was 18% in the rat and 16% in the dog. When the same dose was given in a citric acid solution (pH 2.5), bioavailability rose to 75% in the dog but remained at 20% in the rat.

For most substances limited absorption is due to solubility; therefore, for acidic and basic compounds the relationship between solubility and pH (or intrinsic dissolution rate and pH) has to be assessed (Figure 12). Salt formation can modify this behavior (Figure 13), but reprecipitation or dissociation may appear during absorption in living cells.

The fourth example given in **Table 3** (see **Section 5.21.3.3**) shows the impact of salt formation on the IDR of a weak diacidic drug. A factor of about 100 in IDRs was found between the sodium hemisalt and the monosodium salt.

For the basic protein kinase inhibitor LY333531, which was developed for the treatment of complications in diabetes, Engel and co-workers<sup>100</sup> selected the salt form based on a two-tier approach. The following salts were manufactured, hydrochloride, sulfate, mesylate, succinate, tartrate, acetate, and phosphate, and their physicochemical properties compared. In the first tier, selection was done based on crystallinity, solubility, and manufacturing purification. The remaining candidates were hydrochloride anhydrous and monohydrate and the mesylate monohydrate. The polymorphic behavior, stability, filterability, purification behavior, and bioavailability in dogs were compared. The mesylate monohydrate was selected due to a 2.6-fold higher bioavailability. This difference was presumed to be due to the fivefold higher solubility of mesylate in water; the common ion effect of hydrochloride in the GI tract was also discussed.

Piroxicam is a zwitterion with two  $pK_a$  values: 1.86 and 5.46. Its monoethanolamine salt was proven to have the highest bioavailability corresponding to the highest dissolution rate at pH 6.8.<sup>101</sup> Patent applications for the enhancement of bioavailability are increasing. For example, the arylsulfonic acid salts improve oral bioavailability of imidazopyrimidine antiviral agents as base by a factor greater than 2.<sup>102</sup> A factor of about 10 was also found between bendazac and its lysine salt.<sup>103</sup> A recent example demonstrating the importance of salt selection in obtaining in vivo exposure has been given for the weak acid PNU-103017 and its calcium, sodium, lysine, and arginine salts.<sup>104</sup> The solubility of codeine base at  $8.3 \text{ mg mL}^{-1}$  in water was increased to  $435 \text{ mg mL}^{-1}$ .<sup>105</sup>

Enhanced solubility does not necessarily translate into better in vivo absorption. There are several reports of salts with differing solubilities behaving similarly in bioavailability studies. Better solubility may simply be a pH effect that is cancelled in the gastric or intestinal milieu, with solubility changing to reflect local pH. Conversely, it is also feasible that the pH engendered by a salt in its microenvironment facilitates dissolution, the salt acting as its own buffer. Once in the solvated state, the dynamics of transport or reprecipitation may be such that there is a net enhancement of amount dissolved and absorbed.

According to Davies, the motto “changing the salt, changing the drug”<sup>106</sup> should be taken into consideration. Once a drug has been marketed, there may be sound reasons for reformulating it in a different salt form to change its physicochemical properties. An example is provided by the analgesic propoxyphene, which was originally formulated as a hydrochloride salt. Propoxyphene was widely used in a fixed-dose combination with aspirin, but since aspirin proved to be unstable in close physical contact with propoxyphene hydrochloride, a reformulation was necessary. When propoxyphene was reformulated as a napsylate salt, there was no problem of aspirin instability. The relative insolubility of the napsylate salt form compared with the hydrochloride was also an advantage, as it reduced the potential for parenteral abuse of propoxyphene and its toxicity in oral form. The pamoate salt of pyrantel is reported to be three times as effective as the citrate against large bowel parasites, including resistant strains, because of its lower rate of absorption and consequently greater retention in the gastrointestinal tract. Some cations and anions are known to be associated with toxic effects and will contribute to the intrinsic toxicity of the salt form. For example, lithium cations have no toxic effect in small quantities but when ingested in large amounts can cause irreversible damage to the kidney. Similarly, tartrate anions, which are usually absorbed only minimally from the gastrointestinal tract, can cause renal damage if they reach the circulation in high concentrations. In addition, pravadoline maleate caused renal tubular lesions in the dog, as a result of maleic acid formed from the maleate anion.<sup>106</sup>

The relevance of salt selection and its impact on bioavailability were first emphasized by Berge and colleagues<sup>107,108</sup> who discussed its most important factors. Examples of this and discussions about the counterion have been reviewed recently,<sup>3</sup> with in-depth discussions on possible counterions and their physical and toxicological properties, the physicochemical properties of salts and polymorphs, the pH effect, as well as the toxicological impact. Examples of salt selection and manufacturing are presented and some patent issues discussed. **Table 5** offers a comparison of the bioavailability of the acid (3%), the monosodium salt (15%), and the disodium salt (50%) of PNU-140690.<sup>109</sup> **Table 5** also gives the results of the solubilities at saturation (maximal concentration in water) and the IDR (see <sup>3</sup>: p. 93). The ranking of bioavailability and of in vitro results are the same.

Counterions can affect all properties from melting point to solubility, hygroscopicity, stability, crystallinity, morphology, and feasibility. The increase in solubility can be obtained with strong acids for weak bases or with carboxylic or hydroxylic acids. Mono-, di-, or tri-functional groups may give competition between different salt forms. Kinetic factors are also important since reprecipitation into the base may occur for very weak acids or bases. Competition between salt-forming agents and buffers of measurement are often observed.<sup>15</sup>

**Table 6** shows the results of a screening for salt selection of a new drug candidate. A compromise between solubility and stability was found and the hydrogen maleate salt (hml) chosen. **Figure 19** demonstrates the impact of salt forms on the morphology of crystals obtained for a drug candidate.

**Table 5** Comparison of bioavailability in dogs and IDR in water for PNU-140690 (acid,  $pK_a$  6.2 and 7.6, monosodium and disodium salts)

| <i>Form</i>     | <i>Bioavailability (%)</i> | <i>IDR (<math>\mu\text{g cm}^{-2} \text{s}^{-1}</math>)</i> | <i>Max. concentration in water (<math>\mu\text{g mL}^{-1}</math>)</i> |
|-----------------|----------------------------|---|---|
| Acid            | 3                          | <0.2  | 60  |
| Monosodium salt | 15                         | 115   | 530   |
| Disodium salt   | 50                         | 450   | 650   |

hfu, hydrogen fumarate; hml, hydrogen maleate; ch, hydrochloride; hta, hydrogen tartrate; hmo, hydrogen malonate.

The selection of the salt form is the first study to be done with new drug candidates. All high-throughput screening systems considered at drug discovery provide salt selection as well as polymorphism screening (*see* Section 5.21.2.4).

### 5.21.5.2 Effect of Polymorph, Solvate, and Amorphous Form

The absorption rates of many poorly water-soluble substances depend upon the rate of drug dissolution. Because of the effect of solid-state forms on solubility and dissolution rates the use of different amorphous polymorphs would be expected to affect the bioavailability. Some well-known examples are chloramphenicol palmitate<sup>4</sup> and carbamazepine.<sup>110</sup> Differences were also observed for chlortetracycline<sup>111</sup> and sulfamethoxazole.<sup>112</sup> Other examples are summarized in <sup>113</sup>. However, no impact in vivo was found for proglumetacin maleate<sup>114</sup> and phenobarbital.<sup>115</sup> The amorphous solid state is extremely attractive but its stabilization is a challenge.<sup>116</sup>

**Figure 19** Surface electron microscopy of different salt forms of a drug candidate: (a) base; (b) hydrochloride; (c) hydrogen maleate; and (d) mesylate. (Reproduced with permission from Giron, D.; Grant, D. J. W. In *Handbook of Pharmaceutical Salts: Properties, Selection and Use*; Stahl, P. H., Wermuth, C. G., Eds.; IUPAC, Verlag Helvetica Chimica Acta: Zürich, Switzerland, 2002, pp 42–81.)

#### 5.21.5.3 Effect of Particle Size

**Figure 20** illustrates the impact of particle size on dissolution. As a consequence correlation with bioavailability has been described for a great number of poorly soluble drugs.<sup>117–124</sup> Bioavailability may be increased by micronization.

#### 5.21.5.4 Complexation, Adducts, and Formulation

The excipients<sup>125</sup> used to solubilize drugs in oral and injectable dosage forms include pH modifiers, water-soluble and water-insoluble organic solvents, surfactants, medium-chain triglycerides, long-chain triglycerides, cyclodextrins, and phospholipids.

The group of solid dispersions comprises different physical systems such as simple eutectic mixtures (reduction of particle size), glass dispersions, amorphous precipitates, or complex formation. Solubility properties differ depending on the properties of the carrier, e.g., griseofulvin absorption increases by solid dispersion based on polyethyleneglycol formulation. Solid dispersions have been reviewed in the literature.<sup>126–129</sup> Certain solid dispersions are formed in order to maintain the drug substance in the amorphous state and are called ‘solid-solutions.’

Polyvinylpyrrolidone polymers have been successfully used. For example, a fourfold increase in bioavailability was obtained for indometacin.<sup>130</sup>

Cyclodextrins are natural derivatives that are able to form complexes with drug substances with a considerable enhancement of bioavailability. Cyclodextrins do not permeate the gastrointestinal mucosa, so their action is to increase availability of dissolved drug substance at the aqueous mucosal surface. There are more than 600 publications on the use of cyclodextrins. Comprehensive reviews have been published by Thomson<sup>131</sup> and Loftsson.<sup>132,133</sup> **Table 7** gives the characteristics of the major cyclodextrins.

Co-crystals (multicomponent pharmaceutical phases in solid state) are able to overcome poor solubility by opening up a large space for nonionizable drug substances. By adjusting the nonactive component, enhancement in the solubility and bioavailability is expected.<sup>134</sup>

Micellar solubilization with surfactants giving colloidal clusters in solution known as micelles has the ability to increase the solubility of sparingly soluble drug substances.<sup>135</sup> Liposomes are self-forming lipid bilayers that are able to solubilize poorly soluble substances.<sup>136</sup> Microemulsions are clear isotropic mixtures of oil, water, and surfactants.<sup>137</sup>

**Figure 20** Influence of the particle size on the dissolution rate of reserpine hydrochloride in 0.1N HCl: (a) particle size 90% < 40  $\mu\text{m}$ ; (b) particle size 90% < 52  $\mu\text{m}$ ; and (c) particle size 90% < 120  $\mu\text{m}$ . ## 5.21.6 Conclusion

The solid-state properties of drug substances have a direct impact on the physicochemical properties relevant for ADME and early toxicity studies. An early selection of the salt and the crystalline form for the development of new active ingredients is recommended. The objective of this selection should be to achieve a soluble, less hygroscopic, reproducible, and stable crystalline form. This should result in a good bioavailability and a linear exposure in toxicity studies. In difficult cases, greater efforts are necessary to enhance solubility via special formulations within a ‘developability assessment.’ The thermodynamic rules show that depending on temperature, pressure, and concentration in solvents, different stable forms may exist. These forms may be incorrectly assessed if phase diagram rules are ignored. Special formulations produced in order to maintain drug substances in a metastable or unstable state should be used with caution in order to obtain reproducible results. Therefore, the thermodynamic principles described in this chapter are highly recommended to avoid misinterpretation of chemical and physical stability during ADME and early toxicity studies.

## Biography

**Danielle Giron** studied engineering at the School of Industrial Chemistry and Physics in Lyon. She holds an MS and PhD in analytical chemistry from the University of Lyon. She joined Sandoz in 1971 to establish the laboratory of thermal analysis and polymorphism. With different positions in analytical and research development at Novartis, she gained a broad experience of the development process from research to production for drug substances and drug products. She has written more than 50 published journal articles and book chapters, and speaks regularly at conferences in Europe and the US. She is President of the Swiss Society for Thermal Analysis and Calorimetry (STK).

Dr Giron won the STK Award in 1992 and the Novartis Leading Scientist Award in 2000. She is presently Group Leader and Principal Fellow at Novartis and is also a private docent at the University of Basel.

### 5.22.1 Introduction: Absorption, Distribution, Metabolism, and Excretion (ADME) in the Drug Discovery Process

The pharmacokinetic behavior of a drug has to be considered during the drug discovery process in order to find compounds that will reach their site of action and maintain their concentration long enough to be able to produce the desired effect. Specific properties are needed for an orally administered drug that is to be dosed once daily. Bioavailability of a compound depends on both absorption and first pass metabolism. To obtain the correct dose regimen, distribution and elimination (metabolism and excretion) properties are important. These ADME properties (absorption, distribution, metabolism, and excretion) are evaluated during the drug discovery process using *in silico*, *in vitro*, and/or *in vivo* systems.

*In vitro* and *in vivo* studies can only be performed on synthesized compounds and are capacity limited, even though high-throughput techniques have largely increased *in vitro* capacity during recent years. The complexity of the experimental data, usually higher for *in vivo* systems compared to *in vitro*, has to be considered as well. Great efforts have been made to develop *in vitro* models that may help to understand and interpret factors that influence the pharmacokinetic characteristics of a compound *in vivo*. However, even *in vitro* systems comprise various factors that influence the behavior of the compounds in different ways.

**Figure 1** Deconvolution of ADME properties to partial effects.

In *silico* methods, in contrast, can also be used for virtual, i.e., not synthesized compounds and can, in general, be applied on very large compound libraries. Nevertheless, in *silico* methods are based on *in vitro* and/or *in vivo* measurements and their applicability is limited by the information that was extracted from these experiments. The quality of the models will depend on the quality, complexity, and understanding of the experimental data they are based on. In order to accelerate the discovery of new chemical entities (NCEs) with acceptable pharmacokinetic properties an increasing number of *in silico* ADME models has been developed. The number of reviews in this area published within the last few years shows the interest in these models.<sup>1–8</sup>

ADME properties are influenced by different factors (Figure 1). Absorption is determined by solubility, permeability (active and passive), and first pass metabolism across the gut wall. Distribution is controlled by permeability through various membranes (e.g., the blood–brain barrier) and by plasma protein or tissue binding. Metabolism is determined by the interaction with metabolizing enzymes and the reactivity of the compound. Excretion of a compound is governed by its physicochemical properties and the interaction with transporter systems. The more general term elimination comprises both metabolism and excretion of the compound.

Many of these factors are themselves affected by different molecular properties, like lipophilicity and hydrogen bonding, but also by structural features like protein binding site complementarity. The passive transcellular permeability of a compound, for instance, is often modeled on molecular size, lipophilicity, and/or hydrogen bonding. All three properties are correlated to each other and a simple, but sufficient model may be achieved by using only one or two of these properties.<sup>9–11</sup> However, if absorption is not primarily passive, i.e., if a carrier-mediated system is involved, the relationship between the molecular structure and the transport protein needs to be considered and therefore three-dimensional quantitative structure-activity relationship (3D-QSAR) techniques or pharmacophoric definitions have to be applied.

The scope of the analysis needs to be considered as well. Local models, on the one hand, are useful when a closely related family of compounds is studied. Global models, on the other hand, are needed if the entire chemical space is to be described in order to identify new interesting chemical series. In both scenarios the experimental data, the compounds, and the descriptors used are critical for building the model. In general, local models for congeneric series of compounds yield acceptable prediction capability within the series. Quantitative models can be obtained and are useful for closely related compounds. For global models, which by definition explore the chemical space, the experimental data most often involves several, possibly unknown factors. For such a diverse data set, a qualitative model that

can discriminate between compounds that are active and nonactive (permeable and nonpermeable, inhibiting and noninhibiting of cytochrome P450 should be considered.

ADME predictions are often based on quantitative structure–activity (property) relationship (QSAR or QSPR) approaches. Several statistical techniques are available and have been used to correlate molecular descriptors to the ADME properties ranging from multiple or single regression analysis, multivariate data analysis like partial least squares analysis (PLS) to nonlinear methods like regression trees or neural networks.<sup>9,12–16</sup>

Molecular descriptors used for ADME modeling need to explain relevant properties such as size, lipophilic and hydrophilic profiles, hydrogen bonding patterns, and structural features specific for the property under analysis, e.g., pharmacophores for a metabolizing enzyme. Additionally, acidity and/or basicity ( $pK_a$ ) of a compound and its (aqueous) solubility need to be considered for a proper description. Useful descriptors can range from simple atom counts, e.g., number of hydrogen bond donor and acceptor atoms, to more elaborate molecular structure description (like volume or polar surface area) or to quantum chemistry derived descriptors, e.g., atomic charges or HOMO and LUMO energies. One way to classify descriptors is to define them as (0D) 1D, 2D, and 3D (and even 4D) descriptors. However, the definition for each class is somewhat ambiguous.<sup>17,18</sup> 1D (0D) descriptors can be defined as those for which no structural information related to the connectivity of the atoms is necessary. Only the sum formula of the molecule is needed. Molecular weight and atom counts, number of atoms or number of a specific atom type, would fit into this definition. ‘Bulk descriptors,’ including log P, for which calculation of at least a 2D structure is necessary, have also been suggested as 1D descriptors.<sup>18</sup> 2D descriptors consider the 2D representation of the molecules. These descriptors are often referred to as topological descriptors. Typical 2D descriptors are connectivity indices and fragment counts, the latter are also suggested as 1D descriptors.<sup>17</sup> 3D descriptors are derived from the 3D structure and both molecular volume and polar surface area would fit into this category. However, polar surface area, which has become widely used in permeability models<sup>11,19,20</sup> can also be obtained from the 2D structure alone.<sup>21</sup> In this chapter we classify the descriptors according to the molecular property they are intended to describe, present descriptors derived from molecular interaction fields (MIFs) and add some other descriptor sets that have been used in ADME predictions.

### 5.22.2 Physicochemical Descriptors

Fairly simple descriptors have been shown to give good correlations to ADME properties. In 1997, Lipinski proposed the ‘rule of 5,’ an important, but not sufficient filter for oral drugs.<sup>22</sup> This ‘rule of 5’ comprises four rules (molecular weight  $MW < 500$ ,  $Clog P < 5$ , number of hydrogen bond donor atoms  $HBD < 5$ , and number of hydrogen bond acceptor atoms  $HBA < 10$ ) and states that good absorption is less likely for a compound if two or more of these rules are violated. However, this can only help for a first interpretation of a molecule – a compound that fulfills all criteria is more likely to be permeable and, thus, also more likely to be orally bioavailable. Nevertheless, not all compounds that do fulfill the criteria have good bioavailability or even good absorption (e.g., acyclovir, fluvastatin, and terbutaline all have bioavailability below 30%,<sup>23</sup> acyclovir also has a fraction absorbed below 30%,<sup>24</sup> and they do not violate any of Lipinski’s rules). In addition, compounds that do not fulfill the criteria are successfully used as drugs (e.g., cyclosporine or digoxin have both bioavailability up to 60% and thus also reasonable high absorption<sup>24</sup>). Since the ‘rule of 5’ is based on the distribution of properties that were calculated for several thousand drugs, such outliers are to be expected. Surprisingly, most of these outliers belong to a few specific compound classes, some of which are known to be substrates to a transport system.<sup>22</sup>

The above study and other analyses show that descriptors for molecular size, lipophilicity, and hydrogen bonding are important for modeling ADME properties.<sup>22,25,26</sup> In the following the impact of these properties on ADME will be illustrated, showing how these properties can be described and explaining especially those descriptors that have been used in ADME predictions.

#### 5.22.2.1 Molecular Size and Shape

Molecular size is generally important for the permeability of compounds. There are reports in the literature showing a correlation between transcellular and/or paracellular permeability and molecular size,<sup>25,27</sup> whereas others emphasize that molecular size determines which absorption route a drug can take: it is suggested that polar compounds with low molecular weight (below 200) may be able to use the paracellular route.<sup>28,29</sup> However, the size limit varies in different regions of the intestine and species differences in paracellular transport have also been shown.<sup>30,31</sup>

Molecular size can be assessed in different ways. The molecular weight is easily calculated from the molecular formula. Also a simple atom count can be seen as a crude measure of molecular size. Other descriptors often used are molecular volume and molecular surface. The molecular surface can be defined as the Van der Waals surface of the

**Figure 2** Solvent-accessible surface area.

molecule, assuming all atoms to be spheres defined by their Van der Waals radii. Another possibility is to define a solvent-accessible surface area with the help of a spherical probe that is 'rolled' over the Van der Waals surface. This probe usually has a radius of about 1.4 or 1.5 Å, thus being the size of a water molecule. However, the solvent-accessible surface area can be defined in two ways, either by the center of the spherical probe<sup>32</sup> or by the contact and re-entrant surface of such a probe.<sup>33,34</sup> The latter type of solvent-accessible surface is often referred to as the Connolly surface, since Connolly *et al.* proposed a feasible and fast algorithm to obtain such a surface.<sup>34</sup> The computational method used will influence the results; in particular, the difference between the solvent-accessible surface area as defined by Lee and Richards and the Connolly surface should be noted (see [Figure 2](#)). Other molecular surfaces are contour surfaces that can be defined by molecular properties like electron isodensity, molecular electrostatic potential, or molecular orbitals.

The molecular volume can be defined according to the molecular surface, e.g., the Van der Waals volume. It can also be determined experimentally from the molecular weight, the liquid density, and the Avogadro number. McGowan's characteristic volume is defined by the sum of atomic volume parameters corrected by a factor for the number of atoms.<sup>35</sup> Another size descriptor is the molar refractivity, which is directly related to the molar volume (molecular weight divided by the liquid density) and a function of the refractive index of the liquid, thus containing information about polarizability. Refractivity is an additive property similar to the volume descriptors and can thus easily be calculated by a group contribution method. Molecular size descriptors are usually highly correlated,<sup>10,17</sup> which makes it unnecessary to use all available descriptors.

Shape descriptors are also often highly correlated to molecular size. Ovality is defined as the ratio between the surface of the molecule and the surface of a sphere with the same volume. Topological indices like connectivity<sup>36,37</sup> or shape indices<sup>38</sup> also give information about the molecular shape. Furthermore, flexibility measures, e.g., the number of rotatable bonds, can be interpreted as information about both size and variable shape of the molecule. It was suggested that less flexibility as measured by the number of rotatable bonds improves oral bioavailability.<sup>39</sup>

Molecular size and shape descriptors are usually part of every descriptor set used in ADME modeling, although they are not necessarily important in the final model. This does not imply that molecular size does not influence the ADME property in question, but rather that molecular size may be considered implicitly in other descriptors like lipophilicity or polar surface area.

### 5.22.2.2 Lipophilicity and Hydrophobicity

Lipophilicity, the 'love of fat,' and hydrophobicity, the 'fear of water,' are often taken as synonyms, but do not exactly describe the same property: hydrophobicity considers the interaction between the compound and water, whereas lipophilicity is a measure of the interaction with a lipid. It has been suggested that hydrophobicity may be a component of lipophilicity<sup>40,41</sup>:

$$\text{lipophilicity} = \text{hydrophobicity} - \text{polarity}$$

[1]

and that lipophilicity may consist of a cavity (volume or size related) and a polarity term (the combination of hydrogen bonding and dipolarity/polarizability)<sup>42</sup>:

$$\log P = aV + \Lambda$$

[2]

( $V$  = molecular volume,  $\Lambda$  = polarity term)

It has long been assumed that molecular size in general and hydrogen bonding or polarity together are largely able to explain lipophilicity.<sup>43,44</sup> In summary, hydrophobicity can be seen as a (mostly) size- or cavity-related term, i.e., only dependent on the molecule itself, whereas lipophilicity includes a polarity factor and depends additionally on the lipid used. Lipids with different polar properties will give different lipophilicity values for the same compound, a phenomenon that is used for assessment of hydrogen bonding.<sup>42,45,46</sup> Lipophilicity, as the ability of a molecule to mix with an oily phase rather than with water, is usually measured as partition coefficient,  $P$ , between the two phases and is often expressed as  $\log P$ .<sup>47</sup>

Lipophilicity was long ago found to correlate to drug potency – the first mention of such a correlation goes back to around 1900.<sup>48</sup> Lipophilicity has also been found to affect a number of pharmacokinetic parameters: higher lipophilicity gives, in general, lower solubility, higher permeability in the gastrointestinal tract, across the blood–brain barrier and other tissue membranes, higher affinity to metabolizing enzymes and efflux pumps, and higher protein binding.<sup>49–52</sup> Good correlations between lipophilicity and such ADME properties can often be obtained, at least within a congeneric series of compounds.<sup>53</sup> However, lipophilicity alone will not be able to predict any ADME property for structurally diverse compounds. For example, Yazdani *et al.* state that there is no simple mathematical correlation between lipophilicity and Caco-2 permeability for a diverse set of more than 50 drugs, although a cut-off value for high permeability could be determined ( $\log D_{\text{oct}} > 0.5$ ).<sup>54</sup> Other workers have reported both linear, bilinear, sigmoidal, or parabolic relationships between permeability and lipophilicity.<sup>12</sup>

Due to the importance of lipophilicity, different ways to assess the value experimentally and to calculate  $\log P$  have been developed: the shake flask method, chromatography,<sup>55</sup> or pH titration<sup>56</sup> are routinely used to obtain experimental lipophilicity values. Since it has been found that  $\log P_{\text{oct}}$ , the logarithm of the partition coefficient between *n*-octanol and water, can be calculated from the sum of the contributions ( $\pi$ ) of the molecular fragments,<sup>57</sup> various fragmental approaches for calculating  $\log P$  have been developed. Either molecular fragments and correction factors,<sup>58–60</sup> or atomic contribution with rather complicated atomic types (Alog P)<sup>61–64</sup> or both approaches together are being used.<sup>65</sup> Other calculation methods include Abraham's linear free-energy relationship (LFER) approach<sup>66</sup> and quantum chemical methods.<sup>67,68</sup> However, quantum chemical methods are not as widely used since they are usually more computationally intensive and do not give better results than the empirical approaches.<sup>58,69</sup> In the mid-1990s, a 3D descriptor for lipophilicity became available, the molecular lipophilicity potential<sup>70–72</sup>: atomic lipophilicity values are projected onto the molecular surface to visualize the 3D property. Available programs and methods for  $\log P$  calculations have been reviewed repeatedly (see 5.27 Rule-Based Systems to Predict Lipophilicity).<sup>69,73–76</sup>

The partition coefficient of a molecule in a system depends on the lipophilic phase used. *n*-Octanol has become the 'golden standard,' being easy to work with and having physicochemical properties similar to lipids. Furthermore, a lot of reference data exist by now.<sup>49,76</sup> Both experimentally obtained and calculated  $\log P$  values usually refer to the partitioning between *n*-octanol and water, if nothing else is stated. This parameter is sometimes also termed  $\log K_{\text{OW}}$ .<sup>17</sup> However, it is important to distinguish between the pH-independent partition coefficient,  $P$ , and the pH-dependent distribution coefficient,  $D$ . The former expresses the quotient of the concentrations of the neutral compound in both phases, whereas the latter expresses the quotient of the concentration of all ionized and unionized species of the compound in both phases. It is generally assumed that (almost) only the unionized species can partition into the lipid phase.<sup>49</sup> Although ionized species are probably able to partition into the lipid phase, at least together with a counter ion,<sup>77</sup> the partition coefficient of such an ionic species is usually about three orders of magnitude lower than the partition coefficient of the neutral species (i.e., if  $\log P_{\text{neutral}}$  is 4,  $\log P_{\text{ion}}$  is about 1).<sup>78</sup> It is, thus, easily understandable that  $\log D$  will become lower the more of the ionized species is present at the investigated pH. Experimental  $\log D$  values are often transformed into the corresponding  $\log P$  value by utilizing this theory, provided that the  $\text{p}K_{\text{a}}$  value of the investigated compound is known or can be obtained. However, possible ion pair partitioning is not always considered (see 5.18 Lipophilicity, Polarity, and Hydrophobicity). Another way to obtain  $\log P$  is to ensure that (almost) only the unionized compound is present during the experiment by using a pH far from the  $\text{p}K_{\text{a}}$ . However, it is likely that  $\log D$  at physiological pH is actually the more interesting parameter, since it gives the lipophilicity at a relevant pH. The pH to consider is 7.4 if blood/body tissue conditions are studied and around 6.0–8.0 in order to mimic the conditions along the gastrointestinal tract. pH varies from very acidic in the stomach, around pH 6.0–6.5 in the proximal small intestine to slightly basic in the colon, pH 8.0.<sup>79</sup> pH varies also with food intake.<sup>80</sup> Calculating  $\log D$

values has been found more troublesome than log  $P$  values since  $pK_a$  values are not as easy to predict (see 5.25 In Silico Prediction of Ionization).<sup>81</sup> A recent study showed that  $pK_a$  values predicted by ACDlabs<sup>82</sup> were found in some cases to be very different from those experimentally obtained, especially for new types of chemical structures.<sup>83,84</sup> This discrepancy will affect the quality of the log  $D$  prediction. Newer versions of this software allow training with in-house data sets to refine the predictions.

### 5.22.2.3 Hydrogen Bonding

Hydrogen bonding has been found to be an important part in structure permeation relationships.<sup>9,19,85,86</sup> Hydrogen bonds are also important for molecular recognition and thus will not only determine a compound's activity but also its metabolism or transport properties.

One way to assess hydrogen bonding strength experimentally is the measurement of hydrogen bonding equilibrium constants: hydrogen bond donors are measured against a common hydrogen bond acceptor and acceptors against a common donor. Abraham and co-workers found that data measured against different hydrogen bond acceptors/donors could be combined to give general hydrogen bonding scales for donors and acceptors, respectively, the  $\alpha$  and  $\beta$  scales.<sup>66</sup> The applicability of these descriptors has been enhanced by an empirical calculation method based on a group contribution approach.<sup>87,88</sup> However, this approach can be erroneous for druglike molecules, which are usually larger compounds with various chemical functions.<sup>10,89</sup> Intramolecular hydrogen bonding may be difficult to account for by a group contribution approach. Hydrogen bond donor acidity and acceptor basicity scales can also be obtained by quantum chemistry methods.<sup>90-92</sup>

Another possible way to obtain hydrogen bond activities is to investigate the thermodynamics of hydrogen complex formation. Raevsky *et al.*<sup>93</sup> collected a thermodynamic, hydrogen bonding database of several thousand reactions and used these data to statistically determine  $C_a$  (proton acceptor free energy factor) and  $C_d$  (proton donor free energy factor) values that fitted the  $\Delta H$  (change in enthalpy) and  $\Delta G$  (change in free energy) values measured. Both  $C_a$  and  $C_d$  were found to correlate well with Abraham's hydrogen bonding scales and can be calculated for new compounds.<sup>93</sup>

Lipophilicity of a given compound is reported to be partly explained by its hydrogen bonding ability. This can be used to estimate hydrogen bonding ability by comparing the partition coefficients between water and different lipophilic phases, which need to be different in respect to their hydrogen bonding ability.<sup>42,94,95</sup> The lipid used as 'golden standard' for lipophilicity measurements, *n*-octanol, has some hydrogen bonding ability whereas a hydrocarbon solute, like cyclohexane or *n*-heptane does not. It has been suggested that  $\Delta \log P$  obtained from the difference between log  $P_{oct}$  and log  $P_{hept}$  will mainly capture the hydrogen bond donor capacity of a solute,<sup>95</sup> but also its polarity or polarizability may be encoded.<sup>96,97</sup>  $\Delta \log P$  (defined as difference between log  $P_{oct}$  and log  $P_{cyc}$ ) was found to correlate to brain permeation for a set of  $H_2$  receptor histamine antagonists,<sup>45</sup> showing the relevance of this descriptor. However, this approach is very difficult if not impossible for less lipophilic compounds, because of low partitioning into the heptane (or cyclohexane) phase.<sup>10,19</sup>

The data set mentioned above<sup>45</sup> was also studied by Van de Waterbeemd *et al.*,<sup>19</sup> who suggested that the calculated polar surface area (PSA) might be a more easily accessible descriptor of hydrogen bonding ability. Since then, various different definitions for polar surface area have been used.<sup>19,20,98</sup> The value for PSA will differ depending on what type of surface is calculated (e.g., Van der Waals surface, solvent-accessible surface,<sup>32</sup> or Connolly surface<sup>33,34</sup>) and which atoms are used to define the surface. Nitrogen, oxygen and attached hydrogen atoms usually define a polar surface area, although sulfur atoms have been suggested as well.<sup>9</sup> The type of the calculated surface is especially important if cut-offs from the literature are to be used in other settings: For example, a PSA less than  $140 \text{ \AA}^2$  for better chance of oral absorption is only appropriate if a Van der Waals or Connolly type solvent-accessible surface is used,<sup>11</sup> whereas an accessible surface as originally defined by Lee and Richards will give higher PSA values and needs a higher limit (see Figure 3). For flexible molecules it may also be of interest to obtain a dynamic polar surface area from all relevant, low-energy conformations weighted by the Boltzman distribution.<sup>20,99,100</sup> However, it has been shown that the static polar surface area derived from one reasonable conformation alone, in general, gives very similar results to the computationally much more costly dynamic PSA.<sup>11,99-103</sup> It has also been proposed that an indicative PSA can be derived from the 2D structure alone.<sup>21</sup> In some studies the relative PSA (PSA/total surface area  $\times 100$ ) is used as parameter.<sup>104,105</sup> However, the relative PSA is more related to lipophilicity than to hydrogen bonding,<sup>10</sup> whereas the absolute PSA represents the possible polar interactions in water and is, therefore, related to the energy necessary for desolvation.<sup>106</sup>

Another way to describe hydrogen-bonding properties theoretically is the combination of (calculated) atomic charges with other molecular properties. Dearden *et al.* suggested using the partial atomic charge of the most positive hydrogen atom within the molecule in combination with energy of the lowest unoccupied molecular orbital, obtained

**Figure 3** Polar surface area (PSA) for benzoic acid: (a) Van der Waals surface ( $\text{PSA} = 32 \text{ \AA}^2$ ), (b) solvent accessible surface according to Connolly ( $\text{PSA} = 33 \text{ \AA}^2$ ), (c) accessible surface according to Lee and Richards ( $\text{PSA} = 83 \text{ \AA}^2$ ). Surfaces are drawn and calculated with Molcad within Sybyl<sup>107</sup> (the spherical probe used for surfaces (b) and (c) had a radius of  $1.4 \text{ \AA}$ ).

**Figure 4** Molecular interaction field (MIF) computation.

from a quantum chemistry calculation as a measure for hydrogen bond donor activity.<sup>96,108</sup> A slightly changed descriptor, the sum of the partial charges of all hydrogen atoms connected to a noncarbon atom, was later found to correlate highly to other hydrogen bond descriptors for drug molecules.<sup>10</sup> Charge weighted molecular or partial surfaces, as introduced by Jurs *et al.*<sup>109</sup> can give similar information.

It has been found that simple counting descriptors may give a good enough correlation to interesting ADME properties, e.g., to permeability.<sup>9</sup> Such counting descriptors for hydrogen bonding are the number of hydrogen bond donors and acceptors, which can be defined either as donor and acceptor atoms<sup>22</sup> or as donor hydrogen atom and acceptor electron pair.<sup>26</sup>

### 5.22.3 Molecular Interaction Field Derived Descriptors

The calculation of the interaction energy between a small molecule or particle and a compound in a 3D regular grid yields MIFs (Figure 4) (see 5.25 In Silico Prediction of Ionization). At each grid point in the 3D field the potential energy of interaction between the probe and the compound is calculated. MIFs can represent one interaction type by describing the electrostatic, steric, hydrogen bonding, or hydrophobic interactions. For example, the electrostatic interaction field can be computed using a positive charge as particle. Other MIF types, like the GRID molecular interactions fields,<sup>110</sup> are calculated using probes with more than one interaction capability, such as a water molecule. Thereby, all interactions (electrostatic, steric, etc.) of this probe with the target molecule are summarized in one field. The interaction energies used in the MIF calculation can be derived both from quantum or molecular mechanics approaches. MIFs are sensitive to the orientation and the conformation of the compound investigated. Thus, a proper conformational analysis and alignment of the investigated compounds is necessary in advance when used directly as descriptor sets. Moreover, the use of MIFs in the analysis of structure activity relationships requires statistical projection tools that can cope with the immense number of highly correlated descriptors. Principal component analysis (PCA) and projection to latent structures (PLS) are the methods employed in various approaches.<sup>111,112</sup> The MIF approach has been extensively used within the ADME field in comparative molecular field analysis (CoMFA)<sup>113–123</sup> or selectivity analysis.<sup>124,125</sup> MIFs have further been used to compute molecular descriptors, that are less alignment and/or conformation dependent, such as VolSurf and grid-independent (GRIND) descriptors.<sup>126–128</sup>

### 5.22.3.1 VolSurf Descriptors

The program VolSurf derives molecular descriptors from the GRID molecular interaction fields, based on three different probes, the water ( $\text{H}_2\text{O}$ ), the hydrophobic (DRY), and the hydrogen bond acceptor (O) probes (Figure 5). These probes were selected since properties such as shape, electrostatics, hydrogen bonding, and hydrophobicity are known to influence the interaction of molecules with biological membranes.<sup>127</sup> The descriptors from VolSurf are alignment independent and moderately dependent on the conformation ( $\sim 10\%$  variation with the conformation).

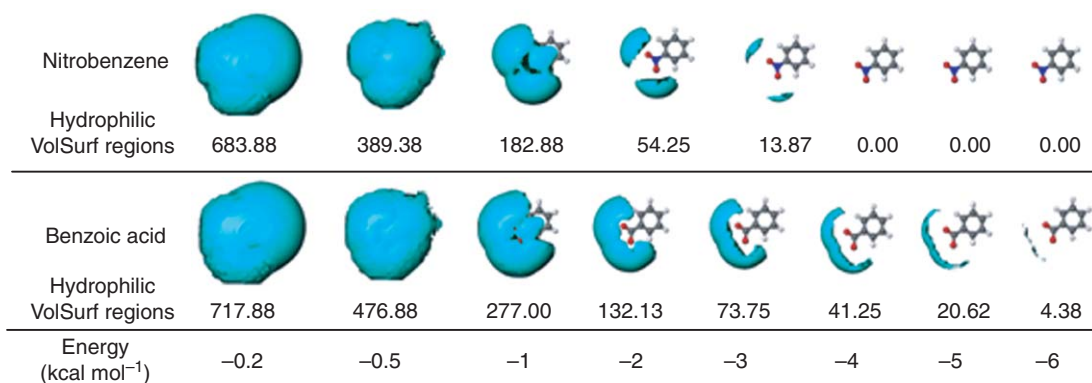

#### 5.22.3.1.1 A summary of VolSurf descriptors

##### 1. Descriptors derived from the water interaction ( $\text{H}_2\text{O}$ probe):

- Molecular surface ( $S$ ) is computed as the isoenergy surface that encircles the compound at the interaction energy level of  $0.2 \text{ kcal mol}^{-1}$ . This descriptor is related to the size of the compound.
- Molecular volume ( $V$ ) is computed as the volume enclosed by the above defined surface, and is related to the size of the compound.
- Rugosity ( $R$ ) is the ratio between the molecular volume and the surface. This descriptor measures how wrinkled the compound is.
- Molecular globularity ( $G$ ) is the ratio of the molecular surface ( $S$ ) and the surface of a sphere with the same molecular volume, i.e., the ‘ovality’ of the compound. This descriptor considers the similarity of the compound compared to a sphere.
- Hydrophilic regions (W1–W8) are defined by the isoenergy surfaces of the interaction energy between molecule and water probe at eight different energy levels:  $-0.2$ ,  $-0.5$ ,  $-1.0$ ,  $-2.0$ ,  $-3.0$ ,  $-4.0$ ,  $-5.0$ , and  $-6.0 \text{ kcal mol}^{-1}$ . It is a measure of the compound’s solvation properties and size, depending on the energy level analyzed. For example, a large hydrophilic region at  $-6.0 \text{ kcal mol}^{-1}$  means that the compound has a strong interaction with water. The hydrophilic region parameters give information similar to the previously described PSA descriptor. However, the hydrophilic regions may be able to distinguish better between different polar groups. For example, the carboxylic acid and the nitro functional groups have similar PSA values ( $40 \text{ \AA}^2$  for nitrobenzene and  $46 \text{ \AA}^2$  for the benzoic acid anion, as calculated by the fast 2D method<sup>21</sup>), but they show different water interaction in the GRID field (Figure 6): At high energy levels ( $-0.2$ ,  $-0.5$ , and  $-1 \text{ kcal mol}^{-1}$ ) the volume of the interaction with the water is quite similar since it represents the steric interaction forces. However, at lower energy levels the interaction volume is bigger for benzoic acid than for nitrobenzene, emphasizing the difference between the two polar groups. The hydrophilic regions at lower energy levels depend on the hydrogen bond and electrostatic interactions.

**Figure 5** VolSurf descriptor visualization. Yellow: volume of the compound. Green: hydrophobic interaction (DRY probe) at  $-1 \text{ kcal mol}^{-1}$ . Blue: hydrophilic interaction (N1 and  $\text{H}_2\text{O}$  probe, as indicated) at  $-4 \text{ kcal mol}^{-1}$ ;  $V$ , volume;  $S$ , Surface area;  $V_{\text{DRY}}$ , volume of the DRY probe at  $-1 \text{ kcal mol}^{-1}$ ;  $V_{\text{H}_2\text{O}}$ , volume for the water probe at  $-4 \text{ kcal mol}^{-1}$ ; WV, volume of the  $\text{H}_2\text{O}$  probe at  $-4 \text{ kcal mol}^{-1}$  divided by the surface area of the compound (capacity factor); HV, volume of the DRY probe at  $-1 \text{ kcal mol}^{-1}$  divided by the surface area; W-L, volume of the  $\text{H}_2\text{O}$  probe at  $-4 \text{ kcal mol}^{-1}$  divided by the volume of the DRY probe at  $-1 \text{ kcal mol}^{-1}$  (hydrophilic-lipophilic balance).

**Figure 6** Comparison of the water interaction and resulting VolSurf descriptors for nitrobenzene and benzoic acid as anion.

- Best volumes are the largest three hydrophilic volumes generated by a water probe at the energy levels of  $-1$  (BV11, BV21, BV31) and  $-3$  kcal mol<sup>-1</sup> (BV12, BV22, BV32). The descriptors represent the three largest isolated water interaction regions at a given energy level, indicating the distribution of the polar groups around the compound.
  - Integy moments (Iw1–Iw8) define the distances between the center of mass of a molecule and the centers of all hydrophilic regions around it at each of the eight energy levels. A higher integy moment value indicates a clearer separation between polar and hydrophobic interaction sites. Again the distribution of the polar groups in the molecule is described.
  - Capacity factors (Cw1–Cw8) are the ratios between the hydrophilic regions at each energy level and the molecular surface and show the concentration of polar interactions on the molecular surface.
2. VolSurf descriptors derived from the hydrophobic interaction (DRY probe):
- Hydrophobic regions (D1–D8) are defined by the isoenergy surfaces of the interaction energy between the molecule and the DRY probe at energy levels of  $-0.2$ ,  $-0.4$ ,  $-0.6$ ,  $-0.8$ ,  $-1.0$ ,  $-1.2$ ,  $-1.4$ , and  $-1.6$  kcal mol<sup>-1</sup>. The definition is similar to the hydrophilic regions but the hydrophobic interactions are considered.
  - Hydrophobic integy moments (ID1–ID8) are the distances between the center of mass of a molecule and the centers of the hydrophobic regions around it at each of the eight energy levels. These descriptors show the distribution of the hydrophobic groups.
3. VolSurf descriptors from both the H<sub>2</sub>O and the DRY probes:
- Local interaction energy minima (Emin1–Emin3) are the interaction energy values for the lowest three local minima for both the H<sub>2</sub>O and DRY probes (in kcal mol<sup>-1</sup>).
  - Local interaction energy minima distances (d12, d13, d23) are the distances between the three lowest local energy minima.
  - Hydrophilic–lipophilic balances (HL1, HL2) are calculated as the ratios between the hydrophilic regions measured at  $-3$  and  $-4$  kcal mol<sup>-1</sup> and the hydrophobic regions measured at  $-0.6$  and  $-0.8$  kcal mol<sup>-1</sup>, respectively. These descriptors represent the balance between hydrophilic and lipophilic (hydrophobic) molecular parts.
  - Amphiphilic moment ( $A$ ) is the distance between the centre of the hydrophobic domain and the center of the hydrophilic domain. This parameter measures the distribution of the polar and nonpolar groups in the molecule.
  - Critical packing parameter (CP) is the ratio between the maximum distance between the hydrophobic groups and the volume of the hydrophobic parts of a molecule, as defined by the DRY probe. In contrast to HL balance, CP refers just to the molecular shape.
4. VolSurf descriptors from the hydrogen bond acceptor interaction (O probe):
- Polar regions (WO1–WO8) are defined by the isoenergy surfaces of the interaction energy between the molecule and the O probe at eight different energy levels:  $-0.2$ ,  $-0.5$ ,  $-1.0$ ,  $-2.0$ ,  $-3.0$ ,  $-4.0$ ,  $-5.0$ , and  $-6.0$  kcal mol<sup>-1</sup>. These descriptors consider the hydrogen bond acceptor capacity of the compounds.
  - Hydrogen bonding descriptors (HB1–HB8) give the differences between the hydrophilic volumes as defined by the water probe (W1–W8) and any other polar probe included, e.g., the O probe (WO1–WO8), for each level considered. They give additional information about the hydrogen bond capacity of the compounds.

#### 5. Additional VolSurf descriptors:

- Polarizability (POL) is an estimate of the average molecular polarizability, calculated from atom contributions.<sup>129</sup>
- Elongation (Elong) is the ratio between the maximum extension of a molecule, considering the most extended conformation, and the extension of the rigid core of the molecule.
- Diffusivity (DIFF) is the estimation of diffusion of a compound in a water solution using the GRID-based VolSurf descriptors.<sup>129</sup>
- Lipophilicity ( $\log P$ ) is the estimation of the octanol–water partition coefficient using a model derived from the GRID-based VolSurf descriptors.<sup>129</sup>

VolSurf-derived descriptors can be used to characterize the interaction of a compound with different environments like water or a hydrophobic lipid membrane. Therefore, they are suitable for studying processes like passive permeability, solubility, unspecific binding to plasma proteins, and passive distribution of the compound to different tissues. Models based on VolSurf parameters show the differences in the lipophilic–hydrophilic balance important for the property in question. Properties that have been modeled successfully with VolSurf descriptors are, for example, solubility and passive permeability.

Solubility is a prerequisite for complete absorption of the compound from the gastrointestinal tract to the blood. Many different modeling efforts to predict solubility can be found in the literature (*see* 5.26 In Silico Predictions of Solubility).<sup>130</sup> The intrinsic solubility (thermodynamic solubility of the neutral species) for a set of 1028 compounds has been modeled using the VolSurf descriptors based on GRID and PLS multivariate analysis ( $r^2 = 0.74$ ,  $q^2 = 0.73$ ).<sup>129</sup> The model interpretation based on the PLS coefficients indicates that the ratio of the surface that has a positive interaction with the water probe and the total surface of the compound (the capacity factor) contribute positively to the solubility, while the hydrophobic interaction and  $\log P$  have a negative contribution.

Passive transcellular transport is mainly determined by water desolvation of the compound before entering the membrane and solvation in a lipophilic environment. In order to account for these processes the interaction of the compound with water and a lipophilic environment has to be computed. This type of interaction is well described by VolSurf descriptors, which were used to model the passive absorption across the Caco-2 cell monolayer (*see* 5.28 In Silico Models to Predict Oral Absorption)<sup>129,131</sup> and the blood–brain barrier (*see* 5.31 In Silico Models to Predict Brain Uptake).<sup>132</sup> However, data from Caco-2 experiments do not only represent the passive pathway, but also a combination of the different absorption routes and mechanisms that affect each compound differently. Moreover, the combination of experimental data from different sources, possibly obtained under different experimental conditions, may fail to give a quantitatively reliable data set. A discriminative model may be more useful in such cases and was therefore used for both Caco-2 cell monolayer and blood–brain barrier permeability.<sup>129,132</sup> This approach was also used for modeling the permeability across an artificial membrane and produced similar results (*see* 5.28 In Silico Models to Predict Oral Absorption).<sup>133</sup>

#### 5.22.3.1.2 Comparison between different experimental models for absorption

Different experimental techniques are used to predict a compound's permeability: transport experiments across a Caco-2 cell monolayer or rat intestinal tissue using the Ussing Chamber technique, physicochemical parameters like  $\log D$ , or retention times in chromatographic systems. In order to find characteristic differences between such techniques permeability/lipophilicity values of a small set of adrenoceptor antagonists obtained in six different systems were investigated: Caco-2 cell monolayers (Caco-2), rat ileum (Ileum), and rat colon (Colon) membrane in the Ussing chamber, distribution in octanol/water at pH 7.4 ( $\log D$ ), immobilized liposome chromatography ( $\log k_{ILC}$ ), and capillary electrophoresis ( $\log k_{CE}$ ).<sup>20,100,134</sup> A model for the experimental results for the small set of compounds in each of these systems was obtained using the VolSurf descriptors. The PLS coefficients for the models were combined in a single matrix and a PCA was performed. The resulting scores plot (**Figure 7**) shows the clustering of the different experimental models as they are seen by the descriptors.

The first principal component explains more than 42% of the variance and discriminates between the biological assays and the experimental physicochemical descriptors. This component is mainly dependent on the hydrophobic surface descriptors. The clear separation between the biological cell- and membrane-based methods on the one hand, and the physicochemical methods on the other hand, indicates that the molecular descriptors most important for distribution in octanol/water ( $\log D$ ), chromatography or capillary electrophoresis may not be as relevant for permeation through a biological cell membrane.

The second principal component (36% of the variance explained) divides the techniques further. The Ussing chamber experiments using rat colon segments is closer to the Caco-2 experiment than the experiment using rat ileum segments. In this principal component the hydrophilic volumes make the largest contribution. These descriptors

**Figure 7** Score plot for the PCA of the PLS coefficients for a comparison between different experimental models for absorption/permeability.

correlate negatively to permeability in general. Their importance in distinguishing the Caco-2 cells and the colon membrane from the ileum membrane could be of physiological relevance with respect to lipid composition of the three biological membranes.

### 5.22.3.2 GRIND Descriptors

The GRIND descriptors were developed in order to keep the pharmacophoric information found in the MIF in an alignment-independent way. This pharmacophoric type of representation may be helpful when modeling active transport, metabolic stability or enzyme inhibition. The Almond software<sup>126</sup> transforms the MIF into distance-based descriptors of the molecule's interaction pattern (Figure 8). The resulting parameters describe the geometry of the interaction and QSAR models can be derived where the interaction with a protein is essential. Since the most relevant interactions are usually described as hydrogen bond acceptor, hydrogen bond donor and hydrophobic interactions, GRID probes that describe these types of interactions are used for the GRIND descriptor computation: N1 (amide nitrogen atom type with 1 hydrogen atom), O (oxygen atom from a carbonyl group), and DRY (hydrophobic group). In addition a description of shape is added using the curvature of the positive energy with the N1 or O probes.<sup>135</sup>

The GRIND analysis does not use all the points in the MIF, but extracts only the most relevant ones. Two criteria are used for the selection of the relevant grid points: the interaction energy, which should be high, and the distance between the selected points. For example, if there are two grid points with the same energy and one is 2 Å and the second one 10 Å away from a previously selected point, the methodology would select the second one. The user can define the balance between the two selection criteria and the number of selected points.

The relevant grid points are then used in the molecular descriptor calculation. Each selected grid point from any of the investigated fields is combined with another grid point from the same or another field. If the default conditions are applied, three fields plus the shape description are used and 10 pairs of interactions are obtained: DRY-DRY, N1-N1, O-O, Shape-Shape, DRY-N1, DRY-O, DRY-Shape, N1-O, N1-Shape, and O-Shape. The energy of the two points, scaled by the maximum energy of the respective probe, is multiplied and the distance between them determined. The distance is used to define the "bin" to which the energy value is to be associated. Only the highest energy value, i.e., the most important interaction, is kept for each distance bin. The use of the maximum energy of interaction in each bin allows saving the coordinates of each point that contributes to the distance. Thus, it is possible to decode the descriptors back into 3D space, which facilitates the model interpretation.

The transformation of the MIF into descriptors based on the distance between the selected points allows an alignment independent analysis of ligand-protein interactions. However, the descriptors still depend on the conformation used.

#### 5.22.3.2.1 Active transport: P-glycoprotein

P-glycoprotein (P-gp) is an important efflux transporter, which was shown to influence both intestinal absorption and distribution into the brain for many drugs.<sup>136</sup> It is useful to apply a combination of descriptors based on the global properties of the compound and descriptors based on a pharmacophoric representation to describe the interaction with

**Figure 8** GRIND descriptors calculation. Step 1: GRID field computation using the DRY, N1, and O probes. Step 2: Selecting the most relevant grid points and distance computation. Step 3: Selecting the highest cross-correlation and autocorrelation values for each distance to obtain the descriptors.

this transporter correctly. Conceptually, the global properties would describe the initial passive membrane permeation required to reach the site of action. The specific ligand–protein interactions are explained by the pharmacophoric descriptors. This approach was successful in the P-gp case, where the two processes are important for transport; passive transport into the cell and active efflux transport from within the cell to the outside. Cianchetta *et al.*<sup>137</sup> obtained an initial model for the inhibition of the P-gp transport using the VolSurf descriptor set alone, with  $r^2 = 0.71$  and  $q^2 = 0.51$ . This initial model was not, however, able to predict the most active compounds. When the authors expanded the model<sup>137</sup> with the GRIND descriptors they obtained better statistics ( $r^2 = 0.81$  and  $q^2 = 0.73$ ) and a similar prediction rate in the entire activity range.

#### 5.22.3.2.2 Metabolic stability: the CYP3A4 case

The rate of metabolism is an important and well-studied factor that contributes to the elimination of the compound from the body. An easy, often used method to obtain metabolic stability data in screening is the determination of the percentage remaining after a certain period of time for a given compound at one concentration in an enzyme incubation. However, this metabolic data is not precise and can only be used to classify the compounds as metabolically stable or unstable. Such data has been used to model CYP3A4 metabolic stability,<sup>138</sup> an enzyme with broad substrate specificity and for which lipophilicity has been described as a major determining factor for affinity. Cruciani *et al.* showed that VolSurf descriptors could be used to obtain a model with reasonable statistics.<sup>129</sup> However, some compounds were not well classified. In order to improve the compound description and the model predictive power, GRIND descriptors were used additionally.<sup>138</sup> The resulting model showed better predictivity for the different compound families, although the overall prediction rates were similar.

#### 5.22.3.3 Alternative Use of MIF-Derived Descriptors

MIFs can be used to investigate similarities and differences between various molecular structures using a new statistical technique, the consensus principal component analysis (cPCA).<sup>139</sup> This technique can analyze the GRID-MIFs of aligned protein structures and decomposes the typical PCA analysis to identify the contribution of each block of variables (i.e., each GRID probe). The data decomposition provides the opportunity to analyze the contribution made by different blocks of data. This statistical analysis technique is included in the software GOLPE.<sup>112</sup> It was used to study the different interaction patterns for CYP2C9, CYP2C19, CYP2D6, CYP3A4, and CYP1A2, a selectivity analysis. The obtained information is useful for predicting the selective sites of metabolism, i.e., those sites in a molecule that will be metabolized by one particular cytochrome. Moreover, the selectivity analysis has also been used to compare crystal structures to homology models for CYP2C5 and CYP2C9.<sup>125</sup>

##### 5.22.3.3.1 Site of metabolism prediction

The elucidation of the site of metabolism in a molecule is one of the most time-consuming experimental tasks in the ADME field. Moreover, in some cases, experiments can only determine the region in the molecule that is metabolized, but not on which atom the metabolic reaction actually occurs. Nevertheless, such information is needed in order to explore the pharmacological activity and the toxic effects of the formed metabolites. Knowledge about the site of metabolism may also help in the chemical protection of the molecule, resulting in a compound that is less liable to metabolic reactions. A new technique called MetaSite<sup>128</sup> has been developed in order to consider the interaction with the CYP enzyme and the chemical reactivity of the compounds towards the oxidation. The protein recognition part compares the interaction profile of the enzyme based on GRID-MIFs and different conformations of the potential substrates. The prediction rates for the site of metabolism for five CYP enzymes (CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4) were validated using more than 100 metabolic reactions in each case (Table 1).

##### 5.22.3.3.2 Selective site of metabolism

The aim of this study was to predict the site of metabolism that is due to one particular CYP enzyme. The investigated CYPs were aligned and the resulting GRID-MIFs used as input for a cPCA, in order to find the interactions specific for each enzyme. The loading values resulting from this analysis were used to scale the original GRID-MIFs. A protein recognition, like the one used in MetaSite, was based on these scaled MIFs in order to identify the selective sites of metabolism for the investigated compounds. In contrast, MetaSite suggests all possible sites, since it is based on the original, not scaled GRID-MIFs of the cytochromes.

The selective site of metabolism was studied for the CYP2C subfamily (CYP2C9, CYP2C8, CYP2C19, and CYP2C18). Tables 2–5 summarize the experimental results. The selective site of metabolism investigation yielded in total 72% good predictions.

**Table 1** Rate of prediction for the site of metabolism; ‘Good prediction’ means that the experimentally determined site of metabolism is among the first three sites predicted by MetaSite

| <i>Cytochrome</i> | <i>Number of reactions</i> | <i>Rate of good prediction</i> |
|-------------------|----------------------------|--------------------------------|
| CYP1A2            | 120                        | 73%                            |
| CYP2C9            | 125                        | 83%                            |
| CYP2C19           | 109                        | 75%                            |
| CYP2D6            | 130                        | 85%                            |
| CYP3A4            | 220                        | 77%                            |

For all CYP2C9 cases analyzed the correct site of metabolism was predicted within the first three suggestions. Eight out of the 11 substrates tested for CYP2C19 were well predicted (the correct site of metabolism was found within the first three options presented). However, the following three compounds could not be predicted well by the selective site of metabolism analysis: (1) diazepam undergoes an *N*-demethylation catalyzed by CYP2C19, but the technique suggested a hydrogen atom abstraction from the phenyl ring; (2) *R*-mephobarbital is hydroxylated by CYP2C19 at the *para* position, while the method selected the *meta* position; and (3) ticlopedine is oxidized by CYP2C19 at two positions, but none of them was found within the three top solutions.

For three out of five CYP2C8 substrates the selective site of metabolism analysis was able to find the correct site of metabolism within the top three solutions. However, retinoic acid and *R*-troglitazone were not correctly predicted. *R*-Troglitazone undergoes a ring opening catalyzed by CYP2C8, but a hydrogen atom abstraction at the methyl groups in the phenyl ring was predicted. This may be due to the fact that the type of reaction, the ring opening, was not considered in the analysis.

There is only one reaction described in the literature as selective for the CYP2C18. The reported metabolic reaction requires the abstraction of the hydrogen at the carbon atom next to the sulphur in the thiophene ring (Table 5), which is close in space to the site selected by the selective site of metabolism analysis.

## 5.22.4 Miscellaneous

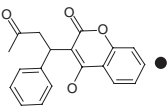

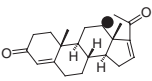

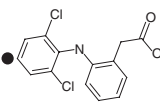

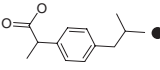

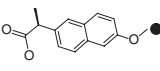

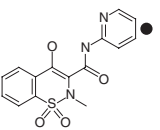

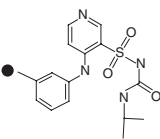

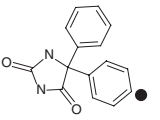

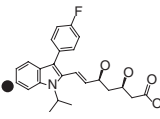

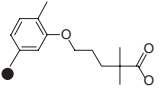

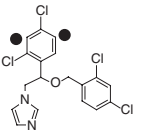

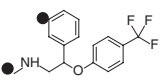

Molecular descriptors are available from various software – Sybyl, MOE, ACD, GRID, etc. – or can be calculated from in house software or simple scripts. Recently, web-based descriptor generation tools have been proposed as well.<sup>169</sup> A molecular descriptor generation software that calculates more than 1500 molecular descriptors is the Dragon software.<sup>170</sup> It includes many of those mentioned here, but also a lot of descriptors that have not yet been used too often in ADME modeling and therefore are beyond the scope of this chapter. The Dragon descriptors are explained in Todeschini’s Handbook of Molecular Descriptors,<sup>17</sup> a general encyclopaedia on descriptors useful for QSAR and QSPR studies.

Below some examples of descriptor sets and other descriptors used in ADME modeling are presented. The descriptor sets usually include descriptors with information on molecular size, lipophilicity, and hydrogen bonding.

### 5.22.4.1 Abraham Descriptors

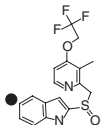

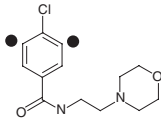

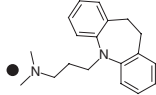

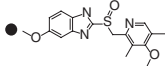

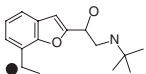

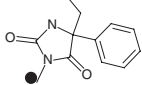

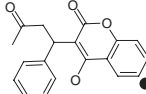

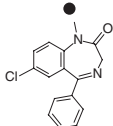

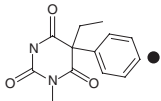

Abraham’s LFER approach<sup>66</sup> uses five descriptors only: *E*, the excess molar refraction, *S*, the solute polarity/polarizability, *A* ( $\alpha$ ), the solute H-bond acidity, *B* ( $\beta$ ), the solute H-bond basicity, and *V*, McGowans characteristic molecular volume (see 5.31 In Silico Models to Predict Brain Uptake).<sup>35</sup> It is easy to see the molecular size and hydrogen bonding descriptors in this set. Lipophilicity information is included as well, since it was shown that the descriptors could be used to estimate partition coefficients, like  $\log P_{\text{oct}}$ .<sup>66,171</sup> The descriptors can be assessed experimentally, tabulated, and used for correlations to physicochemical properties. Often reasonable correlations can be found for which not all five descriptors need to be important. These descriptors can also be obtained theoretically, either based on fragments<sup>87</sup> or on quantum chemical calculations, e.g., the conductor-like screening model (COSMO) approach.<sup>172</sup> Such theoretically derived descriptors were successfully used in several QSPR studies, e.g., for the prediction of lipophilicity and cell permeation.<sup>173,174</sup>

**Table 2** CYP2C9 substrates: the experimentally determined site of metabolism

| Compound             | Structure   | Reaction                                     | $K_i$ ( $\mu M$ )                          | $K_m$ ( $\mu M$ )               | $V_{max}$ ( $min^{-1}$ )                | Reference   |
|----------------------|---|--|--|---------------------------------|---|-------------|
| <i>S</i> -Warfarin   |    | 7-Hydroxylation                              | 20   | $4.1 \pm 0.6/$<br>$5.8 \pm 0.8$ | $0.421 \pm 0.021/$<br>$0.248 \pm 0.018$ | 140–142     |
| Progesterone         |    | 21-Hydroxylation                             | 5.5  | $17 \pm 2$                      | $0.51 \pm 0.02$                         | 140,143     |
| Diclofenac           |    | 4'-Hydroxylation                             | 2  | $3.6 \pm 0.4/$<br>$3.9 \pm 0.3$ | $41/35.6 \pm 1.3$                       | 140,142,144 |
| <i>S</i> -Ibuprofen  |    | 3-Hydroxylation                              |  | 35–82                           |   | 145         |

| R-Mephobarbital |  | 4-Hydroxylation  | 34                |                   |                          | 162       |

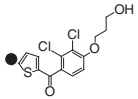

#### 5.22.4.2 Quantum Chemical Descriptors

The MolSurf program<sup>68</sup> uses quantum chemical calculations to derive descriptors that were found useful for ADME property predictions. The program calculates a constant electron density surface that represents the valence region of a given molecule. The electrostatic potential and the local ionization energy are calculated on evenly distributed points on this surface. This information is used to calculate chemically understandable descriptors for the molecular surface, Lewis acid and Lewis base properties, charge transfer characteristics, hydrogen bonding ability, polarizability, polarity, steric factors, and lipophilicity. Norinder *et al.* used these descriptors in a series of studies and found that ADME properties like Caco-2 cell permeability (17 drugs;  $r^2 \sim 0.9$ ,  $q^2 \sim 0.8$ ), human intestinal absorption (20 drugs;  $r^2 \sim 0.9$ ,  $q^2 \sim 0.7$ ), brain-blood partitioning (63 drugs;  $r^2 \sim 0.8$ ,  $q^2 \sim 0.78$ ), and P-gp interaction (22 drugs;  $r^2 = 0.7$ ,  $q^2 = 0.7$ ) could be modeled reasonably well.<sup>175–178</sup> However, in later studies they found that simpler descriptors could actually give reasonable correlations as well.<sup>179</sup>

**Table 4** CYP2C8 substrates: the experimentally determined site of metabolism

| Compound       | Structure   | Reaction                                  | $K_m$ ( $\mu M$ )           | $V_{max}$ ( $min^{-1}$ )                                   | Reference |
|----------------|---|---|-----------------------------|--|-----------|
| Retinoic acid  |  | 4-Hydroxylation                           | 100                         | 0.38   | 163       |
| R-Troglitazone |  | Quinone type                              | $2.7 \pm 2.5$               | $4.2 \pm 1.0$  | 164       |
| Rosiglitazone  |  | Hydroxylation <i>N</i> -demethylation     | $44 \pm 17$<br>$10 \pm 1.3$ | $174 \pm 49$ ( $nmol^{-1}h^{-1}mg^{-1}$ )<br>$146 \pm 8.4$ | 165       |
| Zopiclone      |  | <i>N</i> -Demethylation( <i>N</i> -oxide) | $71 \pm 6$                  | $2.5 \pm 0.1$  | 166       |
| Amiodarone     |  | <i>N</i> -Deethylation                    | $8.6 \pm 2.5$               | $2.3 \pm 0.2$  | 167       |

**Table 5** CYP2C18 substrates: the experimentally determined site of metabolism

| Compound      | Structure  | Reaction        | $K_m$ ( $\mu M$ ) | $K_{cat}$ ( $min^{-1}$ ) | $K_{cat}/K_m$ ( $min^{-1}\mu M^{-1}$ ) | Reference |
|---------------|--|-----------------|-------------------|--------------------------|--|-----------|
| TA derivative |  | 5-Hydroxylation | $9 \pm 1$         | $125 \pm 25$             | 13                                     | 168       |

Quantum chemically derived descriptors include also descriptors like highest occupied molecular orbital (HOMO), lowest unoccupied molecular orbital (LUMO), hardness (LUMO – HOMO)/2, dipole moment, atomic charges, polarizability, polarity, ionization potential, electrostatic potentials, molecular energy values, and others. Quantum chemical descriptors and their use in QSAR/QSPR studies were reviewed some time ago.<sup>180</sup> Descriptors based on quantum chemical calculations were successfully used in ADME studies by, e.g., Lombardo *et al.* who correlated free energies of the solvation in water as computed with the AMSOL program to log BB values.<sup>181</sup>

### 5.22.4.3 Surface-Related Descriptor Sets

Jurs *et al.* introduced the charged partial surface areas (CPSAs)<sup>109</sup> which primarily describe the polar interaction between molecules. The rationale behind these descriptors was the assumption that such interactions are mainly due to the charge distribution within the molecule and that the influence of one single atom depends on its exposure at the surface of the molecule (a solvent-accessible surface as defined by Lee and Richards<sup>32</sup>). Thus, a set of 25 descriptors was defined by summing the partial charges of all atoms with positive (or negative) partial charges and weighting them by multiplication with these partial charges in various combinations. They were found useful for correlation to physicochemical properties such as boiling point, and have also been used for ADME studies, together with other descriptors.<sup>15</sup> This set of descriptors has inspired other scientists to define charge weighted partial surface area descriptors, which have been shown to be hydrogen-bond related.<sup>10</sup>

Recently, an analogously defined set of 25 descriptors regarding the hydrophobic interactions, the hydrophobic surface area descriptors, was presented.<sup>182</sup> Instead of atomic charges, atomic hydrophobicity indices were used. These descriptors were found to be unique descriptors that can capture information regarding hydrophobic intermolecular interactions and should, therefore, be useful for ADME modeling. A first model on BBB data of a data set of 97

commercially available structurally diverse drugs was found to be slightly improved by addition of the hydrophobic surface area descriptors.

Simple partitioned total surface areas alone were shown to be able to classify oral drugs according to their absorption properties.<sup>183</sup> Bergström *et al.* conclude that surface areas describing the nonpolar part of the molecule yield good predictions of solubility, whereas those describing specific polar parts, like parts regarding only hydrogens or other polar atom types, can be used for predicting permeability.

Molecular hashkeys<sup>184</sup> describe a molecule in terms of surface similarity to a given basis set of common molecules, considering steric, polar positive, and polar negative features of the molecule. The hashkey for a given molecule comprises the surface similarities of each of the molecules in the basis set with the best fitting conformation of the molecule in question. It was shown, that such hashkeys were able to predict, the ranking order of fraction absorbed values of a diverse set of compounds.<sup>184</sup>

MS-WHIM descriptors<sup>185</sup> were developed by applying the weighted holistic invariant molecular (WHIM<sup>186</sup>) approach to molecular surface points. By centering the molecular surface coordinates with respect to their property specific weighted mean value and performing a weighted PLS, the resulting molecular descriptors become invariant to both translation and rotation. Thus, MS-WHIM descriptors are alignment independent, but depend on the conformation used for surface generation. Several weighting schemes can be used, e.g., the molecular electrostatic potential, hydrogen bonding capacity, and hydrophobicity. These descriptors were used successfully in a study on binding affinity of 16 coumarine-like molecules to CYP2A5,<sup>185</sup> and in a study on Caco-2 permeability of 17 structurally diverse compounds.<sup>187</sup>

#### 5.22.4.4 Fingerprints

A molecular fingerprint<sup>17,18</sup> in the classical sense represents the molecule by a string of 0s and 1s, which correspond to the presence or absence of specific molecular features. According to the type of features used for the fingerprint, one can distinguish between 2D or 3D fingerprints. 2D fingerprints typically relate to the presence or absence of molecular fragments, functional groups, or atom types within the molecule in question, whereas 3D fingerprints collect three or four features including the corresponding interfeature distances. Fingerprints, where each bit is dedicated to a specific structural feature, are often called structural keys. Another way to define fingerprints is by a specific fingerprinting algorithm, like the one used by Daylight.<sup>188</sup> This algorithm generates several patterns for each molecule and combines them all together by a 'logical OR,' generating the fingerprint of the molecule. The patterns represent the atoms in the molecule, atoms and their closest neighbors, each group of atoms connected by two to four or more bonds. Each pattern is used as seed to a pseudorandom number generator, which results in a fingerprint string for this specific pattern, where typically four or five bits are set. The combination of all pattern fingerprints gives the molecular fingerprint, in which all single patterns are represented. Since there is no predefined set of patterns, it is not possible to assign a pattern to a specific bit. But all the bits of a specific subset's fingerprint are also set in the molecule's fingerprint (even though one specific bit may be contained in more than just one subset). This approach is more general, as the structural features investigated need not to be defined in advance; the resulting fingerprints can be smaller, since there need not to be a bit for each and every structural feature investigated.

Fingerprints are very fast and easy to calculate and compare with each other due to their data structure.<sup>17</sup> Thus, this type of descriptor is especially useful for quickly assessing the similarity of different molecules, for substructure searches, or for selecting the most diverse compounds from a given data set. Fingerprints can be used to check for a druglike score of investigated molecules,<sup>189</sup> which could be interesting in early drug design. The fingerprint approach can also be used in ADME studies by defining a specific metabolic fingerprint as was suggested by Keserü and Molnár.<sup>190</sup> In this case the fingerprints are not binary strings but bin arrays. Each bin is associated with a particular metabolic reaction (or a summary of the molecules and their metabolite properties) and holds a value that indicates how often a specific reaction occurs for the investigated structure. In this broader sense, the previously described molecular hashkeys or the GRID-based GRIND descriptors can also be seen as fingerprints.

#### 5.22.5 Closing Remarks

We have here discussed a number of molecular descriptors that are currently used in the area of ADME modeling and predictions. Some of the descriptor sets, e.g., MIF-derived descriptors, can comprise a huge number of highly correlated descriptors and require statistical tools that can cope with such data, e.g., the PLS method.<sup>12,191</sup> Additionally, variable selection techniques can be used in order to find the most significant variables, which will help the model

interpretation. These techniques are also useful, if several descriptor sets are used, since such combinations will often lead to highly redundant information. An alternative way to cope with this redundancy between different descriptor sets is to model the property using each data set on its own and combine the final models, for example, by hierarchical modeling as implemented in SIMCA.<sup>192,193</sup>

The main molecular properties found important for many ADME properties (lipophilicity, hydrogen bonding, and molecular size) are characterized by all descriptor sets, which is one reason for the data redundancy often found. Another reason is that they can be described in several and very different ways, e.g., by simple physicochemical descriptors or by descriptors based on quantum-chemical calculations or derived from molecular field interactions. Models for ADME properties such as permeability (passive), solubility, or unspecific protein binding can generally be described using only such general molecular descriptors. Other ADME properties, such as active transport or metabolism, which relate to interaction with a protein, need a pharmacophoric type of description, even though lipophilicity – at least for a congeneric series of compounds – may be very important. In this case descriptors based on molecular interaction fields are superior to the physicochemical descriptors. In addition, structural keys that recognize the absence or presence of specific essential molecular fragments can be useful. Furthermore, if the 3D structure of the protein in question, e.g., a CYP protein, is known or could be easily modeled by homology, a description of the ligand–protein interactions can be added.

Selection of the descriptor set to be used also depends on the scope of the model: if a set of closely related compounds is to be investigated, i.e., a local model to be developed, descriptors that have been tailored to this data set can be used. For example, descriptors for selected molecular fragments can be calculated. Local models should help in understanding the molecular properties required to produce certain specified ADME behavior. Therefore, molecular descriptors and statistical techniques that are easy to interpret should be chosen. These models can be used to suggest chemical changes in a molecule to obtain the desired ADME property, or even in the understanding of the complex ADME data.

For global models it is necessary to use descriptors that are available for as many molecules as possible – both for those that are used in the training set and possible molecules that should be predicted with the model. These models are useful for filtering out a great number of virtual (or synthesized) compounds and selecting those with the appropriate properties, but an exact interpretation of the influence of each variable may not be necessary.

Moreover, local and global models may differ in the impact of the complexity inherent in ADME data. Related compounds usually have similar factors that affect their pharmacokinetic behavior, while in a diverse set, which is required for a global model, the different factors could affect the property measured in various ways. For example, Caco-2 permeability data comprise both active and passive transport. In a set of similar compounds one can assume that all of them are either passively absorbed or have affinity to the same transporter(s) in varying degrees. In contrast, in a diverse data set one has to expect that some of the compounds are transported by different transporter proteins, whereas others are just passively absorbed. For example, if the passive route dominates in the data, it will be possible to obtain a reasonable model, and actively transported compounds will most probably be outliers.

Another aspect is the probable type of correlation: in many studies a linear correlation is assumed between the descriptors and the property in question, in others both linear and quadratic terms are used randomly. A good understanding of both the descriptors used and the property investigated will help in selecting the descriptors for which quadratic terms or other types of correlations may be useful, but is also a necessity for proper interpretation of the final model.

## Biographies

**Susanne Winiwarter** studied pharmacy at the University of Vienna, Austria. She received her PhD from the same university in 1991 under the supervision of Dr P Wolschann and Prof G Buchbauer, using molecular modeling techniques to investigate structure–activity relationships. After one postdoctoral year with Prof H J Roth at the University of Tübingen, Germany, she spent several years at the University of Uppsala, Sweden, in the research group of Dr A Karlén, in the Department of Medicinal Chemistry. In 2003, she joined AstraZeneca in Mölndal, Sweden, as senior research scientist.

**Marianne Ridderström** received her PhD in biochemistry in Prof Bengt Mannervik's group at Uppsala University in 1997. Her thesis concerned structure–activity studies of the glutathione-linked enzymes glyoxalases I and II. She joined AstraZeneca R&D Mölndal on a postdoctoral position in 1999 and engaged in structure–activity studies and modeling of CYPs. Since 2001 she has been employed in the DMPK and Bioanalytical Chemistry department at AstraZeneca Mölndal, involved in the *in vitro* metabolism field and metabolism modeling in discovery projects.

**Anna-Lena Ungell** received her PhD degree in zoophysiology 1985 at the University of Gothenburg, Sweden, and after a postdoctoral fellowship in 1985–86 at the University of Würzburg in Germany she received a scholarship from

the Swedish Royal Academy of Science for one year. She started 1987 at AstraZeneca R&D (former Astra Hässle AB), Mölndal, Sweden, and since 2004 has been an Associate Professor in Pharmaceutics at Uppsala University. She presently holds a position as a Team Leader and Principal Scientist at DMPK & Bioanalytical Chemistry, AstraZeneca R&D Mölndal, Sweden. Her group consists of 11 members working as support to preclinical, clinical, and pharmaceutical projects regarding drug absorption and transporter issues. She is responsible for developing models to study drug absorption, screening for structure–absorption relationship using automated screen facilities, and QSAR modeling, evaluating different absorption mechanisms and transporters, which link in vitro animal studies to in vivo pharmacokinetics and evaluate drug–drug interactions.

**Tommy B Andersson** is a Senior Principal Scientist at AstraZeneca R&D Mölndal Sweden. He received his PhD from the University of Gothenburg, Sweden, in 1986 and later became an assistant professor at the same university. Dr Andersson was appointed assistant professor in Drug Metabolism at the Karolinska Institutet, Stockholm in 1998 and was promoted to adjunct professor at the same institute in 2003. He joined AstraZeneca R&D Mölndal in 1993 where he has been responsible for the in vitro metabolism work in drug discovery and development. He is the author and co-author of some 110 original research papers.

**Ismael Zamora** studied chemical engineering and organic chemistry at the Institut Químic de Sarrià in Barcelona (Spain). He received his PhD in organic chemistry in 1998 for studies on the synthesis of molecular modeling of natural products. After a 6-month postdoctoral period with Prof Gabriele Cruciani at the University of Perugia, Italy, he joined AstraZeneca R&D Mölndal, Sweden, in a postdoctoral position for 9 months, and stayed there as a research scientist for another 2 years. After that he founded the Lead Molecular Design Co., devoted to software development in collaboration with Molecular Discovery Ltd. Since 2002, he has been an associate professor at the Pompeu Fabra University, Barcelona, Spain.

### 5.23.1 Introduction

In the study of drugs and the design of new drugs, the realization of the important role played by pharmacokinetic attributes of molecules has become of great importance. Of particular interest are the properties of absorption, distribution, metabolism, excretion, and toxicity, collectively called ADMET. Over recent years, in the drug design process, these properties of candidate drug molecules have become co-equal with biological activity in the goal of creating clinically useful drugs. Many investigators have been describing the serious problems that arise from poor pharmacokinetic and toxicity properties of drug candidates. Estimates have been made that indicate that the percentage of late stage drug candidates that fail to make it to market because of ADMET failures range from 20% to 40%.<sup>1–3</sup> Problems associated with ADMET performance must be identified experimentally early or predicted via

testing, modeling, or other approaches, so that design changes can be made in the candidate molecules or decisions made to abandon the project before significant resources are squandered.

One approach to prediction is through procedures using *in vitro* experiments. These may take the form of simulations using tissue or actual measurements of an ADMET property in an animal. How successful are the predictions of ADMET properties with all of the current technologies? The general view is that they are not good enough to make predictions leading to a steady stream of safe, new drugs to come to market each year.<sup>4</sup> The alternative approach to *in vitro* testing is the process for the creation of models of various types, including structure-based approaches as well as physiologically based modeling and *in silico* models of ADMET properties using quantitative structure–activity relationship (QSAR) methods.<sup>5,6</sup>

These QSAR models are of two general types. One type uses physicochemical properties to describe molecules and then to develop a relationship with an ADMET property. Prominent descriptors in this type of approach are the partition coefficient (*see* 5.18 Lipophilicity, Polarity, and Hydrophobicity; 5.27 Rule-Based Systems to Predict Lipophilicity),  $pK_a$  (*see* 5.16 Ionization Constants and Ionization Profiles; 5.25 *In Silico* Prediction of Ionization), and the Hammett sigma (*see* 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery; 5.22 Use of Molecular Descriptors for Absorption, Distribution, Metabolism, and Excretion Predictions; 5.25 *In Silico* Prediction of Ionization). The information derived from a successful property-based model is indirectly related to structure, and requires further processing to convert it into guidance that is meaningful in terms of molecular structure for chemical modification. The design of a new molecule requires additional development of molecular structure information.

The second type of QSAR *in silico* model is based on a numerical encoding of structure that yields information directly representing molecular structure. These models are derived from nonempirical indices such as the electrotopological state and molecular connectivity. This approach, structure information representation, is of direct value in analyzing the structure for design modification leading to the synthesis of a new molecule.<sup>7,8</sup>

To provide a basis for the presentation of several modeling studies on ADMET properties, we begin with a brief description of the methods for molecular structure description. We consider the structure of a molecule as a source of information. This approach proceeds not to the creation of a geometric distribution of points but to the systematic development of the useful information resident in the structure of a molecule and additional information that can be developed.

### 5.23.2 The Molecule as an Information Network

The initial encounter of two molecules has been conventionally dissected into two separate phenomena in a reductionist approach. Thus, the electronic structure and the topology of the molecule under study have usually been treated as distinct entities. The goal has been to quantify each attribute and enter these independently into the process aimed at acquiring a model of the structure engagement in the encounter. Success by this approach over the years is clear. But we may achieve greater insight if we accept the reality that molecular structure is a representation of the complex system that is made up of atoms and functional groups with internal patterns describable by information from both the electronic content and topological arrangement in an integrated manner.

One useful way to view a molecule is as an information network, with atoms comprising the nodes. Each node has three characteristics. It has a state; that is, it is an element with electrons and protons. Second, it has some relationship to other nodes (atoms) in the network through the bonds directly connecting neighboring atoms and beyond. The valence state is represented by electronic information associated with the set of directly bonded atoms and larger-scale patterns such as multiple bonding, aromaticity, and charge. Finally, each node (atom) has a specific influence on its (connected) bonded neighbors. Each node also manifests its effect on more distant neighbors in the network (molecule). This influence is summarized as the effect of electronegativity on the bonded neighbors through the bonds and on more remote network-connected neighbors as well. The electronegativity effect is a complex emergent property of the (valence) state of the node and its connectedness in the network (the electronic structure and the bonded relationships in the whole molecule). Viewed in this way, the development of structure information is a process of synthesis, leading to structure descriptors, rather than reduction, leading to atomic indices.

### 5.23.3 Structure Information Representation

Based on the concept described above, we can define two structure information systems that are a major part of what we refer to collectively as structure information representation.<sup>7,8</sup> A more complete description of this approach to structure representation is given elsewhere (*see* 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery). We review these two approaches here.

### 5.23.3.1 The Electrotopological State (E-State) Index

Electronic structure, electronegativity, and topology cannot be meaningfully treated as separate aspects to be combined in some fashion, simple linear or otherwise, in order to create a predictive model in structure–activity analyses. Using the network analogy for a molecule, as outlined above, we can say that network structure and function are complex emergent properties of the node structure, including the influence of each node on bonded as well as remote neighbors. The recognition that structure is an emergent attribute casts the molecule into a class of complex systems. Accordingly, an alternative to the reductionist approach must be invoked to model such a system.

We begin by recognizing that the electronic structure of a molecule is a critical factor governing its interaction with another molecule. Based on the principle of logical depth, we accept the premise that it is not meaningful to say that a molecule engages any entity other than one at its own level, such as another molecule.<sup>9</sup> It is not very useful to speak of a molecule engaging a cell. What is happening, at a level that permits quantification, is that the molecule engages another molecule, or molecule-sized feature, that is part of the cell surface. Carrying this principle further, it is significant to consider for study only part of a molecule (an atom, functional group, or fragment) as it engages a comparable-level feature on another molecule. This principle of logical depth leads us to attempt to characterize these molecular features in order to model the possibility, extent, and specificities of a molecule engaging another molecule.

A model fulfilling these expectations must, therefore, address subfeatures of a molecule, encode electronic and topological attributes, and also encode the influence by these same features on neighboring features. This is the philosophy behind the creation of the E-state system over a decade ago.<sup>10</sup> The important features in the design of this system are described below.

In order to characterize the important subfeatures of a molecule that are implicated in the encounters of a molecule with other molecules, we begin by focusing attention on each atom (or hydride group) in the molecule as a distinct entity. Two characteristics of this atom are encoded into a uniform attribution value, both electronic and topological. This unification brings together the electron richness and the influence on electron richness (expressed conveniently through the electronegativity), together with local topology, expressed in a quantification of the relative adjacency of the atom in the molecular skeleton.<sup>10</sup>

Each of these attributes has been addressed and quantified by us in past work.<sup>11,12</sup> The sigma orbital electronegativity of an atom or hydride fragment has been shown by Kier and Hall to be described by an expression that includes counts of the number of valence electrons, the number of hydrogen atoms (in the case of a hydride group), and the number of sigma-bonded atoms other than hydrogen.<sup>10,11</sup> The expression contains the count of the extrajacent electrons on a sigma-bonded atom, which is the count of pi ( $\pi$ ) and lone pair ( $n$ ) electrons. The topology of an atom (or hydride group) in the molecular skeleton is characterized by the count ( $\delta$ ) of its sigma bonds ( $\sigma$ ) to atoms other than hydrogen ( $h$ ):  $\delta = \sigma - h$ . We have shown that the count of pi and lone pair electrons provides a strong relationship to valence state electronegativity.<sup>11</sup> The electron accessibility of the atom or hydride group is described as a ratio of the valence state electronegativity to the topological character, expressed as the  $\delta$  value.

The provisional expression  $(\pi + n)/\delta$  encodes the relative electron accessibility of the particular molecular fragment (atom, hydride group) in isolation from bonded atoms. This expression results in zero values for all C(sp<sup>3</sup>) atoms; so, the equation is modified with a constant value of one in the numerator, giving  $(\pi + n + 1)/\delta$ . Finally, to scale most values to be greater than 1, the expression is modified to give an intrinsic value of the noncovalent intermolecular interaction potential,  $I_i$ , for atom  $i$ :<sup>10</sup>

$$I_i = [(\pi_i + n_i + 1)/\delta_i] + 1 \quad [1]$$

This expression holds for second-row atoms; an expanded form is used for higher rows of the periodic chart.<sup>10</sup>

The count of the pi and lone pair electrons on a bonded atom can be justified as a model of the electronegativity of the atom on both theoretical and experimental grounds. First, the work of Slater has shown that the pi and lone pair electrons have a high probability of being further from the atom core than the sigma electrons, resulting in less shielding. As a result of the presence of pi and lone pair electrons, the atomic core (nuclear protons and inner shell electrons) can exert a greater influence on the sigma-bonding electrons. This effect is the essence of electronegativity. Second, the Kier–Hall electronegativity is very successful in relating to the experimental Mulliken–Jaffe electronegativity derived from the ionization potential and electron affinity of atoms in their valence state.<sup>11</sup> In the correlation of pi and lone pair electron count with valence state electronegativity, the standard error is essentially equal to the known error in the valence state electronegativity.

The intrinsic state,  $I$ , of an atom or hydride group is an incomplete expression of the structure, because that feature is a part of the whole molecule and is affected by other atoms. Each atom in a molecule is in a field of the whole

**Figure 1** Computed E-state values for the atoms in a molecular series with iso-connective skeletons: (a) methylpropanoate, (b) *N*-methylpropanamide, and (c) 3-pentanone.

molecule, a field created by the combined effects of all atoms. The field is an information field, with the information derived from the influences as expressed through electronegativity differences. This influence is encoded into a series of perturbations in units of the intrinsic state of each atom. We have defined this perturbation on an atom as the difference between the intrinsic state of that atom and the intrinsic state of each other atom. The influence is mitigated by the distance through skeletal bonds,  $r_{ij}$ , between the atom and every atom in the molecule. These perturbations are summed and applied to the reference atom intrinsic state to yield the E-state value;

$$S_i = I_i + \sum_j (I_i - I_j) / r_{ij}^2 \quad [2]$$

in which  $r_{ij}$  is the count of atoms in the shortest skeletal path of atoms connecting the reference atom to the perturbing atom. The sum of the intrinsic state and its perturbations is defined as the E-state,  $S_i$ , for atom  $i$  in the molecule under study.

Some aspects of the nature of E-state structure descriptors are represented in Figure 1. In 3-pentanone (Figure 1c), the carbonyl oxygen atom has the largest E-state value, representing both its electron-richness and topological accessibility. This E-state value encodes the electron accessibility of the carbonyl oxygen. On the other hand, the carbonyl carbon atom is both electron depleted and less topological accessible within the molecular structure. The two methyl groups have identical values, in keeping with molecular symmetry, as have the two methylene groups. Both methyl and methylene groups have E-state values less than their intrinsic state values (2.00 and 1.50, respectively) because of electron depletion arising from the high electronegativity of the carbonyl oxygen atom.

In *N*-methylpropanamide (Figure 1b), the E-state of the amide -NH- group is intermediate between the carbon and oxygen atoms because of its intermediate valence state electronegativity. The two methyl groups have different E-state values, being no longer in symmetric positions. Furthermore, the methyl group attached to the nitrogen atom has a smaller value because of the attraction of electrons to the nitrogen atom.

In the ester (Figure 1a), the carbonyl carbon atom has the smallest value among these three molecules. The carbonyl carbon is electron depleted because of the attraction of electrons from both of the oxygen atoms. The carbonyl oxygen atom also has the smallest E-state value (of the three molecules) because of the presence of the other oxygen atom. The methyl groups also have smaller values, as expected (see 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery for more detailed information).

This simple illustration indicates the type of structure information resident in the E-state values and the trends that one can expect in a series of related structures. When E-state descriptors appear in a model, the chemist can draw upon this kind of information to interpret the model in terms of molecular structure for two purposes: (1) understanding the structure features that are important in the property and (2) guidance for structure modification of drug candidates.

The presentation above developed the formalism for the atom-level E-state value, the value computed for each atom in the structure. These values serve very well for investigations of biological activity in which the data are based on a common core skeleton structure. The atom level E-state values can be entered directly into the modeling as

variables. Many such investigations have been reported.<sup>10</sup> For data sets most often encountered in ADMET studies, the data consist of very diverse structures with no common core skeleton. For these studies, the E-state formalism has been extended to the creation of the atom-type E-state. For the atom-type descriptors, all atoms in the molecule are classified into one of many atom types. These atom types are the classic types of organic chemistry, such as  $-\text{CH}_3$ ,  $-\text{CH}_2-$ ,  $-\text{NH}-$ ,  $=\text{O}$ ,  $>\text{C}=\text{}$ ,  $-\text{Cl}$ ,  $-\text{S}-$ , and aromatic C and CH. For the atom-type E-state value of atom type  $X$ ,  $S^T(X)$ , the value is simply the sum of the E-state values for all atoms of that type,  $s_X$ , in the molecule:

$$S^T(X) = \sum_X s_X \quad [3]$$

The atom-type E-state index encodes three different types of structure information:

- (1) the electron accessibility of the atoms of that type;
- (2) the presence/absence of the atom type; and
- (3) the count of atoms of that type in the molecule.

This definition makes it clear that much more than feature count is included in the atom-type E-state. For that reason, the E-state is showing promising use in ADMET studies such as those described later in this article.

It is apparent that E-state descriptors encode information about both the valence electron structure of an atom and also its presence in the network making up the molecule. Interactions within the skeleton result in the perturbations to its intrinsic state. The E-state values are rich in information about the electron accessibilities of the atoms (hydride groups) in the molecule. These atom level descriptors of electron accessibility have been the basis for many published studies on biological activity and properties.<sup>10</sup> This formalism describes the E-state value for each atom (and hydride group) in a molecule. This concept has been extended to the description of other features that are significant for ADMET modeling, including a separate formalism for hydrogen atoms; development of E-state values for atom type; creation of the E-state for a bond; and development of E-state values for bond types.<sup>10</sup> Recently, this approach has been extended to groups or fragments in organic molecules (*see* 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery for an overview of these developments).

### 5.23.3.2 Molecular Connectivity

The E-state formalism focuses on individual atoms, and provides descriptors of the atom within the molecular network. It is also useful and possible to encode structure information representing the whole molecule. In this system we create structure indices encoding information about the connectedness (connectivity) of whole-network depictions of a molecule. The objective is characterization of the whole molecule as a unified entity, that is, as a complex system. For simplicity we define the nodes in a molecular network as representations of chemical groups made up of atoms or of atom hydrides ( $>\text{N}-$ ,  $-\text{NH}-$ ,  $-\text{NH}_2$ ,  $-\text{O}-$ ,  $-\text{OH}$ , etc., as is done in the E-state formalism). The state of each node is defined by a number, the simple electron count, corresponding to the count of the neighbors for each node (the count of sigma bonds, not counting hydrogen, to each atom or atom hydride in the molecule). The network can be dissected into a set of fragments representing one or more nodes, that is, atoms. For a brief presentation of this approach, let us consider only the set of pairs of neighboring nodes. Each set is defined by the simple electron count for the two atoms,  $i$  and  $j$ , in the set; any property of the network is hypothesized to be a function of these sigma electron count values. The numerical value that characterizes the two-atom set,  $c_{ij}$ , is derived by taking the reciprocal square root of the product of the simple electron count values. This value,  $c_{ij}$ , for each fragment is combined by simple addition for all network sets to give a network index (molecular index) called the chi index,  $^1\chi$ .<sup>13</sup>

The nature of some of the structure information in the simple first-order molecular connectivity index  $^1\chi$  is illustrated in Figure 2. The structures in Figure 2a show the increase in the index value as the number of atoms increases. In Figure 2b the heptane isomers (together with  $n$ -heptane in Figure 2a) clearly indicate that the  $^1\chi$  index decreases in value as the degree of branching increases:  $n$ -heptane  $>$  2-methylhexane  $>$  2,3-dimethylpentane  $>$  3,3-dimethylpentane  $>$  2,2,3-trimethylbutane.<sup>13</sup> When this index is part of a model, the chemist can use this structure information in the molecular modification process for design of candidate drug molecules. If the  $^1\chi$  index makes a positive contribution to predicted property values, structures with a decreased degree of branching will tend to have larger predicted property values (*see* 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery for more detailed information).

This quantity is a first-order simple index for the network, encoding the sum of first-neighbor relationships throughout the skeleton of the molecule. This index represents the topology of the molecule as derived from the

**Figure 2** Structures of alkanes to illustrate variation of the simple molecular connectivity index  $1\chi$  (a) with molecular size and (b) with degree of skeletal branching.

undifferentiated connections (skeletal bonds) in that molecule, that is, the set of bonded relationships. This molecule index encodes the topological structure information of the pattern of bonded relationships within the network of the molecular skeleton.

This index is the prototype index in this structure information representation system that has been greatly expanded to describe multiple neighbors and atom states in a molecule.<sup>7,8</sup> Furthermore, it has been shown that this index encodes information about the topology of a molecule as it impacts on nearby molecules in intermolecular interactions.<sup>14,15</sup> Much more detail on the nature of molecular connectivity indices is available elsewhere.<sup>13</sup>

### 5.23.3.3 Nature of Topological Structure Descriptors

The description given above for the basis and formalism of both the E-state and molecular connectivity indices provides a basis for understanding their nature, which is the foundation for the structure information representation approach to molecular structure. This representation is derived from the atomic nature and skeletal connections within a molecule, as usually presented in the molecule connection table. In this sense, these indices represent relationships within the molecule.

It has become a common practice to include molecular structure descriptors in categories based on an assumed dimensionality. Using these rubrics, a three-dimensional descriptor is one that is derived from information built upon atom positions in a three-dimensional space. These positions are defined by their constant relationship to other atoms in a molecule. It is assumed that there is no variation in these dimensions for any specific value of the descriptor. This means that the conformation is constant for that particular descriptor value.

Structure descriptors derived from a molecular graph are not three-dimensional descriptors. They belong to a graph-based category that includes the E-state and molecular connectivity indices. They have been incorrectly described as two-dimensional descriptors. A two-dimensional descriptor would be based upon a statement of a pairwise separation value of two atoms in a molecule and knowledge of a specific angle between three adjacent atoms. Thus, the positions of each atom would be known precisely, in two-dimensional space. This information is not resident in the E-state or molecular connectivity descriptors.

These graph-based descriptors are derived from knowledge of the state of each atom in the molecule and the bonding relationship among them. It is a relational network that depicts the atoms and their neighbors in a model that describes some structure attributes of a molecule. It is an abstraction of the complete structure of a molecule. There is assumed to be sufficient information encoded in such a structure description that it has utility in correlating and predicting the properties of molecules. It is inappropriate to refer to these descriptors in a dimensional sense. It is appropriate to refer to this category of molecular structure descriptors as relational network descriptors or molecular network descriptors.

This article focuses on models of ADMET properties, as discussed in the sections that follow. Each model captures the parallel between the structure of the molecules in the data set and the corresponding property. The molecules are three-dimensional entities engaging with other three-dimensional molecules; the properties arise from those engagements. Furthermore, the models are capable of prediction of the property values. Therefore, the descriptors in the model must contain implicit information about the structure of the molecules, including something of their three-dimensional nature. More detail on this important issue is given elsewhere (*see* 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery).

#### 5.23.4 **Summary of Recent Studies on Absorption, Distribution, Metabolism, Excretion, and Toxicity Properties Using the Electrotopological State with Other Topological Indices**

The combination of the E-state and the molecular connectivity chi indices together with other topological indices as structure representation has proven a useful approach to modeling ADMET properties. The combination of the electrotopological state, molecular connectivity, and related representations of molecular structure has been called the structure information representation.<sup>7,8</sup> The foundation of this approach rests on the extraction of basic salient structure information from the molecular connection table with the resultant development of expressions for valence state electronegativity and volume. As described elsewhere (*see* 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery), this information is the basis for the development of several classes of structure descriptors and their applications.<sup>10,13,16–31,35–39</sup> These studies are aimed at the development of structure information that can lead to improved pharmacokinetic properties and greater safety of drug design candidates. Their focus has been the development of *in silico* methods for validated prediction that can be employed early in the drug design process as well as in the drug maturation stage. Furthermore, high priority is placed on the need for models whose interpretation can be directly implemented in the overall drug design process.

Two threads of thought, validated prediction and direct structure interpretation, converge on the idea that a broad formalism can be built on the structure information representation approach, together with appropriate statistical techniques for model development. We have found the formalism for structure information representation to be a solid foundation for the construction of approaches to ADMET property modeling and structure interpretation in a broad sense, including the development of new structure descriptors and new approaches to descriptor creation.

Several studies illustrate aspects of the modeling approach, and will be described briefly. ADMET investigations are reported here in order of perceived increasing complexity:

- aqueous solubility;
- human intestinal absorption;
- protein binding;
- blood–brain barrier partitioning;
- metabolic stability;
- genotoxicity (Ames mutagenicity);
- risk of human carcinogenicity; and
- hepatotoxicity

##### 5.23.4.1 **Procedures and Statistical Methods**

In Chapter 4.22 on modeling ADMET properties, several terms, symbols, and quantities of statistical nature are regularly used. These terms are summarized, and a very brief description of their nature and use is given. For simplicity, the observed values (dependent statistical variables) will be referred to as the property values (ADMET).

#### 5.23.4.1.1 Training and test sets

To provide for both the separate development of a model and its testing or validation, the original data set is usually partitioned between a training set and a test set, often called the external validation test set. The test set is put aside and not used in any way for model development. The test set is predicted by the model after the model is developed, providing evaluation statistics. Depending on the size of the data set (number of observations or compounds), 10–20% of the whole set may be set aside for testing. Some form of random selection is used to create the test set. In our approach, the whole data set is clustered in a structure space composed of atom-type E-state descriptors and simple molecular connectivity chi indices, providing clusters of structurally similar compounds. Standard clustering techniques, such as Ward's hierarchical method, are used. Compounds for the test set are then selected from each cluster so as to cover the property range, without selecting compounds with the extreme property values in the overall data set. In this manner, the external validation test set is a representative of the whole data set, suitable for testing the model. The training set is used exclusively for the development of the model, including descriptor selection and parameter estimation.

#### 5.23.4.1.2 Modeling methods

Most of the terms used for indicating statistical significance originated in regression analysis with multiple linear regression (MLR) models. These terms are now widely used in other forms of modeling such as artificial neural networks (ANNs), k-nearest neighbor analysis (kNN), and partial least squares (PLS). Most recently, support vector machines (SVMs) have been adapted from their early use with binary data to the analysis of continuous data.

#### 5.23.4.1.3 Statistical terms and symbols

To express statistical results the commonly used terms and symbols are employed. A summary of the symbols is given in [Table 1](#).

Some investigators create many subsets with a model for each, and then use the average of the predictions from all the subset models as a form of consensus or ensemble model prediction. Statistics on the training subsets from such a process are also called cross-validation statistics.

#### 5.23.4.1.4 Randomization tests

Another approach to assessing the quality of the model is to compare the modeling statistics to those obtained from the use of random numbers in place of variables in the data set. The objective of this approach is to determine how much better the model is than one based on random numbers. Some authors have replaced the whole set of independent variables with random numbers and repeated the modeling process, a very time-consuming process. A typically used alternative technique is to randomize only the observed property values many times and repeat the computation of the correlation coefficient. The most commonly reported statistics include the average  $r^2$  for 100 random trials ( $r_{\text{ave}}^2$ ) and the maximum  $r^2$  ( $r_{\text{max}}^2$ ) obtained in the process. The average value provides some indication of the statistical significance; however, the  $r_{\text{max}}^2$  value gives a better estimate of the probability that the model is better than a random one, that is, the chance (1 in 100) that random numbers will provide a correlation with  $r^2 = r_{\text{max}}^2$ .

**Table 1** Terms and symbols used to express statistical information on the models discussed in this article

| <i>Term</i>                          | <i>Symbol/abbreviation</i> | <i>Use</i>   |
|--------------------------------------|----------------------------|--|
| Correlation coefficient              | $r^2$                      | Statistic calculated on the whole training set                           |
| Correlation coefficient              | $q^2, r_{\text{press}}^2$  | Statistic calculated for cross-validation or the external validation set |
| Standard error                       | $s$                        | Statistic calculated on the whole or the standard deviation training set |
| Standard error or standard deviation | $s$                        | Statistic calculated on the whole training set                           |
| Press                                |                            | Predicted residual sum squared error                                     |
| Mean absolute error                  | MAE                        | Statistic for the external test set                                      |

#### 5.23.4.1.5 Acceptable measure of criteria

The measure of statistical quality that indicates an acceptable level for predictive use depends heavily upon the experimental quality of the data set. For excellent physical and physicochemical data, very high  $r^2$  ( $>0.90$ ) and low standard error  $s$  values can be expected. However, for in vitro biological data, such as  $IC_{50}$  for binding, lower values of  $r^2$  ( $>0.80$ ) are usually obtained. For in vivo data on a population of subjects, the range of experiment values for a single compound is much larger; hence, much lower  $r^2$  values are usually obtained. At present, no specified level of correlation has been universally accepted for these studies. In this article, different levels of  $r^2$  are reported as acceptable depending upon the quality of the experimental data. Data taken from public sources, based on several information sources, often reveal a significant spread in values from different experimental protocols.

#### 5.23.4.2 Aqueous Solubility

Early studies by several investigators on small data sets successfully used both E-state and molecular connectivity structure descriptors.<sup>29,30</sup> Recently, larger data sets were investigated with more complex methods to create sound models based on the structure information representation approach.<sup>31</sup> Cross-validation techniques were applied before testing the model on external validation test sets, data that were not used in the development of the models. In this case, the training set was divided into 10 randomly selected sets, and an ANN method was employed to create 10 models as the basis for a consensus or ensemble model. Prediction of the external test set is obtained as the average of the predictions from the 10 separate ANN models.

External validation is considered a necessary part of the determination of the predictive capabilities of the model. In addition, we and our collaborators have sought what we term independent validation. In this process, a group independent from the modelers is sought that can test the model predictions on independently measured data. For example, Lobell has investigated nine available commercial models for aqueous solubility, including one based on the structure information representation approach.<sup>31</sup> Lobell found that the model based on the structure information representation approach gave the best results (among commercially available models) on an independent set of data obtained in his laboratory.<sup>32</sup> Table 2 contains data extracted from Lobell's study, and presents the comparative results from Lobell's work on solubility of 442 predominantly uncharged organic compounds. The model designated as CSLogWS is based on the structure information representation approach.<sup>33</sup>

The results in Table 2 are rank ordered on model quality. At the head of the table is the CSLogWS model with the highest  $r^2$  value and the smallest MAE value. This independent work indicates that the model based on the structure information representation approach is superior to the results of the other commercial models reported. Of particular interest is the much smaller percentage of predictions with large errors, that is, errors greater than 1.0 log unit (last column). These results tend to indicate the quality of the modeling approach, the combination of the structure information representation and nonlinear modeling. Software development continues, and it is expected that this progress will create software with greater accuracy in prediction than reported here.

In a second test of the solubility model, predictions were made on the solubility at pH 7.4 of a set of 80 charged aromatic compounds, including 31 cations, 24 anions, and 25 zwitterions.<sup>31,32</sup> The  $pK_a$  values were estimated by CSpKa,<sup>31</sup> so that solubility could be computed from the intrinsic solubility (CSLogWS) and  $pK_a$  using a relation between  $\log S$  and  $pK_a$  based on standard mass action relations. For this external test set,  $r^2 = 0.77$  and  $MAE = 0.57$ .<sup>31</sup> This result, currently considered as preliminary, is significantly better than those obtained from the only other commercial software for estimating aqueous solubility of charged compounds.

#### 5.23.4.3 Human Intestinal Absorption

The effectiveness of an oral drug is dependent upon sufficient absorption through the human intestines (HIA). Estimates of HIA are very valuable in the early stages of drug design in order to prevent development of candidates with inadequate HIA values.

In this preliminary study, the collected data set consists of 417 therapeutic drugs in which HIA is expressed as the percentage absorbed (%OA).<sup>34</sup> We used the structure information representation modeling approach, implemented with ANN modeling techniques, to develop the final model. The predictive quality of the model was tested on an external validation test set of 195 drugs; 92% of the compounds were predicted within 25% (%OA) of their reported experimental values. Figure 3 provides a plot of predicted %OA values. The ANN model was based on two data sets, one for low molecular weight ( $MW < 251$ ) compounds thought to be involved in passive paracellular transport, and a second set for higher molecular weight compounds ( $252 < MW < 1450$ ) thought to use transcellular transport. The MAE (11% (%OA)) for the test set indicates useful results for this model. However, several compounds appear as

**Table 2** Summary for comparison of models for aqueous solubility prediction

| <i>Method to predict <math>\log(WS_0)^a</math></i> | <i><math>r^2</math></i> | <i>MAE</i> | <i>AE &gt; 1 (%)<sup>b</sup></i> |

outliers based on residuals being greater than 25 (%OA). This study further underscores the need for a larger data set in which the data are more uniform from the experimental point of view, based on the same experimental protocol.

To indicate further the nature of the results, we divided the validation test set predictions into three categories: low, 0–19%OA ( $n = 16$ ); moderate, 20–59%OA ( $n = 21$ ); and high, 60–100%OA ( $n = 158$ ). The percentages predicted in the correct category are as follows: 0–19, 88%; 20–59, 67%; and 60–100, 94%.<sup>33</sup> Figure 4 displays the predictions by bin. Overall, 91% of the compounds were predicted in the correct category. No compound in the low category was predicted to be in the high category, and vice versa, further underscoring the usefulness of the predictions.

These HIA results are usable for both the prediction of categorical results (low, medium, high) or for a continuous value of the percentage absorbed. Important structure descriptors used in this model include atom-type E-state indices for secondary aniline amines and for ether oxygen. In addition, the model includes the E-state descriptor for the >C=O bond type, the E-state for the topological polar surface area (TPSA), and a measure of internal hydrogen bonding, the E-state for a hydrogen bond donor and a hydrogen bond acceptor separated by four skeletal bonds (SHBint4). The model indicates that large TPSA values make a negative contribution to the calculated HIA whereas SHBint4 makes a positive contribution. Both of these indications agree with the understanding of the factors that affect HIA. Use of the model structure descriptors has the combined advantages of being exactly calculated by the software, and do not require any specific mechanism for their interpretation. Therefore, these structure interpretations, drawn from the model, are useful for design to improve absorption. When HIA predictions from the model indicate poor absorption, structure interpretations from the model can guide the chemist in making synthetic modifications to improve absorption.

#### 5.23.4.4 Protein Binding

The binding of a drug to serum proteins in human plasma has a powerful influence on its pharmacodynamic behavior, and can affect the systemic distribution of the drug in several ways. Estimation of this significant ADME property is one of the important activities carried out in the lead optimization stage of drug design.

**Figure 3** External validation test set predictions of HIA on 195 drugs, showing the %OA predicted by the model versus the experimental value. Ninety-two percent of the predictions are within 25% of the experimental values.

**Figure 4** External validation test set predictions on 195 drugs, given in three bins, indicating that the predictions of %HIA by the model yield 91% correct placement in the high, medium, and low categories.

**Figure 5** External validation test set predictions for %PPB of 13 commercial penicillins not used in model development, showing the %PPB predicted by the model versus the experimental value.

In a first study, protein-binding data were obtained (given as the percentage bound, %PPB) for a set of 74 penicillins from a published drug design series.<sup>25</sup> The structures among the substituents are highly varied. The number of atoms in the substituents on the penicillin skeleton range from 1 to 22, compared with 17 atoms in the common scaffold. The data set included penicillins with acyclic, monocyclic, and bicyclic substituents; heteroatoms included nitrogen, oxygen, sulfur, fluorine, chlorine, and bromine. Protein-binding values range from 7.2%PPB to 96.0%PPB. The modeling method, using MLR, employed the structure information representation, and led to a successful (cross-validated) model, with sound direct statistics:  $r^2 = 0.80$  and  $s = 12.1$  (i.e., 12.1% bound, in the units of the experimental data, not necessarily 12.1% of the range or average value). The model is based on five molecular structure descriptors that include E-state indices for aromatic carbons, methylene groups, amines, and halogens; also included is a molecular connectivity descriptor for the degree of skeletal branching and the size of the substituents, designated as  $R_1$ .

In a second study, the predictive capability of the model was successfully tested by the prediction of protein binding for 13 commercial penicillins, an external validation test set not used in model development. The protein-binding values for these 13 compounds effectively covered the training set range from 18%PPB to 92%PPB. The statistics for prediction on this external validation test set are quite acceptable, and compare favorably to the training set statistics:  $r^2_{\text{press}} (= q^2) = 0.84$  and  $MAE = 12.7$ . Figure 5 shows a plot of the predictions on this external test set. This test of the model strongly indicates that results from a model based on a drug design series can be used to predict a set of structures (for protein binding) under consideration for further synthesis and testing. This significant result indicates the quality that is needed in any stage of drug design.

Furthermore, in the third part of this investigation, when 28 cephalosporins were included in the training set, a new satisfactory model was developed for the full data set of 115  $\beta$ -lactams.<sup>25</sup> The substituents contain from six to 21 atoms in the  $R_1$  position of the  $\beta$ -lactam core skeleton. In the  $R_2$  position, substituents contain from one to 12 atoms. Protein-binding values for the cephalosporins range from 2.0% to 98.0%. The full model for 115  $\beta$ -lactams produced satisfactory statistics for prediction, based on cross-validation. For this purpose, 10% of the data was left out and predicted from the remaining 90%. This process was repeated until each compound was left out once. Then, that process was repeated 10 times ( $10 \times 10$  cross-validation), yielding 1150 residual values and the following statistics:  $r^2_{\text{press}} = 0.79$ ,  $s_{\text{press}} = 14.0$ , and  $MAE = 10.9$ . In the  $y$  randomization test,  $r^2_{\text{max}} = 0.16$ .

This  $\beta$ -lactam model is based on eight structure descriptors, including the five obtained in the penicillin model. The three additional descriptors represent features present in the cephalosporins, including E-state descriptors for the carbonyl oxygen and  $-N$  = nitrogen groups. Also included is a molecular connectivity index for the degree of skeletal branching and size of the substituents located in the second position of substitution,  $R_2$ . Structure interpretation of the model was also described in detail in the study.<sup>25</sup> For each descriptor in the model, detailed statements were made about the variation in the predicted protein binding as a result of the variation in the descriptor value. Based on this information, a chemist can design modifications of molecules to increase (or decrease) protein binding, a feature necessary for effective drug design.

In subsequent work, the modeling approach (based on the structure information representation descriptors) was used to develop an ANN model on a larger and significantly more diverse data set of 1000 drugs, including the prediction of an external validation test set.<sup>33</sup> The MAE for the external validation set of 208 drugs is 12.7 (percentage

**Figure 6** External validation test set predictions for %PPB of 208 compounds, showing the %PPB predicted by the model versus the experimental value. Included are eight compounds (green triangles) determined to be extremely nonsimilar to the training set (linkage distance >1500 in hierarchical clustering). Ninety percent of the predictions are within 30% of the experimental values.

bound). Furthermore, 92% of these predicted values lie within 30% (percentage bound) of the experimental value. The external validation  $r^2$  is 0.71. Figure 6 provides a plot of the predicted values for this external test set. During this analysis, several errors were discovered in the original input data: for several compounds the value (percentage bound) in the compendium was actually found in the original literature to be reported as the percentage unbound. For a few other compounds, the experimental value is actually for a metabolite. Data were also found where the endpoint had been measured on nonhuman plasma, such as bovine serum. A clustering technique based on the atom-type E-state descriptors was used to facilitate this error analysis by identifying compounds with an experimental value that significantly differed from structurally similar compounds, suggesting further examination to confirm whether a data error was present.

In an extension of the method, eight compounds had been found to be significantly nonsimilar to the structures of the compounds in the training set. In the hierarchical clustering method (Ward's) used to create the external test set, these eight compounds were found at a large linkage distance from the rest of the data set. These eight compounds were removed from the training set. Subsequent to the testing of the model on the external validation test set of 208 compounds, predictions were made on these eight compounds. Their predictions are shown as green triangles in Figure 6. Seven of the eight predictions fall within the same range of predictive quality as for the test set. This finding may indicate that use of topological descriptors may provide the basis for the prediction of compounds that are not highly similar to those of the training set. Further investigations of this issue are underway.

The investigation on serum protein binding was extended to consider the use of data collected as the high-performance liquid chromatography retention time on immobilized albumin.<sup>26</sup> Retention time has been interpreted as the binding affinity of a compound to albumin. Some investigators have suggested that this highly automated experimental technique might be a suitable substitute for other methods of measuring protein binding. In order to investigate whether the modeling approach used for serum protein binding might also be useful for this alternative type of affinity data, the method was applied to a data set of 94 drugs. The number of (nonhydrogen) atoms in the molecules in the data set ranged from 10 (salicylic acid) to 57 (digitoxin). The molecules contain from one to six rings. The experimental data were modeled as the logarithm of the retention time,  $\log k(\text{HSA})$ . For the training set of 84 drugs, direct statistics are quite acceptable:  $r^2 = 0.77$  and  $s = 0.29$ . These modeling results are better than those reported

using other published modeling methods.<sup>35</sup> In fact, Colmenarejo (*see* 5.36 In Silico Prediction of Plasma and Tissue Protein Binding) found it necessary to remove five compounds deemed to be outliers. The model, based on the structure information representation described above, gave quite acceptable results for 84 compounds, including all five excluded by Colmenarejo. The model is based on six molecular structure descriptors, including atom type E-state descriptors for aromatic carbons, saturated carbon atoms, fluorine and chlorine, and hydroxyl groups. In addition, two molecular connectivity descriptors represent six-membered rings.

Models were examined in several ways before being accepted as predictive tools. In the first test, the  $y$  randomization results are very satisfactory. In an extensive cross-validation process, each compound was left out once in 10 unique leave-out sets. The resulting statistics for this process are reported in the study, and further support the validity of the model. The most stringent test of the model is the prediction of 10 drugs in an external validation test set. For those 10 compounds, which covered the  $\log k(\text{HSA})$  range,  $r^2 = 0.74$  and  $\text{MAE} = 0.31$ . Finally, our investigation presented detailed information on the structure interpretation of the descriptors found in the model. This information can serve as the basis for molecular modification in the drug design process.<sup>26</sup>

#### 5.23.4.5 Blood–Brain Partitioning

Whether drug design criteria require significant brain penetration or demand minimal partitioning into brain tissue, estimation of the brain–blood ratio,  $\text{BB} = [\text{brain}]/[\text{blood}]$ , is essential in drug design. In our first study, we organized experimental data, given as the logarithm,  $\log \text{BB}$ , from 11 literature sources to create a very diverse set of 106 compounds.<sup>28</sup> MLR methods led to models, but the linear technique yielded poor statistics. When nonlinear terms were developed for specific structure descriptors, an adequate model was obtained:  $r^2 = 0.66$  and  $s = 0.45$ . Two issues arose that appear typical of ADMET modeling. First, it was necessary to introduce nonlinear terms into the model in order to achieve useable results. Second, four compounds appeared to be outliers and were removed. Although the exact reasons for outlier status are not clear, two explanations were considered: (1) the eclectic nature of the experimental data, which include several types of experimental protocols, and (2) the possibility that salient structure features are not adequately encoded in the descriptor set. Because this data set is eclectic from the experimental protocol point of view, no reliable estimate of the actual experimental error for the data set is available. However, statistics from cross-validation indicate the model to be useful for drug design purposes.

This model for blood–brain barrier partitioning was also directly interpretable in terms of molecular structure, leading to statements about the manner in which calculated blood–brain barrier partitioning varies with molecular structure as a guide to molecular modification. For example, one of the descriptors in the model is the hydrogen E-state value for hydrogen bond donors (*see* 4.22 Topological Quantitative Structure–Activity Relationship Applications: Structure Information Representation in Drug Discovery). The model indicates that as the descriptor for hydrogen bond donor strength increases,  $\log \text{BB}$  decreases, in agreement with the assumed nature of membrane passage across the blood–brain barrier. Furthermore, the model indicates that the contribution of an hydrogen bond donor group covers a range of values, depending on the bonding environment of the donor group. The range in contribution is traced directly to the fact the E-state value for an atom or group encodes its molecular bonding environment. This bonding environment aspect of E-state descriptors highlights their significant advantage over a simple fragment count, which is insensitive to molecular environment.

In one additional study with the model for blood–brain barrier partitioning,  $\log \text{BB}$  values were predicted for a set of 20039 organic molecules from the Pomona MedChem database.<sup>28</sup> The experimental  $\log \text{BB}$  values were not available for these compounds, but the range of predicted values could indicate the potential for realistic predictions. In this test, 99.3% of the predicted values fell within the same  $\log \text{BB}$  range as the training set. No unreasonable values were computed by the model.

Subsequent unpublished work has extended the range of applicability of the BB model. To deal with the nonlinear nature of the property–structure relation, an ANN model was developed for 103 compounds, and tested by the prediction of an external validation test set.<sup>33</sup> Figure 7 shows the predictions for this external test set. One significant aspect of the new validation test set is that it consists of data on human brain and human cerebrospinal fluid (CSF) as well as data on rat and monkey. Data in the training set are entirely based on rat brain, but the external validation test set includes human brain data as well as CSF data in addition to monkey brain. The validation test results are statistically satisfactory,  $r^2_{\text{press}} = 0.62$  and  $\text{MAE} = 0.39$ , even though the experimental nature of the test data arises from different sources than the training set. To provide a different view of the predictions, the data were divided into three bins, corresponding to low, medium, and high partitioning. These results are presented in Figure 8. Note that 83% of the predictions fall into the correct bin. Furthermore, no prediction on a compound in the high bin falls into the low bin, and vice versa.

**Figure 7** External validation test set predictions on 74 commercial drugs for blood–brain barrier partitioning, showing log BB predicted by the model versus the experimental value. The model is based entirely on data from rat brain. This validation set consists of data from several types of measurements: 18, rat brain; 44, human CSF; 5, human brain; 2, monkey brain; 3, other animals. Eighty-eight percent of the predictions are within 0.75 log units of the experimental values.

**Figure 8** External validation test set predictions on 74 commercial drugs for blood–brain barrier partitioning as log BB given in three bins, indicating that the predictions of the model yield 83% correct placement in the high, medium, and low categories. The model is based entirely on data from rat brain. This validation set consists of data from several types of measurements: 18, human brain; 44, human CSF; 5, human brain; 2, monkey brain; 3, other animals.

### 5.23.4.6 Human Metabolic Stability

A key factor in drug efficacy and toxicity is the metabolic stability of the drug. Part of the approach to this issue is the development of the ability to recognize atom types and/or fragments involved in metabolism in phase I and II metabolism reactions. Furthermore, it is important to establish the ability of QSAR methods to account for the nonlinear relationships between compound structure and the toxic property, effects that arise from the multiplicity of possible mechanisms involved. For these reasons, we engaged in a preliminary investigation of modeling metabolic stability data even though large numbers of such data measured in a consistent protocol are not readily available.

The data for human metabolic stability was obtained from Cypotex, based on in-house data as clearance,  $CL_{int}$ .<sup>49</sup> These values ranged from highly stable compounds ( $CL_{int} < 10$ ) to unstable ( $CL_{int} > 100$ ). The chemical structure diversity of the data set was investigated using principal component analysis (PCA) using 115 topological structure descriptors. The first two components,  $T_1$  and  $T_2$ , account for only 17.2% of the total structure space variance, and only 43.3% of structure space variance was explained by the first nine components. These results indicate high chemical structure diversity among the 769 data set compounds.

A brief description of the experimental data indicates the essential nature of the  $CL_{int}$  values. The solution of a test compound was incubated with human liver microsomes. Reactions were terminated at five time points to provide time development data; analysis was carried out by liquid chromatography–mass spectrometry. Kinetic solubility measurements were made on all compounds to ensure adequate compound solubility. The  $CL_{int}$  ranged from  $\sim 0$  to 500  $\mu L/min$  per milligram of protein. Metabolic stability was indicated as  $CL_{int} < 25$ ; and metabolic instability was indicated as  $CL_{int} > 100$ . From the data set of 769 compounds, 693 compounds were randomly selected as the training set for ANN model development; the 76 remaining compounds were set aside for external validation of the model.

An ANN model was indicated in previous publications.<sup>35,41</sup> The developed ANN model is based on 19 topological descriptors, mainly atom-type, bond-type, and group-type E-state indices. The actual ANN model is called a consensus or ensemble model. In this technique, the final prediction is obtained as the average of the predictions of 10 models. The consensus model yielded correlation statistics, as follows:  $r^2 = 0.77$  and  $MAE = 19$  for a training set of 693 compounds. The validation test set ( $n = 76$  compounds) yielded  $r^2 = 0.56$  and  $MAE = 22$ ; 11 compounds have absolute error  $> 35$ . The  $y$  randomization test also yielded satisfactory results; all the randomized sets yielded  $r^2 < 0.05$  for the train and validation sets for this ANN model, indicating that the model is significantly different from a random selection of input vectors.

These preliminary results on 769 compounds indicate that the structure information representation approach to structure coupled to the consensus/ensemble ANN modeling technique is able to provide an approximate model for metabolic centers for phase I reactions as represented by this data set. The quality of the test set  $r^2$  value is in keeping with the eclectic nature of both the structures and the methods of data measurement. More satisfactory statistical results await a data set based on consistent measurement. Another study using the kNN technique with topological structure descriptors gave similar QSAR findings on metabolic stability of 639 drug-like compounds.<sup>50</sup> Based on these results, it appears that this approach, using the ensemble ANN modeling technique or other nonlinear methods based on topological structure descriptors, is capable of yielding useful results. However, we continue to gather information with the hope of creating a database with more accurate experimental data as the basis for improved models.

### 5.23.4.7 Toxicity

This section consists of a brief presentation of toxicity studies as follows: fish toxicity, Ames test genotoxicity, risk of human carcinogenicity, and hepatotoxicity.

#### 5.23.4.7.1 Fish toxicity

In earlier studies, models were developed for the toxicity of organic chemicals to the fathead minnow (*Pimephales promelas*), based entirely on molecular connectivity.<sup>36–38</sup> Later, Gough and Hall examined the toxicity of amide herbicides<sup>21</sup> using a combination of E-state and molecular connectivity. Recently, using the E-state formalism, Rose and Hall re-examined fish toxicity data (*Poecilia reticulata*), to create an externally validated model.<sup>39</sup> The data set consisted of 92 compounds characterized as phenols, anilines, aromatic hydrocarbons, nitro-aromatics, and halogenated aromatic hydrocarbons. Toxicity values ( $LC_{50}$ ) ranged over four orders of magnitude.

Three E-state atom type descriptors (for chlorine, ether oxygen, and the hydrogen atom with maximum hydrogen E-state value) and one molecular connectivity index ( $^1\chi^v$ ) provided the basis for an excellent model:  $r^2 = 0.87$  and  $s = 0.25$ . An external validation test set consisted of data on three species other than that in the training set, as described in detail by Rose and Hall.<sup>39</sup>

In this study, the E-state model was compared to one based on sophisticated quantum chemical indices<sup>40</sup>; the E-state model was found to be significantly better in statistical quality.<sup>39</sup> Furthermore, direct structure interpretation was given for the model based on structure information representation. These descriptions of structure interpretation can be used directly to determine how toxicity is influenced by changes in the molecular structure of candidate molecules. No structure interpretation was given for the model based on quantum mechanical computations because of the complex nature of the principal components analysis that was used to construct the model.

An important feature of these studies is their applicability to an allied area of molecule design, environmental toxicity, and pollution. As part of the manufacturing process, chemists must consider the potential for toxicity and pollution. The structure information representation approach has shown its ability to assist this process through the development of models that can be predictive of toxicities to fish and other animals. What is learned in the arena of drug design can be useful in human health as well as in the environment.

#### 5.23.4.7.2 Ames genotoxicity

This toxicity study illustrates the application of our method to a standard test required in drug submission to regulatory bodies, the Ames test for mutagenicity, based on mutations developed by chemicals in the bacterial system *Salmonella typhimurium*. The use of the Ames test is based on the assumption that any substance that is mutagenic (for the bacteria used in the test) may also turn out to cause cancer. Although, in fact, some substances that cause cancer in laboratory animals do not give a positive Ames test (and vice versa), the ease and low cost of the test make it invaluable for screening substances for possible carcinogenicity.

Recently, we applied the structure information representation approach to an Ames test data set that included 290 drugs.<sup>41</sup> The data set consisted of 3363 very diverse compounds with ratio of mutagens to nonmutagens as 60/40. For modeling, compounds were designated as mutagen or nonmutagen. An ANN model, developed to deal with binary data, yielded 89% correct classification in the training set and 83% correct in the external validation test set with a low rate of false positives. For 30 drugs in the external test set, false positives were 7%. Figure 9 provides the model statistics along with a comparison to predictions produced by other methods.

In this investigation, using the structure information representation approach, three types of statistical modeling were examined: a nonlinear learning method, an ANN; a nonparametric method, the kNN technique, and a classification method (the decision forest). The results of the three approaches were carefully compared with an emphasis on the use of external validation test sets that included drugs. For this data set, the ANN method provided the best statistical results on the external test set. All of the other methods available for comparison also yielded higher false-positive percentages.

**Figure 9** Comparison of overall predictive accuracy, false positives, and false negatives for the validation of Ames mutagenicity models from three sources; ChemSilico Predict 2.0.3.1 (CSGT), MULTICASE (MCase PCA2i), and DEREK (version 3.4). Validation predictions were made on 217 organic compounds, including 30 drugs. The complete validation set for CSGT consisted of 400 compounds, but comparison was available for only 247 of the 400 because 183 compounds were also in the MULTICASE training set.

Of significant importance for the results of this investigation is the combination of structure descriptors found to be important in the model. First, the whole molecule descriptors, such as molecular connectivity indices, encode significant information on the general structure features such as size, shape, and skeletal variation and complexity. These descriptors appear to provide useful discrimination among various structure classes present in the data set. Second, the atom-type, bond-type, and group-type E-state descriptors encode important structure features such as atoms and bonds associated with important functional groups. Of particular significance is the occurrence of E-state descriptors that correspond to known structure alerts. Several examples are described in the study.<sup>41</sup>

#### 5.23.4.7.3 Risk of human carcinogenicity

A significantly expensive part of the drug approval protocol is the test for risk of human carcinogenicity based on a US Food and Drug Administration (FDA) protocol, performed on rats and mice for 2 years or more.<sup>42</sup> In recent years, otherwise successful drug candidates have failed this test. This kind of late failure is very costly and causes delays in the drug development process. An in silico predictive method that would give reasonably valid predictions of human risk would be invaluable in the early stages of drug design. Such a method would give early warnings so that alternative candidates could be developed to have estimated low risk.

The earlier studies on toxicity suggested that the structure information representation approach might be usefully applied to the prediction of the potential for human carcinogenicity. In conjunction with the FDA (Center for Drug Evaluation and Research), MDL Information Systems used a combination of E-state and molecular connectivity indices to create a model for the human risk of carcinogenicity.<sup>43</sup> Nonparametric discriminant analysis was used on a training set of 1022 drugs. The carcinogenicity risk was indicated as 'high' or 'low,' based on FDA criteria.<sup>42</sup> A form of nonparametric discriminant analysis was used to establish the model, which was validated on an external test set of 50 drugs. For the external test set, this model yielded 76% correct prediction for a 'high' risk of carcinogenicity and 84% correct for a 'low' risk. Of particular importance is the low percentage of false positives, 16%.

#### 5.23.4.7.4 Hepatotoxicity dose-dependent modeling of therapeutic drugs

Drug-induced toxicity and adverse drug reactions are among the primary causes of postmarket withdrawal of drugs. These effects also account for over 50% of the acute liver cases in the USA.<sup>1,3,46,47</sup> Approximately 50% of new pharmaceuticals that show hepatotoxicity effects in clinical drug development also have corresponding effects in animal toxicity studies.<sup>2,45</sup>

A preliminary study was undertaken to assess the feasibility for modeling the hepatotoxicity of drugs. Although data measured by a consistent set of protocols are not available in large numbers, it is believed useful to examine the possibility for modeling this important type of toxicity, even on a small data set. For this reason we consider this a preliminary study. The sources for the data were *Mosby's GenRx* and *Therapeutic Drugs*.<sup>44a,b</sup>

Initially, 366 compounds were obtained from the data source and compiled in the database. Compounds were eliminated on the following basis: duplications (same drug with different associated salts), intravenously or topically administered drugs, and drugs containing coordinated  $\text{Ca}^{2+}$  or  $\text{Mg}^{2+}$  ions. The final number of orally administered drugs used in this study was 291. The dosage was given as milligrams, and assumed to be administered daily. With an assumed average body weight of 60 kg, the assumed daily dosage was converted to millimoles per kilogram. The dosage range covered 41 000 in  $\text{mmol kg}^{-1}$  units for 291 compounds. For modeling purposes, the data were converted to the logarithm scale as  $\log(\text{mmol kg}^{-1})$ , to be used as the dependent variable in modeling. No information was provided on age, gender, or the duration of oral consumption.

The final set of 291 drugs was rechecked for structure duplications.<sup>48</sup> This final set contained 63 of the most prescribed drugs from the 1995 to 2003 Rx list.<sup>44b</sup> An assessment of the chemical diversity of 291 drugs was conducted to establish the diversity of these 291 drugs. First, principal component analysis was performed, using 115 topological descriptors. A second similarity analysis was performed by computing the Tanimoto coefficient between every pair of molecules in the data set.<sup>17</sup> Both methods indicated the significant diversity of the structures in the data set.

As a basis for modeling, the total available set of structure descriptors was trimmed before modeling to an initial set of 210 structure information representation descriptors. Trimming was accomplished by removal of descriptors that only count features and those with a nonzero population less than 3%. An ANN ensemble model was built with a training set of 259 compounds. The average predicted value ( $\log(\text{mmol kg}^{-1})$ ) from the 10 nets produced by the ensemble model was used as the predictive value for the external validation test set of 33 compounds. The dose-dependent range for the training set was 4.6 log units, and 3.4 log units for the 33 randomly selected drugs used for the external validation. The  $r^2$  value for the training set was 0.64, and 0.42 for the external test set. The MAEs for the training and test sets were 0.39 and 0.44, respectively, amounting to about 10% of the range of data in the two sets.

To test whether the 10 descriptors obtained in the ANN model were accidental, two randomizations of the experimental data were made. The correlation coefficients obtained were given as  $r^2 = 0.03$  and  $0.07$ , respectively, for the training set. Similar values were found for the validation set. MLR analysis was also performed, yielding poor results:  $r^2 = 0.42$  for the training set and  $0.03$  for the validation set, using a 10-fold ensemble model with 16 topological descriptors.

Given the lack of any specific information on age, gender, population size, or total dose, these results are very encouraging for this eclectic data set. The MAE for the training set was  $0.39$ . Furthermore,  $76\%$  of the calculated values lie within  $0.6$  log units of the experimental values. Likewise, the 33 drug new chemical entities in the validation test set gave an MAE of  $0.44$ ; and  $67\%$  of the predicted values were within  $0.6$  log units of the experimental values. These results indicate that ensemble ANN modeling techniques using only 10 structure descriptors did an adequate job in predicting dose-dependent hepatotoxicity effects for this rather small and eclectic data set.

### 5.23.5 Software

Computation of the structure information representation descriptors is readily available in software from EduSoft, LC.<sup>52</sup> Furthermore, models for ADMET properties based on these structure descriptors are commercially available from ChemSilico LLC.<sup>33</sup>

### 5.23.6 Conclusions

This article summarizes a small number of QSPR investigations on ADMET properties that indicate the wide applicability of the structure information representation approach that includes the E-state. Each model is validated by prediction on an external validation test set, not used in model development. These test sets are diverse and generally among the largest yet published. The focus of this article is on modeling ADMET properties, but many more investigations have been reported elsewhere.<sup>10,12,14–31,35–39,51</sup>

The E-state description of molecular structure has been presented and shown to be of significant value in encoding information relevant to pharmacodynamic and biological properties. As derived, the E-state indices are based on electron counts and orbital distributions. Their relationship to chemical structure is verified by the ability to relate these indices to electronegativity, molecular volume, molecular orbital free valence, and nuclear magnetic resonance chemical shifts, among other properties.

These atom-based indices, along with whole-molecule topological descriptors, the molecular connectivity indices, have been used to model the pharmacodynamic and biological behavior of molecules of interest as drugs. In particular, we have shown that a class of properties known as ADMET can be successfully modeled using these descriptors.

The models can be used to predict activity within these categories. Since the E-state and molecular connectivity indices are derived from structure, the models created with them can be interpreted directly as molecular structure. Property prediction and drug design are thus derivatives of the models we have discussed here.

## Biographies

**Lowell H Hall** is a physical chemist who has pioneered methods of molecular structure representation for over 30 years. He received the PhD in physical chemistry from The Johns Hopkins University and pursued postdoctoral work at The National Bureau of Standards and Oak Ridge National Laboratory in single-crystal x-ray crystallography. He has been Professor of Chemistry at Eastern Nazarene College, a liberal arts college in Quincy, MA, since 1967. He began his research into quantitative structure–activity relationship (QSAR) models during a sabbatical leave with Lemont B Kier at Massachusetts College of Pharmacy in 1974. Together, Hall and Kier have written four books, eight book chapters, and more than 100 papers. Their most recent book, *‘Molecular Structure Description: The Electrotopological State’* (Academic Press, 1999) presents their E-state approach to molecular structure representation. Hall and Kier are the co-developers

of the structure information representation method as well as topological QSAR modeling. Professor Hall has been a consultant to pharmaceutical companies, a regular participant in the Gordon Conference on QSAR/CADD, and is currently a consultant with MDL Information Systems. He is the creator of the Molconn software, and also runs Hall Associates Consulting. He is a partner in ChemSilico LLC, a producer of model predictors for properties of interest in the pharmaceutical area.

**Lemont B Kier** received a BS in pharmacy from Ohio State University, and a PhD in medicinal chemistry from The University of Minnesota. He has been a pioneer in the development of several theoretical methods used for rational drug design, based on molecular structure. He introduced the use of molecular orbital theory to compute the preferred conformation of molecules. New insight into the pharmacophores of several neurotransmitters and drug molecules were predicted by Kier using these calculations. In another application, Kier pioneered the use of molecular orbital calculated energies to predict intermolecular interactions, now called molecular docking. In the mid-1970s, Kier and Hall developed nonempirical molecular descriptors named molecular connectivity indices. Information derived from these indices is a nonempirical estimate of the valence state electronegativity, called the Kier–Hall electronegativity, closely correlated with the Mulliken–Jaffe electronegativity values. In the mid-1980s, Kier introduced the kappa indices, encoding information about several aspects of molecular shape and flexibility. Another approach to structure description was developed by Kier and Hall, in the early 1990s. This set of descriptors is called the electrotopological state (E-state), and is based on the Kier–Hall electronegativity and the topological characteristics of an atom or group in a molecule.

**L Mark Hall** received a BS in biology with minor degrees in chemistry and writing from Eastern Nazarene College, where he did undergraduate research developing artificial neural network (ANN) quantitative structure–activity relationship (QSAR) models on pesticide toxicity and human plasma protein binding. He has worked as a consultant to vendors that develop computational chemistry software tools. This consulting has included the development of product user guides, software specifications, and quality assurance reports. He has also worked in product development for ChemSilico, helping to develop commercial ANN predictors for human intestinal absorption, human plasma protein

binding, and blood–brain barrier partition. He has published QSAR studies for human intestinal absorption, human plasma protein binding, albumin binding affinity, aqueous solubility, and Ames genotoxicity. He has worked for Hall Associates Consulting on the continuing development of the Molconn molecular descriptor software. These projects include the development of a new class of descriptors designed for use in modeling the acid ionization constant of drugs, the development of a system for recognizing and correcting aromaticity-encoding errors in computer-based molecular structure files, and the development of new approaches to error analysis of QSAR models using novel applications of hierarchical clustering. In 2005, Hall was elected to serve as the Communications Director for the Boston area Group for Informatics and Modeling.

## 5.24.1 Setting the Scene

### 5.24.1.1 The Dimensionality of Molecular Information

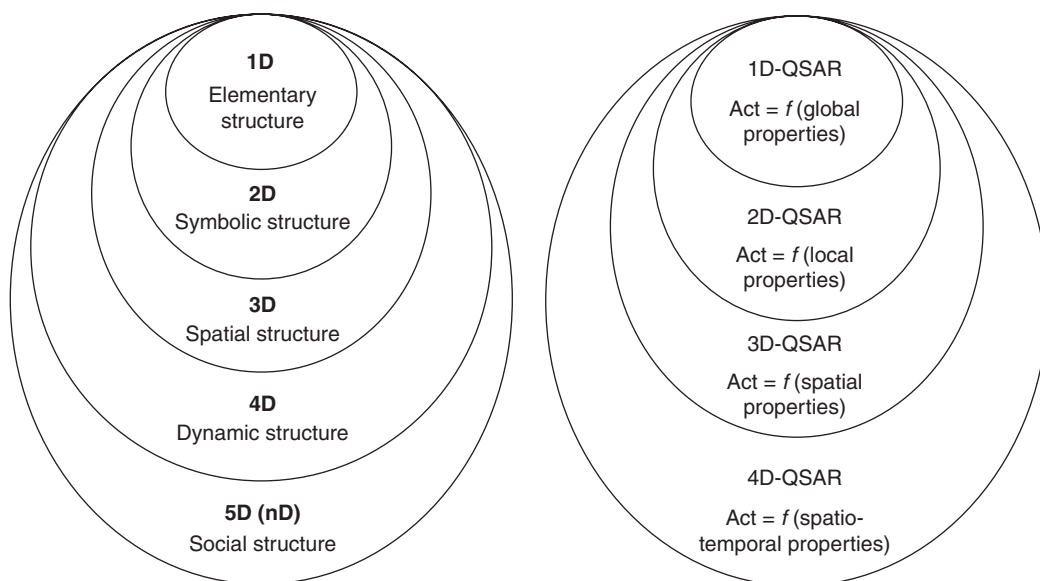

It is a general assumption that molecular properties/attributes can be classified according to their dimensionality corresponding to that of the molecular representation from which the property was derived. As seen in [Figure 1a](#), molecular representations can be divided into elementary (1D), symbolic (2D), spatial (3D), dynamic (4D), and social (5D), and multidimensional,  $nD$ ).<sup>1</sup>

For the elementary 1D depiction, molecules are represented by their chemical formulae. This is the constitution of the molecule in terms of atom content and count. The 1D representation is so poorly informative that it does not unambiguously define a molecule, since all positional isomers have the same molecular formula.

At the 2D symbolic level, molecules are represented by illustrations depicting the presence and the adjacency of atoms of various types. The code letters and connecting lines in these representations are the familiar structures that we normally draw on paper. The main information encoded is the connectivity (i.e., the bonding relationship). The connectivity allows us to dissect a molecule according to its functional groups, facilitating a qualitative interpretation of most chemical phenomena (e.g., reactivity or acid/base equilibria).

The 3D spatial representation includes all the information encoded at the 2D level plus the rich information deriving from the fact that a molecule is an object in 3D space. This information includes the spatial arrangement of atoms or groups (i.e., the conformation), the mantle or buried status of an atom, and the approximate spatial occupancy of parts or the whole of a molecule. Geometric 3D information can be graphically represented using molecular surfaces that give a good approximation of steric requirements (*see* [Section 5.24.2.1](#)). Physicochemical properties of great pharmacological and biological relevance, including hydrophobicity, hydrogen bond donor and acceptor capacity, and lipophilicity depend strongly on the 3D geometry of a molecule. A powerful method to study these recognition forces is the computation of molecular fields, for example molecular electrostatic potentials (MEPs, *see* [Section 5.24.3.1](#)), which encode electrostatic forces, molecular lipophilic potentials (MLPs, *see* [Section 5.24.3.2](#)), which encode hydrophobicity, hydrogen-bonding capacity and polarizability, the recent molecular hydrogen-bonding potentials (MHBPs, *see* [Section 5.24.3.3](#)), and, more generally, molecular interaction fields (MIFs, *see* [Section 5.24.3.1](#)), which can encode a wide range of recognition forces depending on the probes used (e.g., the fields computed with the GRID program, *see* [Section 5.24.3.1](#)).

When time is added to the 3D description, the dynamic 4D profile of a molecule is revealed. This permits consideration of conformational flexibility and prototropic behavior. The dynamic behavior of molecules can be expressed in conformational hypersurfaces, and the ensemble of all conformers of a given compound is often taken as

**Figure 1** (a) A multilevel description of molecular structures and properties. (b) A multilevel classification of QSAR approaches. 1D, one-dimensional; 2D, two-dimensional; 3D, three-dimensional; 4D, four-dimensional;  $nD$ , multidimensional; QSAR, quantitative structure–activity relationships. (Reproduced from Testa, B.; Kier, L.; Carrupt, P. A. *Med. Res. Rev.* **1997**, *17*, 303–326, with permission from John Wiley & Sons, Inc.)

defining a conformational space. Also, the conformer-dependent properties will exhibit variability over time, since there is a one-to-one correspondence between the conformational space and the property values.

Thus far, molecules have been considered to be in isolation. This, however, is only partly correct, since, as Helmholtz repeatedly stated,<sup>2</sup> there exists no intrinsic property, since a property is always the ability of a subject to exert some effects on an object even if the latter is not defined or remains implicit. Such an implicit object is well illustrated by the environment or medium surrounding the subject. This model underlines the interactive nature of a property and implies a dynamic profile, since a property requires a process by which it can emerge and a discrete duration for its manifestation.<sup>3</sup>

Attributes and properties corresponding to the elementary and symbolic levels of description (mainly 1D and 2D properties) are environment-invariant, whereas stereo-electronic properties (mainly 3D and 4D properties) are influenced by the molecular environment. At this level of interaction, the description of molecular structure and properties becomes highly complex, and the molecular environment (e.g., solvent, bulk liquid, or crystal) must be explicitly considered.

A molecule may be viewed as a social entity, exhibiting emergent multidimensional properties from nonlinear interactions with other molecules (which may belong to the same compound as in a crystal, to other chemicals, or to a solvent). These properties are novel with respect to those which emerge at lower levels of description, and in a rigorous sense they can be exhibited not by individual molecules, but by a chemical compound.<sup>4</sup> This concept is also reflected in the social nature of living organisms, which are currently seen as dynamic complex systems that develop and evolve in relation to other organisms and complex environments.<sup>5</sup>

It is interesting to observe that the quantitative structure–activity relationship (QSAR) techniques can be similarly classified according to the dimensionality of molecular properties/descriptors used as independent variables (**Figure 1b**). Thus, the 1D-QSAR approaches correlate global properties (computable or measurable) with biological data, while the 2D-QSAR approaches use, as independent variables, fragmental increments conceptually derived from the dissection of a molecule according to its functional groups (as seen in multivariate Hansch analysis). 2D-QSARs rely on the concept that functional groups influence the biological activity to differing extents, and the independent variables must be focused on most determinant groups, neglecting the unimportant or invariant ones that represent useless ‘noise.’

The 3D-QSAR techniques exploit conformer-dependent variables obtained considering the variation of molecular properties in the space around molecules. These variables are often computed using the molecular field formalism (as in the comparative molecular field analysis (CoMFA) method, *see* [Section 5.24.4.1](#)) or by projecting the molecular properties onto maps (as in the VolSurf approach, *see* [Section 5.24.3.1](#)).

The recent 4D-QSAR approaches attempt to include the property variability in the independent variables used to predict the biological data. These methods are still being developed, and can be divided into those based on flexible fields and dynamic occupancy (*see* [Section 5.24.5.1](#)) and those based on the property space concept (*see* [Section 5.24.5.2](#)).

This chapter is mainly devoted to molecular fields as prototypes of conformer-dependent 3D properties classified according to the form–function–fluctuation triad (*see* [Section 5.24.1.2](#)). Attention is also focused on the use of molecular fields in 3D- and 4D-QSAR approaches and, in particular, on their applications in absorption, distribution, metabolism, and excretion (ADME) predictions. More extended treatments of these computational methods can be found in Volumes 3 and 4.

### 5.24.1.2 The Form–Function–Fluctuation Triad

The growing computational power available to researchers is proving to be an invaluable tool with which to investigate the dynamic behavior of molecular systems, showing that a molecule cannot be considered simply as a static object but must instead be seen as an object whose conformational changes may significantly affect the profile of any of its properties.

The dynamic behavior of molecular systems depends mainly on molecular fluctuations that influence both form (what a molecule is) and function (what a molecule does), delineating the ensemble of all probabilistic transitions a molecule can undergo in form and function. This generates a very large number of molecular states, which are snapshots of the molecule at a given moment in time. Each state is characterized by a unique combination of form (geometric descriptors) and function (associated properties). Reciprocally, any function (property) exhibited by a compound will have a distinct value for each molecular state occupied by that compound.

Fluctuation, form, and function represent the interrelated elements of a triad that schematizes the behavior of any molecular entity. These components cannot be ordered causally or hierarchically. Rather, they are viewed as being of equal importance and feeding on each other. Fluctuation, form, and function can be quantitatively analyzed using appropriate molecular descriptors. Molecular form and its attributes (*see* [Section 5.24.2](#)) can be defined using geometrical (distance, angle, torsion, etc.) or structural descriptors (Van der Waals surface (vdWS), solvent accessible surface,

volume, radius of gyration, etc.), while function can be [Section 5.24.3](#)). Molecular fluctuations can be monitored by analyzing the variability of properties as defined, for example, by their corresponding property spaces (*see* [Section 5.24.5](#)). A property space can also be conceived as the basin of attraction of the property states of a compound.

A physical representation of a basin of attraction of all molecular states is afforded by an energy landscape, namely a hypersurface whose dimensions are the energy of the system, plus all its other variables. Usually, the more probable states of a molecule (i.e., its states of lowest energy) are represented as valleys in the energy landscape, whereas the states of highest energy are represented by peaks, and the transition states as mountain passes.

### 5.24.1.3 Theoretical Bases of Molecular Fields

A molecular field is a classical example of a scalar field, namely a 3D region where a scalar (1D) value is assigned to each point in 3D space.<sup>6</sup> The concept of molecular fields is strictly related to that of molecular grids, a computational approach that divides the space around a molecule in cubic cells (also called voxels), whose edge length defines the grid resolution and, thus, the precision of results. Using the 3D grid approach, molecular field analysis is reduced to the calculation of a field value for each unoccupied grid voxel. The 3D grid approach finds various applications in computational chemistry; for example, the molecular volume can easily be calculated by multiplying the voxel volume by the number of occupied voxels (a voxel is considered occupied if there is at least an atom whose distance to the voxel center is less than the corresponding atomic radius).<sup>7</sup>

Molecular fields fall into two main classes. The first type is represented by MIFs, namely fields whose values are obtained by calculating the interaction energy between a target molecule and a probe located in each unoccupied grid cell. The second type involves fields obtained by projecting on unoccupied cells molecular properties for which atomic contributions have been parameterized.

MIFs are probably the most intuitive molecular fields. The probe can be monoatomic or polyatomic, being a real molecule (e.g., water), a fragment or an atom encoding specific interactions (thus, the neutral oxygen atom probe encodes the ability of a molecule to donate hydrogen bonds). The energy calculation<sup>8</sup> can describe total noncovalent energy or specific contributions – namely electrostatic ( $E_c$ ), Van der Waals ( $E_{vdW}$ ), and hydrogen bonding ( $E_{HB}$ ):

$$E_{\text{tot}} = \sum_p \sum_m (E_c + E_{vdW} + E_{HB}) \quad [1]$$

The first sum ( $p$ ) concerns the probe, and the second ( $m$ ) the molecule atoms.

Molecular fields derived from atomic contributions can be computed for all molecular properties for which it is possible to determine atomic increments (namely lipophilicity, polarizability, hydrogen bonding, and so on). The general formula to compute this type of molecular field is represented by

$$P_{xyz} = \sum_{i=1}^{i=n} a_i f(d_{xyz,i}) \quad [2]$$

where  $P_{xyz}$  is the molecular field value for the point  $xyz$ ,  $a_i$  is the local atomic contribution for atom  $i$ , and  $f(d_{xyz,i})$  is a distance function between atom  $i$  and the field point  $xyz$ . The sum runs over the  $n$  atoms (or fragments) of the considered molecule.

Field visualization is useful to gain insight into the data and to highlight relations between values that may not be apparent from the raw data. The most obvious visualization is color: a set of colors is used to represent the range of values the data can assume. The colors should be chosen to make the values intuitive. A common technique is to use ‘cold’ colors such as blue for low values and ‘hot’ colors such as red for high values; green tones are used for mid-range values. Furthermore, the colored points cannot be represented as such because most would be masked, and relationships in the field values lost. A possible solution is to render the points transparent, increasing their strength from front to back, to render the obscured points more visible (the so-called alpha-blending technique).<sup>9</sup>

In fact, the commonly adopted solution to visualize molecular fields is the projection of field values on surfaces. These visualizations fall in two main classes. The first class involves the projection of field data onto a molecular surface, which yields a colored visualization of the local molecular properties (as seen later in [Figures 4 and 5](#)). But one must note that the surface itself can be considered a particular field where all grid points not on the surface are nil. A second method involves isosurfaces,<sup>10</sup> where grid cells with similar values are connected together by a tessellated surface. Each isosurface can have a different color to make it easier to distinguish, and the isosurfaces should be drawn partially transparent to render them clearer.

Existing MIF-based tools are introduced in the following sections in a progressive and logical manner. A selection of currently available MIF-based tools is presented in [Table 1](#).

**Table 1** A selection of currently available QSAR tools based on MIFs

## 5.24.2 Description of Molecular Form

### 5.24.2.1 Molecular Surfaces: Van der Waals, Solvent-Accessible, and Richards Surface

Although molecules do not have defined surfaces in a strict quantum mechanical sense, formal molecular surfaces have become important tools when analyzing both molecular shapes and local physicochemical properties, allowing fertile applications in rational drug design. Molecular surfaces are based on the modeling of atoms using hard spheres of defined radius, as suggested by the sharp rise of potential energy during the collision of two atoms. The molecular surface can be defined by the union of atomic surfaces for all atoms constituting a given molecule. Moreover, since the bond length is always less than the sum of atomic radii, the surface is modeled using fused spheres by allowing them to interpenetrate.<sup>11,12</sup> The molecular surface depends on the choice of atomic radii: for example, using the Van der Waals radii, one obtains a vdWS of fused spheres, which often represents a good approximation of steric requirements (Figure 2a).

Since in solution only accessible functional groups can interact with the solvent, it becomes important to assess which parts of a solute are indeed accessible. Despite its complexity, this problem can be approximated by rolling a sphere representing a molecule of solvent onto vdWS of the solute, thus obtaining a new smoothed surface defined by the centroid of the sphere, called the solvent accessible surface (SAS).<sup>13</sup> This is equivalent to increasing the atomic radii of vdWS by the radius of the solvent probe. A sphere of 1.4–1.5 Å radius is often taken to model a water molecule (Figure 2b).

A third type of surface representation tries to minimize the excessive extension of SAS by collecting points traced out by the lower face of the probe sphere. This surface is often referred to as a Richards surface or as a solvent excluded surface (SES).<sup>14</sup> It is the union of the 're-entrant' surface, generated by the underside of the probe when it is in contact with two or more spheres and the 'contact' surface that is the part of probe touching the vdWS (Figure 2c). While SAS and vdWS calculations are not very complicated, the SES calculation is a difficult and demanding problem.

A surface can be represented using either a collection of points (as seen later in Figure 5, a dot surface) or a solid rendering (as seen later in Figure 4, surface tessellation). In the second case, the surface is modeled into spherical polygons, permitting a more precise calculation of both the molecular surface and the enclosed volume.<sup>15</sup> Furthermore, the surface tessellation allows the calculation of surface derivatives with respect to the atomic coordinates.<sup>16</sup> The analytical derivatives can be used to evaluate better molecular shape and electrostatic interactions and find successful applications in the analysis of the solvent effects (implicit solvent continuum models), protein structure, enzymatic catalysis, and biomolecular recognition.<sup>17</sup>

**Figure 2** Examples of (a) a vdWS (Van der Waals surface), (b) an SAS (Connolly surface), and (c) an SES (Richards surface). (Reproduced from Pascual-Ahuir, J. L.; Silla, E.; Tunon, I. *J. Comput. Chem.* **1994**, *15*, 1127–1138, with permission from John Wiley & Sons, Inc.)

A precise alignment of molecules is necessary to compare molecular surfaces for similarity or complementarity.<sup>18</sup> This can be done manually by selecting the matching atoms, or automatically by calculating the roto-translational matrix (including three translation and three rotation values) to be used to align two or more rigid molecules. Several approaches to align molecules have been developed. Such methods include the matching of knobs and holes (which is especially useful in complementarity analysis through the computation of solid angles<sup>19</sup>), least squares methods (where a pattern of points is taken on molecular surfaces<sup>20</sup>), methods using surfaces with thickness,<sup>21</sup> and surface comparison by (1) projection onto a plane, (2) gnomonic projection (i.e., onto the surface of a sphere<sup>22</sup>), (3) projection onto a cylinder, and (4) Fourier analysis.<sup>23</sup>

#### 5.24.2.2 The Polar Surface Area (PSA) and Derived Surfaces

The PSA is obtained by subtracting from the molecular surface the area of carbon atoms, halogens, and hydrogen atoms bonded to carbon atoms (i.e., nonpolar hydrogen atoms). In other words, the PSA is the surface associated with heteroatoms (namely oxygen, nitrogen, and phosphorous atoms) and polar hydrogen atoms.<sup>24,25</sup> Palm and co-workers<sup>26</sup> underlined that the polar area is sensitive to 3D conformation for a given molecule, and is thus better described using a weighted dynamic average, which considers all significant conformers, rather than by a single static PSA value. Ertl and co-workers<sup>27</sup> proposed an approach for the fast calculation of the PSA as the sum of fragment-based increments, which allows the rapid analysis of large data sets. An extensive study of PSA values highlights that the polar area correlates better with hydrogen bonding (both donor and acceptor groups) than with lipophilicity ( $r^2 = 0.76$  versus  $r^2 = 0.30$ ).<sup>28</sup>

Conversely, the apolar surface area (ASA, also called the nonpolar surface area) can be computed by considering only carbons, halogens, and nonpolar hydrogen atoms. ASA values are well related to experimentally observed thermodynamic changes in heat capacity and enthalpy for protein-folding processes, protein–solvent interactions, and ligand–receptor binding.<sup>29</sup>

#### 5.24.2.3 Steric Fields

In the first 3D-QSAR approach (the CoMFA method<sup>30</sup>), the steric field was computed by means of the Lennard-Jones (LJ) 6–12 potential energy between the ligand and a  $\text{Csp}^3$  probe. This field is characterized by a very sharp increase at short distances around the vdWS, thus requiring a cut-off value (usually  $+125 \text{ kJ mol}^{-1}$ ), above which it must be truncated. The hardness of the LJ potential makes CoMFA results very sensitive to the relative orientation and precise alignment of molecules. Moreover, this steric field also makes the CoMFA method very dependent on selected conformers, which are treated as rigid bodies despite the fact that both the ligand and receptor can co-adapt with low energy expenditure.

Different approaches have been developed to overcome these pitfalls. Some alternative steric fields, as used in comparative molecular similarity indices analysis (CoMSIA),<sup>31</sup> replace the 6–12 distance function of LJ energy with Gaussian-type functions, such as  $\exp(-\alpha r^2)$  where the  $\alpha$  term provides a smoothing effect. The steric fields so obtained do not require cut-off thresholds, and are less sensitive to conformation and superposition of ligands. Different steric fields are based on the analysis of similarity indices (e.g., the minimum topological difference method<sup>32</sup>) or Van der Waals intersection volumes.<sup>33</sup>

### 5.24.2.4 Overview of Absorption, Distribution, Metabolism, and Excretion Correlations with Descriptors of Molecular Form

Despite the key role played by molecular surface descriptors (namely vdWS, SAS, and SES) in molecular modeling approaches, descriptors of molecular form are often poorly correlated with ADME parameters. Indeed, pharmacokinetic parameters seem more related to molecular size than molecular form. This is shown by molecular weight (in the well known rule-of-five, one of the rules being molecular weight (MW) < 500<sup>34</sup>) and molecular volume. For example, MW and volume appear in several models relating these parameters to blood–brain permeation.<sup>35</sup>

In contrast, the PSA appears in numerous predictive equations, being significantly related to brain penetration,<sup>36</sup> intestinal absorption,<sup>37,38</sup> Caco-2 (adenocarcinoma cell line derived from human colon and used for estimation of human absorption) cell permeability<sup>39</sup> and, more generally, to passive biomembrane permeation in many physiological processes<sup>40</sup> (Figure 3). The remarkable role of the PSA in ADME relationships confirms that the PSA is a suitable descriptor of hydrogen bonding, and, consequently, that hydrogen bonds greatly influence permeation processes. This is further confirmed by the fact that in some predictive equations the PSA can be successfully replaced by well-known descriptors of hydrogen bonding such as  $\alpha$ ,  $\beta$ , or  $\Delta\log P$  (see 5.18 Lipophilicity, Polarity, and Hydrophobicity).<sup>41</sup>

Bergström and co-workers<sup>42</sup> proposed new descriptors of molecular surface obtained from the free surface area of each atom when the molecule is in its lowest energy conformation (also called the partitioned total surface area, PTSA). Both solubility and permeability (e.g., as measured in Caco-2 cell monolayers) were successfully predicted with these descriptors. The nonpolar descriptors are better related to aqueous solubility than the polar descriptors, while the latter are more important for permeability. The advantage of the PTSA approach is that it allows the rapid analysis of large data sets, and avoids dynamic area calculations, which require time-consuming conformational searches.

### 5.24.3 Description of Molecular Function

#### 5.24.3.1 Electronic Properties

Although quantum mechanics can describe molecular interactions with rigorous accuracy, its computational cost is so high that it necessitates approximations leading to a simplified yet accurate description of electronic properties.<sup>43</sup> A classic example of these approximations is the charge density of isolated molecules, which can be calculated by several approaches, ranging from the more accurate ab initio methods (based on wave functions) to empirical ones (based on atomic charges).

Charge densities allow the computation of molecular electrostatic potentials (MEPs), namely the attraction (or repulsion) experienced around molecules by a punctual, positively charged probe.<sup>44</sup> The MEP is thus the property of a molecule (expressed quantitatively at each point in space) to elicit electrostatic interactions (attractive or repulsive) with another molecule. Such a property depends heavily on the nature and geometry of the molecule, and it fluctuates together with its geometry (as seen in Figure 4 for cetrizine<sup>45</sup>). An attractive feature of MEPs is that they can be calculated and measured experimentally (using x-ray diffraction), allowing the validation of novel computational approaches, and even giving due consideration to the limitations of experimental MEPs such as temperature and crystal packing. From the MEP dot values, it is possible to derive a set of descriptors that have found several applications in QSAR analyses, such as minimum, maximum, mean, and variance of positive or negative or overall MEP values.<sup>46</sup> Due

**Figure 3** Relationships between dynamic PSAs (PSA<sub>d</sub>) calculated from conformational searches performed in a vacuum, and (a) percentage of drug absorbed after oral administration to humans (A%) or (b) cell monolayer permeability coefficients (P<sub>c</sub>). (Reprinted from Stenberg, P.; Norinder, U.; Luthman, K.; Artursson, P. *J. Med. Chem.* **2001**, *44*, 1927–1937 © American Chemical Society.)

**Figure 4** 3D MEPs of two representative conformers of the H<sub>1</sub> receptor antagonist cetirizine in zwitterionic form. The positive and negative regions are visualized in blue and red, respectively. It is evident that in folded conformers, the carboxylate group is less accessible, reducing the electron-rich regions. (Reprinted from Pagliara, A.; Testa, B.; Carrupt, P. A.; Jolliet, P.; Morin, C.; Morin, D.; Saïk, U.; Tillement, J. P.; Rihoux, J. P. *J. Med. Chem.* **1997**, *41*, 853–863 © American Chemical Society.)

to their ability to give a conformer-dependent 3D description of the electrostatic properties of a molecule, MEPs are well suited for 3D-QSAR approaches, and their formalism is indeed used in CoMFA<sup>30</sup> (see Section 5.24.4.1) to compute electrostatic fields.

The MEP can also be exploited to compute similarity indices based on electronic properties, as originally proposed by Carbo and co-workers<sup>47</sup> when analyzing similarity between molecules in terms of their electron density. The idea was expanded by Hodgkin and Richards using MEPs to quantify electronic properties and molecular shape.<sup>48</sup> Molecular similarity, as computed using electron density functions (molecular quantum similarity measures) can be successfully correlated with biological activity using principal component analysis (PCA) to reduce the number of variables.<sup>49</sup>

Gasteiger and co-workers<sup>50</sup> have proposed the projection of MEP surfaces on self-organizing networks such as the self-organizing Kohonen neural network. This affords a 2D representation of molecular surfaces that markedly simplifies similarity perception and cluster analysis by extracting the features responsible for biological activity. Moreover, the 2D maps can be exploited to derive molecular descriptors to be used in QSAR analyses.

In order to overcome MEP limits mainly related to the accuracy of atomic charge calculation, Chessari and co-workers<sup>51</sup> proposed the extended electron distribution, a force field that explicitly represents electron anisotropy as an expansion of point charges around each atom. It successfully reproduces the trends in interaction energy and the experimental structures, as in the remarkable case of aromatic edge–face interactions.

Recent studies have concluded that is preferable to calculate the electrostatic fields using the Poisson–Boltzmann equation rather than the usual Coulombic equation. Indeed, the ability of the former to consider solvent-induced electrostatic effects can greatly improve the statistics of 3D-QSAR analyses when electrostatic effects are dominant, giving a more realistic representation of electrostatic forces.<sup>52</sup>

Other electronic fields used in 3D-QSAR include the incorporation of molecular orbital calculations. For example, highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) fields improve the predictive power of models describing specific interactions between ligands and target (e.g., the specific interactions with metalloenzymes such as cytochromes P450, see Section 5.24.4.2.1<sup>53</sup>).

Another method to describe electrostatic interactions in 3D-QSAR involves the electrotopological state (E-state), which applies the formalism of Kier and Hall to develop fields suitable for 3D-QSAR with improved statistics<sup>54</sup> (see 5.23 Electrotopological State Indices to Assess Molecular and Absorption, Distribution, Metabolism, Excretion, and Toxicity Properties). These fields are computed from nonempirical indices, which encode information about electronegativity,  $\pi$  and lone-pair electron content, topological status and inductive effects of neighboring atoms.

The electrostatic potential is strictly correlated with molecular polarizability, since both properties encode information about charge distribution. Polarizability is useful to analyze solvation properties and solute–solvent interactions, and is related to lipophilicity. Bradley and Waller<sup>55</sup> proposed polarizability fields for 3D-QSAR analyses based on atomic contributions and exploiting the additive–constitutive character of this property. In turn, molecular polarizability is directly related to the dipole moment and its derivatives such as quadrupole and octupole moments, vectorial properties that encode displacement of positive and negative charges with respect to the barycenter.<sup>56</sup> Loew and co-workers<sup>57</sup> uncovered significant correlations between lipophilicity and polarizability, proposing equations that yield distinct log *P* values for different conformers of flexible molecules. The relevance of this study is that it was the first approach able to determine the influence of the conformational profile on the lipophilic property of a molecule.

MEPs can be considered as the prototype of MIFs, where the probe is constituted by a punctual positive charge. A MIF is a scalar field obtained by calculating the interaction energy between a target molecule and a probe placed in each unoccupied cell of a regular 3D grid. A given MIF can consider only electrostatic interactions (i.e., Coulomb potential energy fields), or only Van der Waals interactions (by means of Lennard-Jones potentials, e.g., the steric field in CoMFA), or it can take into account the total interaction energy, considering simultaneously all possible noncovalent energy contributions (as seen in Section 5.24.1.3, eqn [1]).

The GRID approach is worth a mention among the MIFs.<sup>58</sup> Indeed, it represents the first and foremost tool to calculate interaction energies between a target molecule and monoatomic probes such as a carbonyl oxygen atom or a negative carboxyl oxygen atom, or polyatomic probes such as water, an amino group, or a methyl group. The soundness of this method lies in the accuracy of its energy function and force field parameters. Although fully empirical, it allows a precise evaluation of the total interaction energy as the sum of three component, namely (1) Van der Waals interactions to measure induction and dispersion phenomena; (2) electrostatic interactions, using a modified form of the classical Coulomb formula to take into account the dielectric discontinuity between macromolecules and the solvent; and (3) hydrogen-bonding interactions using the equation (with a 6–4 form) proposed in the Chemistry at Harvard Macromolecular Mechanics (CHARMM) force field by Brooks and co-workers.<sup>59</sup>

MIF fields obtained with GRID have been extensively exploited in 3D-QSAR, especially using the GOLPE (generating optimal linear PLS estimation)<sup>60</sup> software as a statistical multivariate tool (in the well known GRID/GOLPE combined approach<sup>61</sup>). GRID can be used to characterize polar and hydrophobic interaction sites around target molecules. For example, the water probe can be used to analyze solvation processes, whereas the carbonyl oxygen probe can evaluate the hydrogen-bonding acceptor ability.

In recent years, there has been a strong emphasis on reducing the large amount of data contained in MIFs, discarding redundant or irrelevant information and extracting useful descriptors that are well correlated with experimental data. Among these studies, the VolSurf approach is probably the most significant<sup>62</sup>; its originality resides in the simplicity with which all descriptors are directly obtained from molecular fields of small as well as of large molecules. The VolSurf descriptors have a clear chemical meaning, and do not necessitate the alignment of molecules. Briefly, VolSurf describes a molecule in terms of the spatial distribution of its polar, hydrophobic, electrostatic, and hydrogen-bonding interactions. These descriptors are also called Integy moments, since they express the distance between the center of mass of a molecule and the center of interacting regions.

### 5.24.3.2 Lipophilic Properties

Since it expresses many of the intermolecular forces accounting for molecular recognition, lipophilicity is a suitable molecular property to describe the interactions between a compound and its environment. Moreover, many studies have shown the significance of conformational factors in influencing the solubility, partitioning, and even pharmacokinetic behavior of compounds. In recent years, new approaches have been developed to account for the relations between conformation and lipophilicity by computing the molecular lipophilicity potential (MLP) around a molecule.<sup>63</sup> As a potential based on atomic contributions of experimental partition coefficients, the MLPs encode the variation of lipophilicity in the space surrounding a molecule, and, just like MEPs, they will change with its geometric fluctuations. Due to these characteristics, MLPs can be successfully used as molecular fields in 3D-QSAR. In contrast to MIF fields, MLPs are based on atomic contributions to log *P* and not on the interaction energy with a probe.

Different MLP fields can be derived depending on the choice of atomic contributions or distance function. From a historical point of view, the first definition of lipophilicity potential can be traced to the seminal work of Audry and co-workers,<sup>64</sup> who used Rekker's fragmental values<sup>65</sup> to describe quantitatively the 3D distribution of lipophilicity either in field space or on molecular surfaces. The same computational strategy was adopted by Kellogg and co-workers<sup>66</sup> in their hydrophobic interaction field (HINT), first developed to evaluate hydrophobic effects in molecular docking and protein folding, and progressively expanded into a tool for incorporating hydrophobicity in 3D-QSAR methods.

**Figure 5** MLPs of two representative conformers of cetirizine in zwitterionic form, represented on the SAS area. The polar and hydrophobic parts of the surface are visualized by red and blue dots, respectively. Back-calculation afforded the virtual log  $P$  value of the two conformers. (Reprinted from Pagliara, A.; Testa, B.; Carrupt, P. A.; Jolliet, P.; Morin, C.; Morin, D.; Saïk, U.; Tillement, J. P.; Rihoux, J. P. *J. Med. Chem.* **1997**, *41*, 853–863 © American Chemical Society.)

Finally, the MLP approach of Testa and co-workers<sup>67</sup> uses the atomic fragmental system of Broto and colleagues and a Fermi-type distance function proposed by Brickmann and co-workers<sup>68</sup> to describe the combined lipophilic influence of all fragments in a molecule on its environment. The most appealing feature of the MLP approach is the possibility of computing a virtual log  $P$  value for each conformer, showing that the experimental log  $P$  is a weighted average for all possible conformers (Figure 5). This computational approach has found an experimental proof in recent nuclear magnetic resonance/kinetic studies that measured experimentally the conformational log  $P$  values of some biomolecules.<sup>69</sup> The important point here is that by calculating a virtual lipophilicity for all molecular states of a compound, one obtains an overview of the basin of attraction of all lipophilicity values accessible to that compound, constituting the corresponding lipophilicity space (see Section 5.24.5.2). This range appears much more informative in pharmacological and pharmacokinetic terms than experimental lipophilicity, which is the weighted average of an unknown number of virtual values. Several examples have demonstrated the capacity of molecules to adapt their properties to the molecular environment, existing in more polar/hydrophilic states in water and in less polar/more lipophilic states in lipidic environments. The term ‘molecular chameleon’ was coined to describe such an adaptive behavior.

Recent studies compared the virtual log  $P$  values – along with other conformer-dependent physicochemical properties – of acetylcholine obtained from molecular dynamics (MD) simulations in media of different polarity and complexity, giving a compelling demonstration that a polar medium favors polar conformers, whereas the opposite is true for a solvent of low polarity. The same studies have shown that the virtual log  $P$  values of conformers of a single molecule are well related to the dipole moment but less so to the PSA ( $r^2 = 0.80$  versus  $r^2 = 0.45$ , in water).<sup>70,71</sup>

MIFs can also be successfully used to explore lipophilic properties. The GRID program includes a specific probe (DRY) to evaluate hydrophobic interactions with biological membranes. Its energy ( $E_{\text{DRY}}$ ) is computed using

$$E_{\text{DRY}} = E_{\text{Ent}} + E_{\text{LJ}} - E_{\text{HB}} \quad [3]$$

where  $E_{\text{Ent}}$  is the ideal entropic component of the hydrophobic effect in an aqueous environment,  $E_{\text{LJ}}$  is the Lennard-Jones energy, and  $E_{\text{HB}}$  evaluates the total hydrogen-bonding interactions between a water probe and the target molecule.

### 5.24.3.3 Hydrogen-Bonding Properties

Although hydrogen bonding plays a pivotal role in biomolecular recognition, the development of hydrogen-bonding fields was belated compared with the previous molecular fields. This is due to the difficulty in deriving precise

equations to evaluate the hydrogen bond interaction energy and accurate atomic parameterization from experimental hydrogen-bonding data. The conformer-dependent description of hydrogen bonding can be obtained using three main approaches: (1) quantum mechanical calculations, which are more rigorous but very time-consuming; (2) MIFs obtained by empirical force field calculations, which are quite useful when using precise equations for the hydrogen-bonding energy and suitable probes (e.g., the hydroxy group or a neutral oxygen atom); and (3) projection of atomic increments, mainly taken from solvatochromic analyses. All three methods can give a conformer-specific hydrogen-bonding description, and so are suitable in 3D-QSAR analyses. Furthermore, such methods allow discrimination between donor and acceptor ability, while other hydrogen bond descriptors such as the PSA or  $\Delta \log P$  (namely the difference between  $\log P$  values in octanol and cyclohexane) cannot distinguish between these two components.

Focusing on quantum mechanical approaches,<sup>72</sup> the donor ability can be modeled by using either the energy of the LUMO or the polarizability (or the superdelocalizability) of the heavy atom attached to the donor hydrogen. In contrast, the acceptor ability can be described by using either the energy of the HOMO or the MEP (see Section 5.24.3.1).

MIF calculations require an accurate equation to evaluate hydrogen-bonding contributions. Indeed, several force fields do not include specific terms for hydrogen bonds, but consider it to be implicit in the electrostatic and Van der Waals terms. Conversely, the master energy equation of GRID includes specific terms for hydrogen bonding, making this method useful to evaluate hydrogen bond interaction fields, by selecting suitable probes able to evaluate the hydrogen-bonding capacity (as seen in Section 5.24.3.1).

The third type of hydrogen-bonding field is based on an atomic parameterization that discriminates between donor and acceptor ability. Various methods exist to parameterize the hydrogen-bonding ability of molecules. The simpler descriptors (such as the number of potential hydrogen bond acceptor (HBA) and donor (HBD) groups or the sum of both<sup>28</sup>) are inadequate for atomic parameterization since they account neither for the strength of hydrogen bonds nor for the possibility of intramolecular hydrogen bonds. More sophisticated parameters based on solvatochromic analysis were developed by Taft and co-workers<sup>73,74</sup> in the 1970s, and can be considered as an application of the extrathermodynamic correlations (linear free energy relationships) elaborated by Hammett for chemical equilibria.<sup>75</sup> Abraham<sup>76</sup> and Raevsky<sup>77</sup> have developed quantitative scales of hydrogen-bonding acidity ( $\alpha$ ) and basicity ( $\beta$ ) based on lipophilicity and thermodynamic data (see 5.31 In Silico Models to Predict Brain Uptake). The difference between two different  $\log P$  scales is another experimental hydrogen-bonding descriptor first proposed by Seiler, who successfully correlated hydrogen bonding capacity with  $\Delta \log P$  for 195 heterogeneous molecules.<sup>78</sup> El Tayar and co-workers<sup>79</sup> have developed the  $\Lambda$  descriptor obtained from experimental lipophilicity data and from calculated molecular volumes, to yield an indirect estimate of hydrogen-bonding properties.

On these grounds, hydrogen-bonding fields called MHBPs have recently been developed.<sup>80</sup> They consist of an HBD potential and an HBA potential. MHBPs use a fragmental system based on literature donor ( $\alpha$ ) and acceptor ( $\beta$ ) values, and yield field values with an algorithm similar to that of MLPs. The value for the  $xyz$  point in a field ( $\text{MHBP}_{xyz}$ ) is calculated by

$$\text{MHBP}_{xyz} = \sum_i \sum_j F_{ij} f(d_{j,xyz}) g(U_{j,xyz}) \quad [4]$$

where the first sum defines the number of molecular fragments in the compound, and the second sum the number of polar atoms in the molecular fragment;  $F_{ij}$  is the  $\alpha$  and/or  $\beta$  value of atom  $j$  in fragment  $i$ ,  $f(d_{j,xyz})$  is the distance function between the polar atom  $j$  and the point  $xyz$ , and  $g(U_{j,xyz})$  is the angular function of the angle defined by the point  $xyz$ , the polar atom  $j$ , and the polar hydrogen or the lone pair belonging to the polar atom  $j$ . It is worth noting that eqn [4] includes two geometric functions because hydrogen bonds are directional and the interaction energy decreases when moving away from the hydrogen bond axis.

#### 5.24.3.4 Overview of Absorption, Distribution, Metabolism, and Excretion Correlations with Descriptors of Function

Although the relationships between pharmacokinetic parameters and physicochemical properties go beyond the objectives of this chapter, it appears useful here to describe some significant trends in these relations while avoiding a systematic analysis of such studies.<sup>81</sup>

The noteworthy role of electrostatic factors in molecular recognition finds some significant evidence also in ADME correlations, even if other factors such hydrophobicity also play a major role in pharmacokinetic processes. For example, recent studies have correlated the blood–brain permeation (assessed by  $\log BB$ , see 5.31 In Silico Models to Predict Brain Uptake) with quantum chemical descriptors obtained from MEP surfaces.<sup>46</sup> Perhaps a main drawback of MEP analyses is that they require time-consuming quantum mechanical calculations and are therefore rarely applicable to large chemical libraries.

In contrast, it is well known that lipophilicity plays a key role in determining pharmacokinetic behavior<sup>82</sup>; the opportunity to compute virtual log  $P$  values from MLPs for flexible molecules has therefore found numerous applications in ADME studies. A classic example concerns the differing abilities of the two morphine glucuronides to cross the blood–brain barrier.<sup>83</sup> The MLP approach has demonstrated that these two metabolites have markedly different virtual log  $P$  values, existing in extended, more hydrophilic and folded, more lipophilic conformers. This indicates that the peculiar pharmacokinetic profiles can be attributed to the so-called chameleon effect (Figure 6).

Despite the significant role of log  $P$  in ADME processes, it is worth noting that predictive equations that successfully correlate lipophilicity with ADME parameters are not as numerous as one would expect.<sup>84</sup> This inherent difficulty can be explained considering that pharmacokinetic parameters result from a multiplicity of interactions with a variety of biological constituents that can be seen as fuzzy targets due to their fluctuating diversity. Moreover, a second difficulty is due to the heterogeneity of pharmacokinetic parameters, which, being obtained from complex biological systems, shows a decreased relatedness to molecular properties. These problems become apparent when examining correlations between lipophilicity and skin permeability; for example, it was possible to derive parabolic equations with a significant predictive power when considering separately a homogeneous set of phenols and of nonsteroidal anti-inflammatory agents, but no correlation was obtained for the set of all permeants.<sup>79,85</sup> Similar examples exist for membrane permeation, gastrointestinal absorption and blood–brain permeation. Overall, one can conclude that most correlations have a limited predictive capacity, yet can suggest mechanistic trends, and, as such, are of interest.

The relationships between hydrogen bonding and permeability processes have been validated on numerous occasions. First, as already outlined in Section 5.24.2.4, the PSA, a simple, but effective descriptor of hydrogen bonding, finds various successful correlations with pharmacokinetic parameters. Raevsky and co-workers used hydrogen bond thermodynamics descriptors to predict human absorption data through a nonlinear equation based on HBA and HBD

**Figure 6** MLP of morphine 6-O-glucuronide (M6G) as a (a) folded neutral conformer and (b) as an extended neutral conformer. The MLP is displayed on the water-accessible surface area of the molecule. (Reproduced from Testa, B.; Kier, L.; Carrupt, P. A. *Med. Res. Rev.* **1997**, 17, 303–326, with permission from John Wiley & Sons, Inc.)

thermodynamic potentials.<sup>86</sup> Moreover, when analyzing the correlations between ADME and experimental hydrogen-bonding descriptors, it is worth remembering the pioneering study of Young and co-workers, who<sup>87</sup> in 1988 showed that the difference between log *P* in octanol and in cyclohexane is inversely related to brain penetration for a set of centrally acting histamine H<sub>2</sub> antagonists.

#### 5.24.4 Molecular Fields and Three-Dimensional Quantitative Structure–Activity Relationship

##### 5.24.4.1 Methodological Bases: CoMFA and Derived Methods

In essence, 3D-QSAR methods correlate differences in conformer-dependent properties with biological data. This section will be focused on 3D-QSAR approaches involving molecular field calculations. To compute 3D fields, these approaches require the manual or automatic selection of biologically relevant conformations for all modeled compounds, followed by the manual or automatic superimposition of all selected conformers. These first steps represent a problematic issue because the bioactive conformation is seldom known experimentally. In the absence of such information, it is very useful to assume that, when ligands bind to a target, their steric and physicochemical patterns will be such as to maximize the fit. This is the pharmacophore idea, which defines the basic 3D arrangement of functional groups responsible for biological activity. Nevertheless, one must remember that this is a static concept since it does not consider ligand flexibility nor multiple binding modes to the target.

All 3D-QSAR approaches are based on assumptions such as (1) a unique bioactive conformation is responsible for the biological effect; (2) the binding site is exactly the same for all ligands considered; (3) the affinity is mainly due to enthalpic factors, while the entropic ones are constant and negligible; and (4) other aspects such as flexibility, solvent effects, and kinetic factors can be ignored.

From a historical point of view, 3D-QSAR approaches were born in 1986, when Wold and co-workers proposed use of the partial least squares (PLS) analyses to correlate field values with biological properties.<sup>88,89</sup> They found their precise definition in 1988 with CoMFA,<sup>31</sup> whose diffusion in the scientific community was accompanied by the availability of patented commercial software (Figure 7).

Clearly, the improvement of statistical techniques has played a relevant role in 3D-QSAR developments.<sup>90</sup> In particular, PLS generalizes and combines features from PCA and multiple regression, reducing the large amount of field data to a few significant orthogonal descriptors (also called latent variables or principal components).<sup>91</sup> The correct number of descriptors is chosen for the highest statistical significance. It is worth underlining that  $r^2$  values are not very indicative of significance in 3D-QSARs due to the large number of independent variables. It is therefore necessary to compute cross-validated  $r^2$  values (also written as  $q^2$  or  $r_{CV}^2$ , an estimate of model predictivity) by iteratively eliminating one or more compounds from the data set, deriving a model equation with the remaining set, and predicting the biological value of the omitted compounds. For models with similar cross-validated  $r^2$  values, the model with the smallest standard error of prediction (PRESS) is preferred.

In the CoMFA method, the biological responses are predicted using steric (Lennard-Jones, as seen in Section 5.24.2.3) and electrostatic field values computed for each molecule in the set. Attempts have been made to include other properties in CoMFA; for example, lipophilicity fields (HINT and MLP approaches, see Section 5.24.3.2), MIFs (e.g., as computed with the GRID program, see Section 5.24.3.1), hydrogen-bonding fields (see Section 5.24.3.3), or reactivity fields obtained by quantum mechanical calculations (e.g., HOMO/LUMO fields, see Section 5.24.3.1).

The results of CoMFA correspond to a regression analysis with thousands of coefficients. The common way to present the results is by means of colored contour maps, showing favorable or unfavorable steric and electrostatic regions around the molecules. In detail, green contours indicate regions where an increase in steric bulk will enhance activity, the opposite being the case for yellow contours. For electrostatic fields, blue and red contours usually correspond to regions where an increase of positive or negative charge, respectively, will enhance affinity (as seen later in Figure 9). The results can be used in lead optimization by designing new derivatives based on contour maps or calculating the corresponding fields and incorporating them in predictive models.

Despite the considerable success of CoMFA, some serious problems can arise during analysis and when interpreting results. The most obvious problem concerns the choice of bioactive conformations and the rules for mutual alignment.<sup>92</sup> The comparison can be based on either atom matching or property similarity, but the analysis of highly flexible compounds is always quite difficult and time-consuming. When at least one of the considered molecules is conformationally rigid, the choice of bioactive conformers and the alignment rules are easier, as other compounds have to mimic the geometry of the rigid molecule. The first step can be facilitated if at least one experimentally resolved ligand–target complex can be used as a template, and any source of error can be eliminated when such a complex is

**Figure 7** Historical diagram from the pioneering work of Cramer and co-workers, depicting the main logical steps of the CoMFA approach. The field values obtained inserting molecules in 3D grids (lattice) are used as independent variables to derive predictive models through a PLS technique. (Reprinted from Cramer, R. D.; Patterson, D. E.; Bunce, J. D. *J. Am. Chem. Soc.* **1988**, *110*, 5959–5967 © American Chemical Society.)

known for all molecules; but the question arises of whether CoMFA is the best choice in such cases. A simple iterative approach is to refine CoMFA models, modifying the conformation and/or alignment of molecules that do not fit the model, using preliminary results as a guide to improve the model.

Another source of errors is the hardness of field values, especially the steric ones, which are truncated when exceeding cut-off thresholds. Consequently, contour maps become fragmented and often difficult to interpret. As seen in [Section 5.24.2.3](#), some attempts have been made to resolve this problem by using Gaussian-type distance functions that smooth the field values and do not require cut-off.

Finally, CoMFA results show a significant dependence on the overall orientation of ligands in the grid box.<sup>93</sup> Several studies on the stability of CoMFA have shown that the quality of models can be increased by displacing the aligned molecules in the grid box. For example, the systematic rotation of ligands in the box changed CoMFA  $q^2$  values by as much as 0.5.<sup>94</sup> This can happen when the fields are computed on such a coarse grid that the field values are inadequately distributed. As a rule, a decrease in grid spacing increased the probability of placing the probe atom in a region where the steric and electrostatic fields best correlated with biological activity. Finally, these studies suggested that users have to pay attention to box properties when generating the field values, even if the choice of CoMFA parameters based on the highest  $q^2$  is questionable, as it can bias the results.

Considering these pitfalls, it comes as no surprise that several alternative 3D-QSAR approaches have been proposed in recent years.<sup>95,96</sup> One of the most important is CoMSIA, proposed by Klebe and co-workers.<sup>31</sup> It uses a PLS technique to analyze fields of different physicochemical properties based on similarity indices of aligned molecules. The fields use a Gaussian-type distance function not requiring a cut-off. The results are statistically significant, and the maps obtained are not fragmented, highlighting regions within the area occupied by ligands that require a particular physicochemical property for activity (as illustrated later in [Figure 10](#)). Alternative 3D-QSAR approaches give up the use of grid calculation and project the computed property fields onto molecular surfaces. The use of molecular surfaces should simplify calculations, making the results more realistic, as the interactions between the ligand and the receptor occur near the molecular surface. These nongrid methods (e.g., comparative molecular surface analysis, CoMSA),<sup>97</sup> exploit other statistical techniques such as neural networks or genetic algorithms to improve the statistical goodness of results.

A third type of 3D-QSAR approach tries to resolve the problem of alignment by calculating coordinate-invariant 3D descriptors. For example, the weighted holistic invariant molecular descriptor (WHIM) approach<sup>98</sup> calculates property values using PCA. This procedure assures invariance to translation and to rotation, and molecules do not need to be aligned before computing WHIM parameters. A second method to compute 3D descriptors that does not require alignment of molecules is the VolSurf approach, which has found several applications in ADME predictions (see Section 5.24.3.1).<sup>62</sup> Stiefl and Baumann<sup>99</sup> recently reported a new approach to map property distribution on molecular surfaces based on radial distribution functions (distance-dependent count statistics). The calculated descriptors are invariant to roto-translation, and are well correlated with biological data through chemometric regression techniques in combination with a variable selection to identify highly relevant variables. Vinter and co-workers<sup>100</sup> proposed the FieldScreen approach, which reduces molecular fields to just a few key field points, obtaining a field pattern that represents the ligand from the viewpoint of the protein. This method, being alignment-independent, markedly simplifies field treatment, and is well suited for database screening. Other alignment-independent methods have been proposed recently (e.g., eigenvalues analysis (EVA) descriptors derived from the vibrational frequencies, which are calculated or extracted from experimental infrared spectra,<sup>101</sup> and comparative molecular moment analysis (CoMMA), based on the moments of the mass and charge distribution.<sup>102</sup> However, it is worth remembering that these methods are conformation-dependent. Since the best way to find similar bioactive conformations in a set of molecules is to superimpose them, these methods do not really escape the alignment problem.

Finally, methods based on pharmacophore mapping, even if they do not involve field analysis, can be considered as 3D-QSAR approaches.<sup>103</sup> For example, the program Catalyst analyzes the position in space of chemical functions (namely hydrogen-bonding groups, polar functions, and hydrophobic moieties) of molecules, and generates pharmacophore hypotheses in terms of the 3D arrangement of chemical functions to explain the differences in activity. The activity of a new compound can be quantitatively predicted by means of its ability to fit the pharmacophore model.<sup>104</sup> Clearly, pharmacophore analysis and CoMFA-like approaches are strictly related; indeed, pharmacophore hypotheses can be used to begin 3D-QSAR analyses, by suggesting alignment rules, whereas 3D-QSAR results can be used to validate and explain pharmacophore hypotheses.

#### 5.24.4.2 Applications of Three-Dimensional Quantitative Structure–Activity Relationship Approaches to Absorption, Distribution, Metabolism, and Excretion Predictions

Since 3D-QSAR approaches can account for specific interactions between ligands and a target, and suggest pharmacophore hypotheses, they have found several applications in metabolism prediction. Analogously, 3D-QSAR has been applied extensively to predict the interactions between ligands and transporters, since such targets, like enzymes, are biomacromolecules. Conversely, the prediction of permeation processes finds rarer applications in 3D-QSAR, as the behavior of fuzzy targets is less suitable for these computational methods. This section will consider, in turn, drug-metabolizing enzymes (Section 5.24.4.2.1), transporter proteins (Section 5.24.4.2.2), and permeation processes (Section 5.24.4.2.3).<sup>105</sup>

##### 5.24.4.2.1 Applications of three-dimensional quantitative structure–activity relationship approaches to drug-metabolizing enzymes

###### 5.24.4.2.1.1 Oxidoreductase

The cytochrome P450 enzymes (CYPs, EC 1.14.14.1) are membrane-bound proteins that catalyze oxidative reactions of xenobiotics and endobiotics with broad substrate specificity, playing a key role in drug metabolism. Briefly, CYP catalysis involves reduction of the heme iron, with resulting cleavage of the oxygen–oxygen bond. The electrons are donated by reductases, creating an ‘electron transfer chain.’<sup>106,107</sup>

The CYP proteins are classified into families and subfamilies according to their sequence homology. More than 3000 CYP gene sequences are known. The first three families (CYP1, CYP2, and CYP3) are enzymes involved in drug metabolism, being responsible for about 90% of drug oxidations in humans, while other families play specific roles (e.g., CYP11, CYP17, CYP19, and CYP21 are implicated in steroid biosynthesis).

The 3D-QSAR techniques are suitable for studying CYP-catalyzed oxidations as they can analyze how ligands may bind to these enzymes as substrates and/or inhibitors. It is worth noting that in these studies, 3D-QSAR approaches are mainly used to build pharmacophore models rather than to yield predictive equations of limited interest, due to the complexity of these enzymes and the heterogeneity of their substrates. The soundness of the results was often confirmed by other computational approaches (e.g., homology modeling and molecular docking) and by experimental studies (x-ray crystallography and/or site-directed mutagenesis). This section will consider some relevant examples of 3D-QSAR

**Figure 8** The CYP2B6 substrate pharmacophore illustrating three hydrophobic areas (cyan) and a HBA feature (green), with a vector in the direction of the putative hydrogen bond. (Reproduced from Ekins, S.; Bravi, G.; Ring, B. J.; Gillespie, T. A.; Gillespie, J. S.; VandenBranden, M.; Wrighton, S. A.; Wikel, J. H. *J. Pharmacol. Exp. Ther.* **1999**, 288, 21–29, with permission from the American Society for Pharmacology and Experimental Therapeutics.)

studies on CYP ligands. The relevance of these studies lies in the major role of CYP enzymes in human metabolism; understanding the basis of their activity is important to determine their role and predict effects on new substrates.<sup>108,109</sup>

Extensive analyses have been performed on CYP2B6 substrates using two 3D-QSAR approaches, namely WHIM and pharmacophore mapping.<sup>110</sup> Both methods suggest the crucial relevance of three hydrophobic regions and one HBA, located at defined distances (Figure 8). These results are in agreement with classic QSAR studies that correlated binding affinities to CYP2B6 with log *P* and hydrogen-bonding descriptors.<sup>111</sup> It is interesting to observe that both 3D-QSAR methods, even if conceptually different, yielded very similar results, suggesting some degree of mutual validation, although both methods failed to predict molecules not included in the training set. Docking analyses on homology-modeled CYP2B6 revealed that its binding site consists of three well-defined hydrophobic binding pockets adjacent to the catalytic heme. The size, shape, and position of these hydrophobic pockets are in agreement with pharmacophore models.<sup>112,113</sup>

The inability to predict CYP activity for substrates not included in training sets is explained by considering the broad specificity of these enzymes, which renders difficult or impossible the creation of a unique pharmacophore hypothesis. For example, the CYP2C family can bind both neutral and anionic ligands, and different models were developed to account for these two classes of molecules. All models show a hydrophobic/aromatic region between the hydroxylation site and an electron-rich moiety, which interacts with the heme iron. Extensive analyses of CYP2C9 substrates show that the highest affinity is shown by molecules having two negative regions equally separated from a central aromatic group.<sup>114</sup> Homology models of CYP2C9 have indicated that Phe110 and Phe114 may be involved in aromatic interactions,<sup>115</sup> while mutagenesis experiments have suggested that Arg97 and Arg108 may constitute the cationic binding sites.<sup>116</sup> The key roles of aromatic and electrostatic interactions are also confirmed by classic QSAR analyses, which correlate binding affinities to CYP2C9 with p*K*<sub>a</sub> and log *P* values.<sup>111</sup> A CoMFA analysis of a set of hydantoin and barbiturate substrates revealed that electrostatic features seem unimportant, while steric features and lipophilic properties are well correlated with binding data for these enzymes.<sup>117</sup> This does not imply that electrostatic features of the hydantoin and barbiturate rings are not important in binding, simply that these features are not significant in describing the differences in binding of these compounds.

CYP2D6 is a polymorphic CYP member well known for its absence in 5–9% of the Caucasian population. 3D-QSAR studies on CYP2D6 substrates showed that these molecules are characterized by a basic group at about 5–7 Å from the hydroxylation site, and coplanar aromatic rings.<sup>118</sup> These observations are strongly confirmed by homology modeling and mutagenesis experiments, which showed that two acidic residues (Glu216 and Asp301) interact with the basic group in the ligand.<sup>119</sup> The key role of a basic group was also confirmed by classic QSAR analyses, which correlated binding affinities to CYP2D6 with p*K*<sub>a</sub> values.<sup>111</sup> Comparable analyses with CYP2D6 inhibitors underlined the major

role of hydrogen bonding (as well as features already described for substrates) in accounting for differences in binding affinity.

The complexity and the very broad specificity of CYP enzymes find their greatest expression in the CYP3A subfamily, especially in CYP3A4.<sup>120</sup> Indeed, many data suggest two or more binding modes due to the presence of at least two binding subpockets and one 'effector-binding' region. A more recent hypothesis proposes that the CYP3A4 can exist in multiple conformations regulated by allosteric effects.<sup>121</sup> The CYP3A4 promiscuity has produced a number of theoretical models to predict its enzymatic activity, even if the predictions are often of modest statistical quality. To date, all QSAR analyses indicate the relevance of hydrophobic interactions and at least one hydrogen bond, and the crystal structure of CYP3A4 revealed the main residues involved in these interactions.<sup>122</sup> Docking analyses confirmed the key role of multiple hydrophobic domains in the active site of CYP3A4.<sup>123</sup>

These few examples indicate the increasing interest in modeling human CYPs using 3D-QSAR analyses. Despite their modest ability to predict the enzymatic parameters for heterogeneous molecules, such models can predict qualitatively the ability of molecules to bind to CYPs. As such, they can be useful tools even if they fail to distinguish substrates from inhibitors. Furthermore, the increasing availability of crystal structures or homology models of relevant CYPs should facilitate docking analysis on these enzymatic targets.

To date, 3D-QSAR analyses have accounted for inhibitors and substrates, while the ability of molecules to induce CYPs are just beginning to be evaluated by such methods, due to the lack of sufficiently broad experimental data sets.<sup>124</sup>

Among the other oxidative enzymes involved in metabolism, monoamine oxidases (MAOs, EC 1.4.3.4), particularly MAO-B, have attracted great interest since their inhibitors play diverse roles in the pharmacological management of some neurological disorders. Recent studies applied CoMFA and GOLPE procedures to a large data set of MAO inhibitors, revealing that hydrophobicity and steric hindrance are the main factors involved in binding. Interestingly, docking studies on the crystal structure of human MAO-B have confirmed the CoMFA results and highlighted the role, essential for MAO-B activity and selectivity, of a hydrophobic cavity (the so-called entrance cavity) connecting the surface of the protein to the catalytic cavity.<sup>125</sup> Other studies devoted to specific series of compounds (namely coumarins<sup>126</sup> and indolylmethylamine<sup>127</sup> derivatives) have led to similar results, and underlined the role of lipophilicity in both the affinity and selectivity of such inhibitors.

#### 5.24.4.2.1.2 Transferases

UDP-glucuronosyltransferases (UGTs) are among the most important conjugating enzymes involved in drug-metabolism. Like CYPs, UGTs exist in multiple enzyme isoforms, differing in substrate specificity.<sup>128</sup>

The first studies applied 3D-QSAR techniques to inhibitor and substrates of rat and human UDPs.<sup>129</sup> These studies highlighted the key role of electrostatic factors in inhibition and metabolism. The results are in agreement with those obtained with classic QSAR analyses, which correlated the rate of glucuronidation with the log *P* and p*K<sub>a</sub>* values of ligands.<sup>130</sup> The log *P* term may reflect diffusion to the active site, and p*K<sub>a</sub>* the apparent lipophilicity.

More recent studies have applied the pharmacophore analysis to specific UGT isoforms. In particular, the enzymes in the UGT1A subfamily share common pharmacophore features, with the site of glucuronidation invariably adjacent to a hydrophobic region, and another hydrophobic domain located 6–8 Å from the site of conjugation.<sup>131</sup> Unfortunately, these pharmacophore models are useless to predict rates of glucuronidation, perhaps due to multiple binding modes. Indeed, a more comprehensive study, including substrates of 12 human UGTs and multiple pharmacophore models, has generated good predictability for all considered isoforms.<sup>132</sup>

A second class of conjugating enzymes that attracted great interest are the catechol *O*-methyltransferases (COMTs). These enzymes catalyze the methylation of various catechol derivatives such as catecholamines, catechol estrogens, and their metabolites, and several drug metabolites. There are two forms of COMT coded by a single gene: the soluble, cytosolic form (s-COMT) and the membrane-bound form (mb-COMT), found in the rough endoplasmic reticulum. COMT inhibitors are used as drugs in the treatment of Parkinson's disease. CoMFA analyses<sup>133,134</sup> have revealed the key role played by the electrostatic field in predicting the enzyme kinetic parameters of s-COMT. These studies underline how CoMFA results are sensitive to the method used to calculate atomic charge calculation. Semi-empirical charge calculations performed clearly better than fully empirical ones. The CoMFA results are in agreement with docking analyses of the s-COMT crystal structure, which have revealed the interaction between the catechol oxygen atoms and a Mg<sup>2+</sup> ion involved in catalysis (Figure 9).

Catecholamine sulfotransferase (SULT1A3) is also involved in catechol metabolism. An extensive CoMFA study with 95 substrates has revealed the remarkable role that the electronic and steric fields play in enzyme interaction, as also confirmed by docking analysis.<sup>135</sup> In particular, CoMFA results revealed the importance of an electrostatic interaction near Glu146 in SULT1A3, plus the fact that bulky substituents *para* to the reacting hydroxy group are unfavorable.

**Figure 9** Contour maps of steric (a) and electronic (b) interactions in a CoMFA model obtained to predict the  $V_{\max}$  values of s-COMT ligands. The maps are displayed with the inhibitor entacapone,  $\text{Mg}^{2+}$ , and the cosubstrate AdoMet. Green and yellow denote favorable and unfavorable regions for bulky substituents, respectively. The positive charge is favored near the blue regions, and the negative charge near the red regions. (Reprinted from Sipila, J.; Taskinen, J. *J. Chem. Inf. Comput. Sci.* **2004**, *44*, 97–104 © American Chemical Society.)

#### 5.24.4.2.2 Applications of three-dimensional quantitative structure–activity relationship to transporters

Among known transporter proteins, monoamine transporters such as the dopamine (DAT) and the serotonin transporter (SERT) have been extensively studied. It has been shown that cocaine and other drugs of abuse can bind to monoamine transporters. A number of 3D-QSAR studies were performed to uncover the details of their binding site. CoMFA studies based on phenyltropane derivatives<sup>136</sup> have suggested that an increased negative electrostatic potential near the  $3\beta$  substituent of the tropane ring and the *para* position of the phenyl ring favored inhibition of the monoamine transporters. Recent studies on aryltropanes and piperidinols suggested that DAT and SERT have a large cavity that can accommodate bulky C-2 substituents of tropane, and that the size of substituents in the *para* position in both phenyl rings of piperidinols is important for the inhibition of dopamine reuptake.<sup>137</sup> The CoMFA model of Wright and co-workers<sup>138</sup> indicates that hydrophobic interactions make a dominant contribution to binding. Newman and co-workers<sup>139</sup> also studied *N*-substituted tropanes, concluding that the steric interaction of the *N*-substituent with the DAT is a pivotal factor for the binding affinity. An extensive analysis of piperidine-based analogs of cocaine suggested two possible binding modes at the DAT, in both of which steric and electrostatic fields play important roles.<sup>140</sup>

P-glycoprotein (P-gp), which is encoded by highly conserved MDR (multidrug resistance) genes, is a member of the ATP-binding cassette superfamily of membrane transporters. P-gp transports a wide variety of xenobiotic and cytotoxic endogenous chemical agents out of the cell at the expense of ATP hydrolysis. The effect of P-gp-mediated drug efflux on limiting intestinal absorption, oral bioavailability, and tissue distribution has important implications for the efficacy of pharmacological therapies. 3D-QSAR studies have highlighted the crucial role of hydrophobic interactions and hydrogen bonds to promote the P-gp ATPase activity. Pharmacophore analyses have identified two electron donor groups, 2.5 Å or 4.6 Å apart.<sup>141</sup> Multiple pharmacophore models showed a promising capacity to predict

P-gp substrates.<sup>142</sup> Several 3D-QSAR models have been developed for propaphenone-type molecules<sup>143</sup> and phenothiazines.<sup>144</sup> Extensive analyses of steroid derivatives that act as substrates and inhibitors on P-gp allowed to recognize the basic differences between them. Electrostatic factors are more important for substrates, while strong hydrophobicity is more essential for inhibitors. The steric field appears crucial in both classes, but with different requirements; bulky substituents surrounding C-6 are not tolerated for substrates, while bulky groups around C-3 decrease inhibitory activity.<sup>145</sup> A recent 3D-QSAR study developed a pharmacophore hypothesis for P-gp substrates. The model includes two hydrophobic areas and two HBA groups, and the molecular size plays a major role in the interaction.<sup>146</sup> A more extensive treatment of transporters and their computational approaches can be found elsewhere (*see* 5.04 The Biology and Function of Transporters; 5.32 In Silico Models for Interactions with Transporters, respectively).

Proton-coupled peptide transporters, which are localized at brush border membranes of intestinal and renal epithelial cells, play important roles among the intestinal carriers in peptide absorption. These transporters also have significant pharmacological and pharmacokinetic relevance to the transport of various peptide-like drugs such as beta-lactam antibiotics.<sup>147</sup> CoMFA/CoMSIA analyses of small intestinal peptide carrier (oligo)peptide transporter 1 (PEPT1) substrates indicated that six structural elements favor the binding to PEPT1, namely (1) the presence of bulky side chains (Figure 10), (2) a positively charged N-terminus and a region of high-electron density at the C-terminus, (3) two hydrophilic regions, (4) a preferred hydrophobic region at the C-terminus, (5) an HBD region at the N-terminus, and (6) an HBA region crucial for differentiation between stereoisomers.<sup>148</sup>

A second relevant intestinal carrier is the apical sodium-dependent bile acid transporter (ASBT), which plays a pivotal role in cholesterol transport and represents an interesting target for drug delivery, enhancing the intestinal absorption of poorly absorbable drugs.<sup>149</sup> Pharmacophore mapping revealed the features essential for ASBT affinity, namely one HBD, one HBA, and three hydrophobic moieties suitably arranged. In natural bile acids, ring D, methyl-18, and methyl-21 represent the hydrophobic moieties, the hydroxy group in position 7 or 12 represents the HBD, and the HBA is afforded by the negatively charged side chain. The ASBT pharmacophore hypothesis is in good agreement with the 3D-QSAR models developed using a series of inhibitors and substrates. These models should facilitate the rational design of molecules targeted to the ASBT.<sup>150</sup>

#### 5.24.4.2.3 Applications of three-dimensional quantitative structure–activity relationship approaches to permeation processes

The MOLSURF approach has found several applications in permeation modeling.<sup>151</sup> It is based on surface projection of electronic properties derived from semi-empirical or ab initio methods. Concerning the prediction of blood–brain distribution, Norinder and co-workers<sup>152</sup> used a strategy combining MOLSURF and PLS, and obtained a good predictive model ( $q^2 = 0.78$ ). The most important factors influencing the models were associated with polarity and Lewis base strength. Properties associated with hydrogen bonding were also found to be important, and should be kept to a minimum to facilitate high brain–blood partitioning. High lipophilicity was also identified as favorable for high partitioning. Furthermore, polarizable electrons are also beneficial for the compounds to penetrate the brain, suggesting the positive role of charge–transfer interactions. Similar results were obtained using MOLSURF for intestinal absorption<sup>153</sup> and Caco-2 cell permeability.<sup>154</sup>

To account for the high heterogeneity of their compounds, Wolohan and Clark<sup>155</sup> recently combined field calculations with soft independent modeling of class analogy to predict pharmacokinetic properties. This approach involves molecular alignment using idiotropic field orientation (IFO), a generalization of inertial field orientation. The method incorporates electrostatic and the other molecular fields directly into alignment. Models were presented for human intestinal absorption, blood–brain permeation, and oral bioavailability, showing that this tool can be useful to predict pharmacokinetic behavior and explore the influence of orientation and molecular fields.

Several models have been built using the VolSurf approach. Crivori and co-workers<sup>156</sup> reported a qualitative analysis of blood–brain permeation considering 229 compounds and 72 VolSurf descriptors, analyzed by PLS method. The obtained model predicts the correct blood–brain permeation for over 90% of the compounds (Figure 11). The most important descriptors were the polar ones, which were inversely correlated with permeation. Overall, blood–brain permeation seems governed by a balance of all descriptors rather than a single descriptor type.

Ekins and co-workers<sup>157</sup> compared different 3D-QSAR approaches (namely CoMFA, VolSurf, molecular surface (MS)-WHIM, and Catalyst) to predict Caco-2 permeability using a set of 2-aminobenzimidazole derivatives. The study showed that VolSurf and Catalyst yielded better models, while MS-WHIM and CoMFA were less predictive. This contrasts with previous studies where MS-WHIM was used to predict Caco-2 permeability of more structurally diverse compounds. These observations suggest the value of assessing multiple approaches for permeability prediction, as it

**Figure 10** Contour plots for steric properties in a CoMSIA model obtained from an analysis of peptide substrates of the mammalian H<sup>+</sup>/peptide co-transporter PEPT1. Green regions indicate regions where bulky groups enhance affinity. Yellow regions should be kept unoccupied. (a) Molecular structure of ligands displayed in parts (b) (1 and 2) and (c) (3, 4, and 5). (b) High-affinity substrates 1 (gray) and 2 (purple). (c) Low-affinity substrates 3 (orange), 4 (green), and 5 (purple). Circles in S3 denote substituents in disfavored regions. (Reprinted from Gebauer, S.; Knutter, I.; Hartrodt, B.; Brandsch, M.; Neubert, K.; Thondorf, I. *J. Med. Chem.* **2003**, 46, 5725–5734 © American Chemical Society.)

appears that some methods do better than others for particular data sets. Moreover, the CoMFA model was not improved using the automatic conformer alignment in Catalyst, indicating that the modest CoMFA permeability prediction was due to lack of efficacy of molecular fields, rather than to an uncorrected alignment. Finally, the study demonstrated that 3D-QSAR techniques have considerable value in predicting passive permeability, at least for congeneric series of derivatives, and represent a valuable asset in drug discovery.

The recently proposed MHBP (as outlined in Section 5.24.3.3) have found significant applications in ADME predictions.<sup>80</sup> One study showed that the hydrogen-bonding donor capacity (MHBP<sub>do</sub>), but not the acceptor capacity (MHBP<sub>acc</sub>), appears able to predict oral absorption. This is in agreement with the ratio of HBD and HBA groups in the ‘rule-of-five.’

**Figure 11** A discriminant PLS score plot for a model predicting blood–brain barrier penetration (BBB). The model offers good discrimination between the permeants (BBB +) and nonpermeants (BBB–), since it assigned a correct BBB profile to >90% of the compounds in the data set. #### 5.24.5 Description of Molecular Fluctuation (Four-Dimensional Quantitative Structure–Activity Relationship)

##### 5.24.5.1 Approaches Based on Multidimensional Quantitative Structure–Activity Relationship

One of the main drawbacks of 3D-QSAR approaches is their inability to account for molecular flexibility, restricting the range of compounds that can be tested and introducing assumptions concerning the choice of alignment rules and hypothetical bioactive conformations. Hence, Hopfinger and co-workers<sup>158</sup> proposed a 4D-QSAR analysis formalism based on a Boltzmann sampling of the conformations available to each molecule. This approach aligns the molecules by combining the conformers obtained, and uses PLS techniques as in COMFA to analyze for each alignment the grid cell occupancy values taken as molecular descriptors. A general finding of this method is that a relatively small number of grid cell descriptors is significant in the relationships, providing compact models that are easy to explore and very informative. Finally, the evaluation of all models permits the analysis of the results without respect to alignment and conformational sampling, suggesting a hypothetical bioactive conformation for each ligand. This formalism was also exploited to calculate alignment-independent molecular similarity indices.<sup>159</sup> A recent comparison between such a 4D-QSAR method and a classic CoMFA analysis on a set of ecdysteroids showed that the two best 4D models have the smallest average residuals of prediction and the best cross-validated correlation coefficients.<sup>160</sup>

A second type of multidimensional QSAR approach considers the receptor-to-ligand adaptation, which can influence biological response, especially when this effect is a significant consequence of the ligand-induced triggering mechanism. Vedani and co-workers<sup>161</sup> proposed the Quasar approach, which accounts for induced fit by mapping a ‘mean envelope’ (which comprises the surfaces of all ligands) onto an ‘inner envelope’ (which accommodates the individual ligand). The energetic expenditure associated with this adaptation can be estimated from the mean envelope to individual envelope root mean square shift. Furthermore, such an approach accounts for unknown receptor flexibility by considering several protocols, to adapt the mean envelope to the individual envelope. This variability is measured using an induced-fit varying from 0.0 (no fit) to 1.0 (perfect fit). This variable represents the fifth dimension, leading to a so-called 5D-QSAR. Recently, Martinek and co-workers<sup>162</sup> accounted for ligand flexibility by calculating molecular descriptors based on the free energy encountered during the shift of the ligand conformational ensemble to the active conformation. This

descriptor can be combined with traditional 3D-QSAR approaches giving a '3 + 3D-QSAR' methodology. Furthermore, Lukacova and Balaz<sup>163</sup> described an approach to incorporate multimode ligand binding in CoMFA analyses. Since experimental binding constants can be considered as the weighted average of specific constants for different binding modes, they are predictable as weighted combinations of the field values used to predict specific constants.

#### 5.24.5.2 Approaches Based on the Concept of Property Space

The concept of property space has been applied to large series of compounds to give a quantitative description of chemical space, by characterizing each considered property of each compound with a single value. Applications of this approach include the evaluation of chemical libraries obtained by combinatorial chemistry, or the estimation of the optimal value a given molecular property should exhibit for biological relevance (e.g., indices of drug-likeness).

Whereas this approach has proven very successful in comparing chemical libraries and designing 'combichem' series, it is nevertheless based on the assumption that the molecular properties are discrete, invariant ones. This assumption derives from the restrictions imposed by the handling of huge databases, but like many assumptions it tends to fade in the background and be taken as fact. Yet as chemistry progresses, so does the understanding of molecular structure taken in its broadest sense, namely the mutual interdependence between geometric features and physicochemical properties.

The concept of property space is beginning to be used to gain a comprehensive understanding of the dynamic behavior of a single compound. In this dynamic vision, a molecular property can be described either by an average value or by descriptors defining its property space.<sup>70</sup>

The average value of a property, and especially a weighted average, contains more information than a conformer-specific value (even if of the lowest-energy conformer or of the hypothetical bioactive conformer). However, this average value does not yield information on the property space itself. To this end, one should use descriptors specifying the property range and distribution in relation to conformational changes and other property profiles.

A property space can be defined using two classes of descriptors. The first class includes descriptors quantifying the variability (spread) of values, and the range is probably the most intuitive one. The second class of descriptors relates the dynamic behavior of a given property with other geometric or physicochemical properties. Such correlations can reveal if and how two molecular properties change in a coherent manner.

The relationships between physicochemical properties and geometric descriptors describe the ability of a physicochemical property to fluctuate when the 3D geometry fluctuates. These relationships also lead to the concept of molecular sensitivity, since there will be sensitive molecules whose property values are markedly influenced by small geometric changes, and insensitive molecules whose properties change little even during major geometric fluctuations. One can assume that molecular sensitivity can affect biological properties, as the latter are dynamic properties in themselves whose emergence will depend on the ability of a molecule to fit into and interact with an active site. Work in progress indicates that explorations of the property spaces of bioactive molecules may lead to new and promising tools in dynamic QSARs.<sup>164</sup>

#### 5.24.5.3 Absorption, Distribution, Metabolism, and Excretion Applications of Four-Dimensional Descriptors

The key role of molecular fluctuations in ADME predictions finds compelling evidence in the significant relation between molecular flexibility and oral bioavailability. For instances, Veber and co-workers<sup>165</sup> analyzed 1100 drug candidates, and found that there is an inverse relation between the number of rotatable bonds and oral bioavailability. Furthermore, they showed that a molecule must have less than seven rotors to possess a significant bioavailability (irrespective of the molecular weight). Similar results were obtained by Lu and co-workers,<sup>166</sup> who showed that a compound will have a good bioavailability if it possesses less than 10 rotors and a PSA value smaller than 140 Å<sup>2</sup>.

Therefore, it comes as no surprise that 4D-QSAR approaches have also found successful applications in ADME predictions. Among them, we single out the remarkable and recent study by Hopfinger and co-workers,<sup>167</sup> who predicted the blood-brain permeation of 150 heterogeneous compounds using a combination of 4D-QSAR approaches and cluster analysis. This study divided the data set into clusters based on 4D-QSAR results, and determined predictive QSAR models for each cluster. The results indicate that the properties governing blood-brain permeation may vary across diverse classes of compounds, and that it is essential to cluster compounds into chemically similar classes in order to derive predictive models. 4D-based molecular similarity indices seem more efficient for this clustering than traditional similarity descriptors.

4D-QSAR analysis was also used to study a series of azole CYP51 inhibitors.<sup>168</sup> Ten different alignments were used to build models, and one alignment yielded a significantly better model with higher predictivity than the others. The active site mapped out in this 4D-QSAR study suggests that hydrogen bonding is not prevalent in the interaction, as confirmed by a crystal structure that does not indicate any possible hydrogen bond.

Even without considering the property space concept in its full potentiality, Ekins and co-workers tentatively used the range and standard deviation of MS-WHIM descriptors (obtained considering a set of significant conformers for each compound) as independent variables to predict the biological data of CYP2C9, CYP2D6, and CYP3A4 inhibitors.<sup>169–171</sup> These studies highlight that 4D-QSAR approaches can increase model predictivity compared with 3D-QSAR models, confirming that molecular fluctuations do play a role in biological profiling. The limited role of 4D descriptors in these models may be explained if it is considered that activity and affinity depend mainly on the ability of the ligand to assume well-defined property values, a type of information not encoded in property ranges or standard deviations.

## 5.24.6 Conclusion

MIFs are mathematical models depicting the physical reality of recognition forces surrounding molecules, or, stated in more vivid language, ‘projected’ by molecules around themselves. Such recognition forces account for the long-distance (ion–ion, ion–dipole) and short-distance (dipole–dipole, hydrophobic) interactions between chemical compounds, and they are the physicochemical substratum of all biochemical processes. Their essential significance in the interaction of drugs with small and large biomolecules does not need to be stressed.

It thus follows that understanding, describing and parameterizing MIFs may well prove to be the most fruitful approach to obtaining broad and solid QSAR and quantitative structure–disposition relationship models. As this overview has tried to show, this approach is finding ever increasing applications in relating molecular structures to biological properties.<sup>172,173</sup> But current successes should not hide our conviction that the MIF approach is still in its infancy despite impressive advances in recent years due to theoretical progress and the continuous increase in computer power. It is our belief, which we hope to share with readers, that a huge potential for progress lies in the development of MIF-based instruments and their application to drug research.

## Biographies

**Giulio Vistoli** was born in 1968. He received his Laurea degree in medicinal chemistry at University of Milan in 1994. During his PhD studies with Prof L Villa, he spent a period in Lausanne under the supervision of Prof B Testa with whom he has fruitfully collaborated since 1996. In 1999, he became assistant professor in medicinal chemistry at University of Milan. His recent research focuses on developing the property space concept to explore the dynamic profile of molecular fields, deriving fertile descriptors for dynamic 4D-QSAR analyses.

**Alessandro Pedretti** was born in 1970. He received his Laurea degree in medicinal chemistry at University of Milan, in 1995. After PhD studies with Prof L Villa, he became assistant professor in medicinal chemistry at University of Milan, in 2001. His interests deal mainly with computer programming applied to computational chemistry, realizing novel software tools for molecular modeling and docking analysis. In particular, he developed VEGA (available at [www.ddl.unimi.it](http://www.ddl.unimi.it)), a program able to compute several molecular fields analyzing their dynamic profiles during the simulation time.

### 5.25.1 Introduction

The major component of the human body is water – over 70% by weight.<sup>1</sup> The liver, our main ‘biochemical factory,’ is an amazing 96% water! Many vital biochemical processes either directly involve, or depend on, acid/base ionization of chemical compounds in water. Generally, ionizable molecules exist in aqueous environment as a population of species: one electrically neutral (on each ionization center) and multiple ionized forms; their exact number depends on the ionization center count. Ionized species may have very different properties from the neutral form. From a physiologist’s point of view, this may mean preserving a relatively constant pH of the organism’s fluids via biological buffers, pH-dependent reactivity of biomolecules that have charged functional groups, pH-dependent solubility, and the ability of compounds to distribute through an organism. To a pharmaceutical scientist, the importance of ionization cannot be overstated. It influences almost all the subjects of pharmaceutical science: drug absorption, transport, distribution, and elimination, solubility, formulation, chemical stability, pharmacodynamics, drug analysis, etc. Crossing cellular membranes, for example, is strongly related to molecular lipophilicity understood in terms of the *n*-octanol/water partition coefficient (log *P*). It has been observed that the lipophilicity of ionized forms of a chemical compound is significantly lower than that of the neutral form. This phenomenon is of course related to the energetic cost of

removing the molecule from an aqueous environment and placing it in an organic solvent – removing the hydration layer is in general more difficult in the case of charged forms. Therefore, the neutral form of the same compound will permeate more easily than any of its charged forms. In principle, this trend should extend to relating permeabilities of predominantly neutral versus predominantly ionized drugs at physiological pH and holds true in many cases, indeed. However, one must remember that the observed lipophilicities of ionizable compounds are population averages over all species, i.e., the pH-dependent distribution coefficients ( $\log D$ ). Ionization and pH determine the relative contents of all the mentioned forms in water. It is possible for one ionizable drug to have  $\log D$  in certain pH range equal to or even higher than  $\log D = \log P$  of another drug possessing no ionizable groups. Hence, one must be cautious in permeability comparisons of different compounds. An opposite general trend is observed with regards to the drug's water solubility – a very important factor for solid dosage forms. Ionized (salt) forms will dissolve better than the neutral form due to enhanced hydration. Indeed, a plot of solubility versus  $\log P/\log D$  shows strong, negative correlation between the two. A pharmaceutical formulation scientist must always carefully consider the interplay between these opposite effects and strive for their balance. These issues are specifically addressed elsewhere (*see* 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption; 5.16 Ionization Constants and Ionization Profiles; 5.17 Dissolution and Solubility; 5.18 Lipophilicity, Polarity, and Hydrophobicity; 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery; 5.28 In Silico Models to Predict Oral Absorption) the reader is encouraged to consult these chapters for more details.

The acid/base properties of a chemical compound are quantified by its ionization constants ( $pK_a$ ) that can be either measured or calculated. Experimental aspects of ionization, as well as elementary definitions, are described elsewhere (*see* 5.16 Ionization Constants and Ionization Profiles) in this book and will not be repeated here. Measurement of ionization constants has become more easy and convenient over recent years. However, it requires either purchase, or synthesis and purification, of chemical compounds. This may not always be cost-effective, particularly for early drug discovery scientists who wish to screen up to millions of compounds in virtual libraries. In situations like this, rapid in silico estimation of  $pK_a$  is the most practical way to obtain results.

This chapter will be focused on  $pK_a$  prediction by empirically based computational methods, although first-principles methods of prediction, as well as methods derived from statistical thermodynamics, will also be mentioned. Sections 5.25.2 and 5.25.3 will discuss the theory and algorithmic approaches to the prediction. Currently available software packages will be listed in Section 5.25.4. Available sources of data for  $pK_a$  modeling will be the subject of Section 5.25.5. Finally, Section 5.25.6 will discuss the future of ionization prediction.

## 5.25.2 Theoretical Basis of Ionization Prediction

Before discussing individual predictive algorithms in detail, it is imperative to understand the phenomenon of protolytic dissociation, as well as the factors influencing it. Simple at the first sight, the process of proton detachment from an organic molecule in an aqueous environment is actually quite complex, as it depends on a delicate balance of sizable opposing forces. A discussion of these forces is the subject of the first two subsections. The mutual interactions of individual ionization sites in multiprotic molecules introduce another complication leading to microequilibria theory – the subject of the third subsection.

### 5.25.2.1 Thermodynamic Forces Driving Ionization

Complex phenomena may become tractable after dissecting them into simpler components. Dissociation of a monoprotic organic acid at constant temperature in water is thus considered in terms of a thermodynamic cycle used by quantum chemists to calculate ionization constants<sup>2-4</sup> and depicted in Figure 1.

It is immediately apparent that the process of aqueous dissociation, shown by the bottom reaction, should be understood as proton exchange between an acid, HA, and a base,  $H_2O$ , rather than the simple process of protolysis. The

**Figure 1** Thermodynamic cycle used to calculate the Gibbs free energy change upon acid dissociation in water. Gas phase is symbolized by the '(g)' subscript, aqueous phase by the '(aq)' subscript, while 'hyd' denotes solvation.

negative logarithm of the equilibrium constant for this exchange, the  $pK_a$  is directly related to the free energy change upon ionization<sup>3</sup>:

$$pK_a = \frac{\Delta G_{aq}}{2.303RT} + \text{const} \quad [1]$$

where  $R$  is the universal gas constant and  $T$  stands for temperature. The top reaction in **Figure 1**, conducted in the gas phase, is free of solvation components and its  $\Delta G_g$  can be further expressed in terms of free energies of bond breaking:

$$\Delta G_g = \Delta G_{diss}(H-A) - \Delta G_{diss}(H-OH_2^+) \quad [2]$$

Since the net free energy change of a closed cycle is zero, the aqueous free energy of dissociation can be decomposed as follows:

$$\begin{aligned} \Delta G_{aq} = & \Delta G_{diss}(H-A) + [\Delta G_{hyd}(A^-) - \Delta G_{hyd}(HA)] \\ & + [\Delta G_{hyd}(H_3O^+) - \Delta G_{hyd}(H_2O) - \Delta G_{diss}(H-OH_2^+)] \end{aligned} \quad [3]$$

The last three terms, pertaining to water (labeled further as  $\Delta\Delta G(\text{water})$ ), are constant for all acids and their net effect strongly favors ionization. The  $\Delta\Delta G(\text{water})$  can be defined as the free energy difference for between relative hydration and protonation of the hydronium ion. For the purpose of comparing relative acid strength, it is then sufficient to consider the remaining components: (1) the free energy of breaking the H–A bond in the gas phase, and (2) the difference in solvation between protonated and deprotonated acid. The magnitude of solvation is much greater for ions than for neutral molecules.<sup>5,6</sup> For example, the free energy of solvation for the acetate ion is about 10 times greater than the free energy of solvation of the acetic acid.<sup>5</sup> In the case of weak organic acids, solvation forces cooperate with  $\Delta\Delta G(\text{water})$  driving ionization forward, while the process of breaking the H–A bond opposes it. The case of weak monoprotic bases is quite different in the solvation aspect. Replacing protonated acid HA by protonated base  $BH^+$ , and anion  $A^-$  by free base B in **Figure 1** results in a thermodynamic cycle for base ionization. The aqueous free energy of base dissociation is equal to:

$$\Delta G_{aq} = \Delta G_{diss}(B-H^+) + [\Delta G_{hyd}(B) - \Delta G_{hyd}(BH^+)] + \Delta\Delta G(\text{water}) \quad [4]$$

Unlike acid ionization, which produces two ions out of neutral substrates, the deprotonation of one positively charged base on the left-hand side results in one positive hydronium ion on the right-hand side. For this reason, the sensitivity of  $pK_a$  to solvation is much lower for bases than that for acids. For example, acid strength drops rapidly with the solvent's dielectric constant, while base  $pK_a$  is affected only weakly.<sup>7</sup>

### 5.25.2.2 Molecular Factors Affecting Ionization

Being thermodynamic variables, ionization constants are obviously influenced by ‘environmental’ factors such as temperature, solvent, ionic strength, etc. For the purpose of predictive modeling these variables are assumed fixed, e.g., this chapter considers  $pK_a$  measured in water only. The main reasons for intermolecular  $pK_a$  variability are thus molecular factors that, in the light of aforementioned thermodynamic considerations, influence the stability of the H–A (or B–H<sup>+</sup>) bond and the solvation differential between a product and a substrate of the ionization reaction. For a proton dissociating from the same functional group, the question is how much the rest of the molecule favors (stabilizes) the ionic form over the neutral one. These effects can be either electronic/electrostatic, or steric in nature. The first group can be further subdivided into electrostatic field (through-space), inductive (through-bond), and mesomeric (arising from  $\pi$ -electron delocalization) effects. Since Perrin *et al.* provide an excellent, detailed explanation of these molecular factors,<sup>7</sup> this chapter will only summarize the most important ideas.

Electrostatic interactions between a charged ionization center and electric charges in other parts of the molecule, permanent or induced, may stabilize or destabilize the center depending on whether the prevailing interactions are attractive or repulsive. Of course, polar solvent acting as dielectric usually dampens the magnitude of these field effects. In addition, field interactions determine the amount of electrical work required to remove a proton from the ionization center.

The electronegativity difference between hydrogen and chlorine atoms in, e.g., an HCl molecule causes a net shift of electron density toward the chlorine atom, resulting in charge polarization. This inductive effect acting through chemical bonds is intuitively understood in terms of ‘electron-withdrawing’ and ‘electron-donating’ atoms and groups.

This effect has short range in terms of the number of bonds between the acting group and the ionization center. Naturally, the electron density present in the A–H bond determines its strength; hence density withdrawal will promote ionization and vice versa. Of course, inductive influence is not only limited to bond breaking. It is also strongly related to the relative stabilization of the charged reaction center.

Unlike inductive effects acting through localized bonds, mesomeric influences are long-ranged and depend on existing  $\pi$ -conjugation between remote substituents and the reaction center. If the conjugation exists, then the electric charge resulting from ionization may delocalize, resulting in lower free energy than that expected from electrostatic/inductive effects alone. For example, the  $pK_a$  of simple aliphatic alcohols ranges above 14, whereas that of phenols is around 10. More information on electronic effects can be found in representative publications.<sup>8–46</sup>

Steric factors are much more specific and diverse. Stereochemical constraints may impose isomer-specific electronic/electrostatic interactions. For example, *cis/trans* isomerism is responsible for different electrostatic repulsion in fumaric and maleic acids leading to markedly different  $pK_a$  values.

Conformational effects influence the ionization constants of axial versus equatorial cyclohexane-carboxylic acids. Similar geometrical effects may also induce different solvation patterns, internal hydrogen bonding, and changes in  $\pi$ -electron delocalization. Internal hydrogen bonding provides an extra stabilization of the carboxylate anion in salicylic acid, resulting in lower primary and higher secondary  $pK_a$  in comparison to *p*-hydroxy benzoic acid. Local crowding hinders solvation and thus ion stabilization, leading to raised acid  $pK_a$  and lowered base  $pK_a$ .

This effect is particularly important for larger reacting groups. Steric hindrance to resonance effects is responsible for as much as a 10-fold difference in ionization of *N,N*-dimethylaniline and *N,N*-diethylaniline, as well as blocking the nitro group from achieving anion-stabilizing resonance with the ring in the 3,5-dimethyl-4-nitrophenol.

Some organic molecules isomerize by migrating a proton within the same molecule from one group to another. A well-known example of this tautomerism is keton–enol equilibrium:

In most cases the equilibrium is strongly shifted to the left, but in some systems the enol form may become significant. This has profound consequences for  $pK_a$  prediction as the migration of one proton from carbon to oxygen increases the number of potentially ionizable groups by one. Since  $pK_a$  values of tautomers may be markedly different, they should be treated as separate molecules for predictive purposes.

Effects of the solvent and solvation have been discussed in previous subsection from thermodynamic point of view. However, their importance warrants more detailed consideration. For example, the expected and observed in gas phase order of basicity of methylamines,  $\text{Me}_3\text{N} > \text{Me}_2\text{NH} > \text{MeNH}_2 > \text{NH}_3$  is changed by water to  $\text{Me}_2\text{NH} > \text{MeNH}_2 > \text{Me}_3\text{N} > \text{NH}_3$ .<sup>47</sup> Early treatment of solvent as a dielectric continuum influencing only through-space field interactions<sup>8</sup> turned out to be a crude approximation. The effects of solvent (especially water) are much more complex and subtle. Specific interactions mediated through hydrogen bonding affect not only a reaction center, but also

electronic properties of other molecular groups that interact with it. In turn, neutral and ionized forms of an organic molecule have different influence on the structure of liquid water. Krishnan and Friedman saw four distinct components of solvation: cavity formation, hydrogen bonding, van der Waals dispersion forces, and structure modifying term almost entirely associated with the effect of nonpolar groups on the self-organization of water molecules.<sup>48</sup>

Topsom performed a detailed theoretical study of explicit water molecules interacting with carboxylic acids and amines in gas phase.<sup>6</sup> In the case of substituted acetic acids,  $\text{XCH}_2\text{COOH}$ , it takes just one water molecule hydrogen-bonded to the  $-\text{OH}$  group in substrate, but as many as three molecules directly bonded to the  $-\text{COO}^-$  anion in the ionization product to explain all experimental substituent effects observed in aqueous solution. Similarly, one water molecule attached to  $-\text{NH}_2$  and three water molecules attached to  $-\text{NH}_3^+$  explain aqueous basicities of simple methylamines. In both cases it is the charged species that differentiates  $\text{p}K_a$ . However, explicit hydration with 1–3 waters of just the reaction site in larger molecules like substituted pyridines, quinuclidines, and phenols does not explain their aqueous basicity and acidity adequately. According to Topsom, at larger distances the bulk water influence on the ‘lines of force’ between reaction center and a substituent becomes more significant. Detailed studies by Arnett on literature data of hydration enthalpies of pyridines and pyridinium ions, however, do suggest dominance of the hydrogen bonding term related to the bulk water interacting with these molecules.<sup>49</sup> Bulk water was found to be twice as good hydrogen bond acceptor and hydrogen bond donor as monomeric water toward the pyridinium ions and pyridines, respectively.

Hydration of a substituent may affect its electronic influence on the reaction site: field, resonance, electronegativity, and polarizability. Based on hydration energy alone, the field effect of substituents like  $-\text{H}$ , alkyl,  $-\text{CF}_3$ ,  $-\text{NO}_2$ ,  $-\text{F}$  and  $-\text{CN}$  is not influenced significantly by the specific hydration.<sup>6</sup> At the other end of hydration spectrum are substituents  $-\text{NH}_2$ ,  $-\text{NMe}_2$ ,  $-\text{OH}$ ,  $-\text{OMe}$ ,  $-\text{CHO}$ ,  $-\text{COMe}$ , and  $-\text{CO}_2\text{Me}$  whose effective dipole moment, thus field effect, is significantly changed by the first solvation shell. Calculations also show a significant decrease of  $\pi$ -electron donation by  $-\text{NH}_2$ ,  $-\text{NMe}_2$ , and  $-\text{OMe}$  upon hydration as the lone pair becomes less involved in conjugation. By contrast,  $\pi$ -electron withdrawal by  $-\text{COH}$  and  $-\text{COMe}$  (but not  $-\text{COOR}$ ) is enhanced by hydration.

The decades-old quest toward understanding the aforementioned ‘anomalous’ ordering of aqueous basicities of methylamines was comprehensively summarized by Caskey *et al.*<sup>47</sup> The authors contributed to this knowledge pool by performing effective fragment potential (EFP) calculations of methylamine– and methylammonium–water complexes with the number of water molecules increasing from 0 to 14. The structural, as well as energetic, differences between amines and corresponding ammonium ions are stark. Methylamine molecules are attached to hydrogen-bonded water clusters almost as an afterthought, making one acceptor  $\text{N}-\text{HOH}$  hydrogen bond and only occasionally one more donor  $\text{NH}-\text{OH}_2$  hydrogen bond when applicable. On the other hand, ammonium ions are the ‘center of attention’ of surrounding water clusters, always utilizing all the available protons for donor  $\text{NH}-\text{OH}_2$  bonding. These observations are commensurate with stabilization energetics due to hydration.<sup>47</sup> Methylamines are stabilized to about the same extent as the number of methyl groups increases. In contrast, relative methylammonium ion stabilization decreases with the number of methyl groups. (In concordance with the work of Topsom, the first few water molecules contribute the bulk of hydration enthalpy to ammonium ions.) This is consistent with the results of previous research that the electrostatic term dominates hydration enthalpy of methylammonium ions and decreases with the ion size, thus explaining the observed ordering of methylamine basicities in water.

The above examples are only a tip of an iceberg of research work done on organic ion solvation, but well illustrate the great complexity of this problem.

Finally, statistical factors and microscopic constants mentioned by Perrin and coauthors are manifestations of the same set of important phenomena to which the entire next subsection is dedicated.

### 5.25.2.3 Microequilibria of Acid/Base Reactions

Microequilibria,  $\text{p}K_a$  microconstants, microdissociation, microspecies, and microspeciation – these terms appearing in the chemical literature may mislead the reader into believing that there exists some mysterious microscopic-level theory of proton dissociation, or associate these with quantum chemical description of the said reactions. Nothing can be further from the truth. The terminology simply applies to an accurate description of acid/base equilibria of multiprotic molecules. A brief survey of randomly chosen college chemistry textbooks and scientists in the pharmaceutical industry shows that the microequilibria theory is rarely taught, if at all, even at the graduate level. Instead, an approximate picture of sequential dissociation is presented, where each  $\text{p}K_a$  determined by titration can be ‘assigned’ to specific ionizable functional group in a multiprotic molecule. The accurate description, already noticed by Bjerrum in 1923,<sup>50</sup> is that all protonation sites participate at every stage of multiprotic dissociation.<sup>51–53</sup>

**Figure 2** Molecule of cetirizine and schematic representation of its protonation sites.

The experimentally observed  $pK_a$  constants, called macroconstants from now on, are thus an effect of statistical averaging of individual microdissociation events.

The concepts presented above are best illustrated by an example. The drug cetirizine (ZYRTEC manufactured by Pfizer) (Figure 2) seems to be an ideal candidate. All 12 microconstants and 8 microspecies (protonation states) of this triprotic molecule have been determined experimentally,<sup>54</sup> along with three  $pK_a$  macroconstants: 7.98, 2.90, and 2.12. To interpret the latter, an average organic chemist would immediately say: ‘in a zwitterionic compound like this the 7.98 constant reflects deprotonation of one of the tertiary amine groups, while 2.90 can be assigned to dissociation of the carboxylic acid.’ That leaves the 2.12 constant which must be ‘assigned’ to the remaining amine group. Which one? Our chemist hesitates: “Well, maybe it is 2.12 that represents carboxylic acid.” Of course, that makes 2.90 still “unassigned”...

The difficulties associated with the sequential ionization point of view are apparent and only multiply with the number of protonation sites in the molecule. Let us examine titration experiments closer. Placing cetirizine in a water solution at very high pH eliminates all dissociable protons leaving a negative ion. This fully deprotonated state (FDS) will be our reference state. Addition of a strong acid lowers pH and makes more protons available for binding by cetirizine. Adding positively charged proton to the negative FDS is easier than adding it to the electrically neutral state, while adding a proton to a positive ion is most difficult of all. These simple arguments allow us for a tentative ordering of macroconstants corresponding to the increasing protonation count on cetirizine:

In principle, the overall proton count in each of the macrostates shown above is all that can be deduced from titration experiments. We know that, e.g., in neutral species there is one proton bound somewhere. There is no physicochemical reason to strictly determine which site the proton binds to. In fact, the proton may bind to any available site with nonzero probability. In the neutral macrostate there are three available sites leading to three neutral microstates. There are three different ways of distributing two protons among three sites providing another three microstates in the +1 macrostate. Together with FDS and the fully protonated microstate, there are 8 possible protonation microstates of cetirizine bound together by a network of 12 microequilibria as shown in Figure 3.

The existence of all the depicted microstates has been confirmed experimentally.<sup>54</sup> The neutral macrostate is strongly dominated by a zwitterionic microstate with proton bound to the middle nitrogen. Therefore, the idea of the 7.98 macroconstant being ‘assigned’ to this amine group is a good approximation, justifying the aforesaid sequential protonation point of view. However, ‘assigning’ the remaining two constants, 2.90 and 2.12, to any functional group cannot be done, since the components of +1 macrostate contribute with probabilities of the same order of magnitude. In general, the closer the microconstants are to each other, the less accurate the sequential ionization picture is. It is also noteworthy that so-called ‘statistical factors,’ artificial constructs mentioned in the Perrin’s book<sup>7</sup> as significant correction parameters to  $pK_a$  prediction for symmetric molecules, are quite a natural consequence of protonation microequilibria if identical ionization centers are treated as discernible.

The analysis presented above has profound consequences for in silico prediction of ionization constants. Since macroscopic  $pK_a$  are predicted from molecular structure, having uniquely defined structure with unambiguously positioned protons is a necessary condition of a successful prediction. Unfortunately, unique structures are characteristic of microstates, not macrostates. In conclusion, macroconstants cannot be derived directly from the

**Figure 3** Protonation microequilibria of cetirizine. Arrows are labeled by microconstants measured experimentally.<sup>54</sup> Protonation microstates are labeled by their relative contributions (probabilities) to the respective parent macrostate.

structure. One way of solving this dilemma would be building predictive models from measured microconstants, then combining the results to form macroconstants. Although microconstants have been measured in a few impressive experiments,<sup>54–84</sup> they are available only for a handful of compounds and the applied methodologies are difficult and limited up to triprotic molecules when no symmetry constraints are present.<sup>53</sup> In an iterative approach predictive models may be gradually extended from monoprotic to multiprotic molecules with increasing degree of complexity. Finally, predictive models may be indirectly optimized against observed macroconstants, which were measured for tens of thousands of chemicals, via rigorous application of the microequilibria mathematics. Another difficulty is exponentially growing number of microconstants and microstates as a function of the number of ionizable groups per molecule. Generally, for  $n$  protonation sites there are as many as  $2^n$  microstates and  $n \cdot 2^{n-1}$  microconstants. In the case of a polypeptide containing 20 ionizable groups, the respective numbers are 1 048 576 microstates and 10 485 760 microconstants! Clearly, this presents significant challenge to programmers of predictive software. Many prediction methods avoid this challenge by neglecting microspeciation altogether or by using various approximation schemes. One possible way of overcoming the performance barrier would be guessing the dominant microstates and presenting them as the only representatives of the respective macrostates, thus restoring sequential ionization. Hence, macroscopic  $pK_a$  would be approximated by suitable dominant microconstants at a cost of neglecting lesser microstates. For example, microconstants collected along the dominant protonation path in Figure 3 (7.98, 2.70, and 2.32) approximate the observed macroconstants with the maximum absolute error of only 0.2. Choice of other protonation paths, however, would result in a catastrophic loss of accuracy. Furthermore, the error of this approach becomes larger with the number of ionization centers, as the chance of equivalent and nearly equivalent microstates increases. The quality of prediction in this case strongly depends on the quality of guessing algorithm, which faces an arduous task of a priori determination of prevailing microstates from microequilibria diagrams, such as the one in Figure 3, but with all the numerical labels removed.

Fortunately, in drug discovery and development applications the investigated molecules rarely possess high numbers of ionizable groups. Therefore, exact resolution of complete sets of ionization microequilibria is computationally feasible and there is no need to introduce additional sources of error by using approximate algorithms. In Section 5.25.4, software packages for  $pK_a$  prediction will be labeled by their approach to the microequilibria problem.

### 5.25.3 Algorithms to Predict Ionization Constants

Computational methods of predicting  $pK_a$  can be divided into three major groups. Small molecules are amenable to approaches based on the power of modern quantum chemistry and starting from first principles; this first group will be labeled as quantum chemical methods. On the other end of the molecular size spectrum are proteins and nucleic acids – molecules with large numbers, but with limited variety, of ionization sites. These biopolymers are treatable with the methods derived from statistical thermodynamics, the second group. Methods that use empirical predictive models to predict  $pK_a$  belong to the third group.

#### 5.25.3.1 Empirical Methods for Small Molecules

Empirical methods of small molecule  $pK_a$  estimation can be tentatively divided into three groups based on the approach used:

1. Linear free-energy relationships (LFER) – methods utilizing empirical relations of Hammett and Taft.
2. Quantitative structure–property relationships (QSPR) – methods correlating calculated structural descriptors with  $pK_a$ .
3. Database lookup – methods searching of similar structures in a predetermined database of molecules with known experimental  $pK_a$ .

In this section, we describe scientific principles and review relevant research pertaining to these approaches. Description of individual software packages will be postponed to [Section 5.25.4](#).

##### 5.25.3.1.1 Methods based on linear free-energy relationships

###### 5.25.3.1.1.1 Hammett–Taft constants

Historically, LFER-based methods are the oldest. In as early as 1935, Hammett first discovered a simple linear relationship between the ionization constants,  $K_a$ 's, of benzoic acid (0) and its *para*-substituted derivative (S)<sup>85</sup>:

$$\log\left(\frac{K_a^S}{K_a^0}\right) = \sigma_S \quad [5]$$

where  $\sigma_S$  is a Hammett constant characteristic to a given substituent S. Taft observed similar relations in aliphatic systems.<sup>86</sup> The logarithm of the ionization constant, as shown in [Section 5.25.2.1](#), is proportional to the Gibbs free energy of ionization, hence the LFER acronym. The above relation was later extended to multiple substituents and other classes of compounds:

$$pK_a^S = pK_a^0 - \rho \sum \sigma_S \quad [6]$$

In the above,  $pK_a^0$  symbolizes ionization constant for the parent molecule, while  $\rho$  is a characteristic constant for the entire reaction class considered (and equal to 1 for *para*-substituted benzoic acids) multiplied by the sum of substituent contributions. In principle, the reaction constant is considered independent of individual molecules, whereas substituent constants are assumed to be additive and independent of individual reactions. With the exception of experimentally determined  $pK_a^0$ , values of all other parameters are found by regression.

It should be duly noted that all the LFER methods belong to a general class of perturbational approaches. In short, these methods are valid as long as substituents are small chemical perturbations of the parent molecule. This concept is well illustrated by the following trivial example: when *p*-nitrobenzoic acid is considered as a benzoic acid perturbed by a nitro group, the calculated acidic  $pK_a = 3.42$  agrees very well with experimentally determined<sup>87</sup> value of 3.44 (see [Figure 4](#)). However, when the molecule is split into a formic acid 'parent' and *p*-nitrophenyl 'substituent,' the agreement becomes much worse with calculated  $pK_a = 2.62$ .

Obviously, the parent molecule must carry the bulk of the chemical information (aromatic carboxyl as opposed to aliphatic carboxyl in this case) pertaining to a given reaction series. In this case, the application of substituent corrections to the parent's experimental  $pK_a^0$  may result in highly accurate estimation. Indeed, in many simple systems, the prediction results turned out to be quite precise. For more complex molecules the parent/substituents may not be so clear, leading to ambiguity in selecting an appropriate equation and set of constants.

By the early 1980s, LFER methods had been studied in depth and developed into an elaborate prediction system, now firmly established in both academia and industry. Thousands of Hammett and Taft constants were determined

**Figure 4** Two different ways of splitting *p*-nitrobenzoic acid into a ‘parent molecule’ and a ‘substituent.’ Values of  $pK_a$  are calculated for each split using the LFER approach. Constants and equations were taken from Perrin, D. D.; Dempsey, B.; Serjeant, E. P. *pK<sub>a</sub> Prediction for Organic Acids and Bases*; Chapman and Hall: London and New York, 1981.

experimentally for many systems. Cases where LFER breaks down have been identified.<sup>88–90</sup> Once again, the author is vastly grateful to D D Perrin, B Dempsey, and E P Serjeant for writing such an excellent reference book<sup>7</sup> on the subject, where principles and variations of LFER-based  $pK_a$  prediction have been explained and richly illustrated with a multitude of examples. This enables us to concentrate this chapter on significant methodological developments that occurred after the book was published.

#### 5.25.3.1.1.2 SPARC method: a step beyond Hammett–Taft approach

In the early 1990s Karickhoff, Carreira, and co-workers announced SPARC – an expert system for predicting chemical reactivity from structures.<sup>91–95</sup> The method was a blend of the LFER approach used to compute thermodynamic properties, and Dewar’s perturbed molecular orbital (PMO) theory<sup>96</sup> to describe quantum effects such as electron delocalization energies or  $\pi$ -polarizabilities. The basic philosophy of SPARC is fairly in tune with that described above. A molecule is divided into a reaction center C (equivalent to parent molecule) and a set of one or more perturbors P (substituents). With ‘0’ and ‘f’ describing the initial and final state in a chemical reaction, the energy difference,  $\Delta E \equiv E_f - E_0$ , between products and reactants is expressed as:

$$\Delta E = \Delta E_C + \delta_P(\Delta E_C) \quad [7]$$

where the first term is an intrinsic energy change of the reaction center inferred from experiment and the second describes perturbational corrections facilitated by perturbors. At first glance, eqns [6] and [7] are essentially the same. However, the perturbation term in eqn [7] is not a simple linear function of substituent constants, but a sum of terms corresponding to a number of potential mechanisms for interactions of P and C. For ionization reactions in water, the expansion is:

$$\delta_P(pK_a^0) = \delta_{\text{ele}} + \delta_{\text{res}} + \delta_{\text{sol}} + \delta_{\text{H-bond}} + \delta_{\text{stat}} \quad [8]$$

The individual terms in this expansion describe electrostatic, resonance, solvation, hydrogen bonding, and statistical effects of the perturber(s) (see Section 5.25.2.2). The electrostatic term is further split into three terms:

$$\delta_{\text{ele}} = \delta_{\text{fixed}} + \delta_{\text{mesomeric}} + \delta_{\text{induction}} \quad [9]$$

reflecting interactions of permanent charges and dipoles, and induced charges through mesomeric and inductive effects, respectively. An effort is made to express the  $\delta$ -terms for each perturber P as a product of three portable structural components:

$$\delta_x(C, P) = \rho_C B_{P-C} F_P \quad [10]$$

where  $F_P$  describes the perturber’s ‘strength’ to create the effect  $x$ ,  $\rho_C$  is the susceptibility of the reaction center to effect  $x$ , and  $B_{P-C}$  is the ‘conduction descriptor’ of the intervening bond network between P and C. This expression is obviously reminiscent of the ‘classic LFER’ reaction constants and Hammett–Taft constants. The reader should keep in mind that the  $\sigma_S$  term in eqn [6] is a simple constant wholly describing substituent S, while terms in eqn [10] may be complex functions of the molecular structure, themselves depending on many parameters.

#### 5.25.3.1.1.3 MCASE methodology

At about the same time Klopman and Fercu applied the MCASE expert system to study the primary acidity of thousands of organic acids.<sup>97</sup> Although the title of their paper contains the ‘QSAR’ phrase which seemingly qualifies it for the next section, most of Klopman’s approach is essentially based on the perturbational LFER principles. The MCASE program has been specifically designed for studies of biological or physicochemical activity of chemical compounds.<sup>98</sup> All investigated molecular structures are fragmented into all possible 2–10 heavy atom connected substructures. These fragments are then labeled as ‘active’ or ‘inactive’ depending on the parent molecule activity and some arbitrary threshold. Fragments of highest activity can be used as descriptors (binary indicator variables) in a multivariate regression analysis. Since activity of compounds may be due to different mechanisms, MCASE searches the whole database for a fragment (called ‘biophore’) accounting for the activity of the largest portion of the database. All the compounds associated with this biophore are assumed to possess the same mode of action and are subsequently removed. The process of searching the next biophore is then restarted on the remainder of the data until all the biophores are found. The 2464-acid database used to build a model of primary  $pK_a$  provided 22 distinct biophores, with a carboxylic group being the most important one. All the remaining molecular fragments are called “modulators.” For each database subset characterized by a common biophore a local multivariate linear regression model is built using modulators as descriptors. The equation used by Klopman for  $pK_a$  was:

$$pK_a = \text{const} + \sum r_i n_i M_i \quad [11]$$

where  $M_i$  is a binary {0,1} indicator for the presence of modulator  $i$ ,  $n_i$  is the number of modulators  $i$  in a compound, and  $r_i$  stands for the regression coefficient. Because of the locality of the regression models built for distinct classes of compounds, there are formal similarities between the Klopman method and the classical Hammett–Taft approach. It can be seen by the association of concepts: a biophore can be equivalent to a parent molecule, modulators can be perceived as perturbing substituents, the constant parameter in eqn [11] would resemble the biophore’s intrinsic susceptibility to ionization, like  $pK_a^0$ , and regression coefficients could encode products of reaction and substituent constants. The difference is the scope of the models involved. The equations of classical LFER apply to very narrow classes of compounds; e.g., substituted acetic acids need different equations from those for substituted formic acids. On the other hand, Klopman’s equation for the  $-\text{COOH}$  biophore applies to all carboxylic acids; it is much less ‘localized.’ Nevertheless, the basic principles of the perturbational approach, including fragmentation of molecules, are still preserved.

The real novelty in Klopman’s work is inclusion of additional molecular descriptors in the linear regression equations as ‘modulators,’ but only for selected biophores. The descriptors were physicochemical (log  $P$ , water solubility, molecular weight) and quantum chemical (Hückel MO charge densities, HOMO and LUMO coefficients, absolute electronegativity, and hardness). Whole-molecule descriptors are clearly beyond the concepts of perturbational LFER. Regression coefficients of these descriptors, however, were significantly overshadowed by contributions from fragmental modulators.

#### 5.25.3.1.1.4 Concluding remarks

Since 1981 many researchers have proposed numerous schemes for improving and refining the existing LFER methodologies to predict chemical reactivity. Regrettably, space limitations preclude this author from providing an exhaustive review of these techniques. The interested reader is referred to the original literature, taking <sup>23,25,26,28–33,46,99–101</sup> as a good starting point.

The prediction of all macroscopic  $pK_a$  for molecules with multiple ionizable groups using microspeciation is possible within the LFER framework, but at the expense of adding more substituent parameters. For example, to calculate all microconstants proper to an amine group in cetirizine (Section 5.25.2.3), one would need to know Taft  $\sigma^*$  parameters not only for  $-\text{COOH}$  and  $>\text{N}-$  groups, but also for their ionized forms,  $-\text{COO}^-$  and  $>\text{NH}^+$ . Thus, the number of required parameters for ionizable substituents doubles. Other challenging issues mentioned in Section 5.25.2.3 still remain. To the author’s knowledge, only the SPARC method has been demonstrated as fully capable of computing multiprotic  $pK_a$  through a complete microspeciation.<sup>93,95</sup>

As a prediction system, LFER provides good estimations of  $pK_a$ , but even in its simplest form it requires vast numbers of parameters (many of which must be measured) and highly diverse, huge databases of experimental results. It is therefore very expensive to develop. Of course, it is the reflection of a very large number of possible parent molecules multiplied by various substituent combinations. Mathematically, a complete LFER system consists of thousands highly localized linear regression models plus complex rules of relating model parameters to ever-changing molecular topologies. Again, if a molecule in question falls within the scope of one of these models, the estimate of its

ionization may be of high accuracy. From the point of view of an innovative pharmaceutical chemist, the perturbational nature of the LFER approach may be the source of its weakness when investigated drug candidates are so novel that suitable parent molecules cannot be found in existing databases. It is then necessary to conduct an appropriate series of experiments to arrive at new parameterization of, e.g., Hammett–Taft equations applicable to the studied compounds.

#### 5.25.3.1.2 Methods based on quantitative structure–property relationships

Others chapters in this book (see all the chapters of ‘In Silico Tools in ADMET’ in this volume) well illustrate the success of predicting whole molecule properties from calculated structural descriptors using a QSAR/QSPR approach. In its most general form, the quantity of interest,  $y$ , is a function, sometimes very complex, of molecular descriptors,  $\{x_1 \dots x_N\}$ :

$$y = \sum_j a_j f_j(x_1 \dots x_N; b_1 \dots b_M) + \text{const} \quad [12]$$

where  $a_j$  and  $\{b_1 \dots b_M\}$  denote linear and nonlinear parameters of the model. If all the functions  $f_j$  are simple identities, i.e.,  $f(x) = x$ , then the model is a simple multiple linear regression, most common in the literature. But the above equation may also denote one of the machine learning methods, such as artificial neural networks.<sup>102–120</sup> The main problem in applying eqn [12] to  $pK_a$  prediction is the choice of proper descriptors. Clearly, unlike lipophilicity or solubility, which can be modeled by molecular descriptors, ionization constants localized on specific atoms require a different kind of descriptors.

Similarly to LFER approaches, QSPR models may or may not take microspeciation into account. Microspecies are distinguished naturally if model descriptors take into account the protonation state of other groups. Although quite challenging to model developers, exact and complete inclusion of microspeciation is rewarded with much better  $pK_a$  prediction for multiprotic systems.

##### 5.25.3.1.2.1 Atomic descriptors

Already in 1938 Kirkwood and Westheimer used classical electrostatics of spherical and ellipsoidal molecules immersed in continuous dielectric medium to predict  $pK_a$  shifts of organic diacids.<sup>8–10</sup> Extension of this theory to the electrostatic influence of any monopolar or dipolar substituent at a distance  $r$  from the reaction center results in the following expressions:

$$\begin{aligned} \Delta pK_a &= \frac{q_1 q_2}{2.303 k T \epsilon r} \\ \Delta pK_a &= \frac{q_1 \mu_2 \cos \theta_{12}}{2.303 k T \epsilon r^2} \end{aligned} \quad [13]$$

where  $q_1$  and  $q_2$  are electric charges on the reaction center and substituent, respectively,  $\mu_2$  is the dipole moment of the substituent, and  $\theta_{12}$  is the angle between dipole moment vector and the axis joining the reaction center and substituent. The symbol  $\epsilon$  denotes an effective dielectric constant, whereas  $kT$  is the absolute temperature scaled by the Boltzmann constant. Please note that values of these expressions depend both on a specific reaction center atom and its molecular environment. Hence, eqn [13] can be viewed as the first literature example of an atomic descriptor defined as a function describing an atom in a molecule. It seems natural that atomic descriptors can serve as inputs to QSPR models describing localized properties, like ionization constants, similarly to molecular descriptors used in modeling whole molecule properties.

Examples of atomic descriptors are scarce in the scientific literature. To author’s best knowledge, the following paragraphs will be the first review of this subject. Catalan *et al.* expressed gas-phase proton affinities of oxygen, nitrogen, and carbon bases as multivariate linear functions of 1s orbital binding energies and first ionization potentials.<sup>121</sup> Many other types of quantum-mechanical atomic descriptors were also used by other research groups in developing QSPR correlations for either gas-phase proton affinities, or aqueous  $pK_a$  of narrow classes of compounds.<sup>34,35,39,40,122–128</sup> Unfortunately, quantum descriptors are (still) computationally too expensive to be used in high-throughput in silico predictions. Their review is postponed until the next section. An excellent example of empirical atomic descriptors is described in the 1984 paper of Gasteiger and Hutchings.<sup>129</sup> These authors used residual electronegativities and effective polarizabilities (serving as charge stabilizers) of a protonated group to predict gas-phase proton affinities of alcohols, ethers, their thio analogs, and carbonyl compounds.<sup>130</sup> Noteworthy, these descriptors do include the influence on the ionization center exerted by type and distance of the remaining atoms present in concentric topological spheres. This approach was later extended to ionization in aqueous phase.<sup>131</sup> Recently, Gasteiger

reported on an extended set of atomic descriptors, both empirical and quantum, fed into artificial neural networks that successfully predicted  $pK_a$  of monoprotic  $-C-OH$  and  $-C-SH$  acids and monoprotic  $>N-$  bases.<sup>132</sup> Empirically calculated inductive partial atomic charges by an electronegativity-based algorithm were also utilized as atomic descriptors in QSPR models of  $pK_a$  of organic  $-OH$  acids.<sup>133</sup> Gross *et al.* critically reviewed different partial charge algorithms, most of them quantum-mechanical, with respect to the quality of correlation with  $pK_a$  of benzoic acids<sup>34</sup> as well as phenols and anilines.<sup>134</sup> Partial charges alone, however, may not be sufficient to build a universal  $pK_a$  model applicable to a wide class of compounds. For example, in a series of alkylamines  $NR_xH_{3-x}$  ( $R = Me, Et$ ) the partial charge on the N atom increases with  $x$  implying smaller electron density and diminishing proton affinity.<sup>27</sup> The observed proton affinity trend, however, is quite the opposite. Mercier and co-workers list both empirical and quantum atomic descriptors used along with molecular descriptors in the predictive modeling system OASIS to model  $pK_a$  of purines: atomic topological and steric indices.<sup>135</sup> Rajasekaran revisited the Kirkwood–Westheimer descriptor of electrostatic repulsion between charged groups in dicarboxylic acids,<sup>20</sup> while Charton has analyzed its distance dependence in detail.<sup>25</sup>

All of the above examples are quite limited in scope, although they comprise important stepping stones toward a general predictive model. It is the universality of  $pK_a$  prediction that is the most alluring promise of QSPR models using calculated descriptors. If properly chosen and parameterized, atomic descriptors, calculable for any input molecule, may account for all of the factors influencing protonic ionization and may lead to predictive models that are strong, where LFER approaches are weak in their heavy reliance on experimental constants and their limited scope. Hence, global predictive models will be the focus of the following discussion.

#### 5.25.3.1.2.2 The method of Xing

A predictive model with wide scope was the leading ambition of Xing and coworkers when they applied molecular tree structured fingerprints (MTSF), a novel class of universal atomic descriptors based on SYBYL atom types (Tripos, Inc.<sup>169</sup>), to build QSPR models of  $pK_a$  for 645 acids and 384 bases.<sup>136</sup> The idea of MTSF is very simple: progressive breadth-first traversal of a molecular graph rooted in an ionizable atom and counting specific atom types and functional groups at each search depth level.

This is best explained by an example, shown in Figure 5. Potentially, the ionizable atom type can be any one of the 24 defined in SYBYL (search level 0). There are 33 atomic descriptors (24 atom types and 9 types of functional groups) defined at each subsequent search level. The breadth-first search is truncated on depth level 5. Putting the numbers together, each ionizable atom can be associated with a  $24 + 5 \times 33 = 189$ -dimensional vector of atomic descriptors. The exact number is smaller since ‘impossible’ atom types were eliminated at certain levels. Still, there are many descriptors, which is a concern given the relatively small size of training data sets. Xing *et al.* reduced the independent variable dimensionality by training their model using a partial least squares (PLS) algorithm.<sup>137</sup> The resulting model was able to predict only ‘single’ (i.e., monoprotic, while assuming all other ionizable groups in their neutral state)  $pK_a$  values, but for a wide array of diverse organic acids and bases. The model was tested on an external set of 25 molecules taken from Perrin’s book<sup>7</sup> that were absent from the training sets. It ‘correctly predicted the order of the ionizing strength of individual groups in multiprotic molecules’ from the predicted single  $pK_a$  although in quantitative terms its performance was worse compared to the results of the Hammett–Taft approach used by Perrin. These results well illustrate the serious difficulties in building a universal model for all types of acids or bases, especially when the model uses a single class of descriptors. Overall, the intriguing approach of Xing was probably the first published QSPR model of  $pK_a$  with such a wide scope of applicability and great potential for future development. In their next work Xing and

**Figure 5** An example of MTSF descriptor vector created for the amine atom in the molecule shown. The  $sp^3$  nitrogen atom (type = N.3) constitutes the entire 0th search level by itself. Subsequent levels 1–5 contain counts of any of the shown six atom types leading to a 36-dimensional vector of descriptors.

coworkers managed to significantly improve predictive performance by incorporating the idea of building separate QSPR models for narrower classes of compounds<sup>138</sup>:

1. Aromatic carboxylic, sulfonic and sulfinic acids.
2. Phenols and thiophenols.
3. Aliphatic and alicyclic carboxylic, sulfonic, sulfinic acids plus alcohols and thiols.
4. Acidic nitrogens and carbons.
5. Pyridines (defined here as six-member aromatic rings with at least one nitrogen).
6. Anilines.
7. Imidazoles.
8. Alkylamines.

At the same time, however, the researchers drifted off the modeling universality afforded by their previous approach. Namely, the eight classes were further divided into narrower subclasses depending on chemical characteristics of member molecules. Ionization constants were then modeled as follows:

$$\text{p}K_{\text{a}} = \text{p}K_{\text{a}}^0 + \sum_i a_i x_i + \sum_j g_j y_j + \sum_k q_k z_k \quad [14]$$

where  $\text{p}K_{\text{a}}^0$  is a constant characteristic for each subclass,  $x_i$  and  $y_j$  are atom type and group type MTSF descriptors after PLS analysis,  $z_k$  are class-specific indicator variables, while  $a$ ,  $g$ , and  $q$  symbolize regression parameters. For example, in the first class there were three distinct  $\text{p}K_{\text{a}}^0$  constants, one per each ionizing group type. The indicator variables,  $z_k$ , for the same class consisted of MTSF descriptors calculated for specific atoms at *ortho*, *meta*, and *para* positions on the six-member ring with respect to the acidic group. This definition by itself greatly limits the scope of the model since it excludes, e.g., a carboxyl group attached to a five-membered heteroaromatic ring, fused rings, etc. Characteristic constants,  $\text{p}K_{\text{a}}^0$ , and indicator variables,  $z_k$ , used here are quite reminiscent of the ‘parent molecule’  $\text{p}K_{\text{a}}$  and Hammett substituent constants shown in eqn [6]. Furthermore, multiprotic molecules were assumed to (de)protonate sequentially ignoring microspeciation. Individual protonation states were guessed from the predicted single  $\text{p}K_{\text{a}}$ . The overall performance of this model was greatly improved in comparison to the preliminary model of Xing *et al.* but at a serious cost of scope limitation. The latter is proven by the fact that due to ‘missing parameters’ the new model could not process as many as 4 out of the 25 test molecules.<sup>138</sup> The same test set reported in the first Xing’s paper was processed in its entirety.

#### 5.25.3.1.2.3 Commercial models

Commercial researchers working for various chemistry software companies developed other global QSPR models for  $\text{p}K_{\text{a}}$  prediction. Unfortunately, due to competitive concerns, details of these models were not published. Nevertheless, some information is available from the respective companies’ websites (URL addresses are summarized in Table 1) and posters presented at conferences. CSpKa from ChemSilico is a composite of 12 artificial neural network models for 12 ionization center types using topological and electrotopological descriptors (see 5.23 Electrotopological State Indices to Assess Molecular and Absorption, Distribution, Metabolism, Excretion, and Toxicity Properties). It is not clear whether these descriptors are calculated at the atomic level. On the other end of the spectrum exists the ChemAxon’s ‘ $\text{p}K_{\text{a}}$  Plugin’ to the program Marvin with a complete treatment of microspeciation. Hence, multiprotic ionization is treated accurately, at least in theory. However, the model uses just three simple atomic descriptors (partial charge, atomic polarizability, and occasionally intramolecular hydrogen bond indicator) in simple nonlinear relations for microconstants.<sup>139</sup>

One of the recently developed commercial models can be described in much greater detail, though. While working at Simulations Plus, Inc., the author of this chapter (with a substantial help from coworkers) developed a comprehensive QSPR model for the prediction of multiprotic  $\text{p}K_{\text{a}}$ , now a part of the ADMET Predictor software. For this purpose, we have created a unique and, most importantly, diverse set of 44 empirical atomic descriptors encompassing all the factors that influence ionization (see Section 5.25.2.2). A raw data set of 8590 diverse organic compounds with measured 10 674 multiprotic ionization constants was purchased from BioByte, Inc. (see Section 5.25.5). Each of these  $\text{p}K_{\text{a}}$  values was assigned to the macroscopic protonation states of the respective molecules, mostly through referral to the original literature. Of these, 2143  $\text{p}K_{\text{a}}$  values (complete compounds) were sequestered as an external test set, while 8531 of the remaining constants were used to train the model. We have chosen to construct artificial neural network ensembles (ANNEs) optimized with an early stopping criterion<sup>140</sup> to prevent overtraining. Neural networks are well known for their excellent ability to encode nonlinear relationships between descriptors and a predicted property. The author has developed a special training algorithm that optimizes ANNE weights against measured  $\text{p}K_{\text{a}}$  macroconstants.

<sup>a</sup>Limited to diprotic and perfectly symmetric systems only ('apparent exact' constants in ACD terminology).

<sup>b</sup>Blend of LFER and perturbed molecular orbital (PMO) methods.

<sup>c</sup>Limited to five ionization centers per molecule only.

<sup>d</sup>Estimates only principal acid and base  $pK_a$ .

The artificial neural network outputs in an ensemble correspond to the ionization of individual atoms, while protonation states of all other ionizable atoms are strictly determined, i.e., to microconstants. This, plus the fact that this  $pK_a$  routine can process about 537 complete microstates per second on average (version 1.1.4, Pentium IV/512 MB RAM), allows the model to completely calculate all the  $2^n$  microspecies for an  $n$ -protic molecule, and hence to treat microspeciation exactly. Moreover, we assumed that the main factor determining an atom's ionization is its type, followed by its molecular environment. Consequently, we have built separate ANNEs for the following eight atom types:

1. O in all hydroxyacids (–OH group; alcohols, phenols, carboxyls, sulfo acids, phosphoric acids, etc.).
2. O in basic N-oxides (O=N– group; both aromatic and tertiary aliphatic).
3. S in thioacids (–SH group; thiols, thiocarboxyls, etc.).
4. C in carboacids (–CH<sub>2</sub>– and >CH– groups; barbiturates, acetylacetone, nitroalkanes, etc.).
5. N in acidic aliphatic amides (–NH<sub>2</sub> and –NH– groups; carboxyamides, sulfonamides, etc.).
6. N in acidic aromatic NH (–NH– incorporated into an aromatic ring; uracils, imidazoles, etc.).
7. N in basic amines (–NH<sub>2</sub>, –NH–, >N– groups; aliphatic amines, aromatic anilines, etc.).
8. N in basic aromatic N (–NH– and –N– incorporated into an aromatic ring; pyridines, pyrroles, etc.).

The above types encompass a vast majority of organic acids and bases and reflect the diversity of BioByte database. The corresponding ANNEs are combined into one predictive model within the microequilibria framework. The actual numbers of selected descriptors, as well as network complexity, are commensurate with the representation in the above eight subsets. The fact that it was at all possible to build one ANNE covering, e.g., such a multitude of markedly different aromatic and aliphatic hydroxyacids spelled out in type 1 accounts for the diversity of the employed atomic descriptors. There are no structural limitations and the model is global in the sense of covered atom types. However, the model would not predict ionization of some 'exotic' groups like, e.g., hydroselenides, –SeH. To the author's knowledge, no other LFER or QSPR method would process such acids, either. Of course, if such experimental data becomes available, there is no obstacle to building additional ANNEs.

#### 5.25.3.1.3 Methods rooted in database lookups

Roger Sayle has noticed that direct assignment of 'typical'  $pK_a$  values according to detected ionizable atom types predicts the  $pK_a$  of simple molecules with a standard deviation of 0.95 log units.<sup>141</sup> The observation that similar molecules, or similar molecular fragments, have similar  $pK_a$  is the basis of the last class of methods. A database containing either complete structures or structural fragments and experimental  $pK_a$  is searched for the nearest neighbors of the compound in question. Correction factors may be eventually applied to found  $pK_a$  values. Of course, treatment of microspeciation is not possible in this approach.

### 5.25.3.2 Quantum Chemical Methods

This section starts with the continuation of the QSPR approach, but this time with quantum mechanical descriptors. A brief description of the first principles method is presented thereafter.

#### 5.25.3.2.1 Predictive quantitative structure–property relationship correlations using quantum mechanical descriptors

The diversity, universality, and level of detail represented by quantum mechanical atomic descriptors vastly surpass that offered by empirical atomic descriptors. Therefore, high-accuracy QSPR predictions of ionization are possible in this case. A global model of this kind including multiprotic molecules has not yet been built. The main drawback is the relatively high computational cost of solving the Schrödinger's equation, mandating long processing times per molecule. Numerous authors have studied a multitude of local correlative models. Longuet-Higgins found out that  $pK_a$  differences in the class of heteroaromatic amines are explained by a product of the atomic  $\pi$ -density and local perturbation of the Coulomb integral.<sup>15</sup> Study of the basicity of heteroaromatic nitrogens was continued by Spanget-Larsen who correlated  $pK_a$  and proton affinities with shifts of valence atomic orbital energy occurring upon placing a neutral nitrogen atom in a molecule.<sup>126</sup> The energy shifts were in turn expressed as simple functions of atomic charges and electronic repulsion terms. Semiempirical partial charges, highest occupied molecular orbital (HOMO) energies of the anion, as well as the energy difference between anionic and neutral forms were correlated with  $pK_a$  of phenols and carboxylic acids.<sup>122</sup> The same group of acids plus aliphatic alcohols were revisited again by Citra, who added O–H bond orders to the semiempirical partial charge descriptors.<sup>123</sup> Atomic charges were a frequently recurring type of descriptors. Gross *et al.* evaluated different means of computing partial atomic charges for the purpose of predicting ionization variations in anilines and phenols.<sup>134</sup> The same group later extended the list of studied descriptors to geometrical properties (bond lengths and angles), rotation barriers around C–O bonds, orbital energies, relative proton transfer enthalpies,<sup>39</sup> as well as minimum local properties on molecular surface: ionization energy and electrostatic potential.<sup>40</sup> The quality of these correlations equaled and in some cases surpassed that afforded by empirical Hammett constants. Molecular electrostatic potential was also applied to study the basicity of amines,<sup>44</sup> later extended by computation of hydration effects.<sup>142</sup> Tehan *et al.* embarked on using parameters obtained from frontier orbital theory: electrophilic and nucleophilic frontier electron densities, electrophilic, nucleophilic, and radical superdelocalizabilities, and atom self-polarizabilities to predict  $pK_a$  of, once again, phenols and carboxylic acids,<sup>143</sup> but also amines, anilines, and heterocyclics.<sup>144</sup> Impressive accuracy has been achieved by Adam who correlated ionization of carboxylic acids, phenols and pyridines with the Atoms in Molecules energy of the dissociating proton.<sup>145</sup> Based on the same theory and the same classes of molecules, quantum topological molecular similarity descriptors were tested for  $pK_a$  estimation.<sup>128</sup> Multiple or single linear regression was the modeling method chosen in all of the above treatments, except the last one that invoked partial least squares.

An interesting group of approaches applied comparative molecular field analysis (CoMFA) to  $pK_a$  prediction of benzoic acids and imidazoles,<sup>124,125</sup> and nucleic acid components.<sup>127</sup> CoMFA is usually used to correlate biological activity with molecular structures of very narrow classes of compounds having a common scaffold. In brief, three-dimensional structures of these molecules are superimposed using scaffold atoms, then immersed in a discrete cubic lattice. Next, electrostatic potential energy is calculated at each lattice point with the aid of specific probe (e.g.,  $H^+$  ion). The electrostatic field is generated by partial atomic charges calculated by quantum methods. Energy values are then placed in a matrix whose columns are labeled by individual lattice points and rows by participating molecules. Partial least squares transformation reduces usually large row vector dimensionality and leads to much smaller number of latent components – the CoMFA descriptors. A related technique, comparative molecular surface analysis (CoMSA) was also applied to benzoic and alkanolic acids.<sup>146</sup> Finally, many authors pursued an indirect  $pK_a$  estimation by correlation of Hammett and Taft constants with quantum mechanical descriptors.<sup>11,13,14,17,34,35,147–151</sup>

The above are mere examples of the amount of important research work done in this field. In spite of the large number of papers a general QSPR model utilizing quantum mechanical descriptors has not emerged so far. Up to date research efforts in this arena should therefore be classified as exploratory.

#### 5.25.3.2.2 Ab initio calculation of ionization constants

The most universal computational methods for  $pK_a$  prediction based on first principles of quantum mechanics are also most time-consuming of all. The underlying paradigm here is thermodynamic description of ionization already explained in [Section 5.25.2.1](#). Quantum ab initio methods allow for calculation of the free energy terms present in [eqns \[3\] and \[4\]](#). The inherent difficulty is that the road to the final, relatively small free energy of ionization leads through subtraction of sizable terms. In one anecdote it is said that the problem is equivalent to determining the weight of a

transoceanic ship's captain by weighing the entire ship with the captain aboard, then weighing the ship without him and subtracting the two numbers. Consequently, 'ship weights' in  $pK_a$  prediction must be determined with excruciating accuracy. An error of just  $5.7 \text{ kJ mol}^{-1}$  in calculated free energy corresponds to the  $pK_a$  shift of 1 log unit.<sup>145</sup> Although high-precision calculations of a single molecule energy in gas phase have recently become possible, hydration terms remain a bottleneck hindering progress in this area. Classical molecular mechanics models hydration by surrounding the molecule in question with many water molecules and solving Newton's equations in time domain. Calculations of this kind in quantum realm are still beyond the reach of existing computers. Therefore, many different approximation schemes have been proposed for aqueous hydration. The common method for calculating hydration terms is the polarized continuum method (PCM). In there, solvent is approximated by a homogenous continuum polarized by the solute placed in a cavity. Solvent interactions are then included as one-electron interaction potential terms in the system Hamiltonian. This and other methods have been reviewed by Tomasi<sup>152</sup> and Cramer.<sup>153</sup>

Quite often  $pK_a$  values are calculated indirectly, i.e., instead of aqueous dissociation shown in [Figure 1](#) one calculates the free energy of proton exchange between the molecule in question,  $HAR_1$ , and its close analog,  $HAR_2$ :

Calculations for this isodesmic (i.e., where the number of bonds remains invariant) process are more accurate due to cancelation of errors in the entropy and hydration terms. Still, use of finite basis sets introduces systematic bias in all the energy terms that can result in calculated  $pK_a$  values twice as large as observed.<sup>154</sup>

In principle, any ab initio software package can be used to calculate ionization constants. Program Jaguar has been tailored specifically for this purpose and includes linear empirical correction factors applied to the 'raw' ab initio results (Jaguar 4.2: Schrödinger, Inc.<sup>170</sup>). Each chemical class has its own equation derived from a direct fit to experimental data. It seems then that the Jaguar's 'raw  $pK_a$ ' play a factual role of rather costly descriptors fed into linear QSPR models.

### 5.25.3.3 $pK_a$ Estimation for Biopolymers

Biopolymers (polymeric molecules of biological origin: proteins and nucleic acids) pose a special challenge for  $pK_a$  predictors. Large number of ionization centers, varying solvation environments, and conformational flexibility greatly increase complexity of the problem in comparison to small molecules. In spite of this difficulty, solving this puzzle received significant attention by scores of research groups around the world, since key properties of biopolymers, such as structural folding, stability, ligand binding, enzyme activity, etc., are strongly dependent on pH. Current mainstream methodologies for  $pK_a$  prediction in proteins and nucleic acids are based on classical molecular mechanics and statistical thermodynamics. Since these methods have been thoroughly described in a recent review,<sup>155</sup> we will only summarize major points to help in their understanding.

Unlike small molecules whose topological diversity is almost unlimited, naturally occurring biopolymers are built of monomeric units coming from a limited set of molecules. Ionization properties of, e.g., amino acids, the building blocks of proteins, are well known, and so are the nearest local environments of all possible ionization centers. In tune with LFER principles, the  $pK_a$  of, for example, the  $-NH_2$  group in lysine's side chain can be decomposed into two terms:

$$pK_a^P = pK_a^S + \Delta pK_a^{S \rightarrow P} \quad [15]$$

where the superscript P indicates protein environment, S stands for the bulk solvent, and the  $\Delta pK_a$  term indicates ionization constant shift on going from solvent to protein environment. The above expression is understood in terms of a model compound undergoing the thermodynamic cycle similar to the one depicted in [Figure 1](#). Since protein researchers think in terms of amino acid residues, most often the model compound is a free amino acid whose alpha amino and the carboxyl ends have been substituted by blocking groups, but it can also be reduced to a rigid part of the molecule around the given ionization center.<sup>156</sup> The  $pK_a^S$  term is then the ionization constant of the free model compound in bulk water, in analogy to the gas phase ionization shown in [Figure 1](#). The bottom part of [Figure 1](#) corresponds to the dissociation of the same group while attached to the protein molecule. Ideally, the  $pK_a$  shift would cover an entire set of complex interactions turned on by incorporating the model compound onto the protein backbone. The following equation illustrates key simplifying assumptions made at this point:

$$\Delta pK_a^{S \rightarrow P} = \Delta pK_a^{(pc)} + \Delta pK_a^{(ic)} + \Delta pK_a^{(desolv)} \quad [16]$$

In other words, only the following effects are taken into account: an electrostatic interaction with protein's permanent charges (pc), an electrostatic interaction with other ionization centers (ic), and a desolvation penalty (desolv). It must be stressed out that all of the above terms strongly depend on the protein's conformational flexibility. Other ionization centers are distinguished from permanent charges because their charge state depends on pH. Desolvation energy is a cost of losing a part of the hydration shell when the model compound is placed in the protein environment (compare to vertical arrows in [Figure 1](#)). [Equations \[15\] and \[16\]](#) are then combined and rearranged into pH-independent and pH-dependent terms:

$$pK_a^p = pK_a^{(int)} + \Delta pK_a^{(ic)}(pH) \quad [17]$$

where superscript (int) stands for the intrinsic  $pK_a$  in protein attained when all other ionization centers are neutral. Both terms are calculated with the aid of molecular mechanics force fields and the solution of the Poisson–Boltzmann equation for electrostatic potential, plus the assumed solvation model (continuum dielectric, explicit water molecules, etc.).<sup>155</sup> While  $pK_a^{(int)}$  needs to be calculated only once per given conformation, the mutually dependent interactions of the multiple ionization centers cannot be calculated directly. Instead, Bashford and Karplus proposed microequilibria approach covering all  $n$  ionizable centers in the protein molecule,<sup>157</sup> where the probability of a given ionization site  $i$  to be protonated is given by the Boltzmann weighted sum:

$$p_i = \frac{\sum_{\{\vec{s}\}} s_i \exp(-\Delta G(\vec{s})/RT)}{\sum_{\{\vec{s}\}} \exp(-\Delta G(\vec{s})/RT)} \quad [18]$$

where both summations are performed over the set of all  $2^n$  microstates,  $s_i = 1$  when site  $i$  is protonated and 0 when deprotonated, and  $\vec{s}$  represent an  $n$ -dimensional vector of  $\{0,1\}$  protonation states for  $n$  sites (microstate vector). The free energy of the entire system in a given ionization microstate,  $\Delta G(\vec{s})$ , is given by:

$$\Delta G(\vec{s}) = \sum_{i=1}^n 2.303RT(pK_{a,i}^{(int)} - pH) + 1/2 \sum_{i,j \neq i}^n W_{s_i s_j} \quad [19]$$

where  $W_{s_i s_j}$  represents electrostatic interaction energy between sites  $i$  and  $j$  in their respective protonation states. [Equation \[18\]](#) allows for calculating the expected protonation state in the protein molecule at a given pH, which in turn can be used to calculate the  $pK_a$  shift present in [eqn \[17\]](#). Because of the exponential growth of the number of summation terms in [eqn \[18\]](#), it becomes unrealistically time consuming for  $n > 30$  sites. In one approximation scheme, distant parts of the protein molecule are summed independently at much lower cost, then their interactions are calculated using averaged electrostatic potentials (mean field approximation). Another is based on Monte Carlo samplings of the microstates. The conformational dependence of the above equations should not be forgotten, either. One conformation is not good enough to obtain realistic results. Calculations are performed over an ensemble of conformations collected experimentally, or via molecular dynamics simulations.

Overall,  $pK_a$  calculations of the ionizable sites in biopolymers are a time consuming process. Protein and nucleic acid researchers, however, are rarely interested in the individual  $pK_a$  values of specific sites (which may not be very accurate), but rather in the expected protonation microstate distribution as a function of pH, or simply in the total number of ionizable protons attached in function of pH (the titration curve).

#### 5.25.3.4 A Word about Accuracy

In most cases, modern in silico prediction methods allow for a quick and convenient generation of  $pK_a$  estimates. Although individual features of different prediction methods are directly comparable, a universal global method of assessing the accuracy of these methods does not exist. Test results regarding new compounds have been published, but the numerical values of prediction errors always depend on a particular data set chosen for the test. This observation is valid for any predictive model. Moreover, the reader should keep in mind that all empirical predictive models are trained on an available set of chemicals with measured data (*see* 5.22 Use of Molecular Descriptors for Absorption, Distribution, Metabolism, and Excretion Predictions). Hence, the amount of interpolated chemical space covered by a model is limited to this training set. Beyond that corner of chemical space, the model extrapolates with diminishing accuracy. Errors ranging from 0.1 up to 2.0 log units are possible. For the above reasons, test results using different databases, or databases that are too small, should not be compared directly. Instead, a user is advised to perform a local validation, i.e., to test each method on his/her particular set of compounds with known  $pK_a$ . It is quite

possible that different users will find different methods to be superior. Additionally, different users will be satisfied with different levels of the prediction error, depending on a particular application. For example, estimated  $pK_a$  is often a stepping stone toward in silico prediction of the complete pH-dependent profiles of drug solubility ( $\log S$ ) and lipophilicity ( $\log D$ ) (see 5.16 Ionization Constants and Ionization Profiles; 5.17 Dissolution and Solubility, for detailed explanations). Taking a monoprotic compound as an example, its  $\log S$  and  $\log D$  profiles are relatively insensitive to pH except a narrow region in the vicinity of  $pH = pK_a$  where the profile curve is very steep. Errors in  $pK_a$  estimation may shift the steep part horizontally. Therefore, for users studying drug behavior in blood at  $pH = 7.4$  the accuracy of a  $pK_a$  predicted at, e.g., 7.1 is much more critical than the accuracy of a  $pK_a = 2.3$  estimate. But the latter is much more important for users studying, e.g., drug solubility in stomach. Of course, the same picture for polyprotic compounds is more complicated. It is critical to understand these dependencies, since errors in  $pK_a$  prediction may compound with the errors committed during the modeling of intrinsic solubility and  $\log P$ , respectively.

#### 5.25.4 Software Packages for $pK_a$ Prediction

Currently available software packages for empirical prediction of ionization constants ordered by prediction method are summarized in Table 1. Three computer programs have been around for many years, all are based on the LFER approach: ACD/ $pK_a$  DB from Advanced Chemistry Development, Pallas from CompuDrug, and SPARC from the University of Georgia. Newer software uses either QSPR methodology (Marvin from ChemAxon, ADMET Predictor from Simulations Plus, and CSpKa from ChemSilico), or database lookups (ADME Boxes from Pharma Algorithms and DISCON from the Russian Academy of Medical Sciences). Information presented below has been taken from the respective company websites and publications, where applicable, with the exception of ADMET Predictor personally developed by author. Interested readers are encouraged to contact companies directly.

##### 5.25.4.1 ACD/ $pK_a$ DB and ACD/ $pK_a$ Batch

The  $pK_a$  prediction software from Advanced Chemistry Development comes in two flavors: DB integrated with ChemSketch graphical interface allows for  $pK_a$  predictions one molecule at a time and contains an internal database of nearly 16 000 structures with measured  $pK_a$ , while nongraphical Batch form is designed for large sets of compounds at once (version 8.0). The program uses a large number of Hammett-type equations for the popular substituents and ionization centers. When the required substituent constants are not available from the experimental database for a given substitution position they are estimated from related constants via the calculation of transmission effects. The model is extendable if a user has own database of measured  $pK_a$  values. The DB version displays method of calculations and literature references, if available. Although the software allows for  $pK_a$  microconstants prediction for specific microstates (microconstants of the current form), complete microspeciation is limited to diprotic systems, most likely due to computational performance concerns. Otherwise, 'apparent approximate macroconstants' are calculated from an assumed dominant protonation form. Other limitations involve molecular size (no more than 255 atoms) and the number of ionizable groups (no more than 20). Accepted input formats include internal ACD database, SMILES strings, MDL SDfile, and MDL database file (MDL, Inc.<sup>171</sup>).

##### 5.25.4.2 pKalc Module of Pallas

Not much information about pKalc is available from the CompuDrug website. The program's algorithm uses a set of almost 1000 Hammett- and Taft-like equations. Only the lowest acidic and highest basic  $pK_a$  are considered. Ionized substituents are taken into account, but there is no mention about microspeciation. Development of new Hammett-Taft equations is enabled from user's data. A database of experimental ionization constants is included in the program suite.

##### 5.25.4.3 SPARC

Methods used by academic software SPARC<sup>91-95</sup>, partially funded by the US Environmental Protection Agency (EPA), have been described in detail in Section 5.25.3.1.1. The program runs on a University of Georgia web server and is accessible through a web browser interface. It is probably the only program that, along with water  $pK_a$ , also estimates gas-phase and nonaqueous  $pK_a$  in a variety of solvents. Molecular structure must be submitted as a SMILES string,<sup>158</sup> one molecule at a time. A searchable database of measured  $pK_a$  is also available. Full microspeciation is supported, but quite limited by the code performance. Submission of viomycin, a cyclic peptide with 16 ionizable groups, in full

speciation mode results in the following message: “This will result in ~96468992 calculations and may take as long as 964690.59 minutes” (about 1.8 years). Output includes list of dominant species, microscopic and macroscopic  $pK_a$ , and pH profiles. For some reason, macroscopic  $pK_a$  are not calculated accurately by microequilibria theory equations, but estimated from cross points on the drawn pH profile graphs.

#### 5.25.4.4 Marvin

Similarly to SPARC, ChemAxon's Marvin is a Java-based software application accessible through a web browser. It includes a nice on-line molecular drawing tool. Prediction of  $pK_a$  is performed by one of the ‘Calculator Plugins.’ Molecular structures can be imported in a multitude of formats, but calculations are performed one molecule at a time. Program's method is strong on microspeciation providing a complete microstate distribution of molecules containing no more than 14 ionizable groups making it suitable for multiprotic dissociation. According to an animated demo example, processing time for a 12-group cyclic peptide was 1020 s (17 min, Pentium III/256 MB RAM). On output dominant microspecies are displayed graphically together with their pH-dependent concentration profiles. However, the underlying algorithm for microconstant calculation is extremely simplified: only three atomic descriptors (empirical partial charge, polarizability, and internal hydrogen bonding correction) take into account only selected factors influencing ionization.<sup>139</sup>

#### 5.25.4.5 ADMET Predictor

Methods and models used by ADMET Predictor to predict  $pK_a$  have been described in [Section 5.25.3.1.2](#). Since its inception, the program has been coded with high-throughput batch prediction of a variety of molecular properties in mind. Even though full microspeciation puts exponential demands on the computer's CPU, it is calculated completely for each compound. In a recent test, all 65 536 microstates of the 16-group viomycin were processed in 2 min 2 s (version 1.1.4, Pentium IV/512 MB RAM). In the same test, the 12-group amphotericin B was processed in 8 s. Of course, these are extreme examples as drug molecules have smaller number of ionizable groups on average, resulting in a rate of ~69 compounds per second including the prediction of the full  $pK_a$  spectrum, 244 descriptors, and 50 ADMET properties per molecule. The program accepts inputs in SMILES, SYBYL MAC, MDL MOL, SDF, and RDF formats and can export predicted data in the same form. The atom count is limited to 256 and the ionizable group count is limited to 20 per molecule. Calculation of ionization of isolated aliphatic -OH and aliphatic -C(=O)NH- groups are ignored by default, but can be turned back on when needed. The output includes predicted macroscopic  $pK_a$  and graphical display of contributing microstates with relative percentages and individual proton dissociation probabilities (see [Figure 6](#)) as well as micro- and macrostate distributions as a function of pH.

#### 5.25.4.6 CSpKa

CSpKa from ChemSilico recognizes the following 12 ionization centers:

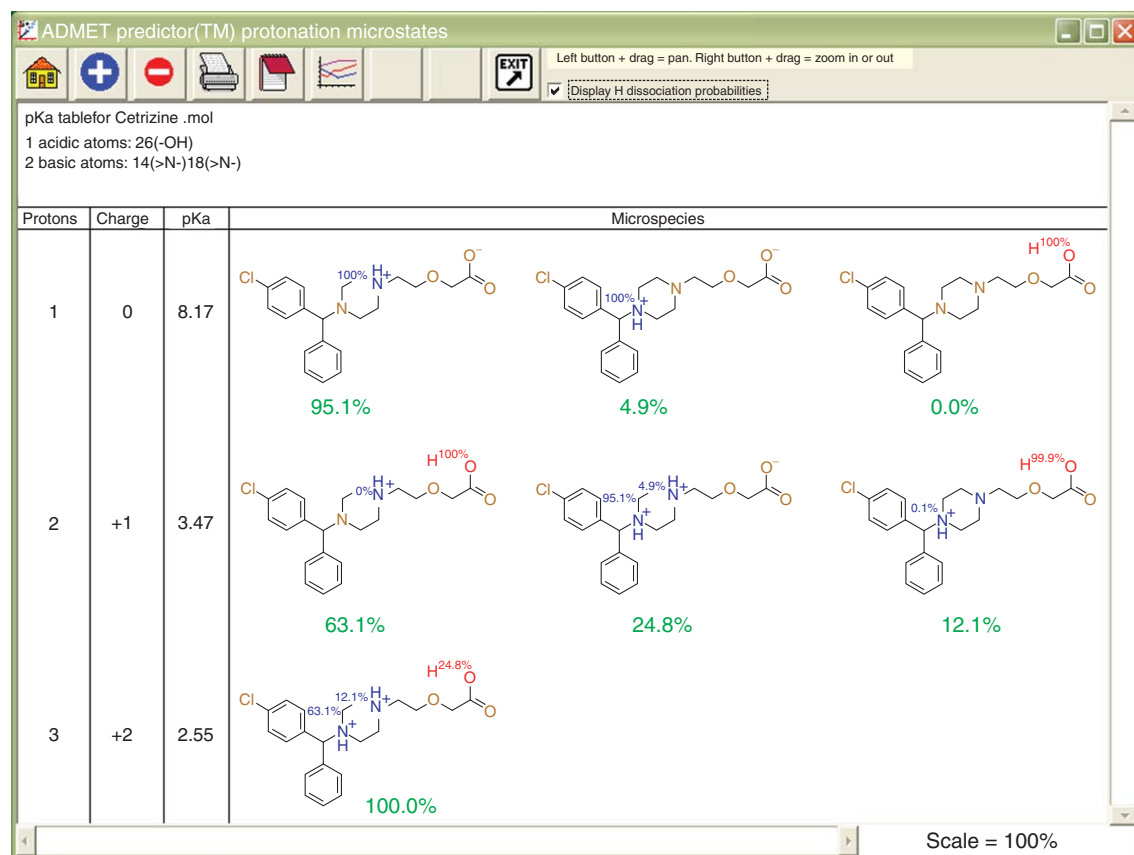

|                    |                      |                 |       |
|--------------------|----------------------|-----------------|-------|
| Aromatic N         | COOH                 | NH <sub>2</sub> | OH    |
| Unsaturated ring N | O=P(OH) <sub>2</sub> | RNR             | O=POH |
| Sulfonamides       | Amides               | NHR             | SH    |

The corresponding 12 artificial neural network models were built upon 16 000 experimental  $pK_a$  for 11 000 compounds. A set of proprietary topological descriptors plus 350 well-known topological and E-state indices are used as input variables.<sup>159</sup> The program accepts structure input in MDL MOL and SDF formats. It is the software's good point that only prediction is returned on output, not a substituted experimental value if the submitted compound was used in the method construction. Prediction is limited up to only five apparent/macroscopic  $pK_a$  per molecule assigned to corresponding groups, thus ignoring microspeciation. According to ChemSilico's web page, “[CSpKa] does not treat microscopic constants due to the inability to calculate such constants accurately except for simple organic compounds.”

#### 5.25.4.7 ADME Boxes

ADME Boxes from Pharma Algorithms includes the Ionization Filter: a model that counts the total number of ionizable groups and estimates one or two primary  $pK_a$  values for the strongest acid and the strongest base, where applicable. The program uses database lookup approach recognizing over 100 electrolyte groups and over 1300 generic skeleton

**Figure 6** Microspecies distribution for cetirizine calculated by ADMET Predictor.

(fragment) classes. On average a skeleton has been derived from five compounds with known  $pK_a$  values. Nearest neighbors are found based on fragment similarity. The novelty is an application of correction factors that 'account for new interactions within generic skeletons.' Over 1000 structures can be processed per minute ( $\sim 16 \text{ s}^{-1}$ ). Along with estimated  $pK_a$  values fractions of different ionic forms are displayed graphically as a function of pH.

#### 5.25.4.8 DISCON

Little information can be discerned from the DISCON web page at the Russian Academy of Medical Sciences. Estimation of  $pK_a$  values is based on the search of the nearest neighbors in the database containing 2471 'chemicals' and 296 drugs. Calculation results include minimal and maximal  $pK_a$  values of neighbors and their dispersion.

#### 5.25.5 Sources of $pK_a$ Data

A lot of experimental data on aqueous ionization of organic chemicals has been collected over the last 150 years. Many dissociation constants have been included in literature compilations<sup>7,160–166</sup> and chemical indexes.<sup>167,168</sup> Examples of electronic resources, free and commercial, are summarized in Table 2.

#### 5.25.6 Outlook

Undoubtedly, as long as inquisitive curiosity remains a part of human nature, in silico methods of ionization prediction will continue to be developed. Since chemical science became an integral part of many commercial enterprises, strong marketing forces will only add an extra motivation toward creation of more and more sophisticated computer models of not only ionization, but also chemical reactivity in general. Definitely, these trends are observed today. LFER methodology has quickly risen from the vast amount of experimental data collected in the twentieth century to the

point of becoming a mature methodology. The amount of available new data continues to be its bottleneck. Unless the large vaults of corporate data (especially in the pharmaceutical industry) are open, no significant new developments are expected in this area. On the other hand, empirical QSPR methods for  $pK_a$  prediction face wide-open possibilities for further development, especially considering the creation of new atomic descriptors. Quantum QSPR approaches still are in their early development stage, but with suitable progress in computational technology they are destined to catch up with empirical methods. It is author's belief that in the future a distinction between 'empirical' and 'quantum' QSPR will blur out. The net result will be one class of methods generating highly effective atomic descriptors fast enough to be usable for high-throughput prediction of high accuracy. First principles ab initio calculations of ionization will unquestionably benefit from advances in computer technology, albeit at a slower pace. Difficulties in proper treatment of solvation effects will hinder further progress, until computational molecular quantum dynamics becomes a reality. One point remains certain regardless of approach: to be effective no method should discard the underlying physical chemistry of ionization, particularly all the factors influencing  $pK_a$  including microequilibria theory.

## Biography

**Robert Fraczekiewicz** has been Product Manager at Simulations Plus, Inc., since August 1998. His primary role at Simulations Plus is the development of a commercial computer program ADMET Predictor for prediction of crucial properties from molecular structure. Dr Fraczekiewicz was also instrumental in developing computational routines present in other software products: GastroPlus, ADMET Modeler, and DDDPlus. Prior to joining Simulations Plus, he completed a postdoctoral fellowship at the University of Texas Medical Branch (1998, Prof Werner Braun), where he developed new algorithms for molecular modeling of proteins in dihedral space including solvent effects (program FANTOM). Dr Fraczekiewicz received his PhD in computational chemistry from the University of Houston in 1996. His thesis included building a computer program for calculating vibrational spectra of molecules (RAMVIB) and its application to study of active centers in metalloproteins. The University of Wrocław, Poland, had awarded the MSc degree in theoretical chemistry and spectroscopy to Robert Fraczekiewicz in 1988. For the next three years, prior to receiving an invitation from the University of Houston, he worked as a staff scientist in the Radioisotope Laboratory, Technical University of Wrocław, Poland, where he also completed a graduate course in computer applications in chemistry.

### 5.26.1 Background

#### 5.26.1.1 Relevance of Solubility for Drug Applications

The importance of addressing physicochemical properties early in the drug discovery process is generally recognized. Inappropriate physicochemical properties are likely to result in poor pharmacokinetics or other problems in drug development.<sup>1</sup> Properties affecting oral absorption are especially important. The flux by passive diffusion through intestinal membranes depends on the effective permeability of the solute and its concentration at the site of absorption, which is limited by solubility.<sup>2</sup> Very high solubility, on the other hand, may be accompanied by poor permeability. Solubility required for good absorption depends on the balance between the solubility, permeability, and potency of the drug molecule. Adequate solubility may vary from 1  $\mu\text{g mL}^{-1}$  for a high-permeability, high-potency compound (clinical dose of 0.1  $\text{mg kg}^{-1}$ ) to 2  $\text{mg mL}^{-1}$  for a low-permeability, low-potency compound (clinical dose of 10  $\text{mg kg}^{-1}$ ).<sup>3,4</sup> The molar solubility (log *S*) of typical orally available drugs spans the range from  $-6$  to  $2$  log units. For comparison, the lipophilicity of typical drug compounds varies in the log *P* range of  $-2$  to  $+6$  (where *P* is the octanol/water partition coefficient). Aqueous solubility can vary considerably depending on the environment (pure water, buffer, gastrointestinal fluid, blood). Solubility in organic solvents may be relevant in different stages of the drug development process. Dimethyl sulfoxide (DMSO) has become especially important for bioactivity screening because of its excellent solvent properties, for instance combinatorial libraries are usually stored in DMSO stock solutions.

### 5.26.1.2 What is Solubility?

The solubility of a solid nondissociating organic compound B is proportional to the equilibrium constant  $K_s$  in the partitioning of the compound between a solid phase and a dissolved phase:

Solubility depends on temperature, pressure, and the polymorphic form of the solid. Thermodynamic solubility is the concentration of the solute in saturated solution in equilibrium with the most stable crystal form of the solid compound.<sup>2,5</sup> Less stable crystal forms and amorphous forms with noncrystalline structure have higher solubility. Solubility reflects the equilibrium competition of solute molecules between themselves (crystal energy) and the solvent (solvation energy).

In aqueous solution, ionizable compounds may be present as various charged species depending on the  $pK_a$  values of the respective ionizable groups and the pH of the solution. Solubility of the uncharged species is defined as the intrinsic solubility  $S_0$ . The effective solubility ( $S_{\text{tot}}$ ), at a particular pH, is the sum of the concentrations of all the compound species dissolved in the aqueous medium.<sup>2</sup> The pH-dependent solubility is usually calculated using Henderson–Hasselbalch-type equations, such as the following that gives the solubility–pH profile for monoprotic acids in a saturated solution of the uncharged species:

$$pK_a = \text{pH} - \log[(S_{\text{tot}} - S_0)/S_0] \quad [2]$$

The pH change is expected to raise the solubility according to eqn [2] with increasing concentration of the ionized species, until at some pH value the solubility product of the salt will be reached and the salt will precipitate. As a rule of thumb, the solubility plateau is assumed to be reached at a log  $S$  level 3–4 log units above log  $S_0$ .<sup>2</sup> The specific response of a compound to counter-ion effects may cause large deviations from the expected pH–solubility profile. Bergström *et al.*<sup>6</sup> found that both the solubility range and the slope for the change of solubility with pH varied by several log units for basic drugs in divalent buffer systems.

### 5.26.1.3 Kinetic and Thermodynamic Aspects of Solubility

Solubility is an equilibrium property. In practical situations, the equilibrium may not be attained, and the kinetically controlled apparent solubility may differ considerably from the equilibrium thermodynamic solubility. A slow dissolution rate may result in low apparent solubility, especially for sparingly soluble solids, because the dissolution rate depends on the equilibrium solubility.<sup>5</sup> The apparent solubility may exceed the thermodynamic solubility, if it is kinetically controlled by slow formation of the most stable crystal form. This may be the case if a solute is added to water in an organic solvent. High apparent solubility may be useful in the early discovery phase, allowing very insoluble compounds to be tested for efficient characterization of structure–activity relationships.<sup>4</sup> However, the thermodynamic aqueous solubility is the most important solubility measure for evaluation of a molecule as a drug candidate.

Thermodynamically, the transfer of solid solute to the solvent can be thought of as occurring by fluidization of the solid and mixing of the supercooled liquid solute with the solvent. The free energy changes of the processes govern solubility. The mole fraction solubility of solute B in solvent S ( $x_S^B$ ) is given by

$$\ln x_S^B = (1/RT)\Delta G_{\text{fus}}^B - \ln \gamma_S^B \quad [3]$$

where  $\Delta G_{\text{fus}}^B$  is the free energy of fusion and  $\gamma_S^B$  is the activity coefficient accounting for liquid state interactions.

Approximate expressions based on thermodynamic considerations have been derived to allow the estimation of solubility from accessible experimental quantities. The  $\Delta G_{\text{fus}}$  term can be approximated from the entropy of fusion ( $\Delta S_{\text{fus}}$ ) and the absolute melting point ( $T_m$ ) as

$$\ln x_S^B = -(\Delta S_{\text{fus}}/RT)(T_m - T) - \ln \gamma^B \quad [4]$$

where  $R$  is the gas constant and  $T$  is the temperature of the solution.

Assuming a constant value for the entropy of fusion, the effect of fluidization can be estimated from the melting point alone. This approximation was first used by Irmann<sup>7</sup> in his fragmental model for aqueous solubility of hydrocarbons and

**Table 1** Expression for the terms of the MOD solubility model<sup>11,12</sup>:  $\ln \Phi_B = A + B + D + F + O + OH$ 

| Term      | Expression   |
|-----------|--|
| <i>A</i>  | $-0.02278(T_m - 298.15)$ or $-\Delta H_{fus}/R(1/T - 1/T_m)$                               |
| <i>B</i>  | $0.5\Phi_S(V_B/V_S - 1) + 0.5 \ln(\Phi_B + \Phi_S^2 V_B/V_S)$                              |
| <i>D</i>  | $-[1.0 + \max(K_{O_i}, K_{OH_i})\Phi_S/V_S]^{-1}\Phi_S^2 V_B/RT(\delta_B' - \delta_S')$    |
| <i>F</i>  | $-r_s\Phi_S V_B/V_S + \sum v_{OH_i}\Phi_S(r_s + b_i)$                                      |
| <i>O</i>  | $\sum v_{O_i} \ln[1 + K_{O_i}(\Phi_S/V_S - v_{O_i}\Phi_B/V_B)]$                            |
| <i>OH</i> | $\sum v_{OH_i} [\ln(1 + K_{OH_i}\Phi_S/V_S + K_{BB_i}\Phi_B/V_B) - \ln(1 + K_{BB_i}/V_B)]$ |

$\Phi$ , volume fraction solubility;  $T_m$ , melting point;  $V$ , molar volume,  $\delta'$ , modified nonspecific cohesion parameter;  $K_{O_i}$ ,  $K_{OH_i}$ , association constants for hydrogen bonding between the solvent and proton acceptor and donor sites of the solute, respectively;  $r_s$ , structure factor of the solvent;  $v_{O_i}$ ,  $v_{OH_i}$ , number of active proton acceptor or donor groups of type  $i$  on the solute;  $b_i$ , constant accounting for the type of hydroxyl group;  $K_{BB_i}$ , stability constant for solute self-association.

halogenated hydrocarbons. Hansch *et al.*<sup>8</sup> found that the aqueous solubility of liquids (and  $\gamma$ ) was correlated with the octanol/water partition coefficient  $\log P$ . Yalkowsky and co-workers<sup>9,10</sup> then derived a model for the prediction of the aqueous solubility from the melting point and  $\log P$ :

$$\log S_w = 0.5 - 0.01(\text{mp} - 25) - \log P \quad [5]$$

where  $S_w$  is the molar solubility in water and mp is the Celsius melting point. The term (mp - 25) is equal to zero for solutes that are liquid below 25 °C. The following approximations were used in the derivation of the model: the entropy of fusion was approximated by  $\Delta S_{fus} = 56.5 \text{ J K}^{-1} \text{ mol}^{-1}$  according to Walden's rule for rigid aromatic compounds; approximation of the partition coefficient by the solubility ratio  $P = S_{oct}/S_w$  gave the relationship  $\log S_w = \log S_{oct} - \log P$  for the aqueous solubility of a liquid solute; and assuming complete miscibility of organic solutes in octanol gave a constant value of 0.5 for  $\log S_{oct}$ .

Ruelle and co-workers<sup>11,12</sup> developed a model that presents a more involved treatment of the solution phase effects. The general form of the model for the volume fraction solubility of solute B in solvent S is given by

$$\ln \Phi_S^B = A + B + D + F + O + OH \quad [6]$$

where  $A$  represents the effects of crystallinity, and the other terms account for the various solute–solvent interactions (entropy of mixing, nonspecific cohesion forces, hydrophobic effect, and interactions of hydrogen bond acceptor and donor sites, respectively) that contribute to the activity coefficient. The  $A$  term can be estimated by Yalkowsky's approximation. For evaluation of the other terms, Ruelle and co-workers derived approximate expressions based on the mobile order and disorder (MOD) thermodynamics (Table 1).

The Yalkowsky and Ruelle models were derived by thermodynamics-based approximations of the terms of eqn [3], and contain no coefficients obtained by fitting experimental solubilities. Both models have been shown to give reasonable predictions, but since experimental parameters are required, they cannot be considered in silico tools. However, the models contribute to the theoretical background useful for hypothesis design in quantitative structure–property relationship (QSPR) model development.

#### 5.26.1.4 Causes of Errors in the Literature

A limit to the accuracy of in silico methods is set by the accuracy of the experimental solubility data. Several types of error may contribute to the uncertainty of solubility values. Pure experimental error is caused by, essentially, random variation in experimental variables (purity of compounds, experimental protocols, analytical methods, etc.). A study of the AstraZeneca in-house database showed an average standard deviation 0.49 log units for repeated measurements on different batches of the same compounds.<sup>13</sup> Katrizky *et al.* calculated an average standard deviation of 0.58 for solubility data from different references.<sup>14</sup> Occasionally, the solubility values reported for one compound may differ by 2–3 log units; this large difference may originate from different experimental protocols, and may reflect the effects of kinetic

control or ionization. In the case of sparingly soluble compounds, slow kinetics may result in values that do not represent thermodynamic solubility, because the system studied was far from equilibrium. The aqueous solubility of ionizable compounds is often measured at pH 7 or in unbuffered water. Inconsistent data sets may be compiled, if the effect of ionization is not taken into account. If solubility is determined in unbuffered water, the pH of the aqueous solution depends both on the  $pK_a$  of the solute and on the total concentration of the solute, and hence its solubility. The error caused by ionization then depends on solubility, and may be negligible for highly soluble acids or bases, but 1 or 2 log unit for sparingly soluble compounds.<sup>15</sup>

## 5.26.2 Relevance and Applicability of In Silico Tools

### 5.26.2.1 When Do We Use an In Silico Model?

There are situations when it is desirable to use an in silico model. One such instance is when there is a need to understand the underlying properties involved in governing the level of solubility. From the derived model it is possible to gain insight into which properties are particularly important and how these properties influence solubility (e.g., whether an increase in a molecular property will promote or impair solubility). Another situation when it is desirable to use an in silico model is for predictive purposes. In this case, the solubilities of a (possibly large) number of (virtual) compounds are to be estimated. Two scenarios are possible: the first is relevant for a small number of compounds for which the solubilities are to be predicted, while the other concerns the opposite situation where a large number of predictions are to be performed. In the former case, perhaps as part of a research project in the lead optimization phase, a more local single model based on physicochemical parameters that are easy to interpret (e.g.,  $\log P$  and hydrogen-bonding properties) is probably the preferred choice. Such a model more directly answers questions such as “Which is the next molecule to make?” in order to improve or maintain the solubility for a particular series of compounds. For the latter scenario (i.e., predictions for large sets of virtual compounds), robustness and speed of prediction are more important than interpretability of the model. Robustness may be increased by consensus or ensemble modeling, where several models, possibly using different statistical techniques and/or descriptors, are used. The reason for focusing on robustness is that subsequent to the predictions of a large set of compounds there is usually a selection procedure where only a small portion of the compounds will be identified for further work (e.g., synthesis or testing). The project team does not want to find out after further work has been performed on this selected subset that too many of these compounds are poorly soluble; solubility prediction will help prevent this scenario.

In silico models can also be utilized in intellectual property situations to either avoid the intrusion of existing patents and still develop compounds with desirable properties or make more educated decisions on how to meet the claims of a particular patent.

As with all other modeling activities, the scope and limits (i.e., the applicability domain) of the derived model in question should be identified to the users of the model (see Section 5.26.2.3).

### 5.26.2.2 Statistical Methods and Their Meaning

The practical methods for in silico prediction of solubility are not thermodynamic or other theoretical models; rather, they are empirical models obtained by statistical fitting of a mathematical model to experimental solubility data. This type of approach is termed QSPR modeling. A QSPR model for solubility typically has the form

$$\log S = f(x_i) \quad [7]$$

where the logarithm of the molar solubility  $S$  is a function of structural variables  $x_i$  calculated for each compound from the molecular structure. The structural variables may be whole-molecule properties (e.g., molecular weight), or topological, geometric, or electronic descriptors calculated from the two- or three-dimensional structure. The function may be a simple polynomial or a complex model such as a neural network (NN). The optimal model is found by fitting candidate models using a regression method. Multiple linear regression (MLR), partial least-squares regression (PLS), or NN regression are the methods used for fitting in most solubility modeling studies.

Development of a QSPR model involves four key issues: (1) selection of a set of compounds with known chemical structure and measured solubility (the training set); (2) selection of the models to be tested and the calculation descriptors; (3) fitting the model to the data with the regression method; and (4) validation of the prediction ability of the model with test sets.

There are a number of statistical terms with which to judge the quality of a derived in silico model:

- The squared correlation coefficient of the training set ( $r^2$ ) is a measure of the variability explained by, or due to regression, and assumes a value between 0 and 1, where values closer to 0 indicate a random model.
- The squared correlation coefficient of the test set ( $q^2$ ) is an estimate of the predictive capability of the derived model. It is either calculated by cross-validation within the training set or on the external test set.  $q^2$  is similar to  $r^2$  but can for poor models assume negative values.
- The average error (AE) and the average absolute error (AAE) are two additional ways to measure the quality of a model. While AE can assume both positive and negative values, AAE can only assume positive numbers, and a value close to 0 for the test set indicates a good predictive capability for the derived model. Also, since positive and negative errors may cancel out in AE and result in an overestimation of the quality of the derived model, a large discrepancy between AE and AAE indicates some systematic error in the model.
- The root mean squared error (RMSE) is a measure of the total error defined as the square root of the mean of the squared sum of errors,

$$\sqrt{\sum (y_{i,\text{measured}} - y_{\text{predicted}})^2 / n} \quad [8]$$

where  $n$  is the number of observations.

- The standard deviation ( $s$ ) is a measure of the degree of dispersion of the data from the mean value and the term is defined as

$$\sqrt{\sum (y_i - y_{\text{mean}})^2 / (n - 1)} \quad [9]$$

Furthermore, validation of the derived model is essential in order to determine its predictive capability on an external test set.

Thorough model validation is an instrumental part of the successful development of any statistical model. Without proper validation the predictive ability of the derived model cannot be estimated. Likewise, the derived model may equally well be nothing more than a random model. Techniques that should be employed to ensure proper validation will now be discussed.

Cross-validation is one method for the internal validation of a proposed model. In cross-validation the training set is divided into groups, usually 4–7, and one group is removed from the set. The model is then derived using the rest of the training set. The developed model then predicts the solubilities of the compounds of the left-out group. Each group is successively left out and predicted in the same manner as just described. The predicted residual error sum of squares (PRESS) is computed from all the predictions. The PRESS value is then compared with the sums of squares for the solubility dependent variable  $y$  (SSY):

$$\sum (y_{i,\text{measured}} - y_{\text{mean}})^2 \quad [10]$$

The squared correlation coefficient  $q^2$  is then defined as

$$q^2 = 1 - \text{PRESS}/\text{SSY} \quad [11]$$

$q^2$  should be  $>0.5$  for the model to be considered to have reasonable practical predictive performance.

An external validation set should be used as an independent test of the predictive ability of a derived model.

Randomization of solubility values is another technique used to validate a model. Here, the values are randomly redistributed among the compounds. A model is then derived based on the redistributed values, and checked for its predictive performance using cross-validation as well as external validation. This procedure is repeated a number of times, typically between 50 and 100. There should exist a clear separation in predictive ability between the model based on the 'true' dependent values compared with models based on redistributed values.

The problem of overfitting may not be revealed by the standard statistical tests. Overfitting means using a model that is more flexible than needed, or includes irrelevant components.<sup>16</sup> Decisions about overfitting need comparison. A model is overfitting if its predictions are not better than those of another, simpler, model.

### 5.26.2.3 Applicability Domain

Another important issue, far too little discussed, is the applicability domain for a particular in silico model. All models in use should have some way of describing the descriptor space in which they operate. This is especially important for models that are mounted and accessed through inter- and intranet web services. It is very important that the users of such models receive feedback in terms of a clear indication if the prediction made by the model is to be regarded as an interpolation or extrapolation to the model. If a derived statistical model is to be regarded as poor from a predictive point of view, this should be done based on valid reasons, namely that the model truly has poor predictive ability and not because the model cannot estimate outliers to the model with acceptable accuracy. In many cases it is difficult, if not impossible, to find out about the compounds used as training set and/or the chemical description used in the model. Thus, many compounds outside the applicability domain of the model will be submitted. The outlier information, and possibly also how far from the model the compound in question is, may in many cases be utilized in a more proactive way than just realizing that a number of compounds submitted to the model for prediction are, in fact, outliers to the present model. Thus, by analyzing the outliers, perhaps virtual compounds, from various points of views (e.g., structural or synthetic), some of these compounds may later be synthesized and tested experimentally. The same compounds may then be incorporated into a revised model that will have a broader applicability domain.

There are different methods for determining whether a particular compound is to be labeled as an outlier or not. Two such measures are the Mahalanobis distance<sup>17</sup> and the residual standard deviation (RSD),<sup>18</sup> that is, the remaining amount of information present in the variables used to describe the compound that has not been utilized by the model. Recently, Sheridan *et al.* investigated different measures that could serve as good discriminators for prediction accuracy in statistical models.<sup>19</sup> They suggested, based on retrospective analysis of QSAR investigations, that the similarity of a molecule to be predicted to the nearest molecule in the training set and/or the number of neighbors in the training set are two good measures for this purpose. Another useful approach using a combination of the convex hull method and uncertainty estimation has been proposed by Fernandez Pierna *et al.*<sup>20</sup> as a practical way for detecting outliers in prediction.

## 5.26.3 In Silico Methods for the Prediction of Aqueous Solubility

Since the turn of the millenium, about half a dozen new QSPR methods have been published yearly for the in silico prediction of aqueous solubility. The published methods represent greatly varying approaches as to the selection of the experimental database, description of chemical structures, model selection and fitting, and validation of the prediction power. In the following discussion the methods are grouped together based on the type of structure representation, and representative examples provided. Most of the methods published since 2000, and selected earlier methods, are summarized in [Table 2](#).

### 5.26.3.1 Data Sets

The original results of experimental solubility measurements are dispersed in the scientific literature or stored in the confidential files of private companies. The data set for solubility modeling may be collected from the original sources, but more often it is obtained from secondary sources, such as reference books, commercial databases, or published compilations of earlier modelers. Models from private companies are usually based on public data combined with proprietary data from one company. Only in exceptional cases has the research group developing a solubility model any control over solubility measurements.

At present, two commercially available databases are the prime sources of published solubilities. The AQUASOL database of the University of Arizona<sup>71</sup> contains almost 20 000 solubility records for almost 6000 compounds extracted from over 1800 references, and the database is updated continuously. The PHYSPROP database of the Syracuse Research Corporation<sup>72</sup> contains more than 6300 experimental solubility records.

Certain smaller published compilations extracted from the large databases or from original literature have been repeatedly used in solubility modeling or used as data sources for new compilations. Huuskonen<sup>21</sup> extracted from the AQUASOL and PHYSPROP databases a set of 1297 compounds representing diverse structures. The data set of Mitchell and Jurs<sup>22</sup> ( $n = 332$ ) was extracted from AQUASOL, and that of Abraham and Le<sup>15</sup> ( $n = 664$ ) was collected from various literature sources. All these compilations are of a general type, containing many small and liquid compounds, several homolog or analog series of simple compounds, and some drugs.

Several small data sets containing a major proportion of druglike compounds have also been compiled and published. Huuskonen *et al.*<sup>23</sup> collected from literature data 211 druglike compounds. Jorgensen and Duffy<sup>24</sup> used this data and

the compilations of Jurs and Abraham to construct a data set of 150 compounds where one-half of the structures could be considered druglike. Venkatesh and co-workers<sup>25</sup> compiled data for 321 druglike compounds from the Analytical Profile of Drug Substances, the Merck Index, and original literature. Only intrinsic thermodynamic solubilities for solid druglike compounds at or around 25 °C were accepted. McFarland *et al.*<sup>26</sup> used intrinsic thermodynamic solubilities measured in-house for 22 drugs. Bergström *et al.*<sup>27</sup> compiled in-house solubility data with other data of confirmed quality. Intrinsic thermodynamic solubilities with known accuracy were obtained for 85 druglike compounds. A majority of the compounds were bases and a minority was nonproteolytes, a distribution in accordance to that of registered drugs. Principal component analysis (PCA) showed that the compounds evenly covered a large volume of the druglike space (Figure 1a). The authors compiled an external test set of 207 druglike compounds from the sets of Huuskonen *et al.* and the set of Jorgensen and Duffy. PCA showed that these compounds were clustered in one quarter of the PCA plot defined by their set of 85 compounds (Figure 1b).

**Figure 1** Score plots of the PCA (first two principal components) performed on all calculated, nonskewed descriptors for two druglike compound sets: (a) the set of Bergström *et al.*<sup>27</sup>; (b) the set compiled from Huuskonen *et al.*<sup>23</sup> and Jorgensen and Duffy.<sup>24</sup> (Reprinted with permission from Bergström, C. A. S.; Wassvik, C. M.; Norinder, U.; Luthman, K.; Artursson, P. J. *Chem. Inf. Comput. Sci.* **2004**, *44*, 1477–1488 © American Chemical Society.)

The origins of the data sets used for model building are given in [Table 2](#). In most cases, inadequate documentation makes it difficult to assess whether a data set represents consistent values regarding thermodynamic equilibrium or ionization. This problem is common to data sets compiled from public sources and from proprietary sources. Most models are probably intended to predict the intrinsic solubility, although this may not be explicitly stated. Whenever the authors specify ionization (pH of measurement or intrinsic solubility), the information is given in [Table 2](#).

Another concern regarding a data set compiled for model building is the distribution of the compounds in the chemical structure space. Although skewness of the data set affects the applicability domain and accuracy of a model, systematic analysis of the distribution of the compounds in the structure space was reported only for one of the data sets listed in [Table 2](#).

### 5.26.3.2 Fragmental Methods

Fragmental methods, also called atom or group contribution methods, are based on the idea that structural fragments have a constant contribution to solubility. A large number of fragments and correction factors usually have to be defined

for modeling a diverse set of complex structures. A typical equation for calculating the aqueous solubility in a fragmental model is

$$\log S_w = a_0 + \sum a_i n_i + \sum b_j m_j \quad [12]$$

where  $a_i$  and  $b_j$  are the contribution coefficients of the  $i$ th group or atom type, and the  $j$ th correction factor, respectively, and  $n_i$  and  $m_j$  are the frequencies of occurrence of the respective fragments or corrections in a molecule. The contribution coefficients are determined by MLR or another regression technique.

The first pure group contribution model for solubility prediction, without additional experimental parameters, was published by Klopman *et al.*<sup>28</sup> The model was based on 52 basic organic atom and functional groups. The model has been refined by defining 118 group parameters.<sup>29</sup> Even more extensive fragmentation schemes have been presented recently. For instance, the atom type classification scheme of Sun<sup>30</sup> defines 234 atom types and correction factors, including 88 types of carbon atom and 55 types of nitrogen atom.

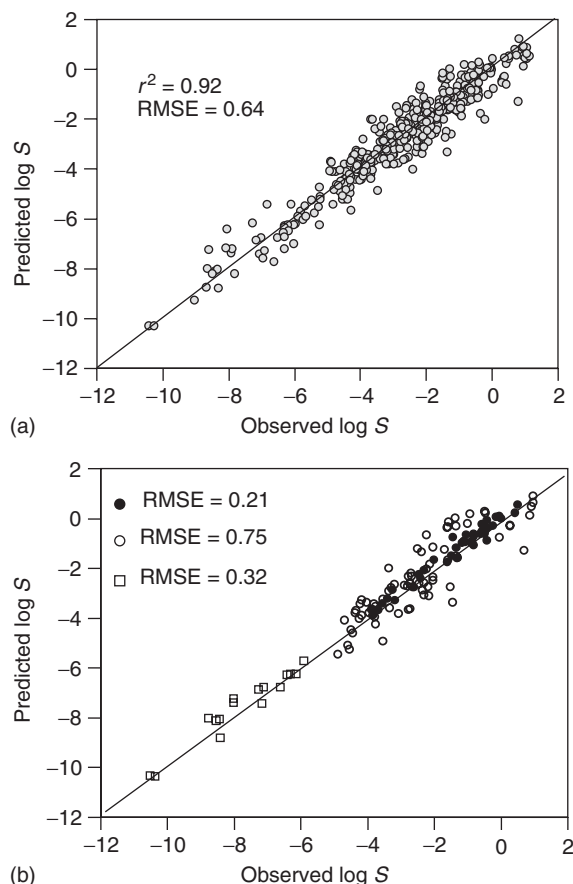

The fragmental method of Clark<sup>31</sup> represents a new approach for decomposing molecules into a series of overlapping fragments, instead of conventionally used discrete fragments. Two classes of fragments were used, one representing basic chemical functionalities, the other representing larger biorelevant fragments. The overlapping substructures were planned to provide more variation than counting discrete fragments, and to allow distinction, for instance, between positional isomers. A large data set of 2427 compounds was extracted from the PHYSPROP database, excluding compounds with extreme  $\log S$  or  $\log P$  values. The data set represents the  $\log S$  range of  $-8.8$  to  $1.2$ , and solubility values measured between  $20$  and  $30^\circ\text{C}$ . The author does not discuss the basis for selection of the solubility values for ionizable compounds.

A predictive PLS model was built using 257 fragments, giving  $r^2 = 0.73$  and an RMSE of  $1.01$  for the training set. The fragments with highest positive impact on solubility were found to be pyridine,  $\text{S}=\text{O}(=\text{O})$ , acetone, amine, and ROH, while highest negative effects were due to naphthalene, bromine, iodine, and sulfur. Correlation of the experimental and calculated  $\log S$  values is shown in Figure 2. The data set represents high structural diversity, and there are a number of compounds with large fitting errors ( $>3$  log units). In fact, the  $r^2$  value for the  $\log S$  range of typical drugs ( $-2$  to  $-6$ ) is not higher than  $0.42$ . The predictive power was validated with an internal test set of 230 compounds and with the set of Huuskonen ( $n = 1297$ ), giving rms errors of  $1.1$  and  $0.82$  log units, respectively. Interestingly, the larger set of Huuskonen was predicted with better accuracy.

The modeling approach using the atom type  $E$ -state indices of Hall and Kier<sup>32</sup> can be considered as a special case of the atom contribution approach. The first solubility model of this type was developed by Huuskonen *et al.*,<sup>23</sup> using a small set of druglike compounds to train a predictive NN. Subsequently, Huuskonen used the same approach, with a larger data set of a general type.<sup>21</sup> Aqueous solubilities at  $20$ – $25^\circ\text{C}$  were extracted from the AQUASOL and PHYSPROP databases for 1297 compounds, representing diverse structures including some drugs ( $15$ – $20\%$ ), but also a large number of simple compounds, such as unsubstituted hydrocarbons or halogenated hydrocarbons. The criteria for selecting solubility values for ionizable compounds were not stated. The  $\log S$  values ranged from  $-11.62$  to  $+1.58$ . The whole data set was used to build NN models, one part as the training set ( $884$  compounds), the other part ( $413$  compounds) as the test set for controlling the training endpoint. The final network, with a  $30$ - $12$ - $1$  architecture,

**Figure 2** Correlation between the observed  $\log S$  and the  $\log S$  predicted by the fragmental model of Clark<sup>31</sup> for the training set.

**Figure 3** (a) Correlation between the observed log *S* and log *S* predicted by Huuskonen's model<sup>21</sup> for the test set. (b) Correlation plot for three subgroups of the test set. ●, aliphatic hydrocarbons and monofunctional oxygen compounds; □, polychlorinated biphenyls; ○, nitrogen heterocycles.

contained 24 atom type *E*-state indices and six other topological descriptors as input variables. The model was trained to best prediction accuracy for the internal test set corresponding to rms errors of 0.47 and 0.60 for the training and test sets, respectively. The low error values are probably related to the flexibility of the nonlinear model with 385 adjustable weights, and may give an overoptimistic view about the generalization ability of the model regarding druglike compounds. Correlation of the predicted and observed solubilities for the test set are shown in Figure 3. Figure 3b shows that the prediction accuracy varies depending on compound type. Very small errors were found for simple compounds, such as the aliphatic cluster (RMSE of 0.21), whereas a more diverse group of nitrogen heterocycles gave an RMSE of 0.75.

The Huuskonen model contains a considerably smaller number of atom types than conventional atom/group contribution models, such as the Sun model, which was based on the same data set. It is usually assumed that the atom type *E*-state indices contain more relevant information than mere counting of atom types. However, it has been reported that comparable prediction ability can be obtained using counts of the corresponding atom types instead of *E*-state indices.<sup>33</sup>

The modeling approach of Huuskonen or his data set has been used to develop several other solubility models, including commercial programs and free Internet methods.<sup>30,34–44</sup> It has been pointed out that the data set is limited in structural diversity, resulting in models that may give disappointing predictions, when challenged with an external test set.<sup>41,43</sup>

### 5.26.3.3 Property-Based Methods

In property-based models, the molecular structures of the solutes are represented by physicochemical parameters or molecular descriptors calculated from two- or three-dimensional molecular structures. Selection of the model variables

may be hypothesis based or computer assisted, or may combine these two approaches. Hypothesis-based modeling typically means that a small number of presumably relevant descriptors are selected for statistical testing. The resulting models are typically straightforward to interpret in terms of medicinal chemistry. The computer-assisted model building typically means calculation of hundreds of descriptors, and the selection of the best descriptor combination and model form from a large number of possibilities. Various computational methods, such as genetic algorithms or entropic based descriptor selection, are used to make the process more efficient. The approach may lead to models that are rather obscure. It is common that a property-based solubility model includes a few terms representing indicators or counts of atom types or functional groups. Some recent models based on large and diverse data sets can be considered to be hybrids of property-based and fragmental models.

#### 5.26.3.3.1 Models based on solvation properties

A group of hypothesis-based solubility models is related to Ruelle's MOD model in that interest is focused on the solvation process. The linear solvation energy relationship model, originally presented by Taft and Kamlet and their co-workers,<sup>45,46</sup> gives an empirical relationship between a solvation-dependent property and five experimental parameters related to solute-solvent interactions. The equation derived by Abraham and Le for aqueous solubility includes an additional hydrogen-bonding cross-term:

$$\log S = 0.52 - 1.00R_2 + 0.77\pi_2^H + 2.17 \sum \alpha_2^H + 4.24 \sum \beta_2^H - 3.3.6 \sum \alpha_2^H \sum \beta_2^H - 3.99V_x \quad [13]$$

$$n = 659, \quad r^2 = 0.92, \quad s = 0.56, \quad F = 1256$$

where  $R_2$ ,  $\pi_2^H$ ,  $\alpha_2^H$ ,  $\sum \beta_2^H$ , and  $V_x$  are the excess molar refraction, the dipolarity/polarizability, the hydrogen bond acidity, the hydrogen bond basicity, and McGowan's characteristic molecular volume, respectively.<sup>15</sup> The equation is based on solubility data for 664 compounds compiled from various literature sources, representing the  $\log S$  range from  $-9$  to  $+2$ . The compound set contained a large proportion of liquids, several homolog series of simple organic compounds, and some druglike compounds. Five compounds (cyclopropyl-5-spirobarbituric acid, uracil, chlorpheniramine, fentanyl, and adenine) were found to be outliers. The correlation between observed and predicted solubilities is shown in Figure 4.

Abraham and Le suggest that the cross-term accounts for solid state effects. However, the model still predicts systematically too high solubility for high-melting-point compounds, resulting in an average absolute error of  $-0.85 \log$  units for the subset of 39 compounds with  $mp > 200^\circ\text{C}$ .

The model aims to predict intrinsic solubility, although the experimental solubilities for ionizable compounds correspond to values observed at the pH of the saturated solution. The effect of ionization is discussed thoroughly by the authors, and is concluded to have a minor contribution to the prediction error.

**Figure 4** Correlation between the observed  $\log S$  and the  $\log S$  predicted by the solvation model of Abraham and Le<sup>15</sup> for the combined training and test sets. Outliers to the model: a, adenine; b, cyclopropyl-5-spirobarbituric acid; c, uracil; d, fentanyl; e, chlorpheniramine.

The descriptor values used to obtain eqn [13] stem from experimental parameters. However, a method for calculation of the solvation descriptors from the molecular structure has been published,<sup>47</sup> and a commercial in silico model, Absolv (see Table 4), has been developed based on Abraham's model.

Jorgensen and Duffy<sup>48</sup> tackled the solvation problem by running Monte Carlo simulation for the solute in water using a small data set of 150 compounds appropriate for the computational approach. Eleven descriptors related to solute–water interaction energies, surface areas, and hydrogen bonding were calculated for the solutes. A five-term predictive MLR model was derived, including four Monte Carlo descriptors and two functional group counts. The calculations, however, take too much time to be practical for predicting larger sets of compounds. The authors subsequently developed algorithms for the rapid estimation of the descriptors from a three-dimensional molecular structure, leading to a more practical method, which has been incorporated in the commercial QikProp program.<sup>49</sup>

#### 5.26.3.3.2 Models based on log *P*

Since the early work of Hansch *et al.*<sup>8</sup> it has been known that the aqueous solubility of liquids is strongly correlated with the octanol/water partition coefficient log *P*, which is also a message of Yalkowsky's model. The solubility of the compounds compiled by Abraham and Le, or Jorgensen and Duffy, is also remarkably well explained by ClogP alone ( $r^2 = 0.78$  and  $0.70$ , respectively). This is true for several other data sets containing a large proportion of liquids and relatively small and simple compounds. Lobell and Sivarajah<sup>50</sup> even found high correlation ( $r^2 = 0.71$ ) between aqueous solubility and calculated log *P* values for 442 druglike compounds that are predominantly uncharged at pH 7.

A group of solubility models is based on the hypothesis that log *P* is the key descriptor, and a few other physically meaningful properties can be found to account for the solid phase effects and inadequacies of log *P*. Typically, a small number of other preselected two-dimensional descriptors has been tested along with log *P*. A representative example, explicitly using Yalkowsky's model as the starting point, is the ESOL model of Delaney.<sup>51</sup>

The initial parameter set of the ESOL model included nine descriptors: calculated log *P* (ClogP), molecular weight (MW), the number of rotatable bonds (RB), the proportion of heavy atoms in a molecule that are located in aromatic rings (aromatic proportion), the noncarbon proportion, the hydrogen bond donor count, the hydrogen bond acceptor count, and the polar surface area. In addition to ClogP, only three parameters were found significant in the MLR analysis of a large training set, leading to the ESOL model:

$$\log S_w = 0.16 - 0.63\text{ClogP} - 0.0062\text{MW} + 0.066\text{RB} - 0.74\text{AP} \quad [14]$$

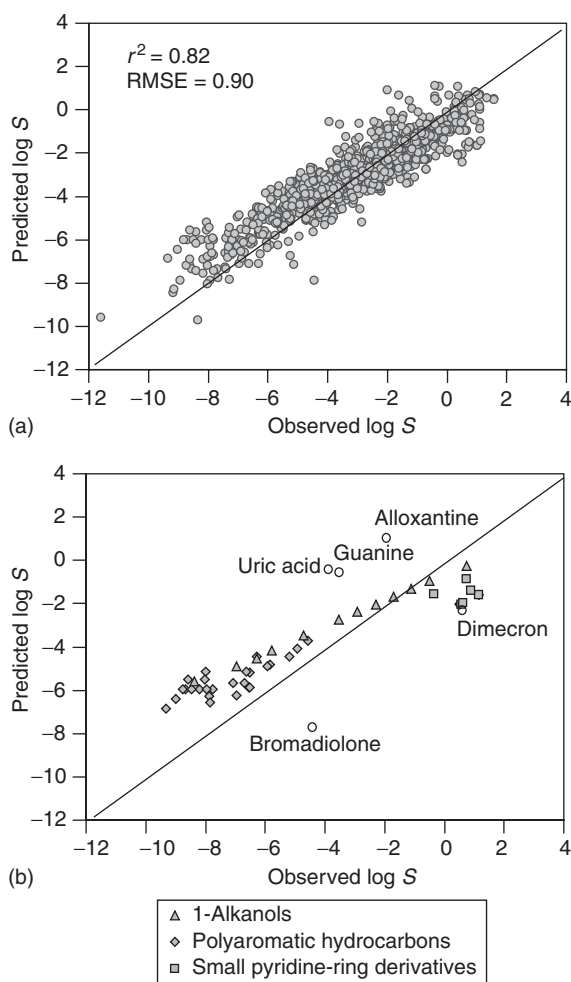

$$n = 2874, \quad r^2 = 0.72, \quad s = 0.97, \quad F = 1865$$

The training data originated from three sources: one subset consisted of 1144 general organic compounds from the literature with a log *S* range of  $-11.6$  to  $+1.6$  and an average MW of 205, the second subset consisted of 485 pesticide products (average MW = 294), and the third subset consisted of 1245 compounds from the Syngenta proprietary database (average MW = 341). The criterion for selecting values for ionizable compounds was not given. Correlation of the calculated and observed solubilities for the first subset is shown in Figure 5. The model was validated using an independent test set of 528 proprietary compounds, a small set ( $n = 21$ ) designed by Yalkowsky and the set of Jorgensen and Duffy ( $n = 150$ ).<sup>24,52</sup> The average absolute errors for the three sets were 0.96, 0.69, and 0.71. The RMSE for prediction of the proprietary test set was 0.96.

The correlation plot in Figure 5 shows some points with large deviations. None of these represent druglike compounds. Besides a few individual outliers, there are also classes of compounds with large systematic errors. For instance, small pyridine derivatives are predicted too insoluble (AE =  $+2.3$ ) and polyaromatic hydrocarbons too soluble (AE =  $-1.7$ ), while the error for 1-alkanols changes with the chain length from  $+1$  to  $-2.8$ . Obviously, this type of error could be minimized by adding correction terms to the model.

The ESOL model contains only two more parameters than Yalkowsky's model. Delaney compared the performance of the two models for 1305 training set compounds with measured melting points, and found AAE = 0.75 and 0.81 for the ESOL and Yalkowsky models, respectively. It was concluded that the non-log *P* terms of the ESOL model probably provide an enhanced estimate of  $\Delta S_{\text{fus}}$  and  $T_m$ .

Other researchers have combined heuristic and computer-assisted approaches to find a few physically meaningful descriptors in addition to calculated log *P*. The MLR model of Cheng and Merz involves six additional descriptors and a hydrogen-bonding cross-term.<sup>53</sup> Liu and Sho developed a 7-2-1 NN with log *P* and six other descriptors.<sup>42</sup> The log *P*-based models seem to have a consensus about the molecular size and flexibility/rigidity being important complementing

**Figure 5** (a) Correlation between the observed log  $S$  and log  $S$  predicted by Delaney's ESOL model<sup>51</sup> for a training subset. (b) Predicted versus observed log  $S$  for five compounds showing the largest fitting errors and three compound groups with large systematic errors.

properties, but the role of hydrogen-bonding descriptors is less clear. Three hydrogen-bonding related terms are presented in the model of Cheng and Merz, while no such term was found significant in the work of Delaney, based on a much larger training set.

The example of Jorgensen's model and the analysis of Delaney's data show that the fit of simple property-based models can be easily improved by adding functional group-specific correction terms to the model. Meylan and co-workers used 15 group indicators besides the molecular weight as additional descriptors in their log  $P$ -based solubility model.<sup>54,55</sup>

Another approach is to include log  $P$  in a large descriptors set, which may comprise two- and three-dimensional structure-dependent properties, topological indices, and various counts typical for fragmental methods. Although no hypothesis about the model is made, the computer-assisted model building typically finds log  $P$  as the most important descriptor. Depending on the data set and the procedure used, the resulting model may resemble a hypothesis-based model with a rather small number of parameters,<sup>13,27,40,56</sup> or resemble a hybrid of property-based and fragmental models.<sup>41,57–59</sup> Examples of the last type are the models of Butina and Gola<sup>58</sup> and of Engkvist and Wrede.<sup>41</sup> Both used a large data set extracted from the PHYSPROP database for more than 3300 structurally diverse compounds. The strategy of Butina and Gola was to combine the calculated log  $P$  with a two-dimensional descriptor set comprising various counts including atom-based fragments, functional groups, and hydrogen bond donors and acceptors. The best results were obtained with a Cubist model that consisted of separate MLR equations for four rule-based subsets. The equations included ClogP and a maximum of 35 other descriptors – 52 descriptors in total. Engkvist and Wrede

developed an NN model with 63-5-1 architecture involving 320 adjusted weights. The 63 descriptors included atom, bond, and ring type counts, and various topological indices, in addition to  $\log P$ .

A few studies compared the power of two- and three-dimensional dependent descriptors in combination with  $\log P$ . It was found that a combination  $\log P$  with two-dimensional descriptors gave a better model than a combination with three-dimensional descriptors,<sup>27,56</sup> or including of three-dimensional descriptors in a model did not lead to significant improvement.<sup>53</sup>

#### 5.26.3.3.3 Other property-based models

One group of solubility models are built without any preselected descriptors or hypotheses about the relationship between structure and solubility, by using computer-assisted selection of an optimal combination of variables from a large pool of calculated descriptors. Hundreds of topological, geometric, electronic, and combination descriptors may be calculated from two- and three-dimensional structures. Semiempirical quantum chemical methods are frequently used for these kinds of computation. A key problem is the effective selection of the best descriptor combination. The work of McElroy and Jurs<sup>60</sup> is a representative example of this approach. They compiled, from the literature, a solubility data set of 399 compounds containing at least one oxygen or nitrogen atom with a molecular weight range of 53–959. Solubility values ranged from  $-7.41$  to  $+0.96$  log units. The three-dimensional structures were optimized, and charge distributions calculated using semiempirical quantum chemical PM3 and AM1 methods. For each compound, 229 descriptors were calculated, including topological, geometric, and electronic descriptors, and combinations of these descriptors. Descriptors with little or redundant information were removed, leaving a reduced pool of 98 descriptors. Two NN models were developed using different procedures to select an optimal subset of descriptors. A feature selection routine based on generalized simulated annealing and MLR resulted in a set of 11 descriptors. The other procedure was fully nonlinear, using genetic algorithm and NN fitness evaluation to select the optimal set of 11 descriptors. The two procedures resulted in remarkably different selections of topological, geometric, and combination descriptors, with only two descriptors in common. Still, the ability of the two models to predict solubility for a random internal test set ( $n = 51$ ) was similar, with an RMSE of about 0.7 log units after removing one outlier. Correlation between the observed solubilities and those predicted by the fully nonlinear model with 11-5-1 architecture is shown in Figure 6. Several other solubility models based on a similar modeling strategy have been published.<sup>14,25,43,60–62</sup> The applicability of this type of models is limited to rather small compound sets due to high computational cost.

#### 5.26.3.4 Consensus or Ensemble Modeling

Consensus modeling, or ensemble modeling means that more than one model is used for prediction and the results are averaged. By using this approach, the weakness of one particular model is compensated by another model, thus obtaining a more robust behavior for the ensemble of models.

Support for the general usefulness of consensus modeling has been provided by the computer simulation of Wang and Wang on consensus scoring for virtual library screening.<sup>63</sup> The simulation suggested that three or four methods are

**Figure 6** Correlation between the observed  $\log S$  and the  $\log S$  predicted by the neural network model of McElroy and Jurs.<sup>60</sup> ○, training set; ▲, test set; Δ, octachlorodibenzo-*p*-dioxin.

**Table 3** Prediction of aqueous solubility using rule-based systems (Rule Discovery System, RDS, [www.compumine.com](http://www.compumine.com)) and ensemble modeling (U. Norinder, P. Lidén, and H. Boström, unpublished results)

| Model type   | Training set |       |          | Test set 1 |       |          | Test set 2 |       |          |
|--------------|--------------|-------|----------|------------|-------|----------|------------|-------|----------|
|              | <i>n</i>     | $r^2$ | <i>s</i> | <i>n</i>   | $r^2$ | <i>s</i> | <i>n</i>   | $r^2$ | <i>s</i> |
| PLS          | 800          | 0.87  | 0.69     | 497        | 0.93  | 0.58     | 21         | 0.80  | 0.82     |
| RDS/ensemble | 800          | 0.97  | 0.35     | 497        | 0.95  | 0.51     | 21         | 0.87  | 0.67     |

sufficient to improve the results significantly. Examples of fortuitous consensus modeling appear in the solubility-modeling literature. Yalkowsky and co-workers<sup>64</sup> found in a study comparing the performance of their model with the Abraham model that the average of predicted  $\log S_w$  values using the two independent methods gives better prediction than either method used alone. Bergström *et al.*<sup>27</sup> developed three different PLS models based on either two- or three-dimensional descriptors, or a combination of both. They found that best results were obtained by averaging the predictions of the three models.

There are commercial software packages such as KnowItAll<sup>73</sup> and the Rule Discovery System<sup>74</sup> that employ consensus modeling. An example of systematic ensemble modeling to obtain more robust predictions instead of a single model is exemplified by a rule-based ensemble model using two-dimensional parameters on the Huuskonen data set (U. Norinder, P. Lidén, and H. Boström, unpublished results). The model consists of hierarchically organized rules by means of recursive partitioning with sets of if-then rules, where the condition part of each rule puts restrictions on some of the variables. In the case of a regression, a numeric value is assigned to the dependent variable (e.g.,  $\log S$ ) for examples covered by a particular rule. The results of the ensemble modeling (50 models) are compared in Table 3 with a single model using traditional PLS methodology.

#### 5.26.3.5 Commercial Software

A number of commercial programs for predicting aqueous solubility have been recently introduced (Table 4). The models used in these programs represent many of the modeling approaches discussed in the previous sections, and some of them are described in the literature<sup>34,49,65</sup> CSlogWS and COSMO-RSol are representative examples of the diversity of the methods. CSlogWS is an NN model predicting intrinsic thermodynamic aqueous solubility using *E*-state indices and other topological descriptors.<sup>34</sup> The model was developed using solubility data for almost 6000 compounds. COSMO-RSol combines a theoretical model to calculate the liquid phase contribution and a QSPR model for the solid phase contribution.<sup>65</sup> The method can be used to predict solubility in any solvent, but due to the density of the functional quantum chemical calculations required, it is not practical for prediction of large compound sets. In addition to commercial programs, there are free programs available on the Internet for prediction of aqueous solubility (Table 4).

#### 5.26.3.6 Accuracy and Applicability of In Silico Tools for Druglike Compounds

The prediction accuracy of a solubility model for druglike compounds may not be straightforward to evaluate from the published validation data. The majority of the data for training and test sets may represent compounds that are very far from drugs regarding structure and physicochemical properties, while regions of druglike structure space are poorly represented. The quality of a model is usually demonstrated by a plot showing the correlation between experimental and predicted  $\log S$  values and by giving the corresponding  $r^2$  value. High correlation may be shown for the whole solubility range, while only modest correlation is true for the most relevant range. The effect is demonstrated in Figure 2.

Using the overall error (rms, AAE, etc.) obtained for a test set as the measure of prediction accuracy may be deceptive as well. As demonstrated in Figures 3 and 5, the magnitude and sign of error may vary with structural type. Tetko *et al.*<sup>36</sup> found that the prediction error of their method increased approximately linearly with molecular size. It has also been found that the error is typically smaller for liquids than for solids, and may increase with melting point. Druglike compounds tend to be complex, large, solid compounds prone to larger prediction errors.

Root mean square errors in the range of 0.5–0.8 log units have been observed for most of the methods shown in Table 2, when tested with a set selected randomly from the data compiled for model development. Some models are

based on large and diverse sets containing probably most of the applicable data in PHYSPROP.<sup>31,41,58</sup> In these cases, RMSEs larger than 1 log unit have been observed for random test sets.

Lobell and Sivarajah<sup>50</sup> collected solubilities for 442 druglike compounds cited in the *Journal of Medicinal Chemistry* between 1982 and 2000. The set represented compounds that were classified as predominantly uncharged at the pH of measurement (MW = 129–903, with an average of 523). This set was used to compare the prediction accuracy of nine commercial or Internet methods with the log *P*-based equation of the authors. CSlogWS along with the log *P* equation showed an AAE of ~0.7. The other eight methods had AAE values between 0.9 and 1.9.

Cheng and Merz<sup>53</sup> tested their model with more than 220 drugs and druglike compounds from the Physician's Desk References and the Comprehensive Medicinal Chemistry database, observing RMSEs of 1–1.2 log units, almost twice the error found for the test set selected randomly from their working data set.

The data set of 85 compounds compiled by Bergström *et al.*<sup>27</sup> was proposed by the authors to represent a balanced coverage of the largest volume of druglike space published so far, and contain only high-quality intrinsic solubility values. We used part of this set (79 compounds with publicly available structures) to evaluate the prediction power of seven methods. All methods predicted an absolute error larger than –3 log units for structure SKF105657. The model of Bergström *et al.* also predicted this compound poorly. The solubility of SKF105657 (log *S* = –8.76) is outside of the typical range for drugs. The RMSE for the other 78 compounds varied from 1.06 log units for ESOL to 1.54 log units for IALOGS (**Table 5**). It is noteworthy that the complex models did not work better than the ClogP model of Lobell and Sivarajah. Consensus modeling improved the accuracy to an RMSE of 1.00 log units. The clearly lowest RMSE obtained for the model for Bergström *et al.* is not comparable, because most of the compounds were present in the training set. The RMSE they report for their external test set is 1.01 log units, and several compounds showed large errors. It can be seen in **Figure 1** that part of the structure space occupied by the external test set is poorly covered by the set of Bergström *et al.*

**Table 5** Prediction accuracy for a set of drug-like compounds compiled by Bergström *et al.*<sup>a</sup>

| Method  | $r^2$       | RMSE        | Compounds with<br>AAE > 2.5 log units |
|---|-------------|-------------|---------------------------------------|
| ESOL <sup>51</sup>  | 0.63 (0.61) | 1.06 (1.12) | 1                                     |
| Absolv <sup>b</sup>   | 0.54 (0.54) | 1.12 (1.17) | 3                                     |
| Lobell and Sivarajah <sup>50</sup> (ClogP model)              | 0.51 (0.52) | 1.15 (1.19) | 5                                     |
| ALOGPS <sup>c</sup>   | 0.54 (0.51) | 1.16 (1.21) | 3                                     |
| Compumine <sup>d</sup>  | 0.46 (0.45) | 1.21 (1.28) | 3                                     |
| QikProp <sup>e</sup>  | 0.53 (0.51) | 1.29 (1.35) | 4                                     |
| IALOGS <sup>f</sup>   | 0.25 (0.23) | 1.54 (1.62) | 8                                     |
| Consensus prediction <sup>g</sup>                             | 0.63 (0.62) | 1.00 (1.07) | 1                                     |
| Bergström <i>et al.</i> <sup>27</sup> (two-dimensional model) | 0.72 (0.72) | 0.89 (0.94) | 0                                     |

<sup>a</sup> Compounds with public structures from the set of Bergström *et al.*<sup>27</sup> excluded SKF105657 ( $n = 78$ ). SKF105657 is included for values in parentheses ( $n = 79$ ).

<sup>g</sup> Average prediction of seven models.

Considering the results discussed above, an RMSE in the range of 1–1.5 log units seems likely for a test set representing broadly druglike compounds. There are probably several reasons for the modest performance: inconsistencies in experimental solubility data, skewed or nonrelevant distribution of compounds in the training set, and inadequate structure representation. The domain of applicability of most solubility models covers only part of the druglike structure domain. Accuracy also varies within the descriptor range of a model. Some parts of the response surface are better covered by training set, or described by more appropriate structural parameters. A description of crystallinity effects is a special challenge for solubility modeling.

## 5.26.4 Methods for the Prediction of Solubility in Organic Solvents

The thermodynamics based MOD model of Ruelle is, in principle, applicable to the calculation of solubility in any solvent, providing that the necessary physicochemical parameters are available. The model has been tested for the prediction of solubility for hydroxysteroids and related compounds in 24 organic solvents.<sup>12</sup> The COSMO-RS method of Klamt<sup>65,66</sup> is also a general model, and, in principle, allows the prediction of solubility in any solvent without any experimental data. The predictive ability has been studied by Ikeda *et al.*<sup>67</sup> for 15 drugs and druglike compounds in three organic solvents. The rms errors for ethanol, acetone, and chloroform were 0.61, 0.84, and 0.56, respectively. A major limitation of the applicability of the method is the long time required for quantum chemical computations using the density functional theory.

A few QSPR studies have been carried out to model solubility in organic solvents. Acree and Abraham<sup>68</sup> investigated the applicability of Abraham's solvation model using a large number of solvents, and anthracene, phenanthrene, and hexachlorobenzene as model solutes. The solvents included aliphatic and aromatic hydrocarbons, alkanols, acetonitrile, and ethyl acetate. The model predicted solubility within an average absolute deviation of 35%. For comparison, the solubilities were calculated also using the MOD model, which gave an average absolute deviation of 110%. The most extensive work on solubility models for organic solvents has been carried out by Katritzky *et al.*, who have modeled around 500 compounds in various series in different solvents, such as various aliphatic and aromatic hydrocarbons, alcohols, and ethers, as well as some dipolar aprotic solvents.<sup>69,70</sup> They used the CODESSA PRO software both for generating the chemical descriptors for the investigated compounds as well as for the subsequent statistical QSPR analysis. They developed a large number of equations for various solvents with high statistical quality. Some general

trends were observed with respect to descriptor occurrence in the various models. A frequency analysis showed that electrostatic, topological, and hydrogen-bonding parameters were the most important, while descriptors related to geometry or derived from quantum chemical calculations were less important, and thermodynamic descriptors were of low importance. The solubility in aliphatic and aromatic hydrocarbon solvents is well described by electrostatic and topological parameters, while solubility in inert solvents (e.g., chlorine-containing solvents such as chloroalkanes or chloroaromatics) are governed, to a large extent, by cavity formation and other nonspecific terms. Thus, variables related to Randic topological indices occur frequently in these models. For protic solvents, parameters related to hydrogen bonding are of major importance. Variables related both to counts of donor and acceptor sites but also to parameters associated with charge-weighted molecular surfaces have a significant impact in these models. Polarizability and polarity as well as Lewis acid basicity are important parameters for describing solubility in polar aprotic solvents.

Despite the importance of DMSO for bioactivity screening, published QSPR modeling studies in are sparse, probably due to the lack of large publicly available experimental databases. The extensive QSPR work of Katritzky *et al.*<sup>70</sup> includes a model for DMSO solubility. A commercial program for predicting DMSO solubility has been recently introduced (Table 4).

## 5.26.5 Conclusion

There are presently a multitude of in silico methods available for the prediction of solubility. Methods representing very different modeling approaches apparently perform well within their domain of applicability, which, however, in most cases covers only a limited volume of the druglike structure space. Improving accuracy and applicability seems to require more consideration of the consistency of the experimental solubility data and the training set composition, although advances in structure representation to account for solid state effects may be the most critical aspect in improving prediction accuracy.

## Biographies

**Jyrki Taskinen** (born 1942) graduated and received his PhD in organic chemistry from Helsinki University of Technology, Department of Chemistry, Finland. He was a professor of pharmaceutical chemistry at the Faculty of Pharmacy, University of Helsinki in 1994–2005, and retired in 2005. Previously, he has worked at the Research Laboratories of the State Alcohol Monopoly and in the R&D Department of Orion Pharma. His research interests include computer-assisted drug design and drug metabolism.

**Ulf Norinder** was born in Sweden in 1956. He received his MS in chemical engineering and PhD in organic chemistry from Chalmers University of Technology, Gothenburg, Sweden, in 1981 and 1984, respectively. He is currently a principal scientist at AstraZeneca R&D Södertälje, and is also an associate professor at the Department of Organic Chemistry, Chalmers University of Technology, as well as an adjunct professor in computational pharmaceutics at the Department of Pharmacy, Uppsala University, Sweden. His research interests include computer-assisted drug design and pattern recognition, with special emphasis on multivariate data analysis.

### 5.27.1 Introduction

Physicochemical properties were recognized as important determinants of biological activity more than 130 years ago. Richardson showed that the toxicities of ethers and alcohols were inversely related to their water solubility<sup>1</sup> and Richet demonstrated a relationship between the narcotic effect of alcohols and their molecular weight.<sup>2</sup> The activity of local anesthetics was independently described by Overton<sup>3</sup> and Meyer<sup>4</sup> in terms of oil/water partition coefficients and the distribution ratio itself was first defined by Berthelot and Jungfleisch in 1872.<sup>5</sup> It was not until the 1960s, however, that the octanol/water partition coefficient system (log *P*) became recognized as a standard system for the description of lipophilicity. Corwin Hansch first proposed the use of octanol/water<sup>6</sup> for a number of theoretical and practical reasons:

- Octanol should be a good mimic for the long hydrocarbon chains with a polar headgroup found in membranes.
- Octanol dissolves water thus emulating the aqueous component of biological hydrophobic regions such as membranes.
- Octanol is cheap, easy to purify and lacks a chromophore, which would interfere with the spectroscopic determination of compound concentrations.

Hansch defined a substituent constant,  $\pi$ , as the difference between the partition coefficients for a parent compound and substituted derivatives:

$$\pi_X = \log P(R_X) - \log P(R_H) \quad [1]$$

In eqn [1] the parent is indicated by the subscript H and the substituent by X. The first series for which this parameter was derived was a set of monosubstituted phenoxyacetic acids and measurements on polysubstituted compounds showed that  $\pi$  values were additive. As more measurements were made, however, it soon became clear that  $\pi$  values were not strictly additive across different parent series, due principally to electronic interactions, and it became necessary to measure  $\pi$  values in other series such as substituted phenols, benzoic acids, anilines, and so on.<sup>7</sup> This proliferation of different  $\pi$  series actually became a major problem in the use of hydrophobic descriptors since it

required the selection of the 'correct' scale for some quite complex molecules. A further complication arises in the choice of substitution position or even parent structure. Most real drug molecules are much more complex than the simple compounds used in the chemical model systems to characterize particular effects. These compounds are selected so that the assignment of effects to particular chemical fragments is unambiguous but it is rarely obvious how these values should be assigned to bioactive structures.

The problem of the selection of an appropriate  $\pi$  scale has been resolved by the increasing use of either whole molecule  $\log P$  values or of 'fragmental' values to describe portions of molecules. The fragmental values have often been produced as by-products of the process of creating expert systems that could be used to predict  $\log P$  values or in attempts to account for hydrophobic effects in molecular modeling systems. In fact, as the 'traditional' QSAR approach to drug design became increasingly combined with molecular modeling techniques in the 1980s, more and more diverse sets of compounds were the subject of study and the 'standard' substituent constants used to describe hydrophobic, steric, and electronic effects were found unsuitable.

In order to measure a partition coefficient using a method such as the traditional 'shake flask' technique<sup>8-10</sup> it is necessary to have a reasonable idea of the expected  $\log P$  value so as to choose the appropriate volumes of octanol and water phases for the partitioning experiment. If a model of biological activity has been constructed using  $\log P$  values then, in order to use the model predictively, it is necessary to be able to calculate  $\log P$  values for compounds that have not yet been synthesized. Finally, as mentioned above, when a set of compounds contains reasonably complex or diverse molecules it is often not possible to use substituent constants such as  $\pi$  and values of  $\log P$  for the whole molecule or molecular fragments are needed. For all these reasons it became obvious that some form of calculation procedure was needed for partition coefficients as discussed in the next section.

### 5.27.2 Early Systems for $\log P$ Calculation

The fragmental approach of Nys and Rekker was one of the earliest systems to be developed for  $\log P$  calculation and was based on a statistical analysis of a large number of measured partition coefficient values to give the 'best' values for particular molecular fragments.<sup>11-13</sup> In actual fact these are not 'best' values but average values and so although they work well in most situations there are certain molecules that require correction factors for some of the fragments. This approach was termed 'reductionist' since it involved the breakdown of measured values into contributions from their component fragments and resulted in a large number of fragments with a small number of correction factors. Many of the correction factors involved multiples of a single term, which in the original reports was called a 'magic' factor.  $\log P$  is calculated in this approach as shown in eqn [2]:

$$\log P = \sum_{i=1}^n a_i f_i + \sum_1^m k_n \text{CM} \quad [2]$$

In this equation  $a_i$  is the number of occurrences of fragment  $f_i$  and the second term is a summation of the number of times ( $k_n$ ) that the correction factor (CM), which has a value of 0.289, has to be applied to each of the  $m$  fragments that need correction. In practice the second term in eqn [2] turns into a simple multiple of CM.

The Rekker system was quickly followed by a 'constructionist' approach due to Hansch and Leo.<sup>14,15</sup> This method was based on the use of a small number of fundamental fragments, derived from very precise  $\log P$  measurements, with a correspondingly larger set of correction factors. The equation for the calculation of  $\log P$  values using this system is very similar to eqn [2] for the Rekker method with the major difference being that correction factors can take on many values and are thus not simple multiples of a constant correction term. The fragments used in the Rekker method are mainly recognizable 'chunks' of a molecule such as functional groups and rings, although they also include some heteroatoms. The fragments used in the Hansch and Leo system, on the other hand, are single atoms apart from polar fragments, which are considered as multiatom groups.<sup>16</sup> Both of these approaches have their advantages and disadvantages. The advantage of Rekker's fragments is that it is easy to make chemical 'sense' of the effect of any change in chemical structure on  $\log P$ ; a disadvantage is that different results may be obtained if the structure is fragmented in different ways. The advantage of the Hansch and Leo method is that it has a set of rules, which will uniquely fragment any structure; a disadvantage is that this fragmentation for some molecules may result in missing fragments. A recent modification to the CLOGP program claims to have reduced the incidence of missing fragments by creating a set of rules to estimate them.<sup>17</sup> Comparisons of the two techniques have concluded, perhaps not surprisingly, that each method gives better results for some sets of compounds than others.<sup>18-21</sup>

At first, the two methods were used to calculate  $\log P$  values manually and this had major drawbacks since not only was it labor intensive but it was also difficult to achieve consistency since even a relatively simple molecule may be

broken into fragments in a number of different ways. The Hansch and Leo technique was the first to be made available as an automated system in the program CLOGP, which used the elegantly simple SMILES (*see* 3.13 Chemical Information Systems and Databases) notation for chemical structure input.<sup>22,23</sup> Since then the SMILES system has been widely adopted as the basis of database systems and as a chemical structure entry system for a variety of chemical modeling programs. An example of a breakdown of the calculation of  $\log P$  for three different molecules by the two techniques is shown in Figure 1. These three compounds were chosen because they show that both methods work well for hydroxyacetic acid, the Hansch and Leo system works better than the Rekker method for 2-phenoxyethanol, and the Rekker system is better for 1,2-methylenedioxybenzene.  $\log P$  calculation systems are now available on-line (*see later*), and these three molecules were submitted to the Virtual Computational Chemistry Laboratory<sup>24,25</sup> website<sup>117</sup> for calculation as shown in Table 1. This website not only calculates  $\log P$  using its own method (ALOGPS) but also links to several other websites to call for calculations. As Table 1 shows, the calculation by the Hansch and Leo system (ClogP) for 1,2-methylenedioxybenzene has been considerably improved to 2.11 compared with 1.34 given by the original system.

Measured  $\log P = -1.11$

**Rekker:**

$$\begin{aligned}\log P &= f_{\text{OH,al}} + f_{\text{CH}_2} + f_{\text{COOH,al}} + 3\text{CM} \\ &= -1.022 \quad \Delta = 0.09\end{aligned}$$

**Hansch & Leo:**

$$\begin{aligned}\log P &= f_{\text{OH}} + f_{\text{CH}_2} + f_{\text{COOH}} + (2-1)F_b + F_{\text{P1}} \\ &= -1.06 \quad \Delta = 0.05\end{aligned}$$

Measured  $\log P = 1.16$

**Rekker:**

$$\begin{aligned}\log P &= f_{\text{C}_6\text{H}_5} + f_{\text{O,ar}} + 2f_{\text{CH}_2} + f_{\text{OH,al}} + 2\text{CM} \\ &= 1.55 \quad \Delta = 0.39\end{aligned}$$

**Hansch & Leo:**

$$\begin{aligned}\log P &= f_{\text{C}_6\text{H}_5} + f_{\text{O}^\oplus} + 2f_{\text{CH}_2} + f_{\text{OH}} + (4-1)F_b + F_{\text{P2}} \\ &= 1.20 \quad \Delta = 0.04\end{aligned}$$

Measured  $\log P = 2.08$

**Rekker:**

$$\begin{aligned}\log P &= f_{\text{C}_6\text{H}_4} + 2f_{\text{O,ar}} + f_{\text{CH}_2} + 3\text{CM} \\ &= 2.17 \quad \Delta = 0.09\end{aligned}$$

**Hansch & Leo:**

$$\begin{aligned}\log P &= 4f_{\text{CH}} + 2f_{\text{C}^\oplus} + 2f_{\text{O}^\oplus} + f_{\text{CH}_2} + 3F_b + F_{\text{P1}} + F_{\text{P2}^\oplus} \\ &= 1.34 \quad \Delta = -0.74\end{aligned}$$

### 5.27.3 Partition in Other Solvent–Water Systems

Partition coefficients and  $\pi$  values have been shown to correlate with measures of biological activity in a very wide variety of experimental systems, ranging from simple protein binding to animal and human effects in vivo. This is presumably because hydrophobic effects are important not only in the intermolecular interactions that occur between a drug and its target site but also in the distribution of a compound within a biosystem, its interaction with competing binding sites, passage across and into membranes, and its interaction with metabolizing enzymes. It may be questioned, however, whether octanol/water is the ‘right’ model system for hydrophobic effects. That it has been successful is without question but might not another model system be more successful? Part of the answer to this is the fact that partition coefficients from many different solvent systems may be modeled by the use of Collander<sup>26</sup> equations:

$$\log P_2 = a \log P_1 + c \quad [3]$$

Here  $\log P_2$  and  $\log P_1$  represent partition coefficients measured in two different organic solvent–water systems with the coefficients  $a$  and  $c$  estimated by least squares fit. This might explain how a single partition coefficient could be applicable to so many different mechanisms since the weighting coefficient implicit in the Collander relationship would be estimated as part of the mathematical modeling process. It has been shown, however, that partition coefficients from other systems do contain extra information, which is useful in the description of biological properties. Young and co-workers demonstrated<sup>27</sup> that the difference between octanol/water and cyclohexane/water  $\log P$  values ( $\Delta \log P$ ) could be used to explain brain penetration as shown in eqn [4] and **Figure 2**. It was suggested that this parameter, first introduced by Seiler,<sup>28</sup> might be a useful general descriptor for brain penetration:

$$\log(C_{\text{brain}}/C_{\text{blood}}) = -0.49(\pm 0.16)\Delta \log P + 0.89(\pm 0.5) \\ n = 20 \quad r^2 = 0.83 \quad s = 0.44 \quad F = 40.2 \quad [4]$$

Extending this concept of the utility of other partitioning systems, Leahy and co-workers suggested that four model systems might be required in order to describe the properties of real membranes.<sup>29</sup> These models consist of water combined with:

- an amphiprotic solvent (e.g., octanol);
- an inert solvent (e.g., any alkane);
- a pure proton donor (e.g., chloroform); and
- a pure proton acceptor.

Propyleneglycol dipelargonate (PGPD) was proposed as a suitable compound for the pure proton acceptor and 216 partition coefficient values were reported along with a calculation scheme for other values. The lack of a wider range of measured values or of any automated calculation procedures is presumably the reason why this approach has not received wider attention.

Partition coefficients in other solvent systems have been reported in the literature but, in general, there have been few reports of attempts to create calculation schemes for them. One notable exception to this is a method known as linear solvation energy relationships (LSER) developed by Kamlet, Taft, Abraham, and co-workers.<sup>30,31</sup> Equations have been developed<sup>32</sup> for a number of solvent–solvent and solvent–gas systems and calculations can be made using the program Absolv.<sup>118</sup> A recent publication describes the calculation of ‘virtual’  $\log P$  values for alkanes and octanol using molecular modeling techniques.<sup>33</sup> The term virtual is used here because the calculations are carried out for individual

**Figure 2** Relationship between blood – brain barrier uptake and  $\log P$  for 20 structurally diverse compounds. (Reprinted with permission from Young, R. C.; Mitchell, R. C.; Brown, T. H.; Ganellin, C. R.; Griffiths, R.; Jones, M.; Rana, K. K.; Saunders, D.; Smith, I. R.; Sore, N. E. *et al. J. Med. Chem.* **1988**, 31, 656–671. Copyright (1988) American Chemical Society.)

**Figure 3** Octanol–water partition of a partially ionized compound. The partition of ions,  $\log P_i^{+/-} = \log P_i^+ + \log P_i^-$ , can significantly contribute to lipophilicity of charged compounds.<sup>116</sup>

conformers and the authors explain how to calculate  $\Delta \log P$  values (octanol/alkane) and even  $\log D$  (see below) values for the water/alkane system. Thus, this approach deals with two separate issues, which affect partition in any solvent system, flexibility, and ionization.

### 5.27.4 Distribution Coefficient

The partition coefficient is defined as the ratio of the concentration of a solute in the organic phase to its concentration in the water phase. This definition applies to a neutral species and, for that matter, the same species. Ionization will clearly affect the distribution equilibrium between the two phases, as will other phenomena such as self-association for whatever reason. The distribution coefficient,  $\log D$ , applies to the measured value of partition for an ionized compound at a particular pH. Assuming that only the neutral form of a molecule will partition into the organic phase then the observed  $\log D$  may be related to the  $\log P$  and  $pK_a$  of the compound, at the pH of the measurement, using an equation such as that shown for monoprotic basic compounds below:

$$\log D = \log P - \log(1 + 10^{pK_a - \text{pH}}) \quad [5]$$

The assumption that only the neutral form will partition into octanol is, at first sight, reasonable, but unfortunately octanol dissolves quite a large amount of water (water saturated octanol contains around 5 M water) and thus charged compounds will partition into it as ion pairs (see 5.18 Lipophilicity, Polarity, and Hydrophobicity). A more complete system of  $\log D$  calculations should consider all possible combinations of partition coefficients as shown in Figure 3. The  $\log D$  of a compound depends not only on the pH but also the concentration and nature of the counter-ions.<sup>34</sup> Having said this, the distribution coefficient is an important quantity in many applications and thus procedures for its calculation are useful, despite flaws in their theoretical basis. The calculation of  $\log D$  is discussed in a later section.

**Figure 4** The number of methodological publications for computational  $\log P/D$  prediction as a function of time (for 2005 it is a projected number). The publications were collected searching PubMed, ISI, and Google scholar servers. The 2000-year peak is partially explained by publication of the dedicated issue of *Perspectives in Drug Design and Discovery* that covered main  $\log P$  prediction methods. (Hydrophobicity and Solvation in Drug Design, Parts I and II, *Perspect. Drug Disc. Des.* **2000**, 17 & 18.)

### 5.27.5 The Explosion of $\log P$ Calculation Methods

The interest of pharmaceutical companies in prediction of the lipophilicity of compounds and multiple success stories about the correlation of this property with important biological and physicochemical properties of molecules caused a growth in the number of methods developed to predict this property. Figure 4 indicates the number of publications with new  $\log P$  calculation methods as a function of time.

The developed methods can be grouped according to two main criteria: according to the type of descriptor sets used, i.e., substructure and whole molecule approaches,<sup>35</sup> and according to the machine learning methods, e.g., linear or nonlinear approaches, used to establish structure– $\log P$  relationships. A simple analysis of the major methods indicates that linear methods tend to use fragment-based descriptors, while the nonlinear methods can exploit more efficiently whole molecular approaches.

Several reviews have examined the developed methods from a point of view of the representation of indices.<sup>35–37</sup> A different strategy is followed here and an analysis is provided according to the type of models used. Since the performance of the methods depends on the number of compounds in the training set, number of indices, machine learning method used as well as composition and diversity of the training and test sets (if the latter was employed), a comparison of the approaches according to their published results, in our opinion, does not really make sense. Thus, instead, a description of the philosophy of the developed approaches is focused on here, including their unique features that make them interesting for the scientific community. A comparison of several methods will be performed using some test sets in Section 5.27.9.

### 5.27.6 Linear Models

#### 5.27.6.1 $\log P$ Prediction Using Fragmental Descriptors

As was mentioned above, the substructure approaches, such as fragmental and atom contribution methods, cut the analyzed molecule into fragments or atoms (as degenerate case of fragments), attribute a particular value for each group, and calculate the  $\log P$  value as:

$$\log P = a + \sum_{i=1}^N b_i G_i \quad [6]$$

where  $G_i$  is the number of occurrences of the group  $i$  and  $a$  and  $b_i$  are regression coefficients. This formula, however, may require additional coefficients,  $F_j$ , known as correction factors:

$$\log P = a + \sum_{i=1}^N b_i G_i + \sum_{j=1}^K c_j F_j \quad [7]$$

The Rekker method, as shown in eqn [2], can be seen to conform to this general equation. A large number of group contribution methods have been developed during the last few years. The most popular methods include those that are fragment based such as ClogP,<sup>17,38</sup> ACD/log *P*,<sup>39</sup> KOWWIN,<sup>40,41</sup> Σf-SYBYL,<sup>42,43</sup> KlogP,<sup>44</sup> HlogP,<sup>45</sup> AB/log *P*,<sup>46</sup> and techniques based on atom-contribution approaches such as AlogP,<sup>47–49</sup> XlogP,<sup>50,51</sup> and SMILOGP.<sup>52</sup> The fragments used in these approaches range from 68 in AlogP<sup>48</sup> to about 2000 in HlogP<sup>45</sup> while the number of correction factors varies from 0 in Alog *P* to several thousand in the ACD/log *P* method.

Many of the fragment-based methods have been reviewed previously.<sup>35,37,53</sup> Only the main features and conceptual differences among the methods are pointed out below.

The poor performance of group contribution methods for the prediction of new compounds can be attributed to the presence of some new groups/correction factors that are not covered in the training set. As mentioned above, a new version of the CLOGP program (v. 4.0 and higher) includes an algorithm for the ‘ab initio’ calculation of the contribution of fragments if they are not found for the training set. Thus, new fragments are easily calculated and included to estimate log *P* for unusual molecules.<sup>17</sup>

ACD/log *P* also has to deal with the missing fragment problem. This program estimates them using a fragmental increment equation similar to the Ghose/Crippen approach<sup>54</sup> and a multilinear equation similar to the Hammett–Palm equation.<sup>39</sup> The result is calculated as a sum of all the fragments. If new experimental data are available, the contribution of some of the fragments, particularly missed ones, can be recalculated from the new data. This option is claimed to significantly improve the accuracy of the program and constitutes the so-called ‘user-training’ feature of ACD/log *P*.<sup>55</sup> The practical application, such as the analysis of a few thousand compounds, however, indicated severe limitations of the method in speed, memory, and disk usage while the resulting improvement of accuracy was only marginal and increased *r*<sup>2</sup> between predicted and calculated values from 0.3 to 0.5.<sup>56</sup>

The KOWWIN program includes an interesting methodology, experimental value adjusted approach,<sup>40</sup> which evaluates the contribution of fragments by comparing closely related analogs. Thus, if a new compound has to be predicted, experimental value adjusted approach identifies the closest analog from the training set and calculates the log *P* of the new molecule by adding or subtracting the contribution of the groups required to transform the query structure into its analog:

$$\begin{aligned} \log P &= \log P_{\text{exp, analog}} + \Delta \log P_{\text{target} \rightarrow \text{analog}} \\ \Delta \log P_{\text{target} \rightarrow \text{analog}} &= \left( \sum b_{i, \text{target}} G_{i, \text{target}} + \sum c_{i, \text{target}} F_{i, \text{target}} \right) \\ &\quad - \left( \sum b_{i, \text{analog}} G_{i, \text{analog}} + \sum c_{i, \text{analog}} F_{i, \text{analog}} \right) \end{aligned} \quad [8]$$

where  $\Delta \log P_{\text{target} \rightarrow \text{analog}}$  corresponds to the sum of contributions of fragments and correction factors required to change the target molecule into its analog. Table 2 demonstrates fragment and correction factors for atropine and cocaine. The sum of contributions to map cocaine to atropine is  $\Delta \log P_{\text{cocaine} \rightarrow \text{atropine}} = 0.26$ . Thus, considering that the experimental atropine value is 1.83, the cocaine value estimated by the experimental value adjusted method is  $\log P_{\text{cocaine}} = 1.83 + 0.26 = 2.09$ ; this is quite a good estimation of the experimental value of this compound, which is 2.30 log units. In a similar way the log *P* value of atropine can be estimated from the experimental value of cocaine as  $\log P_{\text{atropine}} = 2.30 - 0.26 = 2.04$ . Note that the above equation can also be rewritten (it just requires that several terms in the equation are swapped and that the summation fragments and correction factors that are common for target and analog compounds are also included) as:

$$\begin{aligned} \log P_{\text{target}} &= \log P_{\text{predicted, target}} + (\log P_{\text{exp, analog}} - \log P_{\text{predicted, analog}}) \\ &= \log P_{\text{predicted, target}} - \Delta \log P_{\text{error, analog}} \end{aligned} \quad [9]$$

where  $\log P_{\text{predicted}}$  refers to the value predicted using solely the fragment-based approach. This simple mathematical trick gives another treatment of the experimental value adjusted approach – the predicted value of the target compound is corrected using the error of its nearest neighbor. This simple but fundamental equation represents the basis of two other recently and independently proposed methods, SLIPPER<sup>57</sup> and ALOGPS.<sup>58,59</sup>

AlogP<sup>47–49</sup> is a pure atom-based contribution method based on a parameter set of only 68 atom type descriptors. The simplicity and as a result robustness of the method is probably the most remarkable feature of this approach. Because of simple implementation, the AlogP method can be easily reproduced and is implemented in several software packages, e.g., in DRAGON.<sup>60</sup>

**Table 2** Fragment contributions calculated for atropine and cocaine by KOWWIN

| No.   | Type              | Fragment description                  | Coefficient | Number of groups |                      |
|---|-------------------|---------------------------------------|-------------|------------------|----------------------|
|   |                   |                                       |             | Atropine         | Cocaine <sup>a</sup> |
| 1   | Fragment          | –CH <sub>3</sub> (aliphatic carbon)   | 0.5473      | 1                | 2 (+1)               |
| 2   | Fragment          | –CH <sub>2</sub> – (aliphatic carbon) | 0.4911      | 5                | 3(–2)                |
| 3   | Fragment          | –CH (aliphatic carbon)                | 0.3614      | 4                | 4                    |
| 4   | Fragment          | –OH (hydroxy, aliphatic attach)       | –1.4086     | 1                | 0(–1)                |
| 5   | Fragment          | –N< (aliphatic attach)                | –1.8323     | 1                | 1                    |

| 7   | Fragment          | –C(=O)O (ester, aliphatic attach)     | –0.9505     | 1                | 1                    |
| 8   | Fragment          | C(=O)O (ester, aromatic attach)       | –0.7121     | 0                | 1(+1)                |
| 9   | Correction factor | Fused aliphatic ring unit correction  | –0.3421     | 1                | 1                    |
| 10  | Constant          | Equation constant                     | 0.2290      | 1                | 1                    |
| Experimental values of compounds, log <i>P</i> <sub>exp</sub>                               |                   |                                       |             | 1.83             | 2.30                 |
| Cocaine log <i>P</i> value estimated from the log <i>P</i> <sub>exp</sub> value of atropine |                   |                                       |             |                  | 2.09                 |

<sup>a</sup>The number of fragments/correction factors required to change atropine to cocaine is indicated in parentheses.

HlogP<sup>45</sup> uses an extended representation of 2D fragments based on structural keys (i.e., presence or absence of certain groups). The representation of a molecule using these fragments is called a ‘molecular hologram.’ It is possible to control the length of fragments and thus the ‘fragment collision,’ when different fragment types occupy the same bin. This happens when the hologram length is smaller than the number of distinct fragments. The data analysis method used in HlogP is partial least squares regression.

A new version of the KlogP program<sup>61</sup> is also based on fragmental indices but it profits from knowledge of the 3D structure of molecules by means of steric hindrance indices, *H*, proposed by Cherkasov.<sup>62</sup> The modified eqn [6], i.e.:

$$\log P = a + \sum_{i=1}^N b_i(1 - H_i)G_i \quad [10]$$

takes into account the hindrance *H<sub>i</sub>* of the atoms in the fragment *G<sub>i</sub>* as  $H_i = \sum_{j \neq i}^n R_j^2 / A \cdot r_{ij}^2$ , where *A* is a constant, *R<sub>j</sub>* the atomic radius of the *j*th atom, and *r<sub>ij</sub>* the distance between the *i*th and *j*th atoms.<sup>62</sup> The *H<sub>i</sub>* index weights the contribution of different fragments according to their availability to solvent. The use of eqn [10] instead of [7] remarkably increased the performance of the method for drugs and decreased the standard deviation from 1.08 to 0.78 log units for a test set of 137 drugs.

The substructural molecular fragment (SFM) method<sup>63</sup> splits a molecule into fragments of two different types, 'sequences' (I) and 'augmented atoms' (II). For each type of fragment one can define indices of three subtypes AB, A, and B. For example I(B, 2–6) considers only types of bonds from 2 to 6 atoms. In a similar way to HlogP the resolution of the data can be easily controlled by including different numbers of atoms for the generation of fragments. The data analysis in this method is performed using the singular value decomposition.

### 5.27.6.2 log *P* Models Based on Nonfragmental Descriptors

#### 5.27.6.2.1 Methods based on a few theoretically justified descriptors

While fragmental descriptors are one of the most frequently used descriptor systems for the prediction of lipophilicity of compounds, there are theoretical justifications for the use of property-based descriptors.

For two relatively immiscible solvents log *P* can be considered<sup>64</sup> proportional to the molar Gibbs free energy ( $\Delta G_{o \rightarrow w}^0$ ) of transfer between octanol and water:

$$\log P = \frac{1}{RT} \Delta G_{o \rightarrow w}^0 \quad [11]$$

The solvation theory<sup>65</sup> indicates that the major contribution to this energy is the cavity term, usually considered proportional to the volume (or surface) of the solute. Thus, the partition coefficient depends on some molecular properties, which contribute to this energy term.

Mobile order and disorder (MOD) theory provides another nice framework for theoretical analysis of the lipophilicity of compounds.<sup>66</sup> The theory was challenged by Einstein who first proposed to express the equilibrium as time fractions rather than classical ensemble fractions in the Boltzmann model and thus eqn [11].<sup>67</sup> The MOD also uses mobile molecular domains for the calculation of the entropy of mixing compared to quasi-lattice models used in the classical Boltzmann model. Thermodynamically, the partition coefficient can be regarded not only as the ratio of concentrations at the equilibrium but also as the ratio of saturation concentrations or solubilities. Thus, it can be obtained from the differences of its volume fraction solubilities between less polar (octanol) and more polar (water) phases:

$$\log P = (\ln 10)^{-1} [\ln \Phi_B^o - \ln \Phi_B^w] \quad [12]$$

The universal predictive equation for log *P* is given by the MOD theory<sup>68,69</sup> as the sum of Gibbs free energy contributions:

$$\log P = \Delta B_{o/w} + \Delta F_{o/w} + \Delta (O + OH)_{o/w} + \Delta D_{o/w} \quad [13]$$

Here,  $\Delta B_{o/w}$  corresponds to the differences between the two phases in the entropy of the solute–solvent exchange,  $\Delta F_{o/w}$  is the hydrophobic effect-related term accounting for the differences in the propensity to squeeze the solute out of the solution,  $\Delta (O + OH)_{o/w}$  expresses the differences in the strength of the H-bonds that bind the solute and the solvent in both phases, and the last term  $\Delta D_{o/w}$  is similar to the previous one but accounts for the nonspecific forces only.

The general form of eqn [13] reduces to a very simple linear equation relating lipophilicity of molecules and their molar volume ( $V_B$ ):

$$\log P = \Delta B_{o/w} + \Delta F_{o/w} = -0.48 + 0.03328 V_B \quad [14]$$

when the differences in the changes of nonspecific forces ( $\Delta D_{o/w} = 0$ ) are negligible and when no solute–solvent specific interaction takes place in either phase ( $\Delta (O + OH)_{o/w} = 0$ ). Thus, despite different basic assumptions, the main conclusion of both classical solvation and MOD theory are basically the same and provide a direct basis for the empirical correlation of log *P* values to their molar volume or any related property (surface area, parachor, molar refraction, etc.). Indeed, there were multiple log *P* calculation models in-line with the conclusions of these studies. For example, the QlogP model:

$$\begin{aligned} \log P &= 0.032(\pm 0.0002) V - 0.723(\pm 0.007) N + 0.01(\pm 0.0007) I \\ n &= 320 \text{ alkanes, } r^2 = 0.98, s = 0.21 \end{aligned} \quad [15]$$

utilizes the molecular volume (*V*) as its central descriptor as well as a correction parameter to account for the hydrogen bonding effect between the solvent and oxygen–nitrogen-containing functional groups (N) of the solute molecules and

an alkane indicator variable ( $I$ ).<sup>70</sup> The solute size (favors octanol) together with solute hydrogen-bond basicity (favors water) were named as the main parameters of the Abraham's general linear solvation energy equation.<sup>71</sup> Xing and Glen<sup>72</sup> also calculated a significant model for  $\log P$  prediction using just three parameters, polarizability and partial atomic charges on nitrogen and oxygen:

$$\log P = 0.29(\pm 0.07) + 0.199(\pm 0.004)\alpha - 14.9(\pm 0.5)q_N^2 - 8.4(\pm 0.2)q_O^2$$

$$n = 592, r^2 = 0.89, s = 0.65 \quad [16]$$

where  $\alpha$  is the molecular polarizability and  $q_N^2$  and  $q_O^2$  are the total squared partial charges on nitrogen and oxygen atoms, respectively. The model predicts higher lipophilicity values for molecules with bigger polarizability, i.e., molecules that require a bigger cavity are predisposed to move into the 1-octanol.

The use of eqn [13] requires knowledge of solubility data of monofunctional systems that are, to some extent, similar to fragment contributions. A nice feature of the MOD approach is that essentially the same equation can also be applied to derive partition coefficients in other two-phase systems made of two largely immiscible solvents. An application of eqn [13] to a wide set of chemicals in 16 different two-phase systems calculated a standard deviation error of 0.48 log units for 2263 predicted values.<sup>69</sup> However, in its current form the model can only be applied to essentially nonfunctional or monofunctional compounds but not to complex polyfunctional molecules and, in particular, to those with conjugated or internally H-bonded structures.<sup>69</sup>

There were several studies attempting to empirically correlate the  $\log P$  values of chemicals from molecular properties contributing to Gibbs free energy pioneered as early as 1969 by Rogers.<sup>73</sup> The quantum-chemical calculations (MINDO/3 and Hückel-type calculation based primarily on topology) were challenged to predict the partition coefficient by Klopman.<sup>74</sup> The BlogP method, involving 18 parameters, was developed using AM1 methodology.<sup>75</sup>

Despite a great educational influence and explanatory power, the above articles could not be considered as important practical methods. Indeed, the number of compounds used in those studies was usually in the order of several hundreds and the molecules were from structurally simple classes (i.e., alkanes). However, even for such molecular series with limited diversity there was sometimes a need for correction factors and indicator variables (QlogP<sup>70</sup>) to account for nonadditive effects. The descriptors used in the aforementioned articles could be very useful for correlations in homogeneous series of compounds to build local lipophilicity models.

Nevertheless, in recent years new techniques based on quantum-chemical calculations have appeared. A well-known method, QikProp, is based on a study<sup>76</sup> that used statistical Monte Carlo simulations to calculate 11 parameters, including solvent accessible solvent area (SASA), solute-solvent energies, solute dipole moment, number of solute-solvent interactions  $< -2.75 \text{ kcal mol}^{-1}$  (INME), number of solute as donor/hydrogen bonds (HBDN/HBAC), and some of their variations. These parameters made it possible to estimate a number of free energies of solvation of chemicals in hexadecane, octanol, water, as well as octanol/water distribution coefficients. The equation calculated for octanol/water coefficient is:

$$\log P = 0.015 (\text{SASA}) - 0.58 (\text{HBAC}) - 1.09 (\text{no. of amines})$$

$$+ 1.10 (\text{no. of nitro acid groups}) - 0.102 (\text{INME}) - 1.81$$

$$n = 200, r^2 = 0.91, s = 0.55 \quad [17]$$

The dominating term in the equation is the total solvent area of the molecule (SASA). Compounds with larger SASA favor solvation in octanol, which is in accordance with the importance of the size of molecules for lipophilicity of chemicals predicted by both solvation and MOD theory.

Another interesting approach to calculate partition coefficients using quantum-chemical calculations was developed by the Klamt group.<sup>119</sup> The COSMOtherm program describes the interactions in a fluid as local contact interactions of molecular surfaces.<sup>77,78</sup> This makes it possible to derive models for different solvent-water partition systems, including octanol, benzene, hexane, etc.

#### 5.27.6.2.2 Large-scale property-based models

A popular method for calculation of  $\log P$ , MlogP, was developed by Moriguchi and co-workers.<sup>79</sup> MlogP uses the sum of lipophilic (carbons and halogens) atoms and the sum of hydrophilic (nitrogen and oxygen) atoms as two basic descriptors. These two descriptors were able to explain 73% of the variance in the experimental  $\log P$  values for a database of 1230 compounds. The use of 11 correction factors covered 91% of the variance. Because of its simplicity of implementation, the MlogP method was widely used as a calculation and reference approach for many years.

SLIPPER<sup>57,80</sup> calculates lipophilicity as:

$$\log P = 0.267\alpha - \sum C_a \quad [18]$$

which includes only two terms, polarizability ( $\alpha$ ) and the hydrogen bond acceptor strength ( $\sum C_a$ ) of the molecule. Using only these two descriptors the authors calculated good results for a database of 2850 simple compounds ( $n = 2850$ ,  $r^2 = 0.94$ ,  $s = 0.23$ ). However, they pointed out that the problem of predicting lipophilicity for compounds with several functional groups is much more difficult. Therefore, they proposed to correct the  $\log P$  prediction of the target compound according to the lipophilicity values of the nearest neighbors as:

$$\begin{aligned} \log P_{\text{target}} &= \left( 0.267\alpha - \sum C_{a,\text{target}} \right) + \frac{1}{K} \sum_{j=1}^K \left( \log P_{\text{exp},j} - \frac{1}{K} \sum_{j=1}^K 0.267\alpha_j - \sum C_{a,j} \right) \equiv \\ &\equiv \log P_{\text{predicted,target}} + \frac{1}{K} \sum_{j=1}^K (\log P_{\text{exp},j} - \log P_{\text{predicted},j}), \text{ where} \\ \log P_{\text{predicted}} &= 0.267\alpha - \sum C_a \end{aligned} \quad [19]$$

where the  $K$ -nearest neighbors are determined using cosine similarity measure for representation of molecules by molecular fragments. Thus, the actual predicted value is corrected by the average error of its nearest neighbors. It is easy to notice that experimental value adjusted approach of KOWWIN uses exactly the same equation with the exception that correction in the former method is done using only one nearest neighbor and, of course, the predicted values are calculated using a different method. Using this approach the authors significantly improved the statistical results for a large database of 10937 chemicals compared to the use of the original eqn [18].

### 5.27.7 Nonlinear Methods

The dependency of  $\log P$  on chemical descriptors clearly has a nonlinear character. This fact is taken into account in linear methods by introducing correction factors,  $F_j$ , in fragment-based approaches (eqn [7]), use of indicator variables, or development of methods to predict lipophilicity departing from the nearest neighbor analog (KOWWIN and SLIPPER). The use of nonlinear approaches, such as neural networks, makes it possible to more easily incorporate the nonlinear effects in the model and can, generally, result in models with higher prediction ability. This explains the appearance of a large number of studies performed to provide nonlinear modeling of  $\log P$  as a function of molecular parameters.

Some of the first attempts to predict  $\log P$  values using artificial neural networks (ANNs) were published in 1994 and 1995.<sup>81–83</sup> These works analyzed rather small sets of compounds and mainly introduced a new methodology and demonstrated its performance compared to traditional multiple linear regression (MLR) analysis. It is interesting that all of these studies used parameters derived from quantum-chemical calculations and thus were targeted to develop very general models that could predict compounds in the whole chemical universe. The use of advanced methodology for descriptor selection<sup>84</sup> made it possible to significantly decrease the number of required descriptors for the data set of Bodor<sup>75,81</sup> and to calculate improved statistical results for the independent test set used in the original study. Thus, this study demonstrated that the ANN design has a significant impact on the quality of calculated results. Similar conclusions and the importance of variable selection to construct reliable neural network models were also reported elsewhere.<sup>85,86</sup>

The development of  $\log P$  prediction methods based on quantum-chemical parameters was continued by the group of Clark.<sup>87,88</sup> Both these reports were based on 1085 molecules and 36 descriptors were calculated following structure optimization and electron density calculation with the AM1 method. The descriptors selected with an MLR model were used as an initial set of descriptors, which was further optimized by trial-and-error variation. The new analysis also proposed to estimate the reliability of neural network prediction by analysis of the standard deviation error of an ensemble of 11 networks trained on different randomly selected subsets of the initial training set.<sup>88</sup>

The AUTOLOGP program<sup>89,90</sup> was developed using 2D autocorrelation descriptors.<sup>91</sup> The autocorrelation descriptors consider a molecule as a graph with the distance between nodes determined as the smallest number of edges between them. Any atomic contributions  $AC_i$  can be used to calculate products,  $AC_i \times AC_j$ ,  $i, j = 1, \dots, n$ , where  $n$  is the maximal distance in the molecule. The sum of these products for the same distance in the graph gives a component

of the autocorrelation vector for the selected property. The authors used autocorrelation vectors encoding lipophilicity, molar refractivity, and hydrogen bond acceptors/donors. Only 35 autocorrelation indices were required to describe the molecules correctly and model  $\log P$ .

The E-state indices<sup>92,93</sup> were developed to cover both topological and valence states of atoms. These indices were successfully used in many studies<sup>92</sup> and new applications of this methodology are extensively reviewed in this book (see 5.23 Electotopological State Indices to Assess Molecular and Absorption, Distribution, Metabolism, Excretion, and Toxicity Properties). Several articles by different authors demonstrated the applicability of the indices for lipophilicity predictions.<sup>94–99</sup> The ALOGPS<sup>100</sup> program was developed using 12 908 compounds from the PHYSPROP database,<sup>101</sup> which is one of the largest data sets used to predict lipophilicity of chemicals. The neural networks were trained using 73 E-state descriptors and number of hydrogen and nonhydrogen atoms and produced a significant improvement compared to MLR and several other methods, e.g., ClogP,<sup>38</sup> XLOGP,<sup>51</sup> etc., compared in the study. The authors warned that if molecules in training and test sets have different chemical diversity, the prediction ability of programs developed using different methodology but using the same training set is very similar and unacceptably low.<sup>100</sup> Following this observation, a feature to improve the prediction ability of the ALOGPS program was developed using the Associative Neural Networks approach.<sup>58,59,102</sup> This technique made it possible to incorporate new data into the memory of neural networks without their retraining. The basic equation is the same used in experimental value adjusted approach of KOWWIN<sup>40</sup> and SLIPPER-2001,<sup>80</sup> i.e., the prediction of a new compound is corrected by the average error of its nearest neighbors. The principal difference is in the definition of similarity between the molecules, which is defined as the rank correlation in the space of trained models.<sup>59,102</sup> This definition is claimed to be more accurate since it includes the features normalized by the neural network according to the target property, i.e., lipophilicity. The applicability of the method was successfully demonstrated in a number of studies for ‘in-house’ data of pharmaceutical firms.<sup>103,104</sup>

The question of whether one should use diverse or large libraries of compounds was challenged in another study.<sup>105</sup> It was argued that the use of huge libraries containing nondrug compounds may overfit the programs to such series of compounds and thus the developed programs could not predict the drug-like compounds. The authors selected a set of 78 compounds that were outliers for several studies, e.g., KOWWIN,<sup>40</sup> ClogP,<sup>17,38</sup> as well as additional drug-like compounds to give a database of 625 molecules. After the development of their approach, AutoQSAR models, using this set of compounds the authors were able to predict another set of compounds missed from the public databases. It is interesting that contrary to previous studies they calculated the best results for the test set with MLRA but not with ANN and PLS methods. However, since the final test set included just 18 compounds, their conclusions should not be over-generalized.

There have also been studies attempting to correlate  $\log P$  with connection matrices<sup>106</sup> or fragmental indices.<sup>107</sup> The authors calculated improved models and argued that the advantage of the fragment-based descriptors is that they are more easily interpreted. It is interesting that the same group of authors mathematically proved that any topological index can be replaced with a set of fragmental descriptors provided that the structure-property data set is sufficiently large to build statistically significant models.<sup>108</sup> This result is not surprising, considering the fact that as low as 1 bits/atom are required to encode a molecule. Thus, theoretically as low as one to two topological indices calculated with float precision can be sufficient to encode/decode a molecule.<sup>109</sup> Any representation that utilizes a larger number of bits, i.e., fragmental indices, can be used for the same purposes and thus provide equivalent mapping between different representations. Of course, the differences may arise in the number of molecules required to make each model (e.g., based on topological or fragmental indices) statistically significant.

## 5.27.8 1-Octanol/Water Partition Coefficient Calculation Programs

### 5.27.8.1 $\log P$

Since  $\log P$  is such an important property for so many aspects of drug design it is not surprising that there has been a rapid increase in the availability of calculation programs to accompany the ‘explosion of calculation techniques’ Individual programs have been mentioned repeatedly in this chapter so a list of the free, commercial, and web accessible calculation routines are gathered together here. Table 3 is not an exhaustive listing of the available programs and web addresses were correct at the time of writing, of course.

### 5.27.8.2 $\log D$

Calculation of the distribution coefficient,  $\log D$ , as discussed in Section 5.27.4 is complicated by the fact that this requires knowledge of both  $\log P$  and  $pK_a(s)$ . In fact,  $\log P$  values are only true  $\log P$  values if they are measured at a pH at which the ionization of any ionizable groups is suppressed. It is unusual to find measured  $\log P$  values quoted with a

<sup>a</sup> These are stand-alone programs except those marked with \*. Results of programs marked with # are accessible from the Java applet at [www.vcclab.org](http://www.vcclab.org) site.

<sup>b</sup> The fragmental methods refer to the system of Hansch and Leo (HL), Rekker (R), computer identified (C), and atom/fragment contributions (A/F). 'Properties' means that various molecular properties are used in the calculations. 'Atomic values' means that tables of atom-based values are used. 'Topological descriptors' means (usually) electrotopological descriptors.

measurement pH and the assumption, perhaps often wrong, is that the experimentalist chose an appropriate pH. Of course the casual user of log *P* may find it confusing to see measurements reported at pH 2 or 11 when the expected important pH of biological systems is 7.4.

When p*K*<sub>a</sub> values are known then the calculation of log *D* from either measured or calculated log *P* values is trivial. When the p*K*<sub>a</sub> values are unknown, though, the process of log *D* calculation becomes problematic since calculation of the ionization constant of an acid or base is arguably more difficult than the calculation of log *P*. The first step in the calculation of p*K*<sub>a</sub> values for any molecule is the recognition of the ionizable group or groups and this needs an algorithm, which has some chemical 'sense.' Having recognized the groups there are several ways in which p*K*<sub>a</sub> values

<sup>a</sup>log D calculations are available as the user-training feature.

may be estimated including methods based on: the Hammett equation, atomic charges, fragments, semiempirical and ab initio molecular orbital calculations, 3D QSAR, and hybrid (combined methods) systems (see 5.25 In Silico Prediction of Ionization). There is no space to discuss them here but the difficulty of  $pK_a$  prediction means that there are far fewer programs available for  $\log D$  calculation as shown in Table 4.

### 5.27.9 Assessment of Performance

An assessment of the performance of the models is crucial for their application and development of new approaches. There were numerous studies published with a detailed analysis of different  $\log P$  calculation methods attempting to derive an objective opinion about the relative performance of different strategies (i.e., fragmental and whole-molecule approaches) and machine learning methods (i.e., linear versus nonlinear).<sup>37,53,110,111</sup> The model performances in such studies are usually compared on published data or some relatively small test set of publicly available compounds that are normally selected to be diverse and ‘drug-like’ (i.e., drugs or drug-like molecules). The main assumption of such studies is that the analyzed approaches tested on the ‘drug-like’ set will have a similar performance for new unseen ‘drug-like’ molecules. Unfortunately, such assessment of performance of the methods cannot be truly objective. In general, the quality of the models to be compared critically depends on three main parts: (1) molecular descriptors; (2) machine learning approach; and (3) the diversity and the size of the training sets. While the first two items correspond to an intuitive understanding of the ‘quality of the model’ and ‘predictive performance,’ the third item can actually dominate in the method performance. Indeed, numerous studies suggest that the use of only a single compound per series or scaffold of compounds in the training set may improve the prediction ability of the method for the whole series by several times.<sup>55,58,100</sup> Thus, in the absence of knowledge whether the test molecules and/or their analogs were used or not to develop the tested model an objective comparison of the programs is difficult.

We compared several programs, ALOGPS, KOWWIN, IA-logP, CLOGP, XLOGP, miLogP available at the VCCLAB website<sup>24,117</sup> using 20 series of compounds that were published in leading chemical journals during 2003–2004. Six of the series were contributed by pharmaceutical companies or were the result of collaboration between industry and academia. The molecules were downloaded from the LOGKOW database<sup>120</sup> supported by Dr J. Sangster and were checked to eliminate possible typing errors.

The first analysis of the series indicates that most reported 1-octanol/water partition values are  $\log D$  rather than  $\log P$  values. This can be explained logically for at least two reasons, experimental and biological. First, it is considerably easier and cheaper to make measurements of lipophilicity using, for example, phosphate buffer, under fixed pH. The fixed pH can also be efficiently used with cheap experimental methods, such as high-performance liquid chromatography (HPLC), and is most suitable for high-throughput measurement systems. In contrast to that, the identification of  $\log P$  is more complex and requires several steps of titration toward the direction of its neutral form. This may dramatically decrease its solubility and makes measurements of  $\log P$  inaccurate. Second, an argument goes

that the compounds will perform their action on the biological target in the organism under physiological pH (7.4) or a range of pH values in the gut when it should be absorbed by the organism. Although this has appeal, it should be remembered that this 'physiological pH' is a bulk pH, not the pH of the microenvironment where the molecules interact with their receptor.

We used predicted  $pK_a$  values of the ACD and Pallas programs to decide if the analyzed compounds are predicted to be ionized or neutral under the pH of measurements. Eight series were predicted to be neutral at the measurement pH and, interestingly, these series had considerably lower prediction errors with all methods (Figure 5). The mean absolute error (MAE) for these series averaged over all methods was about 0.6 units as shown in Figure 6a. The lowest errors for these sets were calculated using XLOGP (MAE = 0.53).

**Figure 5** The mean absolute error (MAE) of the methods for prediction of different series of compounds. The first eight series are compounds predicted to be neutral at pH of measurements according to the ACD Laboratories and Pallas programs.

**Figure 6** Average mean absolute error (MAE) of different programs for 8 neutral (a) and 12 charged (b) data sets.

**Table 5** ACD laboratories and Pallas log *P* and log *D* values calculated for pyrazolopyridine derivatives<sup>112</sup> using experimental *pK<sub>a</sub>* values

| Compound number | X                  | log <i>D</i> | <i>pK<sub>a</sub></i> | log <i>P</i> |               | log <i>D</i> 7.4 values estimated using eqn [5], calculated log <i>P</i> , and experimental <i>pK<sub>a</sub></i> |               |
|-----------------|--------------------|--------------|-----------------------|--------------|---------------|---|---------------|
|                 |                    |              |                       | ACD labs     | Pallas Prolog | ACD labs  | Pallas Prolog |
| 4               | H                  | 0.96         | 8.23                  | 4.53         | 3.83          | 3.64  | 2.94          |
| 6               |                    | 1.14         | 9.98                  | 4.39         | 3.3           | 1.80  | 0.72          |
| 8               | 4'-F               | 0.70         | 8.14                  | 4.9          | 4.04          | 4.08  | 3.22          |
| 11              | 3'-Cl              | 1.67         | 9.05                  | 3.9          | 3.25          | 2.24  | 1.59          |
| 13              | 4'-Cl              | 1.32         | 7.98                  | 4.70         | 3.57          | 4.01  | 2.88          |
| 16              | 3'-CH <sub>3</sub> | 2.27         | 7.06                  | 5.43         | 4.57          | 5.27  | 4.41          |
|                 |                    |              | MAE                   | 3.30         | 2.42          | 2.17  | 1.45          |

On the contrary, the accuracy of all methods dropped dramatically to MAE = 1.84 if predictions were made for compounds predicted to be charged at the pH of measurements (Figure 6b). This result may suggest that the accuracy of the *pK<sub>a</sub>* prediction is very important for the total accuracy of the programs prediction. However, this is not always the case. Let us consider the series of pyrazolopyridine<sup>112</sup> derivatives that have experimental *pK<sub>a</sub>* and log *D* values for some compounds investigated in the article (Table 5). The ACD labs and Pallas predicted these compounds as uncharged at the pH (7.4) used in the experiment, while, in fact, the compounds were partially ionized at this pH according to the measurements.<sup>112</sup>

Using experimental *pK<sub>a</sub>* values to calculate log *D* using eqn [5] increased the accuracy of both these programs as shown in the table. However, their prediction accuracy remains unacceptably low. Thus, in this example the accuracy of prediction of lipophilicity for uncharged compounds, log *P*, but not the accuracy of the *pK<sub>a</sub>* prediction dominates in the total accuracy of log *D* prediction. Of course, it is also possible that in this case eqn [5] does not apply since the solvation of ionized compounds in 1-octanol should not be neglected. A poor performance of programs to predict log *D* measured by Pfizer<sup>103</sup> and AstraZeneca<sup>104</sup> could be of the same origin.

The self-learning user-training feature of the ALOGPS program can increase the prediction ability of this program. The MAE error of the ALOGPS method after the user-training with molecules from the analyzed series decreased from 0.58 and 1.50 log units to 0.22 and 0.51 log units for neutral and charged series, respectively. For series of compounds from references<sup>113</sup> and<sup>114</sup> there was a 10-fold increase in the accuracy of prediction. The overall performance of the self-training is very similar to previous results.<sup>58,59,102–104</sup> Thus, a few measured values can be used to create very precise models to predict compounds from a similar series. As was mentioned above, KOWWIN, SLIPPER, and ACD Labs provide conceptually similar methods for the user-training feature but they were not tested in this study. On the other hand, the calculated results do not allow a particular statement to be made in favor of any analyzed method.

## 5.27.10 Conclusions and Guidelines

That log *P* is an important property for 'drug design' is without doubt and that it can be calculated with reasonable accuracy for many different chemical structures is also without doubt. The importance of lipophilicity prediction

remains the focus of interest of many researchers who are concerned with its measurement and calculation and this can be seen by the series of conferences on  $\log P$  held in Lausanne and Zurich in 1995, 2000, and 2004. Similarly, the steadily rising number of publications on  $\log P$  calculation as shown in Figure 3 testifies to its importance.

In our comparison of neutral series of compounds all investigated methods performed quite well. However, such a result should not always be expected, particularly if prediction of in-house pharmaceutical data is involved.<sup>59,104</sup> Another interesting question is 'how well should the prediction work?' A review by Morris and Bruneau<sup>115</sup> compares the performance of several  $\log P$  prediction routines on some 1300 proprietary AstraZeneca compounds that have in-house measured values. The correlation between predicted and measured values ranged from as low as 0.26 to the best fit of 0.75, which is still not a very good result. The overall errors were large compared with the results reported for the sets used to develop the methods but this was a 'real' test set and thus the toughest test that any prediction technique could face. The conclusion from this comparison was that the errors seen were quite typical for all the methods when applied to novel, diverse structures and that there was no 'best' method. An important recommendation was to consider what any predicted  $\log P$  value was needed for. If all that is required is to know whether  $\log P$  is 3 or 4 then these calculation techniques may be adequate.

One of the problems with the prediction of almost any property for a new chemical structure lies in the answer to the question "how similar is this structure to the compounds used to develop the property prediction model" and "how reliable is my prediction"? There are ways to answer this question,<sup>46,98,99,109</sup> but the quality of such estimations need yet to be verified in large-scale experiments. Given the fast increase in the number of new methods to predict  $\log P$  and physicochemical and biological properties, the approaches that can cover the largest number of compounds with reasonable error and provide a reliable estimation of their applicability domain will have the most practical value in the pharmaceutical industry. To this extent sharing of data measured in major pharmaceutical firms can have a great impact on the development of the field.<sup>109</sup>

The prediction of lipophilicity of charged compounds is more problematic as has been demonstrated here and elsewhere.<sup>103,104</sup> This may be due to problems in the prediction of  $pK_a$  or  $\log P$  or partition of ions (Figure 3) that is often neglected in modeling. The recent studies to investigate the octanol/water partition coefficients' ionic species ( $\log P_1^+$ ,  $\log P_1^-$ ) were challenged by Zhao and Abraham.<sup>116</sup> This may provide a starting point for development of new approaches for  $\log D$  prediction.

A piece of simple and obvious advice in the use of any predicted value is to compare it with a measured value for a similar structure. With the development of high-throughput methods for physicochemical property measurement it should not be too much of a problem to obtain measured values for new series of interest. These new values may then also be used to improve the predictions using models that have already been built. This can be done using the user-training option provided by several programs, e.g., ACD labs, ALOGPS, SLIPPER, KOWWIN, etc., and fairly good local models for new accurate predictions within a similar series of compounds can be derived. However, a global method to provide reliable global  $\log P$  and  $\log D$  models has yet to be designed.

## Biographies

**Igor V Tetko** graduated (cum laude) from the Faculty of Physical & Chemical Biology, Moscow Institute of Physics and Technology in 1989. He received a PhD in Chemistry (application of artificial neural networks in structure–activity relationship studies) from the Biomedical Department, Institute of Bioorganic & Petroleum Chemistry, Kiev, Ukraine under the supervision of Prof A I Luik in 1994. Currently, he is a senior research scientist at this institution. He was a recipient of the Human Frontier Program Organization (HFSPO) fellowship in 1996 at the Institute of Physiology, University of Lausanne, Switzerland where he continued his postdoctoral work, as assistant diplômé and premier assistant, between 1996 and 2001. In 2001 he became a senior research scientist at the Institute for Bioinformatics, GSF-National Research Centre for Environment and Health, Neuherberg, Germany. Igor is coauthor of more than 80

publications in peer-reviewed scientific journals. His main interests include development and application of artificial neural networks and nonlinear methods of data analysis in chemistry, development of new methods for robust prediction of physicochemical properties of compounds, functional annotation of proteins, and data mining in bioinformatics. He maintains the Virtual Computational Chemistry Laboratory site ([www.vcclab.org](http://www.vcclab.org)).

**David J Livingstone** After working for almost twenty years in industrial pharmaceutical research at Wellcome and SmithKline Beecham, David Livingstone set up the ChemQuest consultancy business in 1995 offering training, advice and contract research to the chemical industry.

Dr Livingstone obtained his PhD in physical organic chemistry from the University of Dundee. He joined the Department of Biophysics and Biochemistry at Wellcome research where he was involved in the design and testing of compounds which improved the ability of hemoglobin to deliver oxygen. By working closely with the computational chemists at Wellcome he was responsible for some of the earliest routine applications of computationally derived properties in QSAR and was a pioneer in the use of pattern recognition methods in drug design.

He is now a visiting professor at the Centre for Molecular Design at the University of Portsmouth. He is a member of the editorial board of three journals and has published more than 80 papers, 12 book chapters, a textbook, and has coedited three books. His recent research interests include: the use of neural networks and other AI methods in QSAR; the prediction of toxic effects by QSAR; the characterization of intermolecular interactions; the development and application of multivariate techniques in QSAR; and the analysis of multiple response data.

5.28.1 Introduction

Most drugs are preferably given by the oral route, since this is the most convenient one for the patient, and contributes to high compliance. Good oral drugs therefore have to achieve high bioavailability ( $F\%$ ), defined as the percentage available in the systemic circulation (Figure 1). Bioavailability is a very complex absorption, distribution, metabolism, and excretion (ADME) property, and often incorrectly confused with absorption ( $A\%$ ).<sup>1,2</sup> Many of the contributing properties to bioavailability are now reasonably well characterized (Figure 2), although their interplay is less well understood. The key contributors to bioavailability include dissolution/solubility, permeability/absorption, interactions with transporters and gut wall, and liver metabolism.<sup>3</sup>

**Figure 1** Schematic definition of oral GI absorption (percentage of dose reaching portal vein) and bioavailability (percentage of dose reaching system circulation). (Reproduced from Van de Waterbeemd, H.; Gifford, E. *Nature Rev. Drug Disc.* **2003**, *2*, 192–204, by permission from Nature Reviews Drug Discovery, copyright (2003) Macmillan Magazines Ltd.)

**Figure 2** Bioavailability and absorption are complex properties that can be the unraveled into more basic contributions that offer chemists guidance in the optimization of their series and compounds.

Absorption can be defined and measured in different ways. A direct way is to measure the percentage of dose reaching the portal vein before entering the liver. Since such studies are not often performed in humans, more indirect methods are generally applied<sup>4</sup>:

- bioavailability measurement;
- excretion in urine and feces following oral administration; and
- the ratio of cumulative urinary excretion of drug-related material following oral and intravenous administration.

A number of high-throughput techniques have been developed in recent years to identify compounds with good oral absorption; as discussed elsewhere in detail (*see* 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption; 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery). These include cell-based methods such as Caco-2, and artificial membranes, such as parallel artificial membrane permeation assay (PAMPA).<sup>5</sup> These methods are resource-intensive in terms of personnel and cost, and the *in vivo* predictions not always reliable. For both reasons, there is increasing interest in developing the best possible *in silico* models for human absorption. However, it is extremely important to understand the strengths and weaknesses of such computational models, and apply these with scientific judgment in the discovery process. Also, *in silico* models are not perfect due to the limitations and accuracy in measured data to build the model, coverage of sufficient chemical space, suitability of the descriptors, and choice of the mathematical tool.

Two types of predictive modeling of human oral absorption can be distinguished. One is based on physiological principles, and attempts to model details of the dissolution/solubility, including dose and formulation variations, and permeability processes, as well as taking into account the effects of transporters and metabolizing enzymes. Others are simpler but not necessarily less successful approaches that ignore effects of solubility, dose, formulation, active transport, and metabolism. This chapter will discuss both of these modeling efforts. An excellent historical account on theoretical transport and absorption models can be found elsewhere.<sup>6</sup> Older models see a membrane as an organic compartment with aqueous compartment on either side. Based on a critical analysis of the processes involved in passive membrane crossing,<sup>6,7</sup> in newer models an aqueous pore pathway has been added to better reflect current views of a membrane.<sup>7,8</sup>

A good understanding of the key properties contributing to oral absorption provides the medicinal chemist with a powerful tool to design new molecules.

Lipinski<sup>9</sup> and others<sup>10–12</sup> were among the pioneers who pointed out that a limited set of descriptors can be defined to distinguish poor and good oral absorption. As early as 1971, in a study of red cell membranes, it was observed that “within the membrane, lipophilic permeability is modified both by steric factors and by the formation of hydrogen bonds with membrane components.”<sup>13</sup>

A quantitative rule which can be used for a qualitative prediction of oral absorption, is known as the rule-of-five,<sup>9</sup> and states that good oral absorption can be expected for compounds with a calculated  $\log P < 5$ , number of hydrogen bond donors (defined as the sum of  $-OH$  and  $-NH$  groups)  $< 5$ , the number of hydrogen bond acceptors (expressed as

the sum of N and O atoms) < 10 and a molecular weight below 500. This simple concept and its modified variants are now widely used in library and singleton design. The general approach to optimized ADME properties has been called property-based design,<sup>14,15</sup> as a complement to structure-based design. These simple rules are also often cited in the context of defining drug- or lead-likeness of compounds.<sup>16</sup>

## 5.28.2 In Vivo Permeability, Absorption, and Bioavailability

### 5.28.2.1 Biological Permeation

#### 5.28.2.1.1 Permeability principles

Molecules can cross the intestinal epithelium via two important routes for permeation, namely passive diffusion and carrier-mediated influx via transporter proteins (*see* 5.04 The Biology and Function of Transporters). For passive diffusion we can distinguish transport via the paracellular and the transcellular routes. For most drugs the passive transcellular route will be the only or major pathway from the gastrointestinal (GI) lumen to the portal vein blood. Transporter proteins may promote (influx) or hinder (efflux) the uptake of drugs.<sup>17</sup> Drugs can also be metabolized in the gut wall, in particular by cytochrome P450 3A4 (CYP3A4),<sup>18,19</sup> which obviously affects their absorption.

Some simple rules are that compounds with a molecular weight of < 200 may use the paracellular pathway to cross a membrane, and are potential candidates for active transport mechanisms, while compounds with a molecular weight above 500 have poorer membrane diffusion characteristics, and may be more susceptible to interactions with P-glycoprotein, both limiting membrane permeation and absorption. For most drugs with a molecular weight in the range of 200–500, the permeation will be driven by passive diffusion.

It has been argued in the literature that most of the absorption takes place in the small intestine (the absorption window concept).<sup>20</sup> The influence of pH, solubility, paracellular and/or transcellular membrane transfer, transporters, and metabolizing enzymes may vary along the GI tract depending on the character (neutral, acid, base, zwitterions, lipophilic, hydrophilic) of the drug.

Neutral compounds tend to cross a membrane more easily than charged species following the pH-partition hypothesis at various pH values. However, deviations have been found. These can be explained by the presence of an unstirred water layer (UWL), also called the aqueous boundary layer. A microclimate pH will prevail in this layer, changing the ionization state of the permeating solute. Ionization is in some cases less susceptible, since, although the molecule may be formally charged, this charge may be considerably delocalized, and therefore less ‘hard.’

#### 5.28.2.1.2 Human perfusion studies

Intestinal effective permeability ( $P_{\text{eff}}$ ) across the intestinal membrane can be measured by regional perfusion, as performed by Lennernäs’s group at the University of Uppsala.<sup>21</sup> Typical  $P_{\text{eff}}$  values are reported in Table 1.<sup>22</sup> A sigmoidal relationship is observed between the percentage absorbed in human ( $A\%$ ) and these  $P_{\text{eff}}$  values, which can be described by

$$A\% = 100 \times [1 - \exp(-P_{\text{eff}})] \quad [1]$$

### 5.28.2.2 Barrier Differences: Comparison of the Gastrointestinal with the Blood–Brain Barrier, Skin, and Other Membranes

Membranes differ from organ to organ in relation to the function they are fulfilling.<sup>23</sup> The basic constitution is of course similar, and consists of phospholipids. However, the concentration of, for example, cholesterol varies between membrane types. Also, the number and distribution of various influx and efflux transporters varies. In addition, cell membranes are equipped with a wide range of transporters and ion channels. In summary, cell membranes are, in principle, similar but not identical. The key molecular descriptors to describe permeability through any type of membrane (e.g., gut wall, skin, blood–brain barrier, spinal meninges),<sup>24</sup> or hepatocytes, are therefore also quite similar. This can be seen by comparing the properties used in the predictive models described in other chapters (*see* 5.28 In Silico Models to Predict Oral Absorption; 5.30 In Silico Models to Predict Passage through the Skin and Other Barriers; 5.31 In Silico Models to Predict Brain Uptake).

### 5.28.2.3 Effect of Dose, Particle Size, Metabolism, Transporter Proteins, Absorption Enhancers, and Food

The role of transporters and metabolizing enzymes in oral absorption is now much better understood, and these can have an important effect on the percentage absorbed.<sup>17–19,25</sup> Dose also plays a critical role, since at higher dosage,

**Table 1** Human effective permeability ( $n = 28$ )<sup>22</sup>

transporters and metabolizing enzymes can be saturated, and their effect is less or not visible compared with (much) lower doses. In addition, pharmaceutical factors such as particle size and the addition of absorption enhancers can modify absorption levels, as well as intake with or without food and disease state, but this is beyond the scope of this chapter and more relevant to late-stage clinical development.

#### 5.28.2.4 Species Differences

The rat is a widely used preclinical animal species for pharmacokinetics studies. Despite differences in clearance and metabolism, and often bioavailability, the volume of distribution and oral absorption appear to correlate well between

human and rat. For a set of 64 compounds the following relationship was published<sup>26</sup>:

$$\begin{aligned} A\%(\text{human}) &= 1.01 \ A\%(\text{rat}) - 0.2 \\ n &= 64, \ r^2 = 0.97, \ s = 5.6; \ F = 2176 \end{aligned} \quad [2]$$

( $r$ ,  $s$ , and  $F$  are defined in the Nomenclature). Equation [2] is particularly valid in the dose-independent absorption range. In a later study comprising 98 compounds, a nearly identical equation was derived<sup>27</sup>:

$$\begin{aligned} A\%(\text{human}) &= 0.91 \ A\%(\text{rat}) + 6.9 \\ n &= 98, \ r^2 = 0.88, \ s = 11, \ F = 675 \end{aligned} \quad [3]$$

A similar good relationship was found for monkey oral absorption data<sup>28</sup> for a set of 43 compounds:

$$\begin{aligned} A\%(\text{human}) &= 1.04 \ A\%(\text{monkey}) - 2.9 \\ n &= 43, \ r^2 = 0.97 \end{aligned} \quad [4]$$

Marked differences between human and dog in the nonlinear absorption profiles were found for some drugs. Caution is thus needed in the interpretation of dog absorption data. Therefore, a further study comparing dog absorption with that of human was less successful<sup>29</sup>:

$$\begin{aligned} A\%(\text{human}) &= 1.58 \ A\%(\text{dog}) - 55.7 \\ n &= 43, \ r^2 = 0.51 \end{aligned} \quad [5]$$

Another way of studying species differences is by use of the Ussing chamber, in which drug transport across small sections of the GI tract can be evaluated.<sup>30</sup> This has been done for rat, dog, monkey, and human tissue. This technique appears to be useful for poorly water-soluble drugs,<sup>31</sup> but is of course low throughput, and therefore mainly suited for a development setting.

### 5.28.3 In Vitro Permeability/Absorption Approaches

#### 5.28.3.1 Physicochemical Properties and Models

Models that address the pH-dependent solubility, permeability, and absorption behavior have been developed, and will be briefly presented in this section. More can be found elsewhere (*see* 5.37 Physiologically-Based Models to Predict Human Pharmacokinetic Parameters).

##### 5.28.3.1.1 Physicochemical profiling

Physicochemical profiling has a long tradition, but only recently became more automated and widely used in the pharmaceutical industry. Excellent reviews on current techniques and technologies have been published.<sup>3,32–35</sup> An overview of typical in vitro screens is given in Table 2. Among the physicochemical properties, solubility, lipophilicity, and ionization ( $pK_a$ ) are considered the most important.

##### 5.28.3.1.2 The biopharmaceutics classification system (BCS)

The BCS is a concept combining permeability and solubility, and is discussed in full detail elsewhere (*see* 5.42 The Biopharmaceutics Classification System).<sup>36</sup> The BCS classifies compounds into four classes according to their permeability and solubility characteristics: class I, high solubility and high permeability; class II, low solubility and high permeability; class III, high solubility and low permeability; and class IV, low solubility and low permeability. Therefore, measurement and/or prediction of both solubility and permeability give a good estimate of developability of a new compound, class I being the ideal profile. This has been called rational drug delivery.<sup>37</sup> A proposal has been made to extend the BCS to six classes.<sup>38</sup>

It has also been argued that, in fact, molecular size and hydrogen bonding should be the basic properties of the BCS,<sup>39</sup> since these are both strongly determinant for solubility and permeability.

### 5.28.3.1.3 Absorption potential

Absorption is not dissolution limited for most drugs, and the main permeability mechanism is by passive diffusion. However, dissolution and solubility can be an issue for some classes of drugs (*see* 5.17 Dissolution and Solubility). The absorption potential (AP) and maximum absorbable dose (MAD) approach discussed below, have been developed to deal with such compounds and get early estimates of potential limited oral absorption.

The AP of a compound is defined as<sup>40</sup>

$$AP = \log[Pf_{\text{non}}(S_w V_L)/X_0] \quad [6]$$

where  $P$  is the octanol/water partition coefficient,  $f_{\text{non}}$  the fraction of un-ionized species at pH 6.5,  $S_w$  the solubility of the un-ionized species in water,  $V_L$  the volume of the lumen contents, and  $X_0$  the dose administered. The authors found a sigmoidal relationship between AP and the fraction absorbed in humans for a small set of seven chemically diverse drugs. The general applicability has not been proven.

### 5.28.3.1.4 The maximum absorbable dose concept

The MAD concept of has been introduced,<sup>41,42</sup> and relates drug absorption to solubility via

$$MAD = S \times k_a \times SIWV \times SITT \quad [7]$$

where  $S$  is the solubility ( $\text{mg mL}^{-1}$ ) at pH 6.5,  $k_a$  is the transintestinal absorption rate constant ( $\text{min}^{-1}$ ), SIWV is the small intestinal water volume (mL), assumed to be ca 250 mL, and SITT is the small intestinal transit time (min), assumed to be 4.5 h (270 min).

### 5.28.3.1.5 Three-dimensional (3D) solubility parameters

Hansen's 3D solubility parameters related to contributions of dispersion forces, polar interactions, and hydrogen bond formation have been used to predict permeation rates for human skin and absorption rates of drugs from the rectum, and to predict GI absorption sites and absorption duration.<sup>43</sup> Such studies might help in the rational choice of dosage forms.

### 5.28.3.1.6 The absorption parameter

A model has been proposed to predict either high or low fraction absorbed for an orally administered, passively absorbed drug on the basis of a new absorption parameter  $\pi$ .<sup>44</sup> The model requires two inputs: the octanol/water partition coefficient  $P$  and the dimensionless oversaturation number  $O_{\text{lumen}}$ , where

$$\pi = P/O_{\text{lumen}} \quad [8]$$

$O_{\text{lumen}}$  is the ratio of the concentration of drug delivered to the GI fluid to the solubility of the drug in that environment, and is equal to the dose-normalized solubility for suspensions, and is unity for solutions. For a list of 98 drugs, 88% were correctly predicted solely based upon whether their  $\pi$  value is greater than or less than unity.<sup>44</sup> Since this approach relies on dose estimates, it is a late-stage candidate selection tool only.

### 5.28.3.1.7 How much solubility and permeability are required?

The MAD analysis also provides an indication to the question of how soluble a drug candidate should be, by rewriting eqn [7] as<sup>41</sup>

$$\text{minimum acceptable solubility} = MAD/(k_a \times SIWV \times SITT) \quad [9]$$

The minimum required solubility ( $S_{w(\text{min})}$  in  $\text{mg L}^{-1}$ ) of a drug has also been proposed<sup>45</sup> to satisfy the equation

$$\text{dose} \times (1 - \text{FA}) - 0.25S_{w(\text{min})} = 0 \quad [10]$$

where 0.25 is the GI volume in liters and FA is the fraction absorbed. Thus, for a 100 mg dose the solubility should be between 400  $\text{mg L}^{-1}$  (FA = 0) and 4  $\text{mg L}^{-1}$  (FA = 1). In reality, these numbers need to be higher, since dissolution is a kinetic process.<sup>45</sup>

The required level of permeability and solubility needed for oral absorption is related to potency.<sup>46</sup> Table 3 gives an indication of the levels of the required solubility, in relation to the projected dose.

**Table 3** Minimum acceptable solubility in  $\mu\text{g mL}^{-1}$  for low-, medium-, and high-permeability compounds at clinical dose<sup>46</sup>

| Projected Dose ( $\text{mg kg}^{-1}$ ) | Permeability |        |      |
|--|--------------|--------|------|
|  | Low          | Medium | High |
| 0.1                                    | 21           | 5      | 1    |
| 1.0                                    | 207          | 52     | 10   |
| 10                                     | 2100         | 520    | 100  |

### 5.28.3.2 Artificial Membranes

**Table 2** lists a number of techniques in use to estimate the in vivo permeability/AP of compounds. Artificial membranes, such as immobilized artificial membranes and the PAMPA approach, have been studied in various forms (see 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery). Other systems<sup>47</sup> include surface plasma resonance<sup>48,49</sup> and surface activity.<sup>50</sup> Membrane affinity can be measured in high throughput using solid-supported lipid membranes.<sup>51</sup>

Based on observations that transport through impregnated artificial membranes is comparable, but not identical, to Caco-2 flux,<sup>52</sup> the PAMPA method was developed.<sup>53–55</sup> Its simplicity, low cost, and high throughput makes it potentially an attractive permeability screen for drug discovery. It is not clear, however, what is the in vivo equivalent of this ‘permeability.’

In one study it was demonstrated that the percentage transport (%*T*) across the PAMPA lipid bilayer correlates to the percentage absorbed in humans (*A*%) via the following equation, derived from a training set of 50 compounds:

$$A\% = 100 \times [1 - \exp(-0.85 \times \%T)] \quad [11]$$

A test set of 42 compounds was poorly predicted with  $r^2 = 0.46$ , or  $r^2 = 0.66$  after removing two outliers. These outliers are actively transported or have a paracellular component. However, in a screening setting, this information may in general not be available. It was concluded that PAMPA might not be sensitive enough to predict human absorption, but that it might rank compound permeability.<sup>56</sup> In another study it was found that intrinsic PAMPA values correlate very well with log *D* measured in a dodecane/water solvent system.<sup>57</sup> This causes doubt about the role of the phospholipids addition in PAMPA. It also shows that PAMPA is in fact simply another type of lipophilicity scale, and its value in predicting human absorption remains unclear.

### 5.28.3.3 Cell-Based Models

Intestinal epithelial cell lines, such as Caco-2, MDCK, and HT29, are widely used to assess the AP of new compounds (**Table 2**).<sup>58,59</sup> These assays can now be run in a 96-well format. (For a detailed discussion, see 5.10 In Vitro Studies of Drug Metabolism.)

### 5.28.3.4 In Situ and Ex Vivo Models

Biological techniques involving isolated tissues (ex vivo) and perfused organs (in situ), including the GI tract, have been used to discriminate between drug candidates as models for intestinal absorption.<sup>60</sup> Since these techniques are very resource-intensive and low throughput, they are nowadays only found in a development departments, and have been replaced in discovery by higher throughput techniques discussed briefly in [Sections 5.28.3.1–5.28.3.3](#).

## 5.28.4 Physiologically-Based Models for the Fraction Absorbed

### 5.28.4.1 Rate Constants of Absorption

Drug distribution is a dynamic process, with only pseudo-equilibrium states in certain organs and membranes in the body. Hence, rates of transport might be more important to consider than equilibrium constants such as permeability

constants and partition/distribution coefficients.<sup>61</sup> Membrane permeability in centimeters per second (e.g., in Caco-2 cells) would be the typical measure for in vitro permeability, and the percentage or fraction absorbed is the measure for human absorption. Although it is widely agreed that most drugs cross a membrane by passive diffusion as the major driving force, it is less trivial which parameter describes this process best. Membrane permeability, absorption rate constant, or absorption clearance can a priori all be used.<sup>62</sup> First-order permeation rate constants ( $k_p$ ) are related to the permeability coefficient ( $P_e$ ) via

$$k_p = (A/V)P_e \quad [12]$$

where  $A$  and  $V$  are the surface and volume of the human GI tract, respectively.<sup>63</sup> Drug absorption kinetics have also been studied in Caco-2 cells,<sup>63</sup> and it was demonstrated that rate constants for cellular uptake into cerebral capillary endothelial cell monolayers might be a better predictor for brain uptake.<sup>64</sup> Absorption rates are often the preferred parameter from in situ single-pass techniques using rat.<sup>65–67</sup>

#### 5.28.4.2 Biophysical Compartment Models

The role of lipophilicity and molecular weight in absorption mechanisms has been studied by, for example, the Plá-Delfina's group, and mathematically described by biophysical compartment models. For a review, see Camenisch *et al.*<sup>6</sup> A biophysical drug absorption model termed PATQSAR (population analysis by topology-based quantitative structure–activity relationship) has been proposed, based upon the topological DARC/PELCO methodology.<sup>66</sup> The model considers the absorption process from the intestinal lumen as the sum of two resistances in series, namely an aqueous diffusional barrier and a lipoidal membrane. Following this approach, it was shown that lipophilicity plays a major role in a sigmoidal relationship with absorption rate constants ( $k_a$ ) obtained from the in situ rat gut technique<sup>67</sup>:

$$k_a = cD^d / (1 + b \times \sqrt{\text{MW} \times D^d}) \quad [13]$$

where  $D$  is the distribution coefficient (measured at pH 7), MW is the molecular weight, and  $b$ ,  $c$ , and  $d$  are regression coefficients. These  $k_a$  values can then be related to the percentage absorbed ( $A\%$ ) as follows:

$$A\% = 100(1 - e^{-k_a}) \quad [14]$$

#### 5.28.4.3 Advanced Compartmental Absorption and Transit (ACAT) Modeling

Much effort went into the detailed description of the absorption processes in so-called ACAT models.<sup>25,68–70</sup> Such oral absorption simulators are based on physiological models of the GI tract, divided into several sections. The effect of compound properties such as  $\log P$ , solubility,  $pK_a$ , and formulation properties, such as particle size, particle density, and diffusion, can be simulated to make estimates on the fraction absorbed and its effect on plasma concentration–time curves.<sup>71</sup> Attempts have also been made to include first-pass metabolism and the effect of transporters in these models.<sup>25,70,72</sup> Eventually, this may well lead to modeling of bioavailability.

Software has become available to perform simulations of the absorption process, for example GastroPlus (Simulations Plus),<sup>70</sup> or the iDEA approach (Lion Bioscience, formerly from Navicte or Trega),<sup>73</sup> as well as newer programs including Simcyp, Cloe PK,<sup>74</sup> and PK-Sim<sup>75,76</sup> (see Table 4).

#### 5.28.4.4 Physiologically-Based Pharmacokinetic (PBPK) Modeling

PBPK simulation modeling (see 5.37 Physiologically-Based Models to Predict Human Pharmacokinetic Parameters; 5.35 Modeling and Simulation of Pharmacokinetic Aspects of Cytochrome P450-Based Metabolic Drug–Drug Interactions) has developed considerably in recent years.<sup>73,74,77,78</sup> In combination with ACAT models it is therefore now possible to simulate the whole body pharmacokinetic events and to predict the human or other species most important pharmacokinetic properties, including estimates of oral absorption. The model parameters are separated into physiological parameters for the species studied and compound-specific parameters, which can be measured or estimated computationally.

Commercial programs (Table 4) include Simcyp, PK-Sim, and Cloe PK. In the future, simulation of pharmacokinetics in virtual humans will no doubt play a greater role in compound design and evaluation.

**Table 4** Commercial software and database used to predict human oral absorption

## 5.28.5 Data Sets and Molecular Descriptors for In Silico Prediction of Human Oral Absorption

### 5.28.5.1 Data Sets

The maximum number of compounds in a data set used thus far in modeling human oral absorption is 1260.<sup>79</sup> Earlier studies were done on much smaller data sets (Table 5).<sup>4,56</sup> Care needs to be taken not to mix data obtained via different methods of experimental estimation of oral absorption, as this dilutes the quality of the data. Another problem is that most data sets are skewed toward high absorption. Therefore, unlike log *P* or solubility data, there is only a relatively small data set available for predictive modeling of oral absorption. Fortunately, drugs from various chemical classes are included that cover a reasonable chemical space and diversity. Another set of data consists of human effective permeability data, which were measured for a relatively small set (*n* = 23) of selected compounds using the Gut-O-Loc balloon technique<sup>80</sup> (see Section 5.28.2.1.2). A compilation of this data has been made<sup>22</sup> (see Table 1).

**Table 5** Human oral absorption ( $n = 169$ )<sup>4</sup>

| <i>Compound</i>      | <i>Absorption (%)</i> | <i>Compound</i>     | <i>Absorption (%)</i> |
|----------------------|-----------------------|---------------------|-----------------------|
| Acarbose             | 2                     | Famotidine          | 38                    |

### 5.28.5.2 Molecular Descriptors for Oral Absorption Prediction

The calculation of many different 1D, 2D, and 3D descriptors is possible using a range of commercially available software packages, such as Sybyl, Cerius2, MOE, Dragon, Molconn-Z, Hybot, BCI, and BCUT. A more extensive discussion on descriptors used in ADME prediction can be found elsewhere (*see* 5.22 Use of Molecular Descriptors for Absorption, Distribution, Metabolism, and Excretion Predictions). Several new descriptor sets are based on quantification of 3D molecular surface properties and these have been explored for the prediction of, for example, Caco-2 permeability and oral absorption. The problem with some of these approaches is that non-intuitive descriptors are used, such as UNI and PMEP in MS-WHIM,<sup>81</sup> or the integrity moment in VolSurf.<sup>82</sup> Modelers have therefore the choice of using complex molecular descriptors and/or more intuitive, simple and obvious molecular descriptors.

The most important properties for absorption and permeability appear to be solubility, and those related to hydrogen-bonding capacity and molecular size of the drug, rather than lipophilicity alone. However, solubility is only used in approaches such as the BCS (*see* 5.42 The Biopharmaceutics Classification System) and physiologically-based models, and is described elsewhere (*see* 5.17 Dissolution and Solubility; 5.26 In Silico Prediction of Solubility). In structure-based QSAR approaches solubility is not explicitly taken into account, but many of the descriptors used in fact do encode for solubility as well (*see* Section 5.28.9 and Figure 6). A short summary of the key descriptors is given below.

#### 5.28.5.2.1 Lipophilicity

Lipophilicity is a key property in transport processes, including intestinal absorption, membrane permeability, protein binding, and distribution to different tissues and organs, including the brain.<sup>83</sup> Octanol/water partitioning ( $\log P$ ) (and distribution ( $\log D$ )) has established itself as the reference solvent system, although other systems have been studied as potential alternatives. Alkane/water partitioning is being used as a model for the blood–brain barrier. Of particular interest is also the nonaqueous heptane/glycol partitioning,<sup>84</sup> although this system is practically quite demanding. A number of comprehensive reviews on the estimation of lipophilicity have been published and are recommended for further reading<sup>85,86</sup> (*see* 5.18 Lipophilicity, Polarity, and Hydrophobicity). Due to its key importance, there is continued interest in developing good  $\log P$  calculation programs. Some computational  $\log P$  approaches are limited by a lack of parameterization of certain fragments. For the widely used CLOGP program (*see* 5.27 Rule-Based Systems to Predict Lipophilicity), missing fragments are estimated, so that a result is always produced, albeit of varying quality.<sup>87</sup> Most predictive  $\log P$  programs refer to the octanol/water partition system. Others, such as  $\log P$  for alkane/water have been discussed, or can be found in the Absolv (ADME Boxes) software (*see* Table 4).

#### 5.28.5.2.2 Hydrogen bonding

A simple measure of the hydrogen-bonding capacity of a molecule is to calculate its polar surface area (PSA), which is the sum of the fractional contributions to the surface area of all nitrogen and oxygen atoms.<sup>88</sup> The physical explanation is that the polar groups are involved in desolvation when they move from an aqueous extracellular environment to the more lipophilic interior of membranes. PSA thus represents, at least in part, the energy involved in the membrane transport of a compound. PSA is dependent upon the conformation of the molecule, but the original method was based on a single minimum energy conformation.<sup>88</sup> Later work has taken into account conformational flexibility, and coined the term ‘dynamic PSA,’ in which a Boltzmann-weighted average PSA is computed.<sup>89</sup> However, in most cases it was demonstrated that PSA calculated for a single minimum energy conformation is sufficient to produce an approximate sigmoidal relationship to intestinal absorption, and differed very little from the dynamic PSA described above.<sup>90,91</sup> A fast calculation of the PSA as the sum of fragment-based contributions has been published,<sup>92</sup> called the topological PSA (TPSA) (Figure 3), allowing the application of these calculations to large compound sets, such as combinatorial or virtual libraries. Other descriptors based on the PSA have been suggested. One example is the partitioned total surface area (PTSA).<sup>93</sup> More recently, the scaled PSA<sup>94</sup> was presented, which assigns scaling factors according to their known hydrogen-bonding characteristics. Another extension is called the high-charged PSA (HCPSA), which only counts contributions from polar atoms with high charge densities.<sup>95</sup> Alternative descriptors for hydrogen bonding include the HYBOT descriptors,<sup>96</sup> or partial atomic charges. Also, the non-polar surface area (NPSA) has been evaluated.<sup>97</sup> A further descriptor is the molecular hydrogen-bonding potential (MHBP), based on the 3D shape of a molecule.<sup>98</sup> It appears that, in particular, the hydrogen-bonding donor capacity (MHBP<sub>do</sub>) correlates better with oral absorption than the hydrogen-bonding acceptor capacity (MHBP<sub>ac</sub>).

#### 5.28.5.2.3 Size descriptors

Molecular weight is often taken as the size descriptor of choice, as it is easy to calculate and is in the chemist’s mind. However, other size and shape properties are equally simple to calculate, and may offer a better estimate of the potential for permeability. These include molecular volume, total surface area, and gyration.<sup>95</sup> Thus far, no detailed,

**Figure 3** Approximate sigmoidal relationship between human oral absorption (data from Zhao *et al.*<sup>4</sup>) and topological polar surface area (TPSA).<sup>92</sup>

systematic investigation has been reported which size descriptor is most relevant. The cross-sectional area  $A_D$ , obtained from surface activity measurements, has been reported as a useful size descriptor to discriminate compounds that can access the brain ( $A_D < 80 \text{ \AA}^2$ ) from those that are too large to cross the blood–brain barrier.<sup>99</sup> Similar studies have been performed to define a cut-off for oral absorption.<sup>100</sup>

#### 5.28.5.2.4 Topological descriptors

There are many ways to use molecular topology as a basis to define molecular topological descriptors (*see* 5.22 Use of Molecular Descriptors for Absorption, Distribution, Metabolism, and Excretion Predictions). The advantage is that these are easy to calculate from the 2D structure. The disadvantage is that the direct relationship to structure is not intuitive, and their use in QSAR approaches is therefore often debated. It has been demonstrated that so-called electrotopological state indices (*see* 5.23 Electrotopological State Indices to Assess Molecular and Absorption, Distribution, Metabolism, Excretion and Toxicity Properties) can be useful to derive predictive models for oral absorption.<sup>101–103</sup> Simple counts of atom types are another easy way to derive useful topology descriptors.<sup>104</sup>

#### 5.28.5.2.5 Other descriptors

Many other molecular descriptors have been tried out in quantitative structure–absorption relationships, as will be discussed in the sections below.

Often, AP can be rapidly estimated using a simple set of descriptors. An evaluation of the use of properties generated with the well-known ACD package (Advanced Chemistry Development, Toronto, Canada) was reported.<sup>105</sup> These ACD properties are derived from 2D graphs, and need no 3D optimization. These simple methods appear to be predictive, with correlation coefficients in the range of 0.73–0.95, depending on the predicted property. This can be considered as sufficient to screen virtual libraries, but insufficient for lead optimization.

Flexibility of a molecule, expressed as the number of free rotatable bonds, has been proposed as an important factor for bioavailability/absorption,<sup>106</sup> but should be used with caution.<sup>107</sup>

Molecular hashkeys have been proposed as a descriptor encoding the surface properties of a molecule, which can be used to predict, for example, properties such as  $\log P$  and oral absorption, applying neural networks or machine learning.<sup>108</sup>

### 5.28.6 Computational Prediction of Human Oral Absorption

#### 5.28.6.1 Types of Models

ADME modeling and, in particular, the prediction of intestinal absorption has been discussed extensively in the literature.<sup>5,16,23,109–118</sup>

For the medicinal chemist the most elegant approach to optimizing compounds for high oral absorption is the modification of a single property that easily relates to molecular structure. We therefore will first discuss the relationship between oral absorption and some of the most popular descriptors. However, complex ADME properties such as oral absorption are more likely to be dependent on a subset of fundamental properties. In Abraham's linear solvation energy relation method, a set of five descriptors has been used to predict a range of solvation-related properties such as partition coefficients in various solvents, blood–brain barrier penetration, and oral absorption. The serious limitation of this approach is that the five descriptors might be intercorrelated, and therefore the equation is statistically not robust.

The most general approach to derive a quantitative structure–property relationship is to select the appropriate subset of descriptors to build a predictive model from a large number (hundreds) of possible descriptors. This might indeed lead to statistically sound models, but suffer from interpretability ('black box' models). In quantitative structure–activity relationship (QSAR) studies as presented here to predict human oral absorption, a key question is: what are good and appropriate descriptors to build the model? The simplest approach is to look at correlations with individual descriptors. Another approach is to make an educated guess, as is done in the Abraham equation. The most common approach is to use a multivariate technique, and let the best descriptors emerge from a larger pool. There are basically two main approaches to deal with the descriptor selection problem, the filter and the wrapper approaches,<sup>119,120</sup> but further discussion is beyond the scope of this chapter.

Good introductory texts to QSAR modeling can be found in the literature.<sup>121,122</sup> The key elements of a QSAR analysis are descriptors and a model. In the remainder of the chapter we have chosen a mixed approach in presenting the various attempts published in the literature. Some headings refer to a particular set of descriptors, while other headings point to a mathematical technique used to derive the model.

The statistics for the equations given below have the following meaning:  $n$  is the number of compounds,  $r$  the correlation coefficient,  $q$  the cross-validated correlation coefficient using the leave-one or leave group out method,  $s$  the standard error of the regression, rms(e) the root mean square (of the standard error), and  $F$  is the Fisher statistic.<sup>122</sup> If reported in the original source, the regression coefficients include either their standard deviation or 95% confidence interval.

## 5.28.6.2 Correlations with Single Descriptors

### 5.28.6.2.1 log $P$ /log $D$ and $\Delta$ log $P$

Most of the membrane models developed in the 1970s used partition coefficients (log  $P$ ) as the key descriptor, and it was later demonstrated that molecular size should be considered as an additional factor. It was suggested that the relationship between lipophilicity and Caco-2 flux could best be described by a set of sigmoidal curves.<sup>123</sup> This study underlined how complex these relationships are, and why one rarely finds good (linear) correlations using single properties alone.

We mention here also the  $\Delta$ log  $P$  approach,<sup>124,125</sup> although this descriptor is in fact a measure for hydrogen bonding and thus similar to the PSA. For a series of azole endothelin antagonists,  $\Delta$ log  $P$  was used to improve their oral absorption.<sup>126</sup>

### 5.28.6.2.2 Molecular weight

It has frequently been observed that permeability, and therefore absorption and bioavailability, decreases with increasing molecular weight. Furthermore, biliary excretion tends to increase with increasing molecular size. Both principles have been nicely illustrated in studies on the peptide-like renin inhibitors.<sup>11</sup> In the analysis leading to the 'rule-of-five,' it was found that 90% of all drugs in the World Drug Index have a molecular weight below 500 da.<sup>9</sup> This observation can therefore be taken as a guide in the design of orally active compounds.

### 5.28.6.2.3 Polar surface area

Following the first report on the use of the PSA to predict central nervous system (CNS) uptake,<sup>88</sup> this also became a popular descriptor for membrane permeability, for example in the prediction of the oral absorption of beta-blockers<sup>89</sup> and the design of peptide analogs.<sup>127</sup> There is a clear sigmoidal trend when plotting human oral absorption data against PSA (see Figure 3). The sigmoidal relationship can be described by

$$A\% = 100/[1 + (\text{PSA}/\text{PSA}_{50})^7] \quad [15]$$

where  $A\%$  is percentage of orally absorbed drug,  $PSA_{50}$  is the PSA at the 50% absorption level, and  $\gamma$  is a regression coefficient.<sup>93</sup> Also, a Boltzmann sigmoidal (general form given in eqn [16]) curve has been used<sup>90</sup>:

$$y = \text{bottom} + (\text{top} - \text{bottom}) / [1 + \exp(x_{50} - x) / \text{slope}] \quad [16]$$

$$A\% = 100 / [1 + \exp(PSA_{50} - PSA) / \text{slope}] \quad [17]$$

As a guide, orally active drugs that are transported by the transcellular route should not exceed a PSA of about  $120 \text{ \AA}^2$ .<sup>128,129</sup> Similarly, for good brain penetration of CNS drugs, this number should even be tailored to  $PSA < 100 \text{ \AA}^2$ <sup>129</sup> or even smaller,  $< 60\text{--}70 \text{ \AA}^2$ .<sup>128</sup>

Poorly absorbed compounds have been identified as those with a  $PSA > 140 \text{ \AA}^2$ . Many compounds do not show only simple passive diffusion but are affected by active carriers, efflux mechanisms involving P-glycoprotein and other transporter proteins, and gut wall metabolism. A further refinement in the PSA approach is expected to come from taking into account the strength of the hydrogen bonds, which in principle is the basis of the HYBOT approach described later.

An absorption model based on the combination of the PSA and lipophilicity (AlogP98) has been suggested,<sup>112,130</sup> distinguishing between compounds that are well absorbed ( $A\% > 90\%$ ) or poorly absorbed ( $A\% < 30\%$ ).

#### 5.28.6.2.4 Nonpolar surface area

The Caco-2 cell membrane permeability of three series of peptides and endothelin antagonists could be predicted by a theoretical model that considered both the polar ( $PSA_d$ ) and nonpolar ( $NPSA_d$ ) parts of the dynamic molecular surface area of the molecules.<sup>97,131</sup> The three peptide series were AcHN-X-phenethylamides, AcHN-XD-Phe-NHMe derivatives and D-Phe-oligomers. Experimental  $\log D$  (octanol/water) values gave a rank order of permeability within each series, but failed across the three series. Possibly, some of the compounds are substrates for one or more transporters present in Caco-2 cells, but this needs further investigation. A strong correlation was found between  $\log D$  and  $NPSA_d$  ( $r^2 = 0.96$ ). A good sigmoidal correlation was obtained when  $P_{app}$  (Caco-2 permeability) was plotted against a linear combination of  $PSA_d$  and  $NPSA_d$ . Thus, this model predicts permeability based on a combination of hydrogen-bonding capacity and hydrophobicity. The latter is thought to be related to the transport of a compound from the aqueous environment into the polar head group region of the membrane, while hydrogen bonding is detrimental to transport into the nonpolar interior of the membrane.<sup>131</sup>

#### 5.28.6.2.5 Percentage polar surface area

The percentage polar surface area (%PSA) has been investigated as another surface property,<sup>127</sup> but without success.<sup>97,131</sup> %PSA is a number between 0 and 100, and is not related to more fundamental phenomena such as solvation energy, as is the case with the PSA.

#### 5.28.6.2.6 Sigmoidal surface fit

Single-descriptor approaches often assume a sigmoidal relationship between a property and oral absorption. These relationships have been studied in more detail<sup>132</sup> and extended to a surface fit taking into account two properties simultaneously. Both symmetric and asymmetric sigmoidal relationships were compared, and often found to perform equally. Models were built for 93 compounds and tested for 31 compounds using descriptors calculated with the MOE software. It was found that the total hydrogen bond descriptor ( $a_T$ ) and the calculated  $\log P$  (SlogP, see 5.27 Rule-Based Systems to Predict Lipophilicity) were most important in the models. The best symmetric surface was given by

$$A\% = 33.1(\pm 0.1) \{ \pi/2 + \arctan[-0.42(\pm 0.09)a_T + 0.39(\pm 0.09)\text{SlogP} + 3.9(\pm 0.9)] \} \quad [18]$$

$$n = 124, \quad r^2 = 0.80, \quad q^2 = 0.79, \quad s = 13.4$$

where  $A\%$  is the percentage human intestinal absorption (Figure 4).

#### 5.28.6.3 Solvation Equation

Instead of looking at only one or two descriptors, a linear free-energy relationship approach based on the 'solvation equation' has been used to predict solution related properties such as solubility, partitioning, blood–brain transport, and GI absorption. These properties are correlated with a set of five molecular descriptors, called Abraham descriptors,

**Figure 4** Surface fit of experimental human intestinal absorption data ( $n=93$ ) using the descriptors  $a_T$  and SlogP.<sup>132</sup> (Reproduced from Deretey, E.; Feher, M.; Schmidt, J. M. *Quant. Struct.-Act. Relat.* **2002**, 21, 493–506, with permission of Wiley-VCH Verlag GmbH.)

which are excess molar refraction ( $E$ ), solute polarity/polarizability ( $S$ ), solute overall acidity ( $A$ ) and basicity ( $B$ ), and the McGowan characteristic volume ( $V$ ).

In a detailed study, the human intestinal absorption of 241 drugs was evaluated.<sup>4</sup> After careful consideration of the data, only 169 compounds (Table 5) could be used to develop the absorption model.

$$A\% = 92 + 2.94E + 4.10S + 10.6V - 21.7A - 21.1B$$

$$n = 169, \quad r^2 = 0.74, \quad s = 14, \quad F = 93 \quad [19]$$

This equation shows that size is beneficial and hydrogen bonding is detrimental to oral absorption. The quality and error of the original data are such that the final model accounts for 74% of the variance and that the predictions have a 14% standard error.

By transforming the data to the effective rate of absorption ( $GI \, k_{\text{eff}}$ ), the following equation was obtained<sup>133</sup>:

$$\log GI \, k_{\text{eff}} = 0.54 - 0.03E + 0.01E + 0.14S - 0.41A - 0.51B + 0.20V$$

$$n = 127, \quad r^2 = 0.79, \quad s = 0.29, \quad F = 0.84 \quad [20]$$

The Abraham descriptors can be calculated by the AbSolv program (available via ADME Boxes; see Table 4). It is important to note that in the Abraham approach, as exemplified by eqns [19] and [20], the selected five descriptors are always incorporated into the equation, despite the fact that some may be intercorrelated.<sup>134</sup> This is not good statistical practice, and may lead to an overestimation of the relevance of the equation, and therefore its general applicability.

#### 5.28.6.4 Multivariate Models

##### 5.28.6.4.1 ADAPT

Over the years, Jurs's group has developed a range of molecular descriptors, which have been implemented in the ADAPT software and used to predict properties such as water solubility and human intestinal absorption.<sup>135</sup> From a larger pool of descriptors, a neural network model selected six key descriptors. Of these six descriptors, three encode for size (cube root of gravitational index), shape (SHDW-6, the normalized 2D projection of the molecule on the YZ plane), and flexibility (NSB, the number of single bonds), while the three others are related to hydrogen-bonding properties (CHDH-1, the charge on donatable hydrogen atoms; SCAA-2, the surface area multiplied by the charge of hydrogen bond acceptor atoms; and SAAA-2, the surface area of hydrogen bond acceptor atoms). A 16% rms error was observed in an external test set.

#### 5.28.6.4.2 MolSurf

The program MolSurf offers a number of descriptors related to physicochemical properties, such as lipophilicity, polarity, polarizability, and hydrogen-bonding ability. Their relevance for predicting oral absorption was investigated using a partial least squares (PLS) analysis.<sup>136</sup> Good statistical models were obtained, revealing that properties associated with hydrogen bonding had the largest impact on absorption and should be kept to a minimum. However, MolSurf analysis is detailed, computationally expensive, and not automated.

#### 5.28.6.4.3 VolSurf

The VolSurf descriptors are a set of descriptors related to the surface properties of a molecule, and are calculated using an H<sub>2</sub>O and a DRY probe in the program GRID. These descriptors have been evaluated in correlations with human absorption.<sup>82,137</sup> A descriptor called 'integy moment' was defined, analogous to the dipole moment, and describes the distance from the center of mass to the barycenter of polar interaction sites at a given energy level. A high integy moment reflects a clear separation between polar and nonpolar parts of a molecule. Hydrophobicity and high integy moments are positively correlated with human intestinal absorption, whereas polarity and a high concentration of polar interaction sites on the molecular surface are detrimental to absorption.

VolSurf has also been used in a successful in silico prediction of intestinal lymphatic transfer of a series of compounds co-administered with a long-chain triglyceride.<sup>138</sup>

#### 5.28.6.4.4 HYBOT

Based on experimental thermodynamic data, hydrogen bond donor and acceptor descriptors have been developed, which have been correlated to permeability and absorption data.<sup>96</sup> It was concluded that both hydrogen bond donors ( $\Sigma\text{Cd}$ ) and acceptors ( $\Sigma\text{Ca}$ ), often in combination with a steric descriptor, are important physicochemical properties for permeation processes. However, due to the frequently observed intercorrelation between donors and acceptors, only the more significant one can be used in multiple linear regression equations, though this problem can be avoided using other statistical tools such as the PLS or neural networks. It may also be more sensible to use the combined acceptor plus donor term.<sup>139,140</sup>

Raevsky<sup>139,141</sup> and others<sup>45,142</sup> pointed out that data presented as the percentage effect or fractional effect such as oral absorption are problematic in linear regression techniques, because predictions can be negative or > 100%. This difficulty may be overcome by transforming the values into logit values (e.g., for the fraction absorbed, FA):

$$\text{logit FA} = \log[\text{FA}/(1 - \text{FA})] \quad [21]$$

These logit FA values can be correlated to a set of independent variables or descriptors. Thus a nonlinear equation can be derived as follows:

$$Z = \text{logit FA} = \log[\text{FA}/(1 - \text{FA})] \quad [22]$$

$$\text{FA}/(1 - \text{FA}) = 10^Z \quad [23]$$

$$\text{FA} = 1/(1 + 10^{-Z}) \quad [24]$$

where

$$Z = f(\text{Xi}) \quad [25]$$

where Xi is a range of relevant physicochemical descriptors.

For a set of 31 compounds, the following nonlinear sigmoidal equation was found<sup>131</sup>:

$$\begin{aligned} A\%/100 = \text{FA} &= 1/(1 + 10^{-[5.05 - 0.36\Sigma\text{Ca} + 0.26\Sigma\text{Cd}]}) \\ n &= 31, \quad r^2 = 0.95, \quad q^2 = 0.92, \quad s = 0.09 \end{aligned} \quad [26]$$

Addition of other descriptors had only little influence. This equation demonstrates the key importance of hydrogen bonding for absorption processes. Such a relationship is very similar to the one obtained using the PSA as another descriptor for hydrogen bonding. However, it appears that these equations do not perform satisfactorily with a test set.<sup>143</sup> In more recent work, QSARs based on the HYBOT descriptors have been combined with a similarity approach,<sup>141,142,144</sup> leading to eqn [27].<sup>141</sup> The prediction is obtained using a model derived from a training set and the

difference of properties between the molecule of interest, virtual or real, and a similar drug with known oral absorption.

$$\begin{aligned} A\%/100 = FA &= 1/(1 + 10^{(-\log[FA_{\text{nrs}}/(1-FA_{\text{nrs}})] - 0.36\Delta\Sigma\text{Ca}(\text{drug-nrs}) + 0.26\Delta\Sigma\text{Cd}(\text{drug-nrs}))}) \\ n &= 100, \quad r^2 = 0.89, \quad q^2 = 0.89, \quad s = 0.11 \end{aligned} \quad [27]$$

where  $FA_{\text{nrs}}$  is the fraction absorbed for a nearest related structure,  $\Sigma\text{Ca}(\text{drug-nrs})$  is the difference in calculated Ca (HYBOT hydrogen bond acceptor factors), and  $\Sigma\text{Cd}(\text{drug-nrs})$  the difference in calculated Cd (HYBOT hydrogen bond donor factors).

#### 5.28.6.4.5 Other multivariate studies

In a study of several data sets,<sup>130</sup> the most appropriate factors to consider predicting passive absorption from structure were lipophilicity, hydrophilicity, and size. The authors chose AlogP98 (*see* 5.27 Rule-Based Systems to Predict Lipophilicity), PSA, and molecular weight as variables to measure these factors. It was concluded that molecular weight was a redundant descriptor since it was seen as a component of both PSA and AlogP98. Sharp, nonlinear drops in permeability were observed below certain values for both descriptors, in line with the sigmoidal relationships observed by many others. The authors stressed the need for large experimental data sets to advance ADME models in general and, in particular, prediction of oral absorption and bioavailability.

Topological descriptors have been used to develop intestinal absorption models. Examples include electro-topological state indices.<sup>101,102</sup> Also, structural descriptors using the CASE program led to successful models.<sup>145</sup> An external test set of 50 compounds had a standard deviation of 12.3% using the model based on 417 drugs.<sup>145</sup>

Using a set of 219 atom-type descriptors and PLS discriminant analysis (PLS-DA) a human intestinal absorption predictive model was derived.<sup>146</sup> The data set<sup>4</sup> of 169 drugs was divided into three classes: >80% absorption, 20–80% absorption, and <20% absorption. A five-component PLS-DA model separated the compounds into these classes with an  $r^2 = 0.92$  and  $q^2 = 0.79$ .

### 5.28.6.5 Other Approaches

#### 5.28.6.5.1 GRID

Using the program GRID (*see* 4.11 Characterization of Protein-Binding Sites and Ligands Using Molecular Interaction Fields), hydrogen-bonding capacity could be quantified using an NH amide probe to explore the hydrogen bond acceptor regions, a carbonyl probe to detect hydrogen bond donor areas, and a water probe to characterize both.<sup>147</sup> The water surface interaction map generated by the water probe appears to be a good descriptor in the prediction of drug permeability, although no improvement over previously reported methods was obtained.

#### 5.28.6.5.2 Neural networks

Neural networks have the attractive property that they model nonlinear relationships. However, they have the disadvantage that they look more like a ‘black box’ approach. Various approaches and different architectures of neural nets have been used in the prediction of biological properties, the most useful of which appear to be the back-propagation and Kohonen nets.

Through the combination of simulated annealing and a neural network approach, a seven-descriptor model for a set of 120 compounds was derived to estimate human intestinal absorption.<sup>148</sup> The chosen descriptors are easy and fast to compute, and therefore would allow screening of larger libraries. However, the overall error of prediction is about 25%, which probably reflects the error on the input data. Clearly, an extension of the database, particularly if populated over the whole 0–100% absorption range, would help to improve the model.

In another study, a set of 86 drug compounds<sup>135</sup> was investigated.<sup>149</sup> Although 57 global molecular descriptors were initially used, in the final model, 15 input descriptors were chosen with a genetic algorithm. The most significant descriptors relate to lipophilicity, conformational stability and inter-molecular interactions reflected by polarity and hydrogen bonding. The rms error for an external prediction set was 16.0%, which is comparable to experimental error in the human absorption data.

The same 86 compounds<sup>135</sup> were studied using only 2D topological descriptors.<sup>150</sup> The data were modeled with a general regression neural network (GRNN) and a probabilistic neural network (PNN), which are variants of normalized radial basis function networks. Both performed well, with an rmse of 22.8% for the external prediction set for a GRNN model, and 80% of the external prediction set were correctly classified for the PNN model.

A set of 141 topological descriptors were used to build an artificial neural network (ANN) model for a set of 417 therapeutic drugs.<sup>102</sup> This was validated by testing 195 new drugs not used in model building; 92% of the compounds were predicted within 25% of their reported value. The PSA and log *P* appear to be important additional properties in the ANN model.

A small set of 28 compounds was studied using a neural network and so-called CODES topological descriptors.<sup>151</sup> This set is too small to give meaningful predictions.

#### 5.28.6.5.3 Decision trees and other rule-based approaches

Recursive classification regression trees (CARTs) are a data-mining tool suitable for exploration of relatively small data sets, as is the case with human oral absorption data. The original CART method is used to bin compounds in a number of predefined classes. A modified version is capable of nonlinear regression, and can produce numerical outputs.<sup>79</sup> A set of 1260 structures was used to build recursive partitioning models for an 899-compound training set and a 362-compound validation set. The fraction of the dose absorbed was divided into six classes of equal size. A set of 28 descriptors was used for the modeling of oral absorption. Two test sets of unpublished proprietary compounds showed 79–86% prediction plus/minus one class. This error level is comparable to current in vitro/in vivo correlations. This in silico approach also appears to be superior to predictions based on data obtained with artificial membranes.<sup>79</sup>

A sequence of recursive partitioning analyses based on multiple physicochemical and structural descriptors for a set of over 1000 druglike compounds using the Algorithm Builder software led to a rule-based algorithm for intestinal permeability.<sup>152</sup> The fragment builder in this software has some unique properties different from other approaches. Interestingly, the model can easily be retrained as compounds with new fragments are added to the training set. The model is currently a two-class model, where poor absorption is <10% and good absorption is >15%. The general applicability of this approach using, for example, different cut-offs for poor, medium, and good absorption needs to be demonstrated.

#### 5.28.6.5.4 Support vector machines (SVMs)

The relatively new QSAR method of SVMs, a machine learning technique, has been used on human intestinal absorption data for 164 compounds.<sup>119</sup> A new descriptor selection algorithm picked out the 50 most relevant descriptors from a pool of in total 2929 descriptors. The high relevance of the TPSA was confirmed in this work. A 12.7% error rate in the predictions was found.

### 5.28.6.6 Hybrid Models Using In Silico and In Vitro Data (In Combo Approach)

QSAR descriptors can be purely computational or experimental. If a mixture of both is required, this can be called an in combo approach.<sup>78</sup> An example is given below.

Relationships with the PSA and several other descriptors using the MOLCAD module within SYBYL have been studied for effective permeability data in humans, based on a single minimum energy conformation.<sup>153,154</sup> For the 13 passively transported compounds in the data set, a linear correlation with the PSA was obtained with  $r^2 = 0.76$ . A plot of these data shows that the trend is possibly sigmoidal, but with some scatter. Even more scatter is observed when all the compounds in the study ( $n = 22$ ) are plotted against the PSA. Clearly, the PSA alone is insufficient to account for effective permeability or absorption. In this case, the cut-off for poor absorption seems to be at the lower PSA values of around  $100\text{\AA}^2$ . This may be due to a scaling difference between methods used here and by others. The outliers, identified as glucose, levodopa, and amoxicillin, are believed to have active uptake mechanisms, and therefore are better absorbed than predicted by the PSA. The following equations have been obtained<sup>153</sup>:

$$\log P_{\text{eff}} = -0.01\text{PSA} + 0.19 \log D_{5.5} - 0.24\text{HBD} - 2.88 \quad [28]$$

$$n = 13, \quad r^2 = 0.93, \quad q^2 = 0.90$$

$$\log P_{\text{eff}} = -0.01\text{PSA} + 0.16\text{CLOGP} - 0.24\text{HBD} - 3.07 \quad [29]$$

$$n = 13, \quad r^2 = 0.88, \quad q^2 = 0.85$$

where  $P_{\text{eff}}$  is the in vivo permeability measured with a single-pass perfusion technique.<sup>21,80</sup>  $\log D_{5.5}$  is the octanol/water distribution coefficient measured at pH 5.5, believed by the authors to be the most relevant value for absorption as it reflects the pH in the unstirred mucus layer adjacent to the intestinal wall. HBD is the number of hydrogen atoms connected to nitrogen and oxygen atoms (i.e., the total potential hydrogen-donating capacity). Since these models are

based on only 13 compounds, the three-parameter eqns [28] and [29] have limited statistical significance. No definitive conclusions can be drawn on the role of a lipophilicity descriptor. The best result was obtained by combining two hydrogen bond descriptors (PSA and HBD) and the experimental  $\log D$  at pH 5.5. However, the partial correlation between the PSA and HBD is 0.82. This sheds serious doubt on eqns [28] and [29], despite the fact that it was derived using PLS. A larger data set is required to more fully explore this approach. The continuous variable PSA is strongly correlated with a simple count of hydrogen bonds. However, the PSA is probably a better reflection of hydrogen-bonding capacity, since it takes conformational behavior into account. Various alternatives for hydrogen-bonding descriptors were explored.<sup>154</sup> Combinations of a general hydrogen-bonding descriptor and a lipophilicity descriptor give the best models.<sup>154</sup>

#### 5.28.6.7 Commercial Softwares

In the discussion presented above, a number of commercial packages have been mentioned, and which are listed in Table 4. Some of these can be used to generate descriptors and/or to generate the models. A number of these products have a preprogrammed human oral absorption model 'off the shelf.' Also included in this overview are sources for oral absorption data.

#### 5.28.7 Prediction of Caco-2 Flux

One in vitro approach to predict human intestinal absorption is to use Caco-2 cell permeability data. A more indirect method consists of predicting Caco-2 flux from physicochemical and/or structural properties. These are models of a model for oral absorption, and one might question the predictive power of such an approach. Among others,<sup>155</sup> a number of predictive Caco-2 models are discussed here.

Initially, it was thought that only poor linear correlation between Caco-2 flux and  $\log D$  values is observed.<sup>156</sup> However, the relationship between permeability and lipophilicity is in fact thought to be sigmoidal,<sup>6,7,123,140</sup> and can be described as

$$A\% = (0 - 100)/[1 + (\log D/\log D_{50\%})^k] + 100 \quad [30]$$

where  $A\%$  is the percentage of orally absorbed drug,  $\log D_{50\%}$  is the  $\log D$  at the 50% absorption level, and  $k$  is a slope factor<sup>93</sup> (compare also to eqns [14]–[17]). Using human absorption data,<sup>157</sup> a sigmoidal correlation between Caco-2 data and octanol/water  $\log D$  values was observed for compounds within the molecular weight range of 200–500.<sup>12</sup> It was also suggested that, in fact, such a sigmoidal relationship exists for each group of compounds with identical molecular weight.<sup>123</sup> Thus, a plot of  $\log P_c$  (permeability) against  $\log D$  (lipophilicity) becomes meaningful when adding the molecular weight (size) contour plots.

However, such relationships to lipophilicity are not always clear-cut. For the solvents octanol, hexadecane, and propyleneglycol dipelargonate (PGDP) as lipophilicity scales, no simple relationships were found for a set of 51 structurally diverse low molecular weight compounds and their Caco-2 permeability coefficients.<sup>158</sup> Furthermore, in the same study no significant correlation was found using  $\Delta \log D$  values, derived from the difference between  $\log D_{\text{hex}}$  and either  $\log D_{\text{oct}}$  or  $\log D_{\text{PGDP}}$  as a measure for hydrogen bonding.

Prediction of Caco-2 permeability using computed molecular properties has been studied by several groups using multiple linear regression (MLR),<sup>95,140</sup> principal component analysis, cluster analysis, linear discriminant analysis (LDA),<sup>159</sup> PLS,<sup>160–163</sup> 3D-QSAR,<sup>164</sup> and membrane-interaction QSAR.<sup>165</sup>

Simple MLR equations can be derived combining a size and hydrogen bond descriptor, such as in

$$\log P_{\text{app}} = 0.008(\pm 0.002)\text{MW} - 0.043(\pm 0.008)\text{PSA} - 5.17(\pm 0.61) \quad [31]$$

$$n = 17, \quad r^2 = 0.69$$

where  $P_{\text{app}}$  is the permeability constant across Caco-2 cells and MW is the molecular weight of the compound.<sup>132</sup> Interestingly, this equation contains no lipophilicity term such as  $\log P$  or  $\log D$ .

In a study of 100 compounds for which Caco-2 data were collected from the literature, cellular permeability was primarily dependent upon the experimental distribution coefficient ( $\log D$ ), the high-charged PSA (HCPA), and the radius of gyration ( $r_{\text{gyr}}$ ).<sup>95</sup> The fraction of rotatable bonds ( $f_{\text{rotb}}$ ) had only a minor contribution.

$$\log P_{\text{app}} = 0.25[-1.8 < \log D < 2.0] - 0.0048\text{HCPA} - 0.19r_{\text{gyr}} + 1.06f_{\text{rotb}} - 4.39 \quad [32]$$

The authors used a spline function for the  $\log D$  term. This term equals the experimental  $\log D$  if within the range  $-1.8$  to  $2.0$ , otherwise it will be either  $-1.8$  for compounds with a  $\log D$  below that value or  $2.0$  for compounds with a higher  $\log D$ . A regression with splines does allow incorporating features that do not have a linear effect over the full property range. The HCPSA takes into account that only highly charged polar atoms will be involved in hydrogen bonding. The radius of gyration is a molecular shape descriptor believed to be more relevant for membrane permeability than molecular weight. Using a test set of 23 compounds,  $r^2 = 0.78$  was found, which is not impressive.

In a PLS study, descriptors including polarization, solvent accessible surface area, hydration energy, heat of formation, and dipole moment have been explored.<sup>161</sup> The 51 compounds in this study were from Yazdani *et al.*<sup>158</sup> Increased  $\log D$  and hydration energy facilitate permeability, and an increased dipole moment of the molecules has a negative effect on the Caco-2 flux. Hydrogen bonding is one of the important factors associated with permeability.

Using 70 descriptors, including lipophilicity, hydrogen bonding, polar surface area, size and charge descriptors, and some nonlinear terms, a PLS model for Caco-2 permeability was derived ( $n = 46$ ,  $r^2 = 0.79$ ,  $q^2 = 0.65$ ) and tested on two external test sets.<sup>162</sup> For a small test set ( $n = 5$ ) the rmse was  $0.45 \log P_{\text{app}}$  units. Overall, 82% of the compounds were correctly classified as low, medium, or high permeability.

A model predicting Caco-2 cell permeability from 2D topological descriptors was developed using a combined genetic algorithm and a PLS method for 73 structurally diverse compounds.<sup>163</sup> The final PLS model consisted of 12 principal components of 24 descriptors, and gave a correlation coefficient of 0.89. However, this must be considered as a very high number of principal components and therefore unreliable for prediction.

A novel set of topological descriptors obtained from graph theoretical methods and LDA as well as MLR was used for 33 structurally diverse drugs and another 18 drugs to test the models.<sup>159</sup> The LDA model discriminates between good and poor-moderate permeability with a global classification of 87.9%.

3D-QSAR approaches have been used to predict permeability through Caco-2 cells for a series of close structural analogs.<sup>166</sup> A comparison was made between Catalyst, CoMFA, VolSurf, and genetic function approximation (GFA) with MS-WHIM descriptors.<sup>81</sup> The Catalyst pharmacophore model appears to give the best predictions (test set versus observed permeability  $r^2 = 0.94$ ). The GFA/WHIM approach gave the poorest results.

Using a data set of 712 compounds for which permeability data were measured using Caco-2 and MDCK cells, a two-class model (above and below  $4 \times 10^{-6} \text{ cm s}^{-1}$ ) was developed using nearest-neighbor classification.<sup>167</sup> The key descriptors were the molecular surface, the number of flexible bonds, the number of hydrogen bond acceptors, the number of hydrogen bond donors, and the PSA. In an external test set of 112 compounds, 93% of the compounds could be classified in one of two permeability classes. The misclassification rate was 15%, and no compounds were misclassified in the nonpermeable group.

One of the problems of developing a general Caco-2 model is the interlaboratory differences in the data. To overcome this problem, a 'latent membrane permeability' concept was developed.<sup>168</sup> In this approach, Caco-2 data from different sources are treated by a computational algorithm to extract the common relationship between the membrane permeability and properties of the compounds.

## 5.28.8 Prediction of Parallel Artificial Membrane Permeation Assay (PAMPA) Data

PAMPA<sup>53</sup> is discussed in more detail elsewhere (*see* 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery). For a set of 43 ionizable compounds and using the Abraham linear free-energy relation method and using calculated Abraham descriptors, a predictive PLS model has been derived for the intrinsic PAMPA permeability ( $P_{0 \text{ PAMPA}}$ )<sup>169</sup>:

$$\log P_{0 \text{ PAMPA}} = -4.03 + 1.06E - 0.95S - 2.26A - 2.84B + 2.58V \quad [33]$$

$n = 43, \quad r^2 = 0.78, \quad q^2 = 0.69, \quad \text{rmse} = 0.92$

In this study, membranes were made from a 2% solution of dioleoylphosphatidylcholine in dodecane. Rigorous stirring compensated for the UWL near the membrane, and to derive the intrinsic permeability for the neutral species. The model clearly demonstrates the relative contributions of various factors to PAMPA permeability. It is unclear how this relates to *in vivo* permeability. It should also be noted, however, that about 20% remains unexplained, which is considerable for a relatively simple physicochemical model. This number is also of the same order as the coefficient of variance of the assay.

In a subsequent study, the Abraham descriptors were measured, leading to a statistically improved equation<sup>170</sup>:

$$\log P_{\text{OPAMPA}} = -3.45 + 0.43E - 1.42S - 3.37A - 4.79B + 4.30V \quad [34]$$

$$n = 41, \quad r^2 = 0.94, \quad \text{rmse} = 0.49$$

This equation is very similar to the expressions obtained for alkane/water partitioning. This therefore demonstrates that  $\log P_{\text{alkane/water}}$  has the same information content as a PAMPA  $P_e$  value.

### 5.28.9 Outlook

A growing consensus is that in silico absorption predictions are as predictable as data from in vitro tests, with the advantage that much less investment in resources, technology, and time is needed. Additionally, it is possible to screen before synthesis.<sup>167</sup> The in silico approach also appears to be superior over predictions based on data obtained with artificial membranes.<sup>79</sup>

In comparing various predictive approaches for human intestinal absorption (Table 6), one should consider the drug discovery stage and the required precision. In early stages, predictions serve to decide on the value of making a library, or at the high-throughput screening stage on making choices between promising series. In later stages, effects of formulation and even patient populations may be of greater interest.

Current purely structure-based in silico predictions of absorption are most likely to be reliable only for compounds that are transported mainly by passive diffusion. The most dominant descriptors for oral absorption are hydrogen bonding, molecular size, and lipophilicity. A minimal set of descriptors can frequently give reasonable models.<sup>142</sup> Probably the best estimations of oral absorption are obtained using an in combo approach (i.e., a hybrid in vitro/in silico approach (see 5.41 The Adaptive In Combo Strategy and Figure 5). This could in a simple form (e.g., mean to take experimental solubility into consideration), as in the BCS approach.

Oral absorption is a complex property (see Figure 2), with contributions from solubility, lipophilicity, permeability, transporters, and metabolism (Figure 6). Therefore, a more realistic predictive absorption model should account for

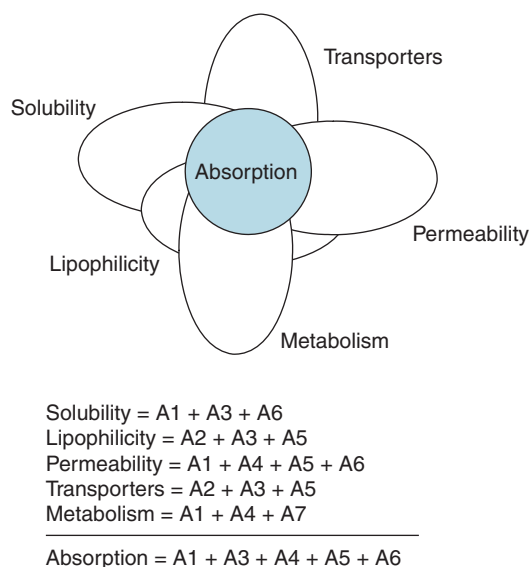

**Table 6** Approaches to absorption prediction

| Compounds   | In vivo                              | In vitro        | In silico                              |
|-------------|--------------------------------------|-----------------|--|
| Virtual     |                                      |                 | Human oral absorption models (Table 4) |
| Synthesized |                                      | Solubility      | MAD                                    |
|             |                                      | Caco-2/MDCK     | BCS                                    |
|             |                                      | $\log D/\log P$ | PBPK                                   |
|             |                                      | PAMPA           |  |
|             |                                      | (see Table 2)   |  |
| Synthesized | Rat, dog, and monkey oral absorption |                 | Allometric scaling                     |

**Figure 5** The in combo approach to the prediction of oral absorption: combination of the in vitro and in silico methods to obtain the best possible estimate of human intestinal absorption.

**Figure 6** Opening the 'black box' of oral absorption prediction. Mechanistic insight is obtained by studying the properties/descriptors (schematically represented here as A1 to A7) influencing the individual contributions of solubility, lipophilicity, permeability, transporters, and metabolism to the overall property absorption (see also [Figure 2](#)). (Reproduced from Van de Waterbeemd, H. Property-Based Lead Optimization. In *Biological and Physicochemical Profiling in Drug Research*; Testa, B., Krämer, S. D., Wunderli-Allenspach, H., Folkers, G., Eds.; VHC: Zürich, Switzerland; Wiley-VCH: Weinheim, Germany, 2006, pp 25–45, with the permission of Verlag Helvetica Chimica Acta AG.)

these basic contributions. More needs to be learned about how to account for transporters involved in active uptake and secretive efflux, and the role of gut wall metabolism<sup>18,19</sup> in such predictions. Some of this learning is already being used in physiologically-based models (see [Section 5.28.4.3](#)). The physiological role of transporters in oral absorption is discussed in Chapter 5.04, while predictive modeling of transporters is reviewed in Chapter 5.33.

For any ADME endpoint, more data of the highest possible quality covering much chemical space will further improve the predictive power of in silico ADME models. As discussed earlier, the data spread over the entire range (0–100% in the case of the amount of oral absorption) within the data set is important.

Combining several approaches gives a consensus prediction that often performs better than the individual models. This has been shown in, for example, log *P* predictions (see the KnowItAll approach). The CEREP/BioPrint models, including their human absorption model, are also typically based on the consensus of two approaches, namely a neural network and a predictive neighborhood behavior (nearest neighbor) model. It is expected that many in silico ADME models, including oral absorption, will in the near future be based on some form of consensus modeling,<sup>171</sup> such as the decision forest.<sup>172</sup>

## Biography

**Han Van de Waterbeemd** studied physical organic chemistry at the Technical University of Eindhoven, The Netherlands, and did a PhD in medicinal chemistry at the University of Leiden, The Netherlands. After post-doctoral research with Bernard Testa at the School of Pharmacy of the University of Lausanne, Switzerland, he held a 5 year

faculty position at the same institution. He also taught medicinal chemistry to pharmacy students at the universities of Berne and Basel in Switzerland from 1987 to 1997. In 1988 he joined F Hoffmann-La Roche Ltd in Basel as head of the Molecular Properties Group. He then moved in 1997 to Pfizer Central Research UK, later Pfizer Global Research and Development, and held various positions in the Department of Drug Metabolism, later called PDM (pharmacokinetics, dynamics and metabolism), including Head of Discovery, and Head of Automation and In Silico ADME Technologies. Van de Waterbeemd has published more than 135 peer-reviewed papers and book chapters, and co-edited 11 books. His research interests include physicochemical and structural molecular properties and their role in drug disposition, as well as the in silico modeling of ADMET properties. He was secretary of The QSAR and Modelling Society from 1995 to 2005.

### 5.29.1 Introduction

Oral dosing is the preferred route of administration for most drugs due to ease of administration and patient compliance. Orally delivered pharmacologically active compounds must have favorable absorption and clearance properties and satisfactory metabolic stability to provide adequate systemic exposure to elicit a pharmacodynamic response. Once ingested, the drug must undergo absorption, distribution, and hepatic metabolism prior to reaching the systemic circulation and becoming bioavailable (*see* 5.02 Clinical Pharmacokinetic Criteria for Drug Research). A bioavailable compound is then able to bind to target receptors and exert a pharmacological effect. Poor bioavailability limits oral administration of drugs, while high clearance limits desirable dosing regimens.

In order to assess oral pharmacokinetic parameters such as bioavailability, it is necessary to administer the drug both intravenously and by the oral route. Bioavailability is then extracted from the combined intravenous and oral concentration–time data. Due to practical, ethical, legal, and safety constraints, pharmacokinetic characterization is often attended to late in the developmental process. Clearly, if pharmacokinetic input is to be available early in drug discovery and development, more viable predictive methodologies are necessary.

The quantitative structure–activity relationship (QSAR) approach developed last century<sup>1</sup> has recently been adapted to construct quantitative structure–pharmacokinetic relationships (QSPkRs).<sup>2</sup> In addition to exploring physicochemical parameters including partitioning, solubility, and charge characteristics, increasing attention is being paid to the extraction of useful information from the molecular structure of a compound for QSPkRs.<sup>3</sup>

QSPkR modeling of bioavailability must take into consideration structural influences on absorption and metabolism of a compound, as well as the variability inherent in human/biological systems. Various computational techniques have been developed, some of which utilize experimental data for model generation while others rely on theoretically derived parameters including those that relate to molecular physicochemical properties. In silico methods depend heavily on the nature and quality of data used to construct models. Model validity, therefore, is influenced by issues of data variability, diversity, and experimental quality. These concepts and the theory behind them will now be discussed in relation to the current status of in silico bioavailability modeling.

## 5.29.2 Theoretical and Biological Basis of Bioavailability Prediction

### 5.29.2.1 Drug-Likeness

Druglikeness may be defined as a complex balance of various molecular properties and structural features which determine whether a particular molecule is drug or nondrug. These properties, mainly lipophilicity, electronic distribution, hydrogen bonding characteristics, molecule size and flexibility, and presence of various pharmacophoric features influence the behavior of a molecule in a living organism, including characteristics such as transport, affinity to proteins, reactivity, toxicity, metabolic stability, and many others. Extensive work has been performed to examine known druglike and nondruglike molecules and to assess what structural motifs are associated with druglike molecules (these concepts are explored in more detail in Volume 4 of this series).

Although absorption and bioavailability are separate parameters, information about absorption can be of benefit for bioavailability modeling. One way to screen out compounds with probable absorption problems is known as Lipinski's 'rule of five.'<sup>4</sup> The rule states that poor absorption or permeation of a drug is more probable when the chemical structure fulfils two or more of the following criteria:

1. Molecular weight (MW) is greater than 500.
2. The calculated log *P* value is above five.
3. There are more than five hydrogen bond donors (–NH–, –OH).
4. The number of hydrogen bond acceptors (–N=, –O–) is greater than ten.

It is important to note that the rule of five does not estimate oral absorption in a quantitative manner, nor are compounds that do not break any of the rule of five criteria necessarily orally bioavailable. The rule of five does not definitively categorize all well and poorly absorbed compounds, although it is simple, fast, and provides a reasonable degree of classification (see 5.28 In Silico Models to Predict Oral Absorption). It follows then, that there is a clear need for quantitative models able to screen large chemical databases to identify new chemical entities (NCEs) with good solubility and oral absorption. Although well-absorbed compounds can have low bioavailability due to high presystemic clearance, low bioavailability for marketed drugs is more common with oral dosage forms of poorly water-soluble, slowly absorbed compounds.

### 5.29.2.2 Pharmacokinetic Properties

#### 5.29.2.2.1 Bioavailability versus absorption

Oral bioavailability is particularly important for lead optimization considering the importance of developing orally administered commercial products. The absolute oral bioavailability (*F*) of a particular compound is defined as the fraction of that compound reaching the bloodstream after oral administration. The terms absorption and bioavailability are often incorrectly and interchangeably used. The confusion occurs when attempts are made to correlate oral

bioavailability with intestinal permeation. Oral absorption can be defined as the amount of drug that passes through the intestinal tissue and enters into the portal vein. In order for a drug to be orally bioavailable, it must survive:

1. Gastrointestinal absorption and metabolism.
2. Blood metabolism (mainly hydrolytic).
3. Hepatic clearance (metabolism and biliary excretion) before reaching the general circulation.<sup>5</sup>

Oral bioavailability can be regarded as a superposition of the major processes of absorption in the gastrointestinal tract and first-pass metabolism in the liver. The percentage bioavailability should be determined primarily by both absorption and metabolism, and any attempt to model bioavailability would require that both properties be taken into account (*see* 5.03 In Vivo Absorption, Distribution, Metabolism, and Excretion Studies in Discovery and Development; 5.05 Principles of Drug Metabolism 1: Redox Reactions; 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions; 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues).

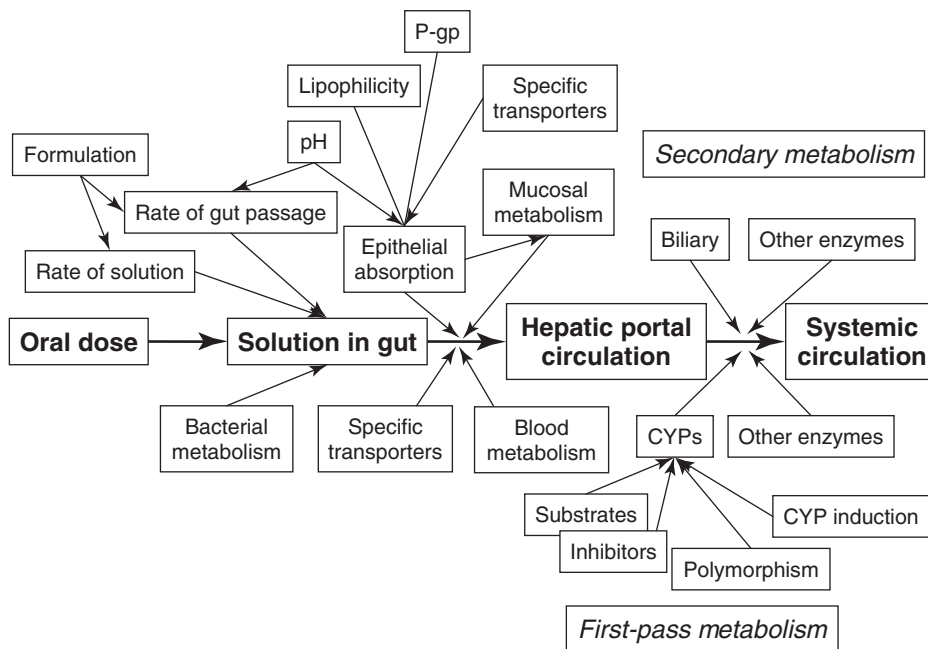

A common method of determining bioavailability is by using area under the curve (AUC) calculations for oral and intravenous doses:

$$F = \frac{AUC_{\text{oral}} \times \text{dose}_{\text{IV}}}{AUC_{\text{IV}} \times \text{dose}_{\text{oral}}} \quad [1]$$

Other methods include amount of a drug absorbed into the bloodstream and urinary excretion studies or cumulative excretion of drug following oral and intravenous administration.<sup>6</sup>

#### 5.29.2.2.2 Factors implicated in bioavailability

There are multiple factors affecting oral bioavailability, including disintegration of the dosage form, dissolution of the drug molecule, metabolism in the intestinal tract or mucosa, permeation across the intestinal mucosa, and hepatic first-pass metabolism and/or drug elimination (Figure 1). Most of these effects are class-specific and cannot be described collectively by known physicochemical parameters, adding to the difficulty of bioavailability modeling. Physicochemical properties currently utilized in drug discovery programs include solubility, lipophilicity, molecular size, hydrogen

**Figure 1** Schematic of some of the logical relationships between components of an oral bioavailability calculation. The model can be divided into pharmaceuticals (formulation), gut physiology and hepatic metabolism (first-pass clearance). An arrow indicates a logical or algorithmic dependence: the model is not complete. CYP, cytochrome P450; P-gp, P-glycoprotein. (Reproduced with permission from Bains, W.; Gilbert, R.; Sviridenko, L.; Gascon, J. M.; Scoffin, R.; Birchall, K.; Hetherington, L.; Harvey, I.; Caldwell, J. *Curr. Opin. Drug Disc. Dev.* **2005**, *5*, 44–51 © The Thomson Corporation and Current Opinion in Drug Discovery & Development.)

bonding capacity, and charge, all of which are considered important molecular features relating to various aspects of drug disposition.<sup>7,8</sup> However, there are no universal rules for their application nor means to foretell which the dominant property in any given situation will be. The search for better molecular descriptors has not decreased the use of established descriptors, nor have recently developed theoretical descriptors been found applicable to all areas of computational pharmacology and pharmaceuticals.<sup>9</sup> The current state of molecular descriptor use is reviewed elsewhere (*see* 5.22 Use of Molecular Descriptors for Absorption, Distribution, Metabolism, and Excretion Predictions).

In order to be bioavailable, oral drugs must comply with the following requirements:

1. Solubility (dissolve in the stomach or intestine under variable pH:  $2 < \text{pH} < 8$ ).
2. Chemical stability (withstand acid hydrolysis in stomach at  $\text{pH} < 2$ ).
3. Permeability (permeate through intestinal membrane by paracellular, transcellular, or active transport).
4. Withstand P-glycoprotein (P-gp) efflux (backward transport through intestinal membrane).
5. Withstand first-pass metabolism in liver and gut wall (susceptibility to metabolic transformations catalyzed by enzymes in liver and intestine).

The gastrointestinal tract can be seen as both a physical and biochemical barrier to oral drug absorption. Absorption across the intestinal epithelium may be passive or active. Passive transport is governed by physicochemical properties whereas active transport involves specific binding of a molecule to a binding site on a transport protein. The former can be modeled with physicochemical and structural properties, whereas modeling the properties of biological membranes still remains a major challenge. This is due to secretory intestinal processes, such as P-gp transport, and gut wall metabolism including by the cytochrome P450 (CYP) isoform 3A4 (CYP3A4).<sup>10</sup> Further information on these systems can be found in elsewhere (*see* 5.04 The Biology and Function of Transporters; 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues).

### 5.29.2.3 Absorption

Intestinal drug absorption, controlled by a number of factors, can be represented by various molecular descriptors (**Table 1**). These factors include: (1) dissolution rate and solubility, determining how fast a drug reaches a maximum concentration in the luminal intestinal fluid; and (2) permeability, which relates to the rate at which a dissolved drug will cross the intestinal wall to reach the portal blood circulation. Following oral administration, the drug must be capable of moving across cell membranes (transcellular absorption) or between tight gaps in between cells of the gastrointestinal mucosa (paracellular absorption). Both transcellular and paracellular diffusion depend upon the properties of drug molecules, such as molecular size, polarity, and lipophilicity.<sup>11</sup> For most drugs, the predominant mechanism of absorption is via the transcellular route (*see* 5.28 In Silico Models to Predict Oral Absorption).

Determination of the dissolution, solubility at different pH values, and permeability properties of drug candidates can thus provide information about their absorption potential. This also allows evaluation of the compounds according to the biopharmaceutics classification system (BCS) (*see* 5.42 The Biopharmaceutics Classification System) which distinguishes four classes relating to various degrees of absorption potential (**Table 2**).<sup>12</sup>

Since drug absorption potential has become a more important criterion for decisions about candidate progression early in the drug discovery process, screening methods are needed to assess drug dissolution and permeability. In silico modeling of ionization, solubility, lipophilicity, and absorption are covered elsewhere (*see* 5.25 In Silico Prediction of Ionization; 5.26 In Silico Predictions of Solubility; 5.27 Rule-Based Systems to Predict Lipophilicity; 5.28 In Silico Models to Predict Oral Absorption, respectively).

**Table 1** Factors influencing absorption

| <i>Characteristic</i> | <i>Sample descriptors</i>   |
|-----------------------|---|
| Solubility            | Solubility parameters, hydrophilic–lipophilic balance, hydrophilic surface area |
| Polarity              | Dipole moment, polar surface area   |
| Lipophilicity         | $\log P$ , $\log D$   |
| Molecular size        | Molecular mass, molar volume  |
| Molecular shape       | Molecular width, length, depth, connectivity indices                            |

**Table 2** Biopharmaceutics classification system (BCS) classification matrix

|                   | <i>High solubility</i> | <i>Low solubility</i> |
|-------------------|------------------------|-----------------------|
| High permeability | Class I                | Class II              |
| Low permeability  | Class III              | Class IV              |

Different carriers and transporters have also been implicated in drug passage across the intestinal mucosa. P-gp is a membrane transporter which functions as a drug efflux pump with a broad spectrum of substrates. P-gp is located on the apical side of the intestinal membrane and is involved in the secretory transport of a wide range of drugs. As well as P-gp itself affecting drug permeability, hydrogen bonding capacity has been implicated in drug efflux since it slows membrane crossing and may therefore increase the affinity of a compound for P-gp.<sup>13</sup>

Other absorption/permeability parameters of interest include membrane permeation measured by hydrocarbon films<sup>14</sup> and or parallel artificial membrane permeability assay (PAMPA)<sup>15</sup> (see 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery), P-gp efflux (see 5.32 In Silico Models for Interactions with Transporters) and hepatic cell metabolism,<sup>16</sup> and transport mechanisms.<sup>17</sup> These experimentally derived parameters may provide useful data for in silico predictive models in the future. Further discussion may also be found elsewhere (see 5.10 In Vitro Studies of Drug Metabolism; 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption).

#### 5.29.2.3.1 Effects of formulation and dose

A number of drugs are not administered orally as the free base or acid due to their poor water solubility, stability, hygroscopicity, crystallinity, or purity. These drugs are usually combined with acids or bases to form a salt or formulated with a lipophilic solvent, a hydrophilic solvent, and a surfactant that interact to assist in dispersion and emulsification. The bioavailability of these drugs depends on their formulation.<sup>18</sup>

Another consideration is the dose-dependent absorption of certain drugs: the percentage of the oral dose absorbed and its resultant bioavailability and excretion may decline with increasing dose.<sup>19</sup> For example, low oral bioavailability of propranolol is due in part to first-pass hepatic extraction. Bioavailability of propranolol is dose dependent, most likely due to saturation of the CYP enzymes. On the other hand atenolol is incompletely bioavailable due to incomplete intestinal absorption with no contribution of hepatic first-pass metabolism.<sup>20</sup> It is difficult to give a definition of such dose dependency since many factors can affect solubility in intestinal fluid and absorption in humans and, therefore, bioavailability. These include absorption mechanisms,<sup>21</sup> drug formulation, food composition, chemical composition, pH of the intestinal secretions, gastric emptying time, intestinal motility, and blood flow.<sup>22</sup>

#### 5.29.2.3.2 Solubility

Solubility of the drug molecule in the specific biological fluid at the site of absorption is an important prerequisite for passive membrane permeation. Solubility depends on the physicochemical properties of the fluid and the lipophilicity and ionization status of the drug. Knowledge and understanding of the dissociation constants ( $pK_a$  values) of a drug may also be helpful for the prediction of its behavior in vivo. The ionization state of a drug compound in a specific body compartment can be calculated by considering its dissociation constants relative to the pH in the body compartment of interest, for example, acidic for stomach, basic for intestine, pH 7.4 for plasma, pH 4.5–8.0 for urine. The ionization state of a drug may affect its solubility, lipophilicity, and suitability for passive transcellular diffusion and/or suitability as a substrate for active transport mechanisms (see 5.16 Ionization Constants and Ionization Profiles; 5.17 Dissolution and Solubility); predictive models are discussed elsewhere (see 5.25 In Silico Prediction of Ionization; 5.26 In Silico Predictions of Solubility). The pH partition model has long been used to correlate  $pK_a$  and partition coefficients with absorption through membranes by passive diffusion.<sup>23</sup>

For compounds that are poorly soluble in the gastrointestinal tract, appropriate pharmaceutical formulations may provide a solution.<sup>24</sup> Formulation design including particle size, co-solvents, and immediate and controlled release formulations, can allow control of release rate into solution<sup>25</sup> and, therefore, rate of transfer into the systemic circulation and bioavailability.

#### 5.29.2.3.3 Lipophilicity

The best-known physicochemical approach to predict membrane permeation is the determination of lipophilicity using the logarithm of the partition coefficient between an octanol and a water phase ( $\log P$ ).<sup>26</sup> The membrane/water

partition coefficient is, therefore, often assumed to resemble the oil/water partition coefficient. Although relationships between  $\log P$  values and intestinal drug absorption have been established,  $\log P$  does not necessarily quantitatively reflect the membrane/water partitioning behavior of a solute.<sup>15</sup> For example, membrane/water partition coefficients for some substituted benzenes and phenols were found to be up to six times higher than octane/water partitioning coefficients,<sup>27</sup> indicating that QSARs based on  $\log P$  can contain a degree of uncertainty in their predictions. Also, polar compounds with hydrogen donor or acceptor groups partition significantly more readily into membranes than predicted by  $\log P$ .<sup>28</sup> Relationships between  $\log P$  and absorption can be drawn, however, by correlation algorithms such as the Collander equation.<sup>29</sup> Lipophilicity is a critical variable implicated in intestinal absorption and membrane permeability in general and has proven useful in predictive bioavailability models.<sup>30</sup> In silico approaches for  $\log P$  calculation include both atomic/substructure contribution methods<sup>31</sup> and whole model approaches which make use of molecular lipophilic potentials (MLP),<sup>32</sup> topological indices, and other molecular properties such as charge density and electrostatic potentials for  $\log P$  calculation.<sup>33</sup> Detailed discussion of the theoretical and practical aspects of lipophilicity and  $\log P$  calculation can be else where found elsewhere (*see* 5.18 Lipophilicity, Polarity, and Hydrophobicity; 5.27 Rule-Based Systems to Predict Lipophilicity).

The  $\log D$  (octanol/water distribution coefficient) value takes into account the extent of ionization as well as the partitioning of various microspecies for each compound in both aqueous and organic phases. Many metabolic and other pharmacokinetic processes can be related to distribution and partition coefficients.<sup>34</sup> For example, the human intestine at pH 6.5 is where oral absorption predominantly occurs, while distribution can be related to the physiological pH value of 7.4.  $\log D$  is thus a powerful descriptor since it contains a correction of the degree of ionization as well as combining aspects of size and ability to form hydrogen bonds.<sup>7</sup>

#### 5.29.2.3.4 Polarity and hydrogen bonding

A molecule that crosses cell membranes via the transcellular pathway needs to penetrate both hydrophilic and hydrophobic regions since cell membranes are composed of a lipid bilayer. As a result, both hydrophilic and lipophilic properties of a molecule should be taken into account when predicting drug permeability. This is encompassed in the hydrophilic-lipophilic balance (HLB) value which is a numerical measure of the overall proportion of mass of a molecule that is hydrophilic. HLB has recently been found to be important in the prediction of oral bioavailability.<sup>35</sup> It is difficult for a drug molecule with a mainly hydrophilic structure to penetrate the outer phospholipid layer of the cell membrane by transcellular diffusion. Hence, the intestinal absorption decreases as the HLB value increases. Amphiphilicity is a more specific parameter than HLB and is determined by the distinction between a polar (hydrophilic) head region and nonpolar (hydrophobic) tail region of a molecule. Amphiphilicity can affect processes such as dissolution and partitioning as well as permeability.<sup>36</sup> It is worthwhile to note that HLB, amphiphilicity, and  $\log P$  are all ratios and indicate relative rather than absolute values of hydrophilicity and hydrophobicity of a molecule. Such ratios can be further utilized, for example in the calculation of MLP which is a whole-molecule value determined by summation of fragmental values of  $\log P$ .<sup>32</sup> The balance of molecular surface properties such as polar surface area (PSA) and nonpolar surface area have also been implicated in human intestinal absorption of drug molecules.<sup>37</sup>

Dipole moment and PSA<sup>38</sup> are both measures of the polarity of a molecule. Dipole moment describes the intramolecular electronic effect which may be related to molecular reactivity.<sup>39</sup> PSA has been found to be related to drug permeability such that drugs with high polarity are less likely to be absorbed by the small intestine and have correspondingly low bioavailability.<sup>40</sup> PSA is a surface descriptor, defined as a part of the surface area contributed by nitrogen, oxygen, and connected hydrogen atoms.<sup>41</sup> As such, it is clearly related to the capacity of a drug to form hydrogen bonds and is, therefore, a hydrogen-bonding descriptor. Molecules with many hydrogen bond donors and a large PSA tend to have low permeability values.<sup>42</sup>

#### 5.29.2.3.5 Flexibility

An analysis of the measured oral availability in rats has revealed the unexpected positive influence of increasing molecular rigidity, measured by the rotatable bond count, and the negative impact of increasing PSA.<sup>43</sup> The commonly held association of increased absorption for compounds with molecular weight less than 500 was proposed to result from greater molecular rigidity rather than lower molecular weight per se. It was found that molecules possessing fewer than 10 rotatable bonds and having a PSA less than  $140 \text{ \AA}^2$  after oral administration generally showed bioavailability in the rat exceeding 20%. These results suggested that such criteria could be used as filters in early discovery to identify drug candidates with minimally acceptable oral bioavailability. These findings, however, were contested in a more recent publication which cautioned the used of such generalizations.<sup>44</sup> It was described that molecular rigidity is a much more complex issue than the simple counting of rotatable bonds, while rotatable bond count has a much less sensitive influence on oral bioavailability than PSA.<sup>44</sup>

#### 5.29.2.3.6 Size and shape

It is well known that the size and shape of a drug can determine its orientation and the rate of movement across biological membranes.<sup>45</sup> Molecular dimensions and shape can be described using molecular width, length, and depth, and using connectivity indices.<sup>46</sup> Compounds with larger molecular width, length, and depth are not well absorbed from the intestinal epithelium due to the large molecular size limiting passage through the paracellular pores. The paracellular route, therefore, restricts passage to mainly small molecules<sup>7</sup> which corresponds to the rule of five indicating good absorption for compounds of MW less than 500.<sup>4</sup> With increasing lipophilicity, the transcellular pathway becomes important but also involves an efflux component which itself can be affected by the rate of membrane transfer.

#### 5.29.2.4 Metabolism

In addition to possible intestinal metabolism by the gut wall enzymes, metabolic reactions in the gastrointestinal tract occur predominantly via CYPs, the major enzyme being CYP3A. More than 50% of drugs may be substrates for CYP3A, potentially resulting in low oral bioavailability due to extensive metabolism in the gastrointestinal tract.<sup>47,48</sup>

CYPs may be induced by a structurally diverse range of xenobiotics including rifampicin, omeprazole, and phenobarbital, as well as cigarette smoking and alcohol.<sup>49</sup> The induction of CYPs leads to two different problems: effects on self, and coadministered drug–drug interactions. On chronic administration ritonavir induces CYP3A leading to a decrease of its own AUC.<sup>50</sup> Regarding the latter effect, an inducible drug can influence the pharmacokinetics of a coadministered drug which shares the same metabolic pathway. For example, rifampicin induces metabolism of ethynylestradiol which can lead to the failure of contraceptive therapy.<sup>49</sup> More sophisticated approaches accounting for drug interactions with transporter proteins<sup>51,52</sup> and metabolizing enzymes are required to enable accurate predictive models to be developed.

It is important to determine not only the stability of a potential drug but also the route of its metabolism. Structural determinants of metabolism, including calculated molecular descriptors, can then be elucidated and incorporated into rational drug design to improve stability and consequent bioavailability and efficacy. Principles of drug metabolism are further discussed elsewhere (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions; 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions; 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues).

#### 5.29.2.5 Impact of Interindividual Variability

Drug concentration is amongst the most important determinants of clinical response to a drug. Variability in pharmacokinetic profiles makes drug concentrations unpredictable: the greater the variability, the greater the magnitude of this problem.

Bioavailability of a drug may vary within the same person over time as well as between different people in a population. The cause of large interpatient pharmacokinetic variability is multifactorial and includes differences in drug absorption, metabolism, or distribution, and complex drug–drug or drug–food interactions.<sup>53</sup> Population subgroups such as infants, pregnant women, and other groups with underlying traits or disease states are also likely to exhibit variable bioavailability and absorption, distribution, metabolism, and excretion (ADME) characteristics.<sup>54</sup> Population variability in clinical data is a reality and should be incorporated into the modeling process.

Although predictive models may be constructed with good accuracy based on a given data set, the quality of such models ultimately reflects the quality of the data: poor-quality bioavailability data with wide uncertainty will result in poor models regardless of apparent accuracy. Care must also be taken when extrapolating outside the limits of model training data.

#### 5.29.2.6 Summary of Determinants of Oral Bioavailability

Theoretical determination of bioavailability relies on derivation of information relating to solubility and permeability which drive passive absorption rates, and metabolic stability including rates and routes of metabolism. The complexity of metabolic routes may necessitate knowledge of information relating to different metabolic pathways for accurate bioavailability prediction. Existing ADME models are structure-based, physicochemical property-based, or incorporate a mixture of both structural and physicochemical descriptors. Numerous descriptors implicated in bioavailability have been described but no universally or common descriptor/s have yet been defined. This is not surprising considering the multiplicity of factors that contribute to oral bioavailability.

### 5.29.3 Data Usage for Bioavailability Prediction

During drug discovery compounds are first screened to find hits, which are then turned into leads from which a clinical candidate hopefully emerges. The challenge is the prediction of human pharmacokinetic characteristics of drugs from preclinical data: accurate prediction would avoid unnecessary clinical evaluation of compounds with poor pharmacokinetic performance in humans.

A number of difficulties should not be overlooked when using computational and physicochemical properties to assess bioavailability. Some relevant properties such as  $\log D$  and hydrogen bonding are in fact conformation-dependent.<sup>55</sup> Further progress in the analysis of molecular states including conformation and ionization, and the development of more appropriate descriptors may lead to improved models in the future.

Numerous methods have been used to predict human pharmacokinetics from *in vivo* animal preclinical pharmacokinetic data<sup>56</sup> including physiologically-based pharmacokinetic (PBPK) (*see* 5.37 Physiologically-Based Models to Predict Human Pharmacokinetic Parameters). Another well-described technique is allometric scaling.<sup>57</sup>

#### 5.29.3.1 Allometric Scaling for Bioavailability

The word allometry refers to bodies that are not isometric but which change with size according to a particular rule. Allometric scaling is an empirical technique and was developed to explain the observed relationships between organ size and body mass of mammals.<sup>58</sup> Relationships revealed between body size and physiological parameters consequently led to the application of allometric scaling in correlating human pharmacokinetics with pharmacokinetic parameters obtained in animal studies.<sup>59,60</sup> According to allometry a number of body processes can be described in a very simple way:

$$Y = A \times X^k \quad [2]$$

where  $Y$  is a body process such as metabolic rate,  $X$  a measure of the size of the organism, for example body surface area or mass, and  $A$  and  $k$  are constants. The constant  $A$  scales across species and is expected to be different for each species.

Numerous studies have attempted to correlate preclinical pharmacokinetics in animal species to pharmacokinetics in humans.<sup>61</sup> Both absolute bioavailability prediction in humans from animal data using interspecies scaling as well as indirect approaches have been described.<sup>62</sup> However, a comparison of absolute bioavailability prediction in humans using allometric scaling (absolute bioavailability versus body mass) with four indirect interspecies scaling approaches suggested different degrees of accuracy of these methods. It was concluded that accurate prediction of absolute bioavailability in humans from animal data was unreliable. Interspecies scaling for bioavailability prediction, therefore, has not become a popular approach.

The major drawback in allometric scaling is its empirical nature. It is very sensitive to both the species in which testing is performed and how/if extrapolations are made. Traditional allometric scaling introduced a large degree of uncertainty into data extrapolations and did not take into account species differences in physiology that could modify drug uptake, metabolism, or physiological responsiveness. Recent methods have combined allometric scaling with *in vitro* human metabolism data in order to overcome species differences in metabolism.<sup>63,64</sup> A rough estimate of categorical bioavailability was successful for a small number of compounds for which *in vivo* data were available<sup>65</sup> despite the fact that only hepatic microsomal metabolism was considered a limitation.

#### 5.29.3.2 In Vivo Bioavailability from In Vitro Data

The methodologies and mathematics behind approaches to predict *in vivo* clearance from intrinsic clearance data have been summarized in a recent review.<sup>66</sup> *In vitro/in vivo* correlations that have included data from both human and preclinical animal species have been achieved in practice.<sup>67</sup> A number of *in vitro* systems can be used to obtain hepatic intrinsic clearance data. The most commonly used systems are liver microsomes, hepatocytes, and cut liver slices. Each system possesses unique advantages and disadvantages. In general, for kinetic experiments, the body of data available suggests that hepatocytes are a superior method with regard to accurate predictions of *in vivo* data, with microsomes also providing good results.<sup>68–71</sup>

As examples, one graphic model utilized permeability in Caco-2 cells and liver microsomal clearance to estimate oral bioavailability<sup>72</sup> while a different mathematical model integrated Caco-2 permeability and hepatic extraction based on microsomal clearance to project oral bioavailability.<sup>73</sup> It was also demonstrated in a retrospective study that oral bioavailability could be predicted by human liver microsomal clearance only when the hepatic first pass was considered to be the limiting factor.<sup>65</sup>

### 5.29.3.3 Input Data Quality and Type

Pharmacokinetics presents a number of unique problems for statistical modeling (Table 3). Data derived from literature sources, particularly *in vitro* data, are usually quite reliable from a qualitative point of view but much less reliable from a quantitative perspective. The quality of such experimental bioavailability data varies enormously and is often restricted in quantity and chemical diversity<sup>74</sup> due to economic and ethical considerations. Another limiting factor is the variability of pharmacokinetic results. Traditional pharmacokinetic studies have placed a priority on minimizing variability through careful control over study participants and other aspects of the experiment, and thus obtain an understanding of bioavailability in only a narrowly defined group.

It is also important to distinguish between uncertainty and inherent biological variability. In practice, the distinction is usually less clear, as illustrated by the often large degrees of error present in available bioavailability data. One study pooled literature values of 49 compounds for which a reliable, numerical range of human oral bioavailability was available (Figure 2)<sup>75</sup> and found that a large proportion of ranges were wide in both absolute and relative terms. Perhaps the most pressing need at this time is for larger, high-quality experimental data sets to provide a sound basis for model building.<sup>76</sup>

The QSAR approach was initially developed from and applied to sets of congeneric chemicals. Development of successful QSARs require the chemical space for training and testing sets to be analyzed followed by identification and removal of structural outliers. QSAR models will then have an applicability domain centered within the range of parameter values used in modeling. Beyond this range, any relationship will fade in an unpredictable manner.

In contrast, models based on large heterologous chemical data sets are less dependent on structural similarity and therefore place less emphasis on eliminating outliers. Excluding outliers subsequent to model construction may render such models statistically invalid if excluded compounds were utilized during model construction or training.<sup>75</sup> Removal of outliers then retraining of predictive models may avoid this problem but introduces another problem of further reducing the size of the data set and, therefore, the chemical space and extrapolative capability of the final model. Small data sets, especially those composed of congeneric compounds, often require the use of leave-*n*-out

**Table 3** Problems with human bioavailability data

| <i>Within studies</i>          | <i>Between studies</i>                          |
|--------------------------------|---|
| Limited number of compounds    | Quality of data/study: methodology and analysis |
| Limited diversity of compounds | Difference in experimental conditions           |
| Narrow range of human subjects | Quantitative versus qualitative data            |
|                                | Variability between studies                     |

**Figure 2** Variability of human oral bioavailability data. (Reproduced with permission from Bains, W.; Gilbert, R.; Sviridenko, L.; Gascon, J. M.; Scoffin, R.; Birchall, K.; Hetherington, L.; Harvey, I.; Caldwell, J. *Curr. Opin. Drug Disc. Dev.* **2005**, 5, 44–51 © The Thomson Corporation and Current Opinion in Drug Discovery & Development.)

cross-validation or a separate testing set to gauge model performance. These testing subsets are, in effect, considered statistically part of the training set of compounds.

For generalizability, large structurally dissimilar data sets cover a broad chemical space and may better reflect the complex aspects involved in predicting bioavailability. Although they may enable the use of a statistically independent validation set of compounds to test true predictive ability<sup>77</sup> such heterogeneous data sets also face greater data quality assurance problems.

One relevant consideration often overlooked in data sets is the inclusion of a range of compounds including both developmental failures as well as successes. Data sets with only successful compounds will be biased and likely unable to detect potential failures.<sup>78</sup>

## 5.29.4 Commercial Tools and Software

A number of commercial entities produce proprietary software capable of predicting a range of ADMET properties. Molecular structures can be input via SMILES (Simplified Molecular Input Line Entry System), MOL files, or other industry standard notation. For the most part, these describe two-dimensional (2D) structure wherein spatial positioning of atoms is of little importance.

Attention must be paid to the three-dimensional (3D) structure of molecules when accounting for energy interactions across space. Energy minimization routines vary depending on the application used while conformation endpoints can depend on the selected solvent such as aqua or octanol, or whether minimization is done in vacuo. Appropriate 3D conformation and energy minimization parameters are essential to extract meaningful information from structural descriptors.

### 5.29.4.1 Available Data Sources

The scope of computational programs and models continues to increase as more compounds are added to bioavailability databases. Several companies specialize in providing experimentally derived libraries of information for bioavailability prediction in addition to supplying data based on high-throughput screening (HTS) (Table 4).

For example, the AurSCOPE database contains drug information for over 7000 compounds collated from the literature. Bioavailability data is available for over 10% of compounds with human bioavailability data currently available for 140 compounds. AurSCOPE is updated regularly and is subject to rigorous internal quality control to ensure data reliability. Another example is the BioPrint database which contains substantially fewer compounds but which contains pharmacologic, ADME screen, and literature data. HTS resources are also available such as the ECLiPS library of over 7.5 million small molecules which is claimed to contain a majority of compounds expected to have good oral absorption due to property calculation and selection criteria.

**Table 4** Commercial computational bioavailability prediction tools

| <i>Product/module</i>              | <i>Supplier/developer</i>  | <i>Capability</i>   |
|------------------------------------|--|---|
| <i>Predictor</i>                   |  |   |
| ADME Boxes                         | Pharma Algorithms<br><a href="http://www.ap-algorithms.com">www.ap-algorithms.com</a>  | Prediction of bioavailability, physicochemical parameters, aqueous solubility, solvation, $pK_a$ , P-gp substrate specificity   |
| truPK<br>Bioavailability predictor | Strand Genomics<br><a href="http://trupk.strandgenomics.com">trupk.strandgenomics.com</a>  | Bioavailability, plasma protein binding, volume of distribution, elimination half-life and rate of absorption prediction models; based on 2D structure and small validation set |
| KnowItAll<br>ADME-Tox              | Bio-Rad Laboratories<br><a href="http://www.knowitall.com">www.knowitall.com</a><br><a href="http://www.bio-rad.com">www.bio-rad.com</a> | ADME prediction including bioavailability, analytical informatics, database building and mining, structure drawing, reporting   |

A significant problem is the degree of human bias in selecting compounds to be included particularly in smaller libraries. This may be due to availability and costs of reagents, pharmacokinetic considerations, and preferences of medicinal chemists themselves in producing samples of such compounds.<sup>79</sup> Compound databases should ideally contain experimentally derived data from marketed drugs, failed drug candidates, bioactive natural substances, and withdrawn drugs in order to avoid bias towards established drug like molecules.

#### 5.29.4.2 Bioavailability Prediction Software

There are few commercial programs that specifically predict bioavailability of compounds (Table 4). The majority come with bundled modules that allow bioavailability estimation in addition to deriving other parameters.

ADME Boxes<sup>80</sup> predicts bioavailability using a combination of probabilistic and mechanistic methods. Experimental data and proprietary algorithms take into consideration water solubility, acid stability, passive and active intestinal transport characteristics, P-gp efflux susceptibility, and first-pass metabolism to classify compounds into low (<30%), moderate (30–70%) and good (>70%) bioavailability classes. Although classification provides less information than quantitative prediction, this may be sufficient simply for screening purposes. The probability or certainty of classification is also provided in ADME Boxes to give a measure of confidence. The database contains 723 compounds for which bioavailability data is provided as averages of experimental values and ranges found in clinical trial and review publications. As discussed previously, drug information extracted from the literature may not comprise data generated under the same experimental conditions. The relatively small number of compounds in the database also limits the chemical space represented.

Strand Genomics utilized an even smaller dataset of 227 compounds from mostly commercially available preparations to develop a specific prediction model for bioavailability. Their truPK Bioavailability predictor<sup>81</sup> incorporated the use of artificial neural networks, decision trees, and support vector machine technology to identify relevant descriptors from which a predictive model was developed. Strand Genomics offers other customizable models using focused training and validation data sets which may counter some of the potential bias in their data. Clinical data supplied by manufacturers need also be treated with caution since these may potentially be skewed towards favorable results, in a similar manner to publication bias in the literature.<sup>82</sup>

Validation of models in KnowItAll is achieved with consensus modeling for both continuous and classification models. In consensus modeling, a number of individual models are generated from which a weighted average is calculated to best match experimental data. The compound database taken from the literature<sup>30</sup> contains 232 compounds and their bioavailability classification into one of five categories:  $\leq 20\%$ , 20–49%, 50–79%, and  $\geq 80\%$ . One advantage of the database is its widespread use which enables comparisons with other studies to be performed. Database size is again, however, a limiting factor. The ADME-Tox module<sup>83</sup> for bioavailability prediction provides a distinct advantage over static models since it enables data to be added or removed when needed, thus allowing models to be updated and expanded upon without new models required to be generated. The suitability of commercial applications for bioavailability predictions needs to weigh the relative importance of chemical space representation, postmodel construction flexibility, purpose (quantitative or qualitative predictions), and cost.

Generic software and modeling approaches enables a great deal of flexibility to be adopted for in silico bioavailability prediction. Programs such as artificial neural networks (ANN), genetic algorithms (GA), and expert systems are readily available both commercially and as open-access code, and can be customized for modeling tasks and to the data available. Several recent applications of these programs for bioavailability prediction have been published<sup>84,85</sup> with reasonable success for the small data sets used. Custom operations using other proprietary software such as Equibits Foresight<sup>86</sup> in KnowItAll and the QSAR module of SYBYL<sup>87</sup> can also be performed for construction of predictive models. Comparative molecular field analysis (CoMFA) and soft-independent modeling of class analogy (SIMCA) methodologies have been utilized for bioavailability prediction.<sup>88</sup> These both require that appropriate 3D structure of molecules be obtained using appropriate energy-minimization routines to extract relevant information from molecular fields. It should be noted though, that conformation-independent techniques can deliver better correlative models than by using CoMFA.<sup>89</sup>

The various commercial computational resources available for in silico bioavailability prediction allow a flexible approach to be taken. The continued increase in availability of quality data will see commercial databases advancing in scope and size. In addition to ever-improving algorithms and computing capabilities, this will doubtless enable both proprietary and generic models to become better validated and more accurate in the future.

## 5.29.5 Current Models

### 5.29.5.1 Absorption and Bioavailability Prediction

Several approaches have focused on predicting the required physicochemical properties for drug-like pharmacokinetics for NCEs.<sup>90,91</sup> Studies combining MW and PSA have revealed that recently marketed orally bioavailable drugs mostly have  $MW < 500$  and  $PSA < 120 \text{ \AA}^2$ .<sup>92</sup> From data on 20 selected compounds, it has been shown that  $PSA > 140 \text{ \AA}^2$  results in incomplete ( $< 10\%$ ) oral absorption whereas  $PSA < 60 \text{ \AA}^2$  results in excellent ( $> 90\%$ ) absorption.<sup>93</sup> Other computational models including dynamic PSA have been reported<sup>41,94</sup> although these have no advantage over PSA calculated from the minimum energy conformation.

Assuming good metabolic stability, the two key parameters controlling drug absorption are membrane permeability and dose/solubility ratio.<sup>95</sup> It has recently been shown that when the aqueous solubility of drugs is less than  $100 \mu\text{g mL}^{-1}$  dissolution is the limiting factor for oral absorption.<sup>95</sup> Oral bioavailability of drugs that are sparingly soluble and do not have significant first-pass metabolism are, therefore, dissolution-limited and may have dose-dependent bioavailability. Modeling dose-dependency of ganciclovir demonstrated the utility of experimentally determined physicochemical parameters in one study.<sup>96</sup> Permeability, surface area, transit time, solubility, and dissolution rate data obtained from a consortium of pharmaceutical companies and the literature and were used to construct a physiological simulation model to predict the fraction of drug absorbed into the portal vein ( $FD_p\%$ ). These models, for both human and dog, were tested with 12 compounds exhibiting a wide range amongst the physicochemical parameters included and also for a further three commercial drugs. The model qualitatively delineated compounds with low and high absorption values as evidenced by good  $FD_p\%$  prediction. Although limited by the small number of compounds and  $FD_p\%$  not being a true measure of bioavailability as claimed, the methodology and results obtained were encouraging. Another study utilized calculated  $FD_p\%$  and other experimentally derived parameters to classify human and rat bioavailability of 140 compounds.<sup>73</sup> Results suggested that low in vitro bioavailability was reasonably well correlated with low in vivo bioavailability. Misclassification rates corresponding to large numbers of false positives and false negative were minimized around in vitro bioavailability of 15% suggesting that the utility of the model was limited to identifying compounds with low in vivo bioavailability only.

### 5.29.5.2 Classification Models

Qualitative prediction or classification of oral bioavailability may be a less demanding goal than quantitative prediction. In one early study, fuzzy adaptive least-squares (FALS) analysis was used to develop a structure–bioavailability relationship for 188 known drugs.<sup>97</sup> Three separate models based on this expert system approach were developed for the three classes of compounds: aromatics, nonaromatics, and heteroaromatics. A number of physicochemical and structural descriptors were generated including  $\log P$ , MW, and functional group counts. Interestingly, squared transformations of both  $\log P$  and MW were performed to account for nonlinearity amongst the data but only the  $MW^2$  variable was included in the final aromatic model. The negative influence of MW on bioavailability found in this study has been corroborated in more recent, extensive work.<sup>43</sup> Compounds were classified into one of three classes, for bioavailability values  $< 50\%$ , between 50% and 89%, and  $> 89\%$ . Although representing a wide variety of structures, there was no discussion of the range of actual bioavailability values used and, since this data set consisted of marketed drugs, there may have been some bias towards compounds with high clinical bioavailability. Model performance was gauged by leave-one-out cross-validation which is not a true measure of predictive ability unlike predictions for an independent validation set of compounds.<sup>77</sup> Nevertheless, the reasonably accurate classifications of the wide range of chemical structures enabled some discussion of the influence of various descriptors on bioavailability. The complexity inherent in bioavailability prediction<sup>85</sup> was demonstrated by the opposite effects of  $-\text{OH}$  groups on bioavailability for the different classes of compounds.

Structural and physicochemical descriptors similar to those in the study described above were used in combination with the ordered multicategorical classification method using the simplex technique (ORMUCS), an adaptive least squares (ALS) approach, to categorize bioavailability of a total of 272 drugs.<sup>30,98</sup> In addition to being the most extensive study yet conducted in this field, the authors introduced a new parameter,  $\Delta\log D$  (Figure 3). This was defined as the difference between the logarithm of the distribution coefficient at pH 6.5 (intestine) versus pH 7.4 (blood) for an ionizable species. The purpose of this descriptor was to account for the apparent higher bioavailability observed for many acidic compounds.

Bioavailability data for these commercial compounds were extracted from the literature and placed into one of four categories based on their oral bioavailability:  $\leq 20\%$ , 20–49%, 50–79%, and  $\geq 80\%$  (Table 5). Classification of both training and testing data was found to be more accurate for compounds with higher bioavailability for which there were

**Figure 3** Distribution of  $\log D_{6.5}$  within each bioavailability class showing broader distribution as bioavailability decreases. (Reproduced with permission from Yoshida, F.; Topliss, J. G. *J. Med. Chem.* **2000**, 43, 2575–2585. Copyright year (2000) American Chemical Society.)

greater numbers of available compounds. Poor predictions for compounds with low bioavailability may be due to the complexity introduced by extensive enzymatic metabolism of these compounds.<sup>85</sup> An overall classification rate of 71% was achieved, with 97% correct being obtained within one class. Furthermore, 60% (95% within one class) of the 40 independent testing compounds were also correctly classified using this linear QSAR equation.

Of the various descriptors in the final models,  $\log D_{6.5}$  was shown to exert a significant negative influence on bioavailability while similar effects were seen for phenolic  $-\text{OH}$  and  $-\text{SO}_2\text{NH}_2$  groups. The results indicated the feasibility of obtaining reasonable estimates of oral bioavailability from molecular structures when physically and biologically meaningful descriptors are employed. These conclusions must be taken in light of the accuracy of the model which has since been improved.<sup>84</sup>

A recent adaptive fuzzy partitioning (AFP) study<sup>84</sup> employed the same data and classification system as described above<sup>30</sup> as well as including a further set of 235 compounds extracted from elsewhere in the literature. This study exploited a number of innovative approaches including fuzzy logic (FL), GA, and self-organizing map (SOM) techniques to select descriptors and construct models (the success of GAs has been reported elsewhere<sup>75</sup> although results have not been subject to review). Classification results for independent testing compounds (true predictive ability) were improved over the previous study<sup>30</sup> with similarly better classification achieved for compounds with higher recorded bioavailability. The descriptors used were 2D topological and electrotopological descriptors as well as  $\log D$  and  $\log P$  variables, all generated in silico from molecular structure. After selection of an optimal descriptor subset, it was found that compounds in the independent testing set were not fully representative of the training set. The authors therefore reselected testing compounds that better represented the training set in the descriptor hyperspace. While adequate representation is strongly desirable to validate models, bias introduced by nonrandomly selecting testing compounds from a relatively small data set can generate potentially artificial results.

A higher level of descriptor complexity, involving derivation of information from 3D drug structure using CoMFA, has been described.<sup>88</sup> Following descriptor calculation from drug structure and conformation, principal component analysis (PCA) was used to determine independent latent variables that best characterized descriptor class and combinations. Human bioavailability data taken from two literature sources for 606 compounds<sup>5,30</sup> involved nominally continuous values but, due to the large errors in determination, values were considered of a qualitative nature. Categories were conveniently divided into distinct classes (0–15%, 25–36%, 45–76%, and 80–100%) which reduced the effects of poor data quality and borderline predictions. Separate and combined models for the two data sets were constructed and it was found that the large, combined data set did not necessarily achieve superior predictions. This emphasized the effects of data variability since original values were collated from a variety of sources initially.<sup>5,30</sup> The two separate models were validated with an independent set of compounds with only 8 from 20 and 9 from 41 compounds correctly classified (Table 6). Better results (16 from 18 and 31 from 41, respectively) were claimed when correct classification was extended to plus or minus one category level. The literature data used was biased towards

<sup>a</sup>A, acid; B, base; N, neutral. Compounds not significantly ionized at pH 6.5 and 7.4 (Δlog *D* = 0.00) are designated as neutral.

<sup>b</sup>log *D*<sub>6.5</sub> − log *D*<sub>7.4</sub>.

<sup>c</sup>Derived from the CLOGP value.

<sup>d</sup>Derived from MLOGP value.

<sup>e</sup>Estimated.

<sup>f</sup>Bioavailability ≤20% (class I), 20–49% (class II), 50–79% (class III), ≥80% (class IV).

compounds with high bioavailability which may also have skewed predictions to the higher categories. Furthermore, although a novel approach was described, given the absolute margins between categories these models may not be sufficiently accurate in today's highly demanding drug discovery arena.

### 5.29.5.3 Quantitative Models

#### 5.29.5.3.1 Regression models

The ability to accurately predict bioavailability in a quantitative manner for virtual compounds would be of immense value in drug discovery and development. The first published study to develop a quantitative structure–bioavailability relationship<sup>99</sup> made use of data for 591 compounds obtained from the literature. The multiple linear regression (MLR) model was optimized using recursive partitioning to analyze descriptor interactions. Only simple one-dimensional (1D) descriptors were required and consisted of 608 substructure counts for each molecule. From the final regression equation the relative influence of individual descriptors was able to be characterized. This information may be applied in library screening although should be considered along with the effects of all significant descriptors included in the final model. The 85 descriptors in the final model corresponded to approximately seven observations per descriptor, a

fact which the authors claimed negated the chance of the model being overfitted. Nevertheless, the descriptor hyperspace was not analyzed for correlations or overlap and, based on the large number of descriptors in the final model and the minor structural variations between these descriptors, it is likely that some redundancy existed in the model. The authors also offered a comparison with benchmark rule of five<sup>4</sup> classification. This was performed by applying a good/poor bioavailability cutoff value of 20% to the leave-one-out predictions of the quantitative model. Comparisons were made between absorption and bioavailability which are separate pharmacokinetic parameters. Since oral bioavailability cannot exceed human intestinal absorption, compounds with low absorption may be assumed to have low bioavailability. The same is not necessarily true in reverse, however, since bioavailability may be limited by presystemic metabolism rather than being absorption-dependent.

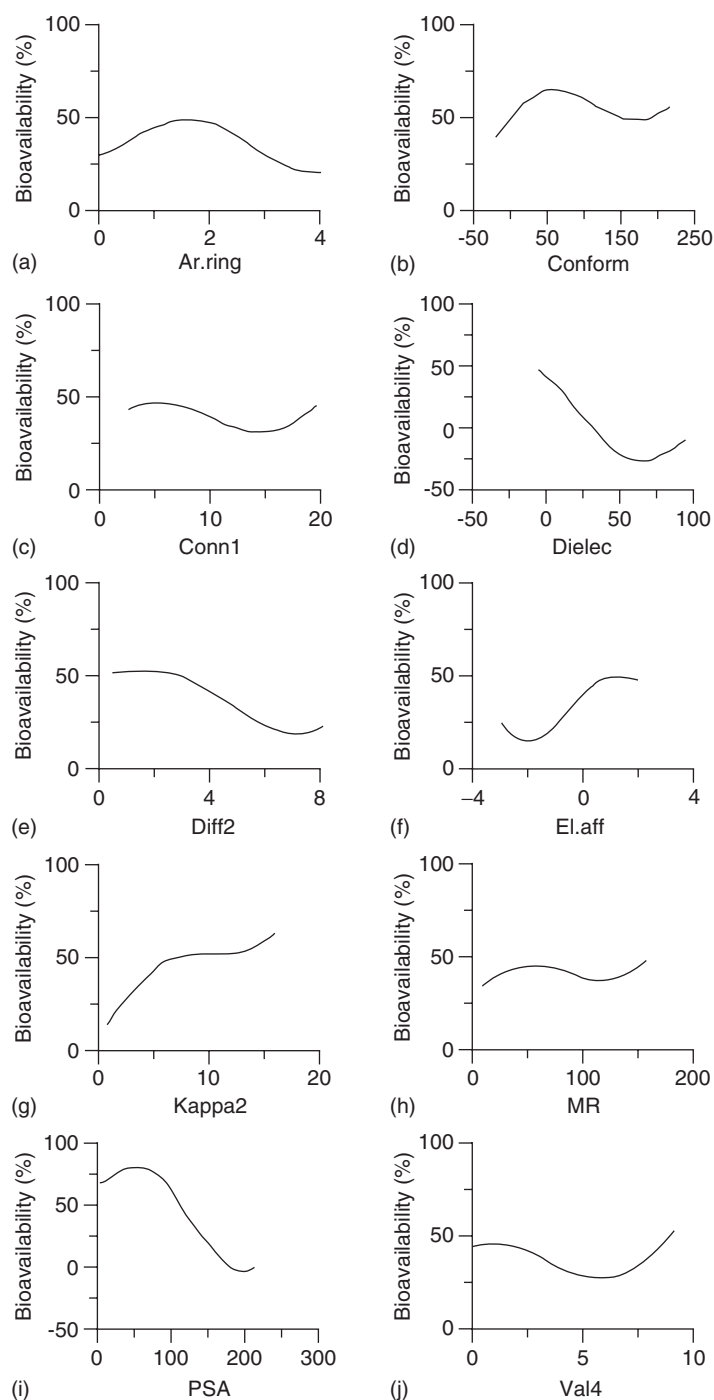

Model performance was consistent with  $r^2$  values of 0.71, 0.63, and 0.58 reported for the regression equation, leave-one-out cross-validation, and leave- $n$ -out cross validation respectively. Even though both leave-one-out and leave- $n$ -out validations were carried out, more rigorous model testing was not performed, for example, validation of the final model by an independent set of compounds.

A smaller MLR study of 169 compounds used leave-10-out testing to validate a quantitative model containing eight theoretical descriptors.<sup>35</sup> Regression results for this model were poorer than those in the previous study.<sup>99</sup> True predictive ability, however, was encouraging as evidenced by absolute predictions and differentiation of compounds with low and high observed bioavailability. Complexity of descriptors was increased to include numerous topological 2D variables as well as quantum chemical descriptors. The questionable benefits gained from using the more complex descriptors may not necessarily justify their use in this case. Nevertheless, useful information concerning the influence of calculated parameters was described. This included the positive influences of electron affinity, aromatic ring count, and hydrogen bonding on bioavailability as well as the negative influences of highest occupied molecular orbital (HOMO), log  $P$ , molar volume, HLB, and water solubility. Such regression models imply a linear relationship between descriptors and bioavailability but this may not always be the case.

#### 5.29.5.3.2 Artificial neural network prediction

Since oral bioavailability is an inherently nonlinear process, the most appropriate modeling techniques may be those which are nonlinear themselves. ANNs are one such soft-computing paradigm of which there are several varieties. The utility of a radial basis function (RBF) ANN was demonstrated in a recent a quantitative structure–bioavailability relationship study.<sup>85</sup> The data set of 167 compounds obtained from the literature was divided into separate training, testing, and independent validation subsets. Even though the validated model made acceptable predictions, it was better able to qualitatively differentiate between poorly and highly bioavailable compounds. Naloxone, naltrexone,

idarubicin, and losartan with low bioavailabilities were predicted as such but the model incorrectly assigned labetalol a high value. Predictions for metoclopramide, ranitidine, paracetamol, methyldopa, and nifedipine with somewhat higher bioavailabilities were well predicted but hydrochlorothiazide was given a low value. Propylthiouracil, cephalixin, and lamotrigine with high absolute bioavailabilities all had acceptable predicted values.

**Figure 4** Descriptor response graphs for optimum ANN bioavailability model for structurally diverse dataset. (Reproduced from Turner, J. V.; Maddalena, D. J.; Agatonovic-Kustrin, S. *Pharm. Res.* **2004**, *21*, 68–82, with kind permission of Springer Science and Business Media.)

The descriptor hyperspace consisted of 1D constitutional, 2D topological, and 3D quantum chemical variables all of which were represented in the final model. Of particular note was the finding that individual descriptors influenced compound bioavailability in a nonlinear fashion (Figure 4). This was more consistent with the complex nature of bioavailability being determined by numerous biophysical and physicochemical processes rather than the simple relationships reported elsewhere.<sup>30,97</sup> Important descriptors found were aromatic rings (Ar.ring), conformational minimum energy (Conform), connectivity index order 1 (Conn1), dielectric energy (Dielec), connectivity difference index 2 (Diff2), electron affinity (El.aff), Kappa shape index 2 (Kappa2), molar refractivity (MR), polar surface area (PSA), and valence connectivity index order 4 (Val4). RBF ANNs are better able to correlate model inputs with the output parameter than conventional multilayer perceptron ANNs,<sup>100</sup> hence this model provides good confidence in the influence these descriptors have on bioavailability.

#### 5.29.5.4 A Bioavailability Score

One recent study described a bioavailability scoring system based on analysis of 553 compounds containing 99 different rings and 180 side chains with experimentally determined rat bioavailability data.<sup>101</sup> Validation of the results was provided with human bioavailability values from the literature. It was shown that none of the rule of five,  $\log P$ ,  $\log D$ , or the combination of the number of rotatable bonds and PSA could be used to successfully predict a compound having bioavailability greater than 10% in the rat. Instead, different properties of compounds depending on their predominant charge at biological pH were shown to govern bioavailability. It was concluded, therefore, that different physical properties are required for negatively charged compounds at pH 6–7 than for uncharged or positively charged compounds. The scoring system described was useful for classifying bioavailability in rat, Caco-2 permeability, and intestinal absorption in humans. Further work in this field may see development of a similar scoring system with greater success in human bioavailability characterization.

### 5.29.6 General Discussion and Conclusion

Data-driven modeling has been actively applied within drug discovery for several decades and now has the potential to impact all stages of the drug discovery process. While early efforts were focused on target affinity optimization, applications to lead finding and ADMET property prediction have more recently emerged. The dramatic increase in size of compound libraries and ultra-HTS has resulted in greatly increased rates at which biological activity data can be obtained. Nevertheless, research and development time-lines have remained virtually unchanged.<sup>102</sup> Data from HTS and other in vitro experiments have now been used to develop a first generation of ADMET predictive in silico tools which can be used in the early stages of the drug discovery process including library design and compound screening. The progress of qualitative and quantitative models using literature data and purely in silico methods is also encouraging.

Computational models, by their very nature, are dependent on the data used to generate them and on the understanding and insight of the scientists who created those models. This is especially true for bioavailability prediction considering the multiplicity of factors influencing drug translocation from the gastrointestinal tract into the systemic circulation. It follows that the availability of sufficiently good quality databases is another limiting factor for in silico bioavailability prediction.

Indication of potential bioavailability should ideally be obtained during drug discovery prior to clinical trials. Currently, early screening for absorption may be performed using simple methods such as the rule of five which rely on structural considerations only. This principle should be applied to bioavailability since this pharmacokinetic parameter has additional clinical and developmental implications including pharmacodynamic effects and dosing regimens. The complex nature of bioavailability renders this a considerable challenge. Similarly, in vitro/in vivo correlations using experimentally derived data have established utility in absorption prediction but are of limited use for bioavailability. Recent progress in the field is encouraging as predictive models become more refined and broader in scope. Purely in silico tools for bioavailability prediction have the potential to contribute significantly to drug discovery and development and, as they improve, will become a key component in the early stages.

## Biographies

**Joseph V Turner**, BMedSc (Hons), MBBS, PhD, is currently affiliated with the Rural Clinical Division of the School of Medicine, The University of Queensland, Australia. He hails from Armidale in country New South Wales and gained his Bachelor of Medical Science (Honours) from The University of Sydney in 1999. Joseph subsequently undertook postgraduate research and teaching in pharmaceutics at the Faculty of Pharmacy, The University of Sydney, and was awarded his PhD in 2004. His research focused on the use of artificial intelligence systems for the prediction of human pharmacokinetic parameters, a field in which he has a number of refereed publications and maintains an active interest.

Joseph is an altruist and has a passion for rural and remote healthcare provision, evident throughout and beyond his medical training at The University of Queensland.

**Snezana Agatonovic-Kustrin**, after being awarded a Bachelor of Pharmacy, accepted an assistant lectureship position at the Faculty of Pharmacy in Belgrade, Yugoslavia, where she was also involved in drug quality control with the Department of Drug Analysis. During this time she completed her Master of Pharmaceutical Science and PhD in Pharmaceutical Chemistry. From 1995 she held a number of academic positions in different pharmacy disciplines internationally, teaching in pharmaceutical chemistry, pharmaceutics, and medicinal chemistry. She has also been involved in development of major pharmacy curriculum components of the Bachelor of Pharmacy and related postgraduate courses.

Snezana recently joined the School of Biomedical, Biomolecular and Chemical Sciences at The University of Western Australia as a Senior Lecturer in Pharmaceutical Technology and Medicinal Chemistry, to assist in curriculum development and establishment of the Master of Pharmacy programme.

She has a diverse range of research interests including quantitative structure–activity relationship analysis, dosage form design, development and optimization of novel drug delivery systems especially of liquid dosage forms for pediatric patients, and quality evaluation of generic drugs including identification and quantitative control of their crystal or enantiomeric purity. Other research has included the application of statistical design, computer optimization techniques, and artificial neural network modeling.

## 5.30 In Silico Models to Predict Passage through the Skin and Other Barriers

### 5.30.1 Introduction

Membranes form biological barriers controlling and restricting the movement of molecules in vivo. [Table 1](#) summarizes the main routes by which chemicals may be taken up or excreted by an organism. Different molecules will cross membranes at different rates, depending on their physicochemical properties and attributes. Understanding, quantifying, and formalizing the relationship between physicochemical properties and membrane permeability will allow for the development of predictive models. Such models are often termed quantitative structure–activity relationships (QSARs) or, more specifically, quantitative structure–property relationships (QSPRs). They are encompassed in what is popularly termed ‘in silico predictive science.’

The modeling of the transfer of molecules across biological membranes in this chapter will assume that passive diffusion. Such a process is thermodynamically driven, whereby a concentration gradient is required to achieve flow across a membrane. Thermodynamics drives the process such that the concentration gradient is diminished. Such transfer can be described in terms of the amount  $M$  of a chemical flowing through unit area (cross-section)  $S$  of a

**Table 1** A summary of the main barriers to the uptake and excretion of compounds in vertebrate organisms, with an emphasis on the delivery of drugs

| <i>Uptake</i>                       | <i>Excretion</i> |
|-------------------------------------|------------------|
| Skin                                | Renal            |
| Eye                                 | Breast milk      |
| Placental blood                     | Semen            |
| Fish gills                          | Bile             |

<sup>b</sup> See 5.31 In Silico Models to Predict Brain Uptake.

membrane in a particular time  $t$ . The transfer across the membrane, in these terms, is known as the flux  $J$ . These parameters are related by Fick's first law<sup>1</sup>:

$$J = \frac{dM}{S \cdot dt} \quad [1]$$

The flux of a compound through a membrane is also related to its intrinsic ability to diffuse through a membrane, i.e., its diffusivity. The diffusivity can be quantified in terms of a diffusion coefficient  $D$ . Other essential properties are the concentration  $C$ , and the thickness of the membrane (or the distance of movement perpendicular to the membrane)  $x$ . Thus, these parameters are related by:

$$J = -D \frac{dC}{dx} \quad [2]$$

With regard to biological membranes, there are many factors that can affect  $D$ , notably the concentration at the membrane, ionization, temperature, and effect of co-solvents (e.g., in formulation). Other physical properties can also affect  $D$ , though most, e.g., pressure, are less relevant for the modeling of flux across biological membranes. Modeling the membrane transfer of molecules assumes these properties to be constant, and an experimental test protocol is designed to achieve this. Thus, differences in flux relates between molecules should be related directly to their properties in a well-designed and executed test procedure.

Therefore, even a basic thermodynamic model of membrane passive diffusion provides a number of parameters that may be amenable to modeling. Key amongst these are the flux and diffusion coefficient. However, in practical terms a number of other quantities are also measured and have been considered for modeling. These are often dependent on the experimental protocol and requirements for the measurement.

There is great interest in measuring the ability of compounds to cross a large number of membranes. Readers may well wish to concentrate on optimizing drug activity, but they should also be aware of the efforts made in risk assessment. For instance, the experimental measurement, or prediction, of skin permeability can be useful in assessing the possible topical delivery of drugs. In addition, QSPRs for skin permeability are also very useful in risk assessment in a variety of areas, e.g., occupational or occasional exposure. Within these areas it is important to be able to quantify uptake for different scenarios, for instance, for a worker continually exposed to a pesticide spray, or an accidental splash. For other membranes, e.g., the blood–placenta barrier, most uses will be for risk assessment purposes. In terms of the evaluation of risk, there is a clear need for this information, as a potentially hazardous compound will have a reduced risk if it is not able to be absorbed.

In terms of predicting membrane permeability, QSARs, or other models, should ideally be mechanistic in nature.<sup>2</sup> What this means in practical terms is that the descriptors used in the model should be capable of some form of interpretation. Thus, it is expected that molecular features such as lipophilicity will generally control the passage across

a lipid bilayer. Hydrogen bonding with phospholipids may retard transfer. In addition, molecular size and ionization may influence the ability to permeate through a membrane. Therefore, descriptors for these features can be used with confidence when modeling permeability. Inevitably, however, this is not an exhaustive list of physicochemical effects and other descriptors may be appropriate in certain QSPRs. In terms of an interpretable QSAR, preference is usually given to a transparent model with a 'clearly defined algorithm.' Regression analysis, in its various forms, meets these criteria. At the other end of the spectrum more multivariate and nonlinear techniques such as neural networks are perceived to be less interpretable. This does not exclude the use of such techniques, but it should be noted that transparency, which is most cherished, can be more difficult to ascertain from such models!

The aim of this chapter is to describe some of the approaches to predict, using a variety of in silico approaches, membrane permeability. The membranes considered in this chapter include the skin, the cornea, the placenta, the testis, as well as blood–(breast) milk transfer and renal excretion. Uptake across the gastrointestinal tract and blood–brain barrier (BBB) is not dealt with in this chapter as it is considered extensively elsewhere in this volume (*see* 5.28 In Silico Models to Predict Oral Absorption; 5.31 In Silico Models to Predict Brain Uptake). There is an emphasis on practical models for these membranes and an illustration of application, applicability, and future research requirements.

### 5.30.2 Dermal Penetration

The skin is the largest organ in the human body and provides an excellent biological protection against most chemicals. While the skin does have barrier properties, it is entirely possible for chemicals to permeate the skin. An appreciation of this process is beneficial for the increasingly popular use of transdermal drug delivery as well as for risk assessment following topical exposure to xenobiotics.

There are many methods to determine how much of a chemical will be transported across the skin, and many measurements that can be made and parameters that can be determined. These may be generalized into in vivo and in vitro measurements. From a practical point of view, in vitro measurements are easier to obtain and more widely available than in vivo measurements. They are also more likely to present the modeler with a greater selection of parameters (e.g., maximal flux, permeability coefficient etc.) to model. It should, however, be remembered that many experimental difficulties remain with measuring skin permeability either in vivo or in vitro. It is beyond the remit of this chapter to discuss these further<sup>3–5</sup> but these will impact on the precision of experimental data and thus the resultant accuracy of the models. Two guidelines for skin absorption have recently been adopted by the Organization of Economic Co-operation and Development (OECD), both on April 13, 2004, for in vivo measurement (OECD Guideline 427<sup>78</sup>) and for in vitro measurement (OECD Guideline 428<sup>77</sup>). It is hoped that use of these guidelines will provide reliable data for QSAR modeling in the future.

#### 5.30.2.1 Quantitative Structure–Activity Relationships for Skin Permeability

##### 5.30.2.1.1 Flynn database of skin permeability coefficients

There are a number of excellent reviews of QSARs that may be used to predict the ability of chemicals to cross the skin.<sup>3–10</sup> As such, this chapter will be restricted to the more useable and general models, or those with a particular interest or novelty. As with all QSAR modeling, predictivity is dictated by the data available to model. Key amongst the databases (*see* Table 2 for a full listing) has been the Flynn<sup>11</sup> data set. This is a collation of historical skin permeability coefficients ( $K_p$ ) for 94 compounds taken from literature sources. Although not originally intended for modeling, there have been numerous attempts to develop models from this compilation.

##### 5.30.2.1.2 Modeling skin permeability coefficients with lipophilicity and molecular size

First amongst the modelers of the Flynn database were Potts and Guy,<sup>12</sup> who postulated that partition into the skin ( $K_p$ ) is strongly related to lipophilicity, which may be quantified by the logarithm of the octanol/water partition coefficient ( $\log P$ ) and to diffusion through the skin, which is related to the size of the molecule, which in turn is easily quantified by molecular weight (MW). Thus, a general equation can be formulated to relate  $K_p$  to physicochemical properties:

$$\log K_p = \text{lipophilicity} - \text{molecular size} + \text{constant} \quad [3]$$

or, putting the terms  $\log P$  and MW into eqn [3]:

$$\log K_p = a \log P - b \text{ MW} + c \quad [4]$$

where  $a$  and  $b$  are the coefficients on the variables; and  $c$  is the constant.

**Table 2** A nonexhaustive list of permeability databases suitable for modeling

| <i>Measurement and membrane</i>  | <i>Number of compounds</i>  | <i>Type of compounds</i>                         | <i>Comments</i>  | <i>Reference</i>                               |
|--|---|--|--|--|
| Permeability coefficients through human skin in vitro  | 94  | Miscellaneous organic compounds, drugs, steroids | Historical database now updated with more reliable values (see Cronin <sup>6</sup> )                       | Flynn <sup>11</sup>                            |
| Permeability coefficients through human skin in vitro  | 94  | Miscellaneous organic compounds, drugs, steroids | Updated Flynn <sup>11</sup> database with new measurements   | Cronin <sup>6</sup>                            |
| Permeability coefficients through human skin in vitro  | 99  | Miscellaneous organic compounds, drugs, steroids | A reliable database of $K_p$ values  | Wilschut <i>et al.</i> <sup>33</sup>           |
| Permeability coefficients through human skin in vitro  | 98  | Miscellaneous organic compounds, drugs, steroids | Modified and updated Flynn <sup>11</sup> database  | Buchwald and Bodor <sup>20</sup>               |
| Miscellaneous in vitro and in vivo permeability endpoints for human skin   | Over 300  | Miscellaneous organic compounds, drugs, steroids | A web-based and fully searchable database with over 1600 in vitro and 800 in vivo results                  | Fitzpatrick <i>et al.</i> <sup>22</sup>        |
| Permeability coefficients through human skin in vitro  | 119   | Miscellaneous organic compounds and drugs        | Reliable database corrected for temperature and ionization   | Abrahams and Martin <sup>24</sup>              |
| Human skin/water partition coefficients  | 45  | Miscellaneous organic compounds and steroids     | Reliable database  | Abrahams and Martin <sup>24</sup>              |
| Permeability coefficients through human skin in vitro  | 112   | Miscellaneous organic compounds, drugs, steroids | Modified and updated (cleaned) database from Wilschut <i>et al.</i> <sup>33</sup> Available electronically | ten Berge database <sup>32</sup>               |
| Permeability coefficients through human skin in vitro  | 127   | Miscellaneous organic compounds, drugs, steroids | A fully validated database in terms of quality assurance, in addition to much additional information       | Vecchia and Bunge <sup>43</sup>                |
| Stratum corneum/water partition coefficient  | 76  | Miscellaneous organic compounds, drugs, steroids | A fully validated database in terms of quality assurance, in addition to much additional information       | Vecchia and Bunge <sup>44</sup>                |
| Various databases of permeability through the cornea, sclera, conjunctiva, corneal epithelium, stroma, and endothelium | Over 150 compounds; the corneal permeability database is the largest (over 110 compounds) | Miscellaneous, mainly drugs                      | A number of different databases of varying quality   | Prausnitz and Noonan <sup>45</sup>             |
| Blood to breast milk (milk-to-plasma (M/P) concentration ratio)  | 60  | Drugs  | A compilation of historical data of varying quality  | Agatonovic-Kustrin <i>et al.</i> <sup>58</sup> |
| Blood to breast milk (M/P concentration ratio)   | 115   | Drugs  | A compilation of historical data of varying quality  | Katritzky <i>et al.</i> <sup>61</sup>          |

Table 2 Continued

| Measurement and membrane  | Number of compounds | Type of compounds           | Comments  | Reference   |
|---|---------------------|-----------------------------|---|---|
| Various measures of blood to placenta transfer  | Over 100            | Miscellaneous, mainly drugs | A number of different databases of varying quality and size       | Pacifici and Nottoli <sup>51</sup>  |
| The unchanged drug excreted in the urine, expressed as a percentage of the intravenous dose | 160                 | Drugs                       | Historical data compiled from Brunton <i>et al.</i> <sup>54</sup> | Manga <i>et al.</i> <sup>55</sup>   |
| General pharmacokinetic properties of drugs   | Hundreds            | Drugs                       | Many and varied data  | Brunton <i>et al.</i> <sup>54</sup>   |
| Polydimethylsiloxane (PDMS)   | 256                 | Aromatic organic compounds  | A consistent and high-quality database                            | Chen <i>et al.</i> , <sup>69,70</sup> as compiled by Cronin <i>et al.</i> <sup>72</sup> |

Fitting the 94  $K_p$  values to eqn [4] reveals the following, well-established equation:

$$\log K_p = 0.71(\pm 0.06) \log P - 0.0061(\pm 0.006) \text{MW} - 6.3(\pm 0.8) \\ n = 93, r^2 = 0.67 \quad [5]$$

where the numbers in parentheses are the standard deviation on the regression coefficients;  $n$  is the number of observations; and  $r^2$  is the square of the correlation coefficient.

Equation [5] is seminal in the development of QSPRs for skin permeability and is referred to frequently in this chapter, and by other authors, as the 'Potts and Guy equation.' Since its publication, more accurate  $\log P$  data have become available and a more thorough QSAR analysis in statistical terms is warranted. To this end, Cronin<sup>6</sup> performed a new regression analysis of the complete Flynn<sup>11</sup> data set, resulting in the following:

$$\log K_p = 0.60 \log P - 0.0058 \text{MW} - 2.64 \\ n = 94, r^2 = 0.64, s = 0.79, F = 84 \quad [6]$$

where  $s$  is the standard error on the estimate; and  $F$  is the Fisher statistic.

Numerous workers were enthused by the Potts and Guy model to attempt to develop models for skin permeability coefficient further, in particular by improving statistical fit through the use of different physicochemical and structural properties. These mainly accounted for a subgroup of permeability coefficients for the steroids, which some workers also removed from the data set and modeled separately. Later studies e.g.,<sup>1-4,13</sup> showed that the original steroid permeability coefficients, which dated back to the 1960s, were not concordant with more recent measurements, indicating possible experimental error. When the original permeability coefficient data were substituted for the modern data, a better fit was observed. This would appear to be a salutary lesson for all QSAR modelers. The model, redeveloped by Cronin<sup>6</sup> with the new data, was:

$$\log K_p = 0.60 \log P - 0.0053 \text{MW} - 2.64 \\ n = 94, r^2 = 0.70, s = 0.68, F = 112 \quad [7]$$

Further analysis of the standard residuals from eqn [7] shows that some compounds, typically the steroids, are significant outliers. A number of approaches can be taken to this problem: (1) a 'let-it-be' attitude of doing nothing; (2) adding further descriptors to account for the steroids; or (3) removing the possibly erroneous data. As there is significant evidence that the permeability coefficients for the steroids were poor quality, Cronin<sup>6</sup> elected to remove 19 compounds, with steroid-type structures and for which there are no new data. Their removal results in the following QSAR, which has similar regression coefficients to eqn [7] and a better statistical fit:

$$\log K_p = 0.61 \log P - 0.0058 \text{MW} - 2.54 \\ n = 75, r^2 = 0.75, s = 0.63, F = 112 \quad [8]$$

Some compounds remain outliers, e.g., sucrose, although the model is not developed further. It is up to model users how they wish to use any of eqns [5–8] (or the QSARs) described below. Hopefully, future validation exercises for regulatory purposes will help resolve these issues.

The value of Potts and Guy approach was confirmed by Fujiwara *et al.*,<sup>15</sup> who extracted an ‘essential’ QSAR from those developed on a number of data sets. Ten skin permeability data sets were collected from the literature, including a total of 111 permeability coefficients in human, hairless mouse, or hairless rat skin for 94 structurally diverse compounds (the data are not reported in the manuscript but are almost certainly analogous to the Flynn<sup>11</sup> data set). QSARs based on  $\log P$  and MW were developed for all 10 data sets. These QSARs were analyzed simultaneously, assuming that all sets shared a latent, common factor as far as the structure/permeability relationship is concerned. Using a novel statistical technique, the so-called latent score variable or latent membrane permeability, the analysis confirms the role of  $\log P$  and MW, with approximately equal contributions to the prediction of skin permeability.

A database of over 100 physicochemical properties and skin permeation was compiled by Health Canada.<sup>16</sup> Analyses were performed using linear regression and QSARs for  $K_p$  based on  $\log P$  were improved by grouping the compounds according to their respective molar volumes. This data set was reanalyzed by Cronin *et al.*,<sup>17</sup> who confirmed the role of the Potts and Guy approach, as well as the influence of a number of outliers (as noted above) on the data set. While the data set presented was larger than the original Flynn database, the work on these data has been criticized, correctly, as some of the data appear to have been predicted by the Potts and Guy equation (or something similar to this). This, of course, is not good practice in QSAR development. The problems of the Kirchner *et al.*<sup>16</sup> data set and the models developed by Cronin *et al.*<sup>17</sup> were exemplified by Poda *et al.*<sup>18</sup> and later by Frasch and Landsittel.<sup>19</sup>

#### 5.30.2.1.3 Other approaches to modeling skin permeability coefficients

Buchwald and Bodor<sup>20</sup> collated data for the permeability coefficients of 98 compounds. This data set is, in effect, based on the Flynn database but, similar to the analysis of Cronin<sup>6</sup> (eqn [7]), updated to include more recently published data and also some of the corrected historical values (e.g., from Johnson *et al.*<sup>21</sup>). For the 98 compounds a relationship similar to the Potts and Guy<sup>12</sup> QSPR (eqn [8]) was obtained:

$$\log K_p = 0.60(\pm 0.04) \log P - 0.0052(\pm 0.0042) \text{ MW} - 6.02(\pm 0.12) \\ n = 98, r^2 = 0.75, s = 0.59, F = 144 \quad [9]$$

It is interesting to note that, while the data set has been ‘cleaned’ in terms of the steroid data, some of the outliers found by Cronin *et al.*<sup>17</sup> (e.g., digitoxin, ouabain, sucrose, etc.), which have legitimate physicochemical reasons for being removed, remained in the data set. This may explain the slightly lower  $r^2$  than might reasonably be hoped for.

The analysis of the enlarged data set was extended by Buchwald and Bodor,<sup>20</sup> who correctly noted that  $\log P$  and MW are relatively collinear for this data set. Collinearity of variables in a linear regression analysis is associated with instability, which may lead to false relationships being formed. To counteract this,  $\log P$  and MW were replaced by terms relating hydrogen bond acceptor ability ( $N$ ) and the effective van der Waals volume ( $V_e$ ):

$$\log K_p = 0.013(\pm 0.0014) V_e - 0.49(\pm 0.036) N - 5.94(\pm 0.12) \\ n = 98, r^2 = 0.72, s = 0.60, F = 124 \quad [10]$$

In order to account for changes in hydrogen-bonding between the octanol and water phases, eqn [10] was rearranged to give:

$$\log K_p + 0.72 N = 0.021(\pm 0.0007) V_e - 6.25(\pm 0.14) \\ n = 98, r^2 = 0.91, s = 0.74, F = 1010 \quad [11]$$

This latter model (eqn [11]) requires further investigation to clarify its meaning and application. While the statistical fit of eqn [10] was slightly lower than that for eqn [9], the authors claim that these parameters negate the reliance on  $\log P$  and  $V_e$  is a better estimate of molecular size than MW. Despite the lack of physicochemical similarity, Geinoz *et al.*<sup>8</sup> note that the two parameters  $N$  and  $V_e$  are highly correlated statistically, which many consider to be a drawback in regression-based QSARs.

A European Union Fifth Framework project, entitled Evaluation and Predictions of Dermal Absorption of Toxic Chemicals, more commonly known as the EDETOX project (project number QLKA-2000-00196), has confirmed the significance of the descriptors and mechanistic interpretation of the Potts and Guy equation by the measurement of further data. At the present time the best place to obtain information on the EDETOX project is from its website. The

website also contains an online database that comprises data produced by in vitro and in vivo percutaneous penetration studies. These have been compiled from the published literature, and data generated during the EDETOX project have also been entered. The database has allowed for the Potts and Guy data set to be extended from 94 chemicals published by Flynn to over 140 (S. C. Wilkinson, 2004, personal communication). Further information on this database and modeling is available from Fitzpatrick *et al.*<sup>22</sup>

The effect of the experimental design of the measurement of skin permeability has, until recently, been insufficiently studied. For instance, Martinez-Pla *et al.*<sup>23</sup> investigated the effect of pH of formulations on the dermal absorption of chemicals. These authors confirmed using biopartitioning micellar chromatography (BMC) that the pH at which the measurement is taken will influence the modeling, and especially the parameterization of lipophilicity. The hypothesis that ionization, and also temperature of the test system, are important for modeling skin permeability was confirmed by Abraham and Martins.<sup>24</sup> These authors adjusted literature values of the permeability coefficients through human skin from water for ionization in water and for the temperature of the test system. The  $\log K_p$  values obtained for 119 solutes, which were adjusted for temperature (to 37 °C) and for ionization, were correlated with Abraham descriptors to yield the following equation:

$$\begin{aligned}\log K_p = & -0.11(\pm 0.12) E - 0.47(\pm 0.09) S - 0.47(\pm 0.09) A \\ & - 3.00(\pm 0.15) B + 2.30(\pm 0.14) V - 5.43(\pm 0.10) \\ n = 119, r^2 = 0.83, s = 0.46, F = 112\end{aligned}\quad [12]$$

where  $E$  is the solute excess molar refractivity (in units of  $(\text{cm}^3 \text{mol}^{-1})/10$ );  $S$  is the solute dipolarity/ polarizability;  $A$  and  $B$  are the overall or summation hydrogen-bonding acidity and basicity respectively; and  $V$  is the McGowan characteristic volume (in units of  $(\text{cm}^3 \text{mol}^{-1})/10$ ).

Evaluating eqn [12] further, three separate test sets of 60 compounds had  $\log K_p$  predicted with an  $s$  of 0.48 log units. The main factors shown to influence  $\log K_p$  are solute hydrogen bond basicity, which lowers the permeability coefficient, and solute volume, which increases it.

Human skin/water partition coefficients ( $\log K_{sc}$ ) were collected for 45 compounds and yielded the following equation<sup>24</sup>:

$$\begin{aligned}\log K^{SC} = & 0.34(\pm 0.13) E - 0.21(\pm 0.10) S - 0.024(\pm 0.14) A \\ & - 2.18(\pm 0.16) B + 1.85 V(\pm 0.11) - 0.34(\pm 0.09) \\ n = 45, r^2 = 0.93, s = 0.22, F = 97\end{aligned}\quad [13]$$

The TOPological Sub-structural MOlecular DEsign, topological substructural approach (the so-called TOPS-MODE methodology) was used by Estrada *et al.*<sup>25</sup> to develop a model for the permeability of a series of 12 commercial solvents through living human skin (for more details on the TOPS-MODE methodology, see Estrada *et al.*<sup>25</sup>). This model accounted for more than 95% of the variance in the experimental permeability of these solvents. Using the derived model, the structural factors responsible for the permeability of this series of solvents through living human skin were identified. Methyl groups bonded to heteroatoms or to  $\text{CH}_2$  groups resulted in the greatest contributions to skin permeability. In contrast, groups of the type  $\text{X}=\text{O}$  ( $\text{X}=\text{S}, \text{C}$ ) were found to inhibit penetration. While there are only a small number of compounds utilized, this is an interesting paper as it makes a good attempt to relate structure back to activity (in this case, permeability) using a topological approach, something that is sadly missing from most topological QSAR studies. The applicability of the TOPS-MODE methodology should be demonstrated to a larger data set.

There may also be some value in the use of nonlinear models to predict skin permeability coefficients. For instance, Degim *et al.*<sup>26</sup> used artificial neural network (ANN) analysis to predict the skin permeability of selected xenobiotics.  $\log K_p$ , for 40 compounds, were obtained from various literature sources. A regression equation, based on  $\log P$  and a cross-multiplied term for MW and partial charges of the penetrants ( $\text{MW} \times \text{charge}$ ) for the skin permeability for the set of 40 compounds had reasonable statistical fit (and similar to that for the Potts and Guy equation):

$$\begin{aligned}\log K_p = & 0.59 \log P - 0.0028 \text{MW} \times \text{charge} - 2.64 \\ n = 40, r^2 = 0.67\end{aligned}\quad [14]$$

An ANN was developed for the  $\log K_p$  values for the same 40 compounds. It had  $r^2=0.997$ . While this seems to be a good model, further investigation is required to ascertain what a realistic level of predictivity is from such a model. In addition, these techniques are considered to lack transparency (i.e., no formal model is presented), are complex, and do not provide a easily portable algorithm as compared to, for instance, regression analysis.<sup>2</sup>

Nonlinear methods were also used in a similar fashion by Pannier *et al.*<sup>27</sup> These authors applied three fuzzy inference models using subtractive clustering to define natural structures within the data and assign subsequent rules. Each model was evaluated using the Flynn<sup>11</sup> data set. Fuzzy inference models successfully predicted skin permeability coefficients, with  $r^2$  ranging from 0.83 to 0.97. The lowest correlation coefficient resulted from a model using log  $P$  and MW as inputs with two input membership functions evaluated by two fuzzy rules. The correlation coefficient of 0.97 occurred when log  $P$  and hydrogen bond donor activity were used as inputs with three input membership functions evaluated by three fuzzy rules. Again, there is a suspicion of overfitting in these models, and a realistic evaluation of predictivity is required.

A completely novel approach to modeling skin penetration has been applied by Santos-Filho *et al.*<sup>28</sup> A set of 152 compounds was collated from the literature; of these, 40 were selected to be representative and were those on which modeling was performed. This study combined so-called membrane-interaction (MI) descriptors with more traditional QSAR parameters. Molecular dynamics simulations were employed to determine how each test compound (solute) interacts with a model dimyristoylphosphatidylcholine (DMPC) monolayer membrane model. The authors claim that MI-QSAR models may capture features of cellular membrane lateral transverse transport involved in the overall skin penetration process by organic compounds. The MI methodology has previously been applied to model eye irritation and Caco-2 cell permeation coefficients, and is described in detail elsewhere.<sup>29</sup> A large number of regression-based models are reported; the best have been found to be those non-MI-QSAR and MI-QSAR descriptors. For instance:

$$\begin{aligned}\log K_p &= 0.22 \log P - 0.14 E_{ss}(\text{tor}) - 0.05 E_{\text{inter}}(\text{vdW}) - 2.97 \\ n &= 39, r^2 = 0.80, q^2 = 0.77\end{aligned}\quad [15]$$

where  $E_{ss}(\text{tor})$  is the torsional energy at the total intermolecular system minimum energy for the solute;  $E_{\text{inter}}(\text{vdW})$  is the energy of the van der Waals penetrant-membrane interaction; and  $q^2$  is the leave-one-out cross-validated coefficient of determination.

Further improvements to these models are reported by increasing the number of descriptors up to six, and also by including quadratic terms. The use of these MI parameters is a novel and mechanistically appealing approach. It is hoped that the technique can be applied to all 152 compounds in the data set, and also that recommendations could be made for which is best of the 16 QSPRs published by Santos-Filho *et al.*<sup>28</sup> in terms of simplicity, robustness, and ease of application.

#### 5.30.2.1.4 Modeling of maximal flux

As noted in the introduction, a number of other measurements are available from the experimental determination of skin absorption, some of which may be amenable for modeling. For instance, Magnusson *et al.*<sup>30</sup> have investigated the modeling of maximal flux ( $J_{\text{max}}$ ). These authors used values from an aqueous solution across human skin; these values were acquired or estimated from experimental data and correlated with solute physicochemical properties. Whereas epidermal permeability coefficients  $K_p$  are optimally correlated to log  $P$ , MW was found to be the dominant determinant of  $J_{\text{max}}$  for these literature data:

$$\begin{aligned}\log J_{\text{max}} &= -0.019 \text{ MW} - 3.90 \\ n &= 87, r^2 = 0.85\end{aligned}\quad [16]$$

Addition of other physicochemical parameters to MW by forward stepwise regression only marginally improved the regression with a melting point (mp) term ( $r^2=0.88$ ) and then hydrogen-bonding acceptor capability ( $H_a$ ;  $r^2=0.92$ ) being significant. Evaluation of eqn [16] was performed with a number of other data sets, including an aqueous vehicle with full- and split-thickness skin ( $r^2=0.78$ ,  $n=56$ ). An analysis of the entire database gave the equation:

$$\begin{aligned}\log J_{\text{max}} &= -0.014 \text{ MW} - 4.52 \\ n &= 278, r^2 = 0.69\end{aligned}\quad [17]$$

with inclusion of mp and  $H_a$  increasing  $r^2$  to 0.76 ( $n=269$ ).

There is considerable motivation to develop simple qualitative rules for predicting skin penetration. Such a scheme was proposed by Flynn<sup>11</sup> for skin permeability coefficients. More recently Magnusson *et al.*<sup>31</sup> have proposed simple rules to define the potential of compounds to cross the skin. In vitro maximal flux values ( $J_{\text{max}}$ ) across human skin were collected for 87 compounds. Penetrants were assigned as being 'good' ( $J_{\text{max}} > 10^{-5.52} \text{ mol cm}^{-2} \text{ h}^{-1}$ ), 'bad' ( $J_{\text{max}} < 10^{-8.4} \text{ mol cm}^{-2} \text{ h}^{-1}$ ) or 'intermediate' based on mean  $\pm 1$  standard deviation. The study examined the

**Table 3** Simple structural rules for the potential of compounds to cross the skin based on in vitro maximal flux values ( $J_{\max}$ ), as defined by Magnusson *et al.*<sup>31</sup>

| <i>Property</i> | <i>Good penetrants</i> | <i>Bad penetrants</i> |
|-----------------|------------------------|-----------------------|
| MW              | $\leq 152$             | $> 213$               |
| $\log S$        | $> -2.3$               | $< -1.6$              |
| HB              | $\leq 5$               | $\geq 4$              |
| $\log P$        | $< 2.6$                | $> 1.2$               |
| mp              | $\leq 432$             | $\geq 223$            |

possibility of using fundamental and easily obtainable physicochemical properties, such as MW, mp (K),  $\log P$ , water solubility ( $S$ , molarity), and the number of atoms available for hydrogen-bonding (HB). Structural rules were developed for good penetrants and are summarized in Table 3. Discriminant analysis using MW, HB and  $\log P$  correctly assigned 70% of compounds, with no good penetrants being misclassified as bad or vice versa. This approach confirms the role of these fundamental physicochemical properties and provides very simple rules for their application.

### 5.30.2.2 Freely Available Expert Systems and other Formalized Models for the Prediction of Skin Permeability

Expert systems are useful as they have the capability of formalizing QSARs, QSPRs, and structure–activity relationships into user-friendly tools for the prediction of an endpoint directly from structural input. Several expert systems for the prediction of skin permeability are available. The best presented is the dermal permeability coefficient program (DERMWIN). This program is freely available from the US Environmental Protection Agency (EPA) through the EPISuite software and can be downloaded from its website. DERMWIN estimates the dermal permeability coefficient ( $K_p$ ) and the dermally absorbed dose per event (DAevent) of organic compounds. Structures are entered into DERMWIN through the Simplified Molecular Input Line Entry System (SMILES) notation or can be retrieved for over 103 000 compounds from their Chemical Abstract Service (CAS) registry numbers. DERMWIN estimates a  $\log P$  value for every SMILES string using the KOWWIN program and will automatically revert to an experimental  $\log P$  value should one be available. DERMWIN uses a version of the Potts and Guy<sup>12</sup> general equation to predict  $K_p$  for all structures:

$$\log K_p = 0.71 \log P - 0.0061 \text{ MW} - 2.72 \quad [18]$$

DERMWIN also makes  $K_p$  estimates for the alcohol, phenol, and steroid chemical classes using the following class-specific equations:

*(Aliphatic) alcohols*

$$\log K_p = 0.544 \log P - 2.88 \quad [19]$$

The aliphatic alcohol equation applies to any structure (except steroid-types) containing the –OH functional group connected to an aliphatic carbon.

*Phenols*

$$\log K_p = 2.39 \log P - 0.39 (\log P)^2 - 5.2 \quad [20]$$

The phenol equation applies to any structure containing the –OH functional group connected to an aromatic carbon.

*Steroids*

$$\log K_p = 1.01 \log P - 5.33 \quad [21]$$

DERMWIN also uses two methods to estimate the dermally absorbed dose per unit area per event (DAevent).

A calculation method is also provided by Ten Berge,<sup>32</sup> and is well described on his website. The website gives a good indication of the science behind the prediction. Skin permeation coefficients have been expressed mathematically as a

complex of permeation coefficients, presenting the permeation through the subparts of the skin:

$$K_{p(\text{skin-water})} = \frac{1}{(1/(K_{\text{lip}} + K_{\text{pol}})) + (1/K_{\text{aq}})} \text{ cm h}^{-1} \quad [22]$$

$$\log K_{\text{lip}} = b1 + (b2 \times \log P) + b3 \times \text{MW}^{0.7} \quad [23]$$

$$K_{\text{pol}} = \frac{b4}{\text{MW}^{0.7}} \quad [24]$$

$$K_{\text{aq}} = \frac{b5}{\text{MW}^{0.7}} \quad [25]$$

where  $K_{\text{lip}}$  is the partition coefficient into the lipid layer;  $K_{\text{pol}}$  is the partition coefficient into the protein layer;  $K_{\text{aq}}$  is the partition coefficient into the aqueous layer; and  $b1$ ,  $b2$ ,  $b3$ ,  $b4$ ,  $b5$  are regression coefficients.

Ten Berge<sup>32</sup> postulated that if the mathematical model is really a good description of the permeation process, it should be possible to estimate the regression coefficients from experimental results. To illustrate this, the paper of Wilschut *et al.*<sup>33</sup> provides an extensive database of measured dermal permeation coefficients for human skin. A slightly modified (cleaned) database was used to estimate the regression coefficients of eqns [22–25]. The results for the regression coefficients are:  $b1 = -1.74$ ;  $b2 = 0.72$ ;  $b3 = -0.060$ ;  $b4 = 0.00030$ ; and  $b5 = 4.21$ .

Regression coefficients  $b1$ ,  $b2$ , and  $b3$ , accounting for the lipid permeation, are all statistically significant. However,  $b4$  and  $b5$  were not significant, which ten Berge<sup>32</sup> explained with pragmatic and empirically based considerations. If a compound has a  $\log P$  less than 0,  $K_p$  is increasingly controlled by the permeation coefficient through the protein layer (regression coefficient  $b4$ ). Conversely, if a compound has a  $\log P$  greater than 4, the  $K_p$  coefficient is controlled by the aqueous permeation coefficient through the water layer below the stratum corneum (regression coefficient  $b5$ ). The database of Wilschut *et al.*<sup>33</sup> is underpopulated with compounds with  $\log P$  less than 0 and greater than 4, thus  $b4$  and  $b5$  were less accurately estimated. Moreover,  $b4$  and  $b5$  are only controlled by MW. These, and other conclusions regarding the regression coefficients  $b1$ – $b5$ , illustrate the beauty of breaking the permeability process down into its component parts and also, importantly for modeling, that passive diffusion through the skin is not a simple single-event phenomenon. It can also be observed that water solubility is important, as an increasing skin permeation coefficient does not always result in a higher skin permeation rate of the pure substance in contact with the skin. This is because the substance has to permeate the postulated water layer below the stratum corneum.

Water solubility may also be modeled (by an inverse relationship) with  $\log P$ , and may explain why some models contain a quadratic function with  $\log P$  and the relative success of nonlinear approaches (*see* 5.26 In Silico Predictions of Solubility).

Ten Berge<sup>32</sup> has also prepared some online software for use. A Windows version of the SKINPERM program is available from his website and formalizes eqns [22–25] for ease of use. Also available from this website is a Microsoft Excel file containing the database taken from Wilschut *et al.*<sup>33</sup> with slight modifications.

### 5.30.2.3 Other Issues in Modeling Skin Permeability

Current opinion is that percutaneous absorption can only be predicted for pure substances in an aqueous mixture, at an infinite dose.<sup>3</sup> While this is acceptable for modeling, it is simplistic and lacks an appreciation of the effects of formulations and mixtures, and the assumption of infinite dose is not realistic of most accidental and occupational exposure scenarios (although this may be what is strived for in dermal delivery of drugs).

Of these areas, there is certainly interest in predicting the relative enhancing effect of a solvent in a solution. There is much background knowledge regarding skin penetration enhancement<sup>34,35</sup>; however, currently no methods to ‘predict’ conclusively the effect of vehicles and solvents exist. Such an ability would be of particular benefit, for instance, in the assessment of toxicological endpoints such as skin sensitization.<sup>36</sup> An excellent review of structure–activity relationships for skin penetration enhancement, and compilation of data for this endpoint, is available from Kanikkannan *et al.*<sup>37</sup>

Some recent advances in the prediction of the effect of skin penetration enhancers are worthy of further consideration. Warner *et al.*<sup>38</sup> reported the findings of studies on the influence of *n*-alkanols, 1-alkyl-2-pyrrolidones, *N,N*-dimethylalkanamides, and 1,2-alkanediols as skin permeation enhancers on the transport of a model permeant, corticosterone. The effects of sodium lauryl sulfate (SLS) on the stratum corneum partitioning and permeability in porcine skin of 10 agricultural and industrial chemicals in water, ethanol, and propylene glycol was investigated by

van der Merwe and Riviere.<sup>39</sup> Some quantitative studies have also been performed to relate the degree of enhancement to structure. Borrás-Blasco *et al.*<sup>40</sup> studied several concentrations of SLS on skin permeability. These effects were investigated using seven drugs, selected to cover a broad range in  $\log P$  (from  $-0.95$  to  $4.2$ ). Skin pretreatment with aqueous solutions of SLS does not increase  $K_p$  for the lipophilic compounds ( $\log P \geq 3$ ). For the other drugs, the increase in  $K_p$  depended on the concentration of SLS used in the skin pretreatment, and on the lipophilicity of the compounds tested. A QSAR was developed between SLS enhancer efficacy (ER) and  $\log P$ .

QSAR techniques were also used by Ghafourian *et al.*<sup>41</sup> to investigate the activities of naturally occurring terpenes, pyrrolidinone, and *N*-acetylproline derivatives on the skin penetration of 5-fluorouracil, diclofenac sodium, hydrocortisone, estradiol, and benazepril. The resulting QSARs indicated that, for 5-fluorouracil and diclofenac sodium, less hydrophobic enhancers were the most active. For instance, for 26 terpene enhancers:

$$\log \text{ER} = -5.79(\pm 0.95) q^- - 0.46(\pm 0.13) E_v/10^4 + 0.14(\pm 0.26) \\ n = 26, r^2 = 0.63, s = 0.33, F = 19 \quad [26]$$

where  $q^-$  is the lowest atomic charge in the molecule; and  $E_v$  is the free energy of vaporization.

Although  $q^-$  is an electrostatic parameter explaining electrostatic interactions, it has been shown that it can also model hydrogen bonding in QSAR equations, with 'low'  $q^-$  values (high negative charges) leading to 'high' ability to accept hydrogens in hydrogen-bonding interactions. Thus it may be concluded that hydrogen-bonding has some controlling influence in skin permeability enhancement.

In contrast to eqn [26], skin penetration enhancement of hydrocortisone, estradiol, and benazepril showed a linear relationship with  $\log P$ . For instance, the enhancement ratio of terpenes towards hydrocortisone was:

$$\log \text{ER} = 0.15(\pm 0.03) \log P + 0.72(\pm 0.09) \\ n = 12, r^2 = 0.76, s = 0.089, F = 32 \quad [27]$$

There is clearly a lack of consistent information for the prediction of the skin penetration enhancement of chemicals. Some of the studies indicate that lipophilicity, as well as hydrogen-bonding, of enhancers is, at least partially, a driving force. There is a great requirement for a coherent set of systematic studies of varying enhancers on a suitable selection of permeants.

#### 5.30.2.4 Data Sources for Skin Permeability Modeling

Reading this chapter, recent reviews, and reference to the recent EDETOX project should confirm that there are a reasonable number of data for skin absorption openly available (some of the major data sources are listed in Table 2). Data sourcing and quality assessment are important concerns, and these items are described in detail with regard to predictive modeling by Cronin.<sup>42</sup> There are a number of documented quality issues with the skin permeability data.<sup>13,14</sup> Despite that, some of the databases listed in Table 2 are of particular use for modeling. When studying the data sources, the attention of the reader should be drawn to a number of issues. Firstly, the classic Flynn database<sup>11</sup> was never intended for the level of scrutiny, manipulation, and interpretation that it has received. Secondly, later databases, e.g., those presented by Wilschut *et al.*<sup>33</sup>; Vecchia and Bunge,<sup>43,44</sup> and the EDETOX project,<sup>22</sup> are of higher quality and have been better scrutinized in terms of suitability for modeling.

#### 5.30.3 Corneal Permeability

An appreciation of the penetration of a compound through the corneal membrane has a number of potential applications. Most research is focused towards the ocular delivery of drugs. However, there could also be important implications for risk assessment, i.e., if a compound is known to be able to cross the cornea then there may be possible harmful effects to the eye. Conversely, if it is not able to cross the membrane then toxicity assessment may not be required. As described below, data for transcorneal permeability are available, and some modeling of the data has been performed, but generally there is much less interest than for other permeability endpoints. The lack of work in this area as compared to, for instance, dermal penetration may reflect the smaller market for the ocular delivery of drugs and that a full suite of validated *in vitro* assays is available for endpoints such as eye irritation and corrosion.

Measured corneal permeability coefficients are available from the open literature. For instance, Prausnitz and Noonan<sup>45</sup> have listed over 300 permeability measurements for the cornea, sclera, and conjunctiva, as well as from the corneal epithelium, stroma, and epithelium for nearly 150 compounds taken from more than 40 different studies. Inevitably this number should have increased in the best part of a decade since publication. For the reasons noted above, the database is made up mainly from druglike molecules.

The structural basis of the permeability of the membranes in the eye to chemicals was considered by Prausnitz and Noonan,<sup>45</sup> and latterly their data were formalized by Worth and Cronin<sup>46</sup> to develop some general models. Using corneal permeability coefficients ( $K_{p\text{-corneal}}$ ) for 112 compounds taken from Prausnitz and Noonan,<sup>45</sup> Worth and Cronin<sup>46</sup> illustrated that, analogous to dermal penetration, a simple and mechanistic model could be developed on descriptors for lipophilicity ( $\log P$ ) and molecular size (MW). To model the data set, seven compounds were removed as being outside the acceptable range of the properties or as being outliers:

$$\begin{aligned}\log K_{p\text{-corneal}} &= 0.39 \log P - 0.0033 \text{ MW} - 4.77 \\ n &= 105, r^2 = 0.51, q^2 = 0.47, s = 0.46, F = 53\end{aligned}\quad [28]$$

A more thorough QSAR analysis was performed using other established QSAR descriptors. A significant equation was derived based on descriptors for hydrogen-bonding (number of potential hydrogen-bonding a molecule can form;  $n_H$ ), lipophilicity ( $\log P$ ) and molecular shape (the topological third-order kappa index:  $\kappa_3$ ). In order to develop models, a total of 17 compounds were removed from the data as being outliers in one or more of the three variables:

$$\begin{aligned}\log K_{p\text{-corneal}} &= 0.23 \log P - 0.068 n_H - 0.17 \kappa_3 - 4.35 \\ n &= 95, r^2 = 0.52, q^2 = 0.47, s = 0.46, F = 33\end{aligned}\quad [29]$$

Under no circumstances could eqns [28] and [29] be considered as ‘good’ models in terms of statistical fit. However, it must be remembered that their fit probably reflects, and is realistic of, the measurement of corneal permeability, i.e.,  $s = 0.46$  in eqn [29], which is approximately equivalent to expected experimental error. Further evidence for the relevance of these equations is provided by Yoshida and Topliss,<sup>47</sup> who, analyzing smaller data sets (of approximately 20 compounds) confirmed the role of lipophilicity, hydrogen-bonding, and ionization. It should be noted that the effects of ionization were not considered by Worth and Cronin<sup>46</sup> and may provide some improvement in the models. The importance of lipophilicity in the prediction of transcorneal permeability was also noted by Kishida and Otori.<sup>48</sup> Edwards and Prausnitz<sup>49</sup> also modeled the passive, steady-state permeability of cornea and its component layers (epithelium, stroma, and endothelium) as a function of drug size and membrane-to-water distribution coefficient ( $\phi$ ). The approach provided strategies to enhance corneal permeability by targeting epithelial paracellular pathways for hydrophilic compounds ( $\phi < 0.1 - 1$ ), epithelial transcellular pathways for intermediate compounds, and stromal pathways for hydrophobic compounds ( $\phi > 10 - 100$ ). The effects of changing corneal physical properties (e.g., to mimic disease states or animals models) were also examined. This last point is of considerable interest, for instance, in understanding permeability for patients when a drug is not being applied to a healthy membrane (as would be expected in a disease state).

Agatonovic-Kustrin *et al.*<sup>50</sup> used a neural network approach, based on experimentally derived values of corneal permeability ( $\log C$ ), for 45 compounds. Using a very large descriptor pool (1194 calculated molecular structure descriptors) a genetic algorithm was used to select a suitable subset of parameters to model  $\log C$ . A supervised network with a radial basis transfer function was applied, resulting in the best model having an architecture with four input descriptors and 12 hidden neurons. Inevitably, good correlations were obtained with these networks, with the correlation coefficient greater than 0.87 and 0.83 for the training and testing data sets respectively. Even with this good statistical fit, the small number of compounds in the model and complex architecture mean that the model must be treated with caution. The authors are pragmatic and recommend that expectations must be reasonable and large error limits accepted for predicted values from the models.

#### 5.30.4 Transfer from Blood to Placenta

There is great and obvious concern about the effects of drugs and other xenobiotics on the developing fetus. This is exacerbated by the complexity and resource-hungry (in terms of time, finances, and animals) nature of reproductive toxicology. There are considerable efforts to find alternatives to the traditional reproductive toxicology tests, although there is a growing appreciation that a (possibly large) number of effects will need to be modeled. Part of this will obviously be the pharmacokinetic effects, and uptake is a simple place to start. It would be of great benefit to know whether a compound will be taken up across the placenta or into the testis (*see* Section 5.30.7). With regard to the development of new pharmaceuticals, benefits include reduction in the cost of development, the ability to identify toxic compounds early in the development pipeline, and a reduction in animal usage. Non governmental organizations are in favor of techniques such as the isolated dually perfused human placenta assay (*see* below), as it does not require animals and fresh placentas are constantly available. Regulatory agencies desire improved techniques to assess the safety of medicines more rapidly. An additional bonus could be that the understanding of the placental barrier may allow drugs to be developed to treat the unborn fetus.

Predictions of placental transfer could have a specific application in the risk assessment of pharmaceuticals, as well as other chemicals. If it may be predicted with some certainty that a compound will not be absorbed, then there should be no risk associated with it, despite any hazards that may be identified. Thus, the accurate modeling of the transfer of molecules across the placenta is desirable in terms of risk assessment at the very least.

It should, however, be remembered that, of mammalian membranes, the placenta is unique in that it separates the blood of two individuals and allows for the delivery of oxygen and nutrients to the fetus. As a starting place to learn about the assessment of placental transfer of drugs, the reader should consider the review from Pacifici and Nottoli.<sup>51</sup> This review describes not only the experimental measurement, but also the role of gross physicochemical properties important in placental transfer. There are a variety of methods to measure absorption across the placental membrane. A search of the available literature indicates that there is a reasonable amount of data available, some of which may be suitable for modeling. These data are given in many units (from a variety of assays) including: level in the placenta ( $\text{pg g}^{-1}$ ); percentage transfer across the placenta; plasma enrichment (%); transplacental pulse fluxes ( $\mu\text{mol min}^{-1} \text{kg}^{-1}$ ); permeability ( $\text{cm}^3 \text{min}^{-1} \text{g}^{-1}$ ); and the clearance index standardized to antipyrine:

$$\text{Clearance index (CI)} = \frac{\text{Test compound clearance}}{\text{Antipyrine clearance}} \quad [30]$$

Clearance towards the fetus is calculated as follows:

$$\text{Clearance index (CI)} = \frac{(F_v - F_a) \times Q_f}{M_a} \quad [31]$$

where  $F_v$ , fetal vein concentration;  $F_a$ , fetal artery concentration;  $Q_f$ , fetal flow rate; and  $M_a$ , maternal artery concentration.

Antipyrine was chosen for comparison as it is a small lipophilic molecule that is known to be transported across the placenta via passive diffusion. Its use as an internal standard is beneficial as it corrects for experimental variabilities such as placenta weight, blood flow, and placental exchange surface area. This then allows clearance index data from different sources to be compared without having compatibility issues. The use of the clearance index leads to a more consistent measure of transfer rate. A database has been created by the authors of this chapter (as part of the European Union 6th Framework ReProTect Integrated Project) containing clearance index data for 109 structurally diverse compounds and is due for publication in 2006 (please contact the authors for further details).

Despite the data being openly available, due to the structural differences in placenta from different species, extrapolation from other species to humans is not possible except for primates. Therefore an *in vitro* technique is now employed that uses fresh human placental tissue in order to determine experimentally placental transfer characteristics. This is known as the isolated dually *in vitro* perfused placenta assay.

There have been relatively few attempts to develop models for the transfer of molecules across the human placental barrier. As with the modeling of other membranes, these assume that a passive diffusion process is to be quantified. Thus, the capabilities to influence transfer of the active transporters known to be present in the placenta, such as P-glycoprotein (P-gp), multidrug resistance protein-1 and -2 (MRP1, MRP2), and breast cancer resistance protein (BCRP),<sup>52</sup> are ignored. In addition, it is appreciated that the placenta has considerable metabolism capacity, although this is not taken account of in the modeling.

The models that are available indicate the role of physicochemical properties such as lipophilicity. For instance, Akbaraly *et al.*<sup>53</sup> derived a QSAR using the placental transfer ratio (TR) with respect to antipyrine, the so-called clearance index described above. Akbaraly *et al.*<sup>53</sup> discovered a significant parabolic (as well as biphasic) relationship with  $\log P$ , following the removal of two outliers:

$$\begin{aligned} \log \text{TR} &= 0.21(\pm 0.016) \log P - 0.074(\pm 0.0089) (\log P)^2 - 0.133(\pm 0.029) \\ n &= 19, r^2 = 0.92, s = 0.95, F = 93 \end{aligned} \quad [32]$$

where the numbers in parentheses are 95% confidence intervals on the regression coefficients.

It should be noted that the  $\log P$  values used were measured at 37 °C using a buffer at pH 7.4. Work in the laboratory of the authors of this chapter has not been able to repeat the success of the above equation due to differences in the reported measured  $\log P$  values and those calculated using more up-to-date calculation methods.

Since the publication by Akbaraly *et al.*<sup>53</sup> in the mid-1980s there has been little subsequent development of QSARs for placental transfer. There have been a number of papers exploring the placental barrier and further data have been generated, but these have not been developed into a new QSAR. Although no quantitative studies have been published, Pacifici and Nottoli<sup>51</sup> summarized a number of possible factors determining the extent of placental transfer. For instance, drugs with MWs greater than 500 Da have an incomplete transfer across the human placenta. This is in

line with similar findings relating to molecular size and passage across many, if not all, human membranes. Most (but not all) strongly dissociated acidic drug molecules have incomplete transfer. However, the extent of drug-binding to plasma protein does not appear to influence transfer of drugs across the human placenta. While these simple physicochemical rules may give some clues for risk assessment, they are not wholly suitable for discounting molecules as not being able to cross the placenta.

### 5.30.5 Renal Excretion

Excretion is an essential property to model if drug bioavailability is to be predicted successfully. Renal excretion of drugs and their metabolites is one of the key routes of drug clearance; the role of renal excretion in the prediction of pharmacokinetic parameters is well reviewed by Duffy.<sup>7</sup> It is also one of the more difficult properties to assess, as there is no direct measure of it, and those data that are available are not easy (i.e., often they are in the form of a percentage) to model. Typically data are obtained from literature sources, such as the ever-popular compilation of drug absorption, distribution, metabolism, and excretion data published by Brunton *et al.*,<sup>54</sup> commonly known as *Goodman and Gilman* (at the time of preparation of the manuscript, up to its 11th edition). Despite renal clearance being a useful parameter, there appear to be few models for it in the literature. An available model is described below.

Manga *et al.*<sup>55</sup> attempted to model the unchanged drug excreted in the urine, expressed as a percentage of the intravenous dose, administered for 160 drugs. This was an indirect attempt to model drug biotransformation. The data were categorized into classes according to excretion ranges. The cut-off values between those ranges were defined so as to enable optimal modeling. Modeling of the drug metabolism data was attempted utilizing a hierarchical approach comprising a set of rules combining both linear discriminant analysis and recursive partitioning. The model developed into a decision tree involving the following descriptors: the logarithm of the distribution coefficient at pH 6.5 ( $\log D_{6.5}$ ), counts of H-bond donors, ionization potential, total energy, electronic energy, counts of OH groups and COOH groups and the sum of the total net charges. Overall, this model assigned 90% of the compounds correctly. The model was successfully validated using an external test set of 40 compounds. This approach indicates a number of issues in the modeling of these endpoints, namely that nonlinear techniques are required, and also the probable role of ionization (i.e., the use of  $\log D$  as opposed to  $\log P$ ) and hydrogen-bonding.

### 5.30.6 Transfer from Blood into Breast Milk

Xenobiotics, drugs, and other chemicals have the capability to pass from a mother's blood into breast milk. This could clearly be of great concern for a breast-feeding mother to prevent (accidental) exposure to a baby. There is no formal guideline to assess breast milk transfer, although it is accepted that the most straightforward method is to measure directly concentrations in the milk and blood. These may be extrapolated to others through the use of the milk-to-plasma (M/P) ratio. There are clear difficulties in obtaining these values, not least the practical and ethical problems associated with sourcing nursing women to take part in trials. Thus there are few M/P data, and it does present a greater emphasis on the modeling of this endpoint.

In terms of modeling this endpoint, again relatively little has been performed in comparison to, for instance, dermal penetration. We are fortunate to have an excellent review into models and methods for predicting drug transfer into human milk by Fleishaker<sup>56</sup> and the reader is referred to this paper as a starting point for information. Meskin and Lien<sup>57</sup> provided the most fundamental models of M/P based on regression analysis, and  $\log P$  and MW for acidic drugs, and  $\log P$  and a parameter based on ionization for basic drugs. The fit for these models was only moderate, but probably realistic of the data being modeled.

Agatonovic-Kustrin *et al.*<sup>58</sup> extended a previous study<sup>59</sup> using a neural network. The latter study expanded the previous data set of M/P values for 60 drugs to that for experimentally derived M/P values, taken from the literature, for 123 drug compounds. Descriptors were selected with a genetic algorithm and modeled using an ANN. A nine-descriptor neural network model was developed. The descriptors applied included the percentage of oxygen, parachor, density, highest occupied molecular orbital energy, and a number of topological indices. These were considered to indicate that molecular size, shape, and electronic properties are important to predict drug transfer into breast milk. The data collected by Agatonovic-Kustrin *et al.*<sup>58</sup> were reanalyzed by Yap and Chen.<sup>60</sup> These authors removed one erroneous value, norfluxetine, and split the data set into a training set (102 compounds) and test set (20 compounds). Yap and Chen<sup>60</sup> also used a genetic algorithm to select seven descriptors possibly representing polarizability, electronegativity, and steric properties. A neural network approach was found to model the data much better than regression analysis on the basis of the prediction of values for the test set.

Katritzky *et al.*<sup>61</sup> have also searched the literature to obtain experimentally derived M/P ratio values for 115 widely used pharmaceuticals. Based on the data set, for 100 commonly used drugs, a seven-parameter regression-based QSAR model was derived showing satisfactory fit. While definitive mechanistic interpretation is not provided, the descriptors applied in the model encode possible information on hydrogen-bonding and molecular shape and symmetry. The commonality between the Agatonovic-Kustrin *et al.*<sup>58</sup> and Katritzky *et al.*<sup>61</sup> data sets has not been assessed at this time.

### 5.30.7 Blood-Testis

Related to the interest in predicting transfer across the placenta is interest in the modeling of the blood-testis barrier. If a chemical is able to cross this barrier from the blood, then it may damage the testes themselves, or the spermatozoa contained therein. Ideally these effects will be found by reproductive toxicity testing, but it is likely that many are still unquantified, and may only be obtained by large-scale epidemiological studies (for a full description of the function of the blood-testis barrier, see Bart *et al.*<sup>62</sup>). The ongoing concerns about endocrine disruption, and its possible relationship to falling sperm counts in men, are a good example. The possible place of predictions of blood-testis transfer in integrated testing strategies can be considered to be similar to those for placental transfer (see above). Namely, if a compound is observed or predicted not to be able to be taken up into the testes, then it will be of lower concern for risk assessment. This has all the possibilities for reductions in costs and animal usage as noted previously. In addition, an understanding of the role of blood-testis transfer may assist in the optimization of drug delivery for the treatment of testicular tumors and other disease states.

Of all the membranes considered in this chapter, there are probably fewer openly available experimental data for blood-testis transfer than any other membranes. This probably reflects the subtlety, as well as the experimental complexity, of this endpoint. Inevitably, in terms of modeling this means that very limited (if any) models are available, and only a limited comprehension of the structural basis of transfer. A number of parameters from experimentation may be useful for modeling purposes, including: transfer rates ( $\log k$  ( $\text{min}^{-1}$ )); absolute concentrations ( $\text{ng g}^{-1}$  (ml)); concentration in the testis ( $\mu\text{g g}^{-1}$ ); and the testis uptake index. The latter index is calculated according to Sakiyama *et al.*<sup>63</sup>:

$$\text{Testis uptake index (TUI)} = \frac{\text{Extraction of the test compound}}{\text{Extraction of the reference compound}} \quad [33]$$

To obtain these values, drug compounds are administered via injection along with radiolabeled butanol (which acts as a highly diffusible reference compound).

The literature contains some basic information about the role of structural properties to determine transfer from the blood to the testis. Johnson and Setchell<sup>64</sup> determined that the blood-testis barrier excluded high-molecular-weight immunoglobulins from seminiferous tubules. Okumura *et al.*<sup>65</sup> demonstrated that the permeability of the blood-testis barrier to nonelectrolytes was dependent on their molecular size. These studies are in further agreement with the known role of molecular size to influence uptake and suggest bulk flow through water-filled pores.

Due to the paucity of data, and the fact that there are few consistent data sets with more than five compounds, there are few QSARs to review for blood-testis transfer. Of these, Lien<sup>66</sup> modeled the transfer rate constant ( $k$ ,  $\text{min}^{-1}$ ) of some acidic drugs through the blood-testis barrier and determined a strong relationship with the chloroform/buffer distribution coefficient ( $D_{\text{CHCl}_3/\text{B}}$ ):

$$\begin{aligned} \log k &= \log D_{\text{CHCl}_3/\text{B}} - 1.59 \\ n &= 7, \quad r^2 = 0.86, \quad s = 0.19 \end{aligned} \quad [34]$$

The mechanistic interpretation of  $\log D_{\text{CHCl}_3/\text{B}}$  is not clear, although it may emphasize the role of partitioning. Clearly, however, such a QSAR, based on only seven compounds and a relatively unfamiliar descriptor and with no proper documentation, is of limited practical use.

### 5.30.8 Other Membranes

#### 5.30.8.1 Fish Gills

For environmental risk assessment it is useful to be able to estimate uptake of compounds, although these experiments are seldom performed, presumably due to their complexity and ease of measurement of fish lethality. Despite these practical difficulties some values for uptake across the fish gill are available and a limited amount of modeling is possible.

McKim *et al.*<sup>67</sup> published the percentage uptake efficiency of the trout (%uptake) for 14 chemicals. A limited QSPR analysis (unpublished results) reveals that one compound (mirex) is a significant outlier in the relationship with lipophilicity. The reason for this is unclear, though it is noted that the published (measured)  $\log P$  of this compound was 5.28, whereas the value reported by McKim *et al.*<sup>67</sup> was 7.50. The latter value would appear to be a more reliable estimate of the hydrophobicity of mirex. Removal of this compound reveals a statistically significant quadratic relationship with  $\log P$  (see 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption):

$$\begin{aligned} \% \text{uptake} &= 25 \log P - 2.5(\log P)^2 - 7.67 \\ n &= 13, r^2 = 0.93, s = 6.4, F = 62, \log P(\text{optimal}) = 5.14 \end{aligned} \quad [35]$$

A quadratic relationship with  $\log P$  was also seen for rate of absorption (primarily across the gills) in the guppy ( $k_{\text{gill}}$ ) for the 16 compounds reported by Saarikoski *et al.*<sup>68</sup>:

$$\begin{aligned} \log k_{\text{gill}} &= 0.80 \log P - 0.073(\log P)^2 + 0.017 \\ n &= 16, r^2 = 0.90, s = 0.17, F = 56, \log P(\text{optimal}) = 5.51 \end{aligned} \quad [36]$$

#### 5.30.8.2 Quantitative Structure–Permeability Relationships for other Routes of Uptake and Excretion

**Table 1** clearly identifies a number of routes of exposure and clearance. This chapter has emphasized those where there is significant QSAR and QSPR analysis. It is with some surprise that few, if any, models exist for important routes such as uptake across the lung and excretion into bile.

#### 5.30.9 Artificial Membranes

One of the major bottlenecks in developing QSPRs further is the paucity of available data. This has certainly held back the development of models for all the biological barriers discussed in this chapter. In addition, much of the variability in data quality and reliability can be accounted for by variations in the membranes themselves. It should not be ignored by modelers that most excised biological membranes are very delicate, and obtaining a source of a suitable membrane is difficult for a number of practical and ethical reasons. With regard to humans, as an example, it can only be obtained from cadavers, or following cosmetic (voluntary) surgery or other procedures such as amputations. It is well recognized that skin sourced from different parts of the body has different permeabilities, therefore obtaining consistent measured values may be difficult. Obtaining animal skin may also be fraught with ethical and legal reasons (e.g., in the UK, legislation requires pig skin to be boiled before distribution, thus destroying its integrity). Because of these and other issues, there has been considerable interest in the use of ‘artificial’ membranes. The area where this has been most commonly applied is in the assessment of skin penetration (particularly for product development of topical formulations). Most artificial membranes are some type of porous plastic, such as silastic and dialysis bags. This brief section will concentrate on the modeling of membrane transfer and the information it should give us. Consideration of other types of in vitro barrier systems, e.g., Caco-2, is provided elsewhere in this volume.

##### 5.30.9.1 Polydimethylsiloxane

An excellent database of flux values through a PDMS membrane has been developed by Chen *et al.*<sup>69,70</sup> and Matheson *et al.*<sup>71</sup> The authors report flux through PDMS for over 250 compounds: the one drawback is that all compounds are aromatic or cyclic. There are no aliphatic or noncyclic compounds in the database. Despite this, the database has good structural heterogeneity. Flux values for 103 compounds from 15 ring classes, including benzene, quinoline, naphthalene, pyridine, naphthyridine, furan, benzofuran, imidazole, benzimidazole, indole, thiophene, pyrrole, pyrazole, pyridazine, and pyrazine were reported by Chen *et al.*<sup>69</sup> Maximum steady-state flux was measured using isopropyl alcohol as solvent. In a simple QSAR study, partial charge calculations combined with solubility and MW provided a good estimation of flux for all 15 classes of compounds. The flux of the imidazoles was found to be systematically slower than expected, while that of aliphatic amines was faster. Indicator variables for these types of compound were included in order to improve the model. Chen *et al.*<sup>70</sup> subsequently reported the maximum steady-state flux of 171 compounds through PDMS membranes, using isopropyl alcohol as solvent, as a demonstration of the former QSAR approach. The new data included a variety of substituted benzenes, naphthalenes, thiophenes, benzimidazoles, pyridines, quinolines, isoquinolines, pyrimidines, triazoles, and other heterocyclic classes. Chen *et al.*<sup>70</sup>

concluded that permeability decreases significantly as the atomic charge of diffusant is increased. It was considered that atomic charges can be used to represent polarity and is related to this property for an electrically neutral compound. In similar studies, Matheson and Chen<sup>71</sup> reported the release of 52 compounds (half benzene and half pyridine derivatives) into water, loaded at their solubility limits in a filter-supported PDMS matrix. Solubility of the solid compounds in the matrix was related to the mp, MW, partial atomic charge of the solutes, and an indicator variable for pyridines. Release of the compounds from the matrix into water was controlled by the matrix itself, with the initial release following the square root of time relationship. The release coefficient was defined as the slope of the linear portion of the  $Q$ -versus- $t$  plot and was well predicted by mp, hydrogen-bonding energy group contribution, partial atomic charge in combination with an indicator variable as predictors (which could suggest it is solubility-dependent).

The data sets reported by Chen *et al.*<sup>69,70</sup> do provide a surprisingly good and consistent data set for modeling purposes. Cronin *et al.*<sup>72</sup> combined these two data sets and, after removing some duplicate compounds, developed QSPRs for maximum steady-state flux values for 256 compounds through a PDMS membrane ( $J_{\text{PDMS}}$ ). Forty-three physicochemical parameters were calculated for each compound and their significance to flux determined. Removal of 14 outliers enabled derivation of a significant three-parameter QSPR based on the number of hydrogen bond acceptor and donor groups (HA and HD, respectively) and sixth-order path molecular connectivity ( ${}^6\chi$ ):

$$\begin{aligned}\log J_{\text{PDMS}} &= -0.56 \text{ HA} - 0.67 \text{ HD} - 0.801 {}^6\chi - 0.38 \\ n &= 242, r^2 = 0.81, s = 0.46, F = 338\end{aligned}\quad [37]$$

In contrast to the findings of Chen *et al.*,<sup>70</sup> Cronin *et al.*<sup>72</sup> concluded that the mechanism of flux across a PDMS membrane is based mainly on hydrogen-bonding effects. In addition, Cronin *et al.*<sup>72</sup> investigated whether PDMS could act as a surrogate for skin flux measurements. There were no comparative flux measurements for both PDMS and skin, so an exercise was performed to compare the QSARs. Log  $P$  and MW (the parameters from the Potts and Guy equation (eqn [5])) were used to model PDMS flux. The coefficients of the QSPR based on these two parameters were not the same as those for skin, and a much reduced correlation coefficient was observed ( $r^2 = 0.55$ ) as compared to eqn [37]. The authors concluded that permeation through PDMS occurs via a mechanism of action different from that of penetration of the skin in humans and that the artificial membrane may not be a good surrogate for skin. It must, however, be remembered that the data for  $J_{\text{PDMS}}$  were measured using isopropyl alcohol as solvent, and skin flux measurements use aqueous solutions. The effect of the solvent is not known at this time.

The data set measured by Chen *et al.*<sup>69,70</sup> and organized and modeled by Cronin *et al.*<sup>72</sup> was also modeled by Agatonovic-Kustrin *et al.*<sup>73</sup> A QSPR for the maximum steady-state flux values through PDMS was developed using an ANN. A total of 42 molecular descriptors were calculated for each compound and a genetic algorithm was used to select the most relevant. Again, in contrast to the findings of the previous studies, the model developed indicated that molecular shape and size, intermolecular interactions, hydrogen-bonding capacity of drugs, and conformational stability were important. A 12-descriptor neural network model has been developed for the estimation of log  $J$  values. The root mean square error was found to be 0.36 for the training set and slightly higher, at 0.59, for the test set.

### 5.30.9.2 Quantitative Structure–Property Relationships for other Artificial Membranes

There have been a small number of other QSPR studies on artificial membranes in the past few years. Cross *et al.*<sup>74</sup> examined the relationship between solvent uptake into a model membrane (silicone) with the physical properties of the solvents (e.g., solubility parameter, mp, MW). The topical penetration and retention kinetics of hydrocortisone from various solvents were also assessed. The sorption of solvents into the membrane ( $V_F$ ) was related to differences in solubility parameters (the difference between the solubility parameter for the vehicle ( $\delta_v$ ) and the membrane ( $\delta_m$ )), MW and hydrogen-bonding acceptor ( $\alpha$ ) and donor ( $\beta$ ) ability:

$$\begin{aligned}V_F &= 0.735 - 0.0015\text{MW} - 0.10|\delta_v - \delta_m| - 0.512\alpha + 0.087\beta \\ n &= 28, r^2 = 0.76\end{aligned}\quad [38]$$

The authors concluded that a simple QSPR can predict the sorption of solvents into silicone membranes. Changes in solute diffusivity and partitioning appeared to contribute to the increased hydrocortisone flux observed with the various solvent vehicles.

The molecular properties that influence solute permeation across silicone membranes were assessed by Geinoz *et al.*<sup>75</sup> Permeability coefficients ( $K_{\text{p(sil)}}$ ) of a series of model solutes across silicone membranes were determined from simple transport experiments using a pseudo-steady-state mathematical model of the diffusion process. QSPRs were

developed utilizing the difference between octanol/water and 1,2-dichloroethane/water partition coefficients ( $\Delta \log P_{\text{oct/dce}}$ ). This parameter is associated with H-bond donor activity and was supplemented by the computationally derived molecular hydrogen-bonding potential. Hydrogen bond donor acidity and lipophilicity were shown to influence permeation across silicone membranes greatly:

$$\log K_{\text{p(sil)}} = 0.56(\pm 0.37) \log P - 0.011(\pm 0.0067) \sum \text{MHBP}_{\text{do}} - 1.16(\pm 0.72) \quad [39]$$

$$n = 16, r^2 = 0.77, q^2 = 0.61, s = 0.35, F = 21$$

where  $\sum \text{MHBP}_{\text{do}}$  is the sum of the calculated molecular hydrogen bond donor potential and the numbers in parentheses are 95% confidence intervals on the regression coefficients.

Furthermore, for a limited data set, a significant relationship was determined for solute permeation across the silicone membranes and through human epidermis ( $\log K_{\text{p(epi)}}$ ).

$$\log K_{\text{p(sil)}} = 1.15(\pm 0.36) \log K_{\text{p(epi)}} + 1.29(\pm 0.58) \quad [40]$$

$$n = 7, r^2 = 0.90, q^2 = 0.83, s = 0.19, F = 46$$

where the numbers in parentheses are 95% confidence intervals on the regression coefficients.

Geinoz *et al.*<sup>75</sup> concluded that they had determined the key molecular properties controlling solute permeation across silicone membranes. In contrast to the findings of Cronin *et al.*<sup>72</sup> who used a lateral approach to determine there was not a significant relationship between PDMS flux and that across skin, Geinoz *et al.*<sup>75</sup> showed that there is a good relationship between silicone and human skin  $K_{\text{p}}$  by the construction of a carefully chosen data set.

The modeling of permeability coefficients of various compounds through low-density polyethylene at 0 °C was investigated by Gonzalez and Helguera<sup>76</sup> using the TOPS-MODE approach. A model ( $r^2 > 0.92$ ) was developed for the experimental permeability of 38 organic compounds using the TOPS-MODE parameters. The TOPS-MODE methodology outperformed other QSAR techniques and gives some interpretation as to the contribution of different fragments to the permeability coefficients.

### 5.30.10 Recommendations

There is a great deal of work in the development of QSAR and QSPRs for membrane permeability. This has varied greatly in terms of the approach and philosophy taken, and the quality of the resultant model. Some recommendations for use and the further development of the models are given below.

- QSAR modeling of membrane transfer of any sort works best (or, in most cases, requires) steady-state, infinite-dose data such as a permeability coefficient.
- QSAR modeling of membrane transfer works best for passive diffusion. Much more effort is required to understand, quantify, and model the effects of active transport and metabolism for many of the membranes described in this chapter.
- More effort is required (especially for risk assessment scenarios) to resolve issues for nonsteady-state application such as finite-dose exposures.
- More work is required on the effects of formulation, solvents, and mixtures through all membranes.
- There must be realistic expectations for predictions from models of membrane transfer taking into account experimental limitations.
- Evaluation of models, with the possible long-term aim of validation for regulatory purposes, is recommended.
- The development of simple and, preferably, freely available software (such as DermWin and SKINPERM) for the prediction of membrane transfer would be useful, but must be used with caution due to the limitations of the models.
- With the possible exception of skin, more high-quality, consistent data are required.
- A greater assessment of the role of artificial membranes to act as surrogates for biological membranes is required.

### 5.31.1 Introduction

One of the key pieces of information needed in designing novel therapeutic agents is the ability of a compound to cross the blood–brain barrier. This information is needed for different reasons depending on the therapeutic endpoint of the drug. For neurological and psychiatric disorders the molecular targets reside in the brain and it is necessary for compounds to achieve efficacious concentrations in the vicinity of the target. However, equally important today is the desire to prevent undesirable side effects in peripherally acting drugs and in many cases this includes the necessity to limit the brain penetration of compounds. An example of this would be the antihistamine compounds where the first-generation compounds penetrated the brain and caused sedation. In more recent years it has become desirable for new therapeutic agents in this class to have minimal brain penetration and consequently no sedative effect.<sup>1</sup> The nature of the blood–brain barrier<sup>2</sup> is such that many exogenous substances are unable to penetrate it. The junctions between the endothelial cells of the barrier are tight (transendothelial electrical resistance, TEER, value  $\sim 8000 \Omega \text{ cm}$ ),<sup>2,3</sup> eliminating the ability of compounds to enter the brain by a paracellular route, a route available for some compounds to be absorbed from the intestinal tract.<sup>4</sup> In addition, many potential therapeutic agents are substrates for the efflux protein P-glycoprotein (P-gp).<sup>5,6</sup> P-gp is present on the luminal side of endothelial cells of brain capillaries and has the effect of binding to compounds and pumping them out of the brain (*see* 5.32 In Silico Models for Interactions with Transporters). In consequence, the brain penetration for these compounds is severely limited. The effect of P-gp can be confirmed by studies that compare the uptake into the brain for compounds in wild-type (wt) mice and knockout (ko) mice (genetically modified mice where P-gp is absent). These studies show that the brain penetration is greatly enhanced in ko mice if a compound is a P-gp substrate.<sup>5,6</sup> In vitro models of the blood–brain barrier, in which the transport of compounds through cell monolayers is measured, have been set up and can be used as permeation screens. They ‘mimic’ the blood–brain barrier and hence provide the means for scientists to ‘screen’ compounds for their potential to penetrate the blood–brain barrier. The difficulty of maintaining the tight junctions between cells and in developing robust cell-based systems that express a full complement of transport proteins has meant that, to date, these in vitro methods have had limited utility in screening pharmaceutical agents although they have their place in specific mechanistic studies (*see* 5.12 Biological In Vitro Models for Absorption by Nonoral Routes). This means that in vivo experiments are still the main method of assessing the brain uptake of compounds. These experiments are costly both in terms of quantity of compound needed and number of animals required. Hence, there is a drive within

the pharmaceutical industry to limit these experiments for both ethical and economic reasons. In silico models of brain penetration are one technique that can help in this respect.

Early in the drug discovery process large numbers of compounds are proposed for synthesis using combinatorial design methods. Here the use of in silico methods is particularly applicable if the calculations are sufficiently fast that they can profile thousands of compounds in a few minutes. In the later stages of lead optimization the project team is likely to have smaller numbers of compounds they wish to profile and will accept a slower calculation time per compound, particularly if it results in a more reliable prediction.

There is a wealth of information published in the literature and in the databases of pharmaceutical companies on compounds for which brain penetration has been measured<sup>7–13</sup> or on compounds that are known to exhibit CNS (central nervous system) mediated pharmacological effects.<sup>14–17</sup> By combining this information with knowledge about the molecular properties of compounds, it is possible to develop in silico models of brain penetration. Scientists are now able to use these models to make reasonably accurate predictions about which compounds are likely to have good brain penetration and which are not. This results in an ability to bias both the synthetic effort and prioritization for in vivo testing toward the compounds most likely to have the desired brain penetration profile.

Details of many in silico methods that attempt to predict a variety of measures of brain uptake have been published and reviewed.<sup>7,18–21</sup> Here, an attempt has been made to bring all this work together and analyze the common features responsible for brain uptake (or lack of it) and to consider their application in the delivery of therapeutic agents to the brain.

### 5.31.2 Measures of Brain Uptake

The terms ‘brain uptake’ or ‘brain penetration’ are frequently used to describe entry of compounds into the brain, but without any precise definition. They are in fact ‘catch-all’ phrases that encompass a variety of processes in which chemicals are transferred to the brain. The term ‘brain uptake’ is used here in the sense of a general term that includes various ways in which chemicals are transferred.

One of the first measures of brain uptake was that of biological activity. Hansch and co-workers<sup>22</sup> studied the hypnotic activity of a series of depressants and noted that the activity reached a maximum when the water/octanol partition coefficient, as  $\log P_{\text{oct}}$ , was near two. This seems to be the origin of the ‘rule-of-two.’ Timmermans and colleagues<sup>23</sup> appeared to confirm a parabolic relationship between brain uptake and  $\log P_{\text{oct}}$ , but on inspection it is very difficult to distinguish a parabola at all. Waterhouse<sup>24</sup> claimed that Dishino and co-workers<sup>25</sup> had shown a parabolic relationship between brain uptake and lipophilicity as measured by  $\log P_{\text{oct}}$ . The measure of brain uptake was the per cent extraction, as determined by a single pass method involving sequential injection of  $^{15}\text{O}$ -labeled water and  $^{11}\text{C}$ -labeled compound in an ethanol–saline bolus. This measure of per cent extraction would be expected to lead to a sigmoid curve. Dishino and co-workers<sup>25</sup> specifically explained the downturn for the more lipophilic compounds as being due to mixing of the ethanol–saline bolus with blood – the more lipophilic compounds are retained by blood and hence their per cent extraction is less than expected.

Oldendorf<sup>26,27</sup> described a much more rigorous measure of brain uptake, the brain uptake index (BUI). A mixture of a  $^{14}\text{C}$ -labeled compound and  $^3\text{H}$ -labeled water in saline is injected into a rat, and the radioactivity in the brain recorded 15 s after administration. The BUI is then defined as follows, where  $\text{BUI} = 100$  for water:

$$\text{BUI} = 100(^{14}\text{C}/^3\text{H})_{\text{brain}}/(^{14}\text{C}/^3\text{H})_{\text{saline}} \quad [1]$$

The BUI is a useful rank order of brain uptake,<sup>26–28</sup> but is difficult to analyze by physicochemical methods, since it is neither a rate nor an equilibrium quantity. Other measures of brain uptake are now much more commonly used.

The first such measure was introduced by Rappoport and colleagues<sup>29,30</sup> and involved intravenous injection. This was later developed<sup>31,32</sup> into the in situ perfusion technique, in which an aliquot portion of whole blood or plasma or saline containing a radiolabeled compound is injected into an artery and the amount that perfuses through the blood–brain barrier is determined at a given time, typically 1–2 min after perfusion. Many workers have developed this technique, including Deane and Bradbury,<sup>33</sup> and Pardridge and colleagues.<sup>34</sup> Results are obtained as a ‘one point’ kinetic experiment, from which a perfusion coefficient (PC; in units of  $\text{cm s}^{-1}$ ) may be obtained. More usually, permeation is expressed as a product of permeability and surface area (PS; in  $\text{cm}^3 \text{s}^{-1} \text{g}^{-1}$ ). As mentioned, the perfusate can be whole blood, plasma, or various saline solutions, since there is no one generally accepted perfusate. There is no reason why the factors that influence perfusion should be quantitatively the same for the various perfusates, and so the different perfusates must of necessity be considered to be a different system, as regards physicochemical analysis. In all cases, however, the time scale of the experiment is very short, i.e., usually of the order of 1–2 min.

The second measure was described by Young and colleagues,<sup>8,9</sup> in two key papers that have formed the foundation of in vivo data on blood–brain distribution. A compound is administered to a rat and after a given time, the concentration of the compound in blood and in brain is determined. Usually, several rats are sacrificed in this way, in order to ascertain if the blood to brain concentration ratio reaches a steady state. If so, then the blood–brain distribution coefficient (BB) is defined as:

$$BB = [\text{conc. of compound in brain}]/[\text{conc. of compound in blood}] \quad [2]$$

Typically, the distribution coefficient is obtained at intervals of time up to several hours, in contrast to the short time scale of the perfusion technique.

In addition to the in vivo technique developed by Young and colleagues,<sup>8,9</sup> environmental scientists have obtained distribution coefficients for volatile environmental pollutants by an in vitro method. The partition of a volatile compound between the gas phase and blood ( $K_{\text{blood}}$ ) and between the gas phase and homogenized brain ( $K_{\text{brain}}$ ) is determined as:<sup>35,36</sup>

$$K_{\text{blood}} = [\text{conc. of compound in blood}]/[\text{conc. of compound in air}] \quad [3]$$

$$K_{\text{brain}} = [\text{conc. of compound in brain}]/[\text{conc. of compound in air}] \quad [4]$$

Then,

$$BB = K_{\text{brain}}/K_{\text{blood}} \quad [5]$$

Concentrations are usually taken as  $\text{mol dm}^{-3}$  in the gas phase and blood, and  $\text{mol kg}^{-1}$  in brain.

Abraham and co-workers<sup>10</sup> combined the in vivo BB values of Young and colleagues<sup>8,9</sup> for drug compounds with a compilation of in vitro values for environmental volatile organic compounds given by Abraham and Weathersby<sup>37</sup> to yield a set of BB values that has provided the basis of subsequent data sets on blood–brain distribution. It should be noted that the in vivo BB values of Young and colleagues<sup>8,9</sup> refer to rat blood and rat brain, but the in vitro values for environmental volatile organic compounds refer to both human and rat blood and brain.

Pardridge<sup>38</sup> has recently criticized the use of blood–brain distribution by the pharmaceutical industry, and has strongly argued that only the perfusion method is meaningful. However, this argument overlooks the very different time scales of the two methods. In some cases, it might be appropriate to consider perfusion results that indicate how quickly a drug will diffuse through the blood–brain barrier. In other cases, it might be more useful to consider the blood–brain ratio after several hours. In addition, there are complications regarding perfusion from saline of ionizable species, which are discussed later. Most recent work on physicochemical analyses has focused on blood–brain distribution, but both the perfusion and the distribution methods will be considered here.

A third measure of brain uptake is referred to as CNS penetration or CNS activity. Although this seems to be more specific than ‘brain uptake’ it is not a very well defined parameter, and is usually recorded just as CNS + or CNS –. In the review by Seelig and colleagues<sup>14</sup> CNS + / – are assigned using various processes. Later workers have expanded this compilation.<sup>15,16</sup> Ajay and colleagues<sup>17</sup> assigned CNS + on the basis of therapeutic activity of various classes of drugs, but pointed out that the assignment of CNS – is difficult on this basis because absence of therapeutic activity cannot be taken as synonymous with inability to cross the blood–brain barrier. The assignment of CNS + and CNS – will be considered later.

## 5.31.3 Blood–Brain Distribution

### 5.31.3.1 Calculations

By far the majority of papers on in silico calculations of ‘brain uptake’ have dealt with blood–brain distribution,<sup>20,39–66</sup> defined by eqn [2] for the direct determination of drugs, and through eqns [3] to [5] for the indirect determination of volatile pollutants. It should be pointed out that all these in silico calculations attempt to explain passive transport from blood to brain, and do not include processes such as efflux mechanisms or active transport.

If in silico calculations are to be used for screening of large numbers of candidate drugs, it is important that the data set covers as wide a chemical space as possible, especially as the chemical space covered by experimental methods is small. Furthermore, it is essential to provide some predictive assessment of any calculation. Very often, validation methods such as ‘leave-one-out’ are used, but these provide only an assessment of internal consistency. The only way to assess the predictive power of a calculation is to separate the initial data set into a training set and a test set.

The former is used to construct an equation and to predict values of the test set. Since the test set has not been used to obtain the equation, a comparison of predicted and experimental values for the test set yields an assessment of predictive capability. It is common to compare the sets of predictive and experimental values by plotting one set against the other. This is not correct, and it is better simply to obtain statistics on the two sets of data, such as the average error (AE), which is a measure of bias, and the absolute average error (AAE) and standard deviation ( $s$ ), which are measures of goodness-of-fit.

The predictive assessment for a test set refers only to the chemical space of the compounds that make up the test set, and not to the chemical space of the training set. This is why it is important for the test set to cover as wide a range of chemical space as possible, and why test sets of only a handful of compounds yield no real general assessment of predictability.

In **Table 1**, a summary of the various *in silico* calculations to date is given. The number of compounds in the training set and the test set ( $n$ ), and the standard deviation found for the training set and the test set are given. In some cases, the descriptor used is listed.  $\Delta G_h^\circ$  is the standard free energy of hydration of the gaseous compound and PSA is the polar surface area; ANN means that an artificial neural network was used. As can be seen, many investigators give no results for test sets at all, and so no predictive assessment can be made in these cases.

In **Table 2**, the 'best' predictive methods are listed, in terms of the  $s$  value for the test set. There are several calculations that yield predictions with an  $s$ -value of around 0.4 log units for a reasonable number of compounds. We first concentrate on these particular procedures, and then draw some general conclusions from all the calculations listed in **Table 1**.

The simplest calculation is that of Keserü and Molnár<sup>47</sup> who used only one descriptor – the standard free energy of hydration of the gaseous compound ( $\Delta G_h^\circ$ ) in  $\text{kJ mol}^{-1}$ . This was related to values of log BB through the equation:

$$\begin{aligned}\log \text{BB} &= 0.26 + 0.035 \Delta G_h^\circ (\text{kJ mol}^{-1}) \\ n &= 55, r^2 = 0.72, s = 0.37\end{aligned}\quad [6]$$

Here and elsewhere,  $n$  is the number of data points (usually the number of compounds),  $r$  is the correlation coefficient, and  $s$  is the standard deviation. Some years before this work, Lombardo and colleagues<sup>40</sup> also used  $\Delta G_h^\circ$  as a predictor of log BB, although their calculation by AMSOL 5.0 with AM1-SM2 hydration model is considerably more time consuming than that of Keserü and Molnár. Even the latter calculation, at 6 s per molecule, is not very fast in the context of high-throughput screening. Lombardo and colleagues obtained eqn [7], but with  $\Delta G_h^\circ$  in  $\text{kcal mol}^{-1}$ . The corresponding equation in the same units as eqn [6] is given as eqn [8], and it can be seen that the slopes of eqns [6] and [8] are considerably different.

$$\begin{aligned}\log \text{BB} &= 0.43 + 0.054 \Delta G_h^\circ (\text{kcal mol}^{-1}) \\ n &= 55, r^2 = 0.67, s = 0.41, F = 108.3\end{aligned}\quad [7]$$

$$\log \text{BB} = 0.43 + 0.013 \Delta G_h^\circ (\text{kJ mol}^{-1}) \quad [8]$$

Not only do the slopes of the equations differ by a factor of 2.7, but also the actual numerical values of  $\Delta G_h^\circ$  (in the same units) differ greatly between the two methods of calculation. Some comparisons are given in **Table 3**, mostly for simple compounds for which experimental values are available.<sup>67</sup> Differences between the results of Keserü and Molnár and experimental values are so large that clearly great care must be taken over predictions for compounds that are even slightly outside the chemical space used. One reason why the method of Keserü and Molnár<sup>47</sup> works as well as it does is that the slope in eqn [6] is so small that even large errors in  $\Delta G_h^\circ$  are transformed into small errors in the calculated log BB values.

The method of Luco<sup>44</sup> also yields statistics for a test set of 37 compounds ( $s=0.37$ ) that show the predictive capability of the method. Luco uses 18 descriptors from an original set of 25 that include connectivity indices, a shape factor, molecular surface, and counts of hydrogen bond acid and hydrogen bond base groups. A partial least squares (PLS) analysis reduces the variables to a three-component model that correlates log BB for 55 compounds with  $n=55$ ,  $r^2=0.85$ ,  $s=0.32$ , and  $F=102$ ; however, note that the  $F$ -statistic is calculated on the basis of three variables and not 18. For an independent test set of 37 compounds, the  $s$ -value was only 0.37 log units, so that the method of Luco is one of the best, as regards predictability of log BB. However, it not clear how the method can be implemented; Luco<sup>44</sup> calculates the connectivity-topological descriptors with a computer software program obtained privately, and similarly for the calculation of charge and geometrical indexes.

Norinder and Österberg<sup>50</sup> also used a PLS method but this was based on only six descriptors. Four electrotopological state indices were calculated using Molconn-Z, a commercial software package, and the water/octanol partition coefficient ClogP and molar refraction were calculated through the software package Sybyl. Hence, all six descriptors

**Table 1** Summary of recent in silico models of log BB

| Equation                | Desc. <sup>a</sup>               | Training set          |                       | Test set        |                   | Reference |

Desc. is the number of descriptors used.

can be calculated with available software. Two training sets of 28 compounds yielded  $r^2$ -values of 0.75 and 0.78 with corresponding  $s$ -values of 0.39 and 0.37 log units, respectively. The test sets of 30 compounds had  $s$ -values of 0.35 and 0.38 log units. The method of Norinder and Osterberg<sup>50</sup> thus seems to be one of the easiest to implement, and provides a predictive capability unlikely to be greatly exceeded. The only caveat is that the data set is restricted to a total of 58 compounds.

The method of Platts and co-workers<sup>51</sup> is quite different. Five descriptors plus an indicator variable are used in a multiple linear regression analysis. The descriptors are the well-known solvation parameters used in the general equation<sup>68,68a</sup>:

$$SP = c + e \cdot E + s \cdot S + a \cdot A + b \cdot B + v \cdot V \quad [9]$$

**Table 3** Calculated and experimental values of standard free energies of hydration,  $\Delta G_{\text{h}}^{\circ}$ , in  $\text{kJ mol}^{-1}$

| Pentane               | 9.37                | 7.66                | 9.70               |

where SP is the dependent variable such as values of log BB for a series of compounds and the independent variables are solute properties or descriptors as follows.  $E$  is the solute excess molar refractivity in units of  $(\text{cm}^3 \text{mol}^{-1})/10$ ,  $S$  is the solute dipolarity/polarizability,  $A$  and  $B$  are the overall or summation hydrogen bond acidity and basicity, respectively, and  $V$  is the McGowan characteristic volume in units of  $(\text{cm}^3 \text{mol}^{-1})/100$ . Platts and co-workers<sup>51</sup> constructed a large data base of 148 compounds, and used a training set of 74 compounds to predict the remaining log BB values in the test set with an  $s$ -value of 0.38 log units. They used an indicator variable ( $I$ ) for carboxylic acids such that  $I=1$  for carboxylic acids and  $I=0$  for all other compounds. For the total set of 148 compounds Platts and co-workers found:

$$\begin{aligned} \log \text{BB} &= 0.06 + 0.47 E - 0.86 S - 0.59 A - 0.71 B + 0.90 V - 0.56 I \\ n &= 148, r^2 = 0.74, s = 0.34, F = 83 \end{aligned} \quad [10]$$

The indicator variable shows that carboxylic acids are less likely to distribute into the brain than expected from the usual descriptors. Equation [10] is about as good, statistically, as other equations for log BB, but has a decided advantage in pointing out the chemical factors that influence log BB. This will be returned to later. An initial disadvantage of eqn [10] was that descriptors had to be obtained from various experimental values. However, Platts and colleagues<sup>69</sup> showed that a fragmentation scheme could be constructed for the very rapid calculation of descriptors, and hence of log BB. More recently, a fragmentation scheme for the calculation of the descriptors has become available commercially,<sup>70</sup> and so the initial disadvantage no longer applies.

The largest data set used to date is that compiled by Yap and Chen,<sup>65</sup> who set out log BB values for 175 compounds. Of these, 12 were considered as outliers from previous work, and descriptors could not be calculated for the rare gases, leaving 159 compounds for the analysis; 125 were used to construct models, and 30 compounds were left as an independent test set. Yap and Chen set up three methods, all based on descriptors calculated by the DRAGON software. A simple multiple linear regression (MLR) used nine descriptors. A neural network, MLFN, also used nine descriptors and a Bayesian-type neural network, GRNN, employed seven descriptors. Results are summarized in Tables 1 and 2 and show that, for the test set,  $s$ -values of 0.37 to 0.40 (calculated in this work) could be achieved.

The above methods can all predict test sets of log BB to about 0.37 log units, so there is not much to choose between them in terms of predictability. The method of Luco seems difficult to implement, but the methods of Keserü and Molnár,<sup>47</sup> Norinder and Osterberg,<sup>50</sup> Platts and co-workers,<sup>51</sup> and Yap and Chen<sup>65</sup> can all be carried out using commercial software.

In addition to these methods, a number of others can be used to obtain log BB values, though to less accuracy as regards predictions. Of these, the calculations of Feher and colleagues<sup>45</sup> are very simple indeed. Only three descriptors are used: a calculated log  $P_{\text{oct}}$  value, the polar surface area, and the number of hydrogen bond acceptors in an aqueous medium,  $n_a$ . For a training set of 61 compounds, Feher and colleagues<sup>45</sup> obtained the equation:

$$\begin{aligned} \log \text{BB} &= 0.43 - 0.39 n_a + 0.11 \log P_{\text{oct}}(\text{calc}) - 0.0027 \text{PSA} \\ n &= 61, r^2 = 0.73, \text{RMSE} = 0.42, F = 51 \end{aligned} \quad [11]$$

The root mean square error (RMSE) is almost the same as the standard deviation ( $s$ ) except that RMSE has one more degree of freedom (hence, RMSE is trivially less than  $s$ ). The results of predictions through test sets are a little

disappointing, with  $s$ -values of 0.76 and 0.81 for test sets with 14 and 25 compounds. These  $s$ -values have been calculated in this work. Feher and colleagues give RMSE values of 0.63 and 0.79 but these seem to be calculated from plots of predicted versus experimental values, which is not quite correct.

A number of other methods lead to reasonable results, but have no advantage over those mentioned above. Pan and co-workers<sup>63</sup> employed a very simple method that uses only two descriptors, the calculated  $\log P_{\text{oct}}$  value and the polar surface area. Although they used a large data set of 150 compounds, they give few statistics for the full data set, only  $r^2 = 0.69$  and  $q^2 = 0.59$ , and restrict further details to rather small subsets. One of the more recent models is that of Winkler and Burden<sup>64</sup> who used a Bayesian neural network to examine a number of sets of descriptors. They found that a set of seven quite simple molecular descriptors yielded the best results. However, the obtained statistics (see [Tables 1 and 2](#)) are not as good as those of several other models. Narayanan and Guntari<sup>66</sup> examined a data set of 88 log BB values, and calculated 324 descriptors by in-house software. The best three-descriptor model had  $s = 0.42$  and the best four-descriptor model had  $s = 0.39$ , which are no better than many other models. Since the descriptors are very difficult to interpret in terms of chemical structure, the method offers no advantages.

Hou and Xu<sup>61</sup> use only three descriptors, a calculated  $\log P_{\text{oct}}$  value, SlogP, based on their own methodology,<sup>71</sup> the high-charged polar surface area (HCPSA), and a molecular weight (MW) term that takes the value  $\text{MW} - 360$  for compounds with  $\text{MW} > 360$  and zero for other compounds. A linear combination yields the equation:

$$\begin{aligned}\log \text{BB} &= 0.008 + 0.20 \text{ SlogP} - 0.014 \text{ HCPSA} - 0.014 (\text{MW} - 360) \\ n &= 72, r^2 = 0.79, s = 0.36, F = 82.6\end{aligned}\quad [12]$$

Two test sets were predicted through eqn [12]. For the combined sets of 35 compounds we calculate that  $\text{AE} = 0.04$ ,  $\text{AAE} = 0.29$ , and  $s = 0.41$ , using the equation and results listed in the errata of Hou and Xu.<sup>61</sup> Following the success of eqn [12], Hou and Xu<sup>61</sup> re-parametrized the calculation of SlogP, and replaced HCPSA with the more easily calculatable high-charged topological polar surface area (HCTPSA) and derived the equation:

$$\begin{aligned}\log \text{BB} &= 0.13 + 0.16 \text{ SlogP} - 0.013 \text{ HCTPSA} - 0.015 (\text{MW} - 360) \\ n &= 78, r^2 = 0.74, s = 0.38, F = 66.9\end{aligned}\quad [13]$$

Note that in their eqn [24] given as our eqn [13], Hou and Xu<sup>61</sup> use HCPSA, but this must be an error. Also, it seems as though eqn [13] should have  $n = 72$  but this was not mentioned in the errata.<sup>61</sup> When used to predict a combined test set of 35 compounds, an absolute mean error of 0.40 was found, and we calculate an  $s$ -value of 0.44 log units. The advantage of eqn [13] over eqn [12] is that the former can be calculated with greater speed, and is more suitable for high-throughput screening.

Cabrera and co-workers<sup>62</sup> use only three descriptors in their calculation:

$$\begin{aligned}\log \text{BB} &= -0.03 - 0.05 \times 10^{-3} \text{ PS} \times \text{AM} + 0.23 \text{ H} \\ n &= 114, r^2 = 0.70, s = 0.42, F = 127.8\end{aligned}\quad [14]$$

We use a simple notation for the descriptors: PS is related to the polar surface, AM is the atomic mass (which appears to be the mass of atoms in a molecule excluding hydrogen atoms), and H is related to hydrophobicity. The descriptors are calculated by an in-house program, TOPS-MODE. Thus, although eqn [14] is very good, and so is the predictive power, with  $s = 0.43$  for a test set, the method will not be very easy to implement.

### 5.31.3.2 Factors that Influence Blood–Brain Distribution

Although a wide variety of descriptors have been used in calculations of log BB values, they share some common factors. In general, they fall into two classes: (a) descriptors of size of the compound; and (b) descriptors of the polar nature of the compound. In class (a) are molar refraction, connectivity and topological indices, molecular mass, and surface area. In class (b) are descriptors such as polar surface area, partial charges, and functions of hydrogen bond acid or hydrogen bond base groups. In general, class (a) descriptors drive compounds into brain and class (b) descriptors drive compounds into blood. This is, indeed, what would be expected from known properties of blood and brain. According to Abraham and Weathersby<sup>37</sup> and from the tissue compositions given by Poulin and Theil,<sup>72</sup> brain is considerably more lipophilic than blood, and nonpolar compounds will tend to prefer brain and polar compounds prefer blood.

This can be put on a more quantitative basis using eqn [10] of Platts and co-workers. The descriptors  $E$  and  $L$  are nonpolar or size-related, and an increase of either of these leads to an increase of log BB. The descriptors  $S$ ,  $A$ , and  $B$  are

all polar quantities, and an increase in any of these leads to a decrease in log BB. Many descriptors, including PSA, and counts of hydrogen bond acid groups and hydrogen bond basic groups, are approximations to  $A$  or  $B$  (or to  $A$  plus  $B$ ).

We can also investigate the use of  $\Delta G_h^0$  the standard free energy of hydration, as a single descriptor in the calculations of Lombardo and co-workers<sup>40</sup> and of Keserü and Molnár<sup>47</sup> (see eqns [6] and [8]). Equation [9] has been applied<sup>66</sup> to the partition of compounds between air and water, as log  $K_w$ :

$$\log K_w = -0.99 + 0.58 E + 2.55 S + 3.81 A + 4.84 B - 0.87 V \quad [15]$$

The descriptor  $\Delta G_h^0$  can be converted into log  $K_w$  to obtain another version of eqn [7]:

$$\log BB = 0.43 - 0.07 \log K_w \quad [16]$$

Then insertion of log  $K_w$  from eqn [15] into eqn [16] yields eqn [17]:

$$\log BB = 0.50 - 0.04 E - 0.19 S - 0.28 A - 0.36 B + 0.06 V \quad [17]$$

Thus, indirectly, the use of  $\Delta G_h^0$  as a descriptor implies that dipolarity/polarizability, hydrogen bond acidity, and hydrogen bond basicity all favor blood, and volume favors brain. The only anomaly is that eqn [17] has a small negative  $e$ -coefficient instead of a positive  $e$ -coefficient.

A similar analysis can be carried out for log  $P_{oct}$  as a predictor of log BB. Abraham and co-workers have shown that<sup>73</sup>:

$$\log P_{oct} = 0.09 + 0.56 E - 1.05 S + 0.034 A - 3.46 B + 3.81 V \quad [18]$$

So if  $\log BB = c + m \log P_{oct}$ , then the best that can be done is to divide eqn [18] by 4.5 to make the  $b$ -coefficient and the  $v$ -coefficient agree with eqn [10]:

$$\log BB = 0.02 + 0.13 E - 0.23 S + 0.01 A - 0.77 B + 0.85 V \quad [19]$$

There is now one glaring difference between eqn [19] derived from log  $P_{oct}$  and eqn [10], namely that the  $a$ -coefficient in eqn [19] is almost zero. Thus, because log  $P_{oct}$  does not involve hydrogen bond acidity, and log BB depends quite markedly on hydrogen bond acidity, log  $P_{oct}$  cannot be used as a sole descriptor for log BB. Of course, there is nothing to prevent log  $P_{oct}$  from being one out of a number of descriptors.

Abraham and co-workers<sup>74</sup> took advantage of this in their log  $P_{plus}$  method, which simply uses log  $P_{oct}$  as a descriptor and adds the required parameters, to yield eqn [20]. It would be interesting to apply the method to a much larger data set of compounds:

$$\begin{aligned} \log BB &= 0.06 + 0.20 \log P_{oct} - 0.51 A - 0.50 B \\ n &= 57, \quad r^2 = 0.90, \quad s = 0.20, \quad F = 136.1 \end{aligned} \quad [20]$$

The  $\Delta \log P$  parameter of Seiler,<sup>75</sup> is defined through eqn [21], where  $P_{cyc}$  is the water/cyclohexane partition coefficient, and has been suggested<sup>9</sup> as a possible predictor of log BB:

$$\Delta \log P = \log P_{oct} - \log P_{cyc} \quad [21]$$

The factors that influence  $\Delta \log P$  have been established as shown in eqn [22], where the sign has been changed to show more clearly the connection between  $\Delta \log P$  and log  $P_{oct}$ :

$$-\Delta \log P = 0.03 + 0.25 E - 0.68 S - 3.82 A - 1.45 B + 0.83 V \quad [22]$$

Although the signs of the coefficients in the equation for  $-\Delta \log P$  match those in eqn [10] for log BB exactly, the relative magnitude of the coefficients demonstrates that  $\Delta \log P$  cannot be used to predict log BB to any useful degree of accuracy.

In conclusion, there are a number of in silico calculations of blood–brain distribution by passive transport that yield predictions of log BB to around 0.35 to 0.45 log units that could be used for screening purposes. It should be pointed out that the chemical space covered by the test sets in this work is limited by the small number of compounds studied, that is, between 25 and 74. Indeed, only one set of predictions<sup>51</sup> uses a test set with more than 40 compounds.

One point of interest that seems to have been overlooked is that the various calculations of log BB all use descriptors for the neutral species of proton acids and proton bases. Blood has a pH of 7.4 and so on the usual pH/ $pK_a$  calculation, a base with a  $pK_a$  of 9.4, for example propranolol, will be 99.9% ionized at this pH. So either the ionized form of strong

bases can partition across the blood–brain barrier almost exactly as the neutral form, or the usual  $\text{pH}/\text{p}K_a$  calculation does not apply. The latter might well be the case. The  $\text{p}K_a$  we quote for propranolol is that for aqueous solution, and there is no reason why it should be the same in blood. In the latter, a compound will be partly in an aqueous environment and partly bound to plasma proteins, etc. The free fraction in the aqueous environment could ionize according to the aqueous  $\text{p}K_a$ , but the bound fraction will ionize according to the appropriate  $\text{p}K_a$  for the microenvironment.

Quite recently, Rodgers and colleagues<sup>76,77</sup> measured and set up calculations for plasma water/brain partition coefficients. Their results cannot be compared to those surveyed above, but it is of interest that in their calculations they use  $\text{p}K_a$  values of drugs that refer to aqueous solution. Although, following Rodgers and colleagues<sup>76,77</sup> the fraction of a drug in the aqueous environment ionizes according to the aqueous  $\text{p}K_a$ , this may not apply to the bound fraction.

## 5.31.4 Brain Perfusion

### 5.31.4.1 Calculations

The perfusion technique has been used on numerous occasions to obtain PCs or PSs. It has proved very difficult to reach any general conclusions in terms of correlations or predictions of either PC or PS values. One major problem is that different workers have used different perfusate solutions, usually made up in whole blood or in saline. Clearly, diffusion from whole blood will not be the same as diffusion from saline, and so data sets from whole blood or saline experiments cannot be combined. The second problem is that, for the most part, PC or PS values have been obtained only for small data sets.

Much of the early work correlated log PC with various combinations of log  $P_{\text{oct}}$  and molecular weight. Levin<sup>78</sup> showed a linear connection between log PC for perfusion from blood and the function  $\log [P_{\text{oct}} (\text{MW})^{-1.5}]$  for 22 compounds but Pardridge and Triguero<sup>34</sup> obtained only a poor plot of  $\log [\text{PC} (\text{MW})^{-1.5}]$  against log  $P_{\text{oct}}$ . Chikhale and co-workers<sup>79</sup> obtained a reasonable correlation of log PS for seven peptides against  $\Delta \log P$  but a poor correlation against log  $P_{\text{oct}}$ . Begley<sup>80</sup> collected a number of log PC values and showed that there was a rather scattered plot against log  $P_{\text{oct}}$  for 24 compounds. Several other drugs were considerable outliers and included substrates for the P-glycoprotein efflux pump as well as those transported by carrier-mediated mechanisms. Bodor and Buchwald<sup>81</sup> carried out a similar analysis and ‘omitting the obvious outliers’ obtained a reasonable correlation of log PC. However, the PC values used appear to include permeation from both saline and plasma (corrected for protein binding), and for some compounds log  $D_{\text{oct}}$  at pH 7.4 was used instead of log  $P_{\text{oct}}$ . Unfortunately, no numerical details of the PC values are given. In addition to this use of log  $P_{\text{oct}}$  as a descriptor, Liu and Hider<sup>82</sup> showed that for a series of hydroxypyridinones, a plot of log PS against the % polar surface area (%PSA) was an excellent straight line.

The first logical attempt to correlate log PC or log PS values was that of Gratton and co-workers.<sup>11</sup> These workers measured log PS values from saline at pH 7.4 and correlated them through the Abraham equation. They used the  $\text{pH}/\text{p}K_a$  hypothesis to correct for ionization of compounds at pH 7.4; unlike the case for transfer from blood, this is straightforward for perfusion from saline. Abraham<sup>12</sup> later questioned whether a full correction for ionization was necessary. He collected data on perfusion from saline at pH 7.4, and for 30 neutral compounds found the correlation in eqn [23] where PS is in units of  $\text{cm}^3 \text{s}^{-1} \text{g}^{-1}$

$$\begin{aligned} \log \text{PS} &= -0.64 + 0.31 E - 1.01 S - 1.90 A - 1.64 B + 1.71 V \\ n &= 30, r^2 = 0.87, s = 0.52, F = 32.2 \end{aligned} \quad [23]$$

There were two proton acids and five proton bases that were left out of the correlation, as shown in Table 4. Also given in the table are observed values corrected for ionization in saline at pH 7.4, using the given  $\text{p}K_a$  values, on the assumption that only the neutral species permeates. Both the observed and the ion-corrected log PS values can be compared to the calculated values on eqn [23] for the neutral species. In some cases (1A, 4B, and 6B) the calculated values are quite close to the observed (uncorrected) values, implying that no correction need be carried out. In other cases (2A, 3B, and 5B) it seems as though only a ‘partial’ correction is needed, and for 7B a full correction is needed. Correlations of the 30 neutral compounds against log  $P_{\text{oct}}$  and against %PSA showed little more than random effects, with  $r^2 = 0.15$  and  $r^2 = 0.17$ , respectively.

The only other recent analysis of log PS values is that by Liu and co-workers.<sup>13</sup> They measured PS values in units of  $\text{cm}^3 \text{s}^{-1} \text{g}^{-1}$  for permeation from saline for 28 compounds. Of these, 20 compounds underwent passive perfusion.

**Table 4** log PS values for perfusion from saline at pH 7.4 for proton acids and proton bases

| <i>Name<sup>a</sup></i> | <i>pK<sub>a</sub></i> | <i>log PS</i> |                        |                 |
|-------------------------|-----------------------|---------------|------------------------|-----------------|
|                         |                       | <i>Obs.</i>   | <i>Full correction</i> | <i>eqn [23]</i> |
| 22001 (1A)              | 5.30                  | − 2.92        | − 0.82                 | − 2.87          |
| 12002 (2A)              | 3.20                  | − 3.29        | 0.91                   | − 1.64          |
| Propranolol (3B)        | 9.40                  | − 1.02        | 0.98                   | − 0.47          |
| 11003 (4B)              | 8.10                  | − 1.53        | − 0.75                 | − 1.71          |
| 13007 (5B)              | 10.10                 | − 1.57        | 1.13                   | − 0.74          |
| 95005 (6B)              | 7.95                  | − 2.61        | − 1.95                 | − 2.28          |
| 26006 (7B)              | 8.91                  | − 3.31        | − 1.79                 | − 1.48          |

<sup>a</sup>Numbers as in <sup>12</sup>. A denotes a proton acid; B denotes a proton base.

Liu and co-workers<sup>13</sup> started by calculating 50 descriptors for each compound, but reduced these to three descriptors in their preferred equation:

$$\begin{aligned} \log PS &= -2.09 + 0.26 \log D_{\text{oct}} + 0.058 \text{ vas.bas} - 0.009 \text{ TPSA} \\ n &= 23, r^2 = 0.74, s = 0.50, F = 18.2 \end{aligned} \quad [24]$$

Here,  $D_{\text{oct}}$  is the water/octanol partition coefficient at pH 7.4, vas.bas is the van der Waals surface area of the basic atoms, and TPSA is the topological van der Waals polar surface area. Equation [24] includes five proton acids and three proton bases. For all 23 compounds, a very poor correlation of log PS was found against  $\log P_{\text{oct}}$ .

The results of Liu and co-workers<sup>13</sup> are not incompatible with the findings of Abraham.<sup>12</sup> In eqn [24] the small coefficient in the  $\log D_{\text{oct}}$  term means, in effect, that only a partial correction for ionization is made. The results in Table 4 suggest that for six out of the seven compounds a partial correction is necessary in order to comply with eqn [23].

Clearly, as regards any sort of medium- to high-throughput screening, considerably more work will have to be carried out on the perfusion technique in order to ascertain the role of strong proton acids and proton bases. This is by no means straightforward. Wohnsland and Faller<sup>83</sup> have already shown that permeation through a hexadecane membrane is complicated by the presence of an unstirred water layer (UWL) adjacent to the membrane. This leads to permeation–pH profiles for strong acids and strong bases that are not those calculated on the usual pH– $pK_a$  hypothesis. The effect of strong acids and strong bases on perfusion from saline suggests that an UWL is present in this system. Unfortunately, perfusion–pH profiles cannot be obtained in the brain perfusion system because the pH must be maintained at 7.4 in order not to compromise the integrity of the blood–brain barrier. In view of the difficulty of understanding the perfusion mechanism and of predicting perfusion of strong acids and strong bases, the suggestion of Pardridge<sup>38</sup> that blood–brain distribution be abandoned in favor of the perfusion method seems premature, to say the least. In addition, it should be noted that the most recent work on perfusion has used saline as the perfusate, rather than plasma or whole blood. It is not clear what the connection is between perfusion from saline and perfusion from plasma or whole blood, particularly with respect to perfusion of proton acids and proton bases.

#### 5.31.4.2 Comparison of Distribution and Perfusion

Just as we can use eqn [9] to compare blood–brain distribution with, for example, water to octanol partition, so we can compare brain perfusion with various other processes. We list the coefficients in eqn [9] in Table 5. In order to compare coefficients, the form of the equations must be exactly the same, and so we use the equation of Platts and colleagues<sup>51</sup> without the extra indicator variable:

$$\log BB = 0.04 + 0.51 E - 0.89 S - 0.72 A - 0.67 B + 0.86 V \quad [25]$$

Included also are coefficients for partition in the ethylene glycol to heptane system<sup>84</sup> suggested to be a model system for permeation of peptides in a number of systems.<sup>85,86</sup>

**Table 5** Coefficients in eqn [9] for various processes

| <i>Process</i>                 | <i>e</i> | <i>s</i> | <i>a</i> | <i>b</i> | <i>v</i> |
|--------------------------------|----------|----------|----------|----------|----------|
| $\log P_{\text{oct}}$          | 0.56     | − 1.05   | 0.03     | − 3.46   | 3.81     |
| $− \Delta \log P_{\text{cyc}}$ | 0.25     | − 0.68   | − 3.82   | − 1.45   | 0.83     |
| $\log P_{\text{eg/hept}}$      | − 0.08   | − 1.20   | − 3.79   | − 2.20   | 2.09     |
| $\log \text{BB eqn [25]}$      | 0.51     | − 0.89   | − 0.72   | − 0.67   | 0.86     |
| $\log \text{PS}$               | 0.31     | − 1.10   | − 1.90   | − 1.64   | 1.71     |

**Table 6** Comparisons between processes

| <i>Process</i>            | <i>cos θ</i> |      | <i>Distance between the points</i> |      |
|---------------------------|--------------|------|------------------------------------|------|
| $\log P_{\text{oct}}$     | 0.77         | 0.79 | 4.14                               | 3.40 |
| $− \Delta \log P$         | 0.74         | 0.89 | 3.21                               | 2.15 |
| $\log P_{\text{eg/hept}}$ | 0.85         | 0.97 | 3.70                               | 2.06 |
| $\log \text{BB}$          | 1.00         | 0.94 | 0.00                               | 1.76 |
| $\log \text{PS}$          | 0.94         | 1.00 | 1.76                               | 0.00 |

By inspection of [Table 5](#), it can be seen that  $\log P_{\text{oct}}$  cannot be a good model for either  $\log \text{BB}$  or  $\log \text{PS}$ , because it has no real term in solute hydrogen bond acidity. The relationships between some of the other sets of coefficients are not so clear, but can be recognized by two particular methods. In the first method,<sup>87,88</sup> the five coefficients are regarded as points in five-dimensional space. It is simple to calculate distance between the points, and the smaller the distance the closer are the corresponding processes in chemical terms. In the second method, due to Ishihama and Asakawa,<sup>89</sup> the five coefficients define a line passing through the origin. Then the smaller the angle  $\theta$  between any two lines, the nearer are the processes in mathematical or correlational terms.

Values of the distance between the points and  $\cos \theta$  are given in [Table 6](#). Note that  $\cos \theta$  is not directly connected to the correlation coefficient,  $r$ , and that for there to be a reasonable correlation between two processes,  $\cos \theta$  must be very close to unity. As for the distance between the points, for there to be a strong chemical similarity between two systems, then this distance must be less than about 0.5 (on the arbitrary scale in [Table 6](#)).

On both measures of similarity, the processes that refer to  $\log \text{BB}$  and  $\log \text{PS}$  (the latter for permeation from saline) are not closely related.  $\log \text{BB}$  and  $\log \text{PS}$  are therefore two different measures of ‘brain uptake.’ It can be seen also from [Table 6](#) that various parameters such as  $\log P_{\text{oct}}$ ,  $\Delta \log P$ , and  $\log P_{\text{eg/hept}}$  that have been put forward as models for either  $\log \text{BB}$  or  $\log \text{PS}$  are not at all good models. This is one of the reasons why so much effort has been put into devising in silico models for  $\log \text{BB}$ , and why further efforts to obtain more data on perfusion should be expected.

## 5.31.5 Central Nervous System Uptake

### 5.31.5.1 Assessment of Central Nervous System Uptake

The lack of data on measured compound concentration in the brain or on the rate of uptake into the brain has limited the generalizability of in silico models built on these endpoints. This is because the ‘chemical space’ for brain uptake is not necessarily well represented by so few data points. There are only several hundred available in the literature for example. This has resulted in many workers attempting to build in silico models of brain penetration using data for which it is just known whether a compound exhibits a CNS effect (either a therapeutically beneficial effect or a side effect) or that it does not exhibit such an effect. These categories are generally referred to as CNS+ and CNS−, respectively. This approach has the advantage that much more data is available (thousands of data points); however, while there is a good degree of certainty that compounds classified as CNS+ will penetrate the blood–brain barrier, there is considerable uncertainty about whether a CNS− compound really has negligible brain uptake or just

that it is pharmacologically inactive at CNS targets. The use of this type of data can be compared to the now well accepted 'Lipinski rule of five'.<sup>90</sup> Here, the analysis was performed on a compound set assumed to be orally bioavailable because the compounds in the set had United States Adopted Names (USANs). Hence, they were thought to have been progressed to the later stages of compound development, as these would be the only compounds to have had such names assigned. It was also assumed that compounds that had reached this phase of development would have had good bioavailability. The success of the 'Lipinski rule of 5' at removing undesirable compounds from large virtual libraries or screening sets perhaps suggests that despite the uncertainty in the assignments, the approach can be applied equally well to filtering CNS+ and CNS- compounds.

### 5.31.5.2 Factors Affecting Central Nervous System Uptake

As discussed in Section 5.31.2, many papers were published in the second half of the twentieth century that reported quantitative structure-activity relationships (QSARs) between centrally mediated pharmacological activity and lipophilicity.<sup>91</sup> The data were primarily gathered only on small data sets, some as small as five compounds, and are not particularly useful in furthering our general understanding of the relationship between chemical structure and brain uptake. It was not until the 1990s that analysis of larger data sets was undertaken.

Seelig and colleagues<sup>14,92</sup> identified a set of 28 (later expanded to 53) CNS+ and CNS- compounds and used measurements of surface-active properties (such as critical micelle concentration, air/water partition coefficient, and surface area of compound at the air-water interface) to classify the compounds. Interestingly, they used an *in silico* model<sup>93</sup> that identified which compounds were likely to be substrates for the efflux protein P-gp and eliminated them from their analysis set. This allowed them to have more confidence that they were just measuring properties for compounds for which brain penetration was limited by passive diffusion. These experiments resulted in some interesting observations about the optimal properties of molecules for brain penetration, e.g., the molecular cross-sectional area should be  $<80 \text{ \AA}^2$ , and acceptable ranges for air/water partition coefficient,  $pK_a$  values and amphiphilicity. Whilst these relationships perhaps provide some insight into the properties needed for uptake into the brain this approach does not constitute a high-throughput screen that would enable scientists to assess the likely brain uptake of large sets of compounds.

Van de Waterbeemd and co-workers<sup>16</sup> expanded the original Seelig set to a total of 125 compounds and investigated the relationship between calculated physicochemical descriptors and categorical CNS activity. In particular, they looked at ways of calculating properties related to the measured cross-sectional area of Seelig. For the Seelig set they found that the use of molecular weight and a count of the total hydrogen bonds (acceptors and donors) gave as good a separation of the CNS and non-CNS drugs as when the cross-sectional area was used. On the bigger data set, they were able to identify that for compounds to penetrate the CNS they should have  $\text{MW} < 450$  and polar surface area  $<90 \text{ \AA}^2$ . However, this does not mean that all compounds fulfilling these criteria will have good brain penetration. They described the shape of molecules in terms of the principal axes ratio (length/width) and found with only three exceptions CNS+ compounds had this ratio  $<5$ , i.e., CNS+ compounds are not long and thin but are more globular in shape.

In 1999 Ajay and co-workers<sup>17</sup> took the approach of trying to separate CNS+ and CNS- compounds a stage further by categorizing ~65 K compounds as CNS active or inactive from the CMC<sup>94</sup> and MDDR<sup>95</sup> databases. This resulted in a set of 15 K CNS+ and 50 K CNS- compounds. They used seven simple descriptors such as MW,  $\log P_{\text{oct}}$ , hydrogen bond acceptors and donors, and 166 functional group based descriptors to build a neural network that was capable of correctly predicting 92% of the actives and 71% of the inactives in a test set of 275 compounds. In addition, they used a further validation set (80 compounds) for which  $\log \text{BB}$  was known and correctly predicted 97% of the actives and 71% of the inactives. Given the difficulties of correctly assigning the CNS- compounds this methodology gives a remarkably good method for selecting the compounds most likely to penetrate the blood-brain barrier when starting from large virtual libraries of compounds. In their more detailed analysis of the models built using the seven simple descriptors (correctly predicting 70% of the actives and 60% of the inactives in their test set) they concluded that increasing the number of hydrogen bond acceptors, MW, branching in a molecule, or the number of rotatable bonds will result in a compound being less likely to be CNS+. Increasing the aromatic density,  $\log P$ , or the number of hydrogen bond donors results in a compound being more likely to be CNS+. It is worth noting that the observed effect of hydrogen bond donors is in direct contrast with that observed in other studies.<sup>10</sup> The usual observation is that the presence of hydrogen bonding groups (both acceptors and donors) results in a decrease in brain penetration. The latter seems the more easily understandable conclusion as passage through the blood-brain barrier requires a compound to cross a membrane, which is likely to be more difficult for compounds with polar or hydrogen-bonding groups.

Although a much smaller data set was used in the Crivori analysis,<sup>15</sup> the use of the Volsurf descriptors<sup>96</sup> has suggested further insights into the more detailed nature of polarity of molecules that affect their ability to cross the blood–brain barrier. The data set was comprised of 44 compounds (110 when stereoisomers were considered) for which antinociceptive potency was available from an in vivo test. Compounds that had no effect were assumed to have no brain penetration. They validated their model on a set of 120 compounds for which experimental brain penetration data was available. Their partial least squares discriminant analysis (PLS-DA) gave a correct classification of 90% on the CNS+ compounds and 65% on the CNS– compounds. This again highlights the difficulty in predicting CNS– compounds, which could in large part be due to an incorrect assignment in the training data set. Crivori and colleagues observed the usual trends of hydrophobicity favoring brain penetration whereas polarity and hydrogen bonding ability result in less favorable brain penetration. However, in addition they noted that the nature of the polar regions could affect the brain penetration in that diffuse polar regions in molecules allowed them to be CNS penetrant but localized polar regions did not. They further concluded that the distribution of hydrogen bonds and the hydrophilic–lipophilic balance in a molecule could also affect its brain penetration. In contrast to the Seelig and Van de Waterbeemd analysis they observe no correlation between size or shape and brain penetration.

Large data sets (>3 K compounds in each of the CNS+ and CNS– categories) have also been subjected to analysis by other workers.<sup>97–99</sup> The sets and their classifications have also been abstracted from a variety of databases although the problem always remains as to the correct assignment of CNS–. All these workers used fingerprint or fragment-based descriptors and a neural network to separate the classes. Although the classifications are reasonable the models can only be used as black boxes as these types of descriptors do not lend themselves to easy interpretation.

Engkvist and co-workers<sup>99</sup> additionally used a tool (SUBSTRUCT) that fragments molecules and then calculates the molecular sum over all fragments (MSOF). This is calculated as:

$$\sum F_{\text{CNS}+} / (F_{\text{CNS}+} + F_{\text{CNS}-}) \quad [26]$$

where  $F_{\text{CNS}+}$  and  $F_{\text{CNS}-}$  are the fragment frequencies for each fragment in the molecule for each set. If MSOF > 0.5 a molecule is classified as CNS+ and if MSOF < 0.5 it is classified as CNS–. Engkvist suggests that certain fragments are more prevalent in CNS+ compounds than CNS– compounds. For example, carboxyl, hydroxyl, and alkoxy groups occur more frequently in CNS– compounds and halo groups and amines in CNS+ compounds. An alternative explanation could be (as reported previously by many workers) that hydrogen bonding tends to keep compounds out of the brain (carboxyl, hydroxyl, and alkoxy groups) and lipophilicity favors brain penetration (halo groups). The observation that amines occur more in CNS+ compounds could also just be a result of the functionality needed for activity at many CNS targets (lipophilic and basic). For example, the tricyclic antidepressants and opiate agonists and antagonists would be compounds that fall into this category.

Doniger and colleagues<sup>100</sup> achieved comparable predictive power on their set of only 324 compounds and 9 physicochemical descriptors using neural network and support vector machines, the latter giving the better predictability. Adenot and Lahana<sup>101</sup> started with a set of 62 K compounds from the World Drug Index (WDI) and used the anatomical therapeutic chemical classification (ATC)<sup>102</sup> to identify ~1.3 K CNS+ compounds and 360 CNS– compounds. This latter set was further divided into a PGP+ set (91 compounds), i.e., compounds known to be P-gp substrates. They also propose the remaining compounds to be assigned the class PGP–, although there is considerable uncertainty as to the validity of this assignment. They built two PLS-DA models to distinguish CNS+ from CNS– and PGP+ from PGP–, respectively. The PGP<sub>pred</sub> and BBB<sub>pred</sub> values are then plotted against each other to create a ‘CNS drug map.’ Visually at least, this gives distinct regions in which the CNS+, CNS–, and PGP+ compounds lie and could provide a useful way of classifying compounds according to their interaction at the blood–brain barrier. Adenot and Lahana<sup>101</sup> investigated a variety of descriptor types including topological, physicochemical, and 3D geometric and electronic descriptors. They conclude, however, that something as simple as the number of heteroatoms is sufficient to distinguish CNS+ and CNS– compounds. CNS– compounds have more heteroatoms but as with the Doniger analysis<sup>100</sup> this is only likely to be reflecting the overall hydrogen bonding capacity of the CNS– relative to the CNS+ set.

A recent paper by Li and colleagues<sup>103</sup> compared various statistical methods in terms of their ability to classify CNS+ and CNS– compounds. Their data set was made up of 415 compounds and the methods compared were linear regression, linear discriminant analysis, decision tree, probabilistic neural network, k-nearest neighbors, and support vector machines. As with the work of Doniger and co-workers<sup>100</sup> the support vector machine approach yielded the best discrimination. They also found that the use of recursive feature elimination (RFE)<sup>104</sup> showed improved predictability particularly in predicting the CNS– compounds. They started with a large set of descriptors ranging in

complexity from simple counts of hydrogen bonds to quantum mechanical and geometric properties and used RFE to reduce the descriptors. As with other workers they highlight the importance of hydrophobicity, hydrogen bond donors and acceptors, and electrostatic descriptors in describing CNS penetration.

### 5.31.6 General Rules for Brain Uptake

Several groups<sup>2,16,20,41,105</sup> have identified what are now generally referred to as ‘rules of thumb’ for brain penetration. These are not models in that a statistically significant relationship has been obtained between brain penetration and a molecular property. They are better described as observations that the CNS+ compounds fall into different descriptor ranges to CNS− compounds. These ‘rules’ generally follow the same descriptor trends described above for the statistical models of CNS activity.

The most frequently used of these ‘rules’ are PSA ‘cut-offs’ for brain penetration. Kelder and co-workers<sup>41</sup> analyzed the frequency of CNS+ and CNS− compounds for different PSA ranges and concluded that CNS+ compounds were most likely to have  $\text{PSA} < 60\text{--}70\text{\AA}^2$ . Van de Waterbeemd and colleagues<sup>16</sup> put the limit at  $90\text{\AA}^2$ . There are several explanations as to why different workers have chosen different cut-offs. First, the method of calculation is not identical and it has been shown that different calculation methods give different values for PSA.<sup>46</sup> Also, the data sets of Van de Waterbeemd and Kelder are different and in the latter case not particularly large (125 compounds), which could skew the results. Additionally, it is probably the case that both are right and the cut-off chosen depends on whether one wants to classify all the CNS+ compounds correctly and accept some misclassifications of CNS− as CNS+ (most likely for the  $90\text{\AA}^2$  cut-off) or one wants to classify CNS+ compounds correctly but does not want any misclassifications of low CNS as high (most likely for the lower  $60\text{--}70\text{\AA}^2$  cut-off). The effect of using different PSA cut-offs to predict CNS+ and CNS− compounds can be seen from Figure 1. This shows the percentage of compounds with measured low, medium, and high CNS penetration that fall into various PSA classes for a set of compounds measured at GlaxoSmithKline.<sup>106</sup>

Bodor and Buchwald’s analysis<sup>2</sup> of CNS+, but not CNS− compounds, concluded that CNS+ compounds had  $\log P_{\text{oct}}$  in the range 0.5 to 5.5, MW 150–450, 2–4 hydrogen bond acceptors, and 0–2 hydrogen bond donors. This is consistent with the observations of other studies. However, by not using a CNS− set for comparison it could be that Bodor’s ‘rules’ are just reflecting the properties needed in drug molecules in general regardless of their target.

**Figure 1** The distribution of ~1000 compounds with measured high, medium, and low CNS penetration within specified PSA categories. Definitions of CNS penetration classes are: low  $\log \text{brain/blood} \leq -0.7$  [ $\text{brain/blood} \leq 0.2$ ]; medium  $\log \text{brain/blood} > -0.7$  to  $< -0.4$  [ $\text{brain/blood} > 0.2$  to  $< 0.4$ ]; and high  $\log \text{brain/blood} \geq -0.4$  [ $\text{brain/blood} \geq 0.4$ ]. PSA is calculated as in<sup>46</sup> but phosphorus and sulfur are not included as polar atoms.

The more detailed study of Mahar Doan and co-workers,<sup>105</sup> albeit on a small data set (93 compounds), attempted to separate CNS+ and CNS- compounds on the basis of both calculated properties and experimental measures of membrane permeability and P-gp profile. In addition to the observations that CNS+ drugs had fewer hydrogen bond donors, greater lipophilicity, lower PSA and reduced flexibility, they also concluded that CNS+ compounds should have an in vitro passive permeability  $> 150 \text{ nm s}^{-1}$  and should not be a good P-gp substrate.

A review of the methods for predicting brain penetration by Norinder<sup>20</sup> showed that a very simple rule of thumb for brain penetration was that brain penetration will be high if:

$$N + O \leq 5 \text{ (Rule 1) } \text{ or } \log P - (N + O) > 0 \text{ (Rule 2)}$$

where  $N + O$  is the number of nitrogen + oxygen atoms in a molecule. This is consistent with the many other observations of the effect of hydrogen bonding on brain penetration namely that brain penetration is favored by few hydrogen-bonding groups and high lipophilicity. This 'rule' has the attraction that it is extremely simple and quick to calculate yet it is reported to give good predictability on test compound sets (85% for rule 1 and 92% for rule 2). The effect of CNS activity on the descriptors used to determine relationships in these studies are summarized in Table 7.<sup>14-17,92-101,108-114</sup> The findings are no different from those observed on the quantitative [brain]/[blood] data. Most simply, the extent of the hydrogen bonding seems to be the most frequently reported determinant of the likelihood of CNS activity. Low hydrogen bonding favors brain penetration. Hydrogen bonding can be expressed as many descriptor types such as the counts of hydrogen bonds, the Abraham A and B descriptors, and the more complex descriptors of Crivori that describe the nature of the polar regions in a molecule. It can also be argued that high lipophilicity, which is also observed to be a factor favoring CNS+ compounds, is just reflecting the lack of hydrogen-bonding groups in highly lipophilic molecules.

It has been regarded as a puzzle as to why models of brain penetration seem to work so well when very few workers have made any effort to remove P-gp substrates from their training and test sets and yet P-gp is well known to be an important factor in limiting brain penetration<sup>5,6</sup> and many known drug molecules are substrates for P-gp. It seems likely that the reason that this does not appear to matter lies in the observation that compounds with large numbers of hydrogen bonding groups are more likely to be P-gp substrates.<sup>93,115</sup> Didziapetris and co-workers<sup>115</sup> suggest the 'rule of fours' to separate P-gp substrates and nonsubstrates. Compounds with  $N + O \geq 8$ ,  $\text{MW} > 400$ , and acid  $\text{p}K_a > 4$  are likely to be P-gp substrates and compounds with  $N + O \leq 4$ ,  $\text{MW} < 400$ , and basic  $\text{p}K_a < 8$  are likely to be nonsubstrates. Hence, a compound with many hydrogen-bonding groups is likely to be excluded from the brain, not only because the presence of hydrogen bonds limits brain penetration via passive diffusion but also it makes the compound more likely to be a P-gp substrate and so the compound is effluxed out of the brain by that mechanism.

As regards quantitative in silico calculations, the position with regard to blood-brain distribution, as  $\log \text{BB}$ , seems relatively straightforward. The calculations are for passive transport only, and effects such as efflux mechanisms and, indeed, any active transport are not included. Within this set of conditions, there are now several in silico calculations that yield fits of data with errors close to, or even less than, experimental error. Of course, these are only fits, and more weight should be given to calculations that include an assessment of predictive ability through the use of training sets and independent test sets. As shown in Table 2, several in silico calculations can predict  $\log \text{BB}$  to a reasonable degree of accuracy (0.35 to 0.45 log units). All these calculations use descriptors for the neutral molecules and, apparently, no correction is needed for strong proton acids or strong proton bases. Interestingly, goodness of fits and goodness of predictions do not seem to depend either on the descriptors used or on the methods used. Simple descriptors such as polar surface area, molecular weight, volume, hydrogen bond acidity, and hydrogen bond basicity lead to similar fits to those achieved through the use of more complicated descriptors such as electrotopological state indices. Methods used range from multiple linear regression to partial least squares to Bayesian neural networks, but results from the complicated methods appear to be no better than those from the simpler methods. It seems possible that the predictive capability of any calculation depends more on the experimental error in  $\log \text{BB}$  values than on the descriptors or calculational methods used. Therefore, it is likely that future in silico calculations based on the same data sets that have already been used will not lead to predictive capability better than the 0.35–0.45 log units already achieved.

The situation with passive brain perfusion is quite different. There are very few in silico calculations of permeability coefficients with a reasonable number of compounds in the data set, and none with sufficient data to be able to assess predictive capability. Furthermore, the role of strong proton acids and strong proton bases is not well known, and a great deal more data on these types of compound is needed before any reliable in silico calculation of brain permeability can be constructed.

The descriptors identified for separating CNS+ and CNS- compounds are largely similar to those that are able to rank the quantitative measure of brain to blood concentration. It is likely that workers will continue to develop models

**Table 7** Summary of data sets, validation, and descriptor trends for models built using CNS uptake data

for CNS penetration based on CNS+ and CNS- classification in the attempt to better describe the chemical space in which CNS penetrant compounds lie. The challenges in this area will be in obtaining better assessments of CNS- and in improved molecular descriptors.

### 5.31.7 The Future of Brain Uptake Models

Over the last few years several groups of workers have started to question whether the use of the log BB (total compound concentration in brain/total compound concentration in blood) is the best measure of brain penetration to assess the likelihood of a compound having efficacy at a CNS receptor.<sup>38,116,117</sup> It is now thought that the compound concentration in brain extracellular fluid (ECF) is likely to be a better predictor of efficacy. This is sometimes referred to as free brain concentration and a surrogate for its measurement is the cerebrospinal fluid (CSF) compound concentration. Maurer and colleagues<sup>118</sup> recently undertook a study in mice on 33 compounds known to have CNS activity and investigated the relationship between the ratio of the unbound fractions in brain and plasma measured in vitro, the total brain/plasma ratio, and the CSF/brain ratio. In many cases, the fraction unbound in brain was predictive of the CSF/brain ratio. For this compound set there was a large variation in the total brain/plasma ratios but the free compound concentrations in brain and plasma were very similar. Maurer and co-workers<sup>118</sup> suggest these differences in brain/plasma ratios are therefore due to differences in nonspecific binding to plasma and brain tissue. The implication for in silico models is that designing compounds with properties to maximize the brain/blood ratio only increases the nonspecific or 'not useful' binding in the brain. It is anticipated that over the next few years these data will be subjected to in silico analyses and in silico models developed for fraction unbound in brain, for example, which is likely to show very different trends with lipophilicity, for example, than total brain/blood ratio. This does not mean that brain/blood ratio will become a redundant parameter for modeling. It is likely that it will be the balance of brain penetration and fraction unbound that will be the goal for therapeutic agents targeting receptors in the central nervous system.

## Biographies

**Michael H Abraham** is Professor of Chemistry at University College London. His scientific interests include molecular properties that influence solvation and the transport of compounds from one phase to another. He has investigated various processes including gas to solvent and water to solvent partitions, skin permeation, intestinal absorption, brain perfusion and blood–brain distribution, as well as thresholds for odor, eye irritation, and nasal irritation of volatile organic compounds. Professor Abraham was awarded the American Pharmaceutical Association 1992 Ebert Prize for work on general anesthesia and the 2002 Ebert Prize for work on human intestinal absorption. He has published a book, numerous reviews, over 400 research papers, and is rated in the top 100 of the world's most cited chemists.

**Anne Hersey** is Section Head of the ADMET Modelling Group within the Department of Computational Chemistry at GlaxoSmithKline in Stevenage. After obtaining her PhD from the University of Kent at Canterbury, she worked at the Wellcome Research Laboratories in Beckenham, primarily on physicochemical property measurements and their applications. In 1996, she moved to GlaxoWellcome, Ware, to work on the *in silico* modeling of ADME properties. Her interest is in developing and using *in silico* ADMET models to aid the design of molecules with good developability profiles.

### 5.32.1 Introduction

During the past decade the extensive involvement of ATP-binding cassette (ABC) transporters in the pharmacokinetics and pharmacodynamics of drugs has been revealed. These findings established transport proteins as key determinants for drug transport and disposition. Their ubiquitous expression in various organs, particularly those involved in drug excretion (e.g., the liver and kidney) and tissue protection (e.g., the blood–brain barrier, BBB) suggest important physiological implications. Moreover, common pathways involving the same transporters have been identified for many drugs and essential nutrients. These findings point to the involvement of transport proteins in fundamental cellular processes, thus making them extremely significant subjects of investigation. ABC transporters are, furthermore, implicated in the development of de novo or acquired multidrug resistance (MDR) in many human malignancies. Through high overexpression in tumor cells, ABC transporters actively extrude chemotherapeutic drug substrates and reduce their concentration to subeffective intracellular levels, which in many cases results in failure of the cancer therapy. Investigational efforts have two significant aims: (1) the better understanding of the basic biological mechanisms involved and (2) the promotion of therapeutic interventions in medical treatments through identification of novel targets.

Independently of the progress achieved in recent years, the structure–function relationships of most transport proteins are unsolved, and their interactions with various ligands are poorly characterized at the molecular level. This makes it necessary to apply a more operative strategy of investigation that effectively combines experimental and in silico approaches.

This chapter presents an overview of the current approaches for molecular modeling of different transport proteins. As P-glycoprotein (P-gp) is the best characterized and the most significant MDR transport system, it will be in the main focus of discussion.

## 5.32.2 ATP-Binding Cassette Transporter Family

### 5.32.2.1 Physiological Significance and Role in Drug Distribution

The importance of drug transporters for intracellular drug concentration was discovered in tumor cells showing an MDR phenotype.<sup>1</sup> The first MDR transporter, P-gp, initially discovered in resistant CHO cells in 1976,<sup>2</sup> was found to be expressed in various resistant tumor cell lines of animal and human origin.<sup>3</sup> To date, P-gp overexpression is thought to be mainly responsible for MDR in cancer drug therapy. The protein is, furthermore, naturally expressed in many tissues, especially those with barrier functions such as liver, BBB, kidney, intestine, and placenta (*see* 5.04 The Biology and Function of Transporters).

P-gp (the product of the human gene *ABCB1*) belongs to the highly conserved superfamily of ATP-binding cassette (ABC) transporters. Several hundred compounds have been reported to be its substrates and/or inhibitors. They belong to various chemical classes, and generally do not share structural homology. The characteristic features that relate a P-gp compound to the group of the substrates or inhibitors are currently not well defined.

**Table 1** lists well-known P-gp substrates and inhibitors. Among the compounds listed, verapamil, trifluoperazine, and propafenone represent ones of the best studied first-generation MDR modulators. Verapamil is used as a reference compound in most MDR studies, a fact that can be explained by historical rather than scientific reasons. The intensive search for more specific and less toxic MDR modulators led to the development of second- and third-generation MDR modulators, some of which are shown in **Figure 1**.

Similarly to P-gp, several proteins encoded by genes of the subfamily C of the ABC transporters also transport a large variety of substrates. These transporters are named MDR-associated proteins (MRPs). The first subfamily member MRP1 (ABCC1) was discovered in 1987.<sup>4</sup> In small quantities it is present in almost all mammalian cells, and it is expressed in the sinusoidal membrane of liver hepatocytes. MRP1 functions as a multispecific organic anion transporter. Both P-gp and MRP1 confer resistance to a similar but not identical spectrum of cytotoxic drugs.<sup>5,6</sup> MRP1 transports cytotoxic drugs and other hydrophobic compounds only in the presence of glutathione. MRP2 (ABCC2) is expressed on the canalicular (apical) side of the hepatocyte, and promotes biliary transport of anionic conjugates with glutathione, sulfate, or glucuronic acid on one hand, and anticancer drugs such as vinblastine on the other hand. Overexpression of MRP2 is associated with cisplatin resistance in tumor cells.<sup>7</sup> MRP3 is expressed in the intestine and liver, but little is known about its importance for drug distribution. MRP3 transports glucuronated metabolites of drugs.<sup>8</sup> Its substrate spectrum appears to be much narrower than those of MRP1 and MRP2. The human MRP4 and MRP5 proteins are organic anion transporters that transport cyclic nucleotides and some nucleoside monophosphate analogs, including nucleoside-based antiviral drugs. MRP4 also transports prostaglandins.<sup>9</sup>

**Table 2** summarizes compounds shown to interact with MRP family members that are expressed at the BBB and therefore could have implications for brain penetration of central nervous system (CNS)-active drugs.

A novel member of the ABC transporter superfamily is breast cancer resistance protein (BCRP) (ABCG2).<sup>54</sup> It is expressed in the intestine, the bile canalicular membrane, and the placenta.<sup>55</sup> BCRP has been shown to play a role in the absorption and secretion of clinically important drugs. **Table 3** lists substrates and inhibitors of BCRP. This transporter shows wide substrate recognition properties, including neutral, positively, and negatively charged compounds.

In summary, several ABC transporters, alone or in combination, are responsible for MDR and for the absorption, distribution, and elimination of drugs in humans. The next section presents a summary of experimental results on the structure and functioning of different transporters. The results are discussed in relation to their usefulness for in silico studies of the transport proteins, particularly P-gp.

### 5.32.2.2 Experimental Studies of P-Glycoprotein and Related Transporters

#### 5.32.2.2.1 Structural data

High-resolution structures of human MDR proteins from the ABC family have not yet been resolved. However, x-ray structures of several other transporters have recently become available. These structures include MsbA from *Escherichia coli*<sup>90</sup> and *Vibrio cholerae*,<sup>91</sup> obtained in the absence of nucleotide at 4.5 Å and 3.8 Å resolution, respectively, and *E. coli* BtuCD resolved at 3.2 Å.<sup>92</sup>

The lipid transporter MsbA is phylogenetically close to P-gp and the bacterial multidrug transporter LmrA from *Lactococcus lactis*; all believed to act as flippases. MsbA is formed of two monomers, each containing six  $\alpha$  helical transmembrane domains (TMDs) and a nucleotide-binding domain (NBD) linked by an intracellular domain. The homodimer has 12 transmembrane  $\alpha$  helices (six per monomer). MsbA closely resembles the topological organization of P-gp and the degree of sequence homology between both proteins approaches 30%.

**Table 1** Main groups of P-gp substrates and inhibitors

| <i>Class</i>             | <i>P-gp substrate/inhibitor</i>                         |
|--------------------------|---|
| Anticancer drugs         | Anthracyclines (doxorubicin, daunorubicine, epirubicin) |
|                          | Epipodophyllotoxins (etoposide, teniposide)             |
|                          | Taxanes (paclitaxel, docetaxel)                         |
|                          | Vinca alkaloids (vincristine, vinblastine)              |
|                          | Actinomycin D   |
|                          | Topotecan   |
| Cytotoxic agents         | Colchicine  |
|                          | Puromycin   |
| Calcium channel blockers | Diltiazem   |
|                          | Nicardipin  |
|                          | Verapamil   |
| HIV protease inhibitors  | Indinavir   |
|                          | Ritonavir   |
|                          | Saquinavir  |
| Steroids                 | Dexamethasone   |
|                          | Methylprednisolon                                       |
|                          | Progesterone  |
|                          | Testosterone  |
| Hydrophobic peptides     | Cyclosporin A   |
|                          | FK506   |
|                          | Gramicidin D  |
|                          | Rapamycin   |
| Other compounds          | Calcein AM  |
|                          | Digoxin   |
|                          | Dipyridamole  |
|                          | Hoechst 33342   |
|                          | Loperamide  |
|                          | Morphin   |
|                          | Propafenone   |
|                          | Quetiapine  |
|                          | Rhodamine 123   |
|                          | Trifluoperazine   |

The vitamin B<sub>12</sub> transporter BtuCD differs structurally from P-gp: it contains 20 TMDs (versus 12 TMDs), a low degree of homology to the P-gp primary sequence and does not have a domain between the TMDs and NBDs. Additionally to these structural differences BtuCD acts as an influx pump.

The first experimental insight into the three-dimensional (3D) structure of P-gp was obtained by electron microscopy of two-dimensional protein crystals and image analysis at 2.5 nm resolution.<sup>93</sup> The image revealed a large

central pore, which was closed at the inner cytoplasmic face of the membrane. A  $\sim 10$  Å resolution structure of P-gp in the absence of bound nucleotide was also reported, and significant conformational changes were observed upon interaction of nucleotides with the NBDs.<sup>94</sup> Comparing the 3D structure of P-gp in the absence of nucleotide and in the presence of the nonhydrolyzable ATP analog adenosine 5'-( $\beta$ ,  $\gamma$ -imino)triphosphate (AMP-PNP), Rosenberg *et al.*<sup>95</sup> demonstrated that in the ATP-free state the two transmembrane halves form a single barrel with a central pore being open to the extracellular side; in the bound state the TMDs reorganize in a manner that could allow entry of hydrophobic drugs from the lipid bilayer to the central pore of P-gp. Recently, the same group reported an asymmetric configuration of TMDs in the nucleotide-bound state of P-gp at  $\sim 8$  Å resolution.<sup>96</sup>

Comparison of this first 3D structure for an intact eukaryotic ABC transporter with the structures of the prokaryotic MsbA and BtuCD showed significant differences in the packing of the TMD  $\alpha$  helices within this protein family in the absence of bound nucleotide. The structures of the nucleotide-free MsbA from *E. coli*<sup>90</sup> and *Vibrio cholerae*<sup>91</sup> differed in the relative orientations of their NBDs, but both showed a chamber closed at the extracellular side, in contrast to the

open chamber of the unbound P-gp.<sup>95</sup> This basic difference in the structural organization of P-gp and MsbA remains unclear; moreover, the P-gp functional homolog LmrA displays a chamber open to the intracellular site,<sup>97</sup> as observed in the original MsbA structure. The domain organization of the *E. coli* BtuCD resembles an inverted portal opened to the extracellular solution.<sup>92</sup> Although more similar to the unbound P-gp configuration, BtuCD could also not be readily modeled to the P-gp structure. The different number of TMDs (20 versus 12) and the lack of sequence similarity do not allow the reliable determination of which  $\alpha$  helices, if any, correspond to the P-gp TMDs.<sup>95</sup>

Thus, the high-resolution 3D structures of transporters related to P-gp should be used with caution, considering the low degree of homology within the primary sequences of the TMDs, the differences in the helix packing, and protein functions.

#### 5.32.2.2.2 P-glycoprotein functioning

Despite the significant progress achieved in recent years, the interaction of P-gp with its substrates and inhibitors remains a poorly understood process, and the details of the particular mechanisms of action are still subjects of controversy.

Biochemical and structural data agree that the protein undergoes large conformational changes during the transport cycle. P-gp shows a basal ATPase activity in the absence of any added transport substrate. Al-Shawi *et al.* suggested that this activity is an intrinsic mechanistic property of the protein rather than a consequence of transport of an unknown endogenous substrate.<sup>98</sup> According to the ATP switch model for the transport cycle of ABC transporters<sup>99</sup> the transport substrate binds to its high-affinity binding site on the TMDs from the inner leaflet of the membrane. This binding transmits a conformational change to the NBDs, thus enhancing the binding of ATP. The bound ATP molecules generate a closed NBD dimer that itself induces conformational changes in TMDs in such a way that the drug-binding site is exposed extracellularly. The affinity decreases, allowing drug release. During the subsequent steps of the transport cycle the transporter restores its basal configuration.

While the high-affinity binding site is mostly associated with the unbound state of the protein, there is no united understanding of the functional state of the protein in which the binding site adopts its low-affinity conformational state.<sup>100,101</sup> In a study reporting the 3D structure of P-gp<sup>95</sup> it was directly demonstrated that major conformational changes occurred upon nucleotide binding and did not require ATP hydrolysis. Similar results could furthermore be shown for MRP1. A more limited conformational change also occurs upon ATP hydrolysis.<sup>94</sup> This is thought to facilitate the release of the bound drug to the extracellular environment and/or to represent an intermediate step toward the resetting of the transporter to the conformation that corresponds to the high-affinity binding site.

The available structural and biochemical data on P-gp lead to two important conclusions for the modeling of drug–protein interactions: (1) the 3D structural data on MDR transporters obtained to date do not permit a reliable definition of the 3D arrangement of P-gp TMDs and (2) it is very likely that the high-affinity binding site of transported substrates is located on TMDs in conformations that correspond to the ATP-free functional state of the protein.

#### 5.32.2.2.3 Drug-binding sites on P-glycoprotein

Initially, a large common binding site on P-gp was assumed, confirmed by results from ATPase activity assays.<sup>102</sup> Later, a more complex behavior of P-gp became apparent, when cooperative, competitive, and noncompetitive interactions between modulators were observed, suggesting a minimum of two binding sites.<sup>103</sup> These findings were confirmed by different groups.<sup>104,105</sup>

From experiments with proteoliposomes containing P-gp, Shapiro and Ling<sup>106</sup> postulated two distinct binding sites, the rhodamine and Hoechst 33342 sites, which interacted in a positively cooperative manner. Later a third, regulatory, binding site was reported for progesterone and prazosin.<sup>107</sup>

From radioligand-binding experiments, at least four different binding sites were inferred that were able to allosterically communicate.<sup>100</sup>

In a recent review, Safa summarized data on binding sites obtained by competition with photolabeling drugs.<sup>108</sup> Seven binding sites were proposed that partly interacted with each other.

Novel results on the interaction and transport characterization of P-gp have been reported by Loo and Clarke from cross-linking experiments.<sup>109–113</sup> Differences in the cross-linking patterns observed upon the binding of different drugs support the suggestion that substrate binding produces rotation and/or lateral movement of transmembrane (TM) helices. Thus, P-gp could accommodate varying substrates through an induced-fit mechanism. Recently, the same authors reported that TMD5 and TMD8, on one hand, and TMD2 and TMD11, on the other hand, are located close together on the cytoplasmic side of the membrane.<sup>114,115</sup> Their results indicate that TMD2/TMD11 and TMD5/TMD8 between the two halves enclose the drug-binding pocket on the cytoplasmic side of P-gp.

Ecker and co-workers also studied ligand-binding sites, using photoaffinity labeling and mass spectrometry.<sup>116</sup> They reported that TMD3, TMD5, TMD8, and TMD11 were mostly labeled by benzophenone-type photoaffinity ligands, suggesting the involvement of the interfaces between the two halves of the protein.<sup>117</sup>

In summary, P-gp is likely to possess multiple (at least two) distinct drug-binding sites. The binding sites of substrates and inhibitors can be identical, can overlap, or be distinct, and certainly are affected by induced-fit mechanisms. Unfortunately, no 3D structural data on protein–substrate or protein–inhibitor complexes are available to date. Thus, the exact localization and structure of the drug-binding sites remain to be specified. Therefore, *in silico* approaches have a significant role in better understanding the protein structure–function relationships and rational design of P-gp inhibitors.

### 5.32.3 In Silico Approaches

#### 5.32.3.1 In Silico Tools for Modeling Interactions with the Transporters

The application of *in silico* approaches for the modeling of drug–protein interactions has several stages, depending on the level of knowledge available on the structure and function of the modeled protein. Lack of detailed information about the 3D structure of the multidrug transporters and the binding sites involved in the drug interactions precludes the use of *in silico* tools that are based on the so-called structure-based drug design approach (e.g., docking and, related to it, virtual screening). Instead, they are commonly restricted to ligand-based drug design methods. Among the mostly used are different versions of the classical quantitative structure–activity relationship (QSAR) analyses by Hansch<sup>118</sup> and Free–Wilson<sup>119</sup>; three-dimensional quantitative structure–activity relationship (3D-QSAR), comparative molecular field analysis (CoMFA),<sup>120</sup> and comparative molecular similarity indices analysis (CoMSIA).<sup>121</sup> Furthermore, correlations with molecular descriptors can be generated from 3D calculated GRID interaction energies,<sup>122,123</sup> or

converted to a two-dimensional form, such as the VolSurf<sup>124</sup> descriptors. Depending on the number and type of the structural descriptors, different multivariate data techniques are utilized: multiple linear regression (MLR), principle component analysis, the partial least squares (PLS) method,<sup>125</sup> genetic algorithms (GAs),<sup>126,127</sup> and artificial neural networks.<sup>128,129</sup> Pattern recognition methods based on different classification rules are also used.

Earlier in silico applications mostly used QSARs and 3D-QSARs. In recent years, pharmacophore and homology models have rapidly developed in parallel with increasingly detailed information about drug-binding sites and additional 3D structural data on different transport proteins.

### 5.32.3.2 Case Studies of P-Glycoprotein Interactions

#### 5.32.3.2.1 P-glycoprotein assays and data sets for in silico studies

Most experimental data available in the literature relate to drug–protein interactions in cancer MDR, particularly P-gp-associated MDR. In silico methods, when applied to these data, have some limitations. The problems arising from a variety of screening assays used for activity estimation have already been discussed in detail.<sup>130</sup> The main assays for the determination of P-gp interactions are discussed briefly below.

Among the most widely used indirect measurements is the so-called MDR ratio or fold reversal. It is defined as the ratio between the IC<sub>50</sub> value of the cytotoxic drug in the absence and presence of a relatively nontoxic concentration of the modulator<sup>131</sup>:

$$\text{MDR ratio} = \text{IC}_{50} \text{ cytotoxic drug} / \text{IC}_{50} \text{ cytotoxic drug+modulator} \quad [1]$$

The reverse relationship, the increase in cytotoxicity of a subinhibitory concentration of cytotoxic drug in the presence of increasing modulator concentrations is also applied<sup>132</sup>:

$$\text{MDR ratio} = \text{IC}_{50} \text{ modulator} / \text{IC}_{50} \text{ modulator+cytotoxic drug} \quad [2]$$

Both equations reflect a general MDR reversal effect; however, eqn [1] measures the potentiation of drug cytotoxicity in the presence of the modulator and eqn [2] estimates the potentiation of modulator cytotoxicity in the presence of the cytotoxic drug.

MDR ratios can vary substantially for the same modulator, depending on the tumor cell line, the antitumor drug used for preselection, the antitumor drug whose cytotoxic effect is modulated, and, finally, the concentrations of the cytotoxic drug and modulator.<sup>130</sup> Therefore, the comparison of MDR ratios obtained from different cell lines is not straightforward. The ratios register the entire MDR reversing effect of the drug without accounting for a particular modulation mechanism.

Inhibition of the transport activity of the protein is a widely used assay for direct measurement of drug–protein interactions. The decreased intracellular accumulation of a drug or the increased drug efflux can be used to characterize the transport activity. For these experiments, either radiolabeled antitumor drugs (e.g., [<sup>3</sup>H]vinblastine) or fluorescent substrates are used.

The calcein AM influx assay is another assay for measuring P-gp activity. The dye calcein AM is a nonfluorescent P-gp substrate that is intracellularly hydrolyzed to the fluorescent calcein. As calcein is not a P-gp substrate and its permeability through the cell membrane is very low, the increase in intracellular fluorescence over time is an indirect measure of P-gp activity.<sup>133</sup>

The effectiveness of P-gp to expel a substrate depends on its activity and on the uptake rate by passive diffusion. This was shown by kinetic studies using different anthracycline antitumor drugs.<sup>134,135</sup> The balance of drug influx through passive diffusion and its active efflux by the transporter ultimately determines the fraction of the drug entering a particular compartment in the presence of the transporter. It was shown that drug affinity toward P-gp does not affect the distribution of a drug into tissue compartments in cases of high passive permeability.<sup>136</sup> This observation confirms the importance of true affinity measurements for modeling drug–transporter interactions.

The efflux inhibition expressed as IC<sub>50</sub> is considered to be a measure of actual drug-binding affinity, and thus is preferable when modeling drug–protein interactions. IC<sub>50</sub> values can be used to estimate the relative contribution of the protein-mediated transport to the whole MDR modulating effect.<sup>130</sup> In some cases, a high degree of correlation can be observed between the efflux inhibition and the MDR ratio.<sup>137</sup> But efflux experiments can also have drawbacks. Assays using fluorescent anthracyclines could not reveal the true intracellular drug concentration due to drug accumulation in the nuclei accompanied by quenching of drug fluorescence.<sup>138</sup> Additionally, for anthracyclines, dissociation from DNA can be rate limiting, and thus obscure the true efflux capacity of P-gp.<sup>139</sup>

Another problem occurring in both accumulation and efflux assays is associated with the measurement of fluorescence. As an example, the fluorescence of the P-gp substrate Hoechst 33342 is greatly enhanced when bound to DNA or incorporated in a lipophilic environment such as the cell membrane. A recent study demonstrated that daunorubicin and rhodamine 123 decreased the fluorescence of membrane-bound Hoechst 33342 considerably in liposomes containing no P-gp. Thus, either fluorescence quenching or drug-membrane interactions leading to a displacement of Hoechst 33342 from the membrane can interfere with functional assays using Hoechst 33342 as the substrate.<sup>140</sup>

Another assay measures ATPase activity modulation caused by P-gp drugs, and makes use of EC<sub>50</sub> values for stimulation/inhibition of ATPase activity.<sup>141</sup> Although initially suggested to be an appropriate test for P-gp substrates, both substrates and inhibitors were shown to induce ATPase activity.<sup>105</sup> Furthermore, some substrates such as etoposide,<sup>142</sup> daunorubicin, or vincristine inhibit ATPase activity instead of stimulating it,<sup>143</sup> while other substrates and inhibitors have negligible effects.<sup>102,105</sup> Controversial results have been published for some drugs, for example colchicine. Differences in ATPase stimulation by the same drug (e.g., verapamil and vinblastine) have been observed,<sup>141,144,145</sup> suggesting that the ATPase activity assay is sensitive to experimental conditions and may not correlate well with drug affinity and transport activity of P-gp.

Transport assays using a cell line expressing P-gp in a polarized way have become popular when attempting to distinguish between substrates and nonsubstrates. Either the transport of the investigated compound itself or its influence on the transport of a fluorescent marker such as rhodamine 123 is determined. Some studies indicate that the use of rhodamine 123 as a fluorescent marker in monolayer transport assays is rather problematic.<sup>146,147</sup>

A comparison of ATPase activity assays using rhodamine 123 uptake or calcein AM influx led to the suggestion that indirect fluorescence indicator assays (rhodamine 123 or calcein AM) should be used for a primary screening, followed by an ATPase or transcellular transport assay to distinguish between substrates and inhibitors.<sup>142</sup> Polli *et al.* compared 65 different compounds classified either as substrates or nonsubstrates in the literature (Table 5). They used three functional assays: ATPase stimulation, transport across adenocarcinoma cell line derived from human colon and used for estimation of human absorption (Caco-2) monolayers, and increase in calcein fluorescence.<sup>148</sup> Besides unequivocal substrates and nonsubstrates, which showed activity in all or in none of these assays, respectively, a number of compounds were not active in the transport assay, while others were inactive in the ATPase assay. A good example is doxorubicin, a well-known substrate of P-gp, which showed no activity in all three assays. For some compounds such as progesterone and PSC 833, interaction with P-gp is well documented, but no transport by the protein has been registered. Are these compounds substrates of P-gp or not? The answer can be different, depending on the specific property the scientist is looking for. If a CNS-active drug is being developed, transport is of crucial importance. In the case of an inhibitor, tight interactions are desired, and transport abilities are of minor importance.

In summary, a variety of assays can be used to determine drug-transporter interactions, and none of these assays is faultless. The problems mentioned above suggest that a preliminary critical evaluation is absolutely necessary when deciding on the right data to be used for in silico studies.

#### 5.32.3.2.2 Classical quantitative structure-activity relationships: Hansch and Free-Wilson approaches

Different versions of the Hansch analysis, utilizing physicochemical parameters, and of the Free-Wilson approach, making use of indicator variables for the presence/absence of particular structural features, have been used to relate the changes in the chemical structures of various classes of MDR modulators to changes in activity.

The class of propafenone-type MDR modulators has been intensively investigated by Chiba, Ecker, and co-workers. These authors have synthesized a large number of derivatives, and derived several QSARs for this type of MDR modulator.<sup>149-157</sup> In the earlier investigations, fold reversal was determined to quantify anti-MDR activity using a resistant T lymphoblast cell line.<sup>149-151</sup> Later, rhodamine 123<sup>150,151</sup> or daunorubicin<sup>152-159</sup> functional efflux inhibition assays were used.

The results obtained for derivatives with different substituents and modifications in the parental propafenone structure (Figure 2) demonstrated that the structural changes correlate with activity through changes in lipophilicity (log *P*) if only strongly homologous series are considered.<sup>150-153</sup> In a QSAR analysis of a larger data set of 48 propafenone derivatives, molar refractivity (MR) was found to be slightly superior to log *P*.<sup>154</sup> Both parameters, however, could only explain 56% and 55%, respectively, of the variance in anti-MDR activity. To improve the correlation, several structural features were included as indicator variables, yielding a mixed Hansch-type Free-Wilson equation.

The length of the spacer between the central aromatic ring and the nitrogen atom was also varied, and a bilinear dependency of anti-MDR activity on the chain length was observed.<sup>155</sup> Up to a length of five carbon atoms, the activity increased with increasing length of the spacer, and then remained constant up to a chain length of eight carbons.

**Figure 2** Structures of representative compounds used in the development of pharmacophore models for recognition/inhibition of P-gp.

The role of the carbonyl oxygen atom, which can act as a hydrogen bond (HB) acceptor, was further investigated using indanon analogs.<sup>156</sup> No statistically significant difference in anti-MDR activity was found for indanones differing in the position of the carbonyl group. However, inclusion of the charge of the acyl carbonyl oxygen atom in the regression improved the QSAR model of 15 structurally related 4-acylpyrazole derivatives, pointing to the HB acceptor ability of the oxygen atom as a feature contributing to MDR reversal activity.<sup>158</sup>

Further, the HB acceptor strength of 12 amines, amides, and anilines and one ester of the propafenone type was correlated with their P-gp efflux inhibition effect.<sup>157</sup> The HB acceptor strength yielded a model with high predictivity, in contrast to that using log *P* as the descriptor. The authors concluded that the nitrogen atom did not interact with P-gp in a charged form but instead functioned as an electron donor group.

In a recent study, Ecker and co-workers attempted to check the hypothesis about the role of the space-directed hydrophobicity suggested previously in a 3D-QSAR study of propafenone-type modulators<sup>137</sup> (discussed in more detail in Section 5.32.3.2.4). The authors systematically varied hydrophobicity distribution within a series of 32 propafenone derivatives, using different substituents on the nitrogen atom and varying the position of the side chain with the carbonyl group.<sup>160</sup> The results showed that with increasing lipophilicity of the substituent on the nitrogen atom, the

importance of the position of the side chain increased, and the dependency on total lipophilicity decreased. This indicates that with increasing lipophilicity on the amino terminus the influence of the position of the substituent on the central aromatic ring gains increasing relevance, and that the hydrophobicity distribution within the molecule is important for P-gp inhibitory potency, confirming the results from the 3D-QSAR study.<sup>137</sup>

The same group investigated also series of tetrahydroquinoline-, dihydrobenzopyran-, and thienothiazine-type MDR modulators. Restrictions arising from the smaller data sets studied did not allow such a detailed analysis as for the propafenone-type modulators.<sup>159,161</sup> In all series, the best correlations were found with molecular refractivity.

Derivatives based on the verapamil (Figure 2) and related skeletons were investigated as MDR modulators by Teodori *et al.*<sup>162</sup> The compounds were designed by combining the skeletons with potent substituents that had been identified in other studies of different groups of MDR modulators. Attempts to analyze the structure–activity relationships in both a qualitative and quantitative manner led to no general pattern, with the exception that the core moiety of verapamil appeared to be the most useful.

For thioxanthenes and phenothiazines tested as MDR modulators by Ford *et al.*,<sup>131,163</sup> QSAR models were developed employing the Free–Wilson-type analysis.<sup>164</sup> Besides classical MLR, a GA-based MLR was applied, to test the predictivity of the models derived. The length of the chain, the type of the substituent on the basic nitrogen atom, and stereoisomery were found to be significant for the anti-MDR activity of thioxanthenes. For both data sets the activity was additionally dependent on the type of ring system and the substituent in position 2 of the tricyclic ring system. These results pointed to the importance of the relative disposition of the aromatic ring system and the basic nitrogen atom, in agreement with the QSAR studies of Pearce *et al.*<sup>165</sup> and, later, Suzuki *et al.*<sup>166</sup>

The data of Litman *et al.* on the stimulation of ATPase activity<sup>143</sup> was explored to model P-gp–drug interactions using MolSurf parameters and PLS.<sup>167</sup> Twenty-two compounds were selected, omitting large structures such as vinblastine or cyclosporine A. MolSurf parameters included 15 global descriptors, characterizing mostly HB properties. In the final model, the molecular surface, polarizability, Lewis acid property, the number of HB acceptor oxygen atoms, and the acceptor strength of the HB oxygen atoms were selected as parameters. The contribution of the five parameters, accounted for by one significant PLS variable, were almost equal, with the exception of the Lewis acid descriptor, which had a lower regression coefficient in the PLS models (Table 4). Once again, the HB acceptor properties were found to contribute predominantly to P-gp affinity.

A series of taxane-based MDR modulators was investigated by Brooks *et al.*,<sup>168</sup> using a Free–Wilson-type approach. In this study, the influence of the modulators on P-gp was investigated, and, additionally, on MRP1 (ABCC1) and BCRP (ABCG2) using the substrates daunorubicin and mitoxantrone. The observed patterns of the substituent contributions varied between the two substrate structures and the three investigated transport proteins.

A series of 25 xanthine derivatives, analogs of pentoxifylline, were studied as MDR modulators.<sup>169</sup> The best correlation between IC<sub>50</sub> and the descriptors was obtained for a combination of molecular refractivity, crystal density, and calculated log *P*.

Generally, in the QSAR models derived, the descriptors varied between different chemical classes, and most of them held only for homologous series of compounds. In the Hansch analyses, the partition coefficient log *P*, molecular refractivity, and HB acceptor descriptors were the most important characteristics for the MDR modulating activity of the studied drugs. In the Free–Wilson and subsequent 3D-QSAR analyses, a role for the relative disposition of the hydrophilic and the hydrophobic parts was suggested, and confirmed for the propafenone-type MDR modulators.

### 5.32.3.2.3 Classification studies

In classification studies, structurally different compounds are used as training sets to identify structural features as ‘decision rules’ for compounds belonging to a particular group. Large data sets evaluated by multiple assays and widely

**Table 4** A PLS model generated by MolSurf parameters<sup>167</sup>:  $n = 21$ ,  $r^2 = 0.72$ ,  $q^2 = 0.70$ ,  $s = 0.48$ ,  $F = 48.4$

| Parameter                      | Scaled PLS regression coefficient |
|--------------------------------|-----------------------------------|
| Surface                        | 0.260                             |
| Polarizability                 | 0.247                             |
| No. of HB acceptors (O atoms)  | 0.232                             |
| HB acceptor strength (O atoms) | 0.221                             |
| Lewis acid                     | 0.138                             |

varying in their activity values are commonly used. Therefore classifications are mostly performed on either functional estimates (e.g., substrates/nonsubstrates), or activity interval estimates (e.g., high/medium/low activity).

The correctness of the classification rules, however, is highly dependent on the correct division of the compounds into different groups. As discussed in Section 5.32.3.2.1, depending on the assay and the experimental conditions, the same compound can be assigned to different functional or activity groups. Table 5 shows some compounds used in classification studies, for which different assignments have been reported.

Klopman and co-workers performed one of the most extensive classification studies. First, they applied a substructural analysis approach to 137 diverse MDR modifiers, and identified a number of relatively small structural features (biophores) that contributed in a statistically significant way to anti-MDR activity.<sup>170</sup> Data from different tumor cell lines and different measures of the MDR reversal effect were merged in this analysis. Later, the same approach employing the MULTICASE software was extended to 609 structurally and functionally diverse MDR reversal agents whose activities had been determined under the same experimental conditions.<sup>171</sup> The program was able to identify 35 biophores, among them 25 relevant to activity. The biophore contributing the most was C–C–X–C–C, with X = N, NH, or O, where a tertiary nitrogen atom linked to two unsubstituted alkyl groups was preferred. A partially positively charged nitrogen atom was found to be superior, and a quaternary nitrogen atom detrimental, for activity. In Table 5, some of the compounds classified according to the study of Klopman *et al.* are shown. As seen from the table, there is a partial correspondence between the experimental and classification results for many of the drugs shown; for some of them, such as prazosine and yohimbine, totally opposite assignments in the experiment and the classification are recorded.

The extended MULTICASE approach, called MCASE, was also applied to 130 propafenone-type MDR modulators.<sup>172</sup> In total, 10 biophores were identified, from which six gave a statistically significant contribution. The largest and top-scoring biophore contained a large part of the propafenone backbone, whereas the lowest-scoring biophore contained a *meta*-substituted aromatic ring. The predictive capability of this model was tested on structurally related compounds that were not propafenones. A correlation coefficient of  $r^2 = 0.75$  between calculated and observed MDR reversal activity was obtained, suggesting more general applicability of the model.

Bakken and Jurs applied several classification methods to the same data set as Klopman *et al.*, but characterized molecular properties of the compounds by structural descriptors.<sup>173</sup> The potential variables were selected by a GA from a pool of 100 geometric, electronic, polar surface, and topological descriptors. When only topological descriptors were considered, the best models were obtained with nine or six variables, and achieved the highest classification success in the range 83.1–91.1%. These results suggest the potential of topological descriptors for high-throughput screening, as they can be easily generated from the two-dimensional structural formula of the compounds. As in other investigations of structurally dissimilar compounds, inclusion of log *P* did not improve the results.

A set of 44 compounds containing several pesticides was investigated by Bain *et al.*,<sup>174</sup> using a rule-based system to differentiate between 11 transported ligands, 18 inhibitors, and 15 noninteracting compounds. First, the transported substrates were selected if they fulfilled the following four criteria: (1) at least one  $\geq$  six-membered ring system; (2) molecular weight  $> 399$ ; (3) lipophilicity expressed as log  $K_{ow} < 2$ ; and (4) HB potential  $> 8$ . Next, from the remaining compounds, the inhibitors were classified if they fulfilled the following three criteria: (1) at least one  $\geq$  six-membered ring system; (2) molecular weight  $> 247$ ; and (3) dipole moment  $\geq 3.3$ . Compounds that fulfilled neither of the two rules were categorized as noninteracting. Using these rules, transported substrates, inhibitors, and noninteracting compounds were classified with 82%, 72%, and 89% accuracy, respectively. To test their rules, the authors selected six pesticides; five were correctly predicted, leading to an accuracy of 83%. In contrast to the results of other studies, the HB donor, rather than HB acceptor, potential was found to be important.

Gombar *et al.* used linear discriminant analysis to predict whether a given compound was a P-gp substrate or not.<sup>175</sup> The data set consisted of 95 compounds, classified either as substrates or nonsubstrates, based on the results from cell monolayer transport assays. The descriptors included log *P*, molecular refractivity, the electrotopological values of 13 substructures, and counts of 12 substructures. With 'leave-one-out' cross-validation, all substrates were correctly predicted, and only three out of 32 nonsubstrates were incorrectly classified as substrates. For a test set of 58 compounds, 50 (86.2%) were correctly predicted as either substrates or nonsubstrates. In Table 5, the correspondence between the assigned classification and the transport assay through Caco-2 cells can be seen; however, the classification does not completely match the other experimental assays.

A simple rule, termed the 'Gombar–Polli' rule, was developed, which was based on the molecular electrotopological state. According to this rule, compounds with a molecular electrotopological state value  $> 110$  are likely to be substrates, while compounds with a value  $< 49$  are nonsubstrates. When this rule was applied to a test set, 14 compounds were predicted to be substrates, and, indeed, all of them were confirmed to be substrates. Five compounds with a molecular electrotopological state value  $< 49$  were correctly predicted to be nonsubstrates, while the remaining 39 compounds fell into the undefined interval between 49 and 110.

**Table 5** Classification of some P-gp-related compounds according to the results from experimental assays of P-gp activity and classification and modeling studies

| Compound       | <i>P-gp activity assays</i>                             |   |   |   | <i>Classification and pharmacophore studies</i> |                                    |                                 |                             |

B, borderline substrate; I, inducer and substrate; N, nonsubstrate; S, substrate/modulator.

Didziapetris *et al.* developed a set of simple rules to discriminate P-gp substrates from nonsubstrates using a data set of 1000 compounds and a stepwise classification method.<sup>176</sup> From the initially selected molecular descriptors, Abraham's H-accepting  $\beta$ , followed by the molar weight or volume, had the highest discriminating power, and  $\log P$  had the lowest. A compound is predicted to be a substrate if: (1) molecular weight  $>400$  and (2)  $\beta > 1.7$ . As the sum of oxygen and nitrogen atoms is a crude estimate for  $\beta$ , the substrate properties can be roughly estimated by the 'rule of fours': compounds with  $(N + O) \geq 8$ , molecular weight  $>400$ , and acidic  $pK_a > 4$  are likely to be P-gp substrates; whereas compounds with  $(N + O) \leq 4$ , molecular weight  $<400$ , and base  $pK_a < 8$  are likely to be nonsubstrates. Class-specific rules of high discrimination power were developed for structural subclasses with slightly varying cut-off values. The obtained results led to the view that P-gp possesses a large binding site with fuzzy specificity, rather than distinct binding sites. Recently, Xue *et al.* applied the support vector machine learning technique, to derive a model capable of discriminating substrates from nonsubstrates among 201 compounds.<sup>177</sup> From an initial pool of 59 descriptors, 22 remained significant after applying feature selection. Doxorubicin, one of the training set compounds, was erroneously included in the validation set under the name adriamycin, another name used to denote the same compound. In Table 5, the assigned classifications for some compounds used in this study are given for comparison with the other in silico classifications and experimental assays.

In summary, classification studies are suitable if the best candidates among a large number of potential ones are to be selected for further experimental screening. They are a worthy alternative for the in silico screening of large numbers of substrates and inhibitors of transport proteins, at least until more sophisticated methods such as docking and virtual screening become feasible. In addition, the classification rules may help identification of important structural discriminants for functionally different drugs, thus providing more in-depth knowledge on drug-protein interactions.

#### 5.32.3.2.4 Three-dimensional quantitative structure-activity relationship studies

The phenothiazine-type MDR modulators were the first to be investigated using a 3D-QSAR approach.<sup>178</sup> The data set was collected from the works of Ford *et al.*,<sup>131,163</sup> and included both stereoisomers of thioxanthenes. To better decide on a possible alignment of the stereoisomers, a detailed molecular modeling study of *trans*- and *cis*-flupentixol was performed, and the 3D properties of the drugs were compared.<sup>179</sup> When both stereoisomers were aligned to be similar in shape, a good agreement of the hydrophobic HINT<sup>180</sup> fields was found. Therefore, it was suggested that *trans*- and *cis*-flupentixol could have a mirror-like orientation when interacting with P-gp. Interestingly, an opposite effect of *cis*- and *trans*-flupentixol on ATP hydrolysis and substrate recognition by P-gp has been reported,<sup>181,182</sup> suggesting a stereospecific interaction of the isomers with P-gp, in agreement with the modeling results. CoMFA models of 40 phenothiazines, thioxanthenes, and related drugs were further derived, involving steric, electrostatic, and hydrophobic fields alone and in combination. The best models reached high internal and external predictivity, and combined steric and hydrophobic fields.

Phenothiazine type MDR modulators, taken from Ramu and Ramu,<sup>132</sup> were also studied using CoMFA and CoMSIA.<sup>183,184</sup> Once more, the role of hydrophobicity expressed as CoMSIA similarity indices was confirmed. Additionally, the role of the HB acceptor indices for MDR reversal was demonstrated, confirming the contribution of HB acceptor descriptors identified in classical QSAR and classification studies.

Propafenone-type MDR modulators were investigated in several studies. The first 3D-QSAR using CoMFA<sup>137</sup> involved 28 compounds for which P-gp inhibition had already been determined.<sup>150,151</sup> The best models were obtained either with the HINT hydrophobic field alone or in combination with steric and electrostatic fields. Results of this study led to the conclusion that the standard steric and electrostatic fields could not fully represent the main forces driving MDR reversal and directed to the role of the hydrophobicity distribution as an important structural determinant for inhibition of the P-gp dependent efflux. This was further confirmed by comparing activity predictions employing  $\log P$  and hydrophobic fields.<sup>185</sup> Later, a larger set of 70 propafenone-type compounds was also investigated using both CoMFA and CoMSIA.<sup>186</sup> The hydrophobic field alone or in combination with the steric field resulted in the best models again. As no HB donor and acceptor fields were included, the importance of HB acceptor properties was not investigated.

A series of imidazole derivatives that had led to the clinical candidate ONT-093 was investigated using both CoMFA and CoMSIA.<sup>187</sup> The best CoMFA model for 46 compounds was a two-component model in which the electrostatic and steric fields contributed nearly equally. Applying CoMSIA, a two-component model was also obtained with similar, but slightly worse, statistics. Analyzing the contribution of the five CoMSIA fields (steric, electrostatic, H acceptor, H donor, and hydrophobic), only the first four were found to contribute significantly, while the hydrophobic field did not, and was excluded.

The hydrophobic field models, calculated by HINT and CoMSIA hydrophobic indices, were compared in a series of triazine-type MDR modulators.<sup>188</sup> The data set contained 30 derivatives with MDR reversing activity measured by

Dhainaut *et al.*<sup>189</sup> Both CoMFA and CoMSIA models showed comparable results. The role of the hydrophobic fields was confirmed, and the electrostatic field was additionally found to contribute to the MDR reversal effect of the studied compounds.

Thirty sesquiterpenes of the dihydro- $\beta$ -agarofuran type have been investigated with CoMSIA using wild-type and MDR *Leishmania tropica* expressing a P-gp-like transporter.<sup>190</sup> Activity was measured by percentage growth inhibition, and a fixed modulator concentration was used. All five CoMSIA fields were included as descriptors, and additionally the solvation energy of the compounds was considered. Separate models were generated, both for wild-type and MDR *Leishmania tropica*. The best models were obtained with an unusually high number of latent variables – 19 for MDR and 18 for the wild type. This result could be related to the use of the percentage growth inhibition as the dependent variable, as this introduces nonlinearity into the biological response. The electrostatic field had the highest contribution by far, of more than 50%, followed by the HB donor and hydrophobic fields. The contributions of the steric field and solvation energy were marginal.

Although different molecular fields and similarity indices were found to contribute to MDR reversal by different classes of modulators, in general, most of the 3D-QSAR models agreed on the role of the hydrophobic fields for their interactions with P-gp. The steric and HB acceptor fields also were found to contribute significantly. The role of the particular field seems, however, to vary, depending on the particular class studied.

#### 5.32.3.2.5 Pharmacophore modeling

The term ‘MDR pharmacophore’ was first introduced by Pearce *et al.* in pioneering studies on structurally different MDR modulators, including verapamil, vinblastine, vindoline, chlorpromazine, chloroquine, and several reserpine analogs.<sup>191,192</sup> The existence of ‘a conserved element of molecular recognition in modulator binding by P-gp,’ was postulated, which was composed of two aromatic domains and a basic nitrogen atom. Although far from any particular protein-binding site associated with the drugs studied, this first pharmacophore model already presumed some common pharmacophore features of substrates and inhibitors when interacting with the transporter.

Based on analogies to binding of antipsychotic drugs to calmoduline, Hait and Aftab<sup>193</sup> proposed a hypothetical drug-binding site on P-gp for phenothiazines and related drugs. This model involved the same structural domains as proposed by Pearce *et al.*, assuming overlapping of the  $\pi$  orbitals of the aromatic rings of phenylalanine residues in the protein TMDs and of the phenothiazine and thioxanthene ring systems.

Another type of drug–protein interaction was suggested by Suzuki *et al.*<sup>166</sup> In a study of 24 quinoline-type MDR-reversing compounds, including MS-209 (Figure 1), the authors postulated that a nonplanar arrangement of the pharmacophoric aromatic rings was essential for high activity. Additionally, a distance of at least 5 Å between the basic nitrogen atom and the center of the hydrophobic part was set as a prerequisite for high activity within the series.

Later, Etievant *et al.* formulated a distance requirement for P-gp recognition based on structure–activity relationships of a podophyllotoxin series.<sup>194</sup> The authors demonstrated that the presence of an amido group in the fourth position of podophyllotoxin promotes P-gp recognition, and that a distance of 5 Å to the centroid of the trimethoxy aromatic ring appeared to be a predictive criterion for P-gp recognition.

While the interactions between P-gp and the aromatic rings of the drugs, regardless of ambiguity in the type of interactions, were well recognized from the very beginning, the role of the tertiary nitrogen atom remained unclear. Investigating MDR reversal activity of 232 phenothiazines and related drugs<sup>132</sup> and 311 structurally diverse compounds with two or more phenyl rings,<sup>195</sup> Ramu and Ramu came to the conclusion that a permanent charge, as in quaternary amines, abolished activity, and that a carbonyl group could participate in the formation of intra- or intermolecular HBs.

Several studies were undertaken to further elucidate the role of the nitrogen atom and the carbonyl group in the interaction of compounds with P-gp. Chiba *et al.*<sup>150</sup> reported that reduction of the carbonyl group as well as its conversion to a methylether moiety in the propafenon nucleus (Figure 2) led to a remarkable decrease in activity, whereby lipophilicity lost its predictive character as the main determinant for modulator potency. Similarly, the relative positioning of the acyl- and propanolamine side chains also influenced activity, so that the distance between the carbonyl group and the nitrogen atom seemed important. The role of the carbonyl group as an HB acceptor was demonstrated more clearly in another QSAR study of 12 propafenone analogs.<sup>157</sup>

In parallel with the elucidation of the nature of the drug–protein interactions, studies designed to differentiate between the pharmacophore patterns of P-gp substrates and inhibitors have been initiated. Seelig proposed specific recognition patterns for P-gp substrates and inhibitors based on the proximity of HB acceptors in space.<sup>196,197</sup> A general pattern for P-gp substrate recognition was proposed, and considered two types of patterns. Pattern I was formed by two electron donor groups with a spatial separation of  $2.5 \pm 0.3$  Å. Pattern II was formed either by two electron donor groups with a spatial separation of  $4.6 \pm 0.6$  Å or by three electron donor groups with a spatial separation of the two outer

groups of  $4.6 \pm 0.6 \text{ \AA}$ . Substrates with a high affinity for P-gp should have at least one type I or one type II pattern. Binding would increase with the strength and with the number of electron-donor groups involved in type I and type II patterns. For transport, at least two type I patterns or one type I and one type II patterns were necessary. If two substrates are applied simultaneously to P-gp, the compound with the higher potential to form HBs generally acts as an inhibitor. Partitioning into the lipid membrane was proposed to be the rate-limiting step for the protein–substrate interaction, and dissociation of the substrate–protein complex was proposed to depend on the number and strength of the HBs formed.<sup>198</sup> The same substrate recognition principles were, furthermore, proposed for the transport protein MRP1.<sup>199</sup>

The above patterns were derived employing data from different experimental sources. As shown in Table 5, the substrates classified may possess different functionalities in the experiments, thus confirming the importance of the source data used to generate the pharmacophore model.

Using Seelig's pattern approach, Penzotti *et al.* proposed a computational ensemble pharmacophore model to identify substrates of P-gp.<sup>200</sup> A binary classification scheme was applied to a set of 195 compounds (144 for training and 51 for test): compounds were classified as substrates if transported by P-gp, and as nonsubstrates if not transported. This ranking scheme was thought to reduce the error associated with the collection of data from different laboratories, assays, cell lines, and experimental conditions. The top-scoring pharmacophore consisted of one HB acceptor, one HB donor, and two hydrophobic features. Depending on the conformation, different functional groups of the same compound could form the pharmacophore. Although the model of Penzotti *et al.* overcomes some of the drawbacks of Seelig's patterns (data amalgamation and conformational dependence), it only achieves a relatively low correct classification for the substrates: 64% for the training set and 53% for the test set. Interestingly, half of the pharmacophores derived contained a combination of HB acceptor, HB donor, and one or two hydrophobic groups. The presence of an HB donor was highlighted in particular by the authors, in contrast to the patterns found by Seelig.

In a series of publications, Doepenschmitt *et al.*<sup>201–203</sup> and Neuhoﬀ *et al.*<sup>204</sup> reported the affinity of structurally different compounds for the P-gp verapamil-binding site. These and other data on the interactions of structurally divergent drugs with P-gp<sup>205</sup> initiated a number of more sophisticated 3D pharmacophore modeling studies applying programs developed for the automatic identification of pharmacophore models, such as DISCO,<sup>206</sup> Catalyst,<sup>207</sup> and GASP.<sup>208</sup>

Ekins *et al.*<sup>209</sup> used Catalyst to generate 3D pharmacophore models of diverse series of P-gp inhibitors. Several training sets of compounds taken from the literature<sup>204,205</sup> and tested *in vitro* in different assays were studied. Four pharmacophore models were generated, and used to predict the inhibition of P-gp-mediated transport of digoxin, calcein accumulation, vinblastine accumulation, and vinblastine binding. All models contained at least one hydrophobic feature corresponding to either an aromatic ring or an aliphatic hydrophobe. Based on the good correlation between the models for digoxin transport and vinblastine binding, the authors hypothesized that vinblastine and digoxin share the same binding site. As the pharmacophores differed slightly in feature content, angles, and distances, it was suggested that the pharmacophores may correspond to multiple regions within the same binding site. In a further study,<sup>210</sup> a novel P-gp inhibition model was constructed using 16 compounds from the data set for the verapamil-binding site of P-gp by Neuhoﬀ *et al.*<sup>204</sup> The model consisted of one HB-acceptor, one aromatic feature, and two hydrophobes. Comparing the degree of similarity in rank order prediction of previously generated data by this model and other models mentioned above, the authors suggested that verapamil was likely to bind to the same site, or an overlapping site, as digoxin and vinblastine.

Pajeva and Wiese<sup>211</sup> also used the data of Neuhoﬀ *et al.*<sup>204</sup> to develop a pharmacophore model. Representatives of all reported structural classes were included, and the GASP program was applied. A general pharmacophore pattern was proposed for the verapamil-binding site of P-gp that involved two hydrophobic aromatic centers, three HB acceptors, and one HB donor. The distances were calculated as the averages of those found in the most active compounds. The same pharmacophore patterns were identified for enantiomers, in agreement with their binding affinity. It could be demonstrated that the binding affinity of the drugs depended on the number of pharmacophore points simultaneously involved in the interaction with the protein. The results suggest the verapamil-binding site of P-gp to have several points that can participate in hydrophobic and HB interactions, and that different drugs can interact with different receptor points in different binding modes.

Using (*R*)-verapamil, rhodamine 123, vinblastine, colchicine, and calcein AM as a training set, and Catalyst software, Masip *et al.*<sup>212</sup> also generated a pharmacophore model that contained two hydrophobic groups (aromatic or aliphatic chains), one aromatic ring, and two HB acceptors. The model was used to test two peptoids (Figure 2), identified through screening of a library of *N*-alkylglycine trimers that had been shown to cause a higher intracellular accumulation of daunorubicin than verapamil. Some of the conformations of both peptoids with energies close to the minimum conformers were consistent with the pharmacophore model.

A different 3D pharmacophore modeling approach was used by Garrigues *et al.*,<sup>213</sup> who studied a series of cyclic peptides, peptide-like compounds, verapamil, progesterone, and vinblastine for their effects, alone and in combination, on P-gp ATPase activity. The results of manual superimpositions on the MOLCAD surfaces were expressed as distances between selected consensus groups of hydrophobic and polar elements. Two pharmacophores were outlined. 'Pharmacophore 1' was produced from overlays of compounds such as verapamil, cyclosporine A, and actinomycin D, and consisted of one aromatic and two alkyl areas and one HB acceptor group. 'Pharmacophore 2' consisted of one aromatic and three alkyl areas and one HB-acceptor, and involved vinblastine and tentoxin. In order to explain why vinblastine displayed a competitive inhibitory effect with the ligands of the first pharmacophore, the authors suggested that the receptor counterparts of the pharmacophores are closely localized in the same multispecific binding pocket of P-gp. These results were considered to agree with the results by Sharom *et al.*<sup>214</sup> for different binding sites of verapamil, cyclosporine A, and vinblastine.

The group of Ecker *et al.* also used the Catalyst program for the identification of pharmacophore patterns of structurally similar series of benzofuran- and benzopyran-type MDR modulators<sup>215</sup> and propafenones.<sup>216</sup> In their first study, a pharmacophore model consisting of one HB acceptor, one hydrophobe, one aromatic hydrophobic, and one positive ionizable feature was obtained. The pharmacophore model of propafenones additionally involved one more aromatic hydrophobic feature. The positive ionizable group corresponded to the basic nitrogen atom, which could not be defined as an HB acceptor due to limitations of the software. When the authors excluded the ionization function, an HB acceptor was obtained in close proximity to the positively charged center. Although limited to a congeneric series of P-gp inhibitors, these pharmacophore models agree with models derived from structurally divergent P-gp drugs on features related to HB acceptor and hydrophobic interactions.

A pharmacophore model for the Hoechst 33342-binding site (Figure 2) on P-gp was also proposed.<sup>217</sup> The authors used experimental data on small molecules presumed to interact with the H-site of P-gp.<sup>218</sup> GASP produced a pharmacophore model consisting of a minimum of three hydrophobic features and one HB acceptor with the potential involvement of one additional HB donor.

For other MDR-related proteins, far fewer pharmacophore models have been developed. Recent studies demonstrate that the orphan nuclear receptor PXR can regulate the expression of CYP3A4 and ABCB1 simultaneously.<sup>219,220</sup> In human hepatocytes the expression of MRP2 can be upregulated by PXR ligands such as rifampicin.<sup>221,222</sup> Based on EC<sub>50</sub> values for PXR activation, 12 PXR ligands were examined with Catalyst, and a pharmacophore could be generated that was able to distinguish between poor and the most potent activators.<sup>223,224</sup>

In summary, depending on the sets and software used, different combinations of pharmacophore elements were generated. Independent of the variety within the models reported, most of them suggest that a pharmacophore of a P-gp drug should combine at least one HB acceptor and two hydrophobic elements in a particular space arrangement. This combination can be termed 'a conserved pharmacophore pattern,' similarly to the term used by Pearce *et al.*<sup>165</sup> The hydrophobic elements can be either aromatic or aliphatic, or both. Additional HB acceptor and HB donor interactions can also be involved, which is entirely reasonable considering that proteins possess a large number of functional groups that allow both acceptor and donor interactions. Derivation of more sophisticated pharmacophore models related to particular binding sites of the protein will depend on both the use of more relevant experimental data and the application of more sophisticated program tools.

#### 5.32.3.2.6 Homology modeling

Several studies deal with the homology modeling of transport proteins. Among them, P-gp is the most intensively modeled transporter, but others have also been studied (*see* Section 5.32.3.3).

Soon after the x-ray structure of *E. coli* MsbA in the absence of nucleotide was reported,<sup>90</sup> Seigneuret and Garnier-Suillerot published a structural model for the 'open' conformation of P-gp.<sup>225</sup> Comparative sequence analysis, motif search, and secondary structure prediction indicated a high structural similarity between each of the two P-gp halves and the MsbA monomer. The domain organization in the modeled P-gp structure, however, yielded a chamber that was closed on the extracellular side of the TMDs, in disagreement with the low-resolution 3D structure of the unbound P-gp.<sup>93</sup> As most of the residues that were known to be associated with drug binding were not found inside the chamber of the modeled P-gp, the authors suggested that P-gp could exist as open and closed structures.

Stenham *et al.*<sup>226</sup> generated two models of P-gp, refraining from modeling the P-gp domain organization reported by Seigneuret and Garnier-Suillerot.<sup>225</sup> They believed that the inverted V-shaped MsbA dimer, as observed crystallographically,<sup>90</sup> did not represent the physiologically relevant state of the transporter. The first model maintained the NBD:TMD interface suggested by the MsbA template, and the interface between the two halves of P-gp relied on the consensus interaction between the two NBDs reported by Smith *et al.*<sup>227</sup> Although V shaped, the resulting model

had only a limited concordance with the published cross-linking data concerning the intracellular ends of TMDs, and was inconsistent with cross-linking data describing the TMD:TMD interface on the extracellular face of the membrane.<sup>228–230</sup> In the second model, each half of P-gp was modeled on the MsbA structure, and oriented as in the MsbA crystal. The two halves were then placed closer to each other by rotation of TMDs with respect to the NBDs so that the angle between the planes of the TMD:TMD and the NBD:NBD interfaces resembled the equivalent angle in the crystal structure of BtuCD.<sup>92</sup> This model was expected to embody the electron microscopy structure and to correspond to experimental cross-linking data. The correspondence was estimated based on cross-linkers; however, different lengths of cross-linkers were considered. Furthermore, broad intervals instead of particular distances were mostly used to validate the model, and distances measured in different functional states of P-gp (e.g., ATP-bound and vanadate trapped) were simultaneously considered, thus hampering the correct estimation of the reliability of the model.

Pajeva *et al.*<sup>217</sup> also proposed a homology model of P-gp reconstructed from the same *E. coli* MsbA x-ray structure.<sup>90</sup> The amino acids were aligned as in the model of Seigneuret and Garnier-Suillerot.<sup>225</sup> A rearrangement of both halves was performed to achieve an orientation of the NBDs that corresponded to the cross-linking data reported by Lee *et al.*<sup>231</sup> A model of P-gp, called the cross-linking model, was also generated, based on the cross-linking constraints defined by Loo and Clarke.<sup>111,230</sup> TMDs were built as  $\alpha$  helices, the cross-linked amino acids were mutated to cysteine residues, and the helices rotated in such a way that the cross-linked residues faced each other. The distance constraints between the cross-linked cysteine residues were then incorporated into the model. In the following, the orientations of two sets of amino acid side chains were compared in the two models. These included those suggested to be involved in the binding of methanethiosulfonate–rhodamine, as identified in the Loo and Clarke cross-linking experiments, and also those assumed to be the binding site of Hoechst 33342, as defined from pharmacophore modeling (see Section 5.32.3.2.5). The authors found that the amino acid residues had an opposite orientation: in the homology model they faced the membrane, whereas in the cross-linking model the residues were directed toward the pore. They suggested that both models might describe two different functional states of P-gp. Generally, the comparable distances in the cross-linking model by Pajeva *et al.* were shorter than the ranges reported for the second P-gp model by Stenham *et al.*<sup>226</sup> The authors attributed this to the fact that, in contrast to the model of Stenham *et al.*, where cross-linkers of different length were applied, the shortest possible cross-linkers were used as distance constraints.

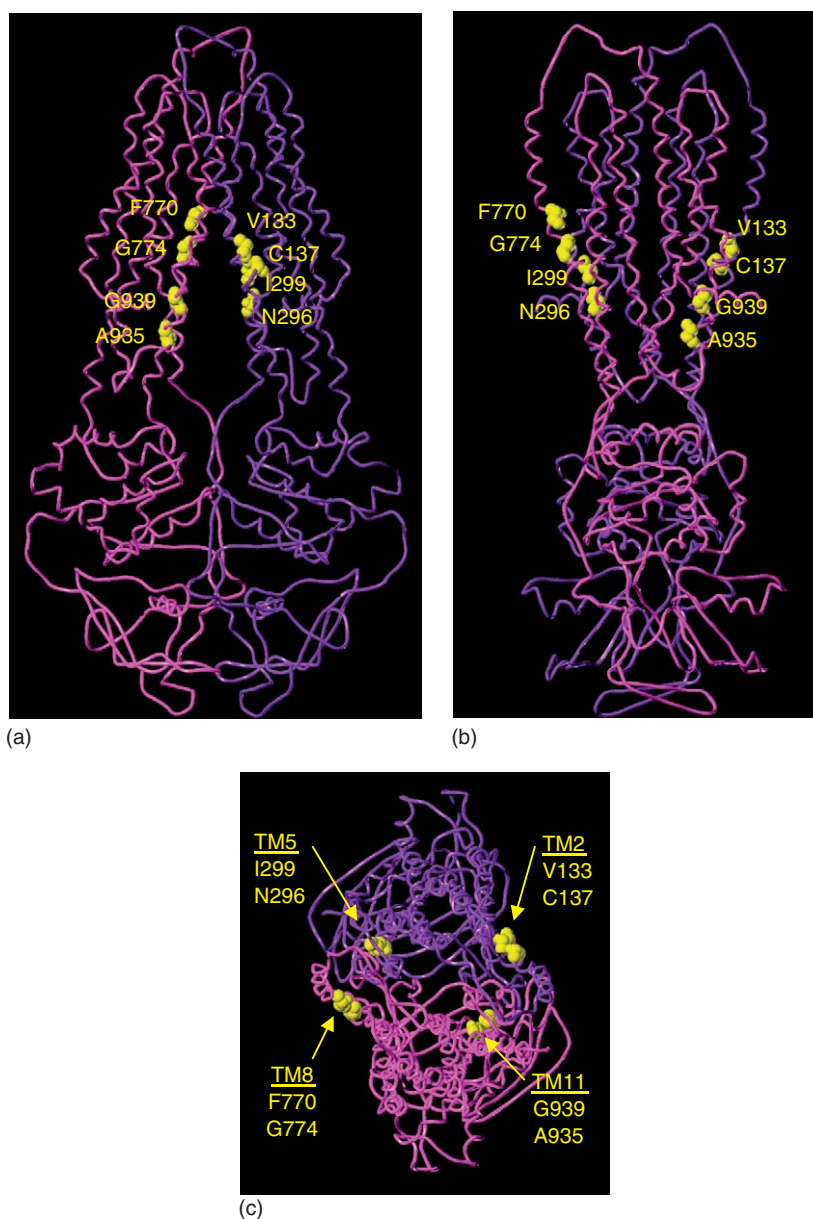

Pleban *et al.*<sup>117</sup> generated a homology model of P-gp based on the nucleotide-free *Vibrio cholerae* MsbA structure.<sup>91</sup> Although the dimer position in the *Vibrio cholerae* MsbA was closer to the low-resolution electron microscopy data of P-gp, the homology model of Pleban *et al.* had a central cavity that was narrower at the extracytoplasmic face, in disagreement with the funnel-shaped form of P-gp with TMDs closer at their cytoplasmic ends. To fit the experimental P-gp structure, the authors repositioned the halves, moving the extracellular ends apart from each other and narrowing them at the cytoplasmic face. The rearranged model was reported to satisfy the majority of distance constraints that were similar to those used by Stenham *et al.*<sup>226</sup>

Very recently the first report on molecular dynamics simulation of an atomic resolution structural model of P-gp together with the lipid bilayer in the presence of transport substrates was published.<sup>239</sup> Similarly to the previously reported P-gp models 3D structural data from different transporters were combined to obtain a model corresponding to the physiologically relevant form of the protein. The so-called ‘solvation exchange mechanism’ was further proposed to explain the broad transport-substrate specificity that based on the P-gp selectivity to positively charged compounds.

The homology models of P-gp generated to date have a common drawback: neither of them copes with the problem of correct modeling of the TMD/NBD:TMD/NBD interface. The repositioning of the P-gp halves in order to achieve a funnel-like form, as in the low-resolution 3D structure of P-gp,<sup>95</sup> is performed manually. These manipulations aim to bring the orientation of the halves in accordance to the cross-linking constraints between amino acid residues reported in experimental studies. To date, there is no clear presentation about the functional state of the protein in which cross-linking distances have been defined. This results in the application of constraints that may hold true only for specific stages of the protein transport cycle. This could explain the fact that the correspondence between the distances achieved in the proposed homology models and the experimental distances reported is not met for most of the cross-linked domains.<sup>117,226</sup>

Recent results by Loo and Clarke on oxidative cross-linking with copper phenanthroline of mutants of human P-gp showed that TMD2–TMD11 and TMD5–TMD8 could be directly cross-linked, and that this linking was inhibited by vanadate trapping or the presence of certain drug substrates.<sup>114,115</sup> Figure 3 shows the location of the mutated residues in the homology model obtained by alignment onto the x-ray structure of *Vibrio cholerae* MsbA<sup>91</sup> using an approach similar to that previously published.<sup>217</sup> As can be observed from the figure, the mutated residues are

**Figure 3** Homology model of P-gp generated from the x-ray structure of *Vibrio cholerae* MsbA<sup>91</sup> with the cross-linked residues (in yellow) in the N-terminal (in purple) and the C-terminal (in magenta): (a) front view, (b) side view, (c) top view.

arranged apart from each other (Figure 3a and 3b), and, additionally, they are oriented oppositely, so that they cannot be directly cross-linked (Figure 3c). The distances between the mutated residues in the homology model are between 15 Å and 25 Å, which is far larger than the required distance of 5–7 Å. This implies that both halves of the protein should be further tilted toward each other, to allow the mutated residues to come closer. Additionally, to be cross-linked, the mutated residues should face each other. This, however, cannot be achieved by tilting only. Obviously, challenges such as finding the correct positioning of the protein domains and the correct correspondence of the P-gp structural models to the functional states remain to be solved. More precise constraining distances, higher-resolution protein and protein–ligand complex structural data, and extensive modeling studies involving molecular dynamics simulations could further throw light on the structure–function relationships of P-gp and its interaction with drugs.

### 5.32.3.3 Modeling of Other Multidrug Transporters

Compared with P-gp, other ABC transporters have not been investigated to the same extent. For several of them, only a few inhibitors with low potency are known. Examples include the MRP1 and MRP2 transporters, for which only very recently have more potent inhibitors been described.

Van Zanden *et al.* investigated a large series of flavonoids as inhibitors of MRP1 and MRP2 in transfected MDCKII cells, and performed the first MRP1-related structure–activity relationship study.<sup>232</sup> Three structural characteristics were found to be important for inhibition of MRP1: the number of methoxylated moieties, the number of hydroxyl groups, and the dihedral angle between the B and C rings. For inhibition of MRP2, only the presence of a flavonol B ring pyrogallol group was identified as important for inhibitory activity.

Hirono and co-workers also tried to identify structural features related to MRP2 recognition using 16 structurally diverse compounds.<sup>233</sup> Two kinds of binding conformations were extracted by a flexible alignment of ligands. For one of them, CoMFA yielded a statistically significant model in which the steric contribution was highest and log *P* contributed only marginally.

Similarly to P-gp, no high-resolution structures of MRPs are available to date. Rosenberg *et al.* were able to obtain structural information for MRP1 to approximately 22 Å resolution.<sup>234</sup> Their data provide evidence for a core structure consisting of two membrane-spanning domains, each followed by an NBD. Unlike P-gp and most other ABC superfamily members, MRP1 contains a third membrane-spanning domain with five predicted TMDs and an extracytosolic amino terminus.

The higher resolution x-ray structure of the *Vibrio cholerae* MsbA<sup>91</sup> initiated homology modeling studies of the bacterial MDR protein LmrA. This protein is a half transporter, and functions as a homodimer. Ecker *et al.* developed a 3D model of the LmrA substrate-binding domain, based on homology modeling and experimental data.<sup>235,236</sup> Photoaffinity labeling with propafenone-type compounds showed that mostly TMD3, TMD5, and TMD6, but also the NBD, were labeled. Linking the experimental data with the homology model, it was suggested that two symmetry-related ligand-binding domains are formed by TMD3 of one monomer and TMD5 and TMD6 of the other monomer. It was concluded that these domains remain close to each other during the entire transport cycle.

Recently, research interest has also focused on organic anion transporting polypeptides (rodent Oatps and human OATPs) that, similarly to P-gp and MRPs, constitute part of the organism detoxification system, and show broad substrate specificity.<sup>237</sup> Yarim *et al.*<sup>238</sup> modeled Oatp1a5–substrate interactions combining a Hansch-type analysis, pharmacophore (using GASP), and CoMFA approaches. The pharmacophore model outlined three important regions: HB donor, hydrophobic, and negatively charged areas; the QSAR and 3D-QSAR models yielded similar predictivity ( $q^2 = 0.71$ ). Using the models, the authors identified potentially new substrate structures that could serve as templates for designing new Oatp1a5–substrates.

### 5.32.4 Conclusions

As outlined by many examples, remarkable progress has been made in recent years in the accurate prediction of interactions with transport proteins, and especially with P-gp. Both experimental and in silico studies have contributed to this progress. QSAR models and classification systems, sufficient to confidently predict drug activity, have been elaborated that allow high-throughput screening of drug candidates. Although a variety of significant descriptors have been identified, most of these studies define size and hydrophobicity as important properties for the interaction with P-gp either as a transported substrate or as an inhibitor. It is worth noting that hydrophobic fields rather than log *P* produce better models, thus pointing to the importance of the space location of the hydrophobic and hydrophilic parts in the drug structure. Additionally, the drug capacity for hydrogen bonding is shown to be an essential contribution to interactions with transporters. Even though the quality of some of the classification models does not permit wholly correct identification of compounds (non)interacting with P-gp, they nevertheless offer a preselection tool for experimental testing.

Several pharmacophore models have been developed that are capable of predicting the recognition of compounds by P-gp at the molecular level. In general, hydrophobic and HB acceptor interactions are the two molecular properties which appear in these models. It seems that at least one HB acceptor and two hydrophobic (either aromatic or aliphatic or both) pharmacophore points in a particular space arrangement are required for recognition by P-gp.

The first homology models contributed to a better understanding of the structure–function relationships of transport proteins; their reliability, however, was not sufficient. With the generation and collection of more precise structural data, further efforts can be made to generate more reliable 3D models.

The in silico models are valuable tools for elucidating the basis of drug–transporter interactions. Their improvement will allow the development of potent and highly specific inhibitors of ABC transporters, potentially giving rise to a new class of effective therapeutic agents in clinical applications such as the treatment of MDR tumors or pharmacokinetic optimizations.

## Biographies

**Michael Wiese** born in Neumünster, Germany, studied chemistry and pharmacy at Kiel University, where he obtained his PhD in pharmaceutical chemistry in 1985 under the direction of Prof J K Seydel. Afterward he worked at the research center Borstel as a Postdoctoral Research Fellow. In 1993, he finished his Habilitation and subsequently, he was awarded a Senior Professor at University of Halle in 1994 and took up his present position as Senior Professor and Head of Department at Bonn University in September 2000. His scientific interests include all aspects of molecular modeling and quantitative structure–activity relationships, in particular, transport proteins and G protein-coupled receptors and their ligands.

**Ilza K Pajeva** born in Bulgaria, studied at Mendeleev Institute of Chemical Technology in Moscow, where she obtained a MSc in chemical cybernetics; in 1989 obtained a PhD in biological science from Bulgarian Academy of Sciences in Sofia; in 1992 awarded a fellowship of the Alexander von Humboldt Foundation and spent 19 months in Borstel Research Center (Germany) under the direction of Prof J K Seydel. Returning to Sofia, she took her present position as an Associate Professor in Pharmacology at Centre of Biomedical Engineering, Bulgarian Academy of Sciences. The main scientific interests include QSAR and molecular modeling, multidrug resistance, and transport proteins.

## 5.33 Comprehensive Expert Systems to Predict Drug Metabolism

### 5.33.1 Introduction

Metabolism initially became an established part of drug development from a recognition of its importance to pharmacological and toxicological profiles. Thus, it was incorporated as part of the safety evaluation process. A widely expressed concept was that metabolism could be used to select the most appropriate species for toxicological evaluation of a drug candidate. This concept is rather simplistic, and clear opportunities to make decisions based on this comparison are seldom encountered, since the choice of species is limited, and species comparisons almost always consists of elaborating degrees of difference. Besides, a small difference in one aspect may prove to have greater significance than larger ones, and other variables such as pharmacokinetics may also be of some importance.

However, as the scientific knowledge of metabolism has developed, there has been an increasingly greater appreciation of the importance of considering metabolism predevelopment during drug discovery and the selection of development candidates, often called lead optimization. This provides the opportunity to incorporate structural features into a compound that can contribute to creating a drug that possesses the desirable pharmacokinetic properties, and avoids possible adverse properties such as toxicity or idiosyncratic drug reactions. Since these objectives can potentially reduce the number of drugs that fail during development and clinical evaluation, it is a compelling concept that has been readily adopted.

While relatively rapid generation of compound-specific metabolic information is possible using in vitro systems and modern analytical techniques, there are resource implications and some limitations to the extent of information that can be obtained. An alternative or complementary approach is to use in silico techniques, which consists of the application of existing knowledge to make predictions based on a consideration of the substrate structure alone. Since this is a theoretical exercise, it is possible to apply this approach as part of a process for designing new structures for modeling, synthesis, and biological screening. Thus, at the earliest stage it is possible to extend the chemical space of a particular compound series by devising modifications that may enhance metabolic stability, provide soft targets for metabolism, and also divert from the formation of potentially toxic metabolites or reactive intermediates.

In summary, there are several areas where the prediction of metabolites can be valuable:

- identifying sites of metabolism, and hence providing input into defining where structural modifications could be made to modulate metabolic stability;
- providing alerts to metabolites that could have potential pharmacological activity;

- providing alerts to the formation of reactive intermediates;
- providing alerts to species differences in metabolism that may be significant during the drug safety evaluation process;
- acting as a tool to aid in structural assignment during the identification of experimentally produced metabolites (e.g., by mass spectrometry and nuclear magnetic resonance); and
- highlighting specific structures to look for as metabolites in experimental investigations and aid identification of unknown metabolites.

Hence, the ability to make any prediction of metabolism can add value to drug discovery and development processes. From their very nature, predictions cannot be expected to always be correct, but performance will improve as knowledge increases. However, the applications of prediction mean that incorrect predictions will not have critical effects, and with intelligent use there is potentially a lot to be gained. The objectives of a prediction system should encompass the following:

- aim to predict the metabolites most likely to be formed;
- generally omit the prediction of minor metabolites (e.g., <5% dose or total metabolites) unless of special importance, such as where reactive intermediates are involved;
- alert to species differences;
- add value and be fit for the purpose; and
- capable of improvement by taking account of advances in knowledge.

### 5.33.2 The Challenge

With broad up-to-date knowledge of metabolic chemistry it is relatively easy to construct the pathways for major possible routes of metabolism for any novel structure. Some examples of metabolites involving more complex intramolecular rearrangements are less easy, but often these represent minor metabolites. However, the real challenge is to define which pathways will actually occur. There are many factors that will contribute to making some substructures and functional groups more or less susceptible, which include steric and electronic effects, the spatial interaction with enzyme active sites, and the physicochemical properties of the whole molecule. In the first instance, prediction requires the ability to decide which of the various options for metabolism will occur. The first option is that no metabolism will be necessary, and the drug is excreted unchanged. There are few examples of drugs that behave in this way, but the prediction of this outcome would be important, and one example is an analog of glutamic acid (**1**).<sup>1</sup> Clearly, compounds like this, which have low lipophilicity, have the requisite properties for efficient excretion, and metabolism is not necessary. A simple prediction rule based on log *P* could be applied, and the influence of lipophilicity on the pharmacokinetic behavior of drugs, which is a consequence of metabolism, has been described.<sup>2</sup>

The second type could be that no phase I metabolism is predicted (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions), only a direct phase II reaction with an existing functional group (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). This process produces a readily excreted conjugate that is not uncommon, an example being ezetimibe (**2**) where the only major metabolite in plasma and urine was a glucuronide of the phenolic function. Oxidation of the benzylic alcohol to a ketone was the only minor phase I metabolite.<sup>3</sup>

When phase I reactions are the only choice, there will invariably be several options for the first-stage reactions, which in different combinations can be part of a sequence. In most cases, not all reactions will occur, at least to give significant amounts of metabolites. There are therefore two challenges, first to be able to assess probabilities of alternatives, and, secondly, to have criteria to terminate reaction sequences on the basis that a metabolite ceases to be a viable substrate for further metabolism and possesses the prerequisite properties to be excreted. Beyond this, there is also the challenge to predict notable species differences and to achieve the sophistication of being able to consider three-dimensional structures.

Species differences are primarily due to variation in the nature, number, and activities of enzymes that catalyze the individual reactions. These differences can be very large, differing by several orders of magnitude when comparing the rate of a reaction in the same organ. By far the greatest amount of knowledge exists for transformations involving the cytochrome P450 isozymes, but our understanding of differences is not generally well understood across the commonly encountered species (*see* 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues; 5.10 In Vitro Studies of Drug Metabolism).

Consideration of the three-dimensional structure of compounds will take account of stereoselectivity in substrate metabolism and stereospecificity of product formation. The former would allow differences in metabolism of enantiomers and diastereoisomers (i.e., substrate specificity) to be predicted, and the latter would define the stereochemistry of reactions where a chiral center is generated (i.e., product stereoselectivity). These are long-term objectives.

### 5.33.3 Use of Knowledge Databases

A fundamental starting point for prediction is the ability to utilize existing knowledge, therefore collating metabolism data into a searchable format is strategically important. There are two such active databases containing information on drug metabolism, namely Metabolite, produced by MDL Information Systems, Inc. (San Leandro, CA, USA), and Metabolism, produced by Accelrys Ltd (Cambridge, UK) (**Table 1**). The latter was originally established using data compiled in the book series *Biotransformations: A Survey of the Biotransformation of Drugs and Chemicals in Animals*,<sup>4</sup> but it has continued to be developed by the addition of both historical and more recent literature data. Products of this type contain information that can be used to assist prediction in various ways. A database of reactions ensures that as a minimum there can be an awareness of all the types of reaction that are known to occur for functional groups and substructures. While most of the reactions are well established, new reactions continue to be found. These include oxidation of an oxime to a nitro group,<sup>5</sup> *S*-glucuronidation of a thiourea-type function,<sup>6,7</sup> and rearrangement of a substituted piperazine to an imidazoline.<sup>8</sup> The importance of a database is that it contains information that is searchable using the chemical structure as the key parameter. Hence, it should be possible to find all information on the metabolites of compounds containing defined substructures, and, if necessary, this could be selected further using in vivo, in vitro, and/or species criteria. Other selection filters could include parameters such as molecular weight and physicochemical properties such as log *P*. Searches can therefore be customized according to the compound of interest and purpose.

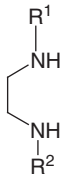

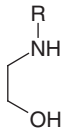

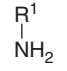

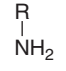

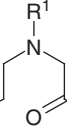

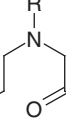

Information extractable from the databases can be used by an individual expert to formulate a prediction or as a basis for developing rules that can be incorporated into a software prediction program. How an individual might use a database can be illustrated by investigating what is known about the metabolic vulnerability and extent of degradation of two related heterocyclic ring systems, piperazine and morpholine (**Table 2**). A search of the Metabolism database showed that cleavage of the ring occurred for 7% of the total compounds (1043) that contained a piperazine group and for 30% of those (349) containing a morpholine group.

**Table 1** Structure-searchable databases for metabolic pathways

| <i>Database</i> | <i>Content</i>                               | <i>Producer and website</i>  |

| Metabolism      | Metabolites of drugs and chemicals           | Accelrys Ltd<br><a href="http://www.accelrys.com">www.accelrys.com</a>   |
| BioPath         | Biochemical pathways of endogenous compounds | University of Erlangen/Molecular Networks GmbH<br><a href="http://www2.uni-erlangen.de/services/biopath">www2.uni-erlangen.de/services/biopath</a><br><a href="http://www.mol-net.de/databases/biopath">www.mol-net.de/databases/biopath</a> |

**Table 2** Occurrence of analogous types of metabolites from piperazines and morpholines

| <i>Metabolite structure</i>   |   | <i>Number of examples</i> |                    |
|---|---|---------------------------|--------------------|
| <i>Piperazines</i>  | <i>Morpholines</i>  | <i>Piperazines</i>        | <i>Morpholines</i> |
|  |  | 11                        | 16                 |
|  |  | 4                         | 4                  |
|  |  | 0                         | 13                 |

Evaluation of the examples indicates that morpholines are more susceptible to extensive metabolism than piperazines. It is always important to ensure that it is valid to use a given example to make conclusions. For instance, the following need consideration:

- confidence in the structural assignments (speculative evidence should be downgraded);
- quantitative importance (minor metabolites should be excluded or given less importance); and
- completeness of the metabolic pathway (the importance of a particular pathway may not be fully estimated if a large proportion of the metabolites are unknown).

The input of human expertise is necessary at this stage to formulate rules that could be used for an expert prediction system.

Databases can also be used in very simple ways to give some basis for making predictions simply by finding out what is known about compounds with a high degree of structural similarity. For instance, there are a number of oral antidiabetic drugs that all contain a benzylthiazolidindione substructure (**Figure 1**). Clearly this could be a potential site of metabolism, but in many cases it appears that the main metabolites occur by oxidation and conjugation at the other end of the molecule when there are sites available.<sup>9–12</sup> Some of these metabolites also appear to have pharmacological activity. It is also of interest that for the compound MK-0767, where there is a blocking substituent on the terminal aromatic ring, the major metabolites are formed by oxidation in the thiazolidindione ring.<sup>13</sup> On this basis it would therefore be reasonable to make some prediction for other compounds with similar structural features.

Analysis of a database can give some idea about the probability of a reaction type, and, importantly, highlight factors that may prevent its occurrence. Oxidation of arylmethyl groups was shown to occur for 89 of 106 compounds containing this group.<sup>14</sup> Where it did not occur, this could be ascribed to two reasons, one being that metabolism occurred at other alternative soft sites such as ester and dimethylamino functions, and the other due to steric hindrance from bulky *ortho* substituents. This type of analysis indicates how rules for basic reactions can be refined to expand the ability to make correct predictions. The use of these metabolism databases has been further reviewed in other publications.<sup>15,16</sup> An automated fragment-based searching and scoring method has been described that can be used in conjunction with any structure-searchable database.<sup>17</sup> The procedure consists of the analysis of the frequency of reactions for a defined structural fragment by mining all examples of specified reactions. The different options for metabolism are compared by calculating the frequency rates of the reactions, and normalizing to the most frequently occurring reaction. This process could be applied to all the key substructures in a drug, but the challenge is then to provide a composite view for the whole molecule.

**Figure 1** Structures of related thiazolidinedione antidiabetic agents, indicating sites of metabolism.

Another somewhat different database is BioPath, which contains the information on the well-known Biochemical Pathways Wall Chart, originally distributed by Boehringer Mannheim in a structure searchable format (see [Table 1](#)). It is possible to search for all the reactions in which a given biochemical, or those containing a certain substructure, occurs either as a substrate or a product.<sup>18</sup> Since many of the enzymes that participate in these processes may also accept drugs as substrates, the ability to search for this information could be a valuable tool in metabolite prediction.

#### 5.33.4 Prediction Based on Reaction Mechanisms

If the mechanism of a particular biotransformation is understood, then it becomes easier to define a rule to predict the influence of changes in substituents on a functional group or substructure, on this reaction. The cytochrome P450-mediated cleavage of isoxazole rings involving breaking the N–O bond is a well-established reaction with many examples.<sup>10</sup> Whether this process will form a dominant pathway when there are other options will depend upon the ease of the reaction. In a series of substituted benzoxazoles of the general formula **3**, ring cleavage was enhanced when R<sup>3</sup> was electron-withdrawing, while an alternative reaction involving cleavage of the isoxazole indole bond (C–N bond) was enhanced when R<sup>1</sup> and R<sup>2</sup> were electron-withdrawing.<sup>19</sup>

Similarly, for an isoxazole in a different structural environment such as **4**, other factors are important. Thus, when R is H, ring cleavage was very facile in rat/human plasma and liver microsomes; however, when R is CH<sub>3</sub>, this pathway appeared to be blocked, and the ring methyl group was hydroxylated.<sup>20</sup> A mechanism of ring opening was postulated

that was dependent upon the presence of a proton on the carbon atom adjacent to the nitrogen atom. These examples illustrate the huge challenge in attempting to predict metabolism and the level of sophistication that may be necessary. Thus, it is easy to define a basic rule for cleavage of isoxazoles and describe the structures of products, but isoxazoles will inevitably occur in complex structural environments with a wide diversity in ring substituents; the challenge is to predict the situations when ring cleavage will not occur. As an example, a report on the metabolism of valdecoxib (**5**), which has a fully substituted ring, showed that the main metabolite was formed by hydroxylation and conjugation of the ring methyl group, and that there was only one very minor metabolite resulting from ring cleavage.<sup>21</sup> This outcome could have been predicted based on the above knowledge of the likely mechanism.

#### 5.33.5 Reactive Metabolites and Intermediates

The importance of trying to identify and avoid structures that may subsequently lead to unacceptable toxicity during preclinical development or idiosyncratic drug reactions during clinical trials or clinical use has become paramount to prevent late-stage failure of development candidates or even clinical withdrawal of marketed drugs. The impact of the above on the discovery and development of new drugs is critical and of key concern to the industry and human health. Many companies are now evolving strategies to deal with these issues, as identified in recent publications.<sup>22,23</sup> These considerations need to be incorporated at early stages of drug discovery rather than only at the lead optimization and selection stage, since it will be more efficient to include candidates in the potency optimization phase that have been designed on the basis of metabolism. One strategy to adopt is to have a mechanism for identifying substructures in substrates or their metabolites that have the potential to cause toxicity (*see* 5.39 Computational Models to Predict Toxicity). The first stage is to capture existing relevant knowledge, and to make sure this is used intelligently. There are some well-known structural groups associated with potential toxicity, such as quinones, which may be formed as part of an oxidative pathway, but there are certainly other less well-known indicators. A recent review has attempted to catalog all the structural groups where bioactivation to reactive intermediates can occur.<sup>24</sup>

Two examples of structures that could be highlighted as having toxicity potential are thiophenes and 3-methyleneindoles. The four thiophene compounds in [Figure 2](#) have all been identified as causing some toxicity.<sup>25</sup> There is evidence that oxidative metabolism is associated with the toxicity, and there are various proposals<sup>26</sup> for the nature of the toxic intermediate(s), including:

- epoxides analogous to those proposed for furans such as ipomeanol, a 3-alkylketofuran<sup>27</sup>;
- *S*-oxidation, since thiophene sulfoxides are known to be very reactive; and
- unsaturated ring-cleaved products, such as unsaturated dialdehydes.

Hence, while it is known that some oxidative metabolism to a reactive intermediate is involved, the exact nature and structure of the intermediate is not known. It is noteworthy that these compounds have keto groups in the 2- or 3-position, so this could form the basis for a structural alert. This makes the alert more selective and therefore more valuable by not raising too many possibly false positives. In proposing a structural alert, it may appropriate to expand the horizon by including structures that are related by simple metabolic reactions. These would include the alcohols and their simple derivatives such as esters and ethers.

3-Methylindole (**6**) is a well-known pneumotoxin, and the mechanism is postulated to involve methyl oxidation, generating a reactive intermediate.<sup>28</sup> Evidence for this intermediate is provided by the identification of a 3-methylene-mercapturic acid metabolite. Pyrrolizidine alkaloids with the general structure **7** are known hepato- and pneumotoxins, and also form glutathione conjugates at the exocyclic methylene group, following formation of a 3-hydroxypyrrole substructure.<sup>29</sup>

There are also reports on the metabolism of two compounds (8 and 9) containing methyleneindole-related groups, both of which form reactive intermediates that are indicated by subsequent formation of glutathione conjugates.<sup>30,31</sup> For the former, an oxidative *N*-dealkylation reaction results in cleavage of the molecule, formation of a pyridine analog of hydroxymethylindole, and a mercapturic acid of this intermediate as a terminal metabolite. The last compound, zafirlukast, is a CYP3A4 inhibitor that may be mechanism based since that is the isozyme that catalyzes formation of the intermediate. The above evidence could be used for defining a structural alert that could be based on 3-methylenepyrrole and precursors (10).

The application of *in silico* techniques to reactive intermediates has a somewhat different objective than prediction of the structures of metabolites, and the performance criteria are not the same. Thus, it is not the objective to accurately predict the structures of metabolites but to raise an awareness of metabolism that could occur to produce reactive metabolites. In some cases the exact nature of the reactive intermediate will not be known. The objective

**Figure 2** Structures of thiophene-containing compounds associated with toxicity.

should be to raise an alert for certain substructures that may have the potential to form the above, but not to predict that they will be formed or even if they are that they will lead to adverse effects *in vivo*. These substructures may be present in the parent molecule or formed in a metabolite. With this knowledge, the options are to consider including new compounds by making structural modifications that could preclude either the presence or the formation of the substructure alert, delete the inclusion of the alerted compounds as lead candidates, or begin to make some experimental investigations if they are strong candidates for other reasons. At the very least it provides a warning that can be kept in mind if any preclinical safety evaluation studies are conducted.

### 5.33.6 Development of Software to Predict Metabolism

#### 5.33.6.1 Enzyme Active Site/Substrate Models

Any systems that can be used to predict specific aspects of metabolism could be used to contribute to a global prediction program. The most obvious is a system to predict the affinity of substrates for cytochrome P450 isozymes and the distribution of products as a consequence of alignment at the active site and steric/electronic components. An approach to predicting aliphatic hydroxylation reactions has been reported by Alhambra and Boyer<sup>32</sup> and Korzekwa *et al.*<sup>33</sup> These have been further extended to derive a general electronic model for cytochrome P450-mediated aromatic and aliphatic hydroxylation.<sup>34</sup> The model was constructed for small molecules where steric orienting effects at the enzyme active site are not of major importance. A more versatile model needs to combine electronic and steric effects. The importance of steric effects on the regioselectivity of quinoline and isoquinoline oxidation has been demonstrated.<sup>35</sup> Quinoline was hydroxylated at the 3-position, the position with the highest activation energy, whereas position 8 with the lowest activation energy was a relatively minor site for hydroxylation. The *N*-oxide was a major product for the isozymes CYP3A4 and CYP2A6, but it was not formed by CYP2E1 or CYP1A2. For isoquinoline the *N*-oxide was formed more predominantly than for quinoline. The conclusion from these investigations was that CYP3A4 and CYP2A6 are less sterically demanding than CYP2E1, CYP2B4, and CYP1A2.

Clearly, if models of the spatial interaction of substrates with enzyme active sites can be constructed and account taken of electronic effects when this is pertinent, they can lead to a prediction of the structures of metabolites. One such program has been developed called MetaSite (Molecular Discovery Ltd),<sup>50</sup> to predict the site of metabolism for substrates of CYP2C9, 2D6, 3A4, 1A2, and 2C9. It uses three-dimensional homology models for the enzymes as well as the three-dimensional structure of the substrates. The method uses GRID flexible molecular interaction field representations of the isozymes combined with different conformational structures of substrate molecules.<sup>36</sup> The predicted site of metabolism is reported as a ranking list of all the hydrogen atoms of each substrate. For CYP2C9, 87 oxidation reactions with 43 substrates only reported to be catalyzed by this enzyme were used to validate the methodology. These substrates displayed reactions consisting of metabolism at one to four different sites. It was concluded that in more than 90% of cases the method correctly predicted the three hydrogen atoms at sites where metabolism would occur. The conformation of the molecules had the biggest impact in the case of flexible molecules with multiple sites of oxidation.<sup>36</sup> A modeling approach for the other important isozymes listed above has also been reported,<sup>37</sup> stating that the first and second predicted options for sites of metabolism were correct to the following extents CYP2C9, 86%; CYP2C19, 81%; CYP2D6, 86%; CYP3A4, 78%; and CYP1A2, 75%. This program does not necessarily predict which isozymes will actually metabolize the substrates. A homology model for CYP2C9 has also been used to predict the sites of reaction for substrates ranked according to likelihood. Of 87 reactions reported to be catalyzed exclusively by CYP2C9, the model predicted the site of metabolism for more than 90% of the substrates within the first three ranked sites. The real test for this approach is whether for compounds with the complexity of structures now associated with drug research, there is sufficient understanding of the nature and behavior of active sites to predict the substrate interaction and when electronic and steric factors play a major role in the process.

Homology models for various cytochrome P450 isozymes have been developed by Lewis, initially based on bacterial CYP102,<sup>38</sup> and more recently using the crystal structure of the first mammalian cytochrome P450, namely CYP2C5.<sup>39</sup> While these models have not been developed into programs specifically to predict metabolism, part of their validation has involved showing that selective substrates fit within the active sites in such a manner that is consistent with the reported experimental data for known pathways of metabolism. Structure–activity relationships have been developed for estimations of reaction rates and clearances of substrates.<sup>40,41</sup> Lipophilicity has been shown to be important for substrate specificity since it combines hydrophobicity associated with molecular size, volume, or surface area with polarity due to the presence of hydrogen bond donor/acceptors in the structure. Log *D*<sub>7.4</sub> becomes important when the substrate contains ionizable groups. Typical log *P* ranges have been collated for various isozymes, although not surprisingly there is considerable overlap. Besides the above, the relative levels of the isozymes are also important in

determining the extent and rate of metabolism and the degree of involvement of a particular isozyme. As the crystal structures of other mammalian isozymes are obtained, the models should improve. Incorporating these structural relationships into a composite metabolite prediction model could allow significant advances in performance.

### 5.33.6.2 Metabolite Prediction Programs

Metabolism is essentially a series of chemical reactions, each with a substrate and products. A computer system capable of recognizing chemical structures and portraying the products of metabolism is an ideal tool to support drug research and development. The requirements of such a system can be defined as follows:

- the ability to enter novel chemical structures;
- contains the available knowledge of all possible metabolic reactions supported by examples;
- contains rules or supporting intelligence that enables distinction between probable, possible, and unlikely metabolites;
- able to alert to reactions where reactive intermediates that have toxicity potential may be formed; and
- alert to possible species differences in probable reactions or species-specific reactions.

Various programs have been developed and made available, but all are still at a relatively low stage of sophistication. These include METEOR,<sup>42</sup> MetabolExpert,<sup>43</sup> META,<sup>44</sup> and the newly introduced MetaDrug<sup>45</sup> (Table 3). All nominally operate in a similar way mechanistically, although there are differences in the knowledge and rules used to arrive at the prediction.

METEOR is a program that was designed to predict the structures of likely metabolites from an evaluation of inbuilt rules on structure–metabolism relationships.<sup>46</sup> During its development it was recognized that it was necessary to have some basis to predict the most likely metabolites rather than all those theoretically possible. This has been approached by using an integrated reasoning engine based on a system of non-numerical argumentation.<sup>47</sup> According to preassigned levels of absolute and relative categorization of the likelihood of reactions and a link to log *P* calculation, metabolites can be predicted for five different levels, namely ‘probable,’ ‘plausible,’ ‘equivocal,’ ‘doubted,’ and ‘improbable,’ which can be preselected. In addition, the number of sequential phase I reaction stages can be selected, which reduces the combinatorial explosion of metabolites that can ensue when there are many different potential sites of metabolism. Query compounds can be constructed using a linked structure-drawing program or an imported molfile. Results can be reviewed that show the structure of the metabolite, highlighting the reaction site. Where cleavage of a molecule occurs, both products are shown. A recent evaluation of its performance has been reported for 10 substrates where the major metabolites were known.<sup>48</sup> For these substrates, 130 first-generation metabolites were predicted and/or identified experimentally. Of these, 30% were correct predictions, 62% apparently false positives, and 8% false negatives. Hence, 70% could be considered incorrect, consisting of 20% false positives due to molecular constraints not being taken into account, 3% false negatives due to missing reactions in the database, and the remainder ascribed to the complexity of biological factors. Utilization of this type of evaluation can help to make improvements to the system.

MetabolExpert uses a knowledge base that, for each transformation, contains a substructure, the product structure, a list of substructures that must be present for the reaction to occur, and a list of substructures whose presence

**Table 3** Currently available metabolite prediction programs

prevents the transformation from occurring. The number of levels of phase I transformations can be selected, and when a phase II metabolite is formed, no further transformations are performed. It operates in two ways, namely compiling a metabolic tree by matching known biotransformations for the respective substructures and functional groups in the molecule, or by making an analogy with information in the database on structurally similar compounds. The analogs available for comparison are listed, and the one used can be selected. This way of working is very similar to using one of the knowledge databases, although these will inevitably contain more extensive data. The basic biotransformation database of version 10.0 is reported to contain 179 transformations. There is also a version called RetroMex, which aims to predict substrates that would generate a defined compound by metabolism.

META is reported to have been assembled by starting with a compilation of the major enzymes involved in metabolism, and assessing the structural sites and their activities for each of these. Rules guiding their application to specific structures is stored in a series of logically linked dictionaries. The program operates on the basis of recognizing targets and subsequent transformations from the input structure, which may be a SMILES code or, more likely, a molfile. Each target/transformation receives a priority value. A stability module is incorporated, which checks if the primary molecular entity is stable or whether it will spontaneously degrade to a stable terminal product. The program can be used to proceed to sequential levels of metabolism. The dictionary of reactions is reported to contain more than 1000 transformations, covering the activity of 30 different enzyme systems, and more than 300 transformations in the stability module.

MetaDrug combines ruled-based metabolite prediction, quantitative structure–metabolism models for major drug-metabolizing enzymes, and gene network tools. Given its novelty, independent validations are required before its potential can be appreciated.

It is difficult to judge the merits of these existing systems, and neither is it appropriate to compare their performance in this chapter. It is inappropriate to compare the number of transformations each contains, since the substructure/functional groups pertaining to a reaction may be defined very specifically or more generally. A fair evaluation of their relative performance would be a rigorous exercise, comparing prediction against experimental data for a wide range of compounds. There is no doubt that it would be relatively easy to show that each performed well for one compound and equally badly for another. But no system should be condemned on the basis of one poor prediction. The overall performance is dependent on the quality and depth of knowledge each contains, which can only be assessed by an extensive evaluation. The question arises of how to quantify performance of a metabolite prediction system. The goal is to predict only those metabolites that are formed. To propose the structures of 20 metabolites in order to predict four that are actually produced is in most cases not helpful, and conversely to propose four metabolites and only predict one of four that are produced is also not a high success rate. Thus, there are two criteria that need to be considered and possible definitions are as follows:

$$\text{prediction coefficient} = C/A$$

$$\text{efficiency index} = C/B$$

where  $A$  is the total number of metabolites experimentally formed,  $B$  is the total number of metabolites predicted, and  $C$  is the total number of metabolites correctly predicted. The target is for both of these parameters is unity.

It could be argued that the prediction coefficient is the most important criterion. Namely, that false positives are less important than the omission of true positives. Clearly, we cannot expect this to be achieved at this stage, but any program can be continuously improved if up-to-date knowledge is incorporated and new rules developed. However, even the above analysis is not straightforward when metabolites are being predicted at different levels of probability, as with METEOR. The value a prediction system adds will depend on the knowledge of the user, and it is likely at this stage that the best human experts will be able to exceed the performance of any software program. There is extensive scope for improvement of the existing systems, since it is fair to comment that none of them yet achieve all the requirements and objectives defined above.

## 5.33.7 Future Development

### 5.33.7.1 Identifying Key Parameters

There is no doubt that our ability to predict metabolism and the processes to use are at an early stage of development. It is undeniably a huge challenge, and one easily dismissed as unachievable. This would be a mistake as long as some positive contribution can be made to drug research, and there is no doubt, as described in this chapter, that this is the case. As long as critical decisions are not made based solely on these predictions, it is a worthwhile exercise. As with any

predictive exercise, it will never be entirely accurate, but we need to function with instructive minds that allow us to be comfortable with the degree of precision that the nature of the subject permits. The software programs that have been developed provide a good basis for evolving to a greater level of sophistication in performance. However, it is likely that this can only be achieved by combining some different approaches to prediction that complement the existing rule-based systems. The factors that contribute to structure–metabolism relationships have been reviewed by Testa and Cruciani,<sup>49</sup> with suggestions about how to take account of these and combine them into a prediction system based on rules and probabilities.

Besides compilation of a dictionary of all possible reactions, the key sequential stages that could be identified in prediction are as follows:

- ascertain that phase I metabolism is likely, based on physicochemical properties ( $\log P$  and  $\log D$ );
- ascertain whether metabolism could be restricted to phase II reactions;
- identify soft sites for metabolism according to hierarchically defined reactions;
- consider the influence of steric/electronic factors on the above, which may downgrade their probability; and
- link to models of cytochrome P450 isozymes active site/substrate interactions to assist in assigning relative probabilities of reactions.

These aspects need to be developed and supported by various initiatives in order to add value to the evolving products.

#### 5.33.7.2 Capture and Collation of Knowledge

One key to improving and keeping systems up to date depends upon using as much information as possible on the metabolism of new compounds. The traditional sources available are the published scientific journals and presentations/posters at scientific meetings. But there is without doubt considerably more information not in the public domain but which could add immensely to the knowledge base. This includes data residing with regulatory authorities and also company archives. There have been some opportunities to utilize data from the authorities, more particularly in the USA, but there must be further possibilities to exploit this process more widely. But the greatest single source of existing data must be in the archives of research-based companies. While a certain amount of this may be considered confidential, there must also be a significant amount that could readily be released for utilization in the interests of scientific progress. The scientific community should support these initiatives, and the challenge is to find the best forum for catalyzing and implementing action.

#### 5.33.7.3 Development of Structure–Metabolism Rules

Some of the aspects of metabolism that could be incorporated to enhance prediction have been referred to in this chapter. These include devising rules based on a detailed understanding of reaction mechanisms, which enables the structural requirements for reactions to be more precisely defined. Knowledge on species differences can be included to add value, and more detailed analysis of existing data might allow the development of more rules for this area. As knowledge of the interaction of substrates with enzyme active sites develops, this provides another evaluation tool to incorporate into a prediction process that can complement other rules. Some additional use of physicochemical properties could be appropriate to develop rules for the termination of phase I reaction sequences.

#### 5.33.7.4 Incorporation of Knowledge into Prediction Programs

The final challenge is to incorporate all of the above into a seamless logical system that can operate reasoning according to rules and output the predictions clearly and concisely. When this can be achieved there will be no doubt that it will outperform the most knowledgeable scientist. The skill at this stage is to use our existing knowledge for predicting metabolism, and to use it in a way that means we gain from any positive contribution that can be taken, while avoiding any negative impact of incorrect predictions.

## Biography

**David R Hawkins** is a graduate in chemistry, and obtained a PhD in organic chemistry from the University of Birmingham in the UK. He began his career as a synthetic organic chemist in drug research for a pharmaceutical company. Subsequently, he has spent more than 30 years in the area of metabolism, and been responsible for directing the work of scientists as a head of department in a contract research organization. He has published more than 100 scientific papers and reviews, covering a range of different aspects of xenobiotic metabolism, and was the founding editor of the book series *Biotransformations*, published by the Royal Society of Chemistry. More recently, he has become involved in the development of methodologies for the in silico prediction of toxicity and metabolism based on structure–activity relationships, and serves as a board director and consultant to a software company in this area.

### 5.34.1 Introduction

Drug metabolism is an immense area of study where drugs undergo a range of enzyme-mediated chemical reactions, such as oxidation, reduction, hydrolysis, hydration, conjugation, and migration. Drug metabolism is normally divided into two phases depending on the reaction, phase 1 (functionalization reactions, e.g., oxidation, reduction, hydration, hydrolysis, or isomerization) and phase 2 (conjugation reactions). In general, the products of phase 1 reactions are more chemically reactive than the parent compound, and phase 1 is seen as the creation of a reactive species prior to true detoxification by phase 2 metabolism. In phase 2 metabolism the substrate is conjugated to a polar hydrophobic group making it more water soluble and suitable for excretion.<sup>1,2</sup>

Cytochrome P450 (also termed heme-thiolate protein P450) is the most important phase 1 enzyme. The cytochromes P450 constitute a superfamily containing over 70 families of membrane-bound heme-proteins that catalyse the oxidative (and sometimes reductive) metabolism of structurally diverse compounds.<sup>3,4</sup>

Phase 2 metabolism is carried out by a diverse group of enzymes acting on diverse types of compounds, generally leading to a water-soluble product that can be excreted in bile or urine. Major enzymes involved in this are glutathione *S*-transferase (GST), methyltransferase (MT), *N*-acetyltransferase (NAT), sulfotransferase (SULT), and UDP-glucuronosyltransferase (UGT).

Due to the extensive impact of drug-metabolizing enzymes on the availability of administered drugs, it would be of considerable value, both in the design of new drugs and also in the understanding of environmental toxins, to be able to predict the metabolic fate of these compounds. A major advance in drug development will be the availability of a tool

that can predict whether a given compound will interact with these drug-metabolizing enzymes, and, if so, which isoform of these it will preferentially interact with. Prediction of  $IC_{50}/K_m/V_{max}$  values, as well as prediction of the site of metabolism of any given compound, will be valuable information to take into consideration during the drug development process. These predictions could significantly reduce the failure rate in clinical trials, by identifying potential problems at the early stages of development. A combination of these *in silico* models/tools can offer great advantages in improving the odds of success in a discovery programme. In the early stages, this can be done by eliminating the guesswork and decreasing the experimental load, while, in later stages, more precise information for a limited number of compounds can be predicted.

Drug metabolism by an enzyme can be thought of as three phases: recognition, accessibility, and reactivity. Early recognition takes place at long distance (i.e., at the protein surface), and is mainly an electrostatic interaction between the substrate and the enzyme. Accessibility is determined by the ease by which the substrates can reach the active site of the drug-metabolizing enzyme; for example, the overall dimensions of the channel leading to the active site (which extends from the surface of the protein to the active site) is in the case of a buried active site very important in substrate discrimination. The topography and size of the active site plays an important role in metabolism of a compound. Reactivity (oxidation, conjugation, etc.) occurs when the substrate has reached the active site.<sup>5</sup> Accessibility, conformation, and orientation of the substrates (leading to multiple sites of metabolism) and thermodynamics are the key determinants in this phase.

The three-dimensional (3D) structure of enzymes can provide a valuable insight into the function, and help derive structure–activity relationships. X-ray crystal structures are desirable, but due to solubility issues and membrane association this has not always been possible for all drug-metabolizing enzymes (e.g., cytochromes P450<sup>6</sup>). In the absence of crystal structures, alternative methods (such as homology models) have been applied. Homology models are based on the theory that proteins with similar amino acid sequences have a tendency to adopt similar 3D structures. This enables prediction of the 3D structures of these enzymes based solely on their amino acid sequences and the 3D structures of proteins with similar amino acid sequences.

Another methodology used in the absence of crystal structures has been the pharmacophore approach. Pharmacophore models utilize the common structural features associated with biological activity in a variety of substrates for a specific enzyme (in this case, binding and metabolism by a particular isoform of these enzymes). Ideally, a pharmacophore should be unique for a particular enzyme, and knowledge of the common ‘core’ features associated with each isoform of these enzymes can be very helpful. Due to lack of similarity and overlap of the common features between different isoforms (e.g., cytochromes P450), the utility of these pharmacophores can, however, be limited.

### 5.34.2 Modeling of Phase 1 Metabolism – Cytochromes P450

Cytochrome P450 is the most important phase 1 enzyme, and belongs to a superfamily containing over 70 families of membrane-bound heme proteins that catalyze the oxidative metabolism of structurally diverse chemicals.<sup>3,4</sup> All members of a particular cytochrome P450 subfamily have a 55% amino acid sequence homology with one another, while members of the same family show an identity of more than 40%.<sup>7</sup> The isoenzymes differ from each other in amino acid sequence, in control by inhibitors and inducing agents, in the substrates they act upon, and the reactions they catalyze. Some isoenzymes have overlapping substrate specificities, acting on the same substrates as each other but at differing rates. Each cytochrome P450 has a unique system of substrate recognition, leading to the observed substrate specificities; for example, CYP2C9 prefers acidic and neutral but not basic substrates, CYP2D6 prefers basic substrates, CYP3A4 metabolizes both acidic and basic substrates, but log *P* plays a role, and CYP1A2 metabolism is governed by size.

Seven of the 57 known human isoforms of cytochromes P450 (CYP1A2, CYP2C9, CYP2C18, CYP2C19, CYP2D6, CYP2E1, and CYP3A4) are responsible for more than 90% of the metabolism of all drugs in current clinical use.<sup>8</sup> Some of these enzymes (especially CYP2D6 and CYP2C9) show polymorphisms, which can either result in rapid or very poor metabolism.<sup>9–11</sup> For example, debrisoquine is extensively metabolized in normal individuals to 4-hydroxydebrisoquine, but poor metabolizers can develop high levels of the parent compound, which may be toxic.<sup>12</sup> The impaired metabolic oxidation of at least 30 drugs with diverse structures and pharmacological actions has been associated with the phenotype of poor debrisoquine metabolism. In a few cases, poor metabolizers may be unable to bioactivate a parent drug, such as encainide, to its therapeutically active metabolites.<sup>13,14</sup> Binding of any drug to these cytochromes P450 can cause drug–drug interactions, which can lead to severe side effects. This has in the last few years resulted in early termination of development, refusal of approval, severe prescribing restrictions, and withdrawal of drugs from the market. Regulators, including the US Food and Drug Administration, have therefore issued guidance for *in vitro* and *in vivo* drug interaction studies to be conducted during development.<sup>15</sup>

### 5.34.2.1 Structural Modeling of Cytochromes P450

The major human cytochromes P450 involved in xenobiotic transformations are from families 1, 2, and 3, with CYP3A4 representing the most important enzyme for phase 1 drug metabolism, which is broadly commensurate with its average percentage of the human hepatic microsomal cytochrome P450 complement.<sup>16</sup> **Table 1** summarizes the more important human cytochromes P450 involved in exogenous metabolism, and indicates typical substrates, inducers, and inhibitors of these enzymes, showing the structural diversity of such compounds. Apart from the determination of structural characteristics of these cytochromes P450 via x-ray crystallography,<sup>17</sup> where six mammalian structures (rabbit 2B4,<sup>18</sup> rabbit 2C5,<sup>19–21</sup> human 2C8,<sup>22</sup> human 2C9,<sup>23,24</sup> human CYP2D6,<sup>25</sup> and human 3A4<sup>26,27</sup>) have been resolved, the challenges for computational chemistry in this area have focused on homology modeling, requirements for substrate selectivity, estimation of binding affinity, and the search for descriptors that may correlate with kinetic data (rates or clearance) for cytochrome P450-mediated metabolism and other absorption, distribution, metabolism, excretion, and toxicology properties.<sup>28,29</sup>

Recently published x-ray crystal structures<sup>30</sup> of human cytochromes P450 (**Table 2**) provide an opportunity for comparing previously reported models of these enzymes, and to establish a degree of validity for homology modeling. For CYP2C8 and CYP2C9, the models have been shown to exhibit  $\alpha$ -carbon root mean square distances of 1.2 Å and 1.5 Å, respectively, thus demonstrating the utility of, in this case, the CYP2C5 crystal structure as a template for generating three-dimensional models for other CYP2C subfamily enzymes.<sup>31–33</sup> An example of a CYP2C9 homology model is shown in **Figure 1**. Furthermore, there may be wider applicability of such crystallographic templates toward the CYP2 family in general, although the recent inhibitor-bound CYP2B4 crystal structure can be expected to represent an ideal template for the homology modeling of CYP2B6. Information from the human cytochrome P450 crystal structures is proving useful for the rationalization of substrate selectivity, which can lead to predictive tools for the high-throughput screening of new chemical entities (NCEs). For example, the active-site volumes of CYP2C8, CYP2C9, and CYP3A4 indicate the likely maximum sizes of substrates and their superimposed templates; also, the topography of these active sites helps to explain, in part, substrate structural preferences (summarized in **Table 3**). For example, there are clear topographical differences between CYP2C8 and CYP3A4 active sites that are in agreement with the known substrate selectivity between these two enzymes, despite evidence for some degree of overlap in this respect. More details with regard to the field of cytochrome P450 modeling can be found in a recent review.<sup>34</sup>

**Table 1** Human cytochromes P450 from families CYP1, CYP2, CYP3, and CYP4<sup>16,123–125</sup>

| CYP   | Hepatic CYP (%) | Drug oxidations (%) | Typical substrates       | Typical inhibitors          | Typical inducers  | Receptor/regulatory factor      |
|-------|-----------------|---------------------|--------------------------|-----------------------------|-------------------|---------------------------------|
| 1A1   | 1               | 3                   | Benzo[ <i>a</i> ]pyrene  | 9-Hydroxyellipticine        | PAHs              | AHR/ARNT                        |
| 1A2   | 13              | 10                  | Caffeine                 | Furafylline                 | PAHs              | AHR/ARNT                        |
| 1B1   | 1<br>4          | 1<br>3              | Estradiol                | Resveratrol                 | PAHs<br>Androgens | AHR/ARNT                        |
| 2A6   |                 |                     | Coumarin                 | Pilocarpine                 |                   | HNF4                            |
| 2B6   | 1               | 4                   | Bupropion                | Orphenadrine                | Phenobarbital     | CAR                             |
| 2C8   |                 |                     | Amodiaquine              | Sulfinpyrazone              |                   |                                 |
| 2C9   | 19              | 25                  | ( <i>S</i> )-Warfarin    | Sulfaphenazole              | Barbiturates      | HNF4, RAR/RXR                   |
| 2C19  |                 |                     | ( <i>S</i> )-Mephenytoin | Fluconazole                 |                   |                                 |
| 2D6   | 3               | 15                  | Propranolol              | Quinidine                   | None              | Constitutively regulated        |
| 2E1   | 7               | 3                   | Chlorzoxazone            | Pyridine                    | Ethanol           | Post-translational modification |
| 3A4/5 | 28              | 36                  | Nifedipine               | Ketoconazole                | Rifampicin        | PXR, GR                         |
| 4A11  | NA              | ~0                  | Lauric acid              | 11-Imidazolyl decanoic acid | Clofibrate        | PPAR                            |

AHR, arylhydrocarbon receptor; ARNT, AHR nuclear transporter; CAR, constitutive androstane receptor; GR, glucocorticoid receptor; HNF4, hepatocyte nuclear factor 4; NA, data not available; PAHs, polycyclic aromatic hydrocarbons; PPAR, peroxisome proliferator-activated receptor; PXR, pregnane X-receptor; RAR, retinoic acid receptor.

**Figure 1** Homology model for human CYP2C9<sup>31</sup> based on the crystal structure of rabbit CYP2C5.<sup>19</sup>  $\alpha$ -Helices and  $\beta$ -sheets are shown.

Modeling of the 3D structure and docking of substrates within these models can be very useful, but is complicated by another factor. Several years ago, evidence started to emerge that CYP3A4 could bind multiple substrates simultaneously.<sup>35</sup> This was later extended to various other cytochromes P450.<sup>36</sup> Further work suggested at least three different binding sites for CYP3A4, with testosterone,  $\alpha$ -naphthoflavone, and midazolam occupying these respective sites,<sup>37</sup> which eventually led to all three of these substrates to be used in CYP3A4 inhibition experiments. For CYP3A4, the existence of multiple binding sites was further confirmed with spectroscopic<sup>38</sup> and, ultimately, crystallographic<sup>26</sup> evidence.

#### 5.34.2.2 Molecular Dynamics (MD) Applied to Cytochromes P450

Although there is likely to be conformational flexibility in both enzymes and their substrates, the overall conformational space can be explored using MD simulations of the enzyme–substrate complex. In fact, it would appear that MD may be able to derive physiologically realistic structures for these complexes irrespective of whether the original 3D coordinates stem from a homology model or a crystal structure, as these probably represent different conformations of the same system that could converge energetically following a dynamics simulation.

**Table 3** Information on CYP substrate characteristics and active site volumes from crystal structures<sup>18,20–22,24,26,126,127</sup>

| <i>CYP</i> | <i>Volume of active site (Å<sup>3</sup>)</i> | <i>Typical substrates/inhibitors</i>                 | <i>General substrate characteristics</i>                                    |
|------------|--|--|---|
| 2A6        | 250  | Coumarin, nicotine, losigamone                       | Relatively small, compact molecules with hydrogen bond donor/acceptor atoms |
| 2B4        | 260  | Benzphetamine, testosterone, 4-chlorophenylimidazole | Relatively small/medium-sized molecules                                     |
| 2C5        | 645  | Progesterone, DMZ, diclofenac                        | Small/medium-sized molecules with hydrogen bond donor/acceptor atoms        |
| 2C8        | 1386   | Cerivastatin, taxol, rosiglitazone                   | Relatively large, S-shaped molecules  |
| 2C9        | 1137   | Flurbiprofen, ( <i>S</i> )-warfarin, diclofenac      | Medium-sized molecules possessing an acidic group                           |
| 3A4        | 1438   | Erythromycin, cyclosporin, nifedipine                | Relatively large, globular molecules  |

In order to prepare an enzyme–substrate complex for an MD run, a likely initial geometry needs to be established. This naturally requires some form of docking facility to derive an appropriate starting point prior to energy minimization and geometry optimization via a combination of molecular mechanics and dynamics procedures. A suggested sequence of stages in the process of generating a homology model from a suitable crystal structure can be outlined as follows:

- (1) molecular mechanics energy minimization calculations on the initial crystal structure;
- (2) changing the appropriate amino acid residues in accordance with the alignment;
- (3) searching the protein databank (PDB) for suitable protein loops;
- (4) checking the side chain torsional angles and modification as required;
- (5) molecular mechanics energy calculations on the raw model;
- (6) docking of the desired substrate or inhibitor; and
- (7) MD simulations on the enzyme–substrate complex.

Of course, various groups of researchers will have different alternatives to the above multistage scheme for producing cytochrome P450 models by homology, and it is recognized that within each step there are several possibilities and a variety of starting conditions.<sup>33,39–41</sup> Nevertheless, the preferred methodology to employ is likely to arise from an experience of comparison between techniques, and of validation against experimental observations.

The choice of crystal structure template for homology model building will, in general, be dictated by primary sequence identity and similarity, following a multiple sequence alignment that may involve several cytochrome P450 from within the same family and/or subfamily. For the human CYP2 family there is a relatively high homology with the rabbit CYP2C5 crystal structure,<sup>19–21</sup> which displays sequence identities of over 40%, and greater than 70% for CYP2C subfamily enzymes (although the human CYP2C9 crystal structures<sup>23,24</sup> are better templates in this case). Once a satisfactory alignment has been produced, it should be an essentially straightforward procedure to generate a raw model by replacement of the necessary amino acid residues, although some residue deletions and insertions may also be required. The latter can be readily achieved via loop searching of the PDB and selection of the most appropriate section of peptide. It is advisable to check the torsional angles of the amino acid side chains in the resultant raw model, and unfavorable steric interactions caused by the above procedures can then be corrected prior to relaxation of the entire structure via molecular mechanics energy minimization.

MD calculations can improve these homology models further, and, indeed, enable a means of full convergence with x-ray geometries, since both are likely to represent alternative points in the conformational space of the overall enzyme. Using the example of CYP2C9 where the original crystal structure shows the substrate (*S*)-warfarin bound preferentially about 10 Å from the heme, it is found that 1–2 ns of MD will bring the substrate approximately 5 Å closer to the heme iron, and at an orientation which is consistent with 7-hydroxylation, the experimentally observed result. Such substrate movements have been reported for bacterial CYP102, where the bound substrate, lauric acid, moves about 6 Å nearer to the heme, following reduction of the enzyme.<sup>42</sup> Moreover, it is noted that, under dynamics simulation, the overall enzyme conformation changes significantly during the 2 ns time frame with specific motions of the structure, especially helical trajectories, cooperatively assisting the translation of (*S*)-warfarin towards the heme

moiety. Consequently, it should be appreciated that crystal structures may not necessarily represent the paradigm for investigating cytochrome P450–substrate interactions and for estimating energies or for deriving other structural information from them. However, a combination of x-ray crystallography, molecular modeling, and dynamics simulation would appear to constitute an appropriate way forward in this, at times, inexact science. The important roles played by the energy calculations, both molecular mechanics and dynamics, in this respect are to relax the entire enzyme structure from its initially constrained solid state form, which is unlikely to be physiologically realistic.

It should also be recognized that some cytochrome P450 crystal structures do not conform to that of the wild-type enzyme, as certain residues have been deliberately modified to assist the crystallization process. For example, there are two particular mutations, S220P and P221A, in the original CYP2C9 crystal structures (PDB codes: 1og2 and 1og5<sup>23</sup>), that have resulted in a conformational feature of the tertiary fold that causes the (*S*)-warfarin substrate to bind on the periphery of the active site rather than at the heme locus. However, the recently published flurbiprofen-bound CYP2C9 crystal structure (PDB code: 1r90<sup>24</sup>) shows the substrate present within the active site at a position and orientation relative to the heme iron, which is consistent with its known route of metabolism. In this case, the enzyme is closer to the wild type with no mutations at the 220 and 221 locations, thus resulting in a more satisfactory conformation. As CYP2C19 has a primary sequence containing a proline residue at position 220, and an otherwise overall high homology (91%) with CYP2C9, then it is reasonable to expect that the 1og2 or 1og5 crystal structures will represent preferred templates for producing CYP2C19 models. Following homology modeling and minimization, however, it is recommended that the structure is validated (e.g., using ProCheck<sup>43,44</sup> or WhatIf?<sup>45</sup>), to ensure that there are no unacceptable protein geometries and that the whole 3D structure conforms to the now well-characterized features of protein structures in terms of backbone and side chain angles.

### 5.34.2.3 Substrate Docking and Binding Interactions of Cytochromes P450

Once a satisfactory geometry has been obtained following energy minimization using molecular mechanics, it is feasible to investigate the docking of substrates. There are several programs available that may be used for this process. One of the most accurate appears to be AutoDock<sup>46,47</sup> as, for cytochrome P450–substrate binding, the energies calculated via this program can be shown to agree well with experimental data for the change in binding free energy ( $\Delta G_{\text{bind}}$ ) obtained from the Michaelis rate constants ( $K_m$ ).<sup>48</sup> This is, however, not the only available method. An extensive overview of models generated for cytochromes P450 and the software used has been published recently.<sup>49</sup> Table 4 shows that, for a set of human cytochromes P450 and their selective substrates, there is a very good concordance ( $r^2 = 0.95$ ) between AutoDock-calculated binding energies and those derived from the apparent  $K_m$  data published in the literature (despite the uncertainties in both the experimental and computational methodologies). Plotting these data shows that the calculated enzyme–substrate binding energies lie close to the 1:1 correspondence line with respect to  $\Delta G_{\text{bind}}$ , derived from

$$\Delta G_{\text{bind}} = RT \ln K_m \quad [1]$$

where  $R$  is the gas constant and  $T$  is the absolute temperature, taken as 310 K for data measured at physiological temperature.

**Table 4** Comparison between calculated and experimental binding energies

| CYP  | Substrate                | $K_m$ ( $\mu\text{M}$ ) | $\Delta G_{\text{bind}}^{\text{expt } a}$ | $\Delta G_{\text{bind}}^{\text{calc } a,b}$ |
|------|--------------------------|-------------------------|---|---|
| 1A2  | Caffeine                 | 180                     | −5.31                                     | −5.88                                       |
| 2C8  | Amodiaquine              | 1.2                     | −8.40                                     | −8.16                                       |
| 2C9  | ( <i>S</i> )-Warfarin    | 4                       | −7.66                                     | −7.81                                       |
| 2C19 | ( <i>S</i> )-Mephenytoin | 54                      | −6.05                                     | −5.71                                       |
| 2D6  | Propranolol              | 1.02                    | −8.50                                     | −8.56                                       |
| 2E1  | Chlorzoxazone            | 65.1                    | −5.94                                     | −5.87                                       |
| 3A4  | Nifedipine               | 15                      | −6.84                                     | −6.76                                       |

<sup>a</sup> The correlation between the experimental and calculated  $\Delta G_{\text{bind}}$  shows  $r^2 = 0.95$  and a slope of 0.999, indicating a very close correspondence between the data.

<sup>b</sup>  $\Delta G_{\text{bind}}^{\text{calc}}$  is the enzyme–substrate binding energy calculated using AutoDock 3.05.<sup>47</sup>

Interestingly, these AutoDock binding energy values were calculated prior to MD runs after the raw structures had been minimized using molecular mechanics. It is possible that the success of AutoDock in this respect lies in its particular scoring function, which takes hydrophobic interactions into account as well as the usual linear combination of hydrogen-bonded, ionic, and  $\pi$ – $\pi$  stacking energies. Moreover, the local dielectric constant can be applied as a correction to the various terms. Other scoring functions are able to account for this factor as well, however, and some may even allow for user-defined scoring functions to be applied. It is possible to estimate binding energies quite satisfactorily using average values for the typical interactions and include a log  $P$ -derived partitioning energy as an approximation for desolvation effects. In such descriptions, the total binding energy can be represented as a linear combination of individual components,

$$\Delta G_{\text{bind}} = \Delta G_{\text{hb}} + \Delta G_{\text{ionic}} + \Delta G_{\pi-\pi} + \Delta G_{\text{desol}} + \Delta G_{\text{rotors}} \quad [2]$$

where the subscripts refer to hydrogen bond, ionic,  $\pi$ – $\pi$  stacking, desolvation, and loss of bond rotation upon binding.

#### 5.34.2.4 Quantitative Structure–Activity Relationship Approaches and Cytochromes P450: Lipophilicity and Substrate Selectivity

The desolvation term in the above linear combination of contributions to  $\Delta G_{\text{bind}}$  (eqn [2]) is equated with the octanol/water partitioning energy,  $\Delta G_{\text{part}}$ , in accordance with

$$\Delta G_{\text{part}} = -RT \ln P \quad [3]$$

where  $P$  is the octanol/water partition coefficient,  $R$  and  $T$  are as defined for eqn [1].

In fact, it is possible to demonstrate that there are so-called lipophilicity relationships for selective substrates of several major human drug-metabolizing cytochromes P450. These can be expressed as  $-\log K_m$  versus  $\log P$  or in terms of the corresponding free energy changes,  $\Delta G_{\text{bind}}$  and  $\Delta G_{\text{part}}$ , respectively. The use of the latter enables one to estimate the total intermolecular interaction energies common to a set of substrates from the value of the intercept on the  $y$  axis for  $\Delta G_{\text{bind}}$  itself. For CYP2B6 substrates, the lipophilicity relationship is one of the most clear,<sup>50</sup> with an intercept corresponding to the average value of a hydrogen bond and  $\pi$ – $\pi$  stack interaction, which is, in fact, found in practice when the substrate interactions are investigated using modeling.

It is also possible to derive a quantitative structure–activity relationship (QSAR) for human cytochrome P450–substrate binding based on the number of active site interactions (i.e., hydrogen bonds, ion pairs, and  $\pi$ – $\pi$  stacks) and  $\log P$  values of 90 compounds that are fairly selective substrates of the major human enzymes.<sup>51</sup> The various coefficients for each contribution agree closely with the average values reported in the literature, and the  $\log P$  coefficient is in harmony with the factor employed to convert this quantity into the corresponding desolvation free energy. Neural network analysis<sup>52</sup> of a similar set of selective cytochrome P450 substrates reveals the major descriptors likely to be involved in enzyme selectivity for the individual cytochromes P450 themselves.

A combined loading of only three parameters:  $pK_a$ , number of hydrogen bond donors/acceptors and molecular mass, produced a 94% concordance with the known selectivity of 60 compounds, and the small number of outliers identified were those substrates capable of metabolism by more than one cytochrome P450.<sup>51</sup> The three descriptors selected by the neural network can all be rationalized in terms of typical characteristics exhibited by cytochrome P450 substrates because, for example, it would be expected that basic compounds are CYP2D6-selective whereas acidic groups represent a common feature in substrates of CYP2C9.<sup>52</sup>

#### 5.34.2.5 Cytochromes P450: Molecular Size and Shape

The size and shape of molecules, together with the number and disposition of hydrogen bond donor/acceptor atoms and aromatic rings are important determinants of P450 selectivity.<sup>51</sup> To an extent, these factors are included in the neural net analysis,<sup>52</sup> although modeling the substrates within the active site region or, possibly, building up a template of superimposed substrates can reveal more information on the structural requirements for occupancy and binding in the heme pocket of the cytochrome P450. This is mirrored by the topography of the active site itself, and the substrate recognition site (SRS) regions,<sup>53</sup> including residues identified by site-directed mutagenesis or known to contact substrates in crystal structures, are presented in Table 5. The SRS regions were identified in the early 1990s as those regions responsible for substrate interactions in the 2-family of cytochromes P450, and later expanded to cover all cytochromes P450.<sup>53</sup>

<sup>a</sup> –, method not used; X, method used; √, method giving best results for this study.

Electronic structure calculations using molecular orbital (MO) methods may often reveal useful information relating to preferred sites of metabolism and the rate or clearance data for cytochrome P450 mediated oxidations frequently correlate with ionization energy. However, other approaches can also yield important information about the energetics of the metabolism process<sup>54</sup> and lead to a prediction of the metabolic route involved.<sup>55</sup> Neural network analyses are proving useful in this respect, as has been shown for CYP3A4 substrates and N-dealkylation reactions.<sup>56,57</sup> Furthermore, the regioselectivity of metabolism by cytochrome P450 enzymes can be explored using MO methods<sup>58</sup> or via a combination of molecular modeling techniques, as has been reported recently for CYP2B6.<sup>39</sup> In fact, the whole area of cytochrome P450 enzyme–substrate selectivity may be explored via specific QSAR approaches,<sup>59</sup> such as that afforded by pharmacophore modeling using such systems as Catalyst,<sup>49,60,61</sup> where even the overlapping specificities (due to high similarities in the substrate-binding site) of CYP3A4, CYP3A5, and CYP3A7 can be examined.<sup>62</sup> The field of cytochrome P450 modeling has been reviewed recently,<sup>34</sup> and the interested reader is referred to this review for further information.

#### 5.34.2.6 Cytochromes P450: Statistical Learning Methods

Recent advances in computer sciences, combined with larger data sets for cytochromes P450 due to high-throughput screening techniques, have led recently to a large number of statistical approaches to predict the involvement of specific cytochromes P450 in the metabolism of compounds and inhibition of cytochromes P450 by specific inhibitors. Compared with QSAR techniques, where a descriptive relationship is sought to describe the inhibition or metabolism or specific energy terms describing these processes,<sup>63</sup> statistical learning methods (or machine-learning algorithms) take a large number of descriptors related to structure, etc., and derive models that can be used to predict new compounds but are not necessarily ‘human readable.’ It is not the intention of this chapter to describe these computational techniques in detail, as this is covered in Volume 4. **Table 6** shows that the approaches have been applied successfully to the inhibition of specific cytochromes P450 such as CYP1A2,<sup>64</sup> CYP2D6,<sup>65</sup> and CYP3A4.<sup>32,66</sup>

#### 5.34.3 Modeling of Phase 2 Metabolism Enzymes

Whereas Phase 1 metabolism involves hydroxylation, oxidation, and reduction pathways, phase 2 metabolism involves primarily conjugation (of the phase 1 metabolites) with a variety of groups (e.g., sulfation, glucuronidation, glutathione

conjugation, acetylation, amino acid conjugation, and methylation).<sup>67</sup> With the exceptions of methylation and acetylation, phase 2 biotransformation reactions result in a large increase in hydrophilicity.<sup>68</sup> Enzymes involved in phase 2 metabolism include, GST, MT, NAT, SULT, and UGT.<sup>67,68</sup> Modeling of phase 2 metabolism has not received as much attention as the modeling of phase 1 metabolism for various reasons, as described below. A short overview of 3D modeling (homology modeling, pharmacophore modeling, and 3D-QSAR) will be presented in the following sections for the main enzymes involved in phase 2 metabolism.

#### 5.34.3.1 Glutathione S-Transferases

GSTs catalyze the nucleophilic attack of the thiol of the tripeptide glutathione (GSH) on electrophilic substrates, a reaction usually resulting in addition or substitution, depending on the nature of the substrate.<sup>68</sup> Many diverse compounds, including toxic xenobiotics and reactive products of intracellular processes such as lipid oxidation, act as GST substrates.<sup>69</sup> The primary function of GST isoenzymes is generally considered to be detoxification of both endogenous and xenobiotic compounds.<sup>70,71</sup> However, GSTs can also lead to the formation of more reactive intermediates, either directly or following conversion of glutathione conjugates by other biotransformation enzymes. In some cases the glutathione conjugates formed are labile, and dissociate to the parent electrophile in other tissues.<sup>71</sup> Substrates for GSTs share three common features: they are hydrophobic, contain an electrophilic atom, and also react nonenzymatically with GSH.<sup>68</sup>

Mammalian cytosolic GST isoenzymes have been grouped in eight families, alpha, mu, pi, theta, kappa, sigma, zeta, and omega,<sup>68,72–75</sup> which are distinguished by molecular masses, isoelectric points, and other properties. The primary sequence homology between subunits of the same family is >70%, while interfamily subunit homologies are approximately 30–40%.<sup>68,70,76,77</sup> In humans, multiple members of each subfamily class are now known.<sup>68</sup> Cytosolic GSTs are found as dimeric proteins comprised of two subunits.<sup>78</sup> Each isoenzyme subunit contains an active site consisting of two binding sites, one for the cofactor GSH (G-site) and one for the electrophilic substrate (H-site).<sup>78,79</sup> Furthermore, one nonsubstrate-binding site (binding compounds that are not conjugated but transported by GSTs) is present in the dimer.

Comparison of cytosolic GST crystal structures reveals that all cytosolic GST isoenzyme subunits share a number of general structural features, though they differ considerably in detail. The tertiary structure and a large part of the secondary structure are generally maintained between cytosolic GSTs from different families and different species.

Microsomal GSTs are membrane bound, and, in spite of the fact that their catalytic function is similar to soluble cytosolic GSTs, they share no sequence identity with the latter GSTs, as was shown by a two-dimensional projection structure of a microsomal membrane-bound GST determined using electron crystallography.<sup>80</sup> Microsomal GSTs occur as a trimer, which forms a pore-like structure with six  $\alpha$ -helices delineating a region with the local symmetry axis in the center, suggesting a membrane transport function for these GSTs.<sup>80</sup> This indicates that for comparable catalytic functions of microsomal and cytosolic GSTs, structurally different enzymes exist.<sup>80</sup>

The first models for a small-molecule bound to a GST isoenzyme suggested both hydrophobic interactions and hypothetical hydrogen bonds to polar groups in the active site to be important for binding and orientation of ( $\alpha$ -bromoisovaleryl)urea for conjugation.<sup>81</sup>

Another small-molecule model was derived for rat GST 4-4 (rGST M2-2; nomenclature adapted from Mannervik *et al.*<sup>82</sup> – the first letter indicates the species (h, human; m, mouse; p, pig; r, rat), the capital following ‘GST’ indicates the class, and the numbers indicate the specific GST), as a surrogate for the polymorphic hGST M1-1.<sup>83</sup> The derived substrate model incorporated information on regio- and stereoselective product formation of 20 substrates covering three chemically and structurally different classes (aromatic diol epoxides, aromatic chlorides, pyrene oxides, and (aza)phenanthrene oxides). The model highlighted three interaction sites responsible for Lewis acid–Lewis base interactions as well as a region responsible for aromatic interactions.<sup>83</sup> This substrate molecule model successfully predicted the conjugation to GSH of 11 substrates of GST 4-4 (representing three classes of compounds) that were not used to construct the model.<sup>83</sup> This small-molecule model was subsequently improved with another series of substrates, which extend beyond the original model in one specific area.<sup>84</sup> Based on these data, additional steric restrictions imposed by the protein in this region have been incorporated into the original small-molecule model.<sup>83</sup>

A small-molecule model based upon GSH analogs was constructed for hGST P1-1, which is expressed at elevated levels in tumor cells. A large number of GSH analogs were used to construct a pharmacophore for the G-site of GST P1-1, overlapping charged and hydrophobic centers.<sup>85</sup> The pharmacophore was consequently docked into the crystal structure of GST P1-1,<sup>86</sup> which indicated complementarity of all the major motifs.<sup>85</sup>

In the 1990s, when crystal structures were not available for all GSTs, several homology models were constructed. As there was generally at least one crystal structure available for each GST family, alignment between amino acid

**Figure 2** Homology model of cytosolic rGST M2-2 showing the dimeric (top/bottom) character of the enzyme.<sup>89</sup>

sequences of the crystal structure and a GST to be modeled was relatively easy when using a GST from the same family as a template for the model, due to the high homology. Furthermore, as the overall tertiary and secondary structures are largely maintained in all GSTs, the quality of the resulting alignments was generally excellent.

Cachau *et al.*,<sup>87</sup> Hsiao *et al.*,<sup>88</sup> and De Groot *et al.*,<sup>89</sup> used the crystal structure of rat mu class GST 3-3 (rGST M1-1)<sup>90</sup> as the template for the construction of homology models for, respectively, human mu class GSTs M1b-1b, M2-2, and M3-3,<sup>87</sup> chicken theta class GST,<sup>88</sup> and rat mu class GST 4-4 (rGST M2-2, shown in **Figure 2**).<sup>89</sup> All models closely resembled the crystal structures upon which the models were based. The modeled GST M2-2 structure<sup>87</sup> agreed remarkably well with the crystallographic structure of human muscle GST M2-2.<sup>91</sup> The orientation of four GSH conjugates docked into the GST 4-4 model appeared to be similar to the orientation of these substrates in a small-molecule model for GST 4-4.<sup>83</sup> The homology model of GST 4-4 (combined with the small-molecule model<sup>83</sup>) was used successfully to identify amino acids that could be involved in binding or activation of substrates in the active site.<sup>89</sup>

Several homology models have been generated for the GST theta family, for example a model for hGST T1,<sup>92</sup> hGST T2,<sup>93</sup> and for the mouse isoforms mGST T1, mGST T2, and mGST T3.<sup>94</sup> The model for hGST T2<sup>93</sup> was used to consolidate the role of specific amino acids in the active site. The mouse models used the crystal structures of hGST T2 as a template, and were used to compare the active sites and explain the inability of mGST T1 and mGST T3 to metabolize 1-menaphthyl sulfate.<sup>94</sup>

The crystal structure of hGST A1-1 has been used to generate homology models for rat GSTs of the alpha family, rGSTA3 and rGSTA5.<sup>95</sup> The resulting models were again used to investigate the importance of specific amino acids in the active site for activity toward conjugation of Aflatoxin B<sub>1</sub>, supported by site-directed mutagenesis.<sup>95</sup>

GSTs from the pi family have so far only been used for docking studies (hGST P1a, hGST P1b, and hGST P1c)<sup>96</sup> and docking algorithm evaluation.<sup>97</sup>

Due to the number of crystal structures currently available for GSTs from all families, pharmacophore and homology modeling for these enzymes is not receiving as much attention as that for the cytochromes P450, compared to the efforts expended in the 1990s.

### 5.34.3.2 Methyltransferases

Methylation is a common but minor pathway for phase 2 metabolism of xenobiotics, and is catalyzed by various enzymes, such as thioether methyltransferase, phenyl *O*-methyltransferase, catechol *O*-methyltransferase (COMT), phenylethanolamine *N*-methyltransferase (PNMT), and histamine *N*-methyltransferase (HNMT).<sup>68</sup> Several modeling

studies have been performed on MTs involved in endogenous pathways (e.g., DNA and RNA methylation), as well as studies in various plants. However, modeling of the human counterparts involved in drug metabolism has received relatively little attention.

A homology model of human HNMT was developed, and used to determine the location of the amino acid linked to polymorphism for this enzyme. This model supports experimental observations with regards to protein stability.<sup>98</sup> A set of homology models for rabbit and human indolethylamine *N*-methyltransferases was obtained, and used successfully to explain the observed species differences and polymorphisms.<sup>99</sup> These homology models were based on the rat crystal structure of COMT.<sup>100</sup> This crystal structure was also used for a docking study that, in combination with experiments using the human enzyme, resulted in various suggestions for mechanisms controlling the methylation by human COMT.<sup>101</sup>

A series of comparative molecular field analysis (CoMFA) studies on PNMT and the  $\alpha_2$ -adrenoceptor was performed in order to investigate the factors that determine potency and selectivity for a series of PNMT inhibitors.<sup>102,103</sup> The results of the CoMFA studies were similar to those of previous QSAR analysis.<sup>102</sup> COMT inhibitors are used in the treatment of Parkinson's disease, but their application is limited due to adverse side effects. Docking in the rat crystal structure, CoMFA analysis, and GRID/GOLPE models were used to examine a series of COMT inhibitors.<sup>104</sup> The three models were in agreement with each other, and suggested that an interaction between the catechol oxygen atoms and the magnesium ion in COMT is important, while several hydrogen-bonding and hydrophobic contacts influence inhibitor binding.<sup>104</sup>

### 5.34.3.3 *N*-Acetyltransferases

*N*-Acetylation is a major route of metabolism for compounds containing an aromatic amine or hydrazine group, which are converted to aromatic amides and hydrazides, respectively.<sup>68</sup> The reaction is catalyzed by NATs, which are found in most mammals, and require the cofactor acetyl-CoA.<sup>68</sup> Humans, rabbits, and hamsters express only two NATs (NAT1 and NAT2), whereas mice express a third (NAT3).<sup>68</sup> NAT1 and NAT2 have different but overlapping substrate specificities, and both show genetic polymorphisms.<sup>68</sup> Homology models have been constructed for both human NAT1<sup>105</sup> and NAT2,<sup>106</sup> based on the crystal structure of NAT from *Salmonella typhimurium* (StNAT). The model for NAT1 was used to predict that human NATs have adopted a common catalytic mechanism from cysteine proteases to accommodate acetyl transfer reactions,<sup>105</sup> while the NAT2 model was used to explain the polymorphism of this enzyme.<sup>106</sup> The crystal structures of *S. typhimurium* and *Mycobacterium smegmatis* NATs were used to generate a homology model of *Mycobacterium tuberculosis* NAT (MtNAT), and were used for specific inhibitor design against MtNAT (which is responsible for resistance against the antitubercular drug isoniazid).<sup>107</sup>

### 5.34.3.4 Sulfotransferases

Sulfate conjugation generally produces a highly water-soluble sulfuric acid ester. The reaction is catalyzed by SULTs, a large gene family of soluble (cytosolic) enzymes, and involves transfer of a sulfonate ( $\text{SO}_3^-$ ). The required cofactor for the reaction is 3'-phosphoadenosine 5'-phosphosulfate (PAPS).<sup>68,108</sup> Although the most common substrates for this enzyme are phenols and aliphatic alcohols, metabolism is not limited to those classes.<sup>68</sup> In mammals, sulfation is involved in the detoxification of therapeutic, dietary, and environmental xenobiotics, and contributes to the homeostasis and regulation of numerous biologically active endogenous chemicals such as steroids, iodothyronines, bile acids, and neurotransmitters.<sup>109,110</sup> In addition, for a large number of procarcinogens sulfation is the terminal step in the bioactivation pathway, and is necessary to reveal their mutagenic/carcinogenic activity. Multiple SULTs have been identified in all mammalian species, and are members of five gene families (SULT1 to SULT5).<sup>68</sup> Crystal structures are now available for seven human SULTs: the cytosolic SULT1A1, SULT1A3, SULT1E1, SULT2A1, SULT2B1A, and SULT2B1B and the Golgi-resident NDST-1.<sup>108</sup> Docking can be used to predict binding modes within these crystal structures, as was done for dopamine in SULT1A3.<sup>111</sup> The PAPS binding pocket is highly conserved, while the substrate-binding site of each SULT reflects the differences in substrate specificity in these crystal structures: the cytosolic SULTs typically recognize small hydrophobic molecules, whereas the Golgi-resident SULTs recognize hydrophilic carbohydrates and tyrosine residues in peptides.<sup>108</sup> The design of SULT inhibitors has focused on exploring environmental toxins and dietary agents, rather than drug development.<sup>108</sup> The crystal structure of mouse Sult1e1 has been used to build a homology model of human SULT1E1 before the human crystal structure was solved, to identify the potential (allosteric) binding pocket using a series of hydroxylated polychlorinated biphenyls.<sup>112</sup>

Similarly, a model of rat aryl sulfotransferase IV (AST IV) was constructed, based on mouse Sult1e1.<sup>113</sup> Docking of a series of *N*-hydroxyarylamines in the homology model of AST IV highlighted specific steric constraints within the active

site, which could explain the change from substrate to competitive inhibitor within this series of compounds.<sup>113</sup> CoMFA has been performed on  $K_m$  values of a series of 35 substrates of rat AST IV, and could explain the activities of six more substrates.<sup>114</sup> The CoMFA results<sup>114</sup> showed a good fit with the predicted active site in the homology model of AST IV.<sup>113</sup>

Four CoMFA models were derived from the  $K_m$  values for 95 substrates of SULT1A3. The different models used subsets of the data set or the entire data set and different molecular alignment rules.<sup>115</sup> All four models were statistically significant, and highlighted factors affecting binding in the SULT1A3 binding site.

Recently, the crystal structures of numerous human SULTs have been obtained by the Structural Genomics Consortium.<sup>116</sup>

#### 5.34.3.5 Uridine Diphosphate (UDP)-Glucuronosyltransferases

Glucuronidation is a major pathway of xenobiotic biotransformation in most mammalian species, and requires the cofactor uridine diphosphate-glucuronic acid.<sup>68,117</sup> The reaction is metabolized by UGTs (also called glucuronyltransferases), which are present in many tissues.<sup>68,117</sup> The site of glucuronidation is generally an electron-rich nucleophilic heteroatom (oxygen, nitrogen, or sulfur).<sup>68</sup> Human UGTs are a family of enzymes that detoxify many hundreds of compounds by their conjugation to glucuronic acid, rendering them harmless, more water-soluble, and, hence, excretable. Genetic inheritance, age, and environmental factors largely determine the different profiles of the inducible hepatic UGTs. Variation in the complement of these UGTs may result in dramatic differences in the safe elimination of toxic metabolites.

UGTs are classified into two distinct gene families: UGT1 and UGT2, the latter showing genetic polymorphisms.<sup>68</sup> In humans, up to 16 different functional UGT isoforms belonging to subfamilies 1A and 2B have been characterized, showing that these isoforms possess distinct but frequently overlapping substrate specificities.<sup>117</sup> Certain unexpected adverse reactions and decreased efficiency of drug therapy may be due to interindividual variations in the expression of UGTs.

Human UGTs have been studied extensively using pharmacophore and 3D-QSMR approaches.<sup>69,118</sup> Pharmacophores for UGT1A1,<sup>69,119–121</sup> UGT1A3,<sup>121</sup> UGT1A4,<sup>118,119,121,122</sup> UGT1A6,<sup>121</sup> UGT1A7,<sup>121</sup> UGT1A8,<sup>121</sup> UGT1A9,<sup>69,121</sup> UGT1A10,<sup>121</sup> UGT2B4,<sup>121</sup> UGT2B7,<sup>121</sup> UGT2B15,<sup>121</sup> and UGT2B17<sup>121</sup> have been reported. Pharmacophore modeling of UGTs is hampered by the ability of UGT isoforms to accommodate multiple substrate-binding modes, and requires the construction of a 'glucuronidation feature' for use in the computational algorithm.<sup>69,122</sup>

Substrates of UGT1A1<sup>120</sup> and UGT1A4<sup>122</sup> share two key hydrophobic regions 3 Å and 6–7 Å from the site of glucuronidation.<sup>119,120,122</sup> These results were confirmed by pharmacophore-based 3D-QSAR and molecular field-based 3D-QSAR (self-organizing molecular field analysis) methods.<sup>118,120,122</sup> An aromatic ring attached to the nucleophilic group was found to increase the likelihood of glucuronidation by UGT1A6, UGT1A7, and UGT1A9.<sup>121</sup> The pharmacophore of UGT1A9 consists of two hydrophobic regions at similar distances to the site of glucuronidation, as for UGT1A1 and UGT1A4,<sup>119,120,122</sup> but also contains a hydrogen bond acceptor feature close to the most distant hydrophobic feature.<sup>118</sup> A large hydrophobic region close to the site of glucuronidation and a hydrogen bond acceptor 10 Å from the site of glucuronidation were common in most UGT2B4 substrates.

#### 5.34.4 Conclusions

It is possible to make use of a considerable amount of accumulated data from experimental determinations and theoretical calculations to understand more about the way in which the selectivity of drug substrates for drug-metabolizing enzymes is encoded in their molecular structures. These features are likely to be complementary to the binding sites themselves, and, therefore, one can make predictions about the likely metabolic fate of new compounds (NCEs) from the currently available knowledge in this area (either using the 3D structures of the enzymes themselves or the accumulated features of known substrates for model building), thus leading to improved lead times for NCE development via high-throughput screening procedures.

So far, most attention has been paid to the prediction of cytochrome P450- and GST-catalyzed metabolism. As we start to understand how to design out metabolism by, for example, cytochromes P450, other metabolic pathways will take over, which will drive the need to understand these other pathways more thoroughly. With the drive to design out drug–drug interactions in an earlier phase of drug development, modeling of other enzymes involved in metabolism will therefore become more and more important. This is, of course, limited by the availability of experimental data to base these models on, like the *in vivo* or *in vitro* data described elsewhere in this volume. Combining *in silico* methods with

in vitro screening (as described in 5.38 Mechanism-Based Pharmacokinetic–Pharmacodynamic Modeling for the Prediction of In Vivo Drug Concentration–Effect Relationships – Application in Drug Candidate Selection and Lead Optimization) will be a very powerful tool in the near future.

## Biographies

**Marcel J De Groot**, after graduating from Utrecht University (the Netherlands, MSc in Chemistry) finished a PhD in Computational Toxicology at the Vrije Universiteit Amsterdam, developing computational models for biotransformation enzymes. In 1997, he worked for half a year as Assistant professor in Computational Chemistry at the Vrije Universiteit Amsterdam, after which he joined the Pfizer Global Research and Development in Sandwich (UK) as a computational chemist. Within Pfizer, Marcel De Groot continues to focus on computational models for biotransformation enzymes and the prediction of ADME and toxicological related issues and is an author of over 40 publications, mainly in the area of computational ADMET.

**David F V Lewis**, after graduating in Chemistry at the University of Bath, gained an MSc in Spectroscopy and, subsequently, a PhD in Theoretical Chemistry from the University of Surrey. He remained at Surrey as a Research Fellow, working with Professor Dennis Parke on the cytochromes P450 and, in 2003, was made Professor of Structural Biology, also receiving a DSc from the University of Bath the same year. David Lewis is the author of two books on P450, and has over 200 publications in peer-reviewed journals. His main interest lies in the molecular modeling of human P450-substrate interactions.

**Sandeep Modi**, after doing, MSc in Chemistry from Delhi University, India, did PhD in Chemical Physics from Tata Institute of Fundamental Research, Bombay, India. He also did postdoc in Cambridge University (Biochemistry Dept) and also in Leicester University (Biochemistry Dept). He joined Glaxo Wellcome in 1997 as computational chemist. Currently, he is working on the development of various ADMET models and their applications in several lead optimization programs.

### 5.35.1 Introduction

Knowledge of drug–drug interactions (DDIs) has become a part of the process of enabling new drugs to be introduced to the market, and there is increasing need for the prediction of such interactions.<sup>1</sup> DDIs not only give potential new drugs a competitive disadvantage, but could lead to labeling restrictions and in extreme cases can lead to the regulatory authorities refusing drug approval or in market withdrawal.<sup>2</sup>

It is known that there are a number of mechanisms for DDIs. The majority of these interactions involve effects at the level of drug-metabolizing enzymes, particularly cytochrome P450 (CYP), and will be the focus of this chapter. However, not every DDI is metabolism-based but may arise from changes in pharmacokinetics caused by absorption,

tissue, and/or plasma binding, distribution, and excretion interactions. Drug interactions involving transporter proteins are now being recognized as important factors, with a number of drugs being substrates and/or inhibitors/inducers of both drug-metabolizing enzymes and transporter proteins. In addition, DDIs may alter pharmacokinetic/pharmacodynamic relationships.

In recent years, a number of drugs have been withdrawn from the market because of problems relating to metabolic DDIs (mDDI). These compounds include drugs such as terfenadine, astemizole, cisapride, mibefradil, and cerivastatin which are metabolized by CYP enzymes, expressed primarily in the liver. The majority of mDDIs result from perturbation of the CYP enzyme system, with inhibition of the respective enzymes being the major reason for this type of interaction. The major CYPs affected by mDDIs involving inhibition are CYPs 1A2, 2C9, 2C19, 2D6, and 3A4,<sup>3</sup> although appreciation of the involvement of CYPs 2B6, 2C8, and 3A5 is increasing.<sup>2</sup>

Drug interactions resulting from CYP enzyme induction, resulting in an increase of enzyme content, occur far less frequently than inhibition.<sup>2,4</sup> CYP3A4 is the major enzyme affected by enzyme induction in humans and drugs such as rifampicin produce marked effects on CYP3A4 substrates<sup>5</sup> such as midazolam.<sup>6</sup> In these cases, the mDDI results in increased clearance of the affected drug, giving a reduced therapeutic effect or even a loss of efficacy. However, inducing agents such as some antiepileptic drugs (phenobarbital and carbamazepine) also upregulate other drug-metabolizing enzymes in addition to CYPs (e.g., conjugation enzymes such as uridine diphosphate-glucuronyl-transferases, UGTs).<sup>7,8</sup>

Although there are examples of clinically relevant DDIs being mediated at the level of transporters,<sup>9,10</sup> these are relatively few in number, and it is often difficult to dissociate CYP inhibition and inhibition of transport processes.<sup>2</sup> Nevertheless, despite the fact that some drug interactions may be due to effects at the level of CYPs, other drug-metabolizing enzymes, and also transporters, CYP inhibition remains the predominant mechanism both in terms of frequency and of the magnitude of the resultant pharmacokinetic effect.

The availability of in vitro metabolism data in early drug discovery has created the opportunity to evaluate better the magnitude of mDDIs. In fact, the potential for mDDIs is continuously measured using in vitro technology throughout the development of a new drug, with increasingly quantitative measurement and the use of clinically relevant drugs. At this stage, the magnitude of a drug interaction can be estimated by incorporating the  $I_u/K_i$  ratio, that is, the ratio of unbound inhibitor concentration to the inhibition constant for a particular CYP enzyme.<sup>11,12</sup>

However, improved prediction of mDDI requires an understanding of the physiological variability and variation in the drug-metabolizing enzyme content encountered in the human population.<sup>1</sup> By incorporating demographic, physiological, pathological, and genetic variation together with the range of CYP contents, it is possible to generate virtual populations that can be used in the estimation of mDDIs. It is this integration of population parameters with drug-specific parameters such as intrinsic clearance ( $CL_{int}$ ) or  $K_i$  which makes this approach a powerful tool in mDDI prediction. In this way, simulation of mDDIs should be able to generate the range of values seen in the clinic and thus be more representative of the true situation.<sup>13</sup> The typical mDDI study carried out in the pharmaceutical industry uses only a small number of healthy volunteers (typically up to 20), whereas a simulation of this type of study can generate a large population, encountered when a drug has been marketed and dosed to a patient population. The influence of the disease status such as hepatic/renal impairment or populations which are predominantly male (heart attack) or female (rheumatoid arthritis) can also be simulated. Thus, simulation techniques can be extremely useful in assessing the impact of drug interaction potential in such populations. This chapter will discuss the main principles for clearance prediction for both classical Michaelis–Menten ( $K_m$ ) and atypical in vitro kinetic data. Additionally, a number of substrate and inhibitor-related characteristics associated with the prediction of both reversible and irreversible DDIs will be reviewed. A number of drugs such as diltiazem and erythromycin are very weak reversible inhibitors of CYPs and would not act as inhibitors of drug-metabolizing enzyme activity in vivo. However, a number of compounds including these drugs act as time-dependent (irreversible) inhibitors of CYPs by inactivating CYPs and thus depleting the pool of active enzyme. This effect is more profound than reversible inhibition because new protein synthesis of the affected enzyme is necessary to remove the inhibitory effect.

Regulatory authorities such as the US Food and Drug Administration (FDA) and the European Agency for the Evaluation of Medicinal Products (EMA) require investigation of the potential for mDDIs. In vitro studies can often provide important indications of the likelihood of a mDDI occurring in vivo and guidances have been issued for these studies to be conducted during drug development. These include the establishment of a set of model CYP substrates and inhibitors which are recommended for use in these investigations. However, in vivo DDI studies remain the definitive method for determining the magnitude of an mDDI. The studies address a number of issues, such as the likely effects on drugs in the marketplace and whether dosage adjustments are necessary for coadministered drugs. Simulations of mDDI using in vitro and in vivo inputs can provide valuable projections of the likelihood and magnitude of an mDDI and the use of such methods are set out in subsequent sections.

## 5.35.2 In Vitro Models for Studying Metabolic Drug–Drug Interaction Potential

### 5.35.2.1 In Vitro Metabolizing Systems

In order to determine the DDI potential accurately the metabolic clearance of the ‘victim’ compound must be fully characterized.<sup>1,14</sup> Once this is performed it should then be a relatively simple matter either experimentally or theoretically to block some of these metabolic pathways, thereby determining the predicted degree of interaction.

Traditionally, human liver microsomes (HLM) have been used for these purposes. HLMs represent a solution of endoplasmic reticular membranes commonly isolated from liver homogenate by differential centrifugation up to 100 000 g. Since these membranes are the major intracellular location of the CYPs, the resultant solution is a highly concentrated reaction environment for studying phase I metabolic reactions, particularly those involving CYPs. The major advantages of using hepatic microsomes include the relative ease of preparation and the ability to store the solutions for long periods of time with little or no reduction in activity.<sup>15</sup>

Typically, an arbitrary concentration (around 1  $\mu\text{M}$ ) of the new chemical entity (NCE) is first incubated with an arbitrary amount of HLM, and then a series of selective CYP inhibitors<sup>16,17</sup> can be used to examine the reduction in measured  $\text{CL}_{\text{int}}$  to derive an impression as to which CYPs are most important in the clearance of this compound. There are several fundamental assumptions to this approach (such as the substrate concentration being significantly below the lowest metabolite  $K_m$  and that of negligible nonspecific binding); however, advances in analytical sensitivity have allowed sufficient limits of quantification so that these can often be accounted for in the experimental design. It has been recognized that an NCE must be assessed as both a potential ‘victim’ and ‘perpetrator’ of DDIs. In parallel to the above experimental approach, where the ‘victim’ potential is explored, another approach is often used, whereby fluorescent CYP-selective probes (resorufin, coumarin, and fluorescein derivatives) are used in the presence of varying NCE concentrations to examine the ‘perpetrator’ potential. Later in the drug development process, as major metabolic pathways are identified and characterized, each particular metabolic route can be explored for liability to DDI.

The advent of recombinant human CYPs (rhCYPs)<sup>18</sup> has provided the opportunity to combine several of these steps and obviate some of the reliance upon the ‘selective’ chemical CYP inhibitors. The enzyme preparations are available from commercial suppliers such as BD BioSciences, Invitrogen, and Cypex. Since these rhCYP systems express only one CYP it is theoretically possible merely to determine the  $\text{CL}_{\text{int}}$  in these and scale them to in vivo both pre- and postmetabolite identification stages (eqn [1]).

$$\text{CL}_{\text{int,met}} = \sum_j \text{CL}_{\text{int,j}} \times A_j \quad [1]$$

where  $\text{CL}_{\text{int,j}}$  represents the intrinsic clearance ( $\text{CL}_{\text{int}}$ ) from a single CYP enzyme and  $A_j$  the abundance of that enzyme in the human liver. The rhCYP systems in common use include those expressed in mammalian (lymphoblast), insect (baculovirus transfected *Trichoplusia ni*), bacterial (*Escherichia coli*), and yeast (*Saccharomyces cerevisiae*) systems.

Discrepancies between  $\text{CL}_{\text{int}}$  derived from HLM and rhCYP have been observed and may be due to several factors, including the extent of nonspecific microsomal binding.<sup>19,20</sup> Although differences between the systems in such binding per amount of microsomal protein are minimal,<sup>21</sup> experiments with rhCYP systems commonly employ lower protein concentrations than those using liver microsomes, which may cause disparity between the extent of nonspecific binding in the two systems, especially for lipophilic basic drugs. The  $\text{CL}_{\text{int}}$  per unit amount of CYP (intrinsic activity or turnover number) may also vary between HLM and rhCYP enzymes: this has been attributed to differences in the concentrations of accessory proteins (cytochrome  $b_5$ , NADPH:cytochrome P450 oxidoreductase) and the lipid microenvironment of the enzyme.<sup>22–24</sup> Several attempts have been made to correct for this discrepancy.<sup>25–27</sup> The initial approach was to use a relative activity factor (RAF) which would account for both this discrepancy and also the relative abundances of CYPs in HLM and rhCYP solutions. Although this approach has been used successfully on several occasions, it fails to address adequately the issues of interindividual variability in CYP expression and the apparent substrate specificity of RAFs. Indeed, the RAF merely demonstrates the amount of rhCYP required to give an equivalent reaction velocity to that of the particular HLM sample used (eqn [2]).

$$\text{RAF}_{\text{h,j}} \text{ (pmol rhCYP mg}^{-1} \text{ HLM)} = \frac{V_{\text{max,HLM}_{\text{h,j}}} \text{ (nmol min}^{-1} \text{mg}^{-1} \text{ HLM)}}{V_{\text{max,rhCYP}_j} \text{ (nmol min}^{-1} \text{pmol}^{-1} \text{ rhCYP)}} \quad [2]$$

An alternative approach would be merely to compare the intrinsic activities of rhCYP versus HLM and provide CYP abundance scaling by simply mathematical means. This approach is described in detail elsewhere,<sup>10</sup> but briefly

it is the above RAF approach adjusted for the actual amount of HLM CYP present rather than a theoretical amount (eqn [3]).

$$\text{VISEF}_j = \frac{V_{\max} \text{HLM}_j \text{ (nmol min}^{-1} \text{mg}^{-1} \text{ HLM)}}{V_{\max} \text{rhCYP}_j \text{ (nmol min}^{-1} \text{pmol}^{-1} \text{ rhCYP)} \times \text{HLM CYP}_j \text{ abundance (pmol mg}^{-1} \text{ HLM)}} \quad [3]$$

Since the ISEF uses the actual CYP abundance of that HLM sample, it is readily scalable to in vivo without the added complications of intersample uncertainty. Although maximum rate of metabolism ( $V_{\max}$ ) values have been used in eqns [2] and [3],  $\text{CL}_{\text{int}}$  values for the relevant activities can also be used.<sup>26,27</sup>

In order to provide accurate and reproducible estimates of DDI potential at an early stage in drug development, the above issues must be taken into account when using both HLM and rhCYP. Human hepatocytes may also be used for the determination of DDI potential, but their practical application is hampered by the plethora of biochemical systems in place. HLM remain the experimental system of choice for providing quantitative predictions of DDI, although this can only be representative if the HLM batch in question has been thoroughly characterized with respect to CYP abundance.

### 5.35.2.2 In Vitro Systems for Assessment of Cytochrome P450 Induction and Transporter Activity

Human hepatocyte cultures are frequently used as an in vitro system to detect potential CYP-inducing agents in humans.<sup>28–32</sup> A number of clinically relevant inducing agents have been shown to induce CYPs known to be affected in vivo at both the mRNA and the catalytically active protein level.<sup>33</sup> More recently, immortalized human hepatocytes, which offer the potential of a more useful screening procedure for CYP inducers, have also been used.<sup>34</sup> Estimation of hepatic enzyme induction involves incubating the cultured cells for a 48–72-h period with a range of concentrations of the test drug (based on anticipated human plasma drug concentrations). A positive control compound, e.g., a known human clinical enzyme inducer such as rifampicin, is also incubated under the same conditions. A drug that produces a greater than twofold increase in enzyme activity (measured with a probe substrate such as midazolam for CYP3A4 activity) or a fold change in enzyme activity that is 40% of the positive control data is considered to be an enzyme inducer. However, although there are data relating the extrapolation of the in vitro measured effects to the in vivo situation, knowledge of the extent of increased enzyme content in vivo due to induction is scarce and therefore difficult to incorporate in simulations.

In addition, the role of efflux and uptake transporters cannot be ignored, although the level of our understanding of these proteins in terms of their quantitation and interplay lags behind that of the CYPs.<sup>10,35,36</sup> Exposure of a drug to enzymes (particularly CYP3A4) during its transit from the gut lumen through the enterocyte and into the hepatic portal system depends on the interplay of transporters, passive membrane permeability, and enterocytic blood flow. A quantitative approach to incorporate these processes in the gut has been described for midazolam, a highly permeable drug.<sup>37</sup> It is possible to estimate the effect of efflux transporters for other compounds by comparing the flux of midazolam in an in vitro system (such as Caco-2 cells) with that of other compounds where these data are reported.<sup>38</sup> For a drug with a high permeability such as midazolam, the flux value approximates enterocytic blood flow but for substrates of efflux transporters flux from the gut into the hepatic portal vein is reduced. For active uptake transporters, studies using drug in the presence of cells incubated at 4 and 37 °C or with selective uptake inhibitors can be used to assess the degree of uptake into liver cells.<sup>39</sup>

### 5.35.2.3 In Vitro Parameters to Measure

A physiological approach to the simulation of mDDIs requires a range of data on tissue blood flow rates and tissue uptake, plasma protein binding, and nonspecific binding of compounds to the in vitro metabolizing system (hepatocytes, liver microsomes, or rhCYPs, enzyme kinetic data (in the form of  $\text{CL}_{\text{int}}$  for substrates and  $K_i$  values for inhibitors).  $\text{CL}_{\text{int}}$  is the enzyme-catalyzed metabolic clearance of a drug which is not influenced by other physiological parameters such as hepatic blood flow. The  $\text{CL}_{\text{int}}$  value is a fundamental link between enzyme kinetics and pharmacokinetics.

Many of the approaches used to calculate the degree of an mDDI rely on estimation of the change of  $\text{CL}_{\text{int}}$  resulting from the interaction of an inhibitor at a particular enzyme (CYP). The determination of this value for a CYP substrate is

frequently determined using HLMs by measuring the half-life (in vitro  $t_{1/2}$ ) of disappearance of the compound at low ( $\leq 1 \mu\text{M}$ ) substrate concentrations,<sup>40</sup> as shown in eqn [4].

$$\text{CL}_{\text{int}} = \frac{0.693}{\text{in vitro } t_{1/2} \times \text{microsomal protein concentration}} \quad [4]$$

The assumption is made that the total  $\text{CL}_{\text{int}}$  is mediated by CYP enzymes. In order to establish which CYPs are responsible for the metabolic process, selective chemical inhibitors are available which can inhibit individual CYP isoforms. Alternatively, rhCYPs can be incubated with the substrate to identify the CYP isoforms involved in metabolism, although adjustment of the rates with recombinant enzymes is necessary, as previously described (*see* Section 5.35.2.1).

For compounds where metabolites have been identified, the  $K_m$  and  $V_{\text{max}}$  parameters for the pathways can be generated. In these cases, the value of  $\text{CL}_{\text{int}}$  for compounds which obey Michaelis–Menten kinetics is obtained as the  $V_{\text{max}}/K_m$  ratio. The incorporation of  $\text{CL}_{\text{int}}$  for compounds which show atypical (non-Michaelis–Menten) kinetic features are described in Section 5.35.3.

It is important to recognize that the value of  $\text{CL}_{\text{int}}$  generated in an in vitro system may be affected by nonspecific binding of the test compound to the in vitro metabolizing system. This binding is referred to in the literature as  $f_{u,\text{mic}}$ <sup>41</sup> or  $f_{u,\text{inc}}$ <sup>42</sup> and is applied as a correction factor to  $\text{CL}_{\text{int}}$  or  $K_m$  values obtained in in vitro incubations (eqn [5]).

$$\text{CL}_{\text{int,u}} = \frac{\text{CL}_{\text{int}}}{f_{u,\text{mic}}} = \frac{V_{\text{max}}}{K_m \times f_{u,\text{mic}}} \quad [5]$$

As shown in eqn [5], estimates of  $K_m$  in vitro are apparent values without appropriate correction for the fraction unbound in the assay system.<sup>21,41–44</sup> Knowledge of  $f_{u,\text{mic}}$  has also been shown to be important for correction of the inhibition constant,  $K_i$ , used for the prediction of mDDI.<sup>45–48</sup> Substrates and inhibitors which are lipophilic bases are particularly affected by nonspecific binding, whereas acidic and neutral compounds are typically bound to a significant extent only if they are highly lipophilic ( $\log D_{7.4} > 3$ ).<sup>49</sup>

Thus, it is only by incorporating such variability in simulations of CL prediction from  $\text{CL}_{\text{int}}$  (eqn [6]), and of mDDI prediction from reduction in  $\text{CL}_{\text{int}}$  due to inhibition, that the variability of the magnitude of the interaction seen in the clinic can be captured.

#### 5.35.2.4 In Vitro to In Vivo Scaling Factors

It has previously been mentioned that the predictive accuracy of in vitro to in vivo extrapolation (IVIVE) approaches can depend greatly upon the in vitro systems of choice. It is also important to examine the extrapolative scaling factors used for sources of uncertainty and variability. The classical scaling approach (as described by Houston,<sup>50</sup> eqn [6]) has been modified to reflect the challenges in scaling from both HLM (eqn [7]) and rhCYPs (eqn [8]), whilst taking into account established measures of interindividual variability. It is important to note that the units in both latter strategies account for the extreme variability of CYP expression in tissues by expressing the rates per unit CYP isoform. The strategy used for scaling total hepatic intrinsic clearance ( $\text{CL}_{\text{H,int}}$ ) from in vitro data is outlined below. Central to these strategies are the amount of microsomal protein per gram of human liver (MPPGL) and the weight of the liver to be projected.

$$\text{CL}_{\text{H,int}} = \text{HLM } \text{CL}_{\text{int}} \times \text{MPPGL} \times \text{liver weight} \quad [6]$$

$$\text{CL}_{\text{H,int}} = \left[ \sum_j \text{HLM } \text{CL}_{\text{int,j}} \right] \times \text{CYP}_j \text{ abundance} \times \text{MPPGL} \times \text{liver weight} \quad [7]$$

where hepatic intrinsic clearances are summed for each contributing CYP ( $j$ ).

$$\text{CL}_{\text{H,int}} = \left[ \sum_j \text{rhCYP } \text{CL}_{\text{int,j}} \right] \times \text{ISEF}_j \times \text{CYP}_j \text{ abundance} \times \text{MPPGL} \times \text{liver weight} \quad [8]$$

It has been demonstrated that human MPPGL has considerable interindividual variability and indeed can vary dramatically between investigating laboratories.<sup>51–58</sup> The experimental technique of differential centrifugation used for preparing HLM can be highly variable and it is therefore essential to determine a recovery factor for each preparation in order to quantify reliably the true MPPGL rather than merely the experimental yield.<sup>58</sup> The most common values in use

of  $52.5^{54}$  and  $45^{59}$   $\text{mg g}^{-1}$  would appear to owe more to their assistance in overcoming underpredictions than any valid human physiological basis.<sup>60</sup> A recent publication has attempted to define a value of MPPGL and also assess the true interindividual variability present.<sup>58</sup> The authors have incorporated adjustments of both yield and assay variability by the means of recovery factor and cross-validated measurements. A further update<sup>61</sup> to this work has established MPPGL in a total of 53 human liver samples and work is ongoing to examine relationships between MPPGL and age, disease state, or medication status of the donors. An overall geometric mean value of  $28 \text{ mg g}^{-1}$  (range  $13\text{--}54 \text{ mg g}^{-1}$ ) has been obtained which appears to encompass other, smaller, data sets. Such a large degree of interindividual variation can obviously be significant when extrapolating to a human population.

The abundance of CYP isozymes in the liver and other tissues is also an issue of great importance. In addition to helping contextualize the results of *in vitro* experiments from a particular liver (or pool of livers), these values are essential in the successful scaling of rhCYP data. A recent exhaustive metaanalysis of the literature,<sup>62</sup> including the most commonly cited source of abundance data,<sup>63</sup> has shown a large degree of interindividual variability for many of the CYPs most commonly involved in drug metabolism. For example, reported CYP3A (3A4) content varies from  $37^{64}$  to  $248 \text{ pmol mg}^{-1}$ .<sup>65</sup> CYP3A4 is the major isoform of the CYP3A subfamily, both in terms of absolute amount and metabolic capacity.

A similar strategy has been pursued for the scaling of hepatocyte  $\text{CL}_{\text{int}}$  (eqn [9]), with slightly greater success, although this system has particular disadvantages for predicting DDI liability, as previously discussed.

$$\text{CL}_{\text{H,int}} = \left[ \sum_j \text{Hepatocyte } \text{CL}_{\text{int},j} \right] \times \text{HPGL} \times \text{liver weight} \quad [9]$$

The approach to defining hepatocellularity (or HPGL, quantity of hepatocytes per gram of liver) is slightly more challenging due in part to the difficulties involved in sourcing, isolating, and handling primary human hepatocytes. The approach has been well described,<sup>7</sup> although published literature has been unclear on the source of the most commonly accepted value of  $120 \times 10^6 \text{ cells g}^{-1}$ . Although widely used,<sup>54,59,66–69</sup> the original methodologies used for determining this number have not been verified, although the original reference value<sup>70</sup> is identical to that verified several years earlier in the rat.<sup>71</sup> Initial estimates<sup>58</sup> ( $n=7$ ) have given a geometric mean value of  $107 \times 10^6 \text{ cells g}^{-1}$  (range  $65\text{--}185 \times 10^6 \text{ cells g}^{-1}$ ), although more recent data<sup>61</sup> ( $n=24$ ) suggest that the true population will be somewhat lower than this.

### 5.35.2.5 Liver Models

Well-stirred, parallel-tube, and dispersion models are liver models used for the prediction of clearance. All three models assume homogeneous distribution of enzymes, no diffusion barriers in the liver, and that only unbound drug is able to cross the membrane and be metabolized. The well-stirred model is a simple and the most commonly used liver model, based on the assumption that the liver is a well-stirred compartment with the drug concentration in the liver being in equilibrium with the blood.<sup>54</sup> From eqn [6] the value for the total  $\text{CL}_{\text{int}}$  of the liver,  $\text{CL}_{\text{H,int}}$  (calculated from the *in vitro* HLM  $\text{CL}_{\text{int}}$ ) can be entered into the well-stirred model to estimate total hepatic blood CL *in vivo*,  $\text{CL}_{\text{H}}$ .

$$\text{CL}_{\text{H}} = \frac{\frac{Q_{\text{H}} \times f_{\text{u,b}} \times \text{CL}_{\text{H,int}}}{f_{\text{u,mic}}}}{Q_{\text{H}} + \frac{f_{\text{u,b}} \times \text{CL}_{\text{H,int}}}{f_{\text{u,mic}}}} \quad [10]$$

where  $Q_{\text{H}}$  is hepatic blood flow,  $f_{\text{u,b}}$  is free fraction of the compound in the blood,  $\text{CL}_{\text{H,int}}$  is the measured intrinsic clearance, and  $f_{\text{u,mic}}$  is the free fraction of the compound in the *in vitro* incubation system (e.g., human hepatic microsomes or rhCYP).

### 5.35.3 Prediction of Clearance by CYP3A Enzymes: Incorporation of $\text{CL}_{\text{max}}$ and Allosteric Kinetics to Measurement of $\text{CL}_{\text{int}}$

#### 5.35.3.1 Theoretical Considerations of Nonlinear Enzyme Kinetics

For many years the Michaelis–Menten model, and the existence of a single active site for the interaction of substrate with drug-metabolizing enzyme, has been used to describe *in vitro* kinetic data for both clearance and inhibition

**Figure 1** Kinetic profile simulations with the resulting Eadie–Hofstee and  $CL_{int}$  plots for autoactivation.

determination. However, it has become increasingly common that atypical (non-Michaelis–Menten) kinetic features are observed.<sup>22,72,73</sup> The phenomena of auto- and heteroactivation; partial, cooperative and substrate inhibition; concentration-dependent effector responses (activation/inhibition); limited substrate substitution and inhibitory reciprocity cannot be readily interpreted using single active-site models. While most of these atypical properties are associated with CYP3A4, recent studies indicate similar kinetic behavior for some other human enzymes, particularly CYP2C9<sup>74</sup> and certain UGTs.<sup>75,76</sup> Atypical Michaelis–Menten kinetics are characterized by two particular types of rate-substrate concentration curves: (1) sigmoidal, believed to result from autoactivation; and (2) convex, resulting from substrate inhibition. Both give characteristic curved Eadie–Hofstee plots that deviate from the linear relationship expected from the Michaelis–Menten model and are useful diagnostic plots for identifying such behavior. These two types of homotropic effects (i.e., when two molecules of the same substrate bind to the active site) are of importance as neither allows the estimation of  $CL_{int}$  in vitro by the standard method previously described.<sup>77</sup>

Autoactivation (positive cooperativity) has been observed for various CYP3A4 substrates, and in various in vitro systems. In order to explain and obtain the appropriate fit for the sigmoidal data, several models have been proposed, from the empirical Hill equation to more complex mechanistic ones.<sup>22,78,79</sup> Autoactivation is characterized by the dependence of clearance on the substrate concentration (Figure 1). As no linear region equivalent to Michaelis–Menten exists, an alternative to  $CL_{int}$  for scaling of in vitro data is required. Maximum clearance,  $CL_{max}$  (eqn [11]) has been suggested as an alternative parameter and provides an estimate for the maximum clearance when the enzyme is fully activated before the saturation occurs.<sup>80</sup>

$$CL_{max} = \frac{V_{max}}{S_{50}} \times \frac{(n-1)}{n(n-1)^{1/n}} \quad [11]$$

### 5.35.3.2 Practical Implications

The significance of nonstandard Michaelis–Menten data in vitro, and their correlation with the in vivo situation remains ambiguous,<sup>73</sup> since to date there are few confirmatory studies in vivo<sup>81,82</sup> and in certain cases their relevance could be questioned.<sup>83,84</sup> The introduction of  $CL_{max}$  as an alternative for  $CL_{int}$ <sup>80</sup> represents one attempt to introduce autoactivation into the in vitro–in vivo scaling strategy. The dependence of clearance on substrate concentrations below the  $K_s$  is associated with positive cooperativity and indicates the possibility of clearance underestimation in rapid in vitro screening procedures based on only one substrate concentration.<sup>77</sup> How precisely the clearance estimate will be altered by the model misspecification will vary from case to case and will be dependent on the number and quality of the data points.<sup>80</sup> In terms of predicting DDIs in vivo, the use of multiple substrates in vitro at various substrate concentrations is recommended to explore the range of possible consequences of a heterotropic interaction.<sup>2,16</sup>

## 5.35.4 Use of Various Inhibitor Concentrations for the Prediction of Drug–Drug Interactions

### 5.35.4.1 Metabolic Drug–Drug Interaction Risk Evaluation

The use of in vitro data to identify the inhibition of CYP-mediated metabolic reaction and hence potential DDIs is attractive. The rapid and simple experimental procedures developed have allowed substantial technological advances in the conduct of in vitro studies. The studies are designed based on the steady-state kinetic approach, i.e., that the

inhibitor concentration should be much higher than the enzyme concentration, such that inhibitor binding to the enzyme does not alter the free concentration of the inhibitor. In an ideal in vitro experimental design the inhibitor concentrations should span from  $0 K_i$  (control),  $1/3 K_i$ ,  $K_i$ ,  $3 K_i$ , to up to  $10 K_i$  values. In case of  $IC_{50}$  determinations the range of inhibition should range from virtually no inhibition to virtually complete inhibition in concentrations evenly spread on a log scale (e.g., 0, 0.1, 0.3, 1, 3, 10, 30, and 100 mM). The substrate concentration range should be in a similar range as that for determination of  $V_{max}$  and  $K_m$ . However, the interpretation of the parameters generated remains problematic due to lack of a quantitative framework for the in vitro–in vivo relationship for DDIs.<sup>1</sup>

The most promising approach to quantitative prediction of DDIs from in vitro data is based on the ratio between the concentration of the inhibitor in vivo at the enzyme active site  $[I]$  and inhibition constant ( $K_i$ ), assuming reversible single-site inhibition. The  $CL_{int}$  of substrate in the presence of inhibitor is reduced by a factor related to the inhibitor concentration available to the enzyme  $[I]$  and the inhibition constant,  $K_i$ . The distinction between competitive and noncompetitive inhibition mechanisms is not relevant when the substrate concentration is much lower than the  $K_m$  value, the commonly encountered in vivo situation that results in linear kinetics.

$$CL_{int,inhibited} = \frac{CL_{int}}{1 + [I]/K_i} \quad [12]$$

The major assumptions for this in vitro–in vivo extrapolation are reversible Michaelis–Menten type of inhibition, applicability of the ‘well-stirred’ liver model, and linear pharmacokinetics for the drug. The metric for the degree of DDI in vivo is the area under the plasma concentration–time curve (AUC) ratio for the plasma concentration in the presence and absence of the inhibitor after multiple oral dosing.<sup>2,16</sup> If the substrate is exclusively eliminated by liver by a single metabolic pathway which is subject to inhibition, the AUC ratio of orally administered substrate in the presence and absence of inhibitor reflects the ratio of clearances, as shown by eqn [13], where  $f_a$  is the fraction absorbed from gut into the portal vein,  $D$  is the dose, and  $f_{u,b}$  is the unbound fraction in blood.

$$\frac{AUC_{inhibited}}{AUC_{control}} = \frac{f_{a,I} \times D_I}{f_a \times D} \times \frac{f_{u,b} \times CL_{int}}{f_{u,b,I} \times CL_{int,I}} = \frac{CL_{int}}{CL_{int,I}} \quad [13]$$

This relationship is based on the assumption that there is no impact of inhibitor on either the intestinal absorption or plasma protein binding of the substrate. Therefore, the AUC ratio is dependent solely on the  $[I]/K_i$  as shown in eqn [14]:

$$\frac{AUC_{inhibited}}{AUC_{control}} = 1 + \frac{[I]}{K_i} \quad [14]$$

According to eqn [14], interactions can be regarded to be low-risk if the estimated  $[I]/K_i$  ratio is  $<0.1$  and high-risk with a ratio of  $>1$ . Figure 2 shows the relationship of the AUC ratio and  $[I]/K_i$  and classifications of the predictions into four zones: (1) true positives (AUC ratio  $>2$ ,  $[I]/K_i >1$ ); (2) true negatives (AUC ratio  $<2$ ,  $[I]/K_i <1$ ); (3) false positives (AUC ratio  $<2$ ,  $[I]/K_i >1$ ); or (4) false negatives (AUC ratio  $>2$ ,  $[I]/K_i <1$ ).<sup>16,85</sup>

**Figure 2** Qualitative zoning for the prediction of drug–drug interactions (AUC ratio) involving CYP inhibition using the  $[I]/K_i$  ratio. The theoretical curve is based on eqn [14] where F – represents false-negative, F + false-positive, and T + true-positive predictions. (Reproduced with permission from Houston, J. B.; Galetin, A. *Drug Metab. Rev.* **2003**, 35, 393–415.)

In recent years there has been much interest in the use of  $[I]/K_i$  to describe the degree of in vivo interaction between two drugs.<sup>12,85–87</sup> The accurate determination of  $[I]$  is problematic as direct measurement is not possible and there is no generally accepted approach for the extrapolation of inhibitor concentration in the plasma to that at the enzyme site. A number of predictions of DDIs have been attempted, with varying degrees of success, using a range of  $[I]$  values in eqn [14] including the average plasma total or unbound concentration or hepatic input concentration of the inhibitor.<sup>3,85,87–89</sup>

The average systemic plasma concentration after repeated oral administration ( $[I]_{av}$ ), and the maximum hepatic input concentration ( $[I]_{in}$ ) can be calculated as illustrated in eqns [15] and [16], respectively.<sup>88</sup> The  $[I]_{in}$  value represents the combination of circulating systemic plasma concentration and the additional concentration occurring during the absorption phase.

$$[I]_{av} = \frac{D/\tau}{CL/F} \quad [15]$$

$$[I]_{in} = [I]_{av} + \frac{k_a \times f_a \times D}{Q_H} \quad [16]$$

where  $F$  and  $\tau$  represent the fraction of dose systematically available and dosing interval, respectively, of the inhibitor used in the in vivo interaction study,  $Q_H$  is the hepatic blood flow ( $1610 \text{ mL min}^{-1}$ ),  $D$  is the dose of an inhibitor,  $f_a$  is the fraction absorbed from the gastrointestinal tract, and  $k_a$  is the absorption rate constant.

Comprehensive analysis of 193 DDIs involving inhibition of CYP2C9, CYP2D6, and CYP3A4<sup>85</sup> has shown that hepatic input concentration as a surrogate for  $[I]$  was the most successful for categorizing CYP inhibitors and for identifying true-negative DDIs. Although false-negative predictions were eliminated in this approach, a significant number of false positives was evident and most true positives were markedly overpredicted (Figure 3). The  $[I]_{in}$  should be considered as an initial discriminator and is recommended, as true negatives can be identified. In addition, this approach would be particularly valuable in drug-screening processes, where false-negative predictions are to be avoided. However, this simple generic approach ignores specific substrate- or inhibitor-related properties that contribute to a number of overpredictions of true-positive interactions. The importance of these properties is evident by the number of true positives that are quantitatively overpredicted. These factors (e.g., the role of hepatic uptake transporters, plasma protein binding, appropriate absorption rate constant, existence of more than one metabolic/elimination pathway, impact of multisite kinetics for CYP3A4/5) require consideration in addition to the  $[I]_{in}/K_i$  ratio in order to progress the prediction of CYP inhibition interactions toward a quantitative basis.

The absorption rate constant ( $k_a$ ) values are frequently not reported in clinical studies; in the absence of this information and in order to avoid false-negative prediction and obtain the largest  $[I]_{in}$ , maximum value of  $0.1 \text{ min}^{-1}$  was suggested as useful, assuming the gastric emptying is the rate-limiting step for absorption.<sup>85,88</sup> Recent studies by Brown *et al.*<sup>87</sup> have shown the impact of appropriate  $k_a$  values for 10 inhibitors for CYP2C9, CYP2D6, and CYP3A4, including azoles, quinidine, fluoxetine, fluvoxamine, etc. Refinement of this parameter resulted in the  $k_a$  values

**Figure 3** The graph shows 193 studies involving drug–drug interactions for CYP3A4 (filled circle), CYP2D6 (filled triangle), and CYP2C9 (filled square) substrates. Open symbols represent mechanism-based inhibitions. (Reproduced with permission from Houston, J. B.; Galetin, A. *Drug Metab. Rev.* **2003**, 35, 393–415.)

2–14-fold lower than the initial estimates and reduction of the relative contribution of the absorption term in comparison with the systemic term to the  $[I]_{in}$  value up to 13-fold in case of itraconazole. In addition, the  $k_a$  value may vary with the dose of inhibitor and the food intake (e.g., ketoconazole<sup>90</sup>), affecting the  $[I]_{in}$  estimate and consequently the predicted AUC ratio.

#### 5.35.4.2 Impact of Parallel Elimination Pathways on the Drug–Drug Interaction Assessment

Predictions of DDIs based on eqn [14] assume that the fraction of victim drug metabolized by the inhibited CYP pathway ( $f_{mCYP}$ ) equals 1. However, parallel pathways of metabolism and renal clearance of unchanged drug will affect the  $f_{mCYP}$  estimate and consequently the predicted degree of interaction and therefore need to be incorporated into the prediction,<sup>91</sup> as shown in eqn [17]. Even minor changes in the  $f_{mCYP}$  value (e.g., from 1 to 0.98) may alter prediction accuracy significantly, as was illustrated in recent studies.<sup>14,87,92</sup>

$$\frac{CL_{control}}{CL_{inhibited}} = \frac{AUC_{inhibited}}{AUC_{control}} = \frac{1}{\left(f_{mCYP} / \left(1 + \left(\frac{[I]_{in vivo}}{K_i}\right)\right)\right) + (1 - f_{mCYP})} \quad [17]$$

A number of approaches can be employed to obtain  $f_{mCYP}$  value. The most explicit method is based on the comparison of phenotyping data in extensive and poor metabolizers, as shown for CYP2D6.<sup>14</sup> A good alternative to this approach is ‘phenocopying,’ based on the difference between the urinary recovery of metabolites in the presence and absence of a selective inhibitor (e.g., tolbutamide in the presence of sulfaphenazole as an inhibitor). CYP3A4 is the most problematic enzyme and the combined information on the urinary recovery of metabolites, biliary excretion, and the recovery of unchanged drug has recently been used.<sup>87,92</sup> As shown in the same systematic analysis, the use of  $f_{mCYP}$  data in the assessment of AUC ratio corrected several false-positive predictions, as well as significantly reduced the extent of overpredictions of true positives, with a minimal bias and high precision observed.

#### 5.35.4.3 Complex Behavior of CYP3A4

Prediction of a potential DDI with CYP3A4 is particularly challenging due to a number of in vitro and in vivo factors, namely complexity of the in vitro kinetics observed for some of the CYP3A4 probes,<sup>22,77</sup> CYP3A interindividual variability in the abundance and activity in both liver and small intestine (with the variable contribution of polymorphic CYP3A5),<sup>93,94</sup> and overlapping substrate specificity with P-glycoprotein.<sup>95</sup>

In order to assess the importance of cooperativity and predict changes in the in vivo plasma concentration–time profile from CYP3A4 in vitro data, an equation (eqn [18]) was derived based on the same rapid equilibrium and steady-state assumptions as the single-site model.<sup>92</sup> In addition to simple  $[I]/K_i$  ratio, this two-site model equation also incorporates changes in the catalytic efficacy ( $\gamma$ ) and binding affinity ( $\delta$ ) in the presence of the inhibitor. In cases when  $\gamma/\delta = 1$ , the two-site prediction equation is reduced to the simple  $1 + [I]/K_i$  relationship.

$$AUC \text{ ratio} = \frac{\left(1 + \frac{[I]}{K_i}\right)^2}{1 + \frac{\gamma[I]}{\delta K_i}} \quad [18]$$

where  $I$  represents the in vivo inhibitor concentration (either  $[I]_{in}$  – input plasma concentration – or  $[I]_{av}$  – average plasma concentration during the dosing interval, whereas  $K_i$  estimates are obtained applying the generic two-site model). When the  $\gamma/\delta$  ratio is either  $>$  or  $< 1$  there is a change in both the position and the shape of the prediction curve, as shown in Figure 4. These simulations were performed for the case of inhibition ( $\gamma \leq 0.5$ ) with a range of different binding affinities for the inhibitor in the presence of substrate. The analysis shows that the inclusion of CYP3A4 kinetic complexities (in the form of the  $\gamma/\delta$  ratio) into the prediction strategy provides an explanation for the occurrence of some of the false negatives and reduces the overestimation of true-positive predictions (e.g., 28-fold for ketoconazole–triazolam interaction).<sup>77</sup>

However, a limitation of the multisite kinetic model approach to the analysis of DDIs lies in its complexity and the number of data points required for full characterization of the in vitro phenomenon observed. A recent study by Galetin *et al.*<sup>92</sup> explored the possibility of alternative and/or pragmatic approaches and substrates and their validity for reliable in vitro–in vivo prediction. Four different CYP3A4 probes, midazolam, testosterone, quinidine, and nifedipine,

**Figure 4** Practical implications of CYP3A4 multisite kinetics in predicting drug–drug interactions from in vitro parameters. The effect of interaction factors (shown as the  $\gamma/\delta$  ratio) on the relationship between AUC ratio and  $[I]/K_I$  ratio where  $\gamma$  = catalytic efficacy and  $\delta$  = binding affinity. (Reproduced with permission from Houston, J. B.; Galetin, A. *Drug Metab. Rev.* **2003**, 35, 393–415.)

were assessed from the prospect of their in vitro complexities and possibility of substrate substitution in prediction of DDI potential. Midazolam and quinidine provided the best assessment of a range of selected 26 CYP3A4 drug interactions with azole inhibitors. Hyperbolic kinetics displayed in vitro for both of the substrates adds to their ‘pragmatic appeal’ in the evaluation of potential DDI compared to nifedipine and testosterone; however, the kinetic complexities of nifedipine and testosterone can be overcome by the appropriate mechanistic analysis. In addition, the study has shown that the extrapolation from one substrate to another (generally problematic in the case of CYP3A4) was successful, yet highly dependent on the incorporation of the detailed inhibitor- and substrate-related information in the prediction.

### 5.35.5 Prediction of Time-Dependent Drug–Drug Interactions

As the most abundant human P450 enzyme in both liver and intestine, CYP3A4 is susceptible to a number of reversible and irreversible metabolic DDIs. Irreversible, often referred to as mechanism-based, inhibition interactions, involve the metabolism of an inhibitor by CYP3A4 (i.e., require NADPH) to a reactive metabolite form which irreversibly inactivates the catalyzing enzyme (therefore removing it from the pool of active enzyme) in a concentration- and time-dependent manner.<sup>96</sup> A key characteristic of this type of inhibition is that inactivation occurs without the release of the reaction product from the catalytic site.<sup>97</sup> The interaction between the inactivating species and enzyme can be either covalent or noncovalent, involving binding to protein or heme moiety, respectively. Compounds such as bergamottin, ethinyl-estradiol, and mifepristone are indicated as covalent binders, whereas nitrosoalkanes formed by N-demethylation of tertiary amine group of macrolides (erythromycin) bind to the heme and inactivate the enzyme.<sup>98</sup>

The two major kinetic parameters that characterize time-dependent inhibition (TDI) interactions are  $k_{\text{inact}}$  and  $K_I$ , the maximal inactivation rate constant and the inhibitor concentration leading to 50% of  $k_{\text{inact}}$ , respectively.<sup>96</sup> The  $k_{\text{inact}}/K_I$  ratio is commonly taken as an indicator of the in vitro potency of a mechanism-based inhibitor. The established method of analysis of mechanism-based inhibitors<sup>2,96</sup> is based on the measurement of the residual enzyme activity using a probe substrate for the enzyme being investigated. This is achieved by preincubation of the range of inhibitor concentrations with the enzyme and cofactors. At set time points an aliquot of this mixture is taken and diluted into a secondary incubation containing the probe substrate and further cofactors; the dilution factor is necessary to reduce the occurrence of competitive inhibition between the inhibitor and marker substrate in the second incubation.

The methods used to obtain  $k_{\text{inact}}$  and  $K_I$  estimates generally vary across studies<sup>99,100</sup> from the CYP3A4 probes used (midazolam, testosterone, or triazolam), their concentration (from below the  $K_m$  to the concentrations equivalent to  $V_{\text{max}}$ ), preincubation-to-incubation time ratio and data analysis method employed, all of which may affect the estimates

of inhibitor potency. Ideally, preincubation-to-incubation time ratio should be at least  $>1$ , and a dilution factor from the preincubation to the incubation stage 1:10 should be applied to reduce the occurrence of competitive inhibition; in addition, the use of high substrate concentrations (equivalent to  $V_{\max}$ ) and nonlinear regression analysis are recommended for obtaining the  $k_{\text{inact}}$  and  $K_I$  parameters. A recent correlation analysis of  $k_{\text{inact}}/K_I$  estimates for five human immunodeficiency virus (HIV)-protease inhibitors by Ernest *et al.*<sup>101</sup> indicated higher potency estimates in recombinant enzymes in comparison to the liver microsomes. However, standardization of in vitro methodology and the use of the CYP3A4 probe at high substrate concentration (equivalent to the  $V_{\max}$ ) in the study by Ernest *et al.*<sup>101</sup> reduced the difference between the in vitro systems (with the exception of saquinavir) to only twofold.

Quantitative in vitro–in vivo drug interaction prediction work has mainly focused on reversible interactions, whereas TDIs were assessed on an individual case-by-case basis.<sup>102,103</sup> In contrast to reversible inhibition, enzyme activity can only be restored by synthesis of a new enzyme, often resulting in significant clinical interactions and a potential for idiosyncratic toxicities. Prediction of TDI using the  $[I]/K_I$  approach with the assumption of reversible inhibition generally results in underprediction of the interaction observed, with a significant number of predictions being classified as false negatives.<sup>1,85</sup> The extent of TDI interaction, incorporating the contribution of parallel elimination pathways (other P450 enzymes or renal clearance, defined by  $1 - fm_{\text{CYP3A4}}$ ), is defined by the eqn [19]<sup>103</sup>:

$$\frac{\text{AUC}_{\text{inhibited}}}{\text{AUC}_{\text{control}}} = \frac{F'_G}{F_G} \times \frac{1}{\frac{fm_{\text{CYP3A4}}}{1 + \sum_{i=1}^n \frac{k_{\text{inact},i} \times I_{u,i}}{k_{\text{deg}} \times (K_{I,u} + I_{u,i})}} + (1 - fm_{\text{CYP3A4}})} \quad [19]$$

The magnitude of interaction is assessed by the increase in the AUC<sub>i</sub>/AUC ratio for the plasma concentration–time profiles in the presence and absence of the inhibitor, respectively, as used previously.<sup>16</sup> In eqn [19],  $k_{\text{inact}}$  represents the maximal inactivation rate constant,  $K_I$  is the inhibitor concentration at 50% of  $k_{\text{inact}}$ ,  $I_u$  is the unbound inhibitor concentration (either the average systemic plasma concentration after repeated oral administration ( $[I]_{\text{av}}$ ), or the maximum hepatic input concentration ( $[I]_{\text{in}}$ ),  $fm_{\text{CYP3A4}}$  is the fraction of victim drug metabolized by CYP3A4,  $k_{\text{deg}}$  is the endogenous degradation rate constant of the enzyme, and  $F'_G$  and  $F_G$  are the intestinal wall availability in the presence and absence of inhibitor, respectively.

The rate of change of active enzyme concentration is determined by the equilibrium between the rates of de novo synthesis and degradation of the enzyme. Previous predictions of TDI<sup>102,103</sup> used CYP3A4 degradation half-life estimates ( $t_{1/2\text{deg}}$ ) obtained in either rat or Caco-2 cells,<sup>104,105</sup> resulting in  $t_{1/2\text{deg}}$  of 14–35 h. Recently, the estimates of human CYP3A4  $k_{\text{deg}}$  from both induction studies and in vitro investigations in liver slices have been collated,<sup>99,100</sup> as shown in Table 1. The estimated decay of CYP3A4 activity is twofold longer in comparison with most other cytochrome P450 enzymes,<sup>100</sup> but comparable to CYP2D6.<sup>24,106</sup> Differential degradation half-lives reported for CYP3A4 and CYP3A5 in vitro (79 versus 35 h, respectively<sup>106</sup>) and less susceptibility to inhibition observed for CYP3A5<sup>107</sup> may contribute to the extent of interindividual variability observed in the magnitude of interactions.

Venkatakrishnan and Obach<sup>24</sup> have indicated the importance of accurate enzyme degradation estimates for the prediction of CYP2D6 inactivation by paroxetine; a recent comparable study was reported for CYP3A4.<sup>99</sup> The impact of interindividual variability of human CYP3A4  $t_{1/2\text{deg}}$  (20–146 h) on the assessment of TDI potential was assessed in addition to the fraction of the victim drug metabolized by CYP3A4 (defined by  $fm_{\text{CYP3A4}}$ ), as this parameter has been shown to have a significant impact on the DDI prediction accuracy.<sup>14,87,92</sup> The sensitivity of the predicted extent of interaction to the differential CYP3A4 degradation rate was dependent on  $fm_{\text{CYP3A4}}$  (as illustrated in Figure 5). The prediction accuracy was very sensitive to the CYP3A4 degradation rate for substrates mainly eliminated by this enzyme

**Table 1** CYP degradation rate constants and the corresponding half-lives in humans

| CYP    | $k_{\text{deg}}$ ( $\text{min}^{-1}$ ) | $t_{1/2\text{deg}}$ range (h) | Method                  | Reference |
|--------|--|-------------------------------|-------------------------|-----------|
| CYP3A4 | 0.00016                                | 20–146                        | Carbamazepine induction | 108       |
|        | 0.00015                                | 17–no decay                   | In vitro – liver slices | 106       |
| CYP3A5 | 0.00032                                | 15–70                         | In vitro – liver slices |           |
| CYP2D6 | 0.00022                                | 51                            | Paroxetine inhibition   | 24        |
| CYP1A2 | 0.0003                                 | 27–54                         | Smoking induction       | 109       |

**Figure 5** Effect of  $f_{m_{CYP3A4}}$  and CYP3A4  $t_{1/2deg}$  on the predicted AUC ratio. Surface simulated for erythromycin  $k_{inact}$  and  $K_i$  values ( $0.025 \text{ min}^{-1}$  and  $13 \mu\text{M}$ , respectively) for  $[I]$  of  $0.5 \mu\text{M}$  over the range of  $f_{m_{CYP3A4}} = 0.4\text{--}1$  and CYP3A4  $t_{1/2deg} = 1\text{--}6$  days; eqn [19] was used with  $F_G'/F_G = 1$ . (Reproduced with permission from Galetin, A.; Burt, H.; Gibbons, L.; Houston, J. B. *Drug Metab. Dispos.* **2006**, *34*, 166–175.)

( $f_{m_{CYP3A4}} \geq 0.9$ ); minimal effects are observed when CYP3A4 contributes less than 50% to the overall elimination in cases when the parallel elimination pathway is not subject to inhibition. The study also indicated the suitability of the mean CYP3A4  $t_{1/2deg}$  of 3 days in the assessment of time-dependent interaction potential.

### 5.35.6 Impact of the Intestinal Metabolic Interactions

Another confounding factor in the prediction of DDI is the possibility of the interaction at the level of the gut wall. Significant intestinal first-pass metabolism may contribute to the interindividual variability observed in bioavailability and extent of DDI for some CYP3A4 substrates. The impact of metabolic intestinal interaction has only recently been considered as part of the prediction strategy.<sup>1,3,99,103</sup>

A certain degree of interaction at the level of the gut wall is to be expected for some CYP3A4 substrates as the small intestine represents the first in the series of the first-pass eliminating organs and is exposed to the orally administered inhibitors or inducers. A number of studies indicated a more pronounced inhibition and induction of intestinal CYP3A4 in comparison to the liver.<sup>110–112</sup> The interpretation of such events must be cautious for compounds that are mutual substrates for P-glycoprotein and CYP3A4 (e.g., ciclosporin, tacrolimus) due to their interactive nature and inverse relationship in the intestine and liver.<sup>113</sup> Intestinal interactions are rarely incorporated in the assessment of interaction potential, whether for reversible or irreversible types,<sup>1</sup> which may represent a limitation for some CYP3A4 compounds. For example, a 2.6-fold greater increase in the AUC ratio after oral dose of midazolam in comparison to the intravenous (i.v.) administration was observed in the presence of clarithromycin, indicating the contribution of intestinal interaction.<sup>114</sup>

The contribution of the enzyme interaction in the intestinal wall can be evaluated by incorporating the ratio of intestinal wall availability in the presence and absence of inhibitor,  $F_G'$  and  $F_G$ , respectively, into the hepatic prediction,<sup>99,103</sup> as shown in eqn [19]. The  $F_G$  control values for the corresponding substrates are obtained indirectly from oral and i.v. administration data assuming complete absorption, negligible intestinal metabolism after i.v. administration, and that the systemic clearance of a drug after i.v. dose reflects only hepatic elimination (eqns [20] and [21])<sup>115</sup>:

$$F = f_a(1 - E_G)(1 - E_H) \quad [20]$$

$$E_H = 1 - \text{CL}_H/Q_H \quad [21]$$

where  $F$  represents the overall oral bioavailability,  $f_a$  is the fraction of the oral dose absorbed intact across the apical membrane of the epithelial layer,  $E_G$  and  $E_H$  are the intestinal and hepatic extraction ratios, respectively,  $\text{CL}_H$  is the hepatic blood clearance and  $Q_H$  is the hepatic blood flow. Figure 6 shows the general relationship between  $F_G'/F_G$  ratio

**Figure 6** Relationship between  $F_G'/F_G$  and inactivation index  $k_{\text{inact}} \cdot I / k_{\text{deg}}(K_i + I)$  for varying degrees of intestinal extraction (0 – 1).  $F_G'/F_G$  was simulated from the relative change in the intestinal intrinsic clearance caused by the inhibitor; this is estimated from the inactivation index parameters. (Reproduced with permission from Galetin, A.; Burt, H.; Gibbons, L.; Houston, J. B. *Drug Metab. Dispos.* **2006**, *34*, 166–175.)

and the relative change in the intestinal clearance caused by an inhibitor. The effect of  $F_G$  ratio is most pronounced for compounds with high intestinal extraction (e.g., buspirone, tacrolimus), whereas it is minimal for the drugs with intestinal extraction of around and below 50% (e.g., indinavir, alprazolam).

The  $F_G'/F_G$  ratio can be determined experimentally from the relative change in the intestinal clearance of a compound in the presence of an inhibitor. However, when this is not available, an initial estimate of the extent of intestinal inhibition can be obtained by assuming the ‘worst-case scenario,’ i.e., the maximum inhibition of intestinal CYP3A4 ( $F_G' = 1$ ). **Table 2** indicates a fivefold range of maximum  $F_G'/F_G$  ratios for the nine CYP3A4 substrates.<sup>99</sup> A limitation of this approach is that the predicted values of the maximal  $F_G'/F_G$  ratio are directly related to the accuracy of the initial estimates of the intestinal extraction and are based on the assumption that the extent of intestinal metabolism after i.v. administration is negligible and that absorption is complete, which may not be correct. For certain high-permeability/low-solubility compounds (tacrolimus, ciclosporin, and lovastatin),<sup>36</sup> possible contribution of the efflux transporters and their interplay with CYP3A4 will affect the initial significance of the intestinal metabolism. For these compounds the relationship between the  $F_G$  ratio and the inhibitor potency will be more complex in comparison to the substrates mainly cleared by metabolism (e.g., midazolam, nifedipine).

### 5.35.7 Concomitant Inhibition and Induction of Cytochrome P450

In some cases, a drug may be both an inhibitor and an inducer of drug-metabolizing enzymes and consequently the effects of such a drug will vary with single and multiple administration. Acute dosing will produce an inhibitory effect, whereas long-term administration will lead to induction of metabolism, usually by increasing the rate of protein synthesis. Thus the net effect of such a compound at any given time point during the course of administration will be a result of both mechanisms. Inhibition and induction of CYP3A4 can occur not only at the liver but also at the gut and the magnitude of the mDDI will depend on the relative concentrations of the interacting compounds in the hepatocytes and the enterocytes.

Ritonavir, the HIV-protease inhibitor, is an example of a compound which is both a potent inhibitor of CYP3A4<sup>123,124</sup> and also an inducer of CYP3A4-mediated metabolism.<sup>125</sup> Furthermore, ritonavir acts not only as a competitive inhibitor of CYP3A4 but also as a mechanism-based inhibitor of this enzyme,<sup>101,126</sup> resulting in the generation of catalytically inactive enzyme in the system.

Human hepatocytes treated with ritonavir showed a marked inhibition of the CYP3A4 marker activity testosterone 6 $\beta$ -hydroxylase but induction of CYP3A4 protein was also detected by immunoblotting techniques.<sup>33</sup> These results can be explained by the potent inhibitory effects of ritonavir on CYP3A4 in the cultures in combination with an inductive effect.

**Table 2** List of  $F_G$  values and the maximum  $F_G$  ratio values for nine CYP3A4 substrates. Complete intestinal inhibition is assumed ( $F_{G'} = 1$ )

| <i>CYP3A4 substrate</i> | $F_G$ | <i>Maximum <math>F_{G'}/F_G</math></i> | <i>Reference</i> |
|-------------------------|-------|--|------------------|
| Buspirone               | 0.21  | 4.76                                   | 3                |
| Ciclosporin             | 0.39  | 2.6                                    | 116              |
| Felodipine              | 0.45  | 2.2                                    | 117              |
| Midazolam               | 0.57  | 1.75                                   | 118              |
| Triazolam               | 0.6   | 1.67                                   | 119              |
| Simvastatin             | 0.66  | 1.51                                   | 3                |
| Nifedipine              | 0.74  | 1.35                                   | 120              |
| Quinidine               | 0.9   | 1.11                                   | 121              |
| Alprazolam              | 0.98  | 1.02                                   | 122              |

Reproduced with permission from Galetin, A.; Burt, H.; Gibbons, L.; Houston, J. B. *Drug Metab. Dispos.* **2006**, *34*, 166–175.

Simulation methodology can be applied to take into account the time course of these effects and the differing mechanisms of inhibition. Thus values for the competitive inhibition constant ( $K_i$ ) and the constants for mechanism-based inactivation ( $K_I$ ,  $k_{\text{inact}}$ ) can be used together with the value for  $k_{\text{deg}}$ , the endogenous degradation rate constant of the enzyme, and incorporated together with the increased synthetic rate of the enzyme (induction). A simulation of the interaction between ritonavir and methadone (a CYP3A4 substrate) has been generated which shows the shift in methadone kinetics from an acute inhibitory effect to an offset of this effect as induction due to ritonavir is manifested.<sup>1</sup> In the absence of clinical data, such simulations may be the only tool that can assess the impact of such a combination of effects over a time course of drug administration.

### 5.35.8 Simulation Software Available for Drug–Drug Interactions

A wide variety of computer software environments exists for the examination of potential DDI. These broadly fall into two categories: high-level computing software adapted for physiologically based simulation and specific biomathematical tools which have been developed for particular uses. Some examples of the former include programs based on the programming languages Fortran and C++, which, although very powerful and flexible, do require some advanced knowledge. Other more general tools include Matlab/Simulink,<sup>138</sup> MathCad,<sup>139</sup> Berkeley Madonna,<sup>140</sup> STELLA,<sup>141</sup> MLAB,<sup>142</sup> ModelMaker,<sup>143</sup> and GNU Octave.<sup>144</sup> All of these packages have been used for pharmacokinetic and/or pharmacodynamic model building and simulation; however, few examples can be found of their application in the predictive determination of DDIs. ACSLXtreme<sup>145</sup> has developed several modules for both pharmaco- and toxicokinetic applications: each of these could in theory be used for the prediction of DDIs. Precompiled modules for some of these applications are available for physiologically-based pharmacokinetic (PBPK) modeling; however, it is unclear whether they have been applied to the task of either individual or population-based DDI prediction. Although undoubtedly powerful tools, they do require a certain degree of specialist knowledge in model construction and mathematical simulation techniques.

Several packages have been developed specifically with pharmacokinetic simulation in mind and come in varying degrees of applicability to the drug metabolism scientist. These include NONMEM<sup>146</sup> and Pharsight's Trial Simulator and WinNonlin.<sup>147</sup> All of these products could be adjusted to perform predictions of DDIs in individuals, although this would require the construction and validation of novel models, again necessitating some degree of mathematical knowledge. Gastroplus<sup>148</sup> is primarily used for the simulation of gastrointestinal absorption but can also be used to investigate DDIs at the level of intestinal CYPs with some minor modifications. Another PBPK software, PK-Sim,<sup>149</sup> may also be used in this manner, although intimate knowledge of the existing exposure model would be necessary. Simcyp Clearance and Interaction Trial Simulator<sup>150</sup> has been developed in association with a consortium of pharmaceutical companies and regulatory authorities to simulate and predict pharmacokinetics and DDIs in populations of individuals. It combines common in vitro and preclinical data with information on human demography, anatomy, physiology, and genetics, resulting in simulations of population pharmacokinetics and DDIs involving both gastrointestinal and liver CYPs. In addition to simple, competitive interactions, enzyme induction and mechanism-based inhibition can also be simulated either alone or in combination with other effects.

Although many software tools are available for the physiologically-based prediction of DDIs, few offer ease of use to the nonstatistician. The flexibility and computational efficiency offered by programming languages such as C++ are largely offset by their relative difficulty of use. However, specialist PBPK modeling programs are often not designed for DDI simulation and must therefore be adapted for this purpose.

### 5.35.9 Success of Predictions

Some of the various difficulties in assessing the *in vitro* parameters required for the extrapolation of *in vivo* human DDIs have already been addressed (see below). The importance of determining the accurate concentrations of both ‘victim’ and ‘perpetrator’ drugs at the active site of the *in vitro* enzyme has been well described.<sup>12,89</sup> The potentially confounding extrapolation factors such as the free fraction of drug in blood, plasma, and the *in vitro* incubation of choice combine to demonstrate the robustness of current extrapolative models and their ability to provide reasonable predictions at all. Since all of the models presented for the extrapolation of DDIs require fixed *in vitro* inputs, the issue of uncertainty in these predictions must be addressed. In order to appreciate fully the impact of uncertainty on predictions of *in vivo* DDIs, this must be separated from biological variability, which is inherent in many of the *in vitro* systems of choice.

Standard experimental approaches of repeating both incubations and analyses and assigning confidence limits to nonlinear fits can be used to dissect out the impact of uncertainty. In a drug discovery setting these are of dubious value as the predictions are largely of a qualitative or categorical nature. It is relatively simple to substitute a range of values for each parameter and determine the sensitivity of the model to this variance. A more thorough approach would involve the use of fuzzy simulations in a similar manner to that already performed for certain PBPK models.<sup>127</sup> Perhaps the most confounding factor in any such sensitivity analyses would be the fact that the sensitivity to each *in vitro* parameter would be entirely drug-specific and therefore at best a set of general guidelines could be derived. A thorough examination of the experimental biases involved in standard experimental designs<sup>128</sup> has revealed that extreme care must be taken in the intelligent design of *in vitro* experiments in order to minimize the error passed into any extrapolative model.

Both uncharacterized HLM and human hepatocytes possess an inherent biological variability which has contributed to the lack of efficacy of some simple IVIVE approaches. When combined with experimental uncertainty, the biological variability of these *in vitro* systems increases the attractiveness of homogeneous rhCYPs.

The uncertainty and variabilities present in *in vitro* experimental systems can also be complemented by a potentially large degree of this observed *in vivo*. Thus it is essential *a priori* to define the target of any extrapolative attempt. Various differences have been observed between the typical healthy volunteer of early clinical studies and the patient for whom the drug has been designed. Differences have been observed in both CYPs<sup>129,130</sup> in addition to the disease-specific differences in demography, and other factors such as plasma protein concentrations.<sup>91</sup> Using the example of ritonavir and sildenafil,<sup>131</sup> it has been demonstrated that the individuals most likely to suffer extreme DDIs are those who would not usually be captured by early clinical investigation.

To a great extent the issue of CYP genetic polymorphisms can be counted as combinations of interindividual variability and DDIs. Once  $f_{mCYP}$  has been defined for a particular drug, the implications for the abolition of a polymorphic CYP has much the same impact as a potent inhibitor of that pathway. Indeed, the phenomenon of ‘phenocopying’<sup>132</sup> has been observed in individuals taking ecstasy (methylenedioxymethamphetamine, MDMA) where they exhibit the metabolic characteristics of CYP2D6 poor metabolizers due to the potent mechanism-based inhibition of the drug. CYP2D6 has been particularly characterized in this respect as 5–10% of European populations are poor metabolizers.<sup>133</sup>

To carry out successful extrapolations, the *a priori* knowledge of the clinical situation should be as complete as possible. Knowledge of the clinical demographics, disease, and genetic status are important, as demonstrated in the example above. Equally important are the issues of formulation and proposed dosage regimen: this has been investigated both clinically<sup>134,135</sup> and by simulation,<sup>136,137</sup> using various pairs of drugs which have been dosed at various intervals relative to each other. The results demonstrated that even altering the relative dosage intervals by as little as 2 h could change the observed DDI (as measured by AUC ratio) by up to sixfold.<sup>137</sup>

To summarize, there are many potentially confounding factors to the successful extrapolation of DDIs from *in vitro* to *in vivo*, those related to the experimental system of choice, the assumptions inherent in the model, and the *in vivo* scenario to be predicted. In order to predict DDI potential accurately in humans, all of these factors must be considered individually and systematically before such strategies can be considered reliable. The prediction of DDIs involves the assessment of multiple factors, including clearance mechanisms for both substrates and inhibitors and the fraction metabolized by specific enzymes. Valid mechanistic approaches described here, based on incorporating population variability (both physiological and genetic), will allow the maximum information on the interindividual variation in the magnitude of a DDI to be obtained.

## Biographies

**Maurice Dickens** has worked in drug metabolism in the pharmaceutical industry since 1984, following the award of his PhD from the University of Surrey, UK. He has held successive positions at Wellcome Research, Glaxo Wellcome, and GlaxoSmithKline and joined Pfizer in 2002.

His current role is to understand the enzymology of biotransformations in human in vitro systems and to assess their relevance in the clinic. He is particularly interested in the prediction of metabolism and potential drug interactions using in vitro and in silico approaches.

**Aleksandra Galetin** is the Pfizer Lecturer in Drug Metabolism and Pharmacokinetics in the School of Pharmacy and Pharmaceutical Sciences, University of Manchester, UK. Prior to her current position she was a postdoctoral research associate in the Centre for Applied Pharmacokinetic Research at the University of Manchester.

Her recent publications centred on the incorporation of homo/heterotropic cooperativity phenomena associated with CYP3A4 (and other enzymes) into the in vitro–in vivo prediction of either clearance or drug–drug interactions. Her current research activities focus on the mechanism-based prediction of human pharmacokinetics, in particular the contribution of the intestinal CYP and UGT enzymes to the clearance and drug interactions and investigations of time-dependent inhibition interactions.

**Nick Proctor** received his PhD from the University of Manchester, UK, under the supervision of Prof Brian Houston, investigating the impact of drug binding in the predictions of human pharmacokinetics and metabolic drug interactions. Nick was the Dr Hadwen Trust Postdoctoral Fellow at the University of Sheffield, UK, and worked on the refinement of automated in vitro–in vivo extrapolation techniques before becoming Business Development Manager for Simeyp in 2004.

## 5.36 In Silico Prediction of Plasma and Tissue Protein Binding

### 5.36.1 Introduction

The reversible strong binding of a drug to its target (whether in the cell membrane, and therefore accessible to the extracellular fluid, or within the cell) is in competition with the reversible binding to multitude of low-affinity sites in the blood and the tissues: plasma proteins, membranes, intracellular proteins and nucleic acids, fat, cellular organelles like microsomes and lysosomes.<sup>1-3</sup> This distribution of the drug through the body conditions its pharmacokinetics. For instance, consider an orally administered drug. After being (partially) absorbed in the intestine, it travels in the circulation through the portal vein to the liver, and there it suffers some initial elimination by hepatic metabolism (the so-called first-pass metabolism). The fraction remaining (bioavailable) is distributed throughout the body, first in the circulation partially bound to plasma proteins, and later to the different tissues, until an equilibrium tissue/plasma distribution is established. Some drugs then remain in the extracellular fluid and do not enter the cells, while some others are able to cross the cell membranes and get inside the cell. With time, the fraction of the drug remaining in blood plasma is eliminated as it passes through the eliminating organs, mainly kidney (renal excretion) and liver (hepatic metabolism), while the tissue/plasma distribution equilibrium is reestablished at the expense of drug molecules leaving the tissues. At any moment, it is only the free drug at the extracellular fluid that is able to bind the target: directly in the case of targets in the cell membrane, or after (partially) crossing the cell membrane in the case of intracellular targets. Although of lower affinity, given the overwhelmingly larger amount of binding sites in plasma proteins and tissues compared to those of the target, the concentration of free drug in the extracellular fluid is determined by plasma protein and tissue binding.

There is an important pharmacokinetic concept that models the distribution of drugs within the body, the so-called volume of distribution,  $V_D$  (also  $V_{D,ss}$ ), which is defined as<sup>1</sup>:

$$V_D = \frac{Dose}{C_o} \quad [1]$$

where  $Dose$  is the administered dose, and  $C_o$  is the initial concentration of the drug in plasma, before elimination starts; here complete bioavailability is assumed. The volume of distribution corresponds to the theoretical volume where the dose should be distributed, if it had the same concentration as in plasma. It is easy to see that:

$$V_D = V_P + V_T \frac{f_{u,P}}{f_{u,T}} \quad [2]$$

where  $V_P$  is the plasma volume,  $V_T$  is the tissue volume outside plasma where the drug distributes, and  $f_{u,P}$  and  $f_{u,T}$  are the fractions of unbound drug in plasma and tissue, respectively. Thus, the volume of distribution increases when the tissue binding is increased ( $f_{u,T}$  decreases) while it decreases when the plasma binding is increased ( $f_{u,P}$  decreases). The importance of the volume of distribution stems from the fact that, in combination with the clearance of the drug (CL, the volume of plasma with the amount of drug eliminated by unit time), it determines the half-life of the drug (the time required to metabolize and/or eliminate half of the administered drug):

$$t_{1/2} = 0.693 V_D / CL = 0.693 \left( V_P + V_T \frac{f_{u,P}}{f_{u,T}} \right) / CL \quad [3]$$

Thus, the half-life of the drug is linear with the volume of distribution.

All these considerations stress the fundamental role that the plasma and tissue protein binding of a drug have in determining both its free concentration in the extracellular fluid and its half-life. They must be considered in order to develop drugs with appropriate pharmacokinetic behavior. Modifications of molecular properties to fix absorption and clearance issues must in this way consider their impact in drug distribution by altering the plasma and/or tissue-binding (and therefore the volume of distribution) properties. In silico models to predict these properties are thus expected to be of much help in drug design. They are probably most useful at intermediate stages of drug discovery, e.g., in the lead optimization and preclinical phases, in order to guide the fine-tuning of the structure of the lead or candidate molecule to improve its pharmacokinetics and therapeutic windows in combination with clearance and toxicity data, as well as to provide first estimates for doses for in vivo assays in animals and humans (in phase I clinical assays). In very early stages like hit selection and the hit-to-lead phase they can be useful to detect extreme values for these parameters: for instance, Kratochwil *et al.*<sup>4,5</sup> found in a set of 408 therapeutic drugs a wide range of plasma protein-binding affinities, although no drugs were found with submicromolar binding. These extreme binding affinities (also applicable to tissue binding) should force the use of very large doses of compound in order to achieve an acceptable saturation of the target, with very negative consequences, such as toxicity, drug-drug interactions, impossibility of oral administration of such a dose given the physicochemistry of the compound, etc.

The present chapter reviews the current models for plasma and tissue protein-binding prediction. The models to predict the volume of distribution are briefly reviewed as well.

## 5.36.2 Biological Background

### 5.36.2.1 Blood, Plasma, and Serum

Human blood is composed of 45% cells, plus 55% plasma. In turn, plasma is an aqueous solution composed of 92% water, 7% proteins, and 1% other solutes such as inorganic ions. Serum is the aqueous solution that remains after precipitating and removing the clotting factors in plasma. Most of the plasma proteins are synthesized in the liver. They are grouped as follows: 60% albumin, 35% globulins, 4% clotting proteins, and 1% regulatory proteins. From the point of view of drug distribution, the most important proteins are human serum albumin (HSA) and  $\alpha_1$ -acid glycoprotein (AGP)<sup>6,7</sup>; there are other less relevant proteins, like lipoproteins. Drug binding to blood cells is also possible, for instance in the case of drugs lipophilic enough to cross the membrane, or positively charged drugs that can bind the anionic phospholipids in the membrane; binding to blood cells is frequently weak and less relevant, though. Binding of drugs to plasma proteins influences the concentration of free drug in the extracellular space, and is especially important as the fraction of drug remaining in plasma is the one that is mainly subject to metabolism and excretion by the eliminating organs. In the next section, the structure and function of the plasma proteins relevant to drug distribution are described briefly.

### 5.36.2.1.1 Human serum albumin

HSA is by far the most abundant protein in serum, with a concentration of about  $40 \text{ mg mL}^{-1}$  ( $\sim 0.6 \text{ mmol L}^{-1}$ ).<sup>8</sup> Its main function is the transport of nonsterified fatty acids in the extracellular compartment, as well as of multiple additional endogenous ligands like bilirubin, bile salts, steroids, hemin, thyroxine, some vitamins, and metal ions.<sup>8,9</sup> In addition, this protein has the striking ability to bind a wide variety of structurally dissimilar drugs, and this is the reason for its importance in drug pharmacokinetics. Two main binding sites for drugs were proposed after biochemical studies: site I, or warfarin site, and site II, or indole-benzodiazepine site.<sup>10,11</sup>

HSA is a member of a multigene family of proteins, including vitamin D-binding protein and  $\alpha$ -fetoprotein.<sup>6,8</sup> It is synthesized by hepatocytes in the liver as preproalbumin, which is further processed intracellularly to remove the corresponding pre- and propeptide sequences, and finally secreted into the blood.<sup>12</sup> It is composed of a single polypeptide chain 585 amino acids long, with 17 disulfide bridges and 66 400 molecular weight.<sup>8</sup> Its primary structure is organized in three consecutive homologous domains (I, II, and III) that evolved from the repetition of an ancestor gene.<sup>13</sup> Each domain is, in turn, composed of two partially homologous subdomains, named A and B. **Figure 1** displays a secondary structure scheme of HSA.

Several crystal structures of HSA, alone or complexed with fatty acids and/or other ligands, have been solved.<sup>14–24</sup> A query in the Protein Data Bank for ‘human serum albumin’ results in 26 entries as of May 2005. These are shown in **Table 1**, together with the ligands (if applicable), resolution, original reference and year of deposition.

All of them display a heart-shaped structure of the protein, with each of the three lobes of the heart corresponding to one of the homologous domains in the primary structure (**Figure 2**). Some 67% of the protein is  $\alpha$ -helical, and each domain comprises 10  $\alpha$ -helices (h1–h10) separated by disordered loops, with six helices in the A subdomains (h1–h6), and four in the B subdomains (h7–h10). Consecutive helices in contiguous domains (h10(I)–h1(II); h10(II)–h1(III)) are aligned, forming long helices.

The crystal structures with fatty acids display multiple sites for the binding of these molecules, some of them overlapping with the drug-binding sites. Fatty acid binding drives a large conformational change in the protein in which domains I and III are rotated around domain II, and the long h10(I)–h1(II) helix is bent (**Figure 2b**).<sup>15,17,18</sup> The crystal structures with drugs have allowed to localize in the three-dimensional structure of the protein the two drug-binding sites described by Sudlow *et al.*,<sup>10,11</sup> at subdomains IIA and IIIA, respectively. **Table 2** lists the binding sites of multiple drugs as observed from crystal structures of HSA–drug complexes. In the cases of warfarin<sup>19</sup> and the two general anesthetics halothane and propofol,<sup>16</sup> the crystals have enough resolution to permit the fit of the drug structures in atomic detail.

All these structures highlight the promiscuity of this protein, that binds multiple and structurally different ligands at different binding sites.

### 5.36.2.1.2 $\alpha_1$ -Acid glycoprotein

Another abundant protein in serum is AGP, with a concentration of about  $1 \text{ mg mL}^{-1}$  ( $\sim 0.02 \text{ mmol L}^{-1}$ ), that can increase several times in acute-phase inflammation reactions.<sup>25</sup> AGP has a role as a natural antiinflammatory and immunomodulatory agent. It is synthesized and secreted to the bloodstream mainly in the liver by hepatocytes, although some extrahepatic synthesis has also been detected.

This acidic glycoprotein is composed of a single polypeptide chain of 183 amino acids and two disulfide bridges. It displays five *N*-linked glycans of high complexity and variable composition (12–20 different glycoforms are observed in normal human serum). The molecular weight thus varies between 41 and 43 kDa, with about 45% of the molecular weight corresponding to the carbohydrate. The polypeptide appears as two or three main forms, namely the A form and the F1 and/or S forms, encoded by three clustered genes: AGP-A, AGP-B, and AGP-B'.<sup>25,26</sup> The A form is encoded by the AGP-B and AGP-B' duplicated genes, while the F1 and S forms are encoded by two different alleles of the gene AGP-A. There is a difference in 22 bases between A and F1 encoding genes, and of a few bases between F1 and S genes.

AGP is another important nonspecific drug binder in plasma. It binds different drugs such as tamoxifen, propranolol, vanilloids, and phenobarbital, and also endogenous compounds, such as retinoic acid, steroids, platelet-activating factor, and heparin.<sup>27</sup> It is normally stated that HSA binds acidic drugs, while AGP binds basic or neutral drugs; this seems an oversimplification, as many basic drugs bind strongly to HSA,<sup>8</sup> and AGP binds acidic drugs like phenobarbital.<sup>28</sup> Given that its molar concentration is about 30 times lower than HSA, in principle its influence in whole plasma protein binding should be negligible compared to HSA.

### 5.36.2.1.3 Lipoproteins

Lipoproteins have been reported to contribute to the plasma binding of very lipophilic drugs.<sup>28</sup> Lipoproteins consist of a central core of lipids (triglycerides and cholesteryl esters) surrounded by a shell of apoproteins and polar lipids

**Figure 1** Secondary structure scheme of HSA, after Sugio *et al.*<sup>14</sup> The domains are color-coded as follows: I, red; II, green; III, blue. Within each domain, A and B subdomains are displayed in dark and light shades, respectively.

(phospholipids and cholesterol).<sup>29</sup> Their physiological role is the transport of cholesterol and triglycerides. Four classes of lipoproteins have been described, differing in size and density: high-density lipoproteins (HDL), low-density lipoproteins (LDL), very-low-density lipoproteins (VLDL), and chylomicrons; the density increases and the size decreases as the proportion of triglycerides of the particles decreases.

### 5.36.2.2 Tissues and Drug Distribution

As plasma represents about 4.5% of total body weight, the ‘tissue’ compartment should be in general more influential in determining the drug concentration in the extracellular fluid, as well as the volume of distribution (eqn [2]) and

**Table 1** Structures of HSA currently present in the protein data bank (PDB) (as of May 2005)

| <i>PDB entry</i> | <i>Ligands</i>                              | <i>Resolution/Å</i> | <i>Reference</i> | <i>Year</i> |

| 1uor             | –   | 2.8                 | 24               | 1998        |

**Figure 2** Three-dimensional structure of HSA.  $\alpha$ -Helical segments are represented by rods, connected by disordered loops. The domains and subdomains are colored following the secondary structure schema in [Figure 1](#). (a) HSA structure without fatty acids (PDB entry 1AO6). (b) HSA structure with (not displayed) fatty acids (PDB entry 1BJ5). Both structures were superimposed through their  $\alpha$ -carbons at domain II. Notice the large conformational rearrangement and rotation of domains I and III upon binding of myristic acid.

therefore the half-life (eqn [3]).<sup>1</sup> Tissues are composed of cells (the water content, the intracellular fluid, is on average about 35% of body weight) and interstitial fluid (about 16%).<sup>30</sup> The interstitial fluid composition resembles that of plasma, including the presence of HSA and AGP,<sup>31</sup> and there is free exchange of small molecules between the two through pores in the capillary walls (an exception to this is the blood–brain barrier, where the capillary endothelial cells are joined by tight junctions and there are no pores). Drugs can bind to tissues by binding to proteins in the interstitial fluids, and/or by binding to cell components, such as membranes, proteins, and nucleic acids; there are also cellular organelles that have a remarkable capacity to store drugs (e.g., microsomes in hepatocytes and lysosomes of low internal pH in several cellular types that trap basic drugs).

The human body has different types of tissues, and [Table 3](#) lists the fractions of body weights for the most important ones.<sup>32</sup> Muscle is by far the most abundant tissue (about 40% of body weight), followed by adipose tissue (about 12%). Some experimental data suggest a strong correlation between the binding ratios in different tissues, indicating a similar mechanism of binding, but not between tissue and plasma.<sup>1</sup>

Binding to adipose tissue has received much attention as fat can dissolve organic solvents and pollutants displaying negligible protein binding, that should result in very high adipose tissue/plasma distribution coefficients<sup>33</sup>; however, this seems not to be the case with lipophilic drugs, because these molecules also display a larger plasma protein binding that cancels out the stronger binding to fat and results in moderate distribution coefficients.

### 5.36.3 Prediction of Plasma Protein Binding of Drugs

In our description of *in silico* models for plasma protein binding of drugs, we will focus on global models developed using large and diverse data sets of drugs, and obtained with human proteins. On the one hand, there are many local models derived from small data sets of structurally related molecules. However, these models do not allow generalizations to the whole medicinal chemical space, as is the case with global models, and describing them here is not possible given the restricted space; they have been reviewed recently elsewhere.<sup>34</sup> On the other hand, large differences between binding data obtained from plasma proteins of different species<sup>5</sup> cast doubt on the validity of models obtained with data sets of nonhuman plasma proteins to predict human plasma protein binding, which is what we are really interested in.

Three main types of global models with human proteins have been derived: (1) models for whole plasma protein binding; (2) models for HSA binding; (3) and one model for AGP binding (although the importance of lipoproteins in the distribution of some lipophilic drugs has been described,<sup>28</sup> no global model has been derived for this type of plasma proteins). The source of data sets in the first case is equilibrium dialysis experiments, ultrafiltration, or ultracentrifugation experiments. HSA data sets are mainly derived from chromatographic techniques, although there is also one work that uses NMR titrations, and another that uses a compilation of HSA association constants gathered from the published works. Finally, the model for AGP uses a data set obtained by means of competition experiments using equilibrium dialysis. All these models are described below. Previous reviews of this area can be found in <sup>5,34</sup>.

#### 5.36.3.1 Literature Models to Predict Whole Plasma Protein Binding

Probably the first model of this type derived using a large and diverse data set was that of Saiakhov *et al.*<sup>35</sup> These authors used a set of 154 drugs with known protein affinities in the form of percentage of drug bound in plasma (%ppb). The source of the data set was mainly Goodman and Gilman's textbook.<sup>36</sup> For the analysis, the 154 %ppb values were categorized into three classes: (1) bound (%ppb > 32%); (2) marginally bound (32% ≥ %ppb ≥ 19%); and (3) unbound (%ppb < 19%) drugs. The MCASE program of Klopman<sup>37</sup> was used to build the model. The program did not find a good correlation of the whole data set with log *P*, the logarithm of the octanol/water partition coefficient. Instead, the program identified eight main biophores, that is, substructures appearing with higher frequencies in the bound and marginally bound categories. For seven of these biophores it was possible to derive local quantitative structure–activity relationships (QSARs) where other substructures and/or physicochemical properties worked as positive or negative modulators. It is interesting to note that, although log *P* did not correlate well with %ppb for the whole data set, in almost all of the local QSARs it appeared as a positive modulator. This probably means that, in general, higher lipophilicity enhances plasma protein binding, although the way and extent of the enhancement depend on the particular structural class of molecules for which the local QSAR is developed. The resulting set of local QSARs displayed good statistics (concordance of 96% for a coverage of 92%). It was validated internally by three runs of cross-validation, and the resulting statistics indicated a good predictive power (average concordance of 85% for a coverage of 81%). Besides, the model was used to predict the %ppb of two penicillins outside the data set, giving predictions very close to the experimental value.

Lobell and Sivarajah<sup>38</sup> built models for the prediction of the following binding parameter:

$$\log\left(\frac{1-f_{u,P}}{f_{u,P}}\right) = \log\left(\frac{\%ppb}{100 - \%ppb}\right) \quad [4]$$

The authors collected from the literature a training set of 226 compounds, and a test set of 94 molecules. The sets were classified in subsets according to their predominant charge state: negatively charged, zwitterionic, uncharged, positively charged, and permanently positively charged. Equations were derived by fitting for each training subset a linear univariate model having as descriptor *A* log *P* (a calculated log *P* obtained with *A* log *P*); for some cases, however, a correlation was not found and a constant binding value was postulated instead. Table 4 collects all the resulting models and their statistics with both the training and test sets.

The statistics show reasonable, but not very good, predictions. All these models displayed similar slopes, although very different intercepts. For the same lipophilicity (*A* log *P*), the charge state determines the binding affinity in this order: negatively charged compounds > uncharged compounds > positively charged compounds > permanently positively charged compounds. Zwitterionic compounds seem always to have low plasma protein binding.

**Table 4** Models by Lobell and Sivarajah for the prediction of plasma protein binding

| Charge state pH 7.4                        | Predicted $\log((1-f_{u,p})/f_{u,p})$ | Training set |       |      | Test set |                    |      |
|--|---------------------------------------|--------------|-------|------|----------|--------------------|------|
|  |                                       | <i>n</i>     | $r^2$ | MAE  | <i>n</i> | $r^2_{\text{ext}}$ | MAE  |
| Negatively charged                         | $0.36A \log P + 0.42$                 | 52           | 0.50  | 0.56 | 25       | 0.46               | 0.51 |
| Zwitterionic                               | $-0.48 (f_{u,p} = 0.75)$              | 21           |       | 0.26 |          |                    |      |
| Uncharged                                  | $0.45A \log P - 0.48$                 | 78           | 0.63  | 0.51 | 38       | 0.56               | 0.54 |
| Positively charged and $A \log P \leq 0.2$ | $-0.95 (f_{u,p} = 0.90)$              | 7            |       | 0.30 |          |                    |      |
| Positively charged and $A \log P > 0.2$    | $0.46A \log P - 1.10$                 | 63           | 0.67  | 0.38 | 33       | 0.51               | 0.51 |
| Permanently positively charged             | $0.38A \log P - 2.10$                 | 5            | 0.98  | 0.07 |          |                    |      |
| All  |                                       | 226          | 0.68  | 0.45 | 94       | 0.51               | 0.53 |

Data taken from Lobell, M.; Sivarajah, V. *Mol. Divers.* **2003**, *7*, 69–87.

Yamakazi and Kanaoka<sup>39</sup> derived models for the prediction of %ppb. The authors used a data set obtained from the literature of 302 %ppb values for a wide variety of drugs. The following expression was used to model the data:

$$\%ppb = \frac{k_1 \exp(\log X) + k_2}{k_1 \exp(\log X) + k_2 + 1} \quad [5]$$

where, for  $\log X$ ,  $\log P$ , or its version that takes into account the ionization state at different pHs,  $\log D$ , was tested. When fitting the model, neutral and basic drugs (143 drugs, including 53 zwitterions) were analyzed separately from acidic drugs (159 drugs, including 71 zwitterions). The best model for neutral and basic drugs used  $\log D_{7.4}$  as an independent variable, and was obtained without zwitterions in the regression ( $n = 84$ ,  $r^2 = 0.80$ , mean absolute error (MAE) = 0.10, six outliers). The prediction of zwitterions with this model was not good. Similarly, the regression for acidic drugs was performed without zwitterions, and only with a reduced subset of 44 compounds displaying a particular two-center pharmacophore. The best model was obtained with  $\log P$  as descriptor ( $r^2 = 0.79$ , MAE = 0.05). The prediction with this model of the zwitterions or the nonzwitterions without two-center pharmacophore was bad. The model was validated with an external set of 20 drugs, none of which was a zwitterion, and with all acidic drugs displaying two-center pharmacophore, giving in this case good predictions ( $r^2_{\text{ext}} = 0.83$ ).

### 5.36.3.2 Commercial Models to Predict Whole Plasma Protein Binding

Besides the literature models described in the previous section, there are several commercial models to predict whole plasma protein binding. **Table 5** gives details of the most relevant ones and gives some information about them.

The MCASE/ADME software implements the model by Saiakhov *et al.*<sup>35</sup> described in the previous section. For the other models the information available is limited; for those displaying more information (ADMET Predictor, truPK, and CSPB) the size of the data set and the quality of the statistics are similar to the literature models.

### 5.36.3.3 Models to Predict Human Serum Albumin Binding

Colmenarejo *et al.*<sup>40</sup> used a data set of binding constants to HSA for 94 diverse drugs obtained through high-performance affinity chromatography (HPAC) in a column with immobilized HSA (see 5.14 In Vitro Models for Plasma Binding and Tissue Storage). The binding parameter modeled was therefore  $\log K'_{HSA} = \log((t - t_0)/t_0)$ , where  $t$  and  $t_0$  are the retention time of the drug and the dead time of the column, respectively. A genetic algorithm was used to search for model equations with good statistics, by trying 53 different molecular descriptors and equation terms of linear, quadratic, spline, offset-quadratic, and quadratic-spline type. Eighty-four compounds were

<sup>a</sup>Size of data set.

selected to train the model, and 10 were used as an external prediction set. Initially, the following nonlinear global model was derived:

$$\begin{aligned}\log K'_{HSA} = & 2.01 \times 10^{-2} + 5.54 \times 10^{-2} AM1dip - 1.22 JursRPSA \\ & - 2.83 \times 10^{-2} (E_{HOMO} + 7.41)^2 + 0.15C \log P - 3.48 \left[ 0.18 - {}^6\chi_{ring} \right] \\ n = & 84; r^2 = 0.78; q^2 = 0.73\end{aligned}\quad [6]$$

where *AM1dip* is a calculated dipole moment, *JursRPSA* is a Jurs polar surface descriptor, *E<sub>HOMO</sub>* is the HOMO energy, *C log P* is a calculated log *P*, and *{}<sup>6</sup>χ<sub>ring</sub>* is the sixth-order, ring-type Kier and Hall topological index (no confidence intervals were provided for the correlation coefficients). The statistics of both the regression (*r*<sup>2</sup>=0.78, lack-of-fit statistic (LOF)=0.12, five outliers) and the internal validations by leave-out-one cross-validation runs and randomization tests were good (*q*<sup>2</sup>=0.73), indicating a good predictive power. The external test set was well predicted too (*r*<sub>ext</sub><sup>2</sup>=0.88). A series of 84 additional runs of the genetic algorithm was used to determine the descriptors most relevant to this system, by counting the frequencies of descriptors in the 84 winning equations. It turned out that just 12 descriptors appeared in these equations, with *C log P* being the most important (it was present in all the equations), followed by *{}<sup>6</sup>χ<sub>ring</sub>*, and descriptors of other types (quantum mechanical, structural, Jurs-type). By starting with only the 12 relevant descriptors, the genetic algorithm selected this second model:

$$\begin{aligned}\log K'_{HSA} = & -0.61 + 6.78 \times 10^{-2} [HBD_{on} - 3]^2 - 9 \times 10^{-6} JursTPSA^2 \\ & - 2.83 \times 10^{-2} (E_{HOMO} + 7.41)^2 + 5.70 \times 10^{-3} AM1dip^2 \\ & + 0.18C \log P + 2.33 {}^6\chi_{ring} \\ n = & 84; r^2 = 0.83; q^2 = 0.79\end{aligned}\quad [7]$$

where *HBD<sub>on</sub>* is the number of hydrogen bond donors, and *JursTPSA* is another Jurs polar surface descriptor. The statistics for the regression (*r*<sup>2</sup>=0.83, LOF=0.10) and internal validation (*q*<sup>2</sup>=0.79) were slightly better than those of eqn [6], although the external set prediction was slightly worse (*r*<sub>ext</sub><sup>2</sup>=0.82). The interpretation given to the model was that HSA binding is driven to a large extent by lipophilicity, which is modulated by other additional factors of different nature (such as structural, quantum mechanical). As we will see later, the data set by Colmenarejo *et al.* has been used in several other studies.

Kratochwil *et al.*<sup>4</sup> used a data set comprising the logarithm of the association constant to HSA (*log K<sub>HSA</sub>*) in the literature for 138 diverse drugs, plus 25 in-house determined binding constants for Roche compounds. Obviously, *log K<sub>HSA</sub>* is related to %ppb by:

$$\log K_{HSA} = \log \left( \frac{\%ppb}{100 - \%ppb} \right) - \log[HSA] \quad [8]$$

where  $[HSA]$  is approximated by the concentration of albumin in plasma ( $0.6 \text{ mmol L}^{-1}$ ). These association constants correlated well with the ones calculated from %ppb values available in the literature in the low-to-medium range, but for high association constants (corresponding to submicromolar binding or %ppb above 99%) there was poor correlation, probably due to the difficulty in measuring accurately %ppb values above 99%. An initial attempt to correlate  $\log K_{HSA}$  with  $\log D_{7.4}$  for a subset of 76 compounds failed to yield a statistically sound model, indicating that lipophilicity alone cannot be used to predict HSA binding. Thus, in order to derive a global model, the authors used two sets of molecular descriptors, vectors in bases obtained from the diagonalization of the similarity matrices of the whole data set. In turn, the similarities are referred to a topological pharmacophore representation (TPR) of the molecules, or to Daylight fingerprints (DFP), respectively. These descriptors were fitted with a partial least squares (PLS) algorithm in order to derive two models. The models predicted well the training set ( $r^2 = 0.72$  and  $0.76$  for the TPR and DFP models, respectively), and randomization tests indicated that they were not the result of chance correlations. However, cross-validation tests did not show good predictive powers ( $q^2 = 0.48$  and  $0.37$  for the TPR and DFP models, respectively). In addition, when the TPR model was used to predict an external data set of 76 HPAC-obtained binding constants for glycine/*N*-methyl-D-aspartate (NMDA) receptor antagonists, the results were very bad ( $r_{\text{ext}}^2 = -0.70$ ). The authors attributed this to several factors: poor diversity of the external set, low similarity between the test set and the training set, and the possible absence of linear correlation of HPAC constants with association constants in the whole range of binding constants of the external set.

Hajduk *et al.*<sup>41</sup> developed a model to predict the logarithm of dissociation constants for binding to domain IIIA of HSA ( $\log K_{HSA-III A}^D$ ). The authors used a data set of dissociation constants of 889 diverse molecules to the isolated domain IIIA of HSA obtained through nuclear magnetic resonance and fluorescence titrations (where 657 molecules displayed negligible binding and were assigned the same dissociation constant of  $2 \text{ mmol L}^{-1}$ ).  $\log K_{HSA-III A}^D$  displayed some correlation with  $C \log P$  but in order to derive a statistically sound model the authors adopted a group contribution approach using the following equation:

$$\log K_{HSA-III A}^D = \sum_i w_i x_i$$

$$n = 889; \quad r^2 = 0.94; \quad q^2 = 0.90 \quad [9]$$

where  $w_i$  is the weighting coefficient of structural descriptor  $i$ , representing a particular chemical group, and  $x_i$  is the number of times  $i$  appears in the molecule. A total of 74 chemical groups were used, obtained by fragmenting the molecules in the training data set. The equation was fitted to the data set, and the resulting model displayed good statistics ( $r^2 = 0.94$ , average error = 0.11) and good predictive power in leave-group-out cross-validation tests and randomization tests ( $q^2 = 0.90$ ). No external validation of the model was performed. However, it was seen that, for a series of antibacterials, a large proportion of those showing a higher than eightfold loss of activity in the presence of serum were predicted to have large affinity for the domain IIIA of HSA. Analysis of the weighting coefficients revealed some trends. For instance, positively charged groups like cyclic or acyclic amines had positive weighting coefficients; that is, they are detrimental for binding; the opposite is seen for negatively charged groups like carboxylic and sulfonic acids. Five- and six-membered rings and chlorine and fluorine also improve binding. More interestingly, there is a general trend for more hydrophobic chemical fragments to enhance binding.

Valko *et al.*<sup>42</sup> modeled the logarithm of an apparent association constant to HSA ( $\log K_{HSA}^{app}$ ), obtained from a fast-gradient HPAC technique developed by the authors. The  $\log K_{HSA}^{app}$  values were determined after calibrating a column parameter ( $\log t$ ) against the  $\log(\%ppb/(101 - \%ppb))$  values for nine drugs, where the %ppb values were taken from the literature. In this way, the %ppb values for an independent set of 68 drugs, obtained by back-calculation from the  $\log K_{HSA}^{app}$  values estimated from the column retention times, displayed an acceptable correlation with those from the literature. A combination of the previous 68 drugs with 52 compounds comprising the so-called Abraham set (containing some simple nondrug molecules) showed some correlation between  $\log K_{HSA}^{app}$  and  $C \log P$ , and worse correlation between  $\log K_{HSA}^{app}$  and  $\text{ACDlog } D$  at pH 7.4 (a calculated  $\log D$  following the model of Advanced Chemistry Development/Labs, usually considered a not very reliable model). This indicates a major role of lipophilicity in binding to HSA, but also the need for additional factors in order to obtain a good model. The Abraham equation was thus fitted to the Abraham set, resulting in this best model:

$$\log K = -1.28 + 0.82(\pm 0.15)R_2 - 0.36(\pm 0.15)\pi_2^H + 0.18(\pm 0.14)\alpha_2^H$$

$$- 1.97(\pm 0.15)\beta_2^H + 1.62(\pm 0.21)\log V_x$$

$$n = 52; \quad r^2 = 0.83; \quad s = 0.33; \quad F = 44 \quad [10]$$

where  $R_2$  is the drug excess molar refraction;  $\pi_2^H$  is the dipolarity/polarizability;  $\alpha_2^H$  and  $\beta_2^H$  are the hydrogen bond acidity and basicity, respectively; and  $V_x$  is the McGowan volume. The model gave good statistics with the training set ( $n = 52$ ,  $r^2 = 0.83$ ,  $s = 0.33$ ,  $F = 44$ ), but when used to predict the set of 68 drugs, many drugs were observed to display much higher binding than predicted (no statistics were given). The authors argued that eqn [10] predicts a 'baseline' affinity based mainly on lipophilicity, and from there one compound could have increased affinity if it has good complementarity with the binding site.

Hall *et al.*<sup>43</sup> used topological and electrotopological descriptors to build a model using the data set of Colmenarejo *et al.* Multiple linear regression (MLR) was used, testing all the possible multivariate linear models up to a maximum number of terms. The best model is this:

$$\begin{aligned} \log K'_{HSA} = & 5.03 \times 10^{-2} (\pm 5.0 \times 10^{-3}) S_{arom}^T + 7.87 \times 10^{-2} (\pm 8.3 \times 10^{-3}) S_{CHsat}^T \\ & + 2.91 \times 10^{-2} (\pm 5.9 \times 10^{-3}) S_{F,Cl}^T + 8.71 \times 10^{-3} (\pm 3.2 \times 10^{-3}) S_{OH}^T \\ & + 2.38 (\pm 0.95) {}^6\chi_{CH}^V + 2.96 (\pm 0.99) {}^5\chi_{CH}^V - 1.18 \\ n = & 84; r^2 = 0.77; s = 0.29; q^2 = 0.70; F = 43 \end{aligned} \quad [11]$$

where  $S_{arom}^T$ ,  $S_{CHsat}^T$ ,  $S_{F,Cl}^T$  and  $S_{OH}^T$  are the sums of atom type E-state descriptors for aromatic carbon atoms, saturated carbon atoms (with hydrogens), fluorine and chlorine, and hydroxyl groups, respectively; and  ${}^6\chi_{CH}^V$  and  ${}^5\chi_{CH}^V$  are the six- and fifth-order valence molecular connectivity chi-chain indexes, respectively. The model displayed good statistics and predictive power ( $r^2 = 0.77$ ,  $s = 0.29$ ,  $F = 43$ ,  $q^2 = 0.70$ , no outliers). The model was validated with randomization and leave-group-out cross-validation tests ( $q^2 = 0.68$ ). It also predicted well the external set, although slightly worse than the model of Colmenarejo *et al.* ( $r_{ext}^2 = 0.74$ , MAE = 0.31). The authors interpreted the model as follows: electron accessibility and/or count of aromatic rings, chlorine and fluorine atoms, nonsubstituted aliphatic chains, electron accessibility and/or number of -OH groups, and six-membered heteroaromatic rings are all features that enhance HSA binding; in contrast, aliphatic chains with electronegative substituents and five-membered heteroaromatic rings all weaken the binding to HSA.

Xue *et al.*<sup>44</sup> derived two models with the data set of Colmenarejo *et al.* The first one was developed using MLR with a heuristic method for descriptor selection. An initial pool of 243 descriptors was tested to search for models while optimizing several statistics. The resulting best model was:

$$\begin{aligned} \log K'_{HSA} = & -2.51 (\pm 0.39) - 0.40 (\pm 0.08) HDCA2 \\ & + 7 \times 10^{-3} (\pm 1 \times 10^{-3}) MSA - 0.15 (\pm 0.02) NO \\ & + 9.21 (\pm 1.39) RNR - 3.94 (\pm 0.66) RNN \\ & + 0.40 (\pm 0.1) BI - 4.5 \times 10^{-2} (\pm 0.01) RNCS \\ n = & 84; r^2 = 0.86; s = 0.22; RMSE = 0.21; q^2 = 0.63; F = 63.9 \end{aligned} \quad [12]$$

where  $HDCA2$  is the area-weighted surface charge of hydrogen-bonding donor atoms,  $MSA$  is the molecular surface area,  $NO$  is the number of oxygens,  $RNR$  is the relative number of rings,  $RNN$  is the relative number of nitrogens,  $BI$  is the Balaban index, and  $RNCS$  is the relative negative-charged surface area. The statistics of this model were slightly better than those of Colmenarejo *et al.* models. However, the leave-out-one cross-validation test ( $q^2 = 0.63$ ) and the external set prediction ( $r_{ext}^2 = 0.71$ ,  $F = 19.3$ ,  $s = 0.47$ ) were worse. The second model was derived by training a support vector machine equipped with Gaussian kernels, and using the seven descriptors selected in eqn [12]. Very good statistics were returned from the regression ( $r^2 = 0.94$ , RMSE = 0.13), and the external set prediction was very good as well ( $r_{ext}^2 = 0.89$ , RMSE = 0.22), better than with the models of Colmenarejo *et al.* The authors interpreted the models as follows: both hydrogen bonding and electrostatic interactions should decrease HSA binding, while hydrophobic interactions, five- and six-membered rings, and molecular branching should enhance it.

Yap and Chen<sup>45</sup> modeled by means of general regression neural network (GRNN) the data set of Colmenarejo *et al.* For comparison purposes, additional models were derived by using MLR and multilayer feedforward neural network (MFNN). A very large pool of 1497 descriptors of different nature was used in the derivation, and they were selected by means of a genetic algorithm. The absence of chance correlations was estimated using randomization tests. The analyzed data set was split into a training set of 75 compounds and an external prediction set of 18 compounds. The best GRNN model obtained had six descriptors: SRW07 (self-returning walk count of order 07), GATS8e (Geary autocorrelation-lag 8/weighted by atomic Sanderson electronegativities), RDF040m (radial distribution function-4.0/weighted by atomic masses), Mor20p (3D-MorSE-signal 20/weighted by atomic polarizabilities), C-040

(an atom-centered fragment corresponding to  $R-C(=X)-X/R-C\#X/X-C=X$ ), and H-050 (an atom-centered fragment corresponding to hydrogen attached to a heteroatom). The GRNN model predicted well the external set ( $r^2=0.85$ , Spearman rho coefficient ( $R_s$ ) = 0.82, and RMSE = 0.2) and was seen not to appear as chance correlation; worse models were obtained with MLR and MFNN. The interpretation given to the model is that hydrogen-bonding ability decreases HSA binding, while polarizability, shape of the molecule, and electronegativity of molecular substituents all influence the binding to HSA, although in a complex way.

#### 5.36.3.4 Models to Predict $\alpha_1$ -Acid Glycoprotein Binding

The only global model found for the prediction of AGP binding is that of Hervé *et al.*<sup>26</sup> The authors used a data set of 35 molecules with  $pIC_{50}$  values obtained by means of equilibrium dialysis experiments, with both the A and the F1/S variants of AGP. Comparative molecular field analysis (CoMFA) was carried out with each variant, selecting the models displaying the largest  $q^2$ . For the A variant the best model ( $q^2=0.57$ ,  $r^2=0.95$ ,  $F=263$ ) had three PLS components and was derived from a CoMFA model using only the steric field. This model field could be approximated by a simple haptophoric model (Figure 3) where the strongly bound ligands should have a nitrogen atom, plus a ring placed in a hydrophobic pocket, and another ring interacting with a hydrophobic area, all separated by well-defined distances. On the other hand, for the F1/S variants no statistically sound model could be derived.

#### 5.36.3.5 Conclusions

The models described in the previous section present some regularities worth mentioning. On the one hand, it seems that in general the binding to whole plasma proteins is well approximated by the binding to HSA alone. For instance, in the work of Kratochwil *et al.*<sup>4</sup> a good correlation was obtained between the association constants for HSA and those calculated from %ppb values for whole plasma proteins, for all the ranges of binding strengths except for very strong binding; the bad correlation in this range seems to be due to experimental unreliability of the %ppb values. Similarly, Valko *et al.*<sup>42</sup> could calibrate a column with immobilized HSA in order to obtain reasonable predictions for %ppb. That plasma protein binding can be approximated by HSA binding is not surprising, as HSA is a promiscuous protein, being by far the most abundant of all the plasma proteins (about 60%). This implies that in general, AGP, with a molar concentration approximately 30-fold lower than HSA, should have a secondary role in determining %ppb. It must be taken into account, however, that in acute-phase inflammation reactions its concentration can increase several times, and this can result in underpredictions for %ppb for drugs with strong binding to AGP if they are administered under these conditions. It is therefore necessary to do more work on the modeling of drug binding to AGP, with larger data sets than that of Hervé *et al.*,<sup>26</sup> and in comparison with whole plasma protein-binding data, in order to clarify the relevance of AGP binding in this area.

On the other hand, the works and models described seem to converge on a similar picture: although statistically sound models cannot be derived where plasma protein binding depends only on lipophilicity (e.g.,  $\log P$ ,  $\log D$ , or their calculated versions), this property can account for a large percentage of the variance. Saiakhov *et al.*,<sup>35</sup> Kratochwil *et al.*,<sup>4</sup> Hajduk *et al.*,<sup>41</sup> and Valko *et al.*<sup>42</sup> calculated such simple correlations between the binding parameter and a lipophilicity descriptor and, although in some cases some correlation was observed, in no case was it enough to derive an acceptable model. However, whether explicitly or implicitly, in almost all of the models lipophilicity appears as a dependent variable where its increase always results in an increased binding. Statistically reasonable models are then achieved in two different ways: a global model for the whole data set is derived by adding more descriptors, or several 'local' simpler

**Figure 3** Haptophoric model proposed by Hervé *et al.*<sup>26</sup> for the binding to the A variant of AGP.

models are derived for subsets of similar molecules, where lipophilicity is the only one or one of the descriptors. Examples of the first case are the models by Colmenarejo *et al.*<sup>40</sup> and Valko *et al.*,<sup>42</sup> while the models by Saiakhov *et al.*,<sup>35</sup> Lobell and Sivarajah,<sup>38</sup> and Yamakazi and Kanaoka<sup>39</sup> are examples of the second case. The models by Hajduk *et al.*,<sup>41</sup> Hall *et al.*,<sup>43</sup> Xue *et al.*,<sup>44</sup> and Yap and Chen<sup>45</sup> probably belong to the first case, but in them lipophilicity is implicitly included by means of other types of descriptor: structural or topological descriptors for lipophilic groups, and molecular surface area. In the model by Kratochwil *et al.*<sup>4</sup> the assignment of HSA binding constants is based on the similarity of the molecule to a set of topological pharmacophores; as these are not made explicit in this paper, it is difficult to judge the role of lipophilicity in their model.

Besides lipophilicity, there seem to be other consistent features in the models: negatively charged groups enhance binding, while positively charged groups tend to decrease it<sup>38,39,41</sup>; this is in agreement with the traditional (but oversimplified) idea that HSA binds predominantly acidic drugs.<sup>46</sup> Also the presence of six-membered rings<sup>40,41,43,44</sup> as well as chlorine and fluorine atoms<sup>41,43</sup> should enhance binding. No complete agreement is observed for five-membered rings: in two models<sup>41,44</sup> they appear to enhance binding, but in one model<sup>43</sup> they decrease it. In addition there is a variety of molecular properties with different modulating effects that are specific to each model.

In summary, prediction of plasma protein binding requires relatively complex models where lipophilicity repeatedly displays a prevailing role, but where other additional descriptors of different type are necessary to achieve statistical significance, such as molecular shape, charge, and electrostatic potential.

### 5.36.4 Prediction of Drug Tissue Binding

Tissue binding used to be described by means of tissue/blood or tissue/plasma distribution coefficients. In the literature these coefficients are frequently called tissue/blood or tissue/plasma partition coefficients, but following a suggestion from one editor the term distribution coefficients will be used instead, as they are actually ratios of the total concentrations of the drug (including all the ionization subspecies) in two phases.

The determination of tissue/plasma or tissue/blood distribution coefficients is much more difficult than plasma protein-binding data, and this has largely precluded the derivation of models to predict these important parameters. Initial models were mainly based on data sets of blood–air and tissue–air partition coefficients of low-molecular-weight, nonionizable chemicals obtained from tissue homogenates or blood.<sup>47–50</sup> Obviously these chemicals are devoid of drug-like properties, but at least the corresponding models provided good starting points for more complex models. In time different models were developed for drugs, using data determined both in vivo (measurements of concentrations in tissue and blood/plasma after administration to animals) and in vitro (equilibrium dialysis experiments with tissue homogenates).

In what follows, a review of the outstanding models to predict tissue/plasma or tissue/blood distribution coefficients of drugs is presented. The specific models for brain/blood distribution, related to the problem of blood–brain barrier permeation of drugs, are not discussed here; they are described in Chapter 5.31 (In Silico Models to Predict Brain Uptake). We focus instead on models developed to predict simultaneously the distribution of drugs through multiple tissues, and again consider only global models derived from large data sets of diverse drugs. The data sets used were obtained from different mammal species besides human (rat, rabbit, mouse), but, as we will see, the models can be adapted to any species and tissues by providing appropriate tissue-specific parameters to the equations.

#### 5.36.4.1 Models to Predict Tissue/Plasma Distribution Coefficients

Poulin and Theil<sup>51</sup> developed mechanistic models to predict tissue/plasma distribution coefficients ( $D_{T/P}$ ) that had as independent variables  $P_{vo/w}$  (the vegetable oil/water partition coefficient of the molecule) and/or  $f_{u,P}$ . In the case of drugs displaying unrestricted homogeneous distribution by passive diffusion, the following equation was proposed:

$$D_{T/P} = \frac{[P_{vo/w}(v_{nl}^T + 0.3v_{pl}^T) + v_w^T + 0.7v_{pl}^T]f_{u,P}}{[P_{vo/w}(v_{nl}^P + 0.3v_{pl}^P) + v_w^P + 0.7v_{pl}^P]f_{u,T}} \quad [13]$$

where the  $v$ -type coefficients are the volume fractions of neutral lipids, phospholipids, or water (subscripts nl, pl, and w, respectively) in the tissue or plasma (superscripts  $T$  and  $P$ , respectively). For drugs with distribution restricted to the extracellular fluid, the corresponding model becomes:

$$D_{T/P} = \frac{F_T f_{u,T}}{F_P f_{u,P}} \quad [14]$$

where  $F_T$  and  $F_P$  are the fractional content of extracellular fluid in tissue and plasma, respectively. The model was used to predict the  $D_{T/P}$  values for 65 basic drugs in eight rabbit, rat, and mouse nonadipose and nonexcretory tissues (269 data points). The experimental volume fractions and  $f_{u,P}$  values were obtained from the literature. The  $f_{u,T}$  values were approximated from the  $f_{u,P}$  values by assuming a concentration of protein in plasma that was double that seen in tissues. The predictions were fairly good ( $r^2 = 0.81$ ,  $s = 1.40$ ), and 85% of the predicted values were within a factor of three of the experimental values. Larger discrepancies were ascribed to additional mechanisms not included in the model (e.g., lysosomal ionic trapping) or errors in the estimated fractions of unbound drug. It is worth noting that these equations have no adjustable parameters, but instead they attempt the prediction of  $D_{T/P}$  from purely mechanistic reasoning.

In a later paper, Poulin *et al.*<sup>52</sup> developed a variation of eqn [13] to predict the  $D_{T/P}$  for adipose tissue. The rationale used was that, on the one hand, protein binding should be negligible in adipose tissue given its low percentage; thus  $f_{u,T} \approx 1$ . On the other hand, the ionization state of ionizable compounds should also strongly affect the partition coefficient in this tissue of low water content, because it is expected that the nonionized species should partition in both the lipid and water fractions, while the ionized species should only be present in the water fraction. Therefore,  $P_{vo/w}$  should be substituted by  $D_{vo/w}$ , the vegetable oil/water distribution coefficient, taking into account the ionization state of the drug. The resulting equation is thus:

$$D_{T/P} = \frac{[D_{vo/w}(v_{nl}^T + 0.3v_{pl}^T) + v_w^T + 0.7v_{pl}^T]f_{u,P}}{[D_{vo/w}(v_{nl}^P + 0.3v_{pl}^P) + v_w^P + 0.7v_{pl}^P]} \quad [15]$$

$n = 16$ ;  $r^2 = 0.90$ ;  $s = 0.44$ ; RMSE = 1.08

The model (again with no adjustable parameters) was validated with a data set of 14 drugs with known adipose/plasma distribution coefficients for rats, rabbits, and humans (16 data points). The predictions with eqn [15] were good ( $r^2 = 0.90$ ,  $s = 0.44$ , RMSE = 1.08). When octanol/water partition coefficients were used instead of the vegetable oil/water distribution coefficients, the prediction error increased significantly, indicating that vegetable oil is a much better surrogate of the lipid fraction in tissues than octanol.

A third mechanistic model is that of Rodgers *et al.*,<sup>53</sup> in this case attempting to predict the tissue/plasma water distribution coefficient ( $D_{T/u,P}$ ): this is the ratio of the concentration of total drug in the tissue to the concentration of unbound drug in plasma. The model is specialized in the prediction of moderate-to-strong bases, and assumes that electrostatic and hydrophobic interactions dominate and the drugs distribute by passive diffusion. The tissues are modeled as composed of extracellular and intracellular water, plus neutral lipids and both neutral and acid phospholipids. The model equation (with no adjustable parameters once again) is as follows:

$$D_{T/u,P} = \frac{D_{T/P}}{f_{u,P}} = v_{cw}^T + \frac{1 + 10^{pK_a - pH_{iw}}}{1 + 10^{pK_a - pH_p}} v_{iw}^T + \frac{K_a[AP^-]_T 10^{pK_a - pH_{iw}}}{1 + 10^{pK_a - pH_p}} + \frac{Pv_{nl}^T + (0.3P + 0.7)v_{np}^T}{1 + 10^{pK_a - pH_p}} \quad [16]$$

where the  $v$ -type coefficients are the volume fractions of extracellular water, intracellular water, neutral lipids, and neutral phospholipids (subscripts ew, iw, nl, and np, respectively) in the tissue (superscript  $T$ );  $pH_{iw}$  and  $pH_p$  are the pHs of intracellular water and plasma, respectively;  $[AP^-]$  is the concentration of acid phospholipids in tissues; and  $K_a$  is the affinity constant for acid phospholipids of the drug. The model was used to predict the  $D_{T/u,P}$  values for 28 basic drugs in 13 rat tissues, including adipose and excretory ones (261 data points). The prediction was good (85.1% of the values within a factor of three to the experimental ones), and better than the predictions obtained using the models by Poulin and Theil<sup>51</sup> and Poulin *et al.*<sup>52</sup> (eqns [13]–[15]). The use of calculated  $pK_a$ 's and  $\log P$ 's instead of experimental ones did not decrease the statistical quality of the model.

#### 5.36.4.2 Models to Predict Tissue/Blood Distribution Coefficients

Zhang<sup>54</sup> developed a predictive model for tissue/blood distribution coefficients. Starting with a mechanistic reasoning, where tissues (but not blood) are described as composed of lipid, proteins, and water, and after assuming

that the concentration of compound in the tissue water fraction equals that of blood, the author came up with this equation:

$$\log D_{T/B} = \log \left( \sum_{i,j} f_j 10^{\log P_{i/B}^j + \log v_i} \right)$$

$$n = 201; \quad r^2 = 0.82; \quad s = 0.29; \quad q^2 = 0.79 \quad [17]$$

where  $f_j$  is the fraction of the compound at ionization state  $j$  (nonionized, positively ionized, negatively ionized),  $P_{i/B}^j$  is some sort of tissue composition/blood partition coefficient for tissue composition  $i$  (lipids, proteins, water) at ionization state  $j$ , and  $v_i$  is the volume fraction of tissue composition  $i$  (approximated by the corresponding weight fraction). The exponents in eqn [17] are approximated as linear combinations of molecular descriptors for polarizability, charge, and hydrogen bonding. The data set analyzed included 36 volatile neutral organic compounds plus 10 basic drugs with known  $P_{T/B}$  for rabbit fat, brain, muscle, lung, and heart (46 compounds and 265 data points). The data set was split into a training set of 35 compounds and 201 data points, and an external validation set of 11 compounds and 64 data points. eqn [17] was fitted to the training set, using experimental weight fractions from the literature and trying different linear combinations of molecular descriptors, resulting in three final models. The results indicate a good fit to the training set ( $r^2 = 0.82$ ,  $s = 0.29$ ,  $q^2 = 0.79$  for the best model), and a good prediction of the external set ( $r_{\text{ext}}^2 = 0.92$ ,  $s = 0.25$ ). As regards the molecular descriptors in the best-fitting model, it is observed that the partition of neutral compounds into lipids depends on polarizability, hydrogen bonding, and charge, while the partition into proteins depends on polarizability; the partition of ionizable compounds into both lipids and proteins depends on charge. An interesting feature of this model is that it can deal with all types of tissue, including adipose and excretory ones.

#### 5.36.4.3 Conclusions

All the models<sup>51–54</sup> described in the previous section adopt a mechanistic or semimechanistic approach where each tissue is described as a mixture of different extents of components (lipids of different types, water, and proteins) and the binding of a drug to a tissue is determined by its affinity for these components and their volume fraction in the tissue. The volume fractions of the components are taken directly from the literature instead of being estimated from a fit of the model to the data. The drug is described physicochemically by its octanol/water or olive oil/water partition coefficients, and (explicitly or implicitly) by its  $\text{pK}_a$ ; in addition, its unbound fraction in plasma (and tissue) is also used as input in the models and taken from experiments. An additional parameter in the model by Rodgers *et al.*<sup>53</sup> is the binding constant to acid phospholipids. The only exception to this trend is the model by Zhang,<sup>54</sup> where, although it is based on mechanistic reasoning and uses the tissue component weight fractions from the literature, the drugs are described by linear combinations of molecular descriptors and the final models are obtained by fits to the data. Thus, currently no purely in silico model (not requiring any experimental input, and based only on molecular descriptors) has yet been developed to predict tissue/plasma or tissue/blood partition coefficients for diverse data sets of drugs.

### 5.36.5 Prediction of the Volume of Distribution of Drugs

As was seen in the introduction, the volume of distribution is a parameter that describes the balance between plasma and tissue binding (eqn [2]). In particular, the volume of distribution of total drug increases when tissue binding increases, and decreases when plasma protein binding increases.<sup>1</sup> The volume of distribution is linear with the half-life of the drug (eqn [3]), an extremely important pharmacokinetic parameter: as (free) drug is less available in plasma, it is less amenable to elimination by hepatic metabolism and/or renal excretion, and the drug lasts longer. This has raised interest in the development of models to predict the volume of distribution, because, in combination with experimental or predicted clearances, this should allow the prediction of drug half-lives. In this section, recent predictive models for the volume of distribution are reviewed.

#### 5.36.5.1 Models to Predict Volumes of Distribution

Poulin and Theil<sup>55</sup> developed a mechanism-based model for  $V_{D,ss}$ , the volume of distribution at steady state:

$$V_{D,ss} = \sum_i V_{T_i} D_{T_i/P} + V_E R_{E/P} + V_P$$

$$n = 118; \quad r^2 = 0.86; \quad s = 0.39 \quad [18]$$

where the  $V$  coefficients are the body volumes of tissue  $T_b$ , erythrocyte, and plasma (subscripts  $T_b$ ,  $E$ , and  $P$  respectively), and  $R_{E/P}$  is the erythrocyte/plasma ratio. All these parameters are obtained or estimated from the literature, except the  $D_{T_i/P}$  parameters, that are approximated by eqns [13]–[15]. Again, the model has no adjustable parameters and is valid for different species by just providing the appropriate species-specific parameters. A data set of 123 drugs with known rat and human  $V_{D,ss}$  was reasonably predicted by the model (i.e., 80% of the predicted values were within a factor of two of the experimental values;  $n=147$ ,  $r^2=0.61$ ,  $s=0.82$ ). However, a subset of 98 drugs within this data set displayed especially good agreement with the experimental data ( $n=118$ ,  $r^2=0.86$ ,  $s=0.39$ ). For these drugs an agreement can be deduced with the assumptions of the model: tissues are composed of different proportions of cellular water and lipids, plus extracellular proteins; drugs bind to the tissue to an extent depending on their lipophilicity and their protein binding. The remaining 25 drugs showed a poorer agreement with the experimental values ( $n=29$ ,  $r^2=0.18$ ,  $s=1.74$ ), which indicates additional factors not taken into account in the model: binding to cellular macromolecules, ionic drug–membrane interactions, lysosomal ion trapping, and active uptake processes. In general, this model predicts a larger  $V_{D,ss}$  for more lipophilic drugs, and a reduced  $V_{D,ss}$  for drugs that bind strongly to plasma proteins.

A slightly different mechanistic approach is that used by Lombardo *et al.* in two works.<sup>56,57</sup> These authors derived a model to predict  $\log f_{u,T}$  for neutral and basic drugs. The  $f_{u,T}$  so estimated could then be used, together with the experimental  $f_{u,P}$ , to predict the volume of distribution using the Oie–Tozer equation<sup>58</sup>:

$$V_{D,ss} = V_P(1 + R_{E/I}) + f_{u,P}V_P(V_{EF}/V_P - R_{E/I}) + \frac{V_R f_{u,P}}{f_{u,T}} \quad [19]$$

where  $V_{EF}$  is the volume of the extracellular fluid (not including plasma),  $V_R$  is the volume of the remainder of the body, and  $R_{E/I}$  is the ratio of extravascular to intravascular proteins. The authors used a data set of 64 basic and neutral structurally different drugs, extended to 120 drugs in the second work. The best model for the extended set was:

$$\begin{aligned} \log f_{u,T} &= 8 \times 10^{-3}(\pm 0.07) - 0.23(\pm 0.04)E\log D \\ &\quad - 0.93(\pm 0.08)f_{i(7.4)} + 0.89(\pm 0.09)\log f_{u,P} \\ n &= 120; \quad r^2 = 0.87; \quad \text{RMSE} = 0.37; \quad q^2 = 0.85; \quad F_{3,116} = 250.9 \end{aligned} \quad [20]$$

where  $E\log D$  is a  $\log D_{7.4}$  determined through a high-performance liquid chromatography method developed by the authors, and  $f_{i(7.4)}$  is the fraction of drug ionized at pH 7.4. The fit was good ( $r^2=0.87$ ,  $\text{RMSE}=0.37$ ,  $q^2=0.85$ ,  $F_{3,116}=250.9$ ,  $P < 0.0001$ , mean-fold error=2.08). The model was internally validated with randomization tests and leave-class-validation tests, resulting in a good predictive power (mean-fold errors between 1.26 and 2.51). It was externally validated with a set of 18 proprietary compounds, giving similar statistics as the previous model (mean-fold error of 2.26). The coefficients indicate that lipophilicity favors tissue binding, as well as electrostatic interactions with membrane phospholipids ( $f_{i(7.4)}$  term); however, the strongest positive correlation is observed with the fraction of unbound drug in plasma, and this is rationalized by the authors from the large amount of proteins in the extravascular compartment.

Lobell and Sivirajah<sup>38</sup> created a fully in silico model. In a similar way to the model that the authors derived for plasma protein binding already described above, the training set was divided into subsets based on their main charge states at pH 7.4, and for each subset the correlation between  $\log V_{D,ss}$  and  $A\log P$  was investigated. In this case, the training set comprised 204 molecules, while the test set had 124 drugs. The resulting models and the corresponding statistics are collected in Table 6.

In general, it is observed that the  $V_{D,ss}$  of compounds with positive  $A\log P$  decreases in the order: positively charged > uncharged > permanently positively charged > negatively charged; while for compounds with negative  $A\log P$ , the trend is: uncharged > positively charged > negatively charged = zwitterionic. Negatively charged compounds always have a very low  $V_{D,ss}$ , while the largest  $V_{D,ss}$  is observed for lipophilic positively charged and uncharged compounds.

### 5.36.5.2 Conclusions

The models by Poulin and Theil<sup>55</sup> and Lombardo *et al.*<sup>56,57</sup> show a strong dependence of the volume of distribution on the unbound fraction in plasma  $f_{u,P}$ . As the experimental unbound fraction in tissues  $f_{u,T}$  is not used explicitly in their models, although it is required to determine the volume of distribution (eqn [2]), this probably indicates that it can be easily modeled from  $f_{u,P}$ . As a matter of fact, Poulin and Theil<sup>55</sup> approximate the former from the  $f_{u,P}$  values by assuming an average concentration of protein in plasma that is double that seen in tissues, while Lombardo *et al.*<sup>56,57</sup>

**Table 6** Models for the prediction of volumes of distribution

| Charge state at pH 7.4         | <i>A log P</i> range | Predicted $V_{D,ss}$  | Training sets |       |      | Test sets |             |      | Average fold error |
|--------------------------------|----------------------|-----------------------|---------------|-------|------|-----------|-------------|------|--------------------|

Data taken from Lobell, M.; Sivirajah, V. *Mol. Divers.* **2003**, 7, 69–87.

approximate it as a linear function of  $f_{u,p}$ ,  $E \log D$  and  $f_{i(7.4)}$ . This is not surprising, taking into account the fact that the composition of the interstitial fluid resembles that of plasma, including the presence of HSA and AGP.<sup>31</sup> This opens the interesting possibility of developing a fully in silico model for the volume of distribution as a ‘hypermodel’ that includes a model for the prediction of plasma protein binding, like those described above, as one independent variable. Another possibility is a development purely from scratch; this is the approach taken by Lobell and Sivirajah.<sup>38</sup> Their model is indeed a set of local models, and the particular model to apply depends on the main charge state of the molecule to predict.

### 5.36.6 Future Directions

The distribution of drugs throughout the body is a complex problem, but of extreme importance in the design of drugs for therapeutic usage. It is no use having a very potent and selective drug if it has too short or long a half-life, if the dosage and concentrations in the extracellular fluid needed to obtain a therapeutic effect result in toxic concentrations at the tissues, or if most of it remains bound to plasma proteins, being unable to reach its target. So, in the same way that appropriate bioavailability and metabolism features are required for a drug to be successful, appropriate plasma and tissue protein-binding properties are also essential for the safe and effective usage of the drug.

Pharmacokinetic considerations like these are being taken into account at earlier stages in the drug discovery process in order to reduce the attrition rate as far as possible. The sooner an issue in this area is discovered, the better the researchers can react to fix it, and if no solution is possible, move the resources to an alternative candidate. In this way, in silico tools like the ones reviewed in this chapter are of great use. On the one hand, they provide predictions of the modeled parameters without the need to perform an experiment; this is very useful in areas like virtual screening, design of combinatorial libraries, and prioritization of compounds to assay, synthesize, or purchase. On the other hand, they rationalize large amounts of previous experimental data, and therefore can be used to suggest sound modifications of problematic molecules in order to resolve distribution-related issues.

The set of works reviewed in this chapter indicates that there are good models to predict plasma and tissue protein binding of drugs. Most of the models display acceptable predictive power and seem to agree in similar basic conclusions. There are, however, several areas of improvement. For instance, there is the need for more improved models for binding to AGP, with larger data sets and for the different variants of the protein, in order to ascertain the role of this protein in whole plasma protein binding, especially under acute-phase inflammation reactions. The models for HSA binding can be improved by taking into account structural information from x-ray structures of complexes with drugs, probably from high-throughput x-ray crystallography; currently, no model for HSA has used the known structure of HSA. Another area of improvement is the development of fully in silico models (not requiring experimental input and based only on molecular descriptors) for tissue binding and volume of distribution using large data sets of

drugs; right now, the models derived with data sets of drugs use experimental plasma protein-binding data as input; the only exception should be the set of models for volume of distribution by Lobell and Sivarajah.<sup>38</sup> The development of models for tissue binding and volume of distribution is largely prevented by the difficulty in the generation of reliable data for tissue binding. These models – and in general the whole area of modeling of distribution-related properties – will benefit from the development of in vitro screens, as well as new noninvasive techniques for in vivo measurements and molecular imaging.

## Biography

**Gonzalo Colmenarejo** received a degree in biology from the Universidad Complutense de Madrid (UCM). After that, he received an MSc in biophysics (UCM) by working in the statistical mechanics of nonspecific ligand binding to DNA. He then received his PhD in biophysics (UCM), with a thesis dealing with the interaction, molecular modeling, and photochemistry of photoactive drugs with nucleic acids. He was a postdoctoral researcher for 2 years in the Department of Chemistry of the University of California at Berkeley, and in the Structural Biology Department of the Lawrence Berkeley Laboratory, in the laboratory of Ignacio Tinoco, Jr, where he solved 3D ribozyme structures by nuclear magnetic resonance and molecular dynamics. Then in 1999 he joined the GlaxoWellcome R&D center in Tres Cantos, Spain, for a position in Cheminformatics. He is currently an Investigator in the Cheminformatics Department of GlaxoSmithKline at Tres Cantos.

### 5.37.1 Introduction

In order to reduce failures in clinic related to poor absorption, distribution, metabolism, and excretion (ADME) properties, it is important to predict human pharmacokinetics (PK) as early as possible to help select the best candidates for development and reject those with a low probability of success. Predicting human PK can also assist in choosing the first dose for a clinical trial; in testing the suitability of the compound for the intended dosing regimen; in predicting any interactions and in predicting the expected variability in man. Furthermore, predicting human PK prior to phase I studies has been shown to result in significant time savings ranging from 1 to 6 months.<sup>1</sup> Previously the use of physiologically-based pharmacokinetic (PBPK) models was limited in drug development mainly due to the mathematical complexity of the models and the labor-intensive input data required. However advances in the prediction of hepatic metabolism and tissue distribution from in vitro and in silico data have made these models more attractive, providing the opportunity to integrate key input parameters from different sources to not only estimate PK parameters and predict plasma and tissue concentration time profiles, but also to gain mechanistic insight into compounds properties.

There is recent evidence of growing interest in applying PBPK for the discovery and development of compounds.<sup>2-4</sup> Thus, strategies for PBPK application in compound research are being published<sup>5</sup> and several commercial PBPK simulation tools have recently become available.

This chapter describes the usefulness of PBPK in predicting human pharmacokinetics during drug discovery and nonclinical development within pharmaceutical research. The potential and limitations as well as the predictive power of the PBPK approaches are also discussed. The specific tools and techniques employed are briefly described and illustrated with a number of examples. The examples chosen illustrate the utility and the potential of PBPK from early discovery to early development.

## 5.37.2 Methods

### 5.37.2.1 Construction of Physiologically-Based Pharmacokinetic Models

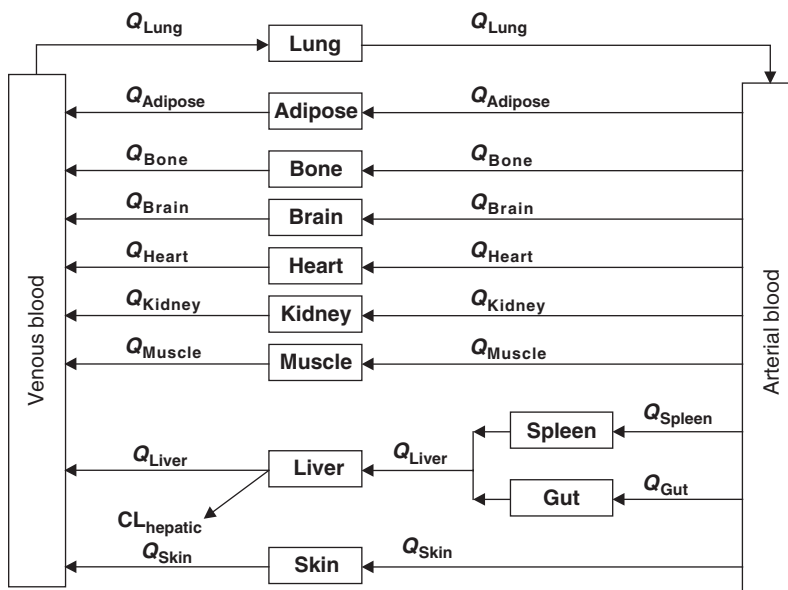

Physiologically-based pharmacokinetic models divide the body into compartments, including the eliminating organs (e.g., kidney and liver) and noneliminating tissue compartments (such as fat, muscle, brain, etc.) which are connected by the circulatory system (Figure 1).

The models use physiological and species specific parameters (such as blood flow rates and tissue volumes) to describe the pharmacokinetic processes. A list of pharmacokinetic parameters with their corresponding definition is provided in Table 1. These physiological parameters are coupled with compound specific parameters such as physicochemical and biochemical parameters (e.g., tissue/blood distribution coefficients and metabolic clearance) to predict the plasma and/or tissue concentration versus time profiles of a compound in an in vivo (animal and/or human) system.

Once a model has been developed, the concentrations in the various tissues can be determined by using the mass balance equation below:

$$(\text{Drug concentration in tissue}) = (\text{Rate of drug distribution into tissue}) - (\text{Rate of drug distribution out}) - (\text{Rate of drug elimination within the tissue}) \quad [1]$$

Depending on the drug and tissue, the distribution is perfusion-rate or diffusion-rate limited. Perfusion-rate limited kinetics tend to occur with relatively low-molecular-weight, hydrophobic drugs which have no problem crossing the lipid barrier of the cell wall. In this case the process limiting the penetration of the drug into the cells is the rate at which it is delivered to the tissue, so that blood flow is the limiting process. By contrast diffusion-rate limited kinetics occurs with more polar drugs that do not freely dissolve in the lipid of the cell membrane and, therefore, have difficulty

**Figure 1** A PBPK model. Q, blood flow; CL, clearance.

**Table 1** Definition of main pharmacokinetic parameters

| <i>PK parameter</i>                  | <i>Definition</i>  | <i>Range of values (human)</i>   |
|--------------------------------------|--|--|
| AUC                                  | Area under the plasma concentration-time curve following intra or extravascular administration of the compound   |  |
| CL                                   | Total clearance<br>This parameter represents the elimination (metabolism and excretion) of the compound from the body  |  |
| CL <sub>H</sub>                      | Hepatic clearance<br>This parameter represents the elimination of the compound through metabolism in the liver and/or biliary excretion  | 0–20 mL min <sup>-1</sup> kg <sup>-1</sup><br>Low: <6 mL min <sup>-1</sup> kg <sup>-1</sup><br>Intermediate: between 6 and 14 mL min <sup>-1</sup> kg <sup>-1</sup><br>High: >14 mL min <sup>-1</sup> kg <sup>-1</sup> |
| V <sub>D</sub> and V <sub>D,ss</sub> | Volume of distribution<br>The volume of distribution (V <sub>D</sub> ) corresponds to the theoretical volume in which the drug would need to distribute to be at plasma concentration<br>V <sub>D</sub> = dose/C <sub>0</sub> (iv)<br>V <sub>D,ss</sub> corresponds to volume of distribution at steady state  | From 0.1 L kg <sup>-1</sup> (distribution restricted to vascular space) to >50 L kg <sup>-1</sup> (high volume due to extensive binding)   |
| t <sub>1/2</sub>                     | Half-life<br>This parameter represents the time taken for the drug concentration in the plasma to decrease by 50%<br>t <sub>1/2</sub> is a function of the clearance and volume of distribution, and reflects how often a drug needs to be administered<br>t <sub>1/2</sub> = 0.693 V <sub>D</sub> /CL   | Few minutes to several months, depending on the drug   |
| A%                                   | Fraction absorbed<br>It is the fraction or percentage of the dose administered which becomes available in the portal vein after intestinal absorption<br>A% = F%(1 - CL <sub>H</sub> /Q <sub>H</sub> ) where Q <sub>H</sub> represents hepatic blood flow  | 0–100%   |

in penetrating into the cell. In this case the diffusion of drug across the membrane, which is independent of blood flow, becomes the limiting process.

For perfusion limitation, the rate of change of drug concentration in a tissue where no elimination occurs can be described as:

$$V \frac{dC}{dt} = Q \left( C_{in} - \frac{C_{in}}{P} \right) \quad [2]$$

where  $V$  is the physical volume of the tissue,  $C$  is the drug concentration in tissue,  $Q$  is the blood flow to the tissue,  $C_{in}$  is the drug concentration entering the tissue, and  $P_{bt}$  is the partition coefficient of the drug between blood and tissue.

When diffusion rate limitation occurs, diffusion to and from the extra cellular space must be taken into account:

$$V_c \frac{dC_e}{dt} = Q(C_{in} - C_e) - P_m(C_e - C_i) \quad [3]$$

where  $V_e$  is the anatomical extracellular volume,  $P_m$  is the membrane permeability coefficient,  $C_e$  is the free extracellular drug concentration, and  $C_i$  is the free intracellular drug concentration.

With organs such as liver, where elimination can occur, the rate of elimination must be included in the mass-balance equation. The rate of elimination is described by:

$$\text{Rate of elimination} = \text{CL}_H C_t \quad [4]$$

where  $\text{CL}_H$  is the hepatic clearance of the drug and  $C_t$  is the concentration in tissue (in this case the liver) at time  $t$ . This term can then be inserted into the mass balance equation, such as that for perfusion limitation:

$$V \frac{dC}{dt} = Q \left( C_{in} - \frac{C_{in}}{P} \right) - \text{CL}_H C_t \quad [5]$$

A recent excellent review of whole body physiological models is provided in.<sup>6</sup> The whole-body model applied in a drug discovery context is described more fully in.<sup>7</sup>

Physiologically-based components for prediction of distribution and metabolism may be combined in a whole-body model and linked to an oral absorption model. Thus, plasma and tissue concentration versus time profiles after intravenous and oral administration may be simulated based upon limited in data and/or in silico estimates.<sup>7</sup> In addition, the whole-body model provides a framework for incorporation of additional processes when these can be estimated.

### 5.37.2.2 Models to Predict Distribution

For each organ included in the PBPK model, estimates of tissue/plasma partitioning are required to quantify the distribution for the compound under study. The tissue plasma partitioning can be estimated in silico using mechanistic tissue composition models<sup>8,9</sup> or can be determined experimentally. Semiempirical methods to estimate tissue plasma partitioning based on in vivo  $V_{D,ss}$  have also been reported.<sup>10</sup> These methods are reviewed below.

Models based on tissue composition have been developed to estimate tissue distribution based on in vitro and in silico data.<sup>8,9</sup> These models have greatly extended the applicability of the PBPK approach to early compound research and development. Briefly, these equations assume that the compound distributes homogenously into the tissue and plasma by passive diffusion where two processes are accounted for:

1. Nonspecific binding to lipids estimated from compound lipophilicity data (*see* 5.18 Lipophilicity, Polarity, and Hydrophobicity), namely  $\log P$  (i.e., octanol/water partition coefficient of the unionized drug) and  $\log D$  (octanol/water distribution coefficient of the ionized + unionized drug measured at a given pH).
2. Specific reversible binding to common proteins present in plasma and tissue estimated from the plasma  $f_u$  ( $f_{up}$ , fraction unbound in plasma). These models have been reviewed in detail.<sup>7,11,12</sup>

An alternative to the tissue composition model is provided with a semiempirical method originally proposed by Arundel.<sup>10</sup> In contrast to the tissue composition model, this approach requires in vivo input data for predicting tissue distribution. In brief, this approach allows the partitioning of a compound into different tissues to be estimated from the observed in vivo  $V_{D,ss}$ , by assuming an empirical relationship between this parameter and the disappearance rate constant ( $k_t$ ) for a particular tissue (except adipose). This approach has been reviewed in detail elsewhere and was applied with some success to predicting tissue distribution in both rats and humans.<sup>10,13</sup>

A number of other approaches have been proposed to predict tissue distribution. These methods include in vitro–in vivo correlations of tissue/plasma partitioning data.<sup>14–20</sup> Other types of prediction methods are of computational nature and consist of mathematical models built in an empirical, semiempirical, or mechanistic framework. The two types of empirical models are (1) regression analyses made between data on in vivo  $V_{D,ss}$  (and tissue/plasma partitioning) and common compound properties (e.g., lipophilicity, ionization, and binding to plasma proteins or lipids),<sup>21–31</sup> and (2) regression analyses made between muscle/plasma partitioning determined in vivo and tissue/plasma partitioning of other nonadipose tissues.<sup>11,32</sup> Another type of semiempirical model is based on the Oie–Tozer equation, which uses physiological and physicochemical input data to estimate  $V_{D,ss}$  in vivo.<sup>22,33</sup>

### 5.37.2.3 Models to Predict Clearance

#### 5.37.2.3.1 Hepatic metabolic clearance

Both empirical and physiologically-based approaches have been developed to predict the *in vivo* hepatic metabolic clearance in animals and humans.<sup>13,34–39</sup> Due to the improved availability of animal and human liver samples, the number of predictions that include *in vitro* data and are based on *in vitro* to *in vivo* physiologically-based direct scaling approaches have markedly increased during the past few years. By applying pharmacokinetic principles, it has recently been shown that human hepatic metabolic clearance can be predicted reasonably well from *in vitro* data.<sup>37,38,40–43</sup> Excellent reviews that cover all aspects of the *in vitro* to *in vivo* scaling have recently been provided.<sup>37,38,41,44</sup>

The strategy allowing this extrapolation of *in vitro* clearance to the *in vivo* situation is depicted in **Figure 2**.

In summary, the first step is to obtain  $CL_{int}$  (hepatic intrinsic clearance) from *in vitro* data. Various *in vitro* systems (e.g., hepatocytes, liver microsomes) are available for these metabolism studies. Thus, *in vitro*  $CL_{int}$  values determined from hepatocyte or microsomal substrate depletion or kinetic assays are normalized for cell or microsomal protein concentration to obtain  $CL_{int}$  in units of  $\mu L \min^{-1} 10^{-6}$  cells or  $\mu L \min^{-1} \text{mg}^{-1}$  and corrected for any nonspecific binding. The second step consists of scaling the activity measured *in vitro* to the whole liver. Depending on the test system, this is achieved by using microsomal recovery factors and hepatocellularity values. Thus, *in vitro*  $CL_{int}$  is scaled to *in vivo*  $CL_{int}$  using a formal scaling procedure:

$$CL_{int} \text{ in vivo} = CL_{int} \text{ in vitro} \times SF \quad [6]$$

where *SF* represents the milligrams of microsomal protein or million cells per gram of liver multiplied by the grams of liver weight as described by Houston.<sup>41</sup> Microsomal recovery and hepatocellularity scaling factors have been reported in the literature for the rat<sup>44</sup> and human.<sup>45</sup> The third stage involves the use of a liver model which incorporates the effects of liver blood flow and blood binding, to convert the estimated  $CL_{int}$  into a  $CL_H$ .

The main liver models used are: the venous equilibrium (well-stirred) model, the undistributed sinusoidal (parallel-tube) model, and the dispersion model. These models share three assumptions: Firstly, the distribution of the drug into the liver is perfusion rate rather than diffusion rate limited; secondly, that only the unbound drug in the blood crosses the cell membrane and occupies the enzyme site; and thirdly that there is a homogeneous distribution of drug metabolizing enzymes within the liver. The latter is not true, as it has been shown that cytochrome P450 (CYP) isoforms are distributed heterogeneously across the liver acinus. Therefore, these liver models do not truly represent the complex physiological nature of the *in vivo* liver situation but represent an approximation. The main difference between these three models is their description of the drug concentration profile within the liver. However, overall there is usually no significant difference between the models and as the well-stirred model is the most mathematically simple it is usually recommended for the prediction of  $CL_H$  from  $CL_{int}$ . In the well-stirred model the liver is conceived to be a single well-stirred compartment with the distribution of the unbound drug being instantaneous and the concentration of unbound drug in the hepatic compartment is assumed to be uniform and equivalent to the hepatic outflow concentration. This model can be successfully used for low clearance compounds where only a relatively small amount of the drug is eliminated in one pass through the liver. However, for high-clearance compounds there will be a higher concentration of drug entering the liver than leaving it, so the predictions are less accurate.<sup>37,38,46,47</sup> With the well-stirred model,  $CL_H$  is calculated as follows:

$$CL_H = Q_H f_u CL_{int} / (Q_H + f_u CL_{int}) \quad [7]$$

where  $Q_H$  is the hepatic blood flow and  $f_u$  is the unbound fraction of drug in the blood.

#### 5.37.2.3.2 Renal clearance

The prediction of renal clearance is based mainly on species scaling as no *in vitro* model is available to scale renal clearance from *in vitro* to *in vivo*. A number of examples support the conclusion that the allometric approach can be

**Figure 2** In vitro–in vivo scaling strategy for hepatic metabolic clearance. The arrows link the different steps of the scaling procedure.

used to predict the renal clearance of a compound in humans.<sup>48–50</sup> In these studies, the best predictions of human renal clearance were achieved when the intrinsic parameters were scaled across species. For example, a successful prediction was achieved for a lactamylvinylcephalosporin, when unbound renal clearance was used for interspecies scaling.<sup>49</sup>

Correlation analysis has also been used successfully to predict the human renal clearance from animal data. Sawada obtained good correlation coefficients for six beta-lactam antibiotics, with good predictions of clearance in humans based on monkey data.<sup>50</sup> As with allometric scaling, the use of an intrinsic parameter (e.g., unbound renal clearance) gave a better prediction and correlation than the corresponding hybrid parameter (bound + unbound renal clearance). Such results were confirmed by a study with 11 cephalosporins,<sup>49</sup> in which correcting for protein binding again improved the correlations between monkey and human.

The glomerular filtration rate (GFR) ratio approach was proposed by Lin.<sup>51</sup> With this approach, renal clearance is estimated using the ratio of the GFR between rats and humans. This approach can be used when minimal preclinical data is available (i.e., when only rat data are available). This method is based on the observation that the ratio of unbound renal clearance for a range of compounds is approximately equal to the ratio of GFR between rat and human (4.8); therefore, the human renal clearance can be estimated from information on the renal clearance in the rat as well as protein binding data in rats and humans.

#### 5.37.2.3.3 Biliary clearance

A battery of in vitro models is available for predicting biliary clearance in vivo. They include: membrane vesicles, cultured hepatocytes, freshly isolated hepatocyte suspensions, hepatocyte couplets, overexpressed cell lines, and transfected cell lines. Overall, the ability of such models to predict in vivo data is qualitative rather than quantitative. Recently, however, the biliary secretion kinetics of selected compounds have been successfully predicted in some initial studies with sandwich hepatocyte cultures,<sup>52</sup> a model which conserves the integrity of the hepatocytes and seems to retain the capacity for biliary secretion.<sup>53</sup>

Attempts to apply allometric scaling techniques to biliary excretion have resulted in poor predictions of human clearance. Thus, the biliary clearances of susalimod<sup>54</sup> and napsagatran<sup>55</sup> were overestimated by 20- and 7-fold, respectively, and other similar failures to predict the human pharmacokinetics from preclinical data have also been reported.<sup>56</sup> These failures are probably due to species differences in the rate of biliary secretion. For example, the MRP2-mediated hepatobiliary transport of temocaprilat displays large differences between human, mouse, rat, guinea pig, rabbit, and dog.<sup>57</sup>

#### 5.37.2.4 Models to Predict Oral Absorption

Oral absorption is a complex process determined by the interplay of physiological and biochemical processes, physicochemical properties of the compound, and formulation factors. Physiologically-based models to predict oral absorption in animals and humans have recently been reviewed<sup>58–60</sup> and several models are now developed to a degree that they are commercially available. The commercial models have not been published in detail for proprietary reasons, but in essence they are transit models segmenting the gastrointestinal tract into different compartments with the kinetics of transit, dissolution, and uptake described by differential equations. For example, the model underlying GastroPlus is known as the advanced compartmental absorption and transit (ACAT) model<sup>58,59</sup> (Figure 3) and is a semiphysiologically-based transit model, consisting of nine compartments corresponding to different segments of the digestive tract. Oral absorption simulations take in vitro and in silico input data such as solubility, permeability, particle size,  $\log P$ ,  $pK_a$  (ionization constant), and dose.

#### 5.37.2.5 Physiologically-Based Pharmacokinetic Modeling Strategy for Prediction to Humans

A PBPK modeling strategy for drug discovery and early development has been proposed recently by Theil *et al.*<sup>5</sup> and is illustrated in Figure 4.

The proposed modeling strategy attempts to evaluate the data generated in drug discovery and early development in a more integrated way, by combining in silico and in vitro prediction methods for absorption, distribution and hepatic clearance to estimate the oral PK profile in humans. The strategy consists essentially of two major steps. The first step is to predict specific absorption, distribution, metabolism, and excretion (ADME) parameters, and then combining their input in a PBPK model to estimate, in a second step, the overall PK after oral and intravenous

**Figure 3** Advanced compartmental absorption transit (ACAT) model. The arrows represent the movement of the compound through the various compartments of the model. (Reprinted from Agoram, B. W. W.; Bolger, M. B. *Adv. Drug Deliv. Rev.* **2001**, 50, S41–S67, with permission from Elsevier.)

administration. Before a prediction to humans is attempted, a comparison of the predicted PK parameters and the concentration/time profiles with in vivo data from animals (rat, dog, or monkey) is performed as a model validation. The rat is usually used, because it is by far the most commonly used animal species for the ADME characterization of compound candidates and because tissue composition models are available in rat and human. A satisfactory prediction for the rat suggests that the prediction for humans might be successful, although this cannot be considered as a full validation.

Thus, the PK in the rat is used to confirm that the PBPK model selected can be used for prediction of human PK. In a first step, disposition PK in the rat after intravenous administration is predicted with a PBPK model by using estimates of tissue: plasma partition coefficients, and hence the derived  $V_{D,ss}$  as well as hepatic clearance as the assumed major component of clearance. If the predicted plasma concentration/time profile in rat describes the experimental data adequately, the intravenous PK in humans is simulated in a second step. In case of major deviations between predicted and experimental concentration/time profile in the rat, model refinements are necessary prior to prediction of human PK.

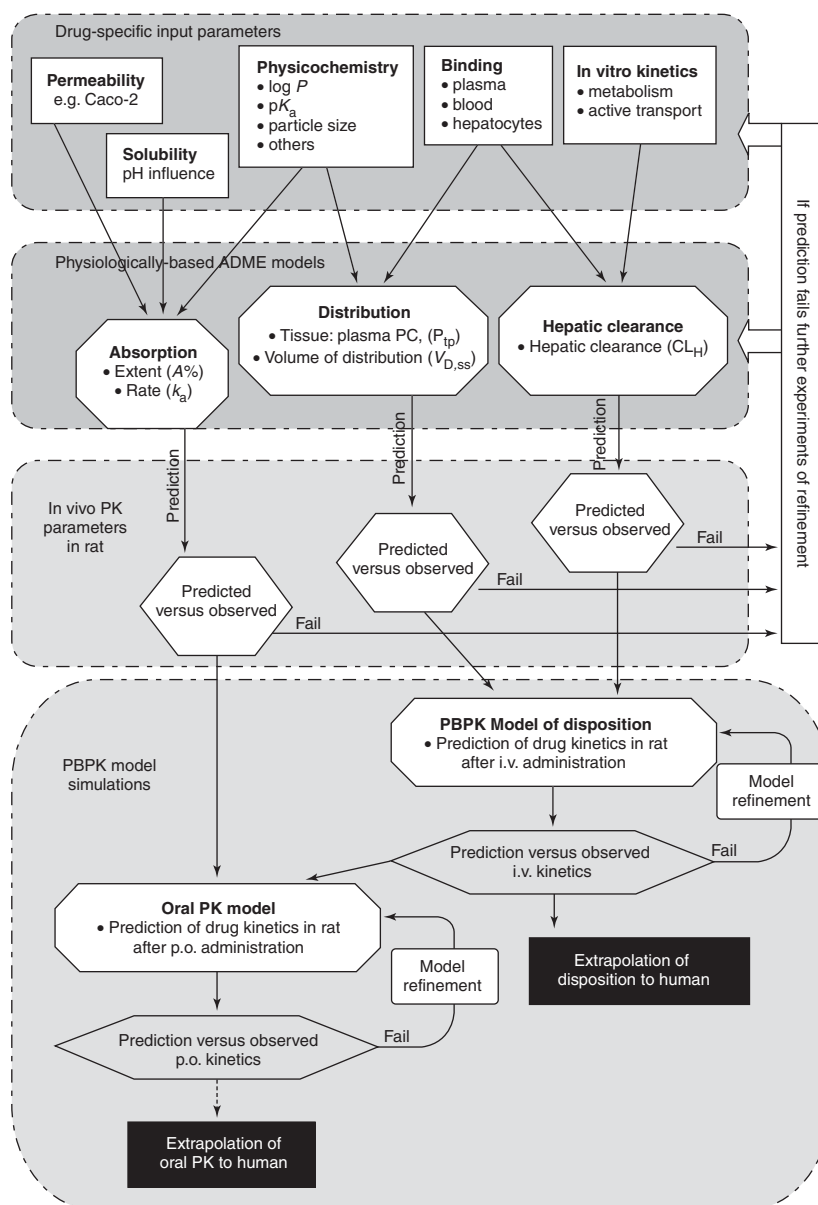

During the drug discovery and development process, more and more data become available and the data obtained are characterized by higher quality. This constantly increasing data quantity and quality potentially improves the model predictions as shown in Figure 5.

The value added by PBPK at the different stages of the discovery and development process, namely for PK simulations prior to in vivo studies, clinical candidate selection extrapolation to humans during the entry into human enabling phase is illustrated in Figure 6 and discussed more in detail in the following section.

### 5.37.2.6 Commercial Tools Available

Several commercial software tools for physiology-based modeling of pharmacokinetic processes exist on the market. Generally these include (1) general simulation software packages, (2) software that simulates separate PK processes such as absorption, metabolism, and interaction, and (3) PBPK software with generic whole-body models.

A program developed to predict intestinal absorption is GastroPlus (SimulationsPlus<sup>72</sup>). In the most recent version, GastroPlus<sup>59</sup> includes a physiological intestinal model for humans in fed and fasted states as well as models for rat, dog, cynomolgus monkey, and mouse. Several additional modules are available for parameter optimization and for

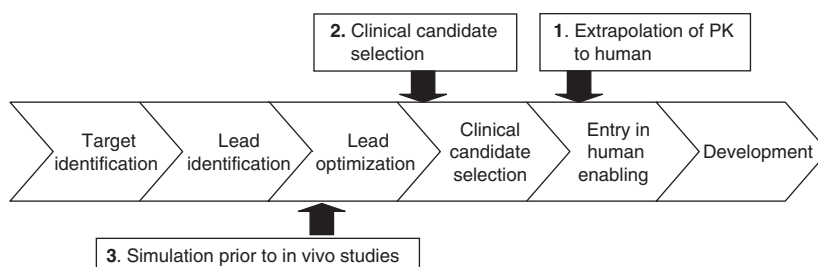

**Figure 4** Strategy for PBPK predictions. (Reprinted from Theil, F. P.; Guentert, T. W.; Haddad, S.; Poulin, P. *Toxicol. Lett.* **2003**, 138, 29–49, with permission from Elsevier.)

combining the absorption model with physiological and compartmental PK models as well as with pharmacodynamic models. The performance of GastroPlus in predicting absorption was evaluated by Parrott and Lavé.<sup>61</sup> In this study, GastroPlus was compared to iDEA another software to predict absorption which is no longer commercially available.

SIMCYP is a software suite specialized in the description of metabolic processes (Simcyp Ltd).<sup>62</sup> SIMCYP utilizes fundamental scaling procedures, described by Houston<sup>41</sup> for the prediction of in vivo hepatic clearance ( $CL_H$ ) from in vitro metabolism data. These in vitro metabolism data are obtained from individual CYP in human-expressed recombinant systems. These are used for predicting not only the mean behavior in individuals, but also in whole populations or in special subpopulations. In order to predict drug–drug interactions involving CYP, SIMCYP utilizes the relationship between the inhibitor concentration at the active site in vivo and the  $K_i$  determined in vitro. Competitive inhibition, induction, and/or mechanism-based inactivation mechanisms can be investigated within this software, according to the principles described by Ito *et al.*<sup>63</sup> and Tucker *et al.*<sup>64</sup> SIMCYP not only predicts the mean value, but also simulates the extremes in the population by applying a Monte Carlo approach.

**Figure 5** Modeling approach within drug discovery and early nonclinical development. (Reprinted from Theil, F. P.; Guentert, T. W.; Haddad, S.; Poulin, P. *Toxicol. Lett.* **2003**, 138, 29–49, with permission from Elsevier.)

Commercial products proposing physiology-based whole-body models allowing the simulation of the whole pharmacokinetic behavior including absorption, distribution and elimination include PK-Sim<sup>4</sup> (Bayer Technology Services)<sup>73</sup> Cloe PK (Cyprotex),<sup>74</sup> and pkEXPRESSTM (Lion Bioscience).<sup>75</sup>

The different technologies for PBPK modeling discussed have all different strengths making them useful for different purposes within the research and development process in the pharmaceutical industry (see Table 2).

### 5.37.3 Applications and Limitations of the Current Methodology

#### 5.37.3.1 Physiologically-Based Pharmacokinetic for Extrapolation of Pharmacokinetics to Humans

A number of publications illustrate the potential of PBPK, both for predicting human pharmacokinetics and for examining species differences in pharmacokinetics. For example, Sawada predicted the human plasma concentration versus time profiles of seven compounds (phenobarbital, phenytoin, hexobarbital, quinidine, tolbutamide, valproate, and diazepam).<sup>65</sup> Using a physiologically-based approach he incorporated the intrinsic (unbound compound) clearance and unbound tissue-to-plasma concentration ratios that were extrapolated from rat data, plus the human plasma protein binding and blood-to-plasma concentration ratios. The concentration–time curves that were predicted for phenytoin, hexobarbital, quinidine, and phenobarbital showed comparatively good agreement with the values observed in human plasma. By contrast, for tolbutamide, valproate, and diazepam, because of poor clearance predictions the areas under the concentration–time curve were poorly estimated.<sup>65</sup>

<sup>a</sup>No longer commercially available.

Successful predictions were also reported in the case of epiroprim.<sup>66</sup> This was achieved by combining PBPK and allometric scaling. Epiroprim, an antimicrobial agent from the diaminopyrimidine family, was considered a challenging compound for the current extrapolation methods because of its large interspecies differences in its pharmacokinetic properties mainly related to mixed elimination pathways, namely hepatic metabolism and biliary excretion of unchanged compound. For the prediction of distribution in humans, the tissue/plasma partition coefficients were predicted using the human tissue composition model based on in silico input parameters. The human clearance was predicted by using allometric scaling combining animal intrinsic in vivo blood clearance and in vitro hepatocyte data in animals and humans. Under these circumstances, PBPK led to reasonable predictions of the in vivo disposition profile of epiroprim in rat and human.

Lumped physiologically-based models (in which the tissues are subdivided into groups, according to their kinetic properties) have been used to predict human plasma concentration–time curves for the melatonin agonist S20098.<sup>67</sup> By combining in vitro metabolism data obtained from human CYP enzymes with partition coefficients in fat and liver, the range of plasma concentrations observed in human could be successfully predicted. In another study<sup>13</sup> a lumped physiologically-based pharmacokinetic model originally developed by Arundel for the rat<sup>10</sup> was extended and applied to human for ten extensively metabolized compounds. Overall, the results showed that this model might be used to predict concentration versus time profiles in human. Irrespective of the compounds' pharmacokinetic and physicochemical characteristics, the average error for the predicted pharmacokinetic parameters (CL (total clearance),  $V_{D,ss}$  (volume of distribution at steady state),  $t_{1/2}$  (half-life)) of the 10 compounds was less than twofold.<sup>13</sup>

Recently, empirical and PBPK approaches were compared for the prediction of human pharmacokinetics using 19 diverse compounds taken from recent clinical development projects at Roche.<sup>68</sup> The original set of compounds included in this analysis represented all the compounds developed at Roche that went into clinical development between 1998 and 2002. From this set biological compounds, prodrugs, and compounds that were not absorbed were excluded. The remaining compounds ( $n = 19$ ) were used in the analysis. The compounds selected covered a wide range of physicochemical and PK properties. All compounds were lipophilic with  $\log P$  values ranging between 1.2 and 6.6, with a mean of 4.0. Five compounds were acids with a  $pK_a < 8$ , seven were bases with a  $pK_a > 6$  and seven were neutral or weakly ionized at physiological pH. Half-life in human ranged from short (0.50 h) to long (200 h). Elimination pathways included hepatic metabolism, renal excretion, biliary excretion, or a combination of these. Fraction unbound in plasma ( $f_u$ ) values ranged from extensive (0.00060) to low (0.89). Distribution consisted of both passive and active processes and varied from limited to widespread. In the rat, absorption ranged from 15% to 100%. Predicted values (pharmacokinetic parameters and plasma concentrations) were compared to observed values in order to assess the accuracy of the prediction methods.

Based on the strategy proposed (*see* Section 5.37.2.5), a prediction would have been made prospectively for approximately 70% of the compounds. The accuracy for these compounds in terms of the percentage of compounds with an average-fold error of less than twofold was 83%, 50%, 75%, 67%, 92%, and 100% for clearance, volume, half-life,  $C_{\max}$  (maximal (peak) plasma concentration), AUC (area under the plasma concentration–time curve) and  $t_{\max}$ , respectively. For the other 30% unacceptable prediction accuracy was obtained in animals; therefore a prospective prediction would not have been made using PBPK. The accuracy for these compounds in terms of the percentage of compounds with an average-fold error of less than twofold was 40%, 40%, 60%, 0%, 40%, and 80% for clearance, volume, half-life,  $C_{\max}$ , AUC, and  $t_{\max}$ , respectively. In general, for compounds that were cleared by hepatic metabolism or renal excretion, and whose absorption and distribution were governed by passive processes, the prediction accuracy was very good (average-fold error less than twofold) using PBPK. Significant mispredictions were achieved when other elimination processes (e.g., biliary elimination) or active processes were involved. PBPK prediction accuracy was significantly improved when any nonlinearities in clearance were incorporated; when both microsomal and plasma binding were included in the scaling of microsomal data; when intestinal metabolism was incorporated for CYP3A4 substrates and when solubility was measured in physiological media for low-solubility compounds. The poorer predictions or the compounds for which a prediction was not attempted with PBPK were often as a result of processes that were not incorporated into the model due to the lack of in vitro input parameters to describe processes such as biliary excretion or enterohepatic recirculation.

The prospective use of PBPK approaches was described recently for one compound.<sup>69</sup> This basic ( $pK_a$  10.3) and lipophilic ( $\log P$  3) compound showed good aqueous solubility ( $9 \text{ mg mL}^{-1}$  at pH 5) and permeability measured in Caco-2 cells was high. Animal pharmacokinetics showed high blood clearance in rats ( $50 \text{ mL min}^{-1} \text{ kg}^{-1}$ ) but low clearance in dogs and monkeys ( $8$  and  $13 \text{ mL min}^{-1} \text{ kg}^{-1}$ , respectively) and a high volume of distribution (between 4 and  $9 \text{ L kg}^{-1}$ ) and moderate binding to plasma proteins (approx. 25%) in all three species.

The volume of distribution predicted using tissue composition based equations was first compared to the observed volume in rat and was found to under predict by threefold. Therefore the predicted partition coefficients were replaced by experimentally determined values from a quantitative whole-body autoradiography study, although caution is needed in using such estimates of tissue partitioning based on total radioactivity since they measure the distribution of both parent compound and metabolites. However, in this case the volume in rat was more accurately predicted using such estimates and so the distribution in human was simulated using these values in a human PBPK model.

Direct physiological scaling of intrinsic clearance in rat and dog hepatocytes gave underpredictions of the observed clearance in both species and this underprediction could not be fully explained by renal or biliary clearance since these were known to be relatively minor (each <10% of total clearance). As this compound is mainly metabolized by CYP3A4, intestinal metabolism may also be important. However in vitro clearance obtained with gut microsomes was not available. Therefore the estimated human clearance was based on direct scaling of intrinsic clearance from human hepatocytes with inclusion of a predicted renal clearance calculated from the unbound renal clearance in rat corrected for the ratio of the GFR in rat to that in man. Finally the absorption in rat and dog had been shown to be well predicted with GastroPlus based on the experimental permeability and solubility data and so the same inputs were used to simulate the human oral profile which is shown in Figure 7 together with the observed data.

All in all, there is growing evidence that physiologically-based models show improved prediction accuracy for extrapolation of human pharmacokinetics over more empirical methods. The PBPK approach is based upon solid physiological principles and so can often be extended in a rational way to include additional relevant information and data. PBPK models offer also a mechanistic framework which contributes to an improved understanding of the compound's properties which ultimately should result in better prediction accuracy. The variability and uncertainty associated with the predictions requires also some special attention. As is apparent from the literature and available clinical data for the compounds studied, there is a large degree of variability in the population both in terms of physiology (tissue volumes, blood flows, transit times, etc.) and biochemistry (plasma binding, CYP expression and activity, etc.). In order to produce predictions that are more realistic of the target population, this variability together with any uncertainty (variations due to assumptions, hypotheses, handling of system, etc.) ideally must be accounted for. The incorporation of these factors can be translated into a measure of confidence in the prediction.

### 5.37.3.2 Early Pharmacokinetic–Pharmacodynamic (PK/PD) Predictions in Human Based on Physiologically-Based Pharmacokinetic and Preclinical Data

In a recent study a mechanistic PBPK and pharmacokinetic/pharmacodynamic approach was reported for the prediction of the human response using the example of a immunomodulator<sup>70</sup> (*see* 5.38 Mechanism-Based Pharmacokinetic–Pharmacodynamic Modeling for the Prediction of In Vivo Drug Concentration–Effect Relationships – Application in Drug Candidate Selection and Lead Optimization). The example was based on the immunomodulator FTY720 (the first

**Figure 7** Observed data and physiologically-based predicted (oral administration) plasma concentration-time profiles in human for a 10 mg dose. (Reproduced with permission from Parrott, N.; Jones, H.; Paquereau, N.; Lavé, T. *Basic Clin. Pharmacol. Toxicol.* **2005**, *96*, 193–199.)

sphingosine-1-phosphate receptor agonist) acting by stimulating the sequestration of lymphocytes into lymph nodes in order to remove cells from blood circulation. A PBPK model incorporating permeability limitations in thymus, brain, and lymph nodes was connected to an indirect response model of the lymphocyte system to characterize the cell trafficking effects. Permeability was obtained after fitting of in vivo tissue data in rat. The  $IC_{50}$  of FTY720 was estimated from monkey; human was assumed to be similar to the monkey. To make predictions of the pharmacodynamic behavior for humans, systemic exposure was obtained from a physiology based model, and an estimate of lymphocyte turnover in human was obtained from preclinical species using allometric scaling. Predictions compared well with clinical results.

### 5.37.3.3 Physiologically-Based Pharmacokinetics Applied to Clinical Candidate Selection

In contrast to empirical techniques, an approach based upon a mechanistic framework can lead to greater insights into the behavior of compounds and offers more potential in the early stages of drug development since it does not require animal in vivo data in several species as is needed for allometric scaling. Therefore, PBPK has a great potential to assist clinical candidate selection where numerous factors need to be considered and data related to the pharmacokinetics and pharmacodynamics of the compounds needs to be combined and compared in a rational way.

An example showing the utility of such an approach was provided recently.<sup>69</sup> In this example in vitro and in vivo data for five potential clinical candidates were combined in PK/PD models to make estimate of the effective human doses and associated exposures and aid in the selection of the most promising compound. To ensure that the decision was based upon significant differences between the compounds, estimates of variability and/or uncertainty were carried through in the modeling of the PK and PD. The five compounds were from the same structural class and showed similar physicochemical properties. Molecular weights were in the range 406–472 g and all compounds were largely unionized at physiological pH. Values of  $\log P$  ranged from 2.1 to 2.9 and permeability was good for all compounds while solubility ranged from 2.2 to 0.009 mg mL<sup>-1</sup>. In vitro receptor binding and plasma protein binding in rat and human and in vivo pharmacokinetic and pharmacodynamic data in rat were also available for all compounds.

In a first step the scaling of intrinsic clearances determined in rat hepatocytes was compared to in vivo clearance. When nonlinearity was accounted for the estimated hepatic metabolic clearance values were in reasonable agreement with observed total clearances which ranged from 7 to 35 mL min<sup>-1</sup> kg<sup>-1</sup> and it was considered appropriate to estimate the expected clearances in human by similar scaling of human hepatocyte data. The error around the mean predicted human clearance was based on the variability seen in different batches of human hepatocytes.

Tissue composition based prediction of volume based on lipophilicity and plasma protein binding showed an average 2.2-fold error and the correlation of predicted versus observed volume for the five compounds was poor. For the prediction of volume of distribution it was assumed that the volume in L kg<sup>-1</sup> in human was the same as the observed

**Figure 8** Simulated AUC at steady state for five potential clinical candidate compounds. Symbols give the mean prediction while lines indicate a 95% confidence range. (Reproduced with permission from Parrott, N.; Jones, H.; Paquereau, N.; Lavé, T. *Basic Clin. Pharmacol. Toxicol.* **2005**, 96, 193–199.)

volume in the rat (ranging from 0.9 to 2.8 L kg<sup>-1</sup> for the five compounds). Due to the uncertainty in the prediction of volume the error range associated with this parameter was set as a uniform distribution over a twofold range.

The effect versus plasma concentration relationship in the rat pharmacodynamic data was shown to be a direct one and was well described by a simple Emax model. Based on preclinical models for efficacy, a 90% effect was considered as the target for therapeutic effect. The effect versus plasma concentration relationship in the rat pharmacodynamic data was shown to be a direct one and was well described by a simple Emax model. A 90% effect was considered as the target for therapeutic effect. Finally the human C<sub>90</sub> (human concentration corresponding to 90% effect) was estimated by accounting for the different affinities of each compound for the rat and human receptors and also for the different free fraction unbound in rat and human. Thus:

$$C_{90 \text{ human}} = C_{90 \text{ rat}} \cdot (K_i \text{ human} / K_i \text{ rat}) \cdot (f_u \text{ rat} / f_u \text{ human}) \quad [8]$$

Finally, absorption in the rat was shown to be well predicted by GastroPlus since good agreement was seen between simulated and observed oral profiles and so the predicted human pharmacokinetics and pharmacodynamics were combined in a GastroPlus human model to allow for estimation of the effective steady state doses and exposures after repeated oral dosing. Incorporation of variability and uncertainty was achieved using some stochastic simulations. The predicted effective doses, and associated exposures including error ranges on the predictions were then provided for the various potential clinical candidates (see Figure 8).

This example showed that the PBPK approach assists a sound decision on the selection of the optimal molecule to be progressed by integrating the available information and focusing attention onto the expected properties in human. Importantly, the method is also able to include estimates of variability and uncertainty in the predictions.

#### 5.37.3.4 Physiologically-Based Pharmacokinetics to Prioritize Compounds Prior to In Vivo Experiment

Drug discovery is increasingly 'data rich' with high-throughput chemistry generating numerous compounds that are rapidly screened for pharmacological and pharmacokinetic properties. Determination of in vivo PK is considerably more costly than in vitro screening and so there is interest in optimizing resources by using simulation to prioritize compounds. However, acceptance of this approach requires extensive validation. The practical value of generic physiologically-based models of pharmacokinetics at the early stage of drug discovery was evaluated.<sup>69,71</sup> In the study reported below, the validation was carried out with rat data but the ultimate aim is to run these predictions in humans.

In the study by Parrott *et al.*, a generic PBPK model was applied to predict plasma profiles after intravenous and oral dosing to the rat for a set of 68 compounds from six different chemical classes. The compounds were selected without particular bias and so are considered representative of current discovery compounds. The physicochemical properties of the compounds are rather different from those of marketed compounds; in particular they have high lipophilicity (mean log *P* of 4) and low aqueous solubility as well as a tendency to neutrality at physiological pH. The more extreme property values can present measurement difficulties and so for consistency all predictions were made on the basis of calculated lipophilicity and protein binding while in vitro measurements of intrinsic clearance in hepatocytes, ionization, solubility, and permeability were used for all compounds.

**Figure 9** Predicted versus observed AUC/dose for 68 Roche compounds. (Reproduced with permission from Parrott, N.; Jones, H.; Paquereau, N.; Lavé, T. *Basic Clin. Pharmacol. Toxicol.* **2005**, 96, 193–199.)

In a first stage distribution was predicted with tissue composition based equations and the estimated tissue partition coefficients were combined with clearance estimated by direct scaling of hepatocyte intrinsic clearance in a PBPK model as described earlier.

In a second stage GastroPlus was used to simulate oral absorption and oral profiles were produced by feeding this predicted input into a compartmental disposition model fitted to the mean observed (intravenous) iv data. For intravenous dosing simulations 60% of the clearance and volume predictions were within twofold of the observed values and the ranking of compounds by predicted versus observed parameters showed correlation coefficients of 0.8 and 0.6 for clearance and volume, respectively. For oral dosing simulations, 40% of the predicted AUC values were within twofold of observed values and the mean fold-error was 4.1. For compounds with measured solubility of less than  $0.012 \text{ mg mL}^{-1}$  only 10% of predictions were within twofold while for compounds with higher solubility 70% were within twofold<sup>69</sup> (Figure 9).

Overall, this study indicated that generic simulation of pharmacokinetics at the lead optimization stage could be useful to predict differences in pharmacokinetic parameters of threefold or more based upon minimal measured input data. Fine discrimination of pharmacokinetics (less than twofold) should not be expected due to the uncertainty in the input data at the early stages. It is also apparent that verification of simulations with in vivo data for a few compounds of each new compound class was required to allow an assessment of the error in prediction and to identify invalid model assumptions.

The value of PBPK for simulating the first-time-in-animal study was illustrated also by Germani *et al.*<sup>71</sup> In this study, the model was used to predict the plasma pharmacokinetics obtained in 24 rat and two mouse pharmacokinetic studies. This study was restricted to the prediction of disposition profiles (i.e., profiles observed after intravenous administration of the compounds). The administered compounds were synthesized as part of a number of different discovery programs. The simulated profiles were generally in agreement with the observed ones. Plasma clearance and mean residence times were well predicted: average fold errors were 2.7 and 2.5, respectively, with approximately one half of the cases predicted within a twofold of observed. Some over prediction of plasma clearance was observed in the range of low clearance values, in case of compounds with  $\log P = 5$  and protein binding of 99%. On the other hand, slight underestimates were observed for molecules with  $\log P$  near zero and protein binding of 99.9%. The error in the volume of distribution at steady state ( $V_{D,ss}$ ) was higher, but still acceptable (average fold error was 3.7).

#### 5.37.3.5 Inclusion of Transporters and Gut Wall Metabolism into Physiologically-Based Pharmacokinetics

Although remarkable progress has been made in the identification and functional characterization of drug transporters, quantitative predictions of pharmacokinetic processes involving membrane transport is still challenging because of the lack of quantitative in vitro models and the sheer number of issues that need to be considered for the modeling approaches to allow an accurate description of the in vivo situation.

Mathematical models incorporating all nonlinear processes in a systematic manner must allow for discrimination of several distinct kinetic processes, such as uptake by passive and active transport, distribution, metabolism (e.g., oxidations and conjugations), and excretion (e.g., biliary excretion). Furthermore, each of the above processes must be linked to the appropriate drug concentration within the relevant medium (i.e., free concentration in plasma for the uptake processes, and the intracellular free drug concentration for the efflux, metabolism, and excretion processes). PBPK models offer the framework to potentially address and link all the foregoing aspects in a mechanistic fashion. Thus, these models should, theoretically, enable the prediction of the *in vivo* kinetics even for compounds for which such complex processes are involved.

Attempts were made recently to model drug absorption of compounds subject to gut efflux and/or metabolism.<sup>59</sup> Thus, using the ACAT model available in Gastroplus based on the assumed P-glycoprotein (P-gp) distribution in the gastrointestinal tract, and optimized  $V_{\max}$  and  $K_m$  for substrate P-gp interactions, reasonable estimates of the *in vivo* plasma concentration profiles and bioavailabilities were obtained for oral digoxin administered alone and after rifampin treatment.<sup>59</sup>

The absorption of saquinavir, a drug metabolized and effluxed in the gut, was also successfully modeled in this study. Saquinavir was the first clinically available human immunodeficiency virus (HIV) protease inhibitor in the USA. It has a very low bioavailability (0.5–2%) due to extensive first pass metabolism by CYP3A4 in the gut and in the liver. It is also a gut P-gp substrate. The bioavailability of saquinavir was found to double when administered with food or with grapefruit juice. The interaction has been attributed to increased hepatic blood flow due to food intake and suppression of intestinal CYP3A4 and P-gp by grapefruit juice respectively. In order to model the absorption of saquinavir, *in vitro* and/or optimized kinetic constants ( $V_{\max}$  and  $K_m$ ) were used for both gut and liver metabolism and the amounts of CYP3A4 in the small intestine and liver were taken into consideration as well as the regional distribution of P-gp in the gut. Based on this model, the relative impact of solubility, passive permeability, efflux, and metabolism in gut and liver on the overall absorption of saquinavir could be estimated.

#### 5.37.4 Discussion

For extrapolation of human pharmacokinetics, physiologically-based models show improved prediction accuracy over more empirical methods. The PBPK approach is based upon solid physiological principles and can be extended to include additional relevant processes. Also, besides satisfactory prediction capabilities, an approach based upon a mechanistic framework can lead to greater insights into the behavior of compounds and offers more potential in the early stages of drug development since it does not require animal *in vivo* data in several species as is needed for allometric scaling.

When applied at the clinical candidate selection phase the PBPK approach assists a sound decision on the optimal molecule to be progressed by integrating the available information and focusing the attention onto the expected properties in human. Importantly, the method is also able to include estimates of variability and uncertainty in the predictions, which should be considered as an important piece of information for decision-making.

The results on the use of generic simulation prior to *in vivo* studies indicate that some caution is required since certain chemical classes were poorly predicted and it is recommended that generic PBPK models should only be applied for prioritization after verification of the simulations with *in vivo* pharmacokinetics for a few compounds of a given chemical class. Such verification will help to identify invalid model assumptions or missing processes where additional data is needed. In addition, for poorly soluble compounds, the use of aqueous solubility is shown to be inadequate for reliable prediction of oral absorption in physiologically-based models.

Important limitations of the generic PBPK approach are realized for compounds that have significant active distribution/absorption processes, where biliary elimination is a major component of the elimination process or where the assumptions of flow limited distribution and well-mixed compartments are not valid and permeability limited distribution is apparent. These drawbacks could be addressed by the addition of permeability barriers for some tissues and by the incorporation of a more complex liver model which addresses active uptake into the liver, active efflux into the bile, biliary elimination, and enterohepatic recirculation. However, this will require the availability of the appropriate input data for quantification of the various processes involved as well as validation of the corresponding *in vitro* to *in vivo* scaling approaches.

Overall, these three examples illustrate how PBPK models can already add value at various stages of the preclinical compound research and development process although one has to keep in mind a number of limitations. Their use is growing and the potential will be fully exploited as powerful and userfriendly software continues to make PBPK models accessible to nonspecialists.

## Biographies

**Thierry Lavé** received his PharmD and PhD in pharmaceutical sciences from the University of Strasbourg in 1992 and 1993. He also received a statistical degree from the University of Paris in 1992 and did an internship in hospital pharmacy from 1988 to 1992 in Strasbourg. Thierry Lavé joined Roche's Department of Preclinical Pharmacokinetics and Drug Metabolism in 1992 and worked in this department as a postdoctoral fellow for 2 years. Thierry Lavé is currently a Scientific Expert at Hoffmann-La Roche and took responsibility for the global modeling and simulation group in preclinical research in 2002. His main area of research is in preclinical modeling of safety, pharmacokinetics, and formulation, physiologically-based pharmacokinetics, interspecies scaling, drug–drug interaction, and all aspects related to early predictions of pharmacokinetics/pharmacodynamics in humans during drug discovery and early drug development. He has published a number of papers in these areas. Thierry Lavé also teaches pharmacokinetics at the Universities of Pharmacy in Basel, Strasbourg, Helsinki, and Besançon.

**Neil Parrott** graduated in physics from the University of Bristol, UK, then specialized in information technology and medical imaging at the University of Aberdeen, UK. In 1988, he started work with Sandoz Pharma as a developer of chemistry and biology databases and search algorithms. Later with Sandoz he joined the combinatorial chemistry group

developing software and automation for high-throughput solid-phase synthesis. In 1998, he joined the Informatics group in Roche Pharma Research where he developed data analysis tools for pharmacokinetic data and led a project to integrate DMPK data into the Roche Research global data warehouse. While working in the DMPK area he became interested in physiologically-based pharmacokinetics and transferred to the Research Modeling and Simulation group where he is now involved in preclinical project support with pharmacokinetic and absorption modeling.

**Hannah Jones** is a Research Scientist within the DMPK department at F Hoffmann-La Roche, where she is responsible for the simulation of human pharmacokinetics for discovery and early development compounds before entry into human. She received a BSc (Hons) in pharmacology and a PhD in drug metabolism from the School of Biological Sciences and the School of Pharmacy at the University of Manchester, UK, respectively. Hannah is interested in the prediction of human pharmacokinetics, including metabolism, distribution, absorption, drug–drug interactions, and the incorporation of variability and uncertainty. She has several research publications in this area.

### 5.38.1 Introduction

The application of pharmacokinetic–pharmacodynamic (PK/PD) modeling in drug development is well established. The primary objective of PK/PD modeling is prediction of the time course of the drug effect in vivo (intensity and

duration) in health and disease.<sup>1</sup> As such PK/PD constitutes the scientific basis for optimization of the dosing and delivery profile of drugs in phase II clinical trials. Furthermore PK/PD modeling is also widely applied as the basis for the design (by clinical trial simulation) and the evaluation of phase III clinical trials.<sup>1,2</sup>

In the meantime PK/PD modeling is increasingly applied in drug discovery and preclinical development. Here the objective is the prediction of the PK/PD properties of novel drugs in humans on the basis of information from (high-throughput) *in vitro* bioassays and *in vivo* animal studies. Specific applications in this context include (1) the selection of drug candidates with a predicted optimal PK/PD profile in humans, (2) acquisition of pertinent information for lead optimization, and (3) the use of preclinical PK/PD information in optimizing early clinical trials.

The use of PK/PD modeling in drug discovery and early development relies on the prediction, in a strictly quantitative manner, of PK/PD properties in humans. Not surprisingly there is a clear trend toward mechanism-based PK/PD models, which have much improved properties for extrapolation and prediction. Mechanism-based PK/PD models differ from empirical, descriptive models in that they contain specific expressions for processes on the causal path between drug administration and effect. These include (1) target site distribution, (2) target binding and activation, (3) transduction, and (4) effect of homeostatic feedback mechanisms. Ultimately effects on (5) disease processes are also considered. Mechanism-based PK/PD modeling relies on the use of biomarkers to characterize quantitatively processes on the causal path.<sup>3</sup>

In this chapter a general overview of the basic principles of mechanism-based PK/PD modeling is presented. Next specific models and pertinent issues with regard to the prediction of PK/PD properties in humans are discussed on the basis of examples, illustrating the utility of preclinical PK/PD modeling in drug candidate selection and lead optimization.

## 5.38.2 Mechanism-Based Pharmacokinetic–Pharmacodynamic Modeling: Concepts

### 5.38.2.1 Pharmacokinetic Considerations: The Rationale of Obtaining Drug Concentrations in *In Vivo* Pharmacodynamic Investigations

In PK/PD modeling the time course of the drug effect *in vivo* is typically considered in conjunction with the time course of the drug concentration in plasma (i.e., the pharmacokinetics of the drug). In a compartmental model, drug disposition is described as the transfer of drug between interconnected compartments, serving to mimic drug absorption and elimination processes. This type of analysis of pharmacokinetics is often considered routine and straightforward.<sup>4</sup>

An important factor, however, is that typically wide differences between drugs in the time course of the concentration are observed. Strikingly, this is also the case for structurally similar compounds with nearly identical receptor binding properties. As result the pharmacokinetic properties of new chemical entities constitute an important selection criterion in drug development.<sup>5</sup> In order to predict the pharmacokinetics properties of new chemical entities in humans, the discipline of physiological pharmacokinetic modeling has been developed.<sup>6</sup> A discussion of this type of modeling is beyond the scope of this chapter, which focuses on the prediction of drug effects rather than concentrations.

The observation of wide differences in pharmacokinetics between structurally similar compounds has important implication for the design of preclinical *in vivo* pharmacodynamic investigations. As was outlined above, due to the wide differences in pharmacokinetics, identical doses of different drugs may result in widely different *in vivo* drug concentration profiles. This wide difference in pharmacokinetics makes the comparison of *in vivo* potency estimates on the basis of dose a meaningless exercise. Furthermore, pharmacokinetic properties typically also differ widely between species, which complicates the interspecies extrapolation of drug potency on the basis of doses. For the above-mentioned reasons is imperative that quantitative *in vivo* pharmacodynamic investigations be based on drug concentration as a measure of internal exposure, rather than dose. To this end in recent years several chronically instrumented rat models have been developed in which, following the (intravenous) administration of a single dose, the time course of the drug effect can be determined in conjunction with drug concentrations.<sup>7–10</sup> It has been amply demonstrated that by PK/PD modeling of these high-density data unique *in vivo* concentration–effect relationships can be obtained, which may be readily extrapolated from laboratory animals to humans.<sup>11,12</sup>

Recently the concept of ‘population’ pharmacokinetic analysis has been successfully introduced in preclinical PK/PD modeling. In population analysis, data from several experiments are simultaneously analyzed allowing estimation of the typical pharmacokinetic parameters in conjunction with their intra- and interindividual variability. Population pharmacokinetic analysis offers the advantage that it enables detailed description of the time course of the drug concentration in individual rats on the basis of sparse data or information obtained in separate experiments. This is particularly important in, e.g., behavioral pharmacology studies where blood sampling may interfere with the behavioral readout.<sup>13</sup>

### 5.38.2.2 Target Site Distribution: The Estimation of Drug Concentrations in the Biophase In Vivo

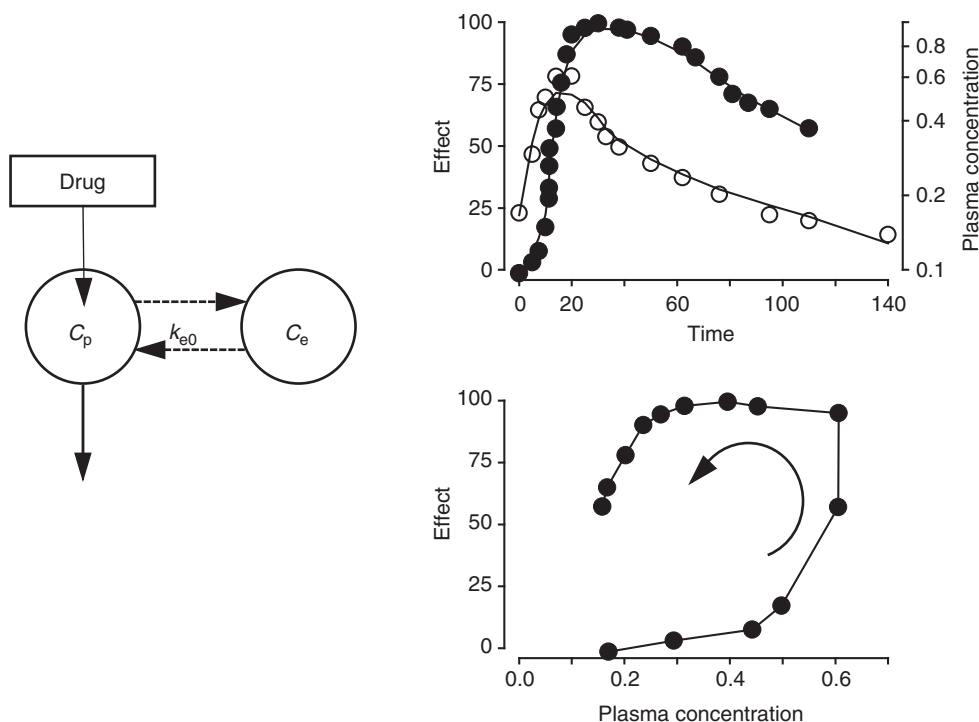

PK/PD modeling studies typically utilize drug concentrations in plasma as a measure of internal exposure to the drug. Most drugs however have a target site in peripheral tissues. For drugs producing their biological effect in a peripheral tissue, distribution to the site of action may represent a rate-limiting step for producing the biological effect. Typically this is reflected in a delay in the time course of the pharmacological effect relative to the plasma concentration, which is commonly referred to as ‘hysteresis’ (Figure 1).

In order to account for hysteresis in PK/PD investigations the so-called effect compartment model has been introduced.<sup>14</sup> In this model the distribution of drug to a hypothetical effect site is described by the following differential equation:

$$\frac{dC_e}{dt} = k_{1e} \cdot C_p - k_{e0} \cdot C_e \quad [1]$$

where  $k_{1e}$  and  $k_{e0}$  are the first-order rate constants distribution into and out of the hypothetical effect compartment and  $C_p$  and  $C_e$  are the drug concentrations in plasma and the hypothetical effect compartment, respectively. In this model the amount of drug entering the effect compartment is considered to be negligible and therefore not reflected in the pharmacokinetics of the drug. Furthermore, for reasons of identifiability, the values of  $k_{1e}$  and  $k_{e0}$  are usually set equal to each other. In this manner it is inherently assumed that in steady state the drug concentration in the biophase is identical to the (free) plasma concentration.

The effect compartment model has been shown to be highly useful in describing delayed drug effects owing to distributional processes. The model has also been successfully applied in preclinical studies to derive meaningful in vivo drug concentration–effect relationships.<sup>15</sup> However, although for many drugs the assumption that in steady state the drug concentration in the effect compartment is identical to the (free) plasma concentration is plausible, this may not always be the case. Particularly for relatively large hydrophilic molecules and for compounds that are substrates for specific transporters distribution to the target site be restricted. This especially concerns drugs with an intracellular

**Figure 1** Schematic representation of the effect compartment model to account for delays (hysteresis) in the time course of the drug effect relative to the plasma concentration. By estimation of the rate constant  $k_{e0}$  the relationship between the drug concentration in plasma ( $C_p$ ) and the hypothetical effect site ( $C_e$ ) is characterized. In this manner target site drug concentration–effect relationships can be derived from plasma concentrations.

target (e.g., cytostatic drugs) and drugs that act in tissues which are protected by specific barriers (e.g., the central nervous system).<sup>3</sup> Recently several specific transporters have been discovered which may restrict the access of a drug to the site of action.<sup>16</sup> For drugs acting in the central nervous system measures of target exposure can be indispensable in PK/PD modeling. A novel technique for obtaining information on target site exposure in the central nervous system is intracerebral microdialysis. An example of the application of intracerebral microdialysis is the investigations on the PK/PD correlation of morphine, where P-glycoprotein and possibly other transporters restrict distribution into the central nervous system.<sup>17</sup>

### 5.38.2.3 Target Site Interaction and Activation: The Pharmacodynamic Basis of Predicting In Vivo Drug Concentration–Effect Relationships

In PK/PD modeling nonlinear drug concentration–effect relationships are commonly described on the basis of a hyperbolic function (the Hill equation or sigmoid  $E_{\max}$  model):

$$E = \frac{\alpha \cdot C^{n_H}}{EC_{50}^{n_H} + C^{n_H}} \quad [2]$$

where  $E$  is the drug effect intensity,  $\alpha$  is the maximum drug effect,  $C$  is the drug concentration,  $EC_{50}$  is the drug concentration at half-maximal effect, and  $n_H$  is the Hill factor, a parameter which reflects the steepness of the concentration–effect curve. Although very useful for descriptive purposes, a limitation is that the Hill equation provides no insight in the underlying factors that determine the shape and the location of the concentration–effect relationship. As such it does not constitute a scientific basis for the prediction of in vivo concentration–effect relationships on the basis of information from in vitro receptor binding assays.

According to receptor theory the in vivo potency (i.e., the  $EC_{50}$ ) and intrinsic activity (i.e.,  $\alpha$ ) are dependent on multiple factors related to the drug (receptor affinity, intrinsic efficacy) and the biological system (receptor density, transducer function relating receptor occupancy to the pharmacological effect) (Figure 2). The prediction of in vivo drug concentration–effect relationships therefore requires a strict separation between drug-specific properties (which can be estimated in in vitro receptor assays) and biological system-specific parameters (which can only be estimated on the basis of in vivo biological systems analysis).<sup>18</sup> Therefore we have developed a mechanism-based PK/PD strategy, which is based on concepts from receptor theory and which constitutes a scientific basis for the prediction of in vivo concentration–effect relationships.<sup>19</sup>

**Figure 2** The shape and location of an in vivo drug concentration–effect relationship depends on the properties of the drug and the properties of the biological system. Mechanism-based PK/PD models describe drug effects in ‘drug-specific’ and ‘system-specific’ parameters. This enables the prediction of in vivo drug concentration–effect relationships in humans on basis of information from in vitro receptor assays and in vivo animal studies.

### 5.38.2.3.1 Full parametric approach to the incorporation of receptor theory: the operational model of agonism

Classical receptor theory combines two independent parts to describe drug action: an agonist-dependent part, incorporating agonist affinity and intrinsic efficacy, and a tissue-dependent part, determined by the receptor concentration and the nature of the stimulus–response relation. The basic form of Black and Leff's<sup>18</sup> operational model of agonism is based on the observation that most agonist concentration–effect curves are hyperbolic in nature. The authors proved algebraically that if the law of mass action governs the binding of an agonist to the receptor:

$$[AR] = \frac{[R_0] \cdot [A]}{K_A + [A]} \quad [3]$$

where  $[AR]$  is the concentration of agonist–receptor complex,  $R_0$  is the total receptor concentration,  $[A]$  the concentration of the agonist, and  $K_A$  is the dissociation equilibrium constant of  $AR$ , then the function relating the concentration of agonist–receptor complex and response can only be a straight line or another hyperbolic. In order to allow for receptor reserve, the linear alternative needs to be rejected in favor of the hyperbolic transducer function, which can be represented as follows:

$$\frac{E}{E_m} = \frac{[AR]^n}{K_E^n + [AR]^n} \quad [4]$$

where  $E$  is the response,  $E_m$  is the maximum system response,  $K_E$  is the value midpoint location of the transducer function, that is  $[AR]$ , that elicits half-maximal effect, and  $n$  is the slope of the transducer function. Combining eqns [3] and [4] yields an explicit model of agonism describing the pharmacological effect in terms of agonist concentration:

$$E = \frac{E_m \cdot \tau^n \cdot [A]^n}{(K_A + [A])^n + \tau^n \cdot [A]^n} \quad [5]$$

where the transducer ratio  $\tau$  is defined as  $R_0/K_E$  as a measure of the efficiency of the occupied receptors into pharmacological effect.

Leff *et al.*<sup>20</sup> have shown that the operational model of agonism can be employed to obtain estimates of affinity and intrinsic efficacy of a partial agonist by comparison with a full agonist. This so-called ‘comparative method’<sup>21</sup> is based on the idea that for a full agonist the Hill equation parameters, intrinsic activity ( $\alpha$ ) and Hill slope ( $n_H$ ), are identical to the operational model parameters  $E_m$  and  $n$  respectively. Therefore, it has been shown previously that when  $E_m$  and  $n$  are constrained to the estimates of  $\alpha$  and  $n_H$  for the full agonist, respectively,  $K_A$  and  $\tau$  for a partial agonist can be estimated by directly fitting the concentration–effect data to eqn [5]. To date the application of the comparative method has been confined mainly to in vitro studies. Recently, however, the operational model of agonism has been successfully applied in a series of investigations on the PK/PD correlations of  $A_1$  adenosine receptor agonists,<sup>22,23</sup>  $\mu$  opioid receptor (MOP) agonists,<sup>15,24</sup> and 5HT<sub>1A</sub> agonists.<sup>25</sup> Simultaneous analysis of in vivo concentration–effect relationships of different compounds within the nonlinear mixed effects modeling software NONMEM has been a key feature in these applications.

### 5.38.2.3.2 Semiparametric approach to the incorporation of receptor theory

A limitation of the operational model of agonism is that it contains a strict assumption on the shape of the transducer function. In theory a transducer function can take any shape. For this reason a semiparametric approach to the incorporation of receptor theory in PK/PD modeling has been proposed. In this approach the interaction between the drug and its receptor is still described by a hyperbolic function (eqn [1]), but no specific assumptions are made on the shape of the transducer function. The approach is based on Stephenson's concept of a stimulus to the biological system as result of the drug–receptor interaction.<sup>26</sup> This stimulus is defined as:

$$S = \frac{E \cdot [AR]}{[R_0]} = \frac{e \cdot [A]}{[A] + K_A} \quad [6]$$

where  $S$  is the stimulus to the biological system and  $e$  is a dimensionless proportionality factor denoting the power of a drug to produce a response in a tissue. An important feature is that the intensity of the drug response is not directly proportional to the stimulus. Instead the response is assumed to be a function  $f$  of the stimulus that is monotonically

increasing and continuous:

$$\frac{E_A}{E_{\max}} = f(S) = f\left[\frac{e \cdot [A]}{[A] + K_A}\right] \quad [7]$$

in which  $E_{\max}$  is the maximum effect of the hyperbolic concentration–effect relationship. Thus the introduction of the function  $f$  dissociates receptor stimulus and tissue response as directly proportional quantities. This also eliminates the necessity for the assumption that a maximal tissue response requires maximal receptor occupancy. This model was further refined by Furchgott,<sup>27</sup> who defined the concept of intrinsic efficacy  $\varepsilon$  as

$$\varepsilon = \frac{e}{[R_0]} \quad [8]$$

thereby directly incorporating the receptor density  $R_0$  into the model as major determinant of the effect. The factor  $\varepsilon$  characterizes the capacity of a drug to initiate a stimulus per receptor. Thus  $\varepsilon$  is a strictly drug-specific parameter. The incorporation of the term  $\varepsilon$  into eqn [5] results in

$$\frac{E_A}{E_{\max}} = f(S) = f\left[\frac{\varepsilon \cdot [R_0] \cdot [A]}{[A] + K_A}\right] \quad [9]$$

Recently, a semiparametric approach to the incorporation of receptor theory in PK/PD modeling has been successfully applied in investigations on  $\gamma$ -aminobutyric acid A (GABA<sub>A</sub>) receptor agonists.<sup>28</sup> A parameterized transduction function to describe GABA<sub>A</sub> receptor activation is presented below (see Section 5.38.3.3).

#### 5.38.2.4 Transduction: The Modeling of Time-Dependent Pharmacodynamics to Derive In Vivo Drug Concentration–Effect Relationships

Transduction refers to the process of receptor activation in the ultimate pharmacological response. Specifically, binding of a drug molecule to a biological target initiates a cascade of biochemical and/or electrophysiological events resulting in the observable biological response. For most receptors (e.g., G protein-coupled receptors) second messengers such as phospholipases (e.g., 1,4,5-inositol triphosphate, diacylglycerol) and nucleotide cyclases (e.g., cAMP) serve as second messengers. For other receptors (e.g., glucocorticoid receptors) transduction is mediated through interaction with DNA thus regulating the expression of second messengers, proteins, or enzymes.

Large differences exist in the rates at which the various transduction processes occur in vivo. In many instances transduction is fast (i.e., operating with rate constants in the range of milliseconds to seconds) relative to the rate constants governing the disposition processes (typically minutes to hours). In that situation the transduction process determines the shape and the location of the in vivo concentration–effect relationship,<sup>18,19</sup> but it does not influence the time course of the drug effect relative to the plasma concentration. In contrast, transduction in vivo can also be slow, operating with rate constants in the order of hours to days, in which case transduction can become an important determinant of the time course of drug action.

As an approach to account for delays in between the drug concentration and effect, Dayneka *et al.*<sup>29</sup> have proposed a family of four in direct response models on the basis of the following equation

$$\frac{dR}{dt} = k_{\text{in}} - k_{\text{out}} \cdot R \quad [10]$$

where  $R$  is a physiological entity, which is constantly being produced and eliminated in time,  $k_{\text{in}}$  is the zero-order rate constant for production of the physiological entity and  $k_{\text{out}}$  is the first-order rate constant for its loss. In this model the drug effect,  $f(C)$ , is described as stimulation ( $[1 + f(C)]$ ) or inhibition ( $[1 - f(C)]$ ) of the factors controlling either the input or the dissipation of drug response ( $k_{\text{in}}$  or  $k_{\text{out}}$ ) in a direct concentration-dependent manner. The indirect response model has been successfully applied in preclinical investigations to derive in concentration–effect relationships of drugs with an indirect mechanism of action.<sup>30</sup>

For the modeling of complex transduction mechanisms, transduction can be modeled mechanistically on basis of intermediary processes between pharmacokinetics and response. In mathematical terms, the so-called transit compartment model has been proposed. This model relies on a series of differential equations to describe the cascade of events between receptor activation and final response.<sup>31</sup> Well-known examples of applications of this type of modeling are the modeling of the genomic effects of corticosteroids<sup>32</sup> and the modeling of hematologic toxicity in

cancer.<sup>33</sup> The transit compartment model is attractive because of its flexibility, but for it to become fully mechanistic, pertinent information on the processes on the causal path is required. This underscores the need for biomarkers to characterize transduction mechanisms.<sup>3</sup>

### 5.38.2.5 Functional Adaptation: Modeling of Homeostatic Feedback to Derive In Vivo Concentration–Effect Relationships

Apart from a delay in the pharmacological response relative to the drug concentration in plasma, complex pharmacological effects versus time profiles may be observed when drug exposure leads to tolerance/sensitization or when homeostatic feedback mechanisms are operative. In those situations modeling of the homeostatic feedback is imperative for deriving in vivo drug concentration–effect relationships. Over the years several mathematical models for the characterization of homeostatic feedback have been proposed.

A useful model to describe complex effect versus time profiles is the so-called ‘push-and-pull’ model.

$$\begin{cases} \frac{dR}{dt} = k_{in} \cdot [1 - f(C)] - k_{out} \cdot R \cdot M \\ \frac{dM}{dt} = k_m \cdot R - k_m \cdot M \end{cases} \quad [11]$$

where  $C$  the drug concentration,  $M$  is a response modifier value, and  $k_m$  is the rate constant for formation and dissipation of the response modifier. Due to its plasticity the push-and-pull model could be successfully applied to describe tolerance to the diuretic response upon repeated administration of furosemide.<sup>34</sup>

Another example of a PK/PD model describing tolerance is the ‘precursor pool’ model.

$$\begin{cases} \frac{dPool}{dt} = k_{in} - k_{loss} \cdot Pool \cdot [1 - f(C)] \\ \frac{dR}{dt} = k_{loss} \cdot Pool \cdot [1 - f(C)] - k_{out} \cdot R \end{cases} \quad [12]$$

where  $Pool$  is the precursor pool value and  $k_{loss}$  is the first-order rate constant for release of precursor into the central compartment. The precursor pool model can conceptually be considered a description of a tachyphylactic system and has been successfully applied to describe the effects of neuroleptic drugs on prolactin balance.<sup>35</sup>

Attempts to model physiological counterregulatory mechanisms have resulted in a series of advanced models describing complex behavior. These models are in part based on the work by Ekblad and Licko.<sup>36</sup> An example is the model proposed by Bauer *et al.* to characterize tolerance to the hemodynamic effects of nitroglycerin in experimental heart failure.<sup>37</sup> In the meantime this type of model of physiological counterregulatory effect has been successfully applied to describe tolerance and rebound to the effects of drugs such as alfentanil and omeprazole.<sup>38–40</sup> Moreover, a dynamic systems model has been proposed, which can account for the complex hemodynamic effects of arterial vasodilators (e.g., nifedipine) for which rate of administration is a major determinant of the effects.<sup>41,42</sup> The most recent development in the incorporation of dynamic systems analysis in PK/PD modeling has been the conceptualization of the so-called ‘set-point’ model.<sup>43</sup> This model was designed to describe complex effects versus time profiles of the hypothermic response following the administration of 5HT<sub>1A</sub> receptor agonists to rats. In this model the indirect physiological response model is combined with a thermostat-like regulation of body temperature. Specifically in the model, body temperature and set-point temperature are interdependent through a feedback loop. This model has been successfully applied in preclinical investigations aiming at the characterization of the in vivo concentration–effect relationships of 5HT<sub>1A</sub> receptor partial agonists.<sup>25</sup>

### 5.38.2.6 Disease: Modeling of Disease Processes to Derive In Vivo Drug Concentration–Effect Relationships

The latest development in PK/PD concerns the modeling of disease processes. Disease models are particularly important for drugs that interact in a highly specific manner with the disease process and that may have no direct observable effects in healthy subjects. Modeling of disease processes is imperative for drugs that are specifically designed to modify disease progression.

Chan and Holford<sup>44</sup> and Holford and Peace<sup>45</sup> were among the first to propose disease progression models for clinical rating scales. In these models the signs and/or symptoms of disease and their response to treatment are modeled

directly, without consideration of the underlying biological system. Recently a theoretical framework for mechanism-based disease progression modeling has been proposed.<sup>46</sup> In the meantime steps have been taken toward the application of such mechanistic models for the effects of thiazolidinedione insulin-sensitizing agents (e.g., pioglitazone) in type 2 diabetes mellitus, using biochemical indices such as fasting plasma glucose concentration (FPG), plasma insulin, and split proinsulin concentrations and % glycosylated hemoglobin (HbA<sub>1c</sub>) as biomarkers.<sup>47,48</sup>

To date there are no reports of preclinical investigations with the aim to derive in vivo drug concentration effect relationships by modeling disease processes.

### 5.38.3 Application of Pharmacokinetic–Pharmacodynamic Modeling in Drug Design and Lead Optimization

#### 5.38.3.1 Adenosine A<sub>1</sub> Receptor Agonists

The endogenous nucleoside adenosine exerts a variety of physiological effects via interactions with a family of G protein-coupled receptors consisting of four subtypes: the adenosine A<sub>1</sub>, A<sub>2A</sub>, A<sub>2B</sub>, and A<sub>3</sub> receptors.<sup>49</sup> The A<sub>1</sub> receptor is the most comprehensively studied adenosine receptor subtype and has been cloned from a number of species, including humans. A<sub>1</sub> receptors are believed to act mainly via the G<sub>i/o</sub> family of G proteins and are widely expressed in the brain, spinal cord and a variety of peripheral tissues such as adipose tissue, heart, eye, adrenal gland, liver, kidney, salivary glands, and GI tract.<sup>49</sup> Despite this widespread distribution, A<sub>1</sub> knockout mice develop normally and display relatively subtle differences compared to wild-type animals, suggesting that adenosine A<sub>1</sub> receptors are particularly important under pathophysiological conditions.<sup>50</sup>

There has been considerable interest in the adenosine A<sub>1</sub> receptor as a potential target for therapeutic intervention for a variety of indications, such as cardiac arrhythmias, metabolic diseases, neurodegenerative diseases, neuropathic pain, and renal disorders.<sup>51,52</sup> Stimulation of the A<sub>1</sub> receptors in the heart produces negative dromo-, chrono-, and inotropic effects and adenosine itself is used clinically to terminate paroxysmal supraventricular arrhythmias and for myocardial perfusion imaging.<sup>51,52</sup> In addition, an N<sup>6</sup>-substituted derivative of adenosine, tecadenoson (CVT-510) is a selective A<sub>1</sub> receptor agonist in phase III clinical trials for the treatment of supraventricular tachycardia.<sup>138</sup> On the other hand, the pronounced cardiodepressant effects induced by stimulating the A<sub>1</sub> receptor have been a major impediment to the research into the development of selective A<sub>1</sub> receptor ligands for other potential indications. One potential strategy to overcome this issue is based on the concept that low-efficacy (partial) agonists may display greater tissue selectivity compared to high-efficacy (full) agonists,<sup>53</sup> and during the last decade significant efforts have been put into medicinal chemistry programs targeting the development of selective, partial agonists for the adenosine A<sub>1</sub> receptor.<sup>52,54,55</sup>

An example of how such tools have been used to develop novel, mechanism-based PK/PD models is a project exploring the potential of a series of deoxyribose and 8-alkylamino analogs of N<sup>6</sup>-cyclopentyladenosine (CPA), which were identified as adenosine A<sub>1</sub> receptor agonists with reduced intrinsic efficacy<sup>54,55</sup> as antilipolytic agents for the treatment of non insulin-dependent diabetes mellitus. Increased levels of non-esterified fatty acids (NEFAs) are a characteristic of non insulin-dependent diabetes and are believed to exacerbate insulin resistance and hyperglycemia. Therefore, selective A<sub>1</sub> receptor agonists may provide a novel therapeutic strategy for the treatment of diabetes, since stimulation of adenosine A<sub>1</sub> receptors in adipose tissue has been shown to decrease NEFA levels in rat and human.<sup>51</sup>

A key first step in this project was the development of an efficient and quality animal model and sensitive analytical assays for simultaneous and detailed characterization of the pharmacokinetics and time course of effect of efficacy and safety biomarkers. For this purpose, conscious, freely moving rats were used with several arterial and venous cannulae which were implanted under anesthesia several days prior to the experiment, which in a single animal allowed for continuous hemodynamic recordings and repeated arterial blood sampling for measurement of drug and NEFA levels following controlled intravenous drug infusion.<sup>56,57</sup>

The CPA analogs that were studied in this in vivo model had previously been demonstrated to display lower 'GTP shifts' in an in vitro binding assay of the adenosine A<sub>1</sub> receptor than CPA itself. The guanosine triphosphate (GTP) shift is defined as the ratio between the apparent affinity in the presence and absence of GTP and is considered to be an in vitro measure of efficacy of A<sub>1</sub> receptor ligands.<sup>54</sup> By applying an integrated PK/PD modeling approach, it was found that the CPA analogs with a lower in vitro GTP shift displayed a reduced cardiovascular response and did indeed behave as partial agonists in vivo as evidenced by a significantly lower estimate of intrinsic activity ( $\alpha$ ) for the effect on heart rate.<sup>56,57</sup> Subsequently, the cardiovascular data for 10 analogs were analyzed simultaneously using the operational model of agonism (eqn [5]) and the 'comparative method' (see Section 5.38.2.3.1), assuming a direct link between drug exposure and pharmacodynamic effect. The key finding of this analysis, which provided the first 'proof of principle' for this mechanism-based PK/PD approach, was that the estimates of in vivo affinity ( $K_A$ ) and efficacy ( $\tau$ ) were highly

**Figure 3** Relationship between in vitro GTP shift at the adenosine  $A_1$  receptor and intrinsic activity ( $\alpha$ ) for the in vivo effect on NEFAs and heart rate in rats.

consistent with the results obtained from in vitro studies, i.e., in vivo estimates of  $K_A$  correlated very well with the in vitro estimates of  $K_i$  and the in vivo estimates of  $\tau$  with the in vitro estimates of GTP shift.<sup>22</sup> A main utility of this approach compared to more empirical modeling strategies is that it provides a more robust basis for prediction of drug effects between different systems, since it explicitly separates drug and system properties in the model. This is exemplified in Figure 3, which shows the nonlinear relationship between the in vitro GTP shift and maximum effect on heart rate in vivo predicted by the mechanistic model.<sup>22</sup> Information like this not only provides novel mechanistic insights but can also be used to design effective and predictive in vitro and in silico screening strategies in drug discovery programs.

In order to validate the hypothesis that reducing intrinsic efficacy within the CPA series could enhance the cardiovascular safety window, the next step in this program was to compare the effects on heart rate with those on NEFA levels. It was indeed found that several analogs displayed profoundly reduced cardiovascular effects but still produced near-maximal inhibition of NEFAs in the rat model.<sup>58</sup> Once again, the operational model of agonism (eqn [5]) was employed to simultaneously analyze the NEFA effects of all ligands, this time incorporated into an indirect effect model (eqn [10]) to account for hysteresis between drug concentration and pharmacodynamic response. This approach yielded estimates of in vivo efficacy and affinity for the adenosine  $A_1$  receptor-mediated effect on NEFAs that could be compared directly with those obtained for the effect on heart rate. The main outcome of this analysis was that on average all compounds displayed an  $\sim 38$ -fold higher efficacy ( $\tau$  in eqn [5]) for the NEFA effect compared to the cardiovascular effect, consistent with findings that the density of adenosine  $A_1$  receptors is  $\sim 25$ -fold higher in adipocytes compared to cardiac tissue.<sup>23</sup> Finally, this integrated PK/PD model for efficacy and safety was linked back to the in vitro data as described above and Figure 3 shows the final model which can predict the therapeutic window in vivo for any compound from in vitro GTP shift data. An important conclusion from the model in Figure 3 is that it indicates that even compounds with GTP shift values close to unity (i.e., ligands that appear to behave as antagonists in vitro) may still produce significant inhibition of lipolysis in vivo, whereas they are expected to be without cardiodepressant side effects. This illustrates our view that mechanism-based PK/PD modeling can yield insights that can provide new directions for drug discovery program in the search for compounds with improved efficacy and/or safety profiles.

### 5.38.3.2 $\mu$ Opioid Receptor Agonists

Opioid receptors are activated by both endogenously produced peptides (known as endorphins or enkephalins)<sup>59,60</sup> and exogenously administered opioid drugs which are among the most effective analgesics known. The opium alkaloid morphine and synthetic analogs are widely used in clinical practice for the treatment of severe pain. The opioid receptors belong to the family of G protein-coupled receptors (GPCRs), which are predominantly signaling through the  $G_{i/o}$  transduction pathway. Four subtypes have been identified:  $\mu$ ,  $\delta$ ,  $\kappa$ , and N/OFQ opioid receptors (MOP, DOP, KOP, and NOP receptors, respectively).<sup>61</sup> An alternative nomenclature proposed by the International Union of Pharmacology to replace the Greek symbols  $\mu$ ,  $\delta$ , and  $\kappa$  by OP3, OP1, and OP2, respectively has not gained wide acceptance in the literature and has now been withdrawn.<sup>62</sup>

The MOP receptor has been the most widely studied member of the opioid receptor family and it is generally believed that the main clinical effects of currently used opioid drugs are mediated predominantly via agonism at this subtype.<sup>63</sup> Despite the fact that morphine and synthetic analogs such as fentanyl are well established in clinical analgesia and anesthesia, there is still considerable interest in the development of novel agents that may address some of the key limitations of existing drugs, in particular the occurrence of prolonged respiratory depression following anesthesia.<sup>64</sup> Another limitation to the long-term use of current opioid drugs as analgesics is the development of tolerance, although the significance of the clinical manifestation of this in some patient populations remains unclear.<sup>61,65</sup>

During the last decade, exciting new insights have been obtained in the molecular and pharmacological properties of the MOP receptor that may provide the basis for the development of the next generation of opioid drugs. For example, although only a single gene for the MOP receptor has been identified, it has been suggested that pharmacologically it may manifest itself as a heterogeneous phenotype, due to for example alternative splicing and heterodimerization.<sup>66–71</sup> In addition, considerable progress has been made in elucidating the molecular mechanisms that may underlie tolerance development to opioid drugs and one of the main hypotheses has been that this phenomenon is due to MOP receptor downregulation and/or desensitization in response to agonism.<sup>61</sup> However, although at the cellular level MOP receptor downregulation, uncoupling, and desensitization can be readily demonstrated in *in vitro* systems, the relevance of these findings in the context of clinical tolerance development to opioid analgesics remains controversial.<sup>61</sup> A number of integrated PK/PD models have been proposed to characterize functional adaptation to the effect of opioids *in vivo*. For example, some models describe tolerance development on the basis of distribution to a hypothetical tolerance compartment<sup>72</sup> whereas others postulate a physiological counter-regulatory mechanism to characterize functional adaptation.<sup>39</sup> A limitation to these models is that they are largely empirical in nature and that they do not incorporate MOP receptor regulation as a main mechanism of functional adaptation. Therefore, more recently focus has shifted toward the development of mechanism-based model to describe, explain, and predict opioid tolerance development.

An example of such an approach is based on the use of quantitative electroencephalogram (EEG) analysis, which has been used successfully as a biomarker for MOP receptor activity in preclinical models and humans.<sup>73</sup> Using the synthetic opioid alfentanil as a reference compound, a rat model was developed in which the amplitudes in the 0.5–4.5 Hz frequency band of the EEG spectrum were used to describe the time course of effect and derive PK/PD relationships for MOP receptor agonists.<sup>73</sup> In order to develop an initial mechanism-based PK/PD model, alfentanil and two, related 4-anilidopiperidine analogs, fentanyl and sufentanil, were studied. *In vitro* studies had demonstrated that these three ligands display very different levels of intrinsic efficacy at the MOP receptor, as judged by the ‘sodium shift’ which is the equivalent of the GTP shift described in [Section 5.38.3.1](#) and is defined as the ratio between a ligand’s MOP receptor affinity in the presence and absence of high concentrations of  $\text{Na}^+$ .<sup>9</sup> Despite the fact that *in vitro* sufentanil behaved as a low efficacy agonist (sodium shift = 2.8) compared to fentanyl and alfentanil (sodium shift = 13.3 and 19.1, respectively), a comparison of the concentration–effect relationships for the EEG effect revealed that *in vivo* the three compounds displayed the same maximal response (intrinsic activity). In order to explain this finding, the operational model of agonism (eqn [5]) was employed to integrate the *in vitro* and *in vivo* data.<sup>9</sup> This analysis showed that the sodium shift *in vitro* provided an accurate prediction of the expression of agonism *in vivo*, that is the *in vivo* efficacy parameter  $\tau$  could be expressed as the product of sodium shift and an agonist-independent constant (4.3). In the operational model of agonism,  $\tau$  is defined as the ratio of total receptor concentration ( $[R_0]$ ) and the midpoint location of the transducer function ( $K_E$ ) which relates agonist-occupied receptors to pharmacological effect (*see* [Section 5.38.2.3.1](#)). Because  $[R_0]$  is specific for a particular pharmacological system and therefore ligand-independent, differences in  $\tau$  are likely to reflect differences in  $K_E$  values between opioid ligands. Importantly, the model predicted that on the basis of the *in vitro* sodium shift it will not be possible to detect ligands that will behave as partial agonists in the EEG model, since a value of the sodium shift close to unity would still be expected to result in the expression of maximal possible intrinsic activity ([Figure 4](#)). This is consistent with findings described for adenosine  $A_1$  agonists in [Section 5.38.3.1](#), which suggests that amplification of agonist properties may often result in the expression of higher levels of efficacy *in vivo* compared to *in vitro*, which calls into question the reliability of some (high-throughput) *in vitro* screens and underscores the important role mechanism-based PK/PD modeling can play in drug discovery programs, in particular ones targeting receptor agonists.

This mechanism-based PK/PD model was successfully applied to predict the *in vivo* potency and intrinsic activity of the novel synthetic opioid remifentanyl and its active metabolite GR90291 in humans on the basis of the results of preclinical investigations in rats.<sup>11</sup> The mechanism-based PK/PD model was subsequently used to describe the rapid functional adaptation observed with alfentanil following repeated administration in the rat EEG model. It was shown that a second administration of alfentanil resulted in a parallel shift of the *in vivo* concentration–effect relationship with an almost twofold decrease in potency ( $\text{EC}_{50}$ ) without affecting the maximal EEG response. In terms of the

**Figure 4** Operational model of agonism simulations showing the predicted in vivo concentration–EEG effect relationships on the basis of in vitro radioligand binding studies for MOP receptor agonists with constant affinity and different sodium shifts. The model predictions were obtained using eqn [5] with the following parameter values:  $E_m = 100\%$ ,  $n = 2.3$ ,  $K_A = 1$ ,  $\tau = 4.3 \times$  sodium shift. The solid and dashed green lines show the model predictions for alfentanil (sodium shift = 19.1) in an intact system and one with a 40% reduction in  $\tau$  due to receptor desensitization or loss.

operational model, this could be explained by the presence of a high ‘receptor reserve’ and a decrease in  $\tau$  reflecting a  $\sim 40\%$  loss of functional MOP receptors without changes in receptor affinity.<sup>74</sup> Interestingly, this model-derived estimate of fractional receptor loss is very similar to ones obtained using molecular techniques following chronic opioid exposure.<sup>61</sup> Further validation of the mechanism-based PK/PD model was obtained using a novel experimental approach of MOP receptor ‘knockdown’ with the irreversible MOP antagonist  $\beta$ -funaltrexamine ( $\beta$ -FNA). It was shown that pretreatment of rats with  $\beta$ -FNA prior to the PK/PD experiment could produce a gradual reduction in the number of MOP receptors in rat brain of 40–60% without affecting the affinity of alfentanil, as judged by radioligand binding studies. Consistent with previous findings which had suggested the presence of a MOP receptor reserve for the EEG effect of opioids in this model, this loss of receptors did not result in a reduced intrinsic activity of alfentanil but in a two to threefold loss of potency in  $\beta$ -FNA-treated animals, again in line with expectations of a reduction in  $\tau$  in the mechanism-based model.<sup>24</sup> An interesting feature of the pharmacological receptor knockdown approach, which differentiates it from more conventional molecular biology ‘knockout’ techniques, is that it provides a dynamic in vivo model system for the investigation of receptor turnover. Thus, it was observed that the effect on the concentration–EEG effect relationship for alfentanil was the same when  $\beta$ -FNA pretreatment was given 35 min or 24 h prior to the PK/PD investigation. In contrast, the marked effects of alfentanil on respiration depression and muscle rigidity appeared to be unchanged following 24 h washout of  $\beta$ -FNA compared to vehicle treatment but were not observed at all following 35 min washout, which could suggest that turnover of receptors mediating respiratory depression and muscle rigidity is faster than that of receptors mediating EEG effects. Whether or not this observation is related to for example differential expression and turnover of MOP splice variants in different tissues remains to be investigated further.<sup>64</sup>

Recently, it has been demonstrated that the in vivo knockdown approach can also be applied to other GPCR systems. For example, it was shown that the irreversible adenosine  $A_1$  receptor antagonist, 8-cyclopentyl-3-*N*-[3-(4-(fluorosulphonyl)(benzoyl)-oxy)-propyl]-1-*N*-propyl-xanthine (FSCPX)<sup>75</sup> produces dose-dependent, irreversible antagonism of the cardiovascular effects of CPA in the conscious rat,<sup>76</sup> an approach which could be used to further validate the mechanistic PK/PD model developed for adenosine  $A_1$  receptor agonists described in Section 5.38.3.1.

### 5.38.3.3 GABA<sub>A</sub> Receptor Agonists

The GABA<sub>A</sub> receptor is a ligand-gated ion channel, with five homologous membrane-spanning subunits that form an integral  $\text{Cl}^-$  channel.<sup>77–80</sup> Upon binding to the receptor, the neurotransmitter GABA facilitates the opening of the chloride channel, resulting in hyperpolarization of the neuron.<sup>81,82</sup> GABA<sub>A</sub> receptors can be formed from a pool of different subunits. Depending on their subunit composition, receptors exhibit distinct pharmacological and

electrophysiological properties. There is a wide variation in the expression of different subtypes in various neuronal populations and in different regions of the CNS. To date, at least 18 human GABA<sub>A</sub> receptor proteins have been described. Furthermore at least eight GABA<sub>A</sub>-receptor subunit types can be distinguished:  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\theta$ ,  $\epsilon$ ,  $\pi$ , and  $\rho$ .<sup>79,83,84</sup>

The GABA<sub>A</sub> receptor is an important target for the development of new drugs for a wide array of CNS disorders such as epilepsy, sleep disorders, anxiety, stress, depression, and cognitive failure.<sup>85–87</sup> The development of novel GABA<sub>A</sub> receptor ligands as innovative drugs is specifically directed toward the design of partial agonists with an improved selectivity of action, inverse agonists for the treatment of cognitive failure, and receptor subtype selective ligands.

Quantitative EEG parameters, specifically power or amplitudes in the  $\beta$ -frequency range, have proven valuable measures of GABA<sub>A</sub> receptor-mediated drug effects in vivo.<sup>88,89</sup> The EEG parameters appear to fulfill many of the characteristics of ideal pharmacodynamic measures, being continuous, sensitive, and reproducible.<sup>90</sup> An important feature of EEG effect measurements is that they can be obtained in both laboratory animals and humans. This enables the investigation of interspecies correlations of the pharmacodynamics.

Increase in  $\beta$ -activity has been used by several investigators to characterize the concentration–effect relationships of a variety of benzodiazepines in both experimental animals<sup>7,12,91,92,101</sup> and in humans.<sup>93–95</sup> In addition, for barbiturates, propofol, and neuroactive steroids, the changes in the  $\beta$ -frequency range has been successfully used as a biomarker in PK/PD investigations.<sup>92,95–97</sup> Interestingly, the GABA reuptake inhibitor tiagabine gives a characteristic change in the EEG comparable to benzodiazepines.<sup>98</sup> Using the  $\beta$ -frequency in the EEG as biomarker, benzodiazepines exhibit nonlinear concentration–effect relationships, which are readily described by the sigmoid  $E_{\max}$  pharmacodynamic model (eqn [2]). Between benzodiazepines wide differences in potency ( $EC_{50}$ ) and intrinsic activity ( $E_{\max}$ ) have been observed. Furthermore, inverse agonists display a negative EEG effect.<sup>91,99,101</sup> Interestingly, neuroactive steroids exhibit biphasic concentration–effect relationships in vivo. At low concentrations the EEG effect increases from baseline to a maximum value, which is approximately two to three times higher than the maximum observed for the benzodiazepine displaying the highest intrinsic activity (diazepam). At higher concentrations the effect decreases below the baseline toward isoelectric EEG. Based on these observations, a novel mechanism-based PK/PD modeling approach for GABA<sub>A</sub> receptor agonists has been proposed, which features a parameterized biphasic stimulus–response relationship.<sup>96</sup> Specifically, this model contains separate expressions to characterize the drug–receptor interaction and the transduction processes. The drug receptor interaction is characterized in terms of in vivo affinity and intrinsic efficacy using a hyperbolic function (eqn [6]). The transduction  $f$  (in eqn [7]) is described by a parabolic function according to:

$$E = E_{\text{top}} - a \cdot (S^d - b)^2 \quad [13]$$

where  $S$  represents the stimulus to the biological system resulting from GABA<sub>A</sub> receptor activation,  $E_{\text{top}}$  represents the top of the parabola,  $a$  is a constant reflecting the slope of the parabola;  $b^{1/d}$  is the stimulus for which the top of the parabola (i.e., the maximal effect,  $E_{\text{top}}$ ) is reached and the exponent  $d$  determines the asymmetry of the parabola. When no drug is present the EEG is equal to its baseline value ( $E_0$ ). Equation [13] then reduces to:

$$E_0 = E_{\text{top}} - a \cdot b^2 \quad [14]$$

Substituting eqn [13] in eqn [14], and rearranging yields:

$$E = E_0 - a \cdot [(S^d)^2 - 2 \cdot b \cdot S^d] \quad [15]$$

This parabolic function is determined by three parameters:  $a$ ,  $b$ , and  $d$ . Parameter  $a$  determines the height of the maximal achievable response ( $E_{\text{top}}$ ) and the steepness of the increasing and decreasing wing. Parameter  $b$  determines the location of  $E_{\text{top}}$  and  $d$  determines the asymmetry of the parabola.

The mechanism-based PK/PD model contains two drug-related and three system-related parameters that cannot be estimated independently from a single biphasic drug concentration–effect relationship. Similar to the analysis with the operational model of agonism, the efficacy for drugs can only be estimated compared to the drug with an efficacy that produces the maximal effects possible in the system. This comparative method, originally proposed by Barlow,<sup>21</sup> is based on the idea that the intrinsic activity of a full agonist is identical to the maximum system response. In the present analysis the neuroactive steroid alphaxalone was assumed to be a full agonist and its in vivo efficacy was fixed to the value of 1, resulting in a possible stimulus range between 0 and 1 for positive modulators. The in vivo efficacy for other drugs was estimated relative to the maximal efficacy of alphaxalone.

The model was applied to the concentration–effect relationships of neuroactive steroids.<sup>97</sup> Simultaneous analysis of the concentration–effect relationships of alphaxalone, pregnanolone, ORG 20599, and ORG 21465 on the basis of the mechanism-based model showed that all observations can be described with a single unique transducer function with parameter  $d = 3.4$ . This indicates that the obtained parameter is indeed system-specific and independent of the drug that was used. With respect to the receptor activation model, it was observed that all neuroactive steroids acted as high-efficacy modulators at the GABA<sub>A</sub> receptor with an intrinsic efficacy equal to that of alphaxalone. Wide differences in in vivo potencies were observed which were consistent with the differences in affinity in an in vitro bioassay.<sup>100</sup> Next the model was applied to the concentration–effect relationships of benzodiazepines, imidazopyridines, cyclopyrrolones, and a  $\beta$ -carboline.<sup>101</sup> These compounds differ in intrinsic efficacy at the GABA<sub>A</sub> receptor displaying the entire spectrum from full benzodiazepines receptor agonists, through partial and silent to inverse agonists.<sup>102–104</sup> Simultaneous analysis of the data on the basis of the mechanism-based model allowed estimation of the in vivo efficacy ( $e_{PD}$ ) and affinity ( $K_{PD}$ ) for each of the compounds utilizing the single unique transducer function that had previously been identified for neuroactive steroids. This analysis revealed that the GABA<sub>A</sub> receptor modulators differ from the neuroactive steroids solely in their in vivo efficacy (Figure 5). A highly significant correlation between the in vitro estimates for efficacy (GABA shift) and affinity ( $K_i$ ) and the corresponding in vivo estimates was observed, confirming the validity of the proposed mechanism-based PK/PD model.

An important feature of mechanism-based PK/PD models is that they have much improved properties for extrapolation and prediction. This concerns especially the prediction of in vivo concentration–effect relationships from in vitro receptor assays, and the interspecies extrapolation from laboratory animals to humans of these concentration–effect relationships. The high correlation between the in vitro estimates for efficacy (GABA shift) and affinity ( $K_i$ ) and corresponding in vivo estimates shows that in vivo concentration–effect relationships can be predicted on the basis of in vitro bioassays. Figure 6 shows the complex relationship between the observed maximum EEG effect of GABA<sub>A</sub> receptor ligands and the GABA shift as a measure of intrinsic efficacy at the GABA<sub>A</sub> receptor in vitro. This relationship is rather shallow at low GABA shifts. This shows that the EEG effect is not a very sensitive pharmacodynamic endpoint for the identification of low-efficacy and near-silent agonists. This is important, since partial and near-silent agonists are of considerable interest therapeutically as they may display a much-improved selectivity of action. In contrast, large differences in EEG effects are observed for compounds with intermediate efficacy (benzodiazepines). Finally, the steepness of the stimulus response relationship at high stimulus intensities makes it difficult to identify differences in efficacy for neuroactive steroids.

**Figure 5** The relationship between drug concentration and stimulus at the GABA<sub>A</sub> receptor for the GABA<sub>A</sub> receptor modulators. Concentration ( $\text{ng mL}^{-1}$ ) is depicted on the x-axis in logarithmic scale and the stimulus is depicted on the y-axis. The results of the mechanism-based PK/PD analysis show that functionally benzodiazepines, imidazopyridines, cyclopyrrolones and  $\beta$ -carbolines behave as partial agonists relative to neurosteroids.

**Figure 6** Prediction of in vivo concentration–EEG effect relationships of GABA<sub>A</sub> receptor modulators from in vitro GABA shift. On the y-axis the observed maximal EEG effect is plotted. Compounds with GABA shifts lower than 1 are negative modulators and give negative EEG response compared to baseline. Compounds with GABA shifts higher than 1 are positive modulators and give positive EEG response compared to baseline. It is predicted that compounds with GABA shifts higher than 2 will give biphasic concentration–effect relationships. Note that the GABA shift is depicted in a logarithmic scale.

For the extrapolation from animal to humans, it is important to obtain information about the shape of the stimulus–response relationship in humans. The exact shape of the transducer function in humans remains to be determined. There are indications however that the transducer function is quite similar, since nearly identical concentration–EEG effect relationships in rats and humans have been observed for a number of benzodiazepines.<sup>12</sup>

#### 5.38.3.4 Serotonin (5HT<sub>1A</sub>) Receptor Agonists

A wide array of selective and less selective 5HT<sub>1A</sub> receptor ligands has been developed. It has been shown that these compounds are of value in the treatment of anxiety disorders and depression. In addition they may be of value in therapeutic indications such as aggression, addiction, seizures, nausea, and neuroprotection. The mechanism of action of 5HT<sub>1A</sub> receptor ligands is not entirely resolved. It is believed however that differences in intrinsic efficacy at 5HT<sub>1A</sub> receptors in different areas in the brain are an important determinant of the therapeutic effect. Specifically so-called near-silent agonists are considered of great interest for a number of indications.

The regional distribution of 5HT<sub>1A</sub> receptors within the brain has been studied in many animal species including the rat, mouse, guinea pig, calf, cat, pig, monkey, and human. It has been shown to be similar in these species.<sup>105</sup> In short, 5HT<sub>1A</sub> receptors are distributed throughout the CNS, but high concentrations are found in the hippocampus, septum, and amygdala, areas that are typically thought to be associated with the control of mood.<sup>106</sup> Interestingly, differences in receptor reserve in various parts of the brain have been demonstrated. For example it has been shown that higher levels of receptor reserve are present in the raphe nuclei (mainly, presynaptic somatodendritic autoreceptors), compared to the hippocampus and hypothalamus (mainly postsynaptic receptors).<sup>107</sup> Hence a ligand may act as a full agonist for a presynaptically mediated response, whereas at the same time it may behave as a partial agonist for a postsynaptically mediated response.

Upon administration of 5HT<sub>1A</sub> receptor agonists a series of responses is observed which are all potentially suitable for PK/PD characterization. These in vivo effects can be classified into four groups: physiological (e.g., induction of hypothermia), endocrinological (e.g., stimulation of corticosterone release), behavioral (e.g., induction of flat body posture or forepaw treading), and therapeutic-like effects (e.g., reduction of fear-induced ultrasonic vocalizations or immobility in the forced-swimming test).<sup>108</sup> The hypothermic response is a continuous, reproducible, objective,

sensitive, and selective 5HT<sub>1A</sub> receptor mediated response, making it an attractive pharmacodynamic endpoint in PK/PD investigations. It is well established that the hypothermic effect of 5HT<sub>1A</sub> receptor agonists is caused by a direct effect on the body's set-point temperature.<sup>109</sup> The hypothermic effect of 5HT<sub>1A</sub> receptor agonists has been studied extensively and is considered one of the most robust 5HT<sub>1A</sub> receptor-mediated responses.<sup>110</sup> It is considered the response of choice for the differentiation between full, partial, and silent agonists at the 5HT<sub>1A</sub> receptor.<sup>111</sup> Furthermore, this effect can be observed both in rodents and in humans<sup>111</sup> thus enabling the investigation of animal to human extrapolation.

In PK/PD experiments in chronically instrumented rats the time course of the hypothermic response was determined in conjunction with plasma concentrations for *R*-8-OH-DPAT, *S*-8-OH-DPAT, flesinoxan, buspirone, buspirone's active (and but nonselective) metabolite 1-PP, WAY-100,135, and WAY-100,635.<sup>43,112–114</sup> Briefly, 8 days prior to the experiment, the rats were operated upon. Indwelling cannulae for drug administration and blood sampling as well as a telemetric transmitter in the abdominal cavity for the measurement of core body temperature were implanted. In the PK/PD experiments, conscious freely moving rats received an intravenous infusion of vehicle (saline) or active drug. The 5HT<sub>1A</sub> receptor ligands were administered in a wide range of doses (high, middle, and low), infusion rates (short, intermediate, and computer controlled) and combinations (*R*-8-OH-DPAT with WAY-100,635). In each experiment from each individual rat approximately serial blood samples were taken and subsequently analyzed to determine the time course of the drug concentration.<sup>43,112–114</sup> Body temperature was measured continuously throughout the experiment using the telemetric system. The affinity and the *in vitro* efficacy (agonist ratio) of the various 5HT<sub>1A</sub> receptor agonists have been determined in a series of receptor binding assays.<sup>25</sup>

In investigations where the hypothermic response is studied in detail, complex effect versus time patterns have been observed suggesting the involvement of homeostatic control mechanisms.<sup>115,116</sup> In order to characterize 5HT<sub>1A</sub>-agonist induced hypothermia in a mechanistic manner a mathematical model which describes the hypothermic effect based on the concept of a set-point<sup>116–118</sup> and a general physiological response model<sup>29</sup> has been proposed.<sup>43</sup> Briefly, as an agonist binds to the 5HT<sub>1A</sub> receptor a stimulus,  $S$  is generated, which in turn drives physiological processes that lower the temperature. This stimulus, which is determined by the drug receptor interaction and hence the drug's affinity and efficacy, can be described by a sigmoid function where  $f(C)$  for example equals eqn [2] or [5]. As  $S$  is assumed to be inhibitory, it is defined as  $S = 1 - f(C)$ . As the drug concentration  $C$  changes with time,  $S$  changes as well, governing the first timescale of the model. The second timescale on which the model operates is governed by physiological principles. The model that describes the hypothermic response utilizes the concepts of the indirect physiological response model as described by Dayneka *et al.* (eqn [10]).<sup>29</sup> In this model the change in temperature ( $T$ ) is described as an indirect response to either the inhibition of the production of body heat or the stimulation of its loss, where  $k_{in}$  represents the zero-order fractional turnover rate constant associated with the warming of the body and  $k_{out}$  a first-order rate constant associated with the cooling of the body. The indirect physiological response model is combined with the thermostat-like regulation of body temperature. This regulation is implemented as a continuous process in which the body temperature is compared with a reference or set-point temperature ( $T_{SP}$ ). It is accepted that 5HT<sub>1A</sub> agonists elicit hypothermia by decreasing the value of the set-point temperature  $T_{SP}$ , and hence  $T_{SP}$  depends on the drug concentration  $C$ :  $T_{SP} = T_{SP}(C)$ . It is assumed that  $T_{SP}$  is controlled by the drug concentration  $C$  through eqn [16]:

$$T_{SP} = T_0[1 - f(C)] \quad [16]$$

where  $T_0$  is the set-point value in the absence of any drug:  $T_0 = T_{SP}(0)$ . Combining the indirect physiological response model with the thermostat-like regulation then yields:

$$\begin{cases} \frac{dT}{dt} = k_{in} - k_{out} \cdot T \cdot X^{-\gamma} \\ \frac{dX}{dt} = a(T_0 \cdot [1 - f(C)] - T) \end{cases} \quad [17]$$

in which  $X$  denotes the thermostat signal. The change in  $X$  is driven by the difference between the body temperature  $T$  and the set-point temperature  $T_{SP}$  on a timescale that is governed by  $a$ . Hence when the set-point value is lowered, the body temperature is perceived as too high and  $X$  is lowered. To relate this decreasing signal to the drop in body temperature, an effector function  $X^{-\gamma}$  was designed, in which  $\gamma$  determines the amplification. Raising this function to the loss term  $k_{out} \cdot T$  therefore facilitates the loss of heat. In eqn [17], body temperature and set-point temperature are interdependent and a feedback loop is created that can give rise to oscillatory behavior, as has been shown.<sup>43</sup> The model is able to reproduce the observed complex effect versus time profiles, which are typically observed upon the administration of 5HT<sub>1A</sub> receptor partial agonists.

A population approach<sup>119</sup> was utilized to quantify both the pharmacokinetics and pharmacodynamics of the 5HT<sub>1A</sub> receptor agonists. This enabled the successful characterization of the time course of the hypothermic effect in terms of physiological parameters and drug specific parameters such as potency and intrinsic efficacy.<sup>43,112–114</sup> In the initial version of the model, the sigmoid– $E_{\max}$  model (eqn [2]) was used to describe the direct concentration effect relationships of the 5HT<sub>1A</sub> receptor agonists at the receptor in terms of potency and intrinsic activity. In a subsequent step, which aimed at the development of a fully mechanistic model, the sigmoid– $E_{\max}$  model was replaced by the operational model of agonism<sup>18</sup> (eqn [5]). In this analysis the value of the system maximum  $E_{\max}$  was constrained to the observed maximum effect for a full agonist *R*-8-OH-DPAT. The values of  $K_A$  and  $\tau$  for the various partial agonists were estimated by directly fitting the operational model of agonism to the combined concentration–effect data. The values of  $K_A$  and  $\tau$  are shown in Table 1 together with the corresponding estimates of affinity ( $K_i$ ) and intrinsic efficacy ( $\log[\text{Agonist ratio}]$ ) in a receptor binding assay. The correlation between  $pK_A$  and  $pK_i$  based on [<sup>3</sup>H]-WAY-100,635 was rather poor ( $P > 0.05$ ) compared to similar *in vivo/in vitro* correlations observed for adenosine A<sub>1</sub> agonists, synthetic opiates, and GABA<sub>A</sub> receptor agonists (see previous sections). Close inspection of this correlation showed that flesinoxan deviated from the line of identity. In fact, the correlation between the  $pK_A$  and  $pK_i$  became statistically significant when flesinoxan was excluded from the analysis ( $P < 0.05$ ). Recently Van der Sandt *et al.*<sup>120</sup> have shown that active transport mechanisms (i.e., P-glycoprotein) at the blood–brain barrier are an important determinant of the brain distribution for flesinoxan. Thus it appears that complexities at the level of blood–brain distribution of flesinoxan explain the observed lack of correlation between *in vitro* and *in vivo* receptor affinity estimates.<sup>25</sup> Between the *in vivo* and *in vitro* efficacy ( $\log \tau$  and  $\log[\text{agonist ratio}]$ ) a significant correlation was found ( $P < 0.05$ ). The correlation between  $\log \tau$  and  $\log[\text{agonist ratio}]$  showed further that the *in vivo* ‘test assay’ was more sensitive for detecting 5HT<sub>1A</sub> activity than the agonist ratio. For example, the significant *in vivo* agonist activity demonstrated for WAY-100,135 was not detected *in vitro*.

Thus by combining the semimechanistic PK/PD model for the hypothermic effect of 5HT<sub>1A</sub> agonists with the operational model of agonism, a full mechanistic PK/PD model was obtained, which proved to be highly predictive of the *in vivo* intrinsic activity of ligands at this receptor. This is important, since the pharmacological and therapeutic properties of 5HT<sub>1A</sub> agonists are closely related to the degree of intrinsic activity at 5HT<sub>1A</sub> receptors. The ability of the *in vivo* assay to detect weak partial agonism underscores the importance of the use of *in vivo* models in the development of 5HT<sub>1A</sub> agonists as clinical agents.

An important advantage of mechanism-based PK/PD models is their optimal properties for quantitative extrapolation of pharmacological responses across species. To this end allometric scaling of the rat PD parameters of the set-point model to predict the response in humans for buspirone and flesinoxan has been applied. Parameters were extrapolated based on body weight ( $M$ ) following simple power laws, according to

$$Y = a \cdot M^b \quad [18]$$

**Table 1** Estimates of *in vitro* and *in vivo* affinity and efficacy for the 5HT<sub>1A</sub> receptor ligands

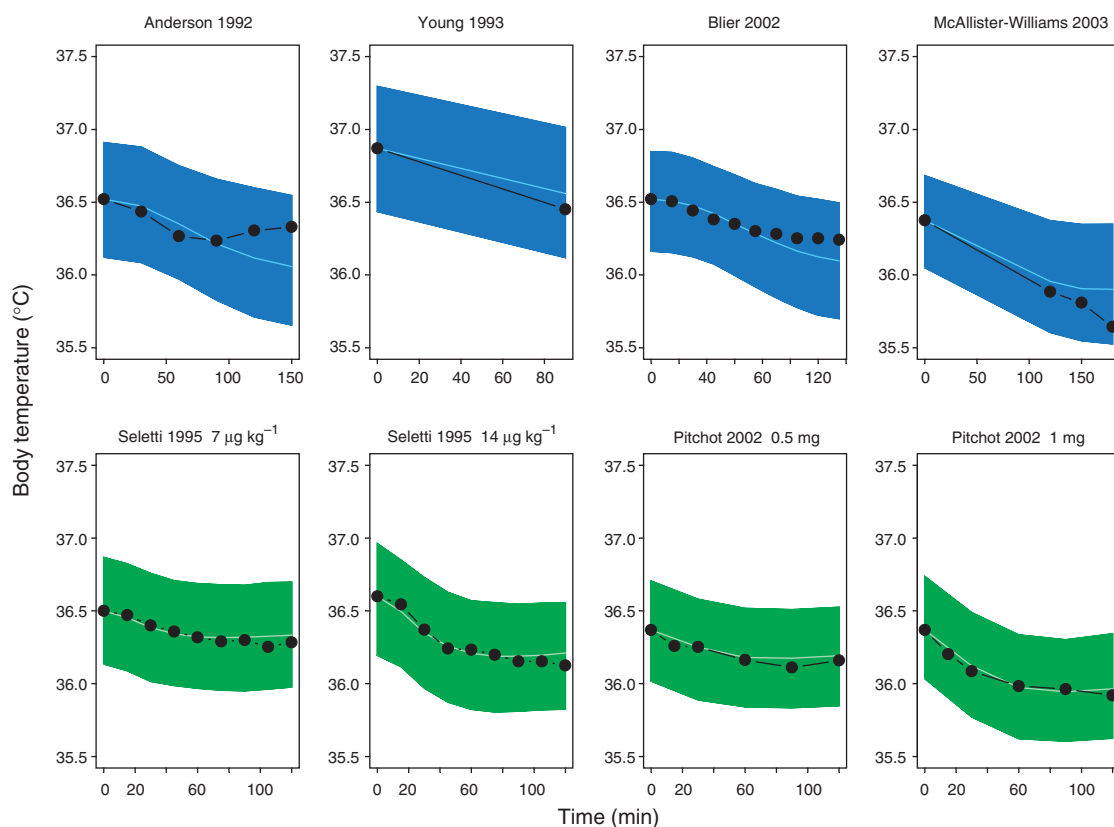

| Drug                | <i>In vitro</i> <sup>a</sup>                |                                      | Agonist ratio | <i>In vivo</i> <sup>b</sup> |               |

<sup>a</sup> *In vitro*: the estimates of affinity ( $pK_i$ ) are determined in the presence of [<sup>3</sup>H]-*R*-OH-DPAT and [<sup>3</sup>H]-WAY-100,635. The ratio between the two  $K_i$ s serves as a measure for efficacy (agonist ratio). The parameters are expressed as mean (SD).

<sup>b</sup> *In vivo*: estimates of *in vivo* affinity and efficacy for the 5HT<sub>1A</sub> receptor ligands on body temperature in the rat. *In vivo* estimates (population mean + coefficient of variation (%)) of affinity ( $pK_A$ ) and efficacy ( $\log \tau$ ) were obtained by fitting the data to the operational model of agonism.

<sup>c</sup> *R*-8-OH-DPAT's value has been fixed to the one obtained in the *in vitro* binding assay.<sup>27</sup>

<sup>d</sup> WAY-100,635 has been determined in a previous analysis.<sup>24</sup>

**Figure 7** Simulated 90th percentile prediction intervals for the hypothermic responses in humans for buspirone (blue)<sup>121–124</sup> and flesinoxan (green)<sup>125,126</sup> by study<sup>125,126</sup> and dose (only the active doses are depicted and the title of each graph denotes refers to the applied study design). The observed hypothermic response is denoted by the filled circles and connecting line.

where the exponent  $b$  assumes multiples of  $1/4$ ,  $Y$  is the parameter of interest, and  $a$  the weight-independent parameter. Typically  $b$  assumes values of  $-1/4$  for growth rates and values of  $3/4$  for rate constants. Considering the fact that the receptor systems are similar across species drug-specific parameters were not scaled. Furthermore, the interindividual variability in response was assumed to be identical between species. Figure 7 depicts the simulated 90th percentile prediction intervals for the hypothermic responses in humans for buspirone<sup>121–124</sup> and flesinoxan.<sup>125,126</sup> Overall the time course of both responses is captured well for both drugs. The results of these preliminary analyses indicate that allometric scaling of mechanistic PK/PD models can be used to predict the pharmacodynamic response in humans. This approach combined with the operational model of agonism provides for a novel way of interpreting in vitro and in vivo pharmacological responses and will ultimately facilitate candidate selections and lead optimization.

### 5.38.3.5 Drug-Induced QT Interval Prolongation

The possibility of torsade de pointes (TdP) is recognized as a potential risk during treatment with over 100 antiarrhythmic and nonantiarrhythmic drugs.<sup>127</sup> TdP is a life-threatening form of ventricular tachycardia and is a documented side effect of over 40 nonantiarrhythmic drugs across all therapeutic drug classes. An unacceptably high incidence of TdP has led to withdrawal from the market of several drugs, including amongst others cisapride, astemizole, and sertindole. For a comprehensive overview of the accumulated evidence for an association between individual drugs and TdP, the reader is referred to<sup>127,128</sup>.

The majority of drugs that promote TdP arrhythmias inhibit the rapidly activating, delayed rectifier potassium current ( $I_{Kr}$ ) channels in cardiac cells. Through that mechanism, they effectively slow down cardiac repolarization, resulting in a measurable prolongation of the QT interval in the surface electrocardiogram (ECG). In clinical safety studies, the QT interval in the ECG is principally used to monitor cardiac repolarization. In the in vitro setting, inhibition of  $I_{Kr}$  conduction in potassium channels encoded by the human ether-a-go-go related gene (hERG) is the

most extensively studied parameter for assessing the torsadogenic potential of drugs. Drug-induced TdP arrhythmias are believed to be triggered by ventricular extra beats, which can be induced by early depolarizations in cells with relatively long repolarization phases.

Although  $I_{K_r}$  inhibition has been identified as a major explanatory factor for drug-induced TdP arrhythmias, the torsadogenic properties of a drug may also depend on drug action on other cardiac ion channels that are involved in repolarization, such as the slowly activating, delayed rectifier potassium channels and L-type calcium channels. Drugs which block the hERG  $K^+$  channel with a relatively high selectivity, are likely to do so with a potency that is similar to the potency for prolonging the QT interval in dog and human.<sup>127</sup> Conversely, a discrepancy is found between in vitro and in vivo conditions for many drugs with mixed ion channel properties. Further data suggest that, irrespective of prolongation of the action potential duration, drug-induced changes in the shape and stability of the action potential and increased dispersion of repolarization across the heart may be critical for arrhythmogenesis, and presumably for the risk of TdP.<sup>129</sup> The conclusion from this must be that the  $I_{K_r}$  current and QT interval prolongation are, in isolation or together, not unambiguously indicative of the risk of TdP arrhythmias.<sup>128</sup> These surrogate outcomes give only probabilistic answers, with the possibility of false positive and false negative findings.

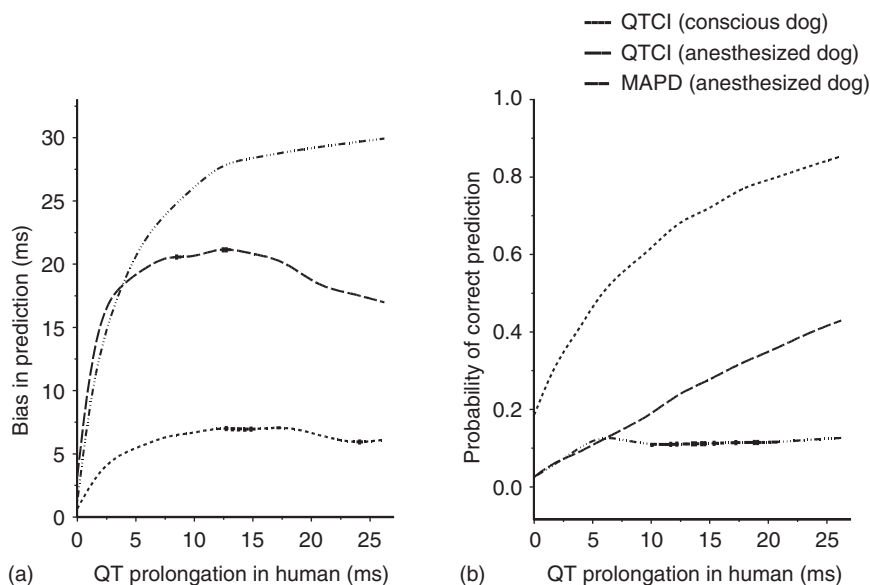

The clinical frequency of TdP requiring a detailed risk–benefit analysis is very low (above 1 in  $10^5$  to 1 in  $10^6$  exposures)<sup>130</sup> and for that reason, TdP is not likely to be observed during clinical development programs. The torsadogenic risk for a candidate drug must therefore be assessed on the basis of surrogate endpoints, which poses an enormous challenge in drug development. In the absence of alternative outcomes that have been studied sufficiently well to replace the QT interval as a measure for torsadogenic toxicity, regulatory agencies require clinical safety studies to be performed with highly precise QT interval measurements. The finding of a prolongation of the QT interval with  $<10$  ms may currently be sufficient reason for denial or withdrawal of marketing approval.<sup>128</sup> It is believed that a drug that does not cause even a small prolongation of the QT interval will probably not be torsadogenic at all, or so rarely that the perceived benefits of the drug outweigh the risk associated with its use.

In the preclinical setting, measurement of QT interval prolongation in the dog is considered to be the most predictive for cardiotoxicity in humans.<sup>131,132</sup> The canine hERG channel has been shown to be biophysically and pharmacologically similar to the human channel<sup>133</sup> and also the other ionic channels that are involved in cardiac repolarization have a similar distribution and activity between human and dog.<sup>131</sup> With regard to the correction of QT intervals for heart rate, the same considerations apply as described above for humans and deserve special attention since the morphology of ECGs is highly variable in dogs.<sup>128</sup>

Prediction of QT interval prolongation by candidate drugs remains a major challenge in drug development. In vitro drug properties and responses measured in animal models are believed to be predictive for the risk of TdP. In this context quantitative PK/PD modeling techniques can be used to establish the quality and limitations of such predictions to the clinic. At present a provisional 30-fold safety margin between the maximally reached free plasma concentration and the in vitro  $IC_{50}$  for  $I_{K_r}$  inhibition is proposed as a general safety guideline for the interpretation of clinical QT studies.<sup>127</sup> Although useful as a screening method, this safety margin does not allow to quantitatively predict the actual level of QT interval prolongation occurring in vivo. Drug-induced QT interval prolongation depends on several other factors, for example a difference between the observed free plasma concentration of a drug and the drug concentration at the effect site. By using an effect compartment model to characterize hysteresis between plasma concentration and QT prolongation, an estimate of the effect site concentration can be obtained even in small studies.<sup>132,134,137</sup>

However, the effect site concentration is not the only factor that needs to be taken into account for predicting QT interval prolongation from in vitro drug properties. The formation of metabolites affecting cardiac repolarization can bias the predictions from in vitro studies<sup>128</sup> and such effects have been observed with active metabolites of terfenadine, astemizole, and cisapride.<sup>135</sup> Despite efforts to perform in vitro studies under physiological conditions, for a range of compounds a systematic 10-fold difference was observed between the in vitro potency and unbound concentrations associated with QT interval prolongation or TdP in clinical studies.<sup>132</sup> The operational model of pharmacological agonism offers the opportunity to summarize such differences into the parameter  $\tau$  defined in eqn [5] while simultaneously including in the model factors such as an effect compartment or the response to active metabolites.

The operational model was recently used to estimate  $\tau$  on the basis of five clinical studies with the class III antiarrhythmic drug dofetilide and estimates of dofetilide potency in the in vitro hERG assay.<sup>136</sup> Dofetilide is a highly selective  $I_{K_r}$  blocker without known active metabolites that distinctly prolongs the QT interval and constitutes a suitable benchmark compound. A population PK/PD model including an effect compartment was developed by combining data from these five clinical studies. Introduction of the in vitro estimate of dofetilide potency for hERG current inhibition resulted in an estimate of  $\tau$  at a value of 6.2. This estimate was used to relate the in vitro current inhibition in a strictly quantitative manner to clinical QT interval prolongation. For example, 10% inhibition of hERG

**Figure 8** (a) The bias in the degree of QT interval prolongation predicted for humans from three measures of cardiac repolarization in dogs as a function of the predicted QT interval prolongation in human; (b) the probability that the prediction from the dog is not different from the true QT response in human.

currents by dofetilide corresponded to 20 ms of QT interval prolongation (95% confidence interval: 12–31 ms). Conversely, 20 ms QT interval prolongation was exceeded with statistical significance at 13% blockade of hERG currents.

In a second study, the operational model was used once more to determine the value of  $\tau$  for dofetilide in the beagle dog. The aim of this study was to determine the predictiveness of experiments in the beagle dog under different conditions. QT interval prolongation was measured in conscious and isoflurane-anesthetized dogs; in the anesthetized dogs also the effects of dofetilide on monophasic action potential duration (MAPD) was determined. A population PK/PD model was developed yielding estimates of  $\tau$  ranging from 5.7 to 10. The left-hand panel in [Figure 8](#) shows the bias in predictions that was observed by directly superimposing the concentration–response relationships of dofetilide in human on top of the curves obtained in the dog models. This figure shows that in the clinically relevant range of 0–20 ms QT interval prolongation, a relative large bias was found in the data on anesthetized dogs compared to conscious dogs. The population model allowed considering in addition to the bias (based on the population mean prediction), also uncertainty and variability in the predictions. The precision of the predictions can be derived from these magnitudes and gives insight into the probability that the responses in the respective models are equal to each other. The right-hand panel in [Figure 8](#) shows that the highest precision was found for prediction from the conscious dog, and that this precision increases with the QT response. This result underscores that relatively large QT intervals can be predicted with reasonable precision from the conscious dog, but that this precision decreases rapidly when attempting to predict <10 ms QT interval prolongation.

#### 5.38.4 Conclusion

This chapter presents an overview of the current status of PK/PD modeling concepts. It is shown that PK/PD modeling has progressed from an empirical descriptive discipline into a mechanistic science. Specific highlights in this development have been the recent incorporation of the principles of receptor theory and dynamic systems analysis in mechanism-based PK/PD modeling. This has resulted in a novel class of mechanism-based PK/PD models with much improved properties for extrapolation and prediction.

In the meantime PK/PD modeling is being widely applied in drug development. This concerns specifically its application in the design and analysis of phase I/II proof-of-concept and dose-finding clinical trials. In such trials it is of importance to maximize the information gathered as to better understand the in vivo safety and efficacy profile of novel drugs. Such analyses in turn facilitate the dose selection, design, and evaluation of confirmatory phase III clinical trials. In this chapter the application of PK/PD in preclinical investigations is illustrated for different drugs and an array of

pharmacodynamic endpoints. It is shown that with mechanism-based PK/PD models in vivo drug concentration–effect relationships can be predicted on the basis of in vitro bioassays as was illustrated for adenosine A<sub>1</sub> receptor agonists (Section 5.38.3.1) and GABA<sub>A</sub> receptor agonists (Section 5.38.3.3). Furthermore, mechanism-based PK/PD modeling enables the prediction, in a strictly quantitative manner, of drugs effects in humans as was shown for MOP receptor agonists (Section 5.38.3.2), GABA<sub>A</sub> receptor agonists (Section 5.38.3.3), 5HT<sub>1A</sub> receptor agonists (Section 5.38.3.4), and drug-induced QT interval prolongation (Section 5.38.3.5). This opens new opportunities in drug development, specifically in drug candidate selection and lead optimization. Thus, mechanism-based PK/PD modeling constitutes a novel scientific basis for the prediction of drug effects in humans, with regard to both efficacy and safety, enabling the selection of drug candidates with an optimal efficacy–safety balance.

To date mechanism-based PK/PD modeling has been mainly applied to ad hoc pharmacological effects of drugs (i.e., effects that can be observed in animals, healthy subjects, and patients at a particular point in time). A new challenge will be the modeling of drug effects on disease processes and disease progression in time. The development of novel animal models of disease and the identification of novel biomarkers, characterizing in a strictly quantitative manner disease processes in vivo, are indispensable in this regard.

## Biographies

**Meindert Danhof** is Professor of Pharmacology and Director of Research of the Leiden/Amsterdam Center for Drug Research at Leiden University in the Netherlands. His research interest is in the development of new theoretical

concepts in pharmacokinetic/pharmacodynamic (PK/PD) modeling. Important contributions in his research have been on the incorporation of (i) receptor theory and (ii) dynamical systems analysis. This has resulted in a new class of ‘mechanism-based’ PK/PD models with considerably improved properties for extrapolation and prediction. His most recent contribution is the development of the concept of ‘disease system analysis’ as the basis for the prediction of drug effects on disease progression.

Meindert Danhof is also Senior Scientific Advisor of LAP&P Consultants BV, which provides a professional infrastructure for consulting on the application of advanced PK/PD modeling concepts to the international pharmaceutical industry.

**Piet Hein van der Graaf** studied Pharmacy in The Netherlands and obtained a PhD in Clinical Medicine at King’s College London (United Kingdom) under supervision of Sir James Black for his work on quantitative pharmacological characterisation of  $\alpha_1$ -adrenoceptors. He subsequently worked as a Post-Doc at the Division of Pharmacology at the Erasmus University in Rotterdam (The Netherlands) with Professor Pramod Saxena and as Team Leader Pharmacology in the Urology Group of Synthelabo Recherche in Paris (France). After this, he moved back to The Netherlands and worked as a Fellow of the Royal Netherlands Academy of Sciences at the Division of Pharmacology of the Leiden/Amsterdam Center for Drug Research with Prof Meindert Danhof on the development of mechanism-based PK/PD models. Since 1999, he has been working at Pfizer Global Research & Development in Sandwich (UK) as Senior Director in Discovery Biology and Head of Sexual Health and currently as Head of Pharmacokinetics & PK/PD in the Department of Pharmacokinetics, Dynamics and Metabolism.

**Daniël M Jonker** obtained his PhD in Mathematics and Natural Sciences at Leiden University (The Netherlands) under supervision of Prof Meindert Danhof and Dr Rob Voskuyl for his work on the mechanism-based analysis of pharmacodynamic drug–drug interactions between antiepileptic drugs. He worked between 2003 and 2005 as a Postdoctoral Fellow at Uppsala University in Sweden with Dr Niclas Jonsson on PK/PD models for predicting QT interval prolongation. Since then he has been working as a Senior Scientist PK/PD at Grünenthal GmbH Aachen in Germany and as a Biomodeling Scientist at Novo Nordisk A/S Bagsværd in Denmark.

**Sandra A G Visser** obtained her PhD in Mathematics and Natural Sciences cum laude at Leiden University (The Netherlands) with her thesis on the mechanism-based pharmacokinetic–pharmacodynamic modeling of the GABA<sub>A</sub> receptor response in vivo. This work was done under supervision of Prof Meindert Danhof, Prof Bert Peletier and Dr Piet Hein van der Graaf. Between 2002 and 2004, she worked as a Postdoctoral Fellow at AstraZeneca R&D Södertälje in Sweden on modeling of tolerance development in temperature regulation and QT prolongation with Dr Johan Gabrielsson. From 2004 onwards she has been working as a Senior Research Scientist specialized in PK/PD analysis within both discovery and development DMPK at AstraZeneca R&D Södertälje.

**Klaas P Zuideveld** obtained his PhD in Mathematics and Natural Sciences cum laude at Leiden University (The Netherlands) under supervision of Prof Meindert Danhof, Prof Bert Peletier, and Dr Piet Hein van der Graaf for his work on mechanism-based pharmacokinetics–pharmacodynamic modeling: application to 5HT<sub>1A</sub> receptor mediated responses. He then worked as a scientific consultant for Pharsight Corporation in the European strategic services group, working with numerous pharmaceutical companies on computer assisted trial design. Since 2002, he has been working at F Hoffman-La Roche Ltd. (Basel, Switzerland) in the clinical modeling & simulation group as a Senior Pharmacometrician. In this position he is responsible for the oncology disease area.

## 5.39.1 Introduction

### 5.39.1.1 Definitions

In order to avoid any potential confusion it is important to first define the terms most often used in describing toxicity and the factors that influence decisions:

- Toxicity is a measure of the degree to which something is toxic or poisonous. The study of poisons is known as toxicology. Toxicity can refer to the effect on a whole organism, such as a human or a bacterium or a plant, or to a substructure, such as the liver.
- Hazard is the general term for anything that has the ability to cause injury or the potential to cause injury. The hazard associated with a potentially toxic substance is a function of its toxicity and the potential for exposure to the substance.
- Risk is defined as the prediction of the likelihood and extent of harm (negative consequences) resulting from a given action:  $\text{risk} = \text{hazard} \times \text{exposure}$ .
- Risk assessment is the identification and quantification of the risk resulting from a specific use or occurrence of a chemical, taking into account the possible harmful effects on individual people or on society of using the chemical in the amount and manner proposed and all the possible routes of exposure. Quantification ideally requires the establishment of dose–effect and dose–response relationships in likely target individuals and populations.
- Safety is the practical certainty that injury will not result from exposure to a hazard under defined conditions: in other words, the high probability that injury will not result.

### 5.39.1.2 Why is Toxicity an Important Consideration in Medicinal Chemistry?

Recent trend analysis in the pharmaceutical industry has shown that the average cost of producing a new drug has risen to beyond US\$800 million, and takes between 12 and 15 years to reach the marketplace. Moreover, fewer than 1 in 10 new drug candidates will reach the market once they enter clinical trials. Toxicity is one of the major causes of attrition, accounting for approximately 30% of the withdrawal of drugs from the market or from a company's development pipeline.<sup>1</sup> Late-stage development failures or withdrawals from the market are very costly, and create an unsustainable business model for the pharmaceutical industry.

Efforts to address this attrition problem require the early consideration of toxicity in the design and synthesis of new drug molecules. Once a chemical has been synthesized, its efficacy and safety profiles are, for the most part, fixed, although different formulations can have an impact on the exposure and toxicity profile of a compound. All that remains is to identify what those biological properties are and to manage the risks presented by the molecule. The ability to accurately predict the potential adverse effects of a novel compound in advance of entering in vivo testing would provide a distinct advantage in the fight to reduce attrition.

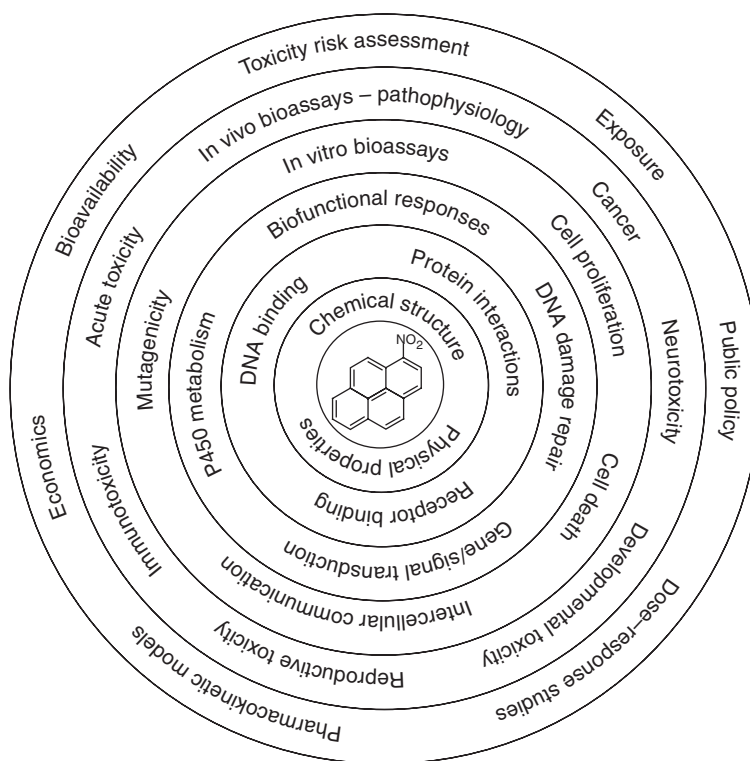

The high-profile market withdrawals of compounds for adverse safety profiles (e.g., Vioxx (rofecoxib), a drug used for the treatment of arthritis and acute pain, withdrawn in September 2004 due to an increased risk of adverse cardiovascular events after long-term dosing<sup>2</sup>) has created a social climate where there is increased scrutiny and pressure on the pharmaceutical industry to make 'safer' medicines and to publicly disclose the risks of taking the medicines that they sell. The safety of new medicines is now of paramount importance to the survival of the pharmaceutical industry.

### 5.39.1.3 The Challenges of Predicting Toxicity

There are many challenges that have to be overcome before one can accurately predict the toxicity of a novel chemical structure. Fundamental issues, such as the complex nature of biological systems and the ability of chemicals to interact with a biological system in multiple ways that could all potentially manifest themselves as similar toxic events, inevitably mean that the problem of predicting toxicity is not straightforward.

The diverse types of information that relate to the characterization of toxicological risk of chemicals<sup>3</sup> can be represented schematically as layers of an onion,<sup>4</sup> with the chemical of concern at the center, and the human health risk assessment in the outermost layer (Figure 1). The intervening layers range from calculated or measured physical properties, to mechanistically defined biochemical interactions, to in vitro cell culture bioassays, to in vivo responses in whole animals and populations. The radius of each layer increases according to the level of biological complexity and proximity to human health risk assessment, whereas the boundaries between the layers separate physically and conceptually distinct types of information. Structure–activity relationships (SARs) are models that attempt to extrapolate from the center of the onion, i.e., the chemical structure, to different types of biological endpoints.

#### 5.39.1.3.1 The nature of toxicity data

### 5.39.1.3.2 Factors affecting the determination of mechanisms of toxicity

“What is there that is not a poison? All things are poison and nothing is without poison. Solely the dose determines that a thing is not a poison.” (Paracelsus, 1493–1541.)

One classic example, where excessive dose and metabolic activation can combine to cause toxicity, is paracetamol. When a person takes paracetamol, metabolism in the liver produces small amounts of *N*-acetyl-*p*-benzoquinone imine (NAPQI) (Figure 2). Under normal dose levels, this potentially toxic compound can quickly form conjugates with glutathione, thus neutralizing the toxic effects of NAPQI.

The problem occurs when the body runs out of glutathione. As glutathione stores are diminished, NAPQI is not detoxified, and covalently binds to the lipid bilayer of hepatocytes, causing centrilobular necrosis, resulting in hepatotoxicity. The maximum daily dose of paracetamol is 4 g in adults and 90 mg kg<sup>-1</sup> in children. A single ingestion

**Figure 2** Metabolic formation of NAPQI and subsequent reaction with glutathione.

of 7.5 g in an adult or more than 150 mg kg<sup>-1</sup> in a child is a potentially toxic dose of paracetamol. Paracetamol toxicity is the number one cause of hospital admission for acute liver failure in the USA, accounting for approximately 40% of all liver transplant cases.<sup>6</sup>

While dose is an important consideration in determining the exposure of a subject to a chemical, it does not always have a direct correlation to the quantity of drug circulating in the bloodstream. The absorption, distribution and excretion properties of a compound will also have a bearing on the observed toxicity resulting from the drug.

#### 5.39.1.3.3 The available data pool for toxicity modeling

Consideration for the toxic effects of a compound is primarily driven by either social concerns for human health and safety via intended or accidental exposure to the chemical, or, in more recent years, it is the potential impact of a chemical on the environment if released in large quantities into the ecosystem. Therefore, the available data pool for modeling chemical toxicity tends to be both structurally and mechanistically diverse.<sup>7</sup> The primary goal of chemical toxicity prediction is to distinguish between toxicologically active and inactive compounds. Typically, multiple mechanisms can lead to the same toxicological endpoint, and therefore predictive models need to be able to distinguish multiple regions of activity amidst a mass of inactive chemical structures.

Toxicity tests, unlike those designed to study the pharmacological interactions of a compound, are often low-throughput and expensive with few in vitro models that have a high correlation with in vivo outcomes. These limitations result in practical and economic barriers to the generation of focused data sets that could be used for toxicity modeling applications.

#### 5.39.1.4 Other Factors Influencing the Need to be Able to Predict Toxicity

In recent years, legislation in both the USA and EU stipulated that companies producing chemicals in quantities greater than 1000 tonnes per annum, often referred to as high-production volume (HPV) chemicals, should provide data on the human and environmental safety of these substances. Current estimates are that less than 10% of the 2500–3000 chemicals that fall under this legislation have sufficient data available for them.<sup>8</sup> In addition to this, other legislation, such as the Safe Drinking Water Act Amendment of 1996 require the US Environmental Protection Agency to assess thousands of contaminants believed to be present in drinking water and to develop and maintain a Contaminant Candidate List for further investigation.<sup>9</sup>

Social pressures to reduce the number of animals used in laboratory testing, particularly in the cosmetic and personal products industries, have resulted in greater interest and need for the ability to predict the human and environmental hazards posed by chemicals. Computer-based or in silico prediction of toxicity is seen as an ideal solution to the problem, as it is fast, cheap, and requires no additional resources. While the overall reliability of any single method for prediction of every possible toxic event is not currently adequate to replace laboratory experiments, at the very least it is hoped that in silico tools could be used to help to identify and prioritize those potential ‘bad actors’ in need of further exploration from those of lesser concern.

While environmental impact is an important consideration for any chemical produced in large quantities, the focus of this chapter will be the use of in silico methods to predict the potential adverse effects of a compound in humans. There are many reports in the literature concerning the prediction of the environmental fate of chemicals.<sup>10,11</sup>

### 5.39.2 Current Methods for In Silico Prediction of Toxicity

Early approaches developed by Hansch & Fujita and Free & Wilson using linear free energy have provided the basic scientific framework for the quantitative correlation of chemical structure with biological activity, and have spurred

many developments in the field of quantitative SARs (QSAR).<sup>12,13</sup> These techniques have been extensively applied to the modeling of medicinal properties, where they are generally used to optimize the pharmacological activity within a series of chemically similar compounds.

However, for many years SARs and QSAR techniques have also been applied to the prediction and characterization of chemical toxicity.<sup>7</sup> These computational techniques have been applied to a wide variety of toxicological endpoints, from the prediction of LD<sub>50</sub> (the dose at which 50% of a population exposed to the chemical will die) and maximum tolerated dose values to *Salmonella typhimurium* (Ames) assay results, carcinogenic potential and developmental toxicity effects. Generally, however, toxicological endpoints such as carcinogenicity, reproductive effects, and hepatotoxicity are mechanistically complex when compared with the prediction of pharmacological activity, and hence this leads to added difficulty when trying to predict these endpoints.<sup>14</sup>

In general terms, *in silico* methods can be categorized into three main classes:

- statistical methods;
- rule-based methods; and
- three-dimensional (3D) molecular modeling techniques.

Each of these approaches has advantages and disadvantages. As with the application of all models, the limitations and trends of the model should be recognized and considered by the user when using them to guide decisions.

### 5.39.2.1 Statistical Approaches to Predicting Toxicity

Statistical approaches use a variety of mathematical algorithms to explore and define the relationships between properties of the compounds and their respective activities. This requires a training set of chemicals from which a multitude of descriptors can be generated, usually calculated from the chemical structure of each compound. These can range from simple structural fragments of two or more atoms and bonds to more complex quantum mechanics calculations of molecular orbital (HOMO/LUMO) ratios.

These descriptors, along with a measure of the activity of each compound are used as substrate for mathematical learning algorithms that derive a statistical correlation between the descriptors and the observed activity. Many different algorithms have been developed in the scientific community to address problems of this type, ranging from the calculation of simplistic statistical frequency (e.g., descriptor X appears more frequently in active compounds than inactive ones) to sophisticated neural networks<sup>15–17</sup> or genetic algorithms.<sup>18,19</sup>

All statistical methods used to derive these relationships can suffer from over-fitting, which ultimately means that the resulting model becomes too specific to the training set of compounds, and reduces the predictive power of the model for compounds not included in the original set. To avoid over-training of the algorithm, the developer will often hold back a representative test set of structures from the training set that can be used to measure the predictive power of the resulting model. Other statistical techniques such as leave-one-out cross-validation are also used to ensure that the model is suitable for use in prediction. If the model generation is considered successful, it can then be used to predict the activity of a novel compound based on the respective values of its descriptors.

#### 5.39.2.1.1 Advantages of statistical approaches

- The algorithms do not need to know the underlying biological mechanisms in order to resolve relationships between the descriptors and the observed activity; the relationships are based solely on mathematical correlations.
- The descriptors identified as being highly correlated to biological activity can potentially lead to a better understanding of the biological mechanism.
- The descriptors used in the model can be a combination of structural, physicochemical, and quantum mechanics-derived values that can lead to a more comprehensive assessment of the complex factors involved in the expression of toxicity.
- Where toxicity is measured quantitatively, these methods can be used to rank order compounds on their relative potency.

#### 5.39.2.1.2 Disadvantages of statistical approaches

- Statistical methods work best if all molecules covered within a given class all act by the same underlying biological mechanism. Variation in mechanisms of action will cause deviations in the relative importance of descriptors within the algorithm, which ultimately lowers the ability of the model to predict accurately. This can be partially overcome by using more sophisticated mathematics.

- The quality of data used to develop the model is critical to the success or failure of the system to predict toxicity.
- The choice of descriptors is fundamental to the success of the model to predict the biological effect. However, the more descriptors used, the higher the likelihood that correlations of chance are discovered that have no real predictive power.
- Descriptors can often be based on theoretical concepts and calculations that are difficult to interpret in terms of their relationships to the chemical structure. This can often leave medicinal chemists at a loss when seeking structures that either maximize or minimize the value of a particular descriptor.
- Confusion can arise where models provide a probabilistic measure of effect. This is a measure of confidence in the classification by the model of toxic versus nontoxic, and should not be mistaken for a measure of relative potency in causing the toxicological effect for the compound.
- While statistical methods require the conversion of the biological effects of the compound into a numerical representation, toxicology is predominantly a descriptive science that relies on observation rather than quantifiable measurements. Even where numerical measurements are made, for example in liver function tests and other clinical chemistry parameters, there exists a natural variation between individual subjects that can result in an imprecise classification in terms of the biological effect.

Given the aforementioned issues, it is not surprising that statistical methods have had limited success in predicting the toxicological properties of novel chemical structures that are not representative of the training set used in developing the model. This can be attributed in part to the quality and quantity of the available toxicology data, but also to the complexity of the toxicological endpoint and breadth of mechanisms that they are attempting to predict.

#### 5.39.2.2 Rule-Based Approaches to Predicting Toxicity

Rule-based approaches, sometimes referred to as knowledge-based approaches, rely on the human interpretation of data to derive relationships between chemical structure and/or physicochemical properties and the biological effects of a compound. While not always necessary, it is useful to have some basic idea of the mechanism by which toxicity is manifested, as this will help establish the chemical properties that could potentially play a role in the expression of toxicity. The development of these relationships or correlations requires a reasonably sized set of chemicals that contains both active and inactive examples, although the size of this data set will often be dependent on the suspected mechanism of action. Where mechanisms are well understood, the number of compounds required to derive a relationship are often lower than where the mechanisms are complex or ill defined.

For example, one mechanism of toxicity is through direct reaction with endogenous biomolecules (e.g., DNA or skin proteins). This mechanism of direct interaction with DNA or proteins has been implicated as one of the major mechanisms involved in the expression of mutagenicity and skin sensitization, respectively. Other types of toxicity can occur through the inhibition of enzyme or cellular activity, such as blockage of the cardiac potassium channel. This channel is sometimes referred to as the human ether-a-go-go-related gene (hERG) channel. hERG inhibition has been implicated in causing prolonged cardiac action potential duration, which is a potential risk factor in torsade de pointes, a cardiac arrhythmia.

The rule development process involves the formation of associations between the properties of a chemical and its observed effects by human experts. The resulting relationships derived from the training set are often expressed as a series of rules that describe the necessary components for the biological effects to manifest themselves on exposure of a biological system to the compound. These rules can be encoded electronically as structural alerts or decision trees, or combinations of the two. The resulting model can then be used to predict the biological properties of novel chemicals.

During the development of a rule-based model, it is unnecessary and often unwise to withhold data from evaluation, as this can lead to gaps in the generation of hypotheses and result in shortcomings in the predictive model. The downside to this, of course, is that the only way to test the performance of the resulting model is to conduct prospective testing of novel chemicals.

The predictions from rule-based approaches are often qualitative or semi-quantitative, using a classification system to indicate a level of concern. However, more often than not, rule-based systems will provide a textual rationale to the end user to explain the basis of its prediction, and aid the user in interpretation and the subsequent direction to take.

#### 5.39.2.2.1 Advantages of rule-based approaches

- Predictions are often based on mechanistic understanding, and usually provide a rationale to the user to help in interpretation.
- Experts can assess data quality during the development of the model, and therefore the system is able to cope with and use imperfect data points.
- The properties used to build the model are usually readily identifiable with the structure, and give the user a clear indication on the component of the structure that is suspected of causing the toxicity.
- The use of textual phrases to classify concern levels allows the user to group chemicals into those of highest and lowest priority.

#### 5.39.2.2.2 Disadvantages of rule-based approaches

- These systems are often labor-intensive and require individuals to possess a working knowledge of both toxicology and chemistry.
- While the developers can uncover or propose novel mechanisms during the analysis, the system itself is incapable of identifying potentially novel relationships. This often results in rule-based systems being biased toward or limited by current knowledge.
- Rule-based systems generally use descriptors that are easily identifiable with properties of the chemical structure, for example, the lipophilicity of a compound as described by the octanol/water partition coefficient often referred to as  $\log P$ . These structure-based descriptors might not adequately capture or describe the toxicological activity of compounds, leading to false-positive or -negative predictions.
- By their very nature, rule-based systems often do not attempt to predict a continuous value of toxicity. Where toxicology endpoints have a continuous measure of activity, as with the inhibition of the hERG potassium channel, they are usually reduced to a simple classification system, for example, low, medium, or high; or positive or negative.

With all predictive models there is often a need to balance false-positive predictions (i.e., predicting a compound to be active when in fact it is not) and false negatives where the system predicts active compounds to be inactive. Rule-based systems often struggle with this balance, as developers have to rationalize their confidence in the mechanism of action with the available data. Inconsistencies among rules have to be guarded against when they are implemented in these systems. When using any predictive model it is important that the user understands the limitations of the system and its relative bias toward false negatives or false positives.

#### 5.39.2.3 Three-Dimensional Approaches to Predicting Toxicity

3D approaches use knowledge about the shape and volume of either the submitted compound or the binding site thought to be involved in the mechanism of toxicity, or both. They often require knowledge that the chemicals act via a common mechanism or biological event. One example where 3D methods have been applied to predict toxicity is the binding or blockage of the potassium ion channel in the prediction of prolonged QT syndrome, another is the identification of substrates for one or more of the P450 cytochromes and their ability to cause induction or peroxisome proliferation. P450 induction where a patient is taking multiple therapeutic medicines has been linked to causing adverse events through prolonged or increased exposure to one of the drugs or decreased efficacy by increased metabolic clearance. This type of effect is often referred to as a drug-drug interaction (DDI).

As with the prediction of efficacy using 3D models, development of a model for toxicity requires, at a minimum, a set of chemicals with a range of known activities for a particular endpoint. If one assumes that these compounds all act via common interactions with proteins it is possible to develop a pharmacophore that describes the essential arrangement of structural components for a compound to express similar biological activity. Other techniques such as volume or molecular planarity estimates can also be used where there is little knowledge of the protein or its binding site.

Similarly, techniques such as comparative molecular field analysis (CoMFA),<sup>20,21</sup> developed by Tripos Inc., can also be applied in these types of situations. CoMFA models use estimates of steric and electrostatic interactions to describe the activities of molecules. The primary limitation in the development of CoMFA models is the need for good structural alignment between not only the molecules used to build the model but also those molecules for which predictions are made.

It is often preferable, although not necessary, to know which protein is involved in the expression of toxicity and its active binding site. This additional knowledge enables the developer to include more accurate estimates of volume restrictions and alternative conformations that may further enhance the prediction of protein–ligand interactions. Techniques such as ligand docking and scoring can be used to rank order chemicals according to their ability to bind to the receptor site. These techniques often have to compensate for flexibility not only in the ligand being docked but also the protein-binding site itself. This can be accomplished by either using multiple conformations of the compound or using energy minimization algorithms after the docking has been performed.

As with statistical methods, 3D models can suffer from over-fitting, which results in the model being too specific to the training set of compounds, reducing its predictive power. It is therefore common for developers to use separate training and test sets to ensure that over-fitting does not occur.

#### 5.39.2.3.1 Advantages of three-dimensional approaches

- Predictions from these 3D approaches are usually based on mechanistic hypotheses of toxicity, and therefore usually provide reliable predictions where the molecule in question acts via this mechanism and is adequately represented in the model training set.
- These approaches take a whole-molecule view to predicting their activity, and can compensate for subtle variations in electronic or steric factors within the structure.
- The predictions made by 3D methods are often numerical estimates of the activity of a molecule, and therefore these approaches are capable of providing a rank ordering of novel chemical structures.

#### 5.39.2.3.2 Disadvantages of three-dimensional approaches

- They rely on the assumption that the compounds in question cause toxicity through their interaction with specific proteins or receptors. Toxicity can also occur as a result of direct covalent binding to proteins or as a result of altering the physical state of the biological system for example by increasing or decreasing intracellular pH levels.
- 3D methods are often computationally intensive and require extensive calculation times to generate predictions. While this can be compensated for by parallelization, it ultimately leads to some level of approximation in the calculation, which can lead to errors in the predictions from the models.
- Often it is difficult to reliably confirm that all the molecules in the training set are acting through a common mechanism or even through interactions at the same binding site within the protein complex. These assumptions can lead to errors in the predictions from these models.
- Most types of toxicity studies do not yield data that are amenable to this type of model development, as often experiments are conducted with a view to observing changes at an organism level and not at the molecular level.

Due to the nature of toxicology studies there are few endpoints where specific proteins have been identified as the primary cause of the adverse effect or where a molecular shape has demonstrated good correlations with the data generated. This has naturally limited the application of 3D approaches to yield truly predictive models for toxicity. As knowledge around the mechanisms of toxicity expand and new technology facilitates more precise measurements of the interactions between molecules and a biological system, these types of approaches will most likely yield the best predictive models. However, the scope of each model needs to be adequately assessed and applied appropriately.

### 5.39.3 In Silico Models for Specific Toxicological Endpoints

#### 5.39.3.1 In Silico Prediction of Genotoxicity

Genotoxicity results from the adverse effects of chemicals on DNA and the genetic processes of living cells.<sup>22</sup> These effects can be in the form of point mutations in the DNA (mutagenicity), DNA strand breaks, or chromosome alterations. For a long time now there has been a strong association between genetic damage and carcinogenicity, especially in biological systems that have the requisite metabolic activation.

In vitro assays for the detection of gene mutations have been in use for over two decades, with the Ames assay<sup>23</sup> being adopted as the de facto gold standard. The standard Ames assay consists of testing a compound against five different strains of *S. typhimurium* in both the presence and absence of S9 metabolic activation in concentrations up to

This rich source of data combined with the regulatory implications of having an Ames-positive result make mutagenicity an obvious target for the development of in silico models to predict the outcome of this assay. Because of the relatively simple mechanisms by which point mutations can occur, this toxicological endpoint renders itself amenable to all types of model development. Indeed, there are many commercial systems that claim to be able to predict mutagenicity (see [Section 5.39.4](#) on commercial systems for more details).

These structural alerts have formed the basis of many predictive models for this endpoint, and been used extensively within the pharmaceutical and agrochemical industry to screen out and avoid potentially genotoxic compounds. The unfortunate consequence of this is that any training set based solely on pharmaceuticals or agrochemicals is going to be heavily biased toward Ames negatives, making the development of robust models difficult for these types of compounds. In a review of some 394 pharmaceuticals currently on the market, only 7.2% of compounds were reported to give a positive response in a bacterial mutation assay.<sup>28</sup> Even taking into account that most Ames-positive compounds are not pursued as viable drug candidates, reports suggest that the percentage of compounds synthesized and tested by the industry that are in fact Ames-positive is only around 10%.<sup>14,29</sup> In contrast, the data set assessed by Ashby and Tennant and their co-workers contained approximately 37% Ames positive compounds.

Given that there are substantial differences between the types of chemicals tested by the NTP and those synthesized by the pharmaceutical industry, models based solely on the NTP data set are unlikely to perform well against pharmaceuticals. This observation has been reported on numerous occasions in reference to the commercially available systems for toxicity prediction.<sup>14,28–30</sup>

**Figure 3** Composite model structure for DNA reactivity.<sup>26</sup>

Some *in silico* models for mutagenicity prediction take the overall Ames result as a simple binary classification in the development of the model (i.e., either positive or negative). However, other methods have sought to make the results of this assay a more continuous variable and hence amenable to statistical analysis. These methods have introduced the concept of mutagenic potency, and several methods for calculating mutagenic potency have been proposed, each with advantages and disadvantages:

- Method 1 uses the maximum increase in revertants as a measure of mutagenic potency, that is, the potency of a compound increases in relation to the maximum increase in revertants observed in the assay. This method provides an absolute measure of the potency, but does not take into account the potential for cytotoxicity that would limit the number of revertants at higher concentrations.
- Method 2 assumes that compounds that elicit positive responses in multiple-strain/S9 combinations are more potent mutagens than those that only show positive responses under a single condition. This method provides a more objective view of potency, but can become a subjective measure where compounds illicit a reproducible and robust high increase in the number of revertants but only under one or two specific conditions.
- Method 3 uses the drug concentration (e.g.,  $\mu\text{g}$  per plate) that induces a 2.0-fold increase in the number of revertants, and therefore the more potent the mutagen the lower the concentration required to yield a positive response. Although this method offers the advantage that the concentration of compound is used, consideration of molar concentrations would further improve this approach. However, this method does not take into account the potential for cytotoxicity to impact on the number of revertants.

Often these methods will focus on particular classes of chemicals, developing mathematical relationships between the mutagenic potency and the chemical structures. One important class of potential mutagens – aromatic amines – has been the focus of attention for many researchers working in this area. This is primarily as a result of their suspected link with carcinogenicity through their presence in cooked foods, diesel fumes, and common environmental contaminants.

#### 5.39.3.1.1 Mutagenicity of aromatic amines

The metabolic activation of aromatic amines is complex<sup>31</sup> (Figure 4). They can be converted to aromatic amides in a reaction catalyzed by an acetyl coenzyme A (CoA)-dependent acetylase. The acetylation phenotype varies among the population: persons with the rapid acetylator phenotype are at higher risk of colon cancer,<sup>32,33</sup> whereas those who are slow acetylators are at increased risk of bladder cancer.<sup>34</sup> This latter association may result from the fact that activation of aromatic amines by *N*-oxidation is a competing pathway for aromatic amine metabolism. Also, the *N*-hydroxylation products when protonated under the acid conditions in the urinary bladder form reactive electrophiles that bind covalently with DNA or proteins to produce macromolecular damage.

An initial activation step for both aromatic amines and amides is *N*-oxidation by CYP1A2. This cytochrome P450 is also responsible for the 3-demethylation of 1,3,7-trimethylxanthine (i.e., caffeine), the distribution of metabolic phenotypes in the population, as well as the disposition of an individual with respect to CYP1A2 metabolism, is relatively easy to determine.<sup>35</sup> The reaction of *N*-hydroxy-arylamines with DNA appears to be acid catalyzed, but they can be further activated by either an acetyl CoA-dependent *O*-acetylase or a 3'-phosphoadenosine-5'-phosphosulfate-dependent *O*-sulfotransferase. The *N*-arylhydroxamic acids, which arise from the acetylation of *N*-hydroxy-arylamines or *N*-hydroxylation of aromatic amides, are not electrophilic; therefore, they require further activation. The predominant pathway for this occurs through acetyltransferase-catalyzed rearrangement to a reactive *N*-acetoxy-arylamine. Sulfotransferase catalysis results in the formation of *N*-sulfonyloxy-arylamides. This complex pathway results in two major adduct types: amides (i.e., acetylated) and amines (i.e., nonacetylated).

The heterocyclic amines are formed during the preparation of cooked food, primarily from the pyrolysis ( $>150^\circ\text{C}$ ) of amino acids, creatinine, and glucose. Heterocyclic amines have been recognized as food mutagens,<sup>36</sup> and they have been shown to form DNA adducts and cause liver tumors in primates.<sup>37</sup> Compared with other carcinogens, their metabolism is less well understood, but *N*-hydroxylation is considered to be a necessary step. Because they are similar in structure to the aromatic amines, it is not surprising that they too can be activated by CYP1A2. The *N*-hydroxy metabolites of 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Tip-P-1), 2-amino-6-methyldipyrido[1,2-*a*:3',2'-*d*]imidazole (Glu-P-1), and 2-amino-3-methylimidazo-[4,5-*f*]quinoline (IQ) can react directly with DNA. Unlike aromatic amines, however, this reaction is not facilitated by acid pH. Enzymic *O*-esterification of the *N*-hydroxy metabolite is important in the activation of these food mutagens, and the *N*-hydroxy metabolite is also a good substrate for transacetylases. This suggests a possible role for these chemicals in the etiology of colorectal cancer in combination with the rapid acetylator phenotype.

**Figure 4** Metabolic activation pathways of aromatic amines.<sup>38</sup>

Through the use of various QSAR techniques, the mutagenic potency of aromatic amines has been correlated to a number of structural descriptors including lipophilicity as represented by the log *P* value of a chemical,<sup>38</sup> the relative stability of the nitrenium ion,<sup>39</sup> and the HOMO/LUMO calculations for class. However, upon further investigation, these methods, while providing an acceptable mechanism for predicting mutagenic potency, were poor at predicting the activity of nonmutagenic aromatic amines. Work conducted by Benigni *et al.*<sup>40</sup> showed that both electronic and steric factors at the amine site also play a role in the crucial metabolic activation of this class of compounds. For a comprehensive review of QSARs for aromatic amines, refer to Benigni *et al.*<sup>41</sup>

#### 5.39.3.1.2 Predictive models for chromosomal damage

In contrast to mutagenicity, very few *in silico* models have been developed to predict the potential of chemicals to cause chromosomal damage. Chromosomal damage can take various forms, including structural aberrations such as clastogenicity, and/or numerical aberrations, including aneuploidy.<sup>42</sup> There are many assays developed for the detection of these endpoints, including the mouse lymphoma assay, *in vitro* cytogenetics assays using human lymphocyte cell lines, and *in vivo* micronucleus assays. Due to their low throughput and higher cost, these assays are often run only when compounds have already been shown to be negative in the Ames assay. Some companies also use higher-throughput screening assays, such as the *in vitro* micronucleus assay, to eliminate potential bad actors earlier in the drug discovery process. Often these company-generated data remain within corporate databases, and as such have not been subjected to the same level of scrutiny as that for Ames mutagens.

Some data on chromosome damaging agents have been published by Ishidate *et al.*<sup>43</sup> and, more recently, by Ojima *et al.*<sup>44</sup> Despite this, only a few attempts have been made to develop predictive models for this endpoint. One reason for this could be the diversity and complexity of mechanisms that are involved in chromosomal damage. Another possibility is that comparing results from the different assays makes combining data from these difficult and can cause problems when applying statistical algorithms to develop QSAR models.

Serra *et al.*<sup>45</sup> report some success using topological descriptors and six-descriptor *k*-nearest-neighbor model to predict structural chromosomal aberrations. This model was built using a training set of some 245 chemicals, and was capable of predicting a test set comprised of 37 chemicals – 26 negatives and 11 positives – with an overall accuracy of 86.5%. Use of support vector machine algorithms<sup>46</sup> on the same training and test sets yielded models with an overall accuracy of 83.8%.

Other QSAR models for chromosomal aberrations have been developed by Tafazoli *et al.*,<sup>47</sup> but these were focused on a specific chemical class of compounds, namely short-chain chlorinated hydrocarbons. As such, the application of this model to noncongeneric data sets is inappropriate.

### 5.39.3.2 In Silico Prediction of Carcinogenicity

Cancer is a disorder in which the mechanisms that control proliferation of cells no longer function adequately. Cancer is considered to be an all-or-none effect (i.e., a tumor is or is not present). Because most cancers are considered irreversible life-threatening changes, chemical carcinogenesis (chemically induced cancer development) has hitherto been perceived by many to be different from other forms of chemical toxicity.

Currently there are no good in vitro assays that can be used to identify carcinogens. Most testing needs to be carried out in vivo, with bioassays for carcinogenicity consisting of exposing adequate numbers of animals to the test substance for a significant proportion of their normal life span. Typically, this is performed using both male and female rats and male and female mice over a 2 year test period. This combination helps to distinguish species and/or gender specificity for the chemical being tested. This test is expensive and time-consuming to conduct, and therefore alternatives or surrogate tests are often employed in advance of carcinogenicity testing, which thereby reduces the number of chemicals for which carcinogenicity data are generated.

One of these surrogate paradigms is genetic toxicity testing, as discussed in the previous section. However, some chemicals can cause cancer by mechanisms other than through direct interaction with DNA,<sup>48,49</sup> and are therefore not detected through the use of genotoxicity tests. These classes of compounds are commonly referred to as nongenotoxic or epigenetic carcinogens. This diversity of mechanisms and high cost of experimental testing has been a significant driving force for the development of in silico models for carcinogenicity.

Despite the high cost to test chemicals, there are in fact many sources of data for carcinogenicity. For example, the International Agency for Cancer Research (IARC) has been compiling and reviewing data on chemicals suspected of causing carcinogenicity in humans for over three decades.<sup>50</sup> Surprisingly there are only 68 unique substances that have been classified as IARC Group 1 Carcinogens (known human carcinogens) and only a further 56 substances categorized as IARC Group 2A Carcinogens (probable human carcinogens). The US NTP has been conducting and reviewing animal toxicity data for chemicals, and to date has compiled carcinogenicity data on over 530 chemicals and mixtures. Other sources of data include the Carcinogenic Potency Database (CPDB), compiled by Gold *et al.*,<sup>51,52</sup> which contains over 1300 chemicals and mixtures, both naturally occurring and synthetic, compiled from public literature sources. It is worth noting that there is significant overlap between the NTP and Gold databases.

A review of the CPDB shows that around 50% of the compounds analyzed were in fact considered to be carcinogenic in rodents.<sup>53</sup> The explanation for this probably lies in the fact that the rodents are given the chemical the maximum tolerated dose (i.e., at chronic, near-toxic doses). Evidence is accumulating to suggest that the high dose itself, rather than the chemical per se, can contribute toward the expression of cancer.<sup>53</sup> The relevance therefore of rodent carcinogenicity testing to the situation where humans are exposed to relatively low levels of these chemicals has to be questioned. The high proportion of positive chemicals has also been attributed to the selective testing of chemicals suspected to cause cancer. One advantage that this bias has yielded is that it makes the data set much more amenable to the development of in silico models.

Many methods have been applied to create predictive models of carcinogenicity with varying degrees of success. While the carcinogenicity endpoint is usually expressed as a binary classification (i.e., positive or negative), some methods have used estimates of carcinogenic potency to differentiate between those that cause cancer at relatively low exposures versus those that require high doses and prolonged exposures. One common method used for determining potency is the use of the TD<sub>50</sub> approach. The TD<sub>50</sub> approach was described by Peto *et al.* in 1984.<sup>54</sup> Put simply, the TD<sub>50</sub> is the calculated daily dose per unit body weight causing a 50% incidence above control of tumors at the most sensitive site.

As with the prediction of genotoxicity, some developers of *in silico* models have focused their attention on specific classes of chemicals such as aromatic amines, nitroarenes, or nitrosamines. For a comprehensive review of structure-based approaches for predicting mutagenicity and carcinogenicity, refer to Benigni.<sup>55</sup>

#### 5.39.3.2.1 Prospective challenges for carcinogenicity prediction

While most developers use a test set to validate the performance of a model, the true test of its predictivity comes from a prospective analysis, that is, where predictions are made in advance of the experimental tests being conducted. The NTP has issued two such prospective challenges to date for chemicals it planned on testing for rodent carcinogenicity. The first of these exercises took place in 1990, when Tennant *et al.*<sup>56</sup> published predictions for 44 chemicals that were due to be tested by the NTP, and invited others to do the same.<sup>57</sup> Seven developers in addition to Tennant *et al.* published their respective predictions prior to completion to testing.<sup>58–64</sup>

In 1993, once testing had been completed, the US National Institute of Environmental Health Sciences conducted an international workshop to evaluate what had been learned from the first predictive exercise. The workshop reached two main conclusions.<sup>65</sup> First, SAR-based models do not perform as accurately as models that utilize biological attributes and, second, models that used multiple attributes to represent the chemical carcinogenicity endpoint performed better than models that were based on one or two attributes.

The comparison between predicted and actual results has been the subject for many discussions and publications.<sup>66,67</sup> Benigni concludes that all systems currently suffer from an inability to distinguish those chemicals that contain a structural alert and are carcinogenic from those that also contain a structural alert but are inactive with the predictions made by the human experts, Ashby and Tennant being the most accurate, getting 75% of the predictions correct (Table 1).

In 1996, the NTP issued a second challenge to system developers to predict the outcome for a further 30 chemicals due to be tested for rodent carcinogenicity.<sup>68</sup> As before, most predictions were published prior to the completion of testing.<sup>69–82</sup> In this exercise there was a greater variety in the systems used to predict the outcome of the rodent carcinogenicity studies. They included several human expert opinions, the use of existing or new *in vitro* assays, as well as the use of computational approaches. This second set of chemicals presented developers with a greater challenge by avoiding chemicals with obvious modes of action or structural alerts. Many chemicals in this second exercise, in contrast to the first, were Ames-negative, implying that carcinogenicity would not be induced through direct interactions with DNA. To compensate for this additional challenge, developers were allowed access to the *in vitro* and short-term *in vivo* test results to aid them in making their predictions.

Benigni in his analysis of the results from this second prospective exercise concluded that at present the best systems for prediction still rely to some extent on human judgment and that the upper limit for accuracy from computational approaches is 65%.<sup>55</sup> Overall accuracy results for each system used for prediction are summarized in Table 2.

In general, the models for noncongeneric chemicals are inferior in their predictive power when compared with the classical QSARs for congeneric series. This is not entirely surprising, since a QSAR for congeners is aimed at modeling only one mechanistic phenomenon, whereas the general models for the noncongeneric sets try to model several mechanisms of action at the same time, each relative to a whole class of carcinogens. Obviously, this broad-sweeping

**Table 1** Concordance between predictions and rodent results

| <i>System</i>                                      | <i>Accuracy</i> |

| FALS <sup>74</sup>                  | 0.50            |
| RASH <sup>70</sup>                  | 0.45            |
| COMPACT <sup>69</sup>               | 0.43            |
| DEREK <sup>76</sup>                 | 0.43            |
| <i>S. typhimurium</i> <sup>68</sup> | 0.33            |
| Purdy <sup>78</sup>                 | 0.32            |
| Progol <sup>71</sup>                | 0.29            |
| MCASE <sup>73</sup>                 | 0.25            |

approach is a much more difficult task. It should be noted that the successful modeling of noncongeners requires the availability of an adequate number of representatives for each chemical class or mechanism of action.

When assessing the potential for toxicity, human experts are more likely to be able to make use of a variety of different sources of information, including the general principles of chemistry and biochemistry, and adapt better to issues that require the simultaneous use of knowledge at different hierarchical levels. Obviously, the opposite is true in the case of the individual chemical classes, where the potency of the QSAR methods can model subtle gradations in a much more efficient way than can the human expert.

A further confirmation of the difficulty in crystallizing the SARs into automatic prediction tools comes from the experience of the Predictive Toxicology Challenge 2000–2001. In this exercise, developers of artificial intelligence algorithms were invited to make predictions on the 30 chemicals proposed by the NTP after training their algorithms on standardized training set. Models were developed, and the results submitted to the Predictive Toxicology Challenge website. Out of the 111 original attempts made by these sophisticated artificial intelligence methods to grasp the information contained implicitly in the carcinogenicity databases that were proposed by the artificial intelligence community, only five sets of predictions were generated that were considered to be better than random.<sup>55</sup>

### 5.39.3.3 In Silico Prediction of Skin Sensitization

Skin sensitization, sometimes referred to as allergic contact dermatitis (ACD), is considered to be one of the largest causes of occupational injury in the USA.<sup>84</sup> It often develops as a result of repeated exposure to a sensitizing chemical agent, and can cause severe and sometimes fatal reactions on subsequent exposure to the chemical. It is thought that skin sensitization occurs when a chemical first reacts with skin proteins either directly or after metabolic activation. In order for this reaction to occur, the chemical must first penetrate the skin at least as far as the viable epidermis. The resulting conjugate is then recognized as a foreign body, and elicits an immune reaction, producing an inflammatory response in the skin.<sup>85</sup> Due to the long-lasting memory of the immune system, once an individual is sensitized, he or she can remain sensitive to further exposure of a chemical for a long period of time.

Experimental techniques for the detection of skin sensitization include the standard guinea pig maximization test, the Buchler test (also performed using guinea pigs), and the more recently developed murine local lymph node assay (LLNA). With the exception of the LLNA, these assays only provide a dichotomous conclusion, that is, the presence or absence of an effect with no measure of the dose–response relationship. The LLNA, however, provides an experimental measure of stimulation at each particular dose that when compared with control animals can be expressed as a stimulation index (SI). For example,  $SI=3$  is the dose required to give a threefold increase in stimulation between treated and control groups in the LLNA. Indeed, use of the calculated or estimated concentration at which  $SI=3$  (more often referred to as EC3) has become a common method to report LLNA data in the literature rather than reporting the experimental concentrations and isotope readings. The EC3 can be taken as a quantifier of the sensitization potential that makes this assay more amenable to the application of QSAR techniques.<sup>86</sup>

Despite the fact that none of these assays is considered high throughput, regulatory requirements for occupational health and safety, as well as the need to demonstrate consumer safety for personal products and cosmetics, has meant that many chemicals have been tested in one or more of these experimental assays. In addition, strong public and political opinion on the use of laboratory animals for testing of personal products and cosmetics has put immense pressure on these industries to develop and adopt alternative methods for identifying skin sensitizers. This pressure has resulted in the release into the public domain of large quantities of data that were traditionally held in the internal archives of private corporations. This release of data along with public pressure was the primary driving force for the development of *in silico* models for the prediction of ACD.

Recent reviews<sup>85,87</sup> of the QSAR models for skin sensitization discuss the many approaches that have been applied in this area. These models range from the application of structural alerts as in the case of the DEREK for Windows (DfW) system<sup>87–90</sup> to more complex structural, topological and *E*-state descriptors.<sup>86,91,92</sup> Rodford *et al.*<sup>85</sup> conclude that while a variety of methods have been employed, each model is constrained by a lack of high-quality data that are sufficient to provide a truly global model for the prediction of skin sensitization. However the adoption of the LLNA will go some way to addressing this need, as this assay is less costly and produces quantifiable results compared to those methods utilizing guinea pigs.

In more recently publications, Li *et al.* have used methods such as random forests, and applied these to the prediction of skin sensitization.<sup>93</sup> The random forest algorithm, originally developed by Breiman,<sup>94</sup> grows a collection, called a forest, of classification trees, and uses these for classifying a data point into one of the classes (*see* Volume 4). Growing a forest of trees and using randomness in building each classification tree in the forest leads to better predictions compared with a single classification tree, and helps to make the algorithm robust to noise in the data set. Using this approach, Li *et al.* claim to get an overall accuracy of 83.5% with a sensitivity and specificity of 84% and 83%, respectively.

Other recent developments by Miller *et al.* have used quantum mechanical calculations to develop SARs for predicting the outcome from the LLNA.<sup>96</sup> This system classifies chemicals as strong, moderate, or weak sensitizers, and the authors claim to be able to correctly classify over 80% of the test set of chemicals. However, it is noted by the authors that this prediction method is not broadly applicable to chemicals that fall outside of its training set. In addition, literature reports on chemicals tested in the LLNA for sensitization have shown that there is often variation in their reported EC3 values, suggesting that a classification scheme may improve the accuracy of *in silico* approaches.

In developing predictive models for skin sensitization it is also important that the ability of a compound to penetrate the skin be taken into account in the model. Permeability coefficients are often expressed in the form  $\log K_p$ , where the units are in centimeters per hour. *In vitro* permeability coefficients for human skin are calculated by measuring the flux across a known area of isolated human skin under a known concentration. Subsequently, many QSAR models have been developed for the calculation of this parameter. For an excellent review of these models refer to Walker *et al.*<sup>97</sup>

In general, skin absorption seems to be primarily dictated by the lipophilicity, molecular size, and solubility of the compound. Often, the  $\log P$  value is used to estimate the lipophilicity, and molecular weight or volume can be used as a measure of size. Some researchers have used the melting point as an estimate of the solubility; however, to date there are no good methods for the structure-based calculation of melting point. Some commercial rule-based systems, such as DfW (*see* Section 5.39.4), have incorporated skin permeability estimates to help improve the performance of the models for skin sensitization, but to date there have been no reports on the success or failure of this technique.<sup>14</sup>

### 5.39.3.4 In Silico Prediction of Other Toxicological Endpoints

#### 5.39.3.4.1 QT prolongation

QT prolongation, in of itself, is not considered to be a toxicity; however, this phenomenon has been observed in human subjects just prior to the onset of cardiac arrhythmias. This co-occurrence has led to a postulated link between QT

and these often-fatal cardiac events, and, for this reason, drug-induced QT prolongation or long QT syndrome has recently been a major cause of drug withdrawals.

One of the primary causes of QT prolongation is thought to be blockage of the hERG potassium channel in cardiac myocytes. While the x-ray crystal structure of the hERG channel has not yet been elucidated, there are examples of bacterial potassium channel structures in the public domain. These structures have been used as the basis for some 3D predictive models in an attempt to identify chemicals capable of causing QT prolongation.<sup>98–101</sup> For a more detailed explanation of models for QT prolongation and its impact on human health (see 5.40 In Silico Models to Predict QT Prolongation).

While hERG plays a significant role in the expression of QT prolongation, there are some 14 other ion channels that can also impact on the adverse event in vivo. The complexity has driven some developers to apply a more holistic systems biology approach to the prediction of QT prolongation, creating complex mathematical models of the processes at a cellular level.

#### 5.39.3.4.2 Respiratory sensitization

Respiratory sensitization is often characterized by episodes of wheezing, coughing, and chest tightness.<sup>102</sup> The condition can be severe and sometimes fatal.<sup>103</sup> The mechanisms by which chemicals can induce this adverse response are uncertain, but are assumed to be immune mediated with some pharmacological and neurological involvement. Currently there are no accepted, well-validated in vitro or in vivo models for the detection of respiratory sensitizers.<sup>85</sup> However, preliminary work by Dearman and co-workers has shown, for a limited number of respiratory sensitizers at least, that these chemicals all elicit a response in the LLNA used for the detection of allergic contact dermatitis.<sup>104,105</sup> Therefore, the suggestion can be made that chemicals that do not cause ACD will be unlikely to cause respiratory sensitization. However, there are significant differences between the mechanisms of these adverse effects that mean that not all contact allergens will necessarily be respiratory allergens.<sup>85</sup>

Despite a lack of accepted models, a review of the available data by Payne *et al.* did yield some structural features (e.g., isocyanates, halogenated diazines and triazines,  $\beta$ -lactams, and diazonium salts) that are thought to be important in the expression of respiratory sensitization.<sup>106</sup>

#### 5.39.3.4.3 Phospholipidosis

Phospholipidosis, a phospholipid storage disorder, is defined by an excessive accumulation of intracellular phospholipids and the concurrent development of concentric lamellar bodies. Phospholipids are structural components of mammalian cytoskeleton and cell membranes. The metabolism of this essential cell component is regulated by the individual cell, and may be altered by drugs that interact with phospholipids or the enzymes that affect their metabolism.<sup>107</sup> Phospholipidosis can occur in multiple target organs, including the liver, kidney, brain, and lungs. While it is considered a disruption of normal cellular function, the long-term implications for human health remain an ongoing debate in the scientific community.<sup>108</sup> Drugs known to induce phospholipidosis all share several common physicochemical properties: a hydrophobic ring structure on the molecule and a hydrophilic side chain with a charged cationic amine group, hence the class term ‘cationic amphiphilic drugs’ (CADs).<sup>107</sup> Amiodarone (Figure 5) is a classic example of a CAD that has been well studied in the public literature and is known to cause phospholipidosis. To date, in silico models for the prediction of this toxicological endpoint have focused primarily on the use of physicochemical descriptors such as  $pK_a$  and  $\log P$  to distinguish between positive and negative structures. Ploemen *et al.* have demonstrated that these two simple parameters are capable of distinguishing between inducers and noninducers.<sup>109</sup> The heuristics used in this exercise were that for a compound to cause phospholipidosis the calculated  $\log P$  (ClogP)

**Figure 5** Structure of amiodarone.

must be greater than 1, and the first basic  $pK_a$  must be greater than 8. In addition, the combined sum of the squares of each parameter must be greater than 90 for the compound to be classed as positive (see eqn [1]):

$$\begin{aligned} &\text{If } (\text{ClogP} > 1) \text{ AND } (pK_a > 8) \text{ AND } (((\text{ClogP})^2 + (pK_a)^2) > 90) \\ &\text{then phospholipidosis} = \text{TRUE} \end{aligned} \quad [1]$$

An independent validation of this proposed model has not been published, and so independent verification is not available. As with all models, it is advisable that validation studies by third parties independent of the original developers be conducted prior to their broad implementation in a research environment.

#### 5.39.3.4.4 Hepatotoxicity

Despite hepatotoxicity being a primary cause of market withdrawals, few developers have turned their attention to predicting this endpoint. Reasons for this could be because of the insufficient volume of high-quality data required to address the problem or because hepatotoxicity covers a multitude of complex endpoints that make relationships to chemical properties difficult to tease out from the available data. To date, only two developers, Lhasa Limited (the developers of DfW) and the Informatics and Computational Safety Analysis Staff (ICSAS) at the US Food and Drug Administration (FDA) have publicly acknowledged that they are working on this toxicological endpoint.<sup>110,111</sup>

Note *et al.* acknowledge that no systematic attempt has been made to provide comprehensive coverage of hepatotoxicity within the DfW knowledge base. However, efforts are underway to improve the predictive performance of DfW for this endpoint through the compilation and analysis of relevant toxicity data from a range of sources. To date, data have been collected for 1139 compounds, for which at least some evidence of hepatotoxicity has been reported either in humans and/or experimental animals. Efforts to derive new structural alerts or make modifications to existing alerts for hepatotoxicity based on the compound classes in the data set are currently ongoing.<sup>110</sup>

The ICSAS group has compiled a database on human liver adverse effects based on reports of ADRs reported to the regulatory authority. Of the 631 compounds contained in this data set, 490 have ADR data available for one or more of the 47 liver effects COSTAR term endpoints. The liver adverse effect data from the five liver enzyme increase endpoints were used to optimize the database for identification of a significant adverse effect. Matthews *et al.* have used the MultiCASE (MCASE) algorithms to develop predictive models based on these data.<sup>111</sup>

#### 5.39.3.4.5 Reproductive and developmental toxicity

Reproductive toxicology is where exposure to a toxin causes adverse effects on either the male or female reproductive system. Developmental toxicity is where exposure to a chemical before conception (by either parent), during prenatal development, or postnatally until the time of puberty, causes the impairment of the normal growth and development of the offspring. In addition, another consideration is teratogenicity, where exposure to a chemical between conception and birth causes malformations in the offspring.

While this type of toxicity is not a common cause for withdrawal of drugs from the market, it can severely limit the population to which drugs can be administered, and hence impacts on their profitability. This fact, along with increasing concern over environmental exposure to chemicals, is driving the industry and regulators to seek ways to rapidly identify compounds that demonstrate this liability.

To date, only a few attempts have been made to develop *in silico* models for these toxicological endpoints. Gombar *et al.* compiled a database of 273 compounds that had been tested in rodents and reported to cause maternal toxicity or fetal anomalies that passed their criteria for data quality and structural inclusion.<sup>112</sup> These compounds were further subdivided into three chemical classes, aliphatic, carboaromatic, and heteroaromatic compounds, with a balanced number of positive and negatives totaling around 90 chemicals in each. The TOPKAT models use electrotopological descriptors as defined by Hall and Kier<sup>113</sup> to relate the adverse effects to the chemical structure. Using this approach, the developers claim, using a leave-one-out jackknife test, to get models with specificities ranging from 86% to 97%, and sensitivities between 86% and 89% for these chemical classes. The authors go on to say that in an evaluation of 18 pharmaceuticals only five had developmental toxicity data available, of which only three were considered to be inside the predictive space of the models although all three were correctly identified. It is worth noting that the training sets for these models are relatively small and that the independent test set is insufficient to accurately gauge their broad applicability or the reliability of the predictions from these models.

Ghanooni *et al.* developed a model using the MCASE technology<sup>114</sup> (see Section 5.39.4 on commercial systems for more details). They used a data set of some 323 compounds retrieved from the Teratogen Information System and a database used by the FDA.<sup>115,116</sup> Using an *n*-fold cross-validation, by withholding 10% of the data from the training set,

yielded models with a pooled concordance of 72.6%. Gómez *et al.* also used MCASE to look at compounds shown to cause developmental toxicity in hamsters.<sup>117</sup> They assembled a data set of 192 chemicals taken from Schardein<sup>118</sup> and an additional 42 physiological chemicals that were assumed to not cause toxicity at physiological concentrations. The authors claim that the overall predictability of the model is 74%, although there is an insufficient number of compounds available for a truly external validation of the model.

In a report from an International Life Science Institute working party, Julien *et al.*<sup>9</sup> conclude that after considering two SAR systems (TOPKAT and MCASE) that have been applied to developmental toxicity illustrates the difficulties in predictive modeling of this type of toxicity. The difficulties stem from the fact that developmental toxicity encompasses a wide range of endpoints, yet there is little knowledge of the mechanisms underlying these diverse endpoints. Thus, *in silico* models for developmental toxicity must rely primarily on using a statistical approach. With this type of methodology, the activity (or inactivity) of each compound in the training set must be captured as a score that can be correlated with the presence or absence of chemical structural features. This requirement poses at least two major challenges: (1) defining the effect on which compounds are scored and (2) having an objective, rational, reproducible and transparent process for scoring compounds on that activity. Given the wide range of ‘effects’ encompassed by developmental toxicity and the complexity in evaluating the data, it is very difficult to score activities in a way that makes biological sense and also allows statistical analysis.

## 5.39.4 Commercially Available Systems for Toxicity Prediction

### 5.39.4.1 Major Systems and Suppliers

There are many commercial systems for the prediction of toxicity available on the market. To date, these systems, in general, fall into one or other of the three categories of models discussed earlier (statistics based, rule based, and 3D). In all cases, each system has advantages and disadvantages, and it is important that the user understands the limitations of each system when using them to help guide decision-making. Table 3 lists the main systems available with their respective suppliers, system category, and key references for additional information.

For a more comprehensive review of DfW, MCASE, TOPKAT, and HazardExpert, refer to the review by Greene.<sup>14</sup>

### 5.39.4.2 Comparisons of System Performances

Most evaluations published on commercial systems to date have focused primarily on one or more of the four market-leading systems, TOPKAT, MCASE, DfW, and Hazard Expert. At the Environmental Mutagen Society meeting in 2003, Greene presented a comparison between all four of these systems, based on a proprietary data set of pharmaceutical-like compounds that had been tested in the Ames assay.<sup>128</sup> The versions of each system used and the criteria used to interpret the results are listed in Table 4.

The compounds used in the evaluation consisted of some 974 legacy Pfizer compounds, of which approximately 10% gave a positive response in the Ames assay, and 268 legacy Warner Lambert compounds, of which approximately 15% were Ames-positive. It should be noted that with an evaluation set of compounds that have a high bias toward

**Table 3** Major commercial systems for toxicity prediction

| <i>System</i>            | <i>Developer</i>   | <i>Category</i>     | <i>Reference</i> |
|--------------------------|--|---------------------|------------------|
| DEREK for Windows (DfW)  | Lhasa Limited ( <a href="http://www.lhasalimited.org">www.lhasalimited.org</a> ) | Rule based          | 14,63,88,119     |

<sup>a</sup> Hybrid systems combine statistical and rule-based approaches.

<sup>b</sup> Know-It-All combines CSGenTox and HazardExpert, to give a consensus model.

**Table 4** Commercial systems, versions, and interpretation criteria used in a cross-platform comparison

| <i>System</i>      | <i>Version</i>   | <i>Criteria</i>  |
|--------------------|--|--|
| TOPKAT             | Main software version 6.1 Ames mutagenicity module version 3.1 | $p > 0.7$ = positive, $p < 0.3$ = negative, $0.3 < p < 0.7$ = indeterminate                        |
| DfW                | Version 6.0  | <i>Salmonella</i> species selected:<br>plausible = positive, equivocal = open, no alert = negative |
| HazardExpert       | Version 5.0  | Used default probabilities to determine call   |
| MCASE <sup>a</sup> | Version 3.45 module A2I  | CASE units $> 19$ = positive, CASE units $< 19$ = negative   |

<sup>a</sup> No compounds were excluded for unknown fragments or other reasons.

**Table 5** Results (as percentages) for DfW, TOPKAT, HazardExpert, and MCASE for the combined set of 1242 compounds

| <i>System</i> | <i>Sensitivity</i> | <i>Specificity</i> | <i>Concordance</i> | <i>Predictive value (positive)</i> | <i>Predictive value (negative)</i> | <i>Coverage</i> |
|---------------|--------------------|--------------------|--------------------|------------------------------------|------------------------------------|-----------------|
| DfW           | 48.8               | 81.9               | 78.7               | 22.5                               | 93.7                               | 100.0           |
| TOPKAT        | 27.4               | 83.4               | 77.6               | 16.1                               | 90.8                               | 87.7            |
| HazardExpert  | 75.2               | 65.1               | 66.1               | 18.9                               | 96.1                               | 100.0           |
| MCASE         | 33.1               | 84.0               | 79.0               | 18.3                               | 92.1                               | 99.9            |

negatives, models that have a tendency toward false negatives (i.e., predict positive compounds as being negative) will naturally have a high concordance measure. Indeed, in this particular case, predicting all compounds to be negative will give an overall concordance of nearly 90%. However, this type of model provides no value in terms of enabling decisions or prioritizing compounds for development. The combined results from both sets of compounds for each system are listed in [Table 5](#).

In [Table 5](#), sensitivity is the percentage of Ames-positive compounds correctly predicted; specificity is the percentage of Ames-negative compounds correctly predicted; concordance is the total percentage of compounds correctly predicted; predicted value of a positive is the percentage of compounds predicted positive that were positive; predicted value of a negative is the percentage of compounds predicted negative that were negative; and coverage is the percentage of compounds for which predictions could be made by the system.

While HazardExpert predicted the greatest number of positive compounds correctly, it also gave the highest number of false positives, predicting almost 35% (over 400 compounds) of the Ames-negative compounds to be positive. There was little difference between TOPKAT and MCASE, the two statistical models, in terms of their predictive power, and DfW was not significantly better, although its ability to predict Ames-positive compounds was better than the statistics-based methods.

Comparisons by other researchers have found similar results when comparing the predictions for mutagenicity against the actual Ames assay results for compounds. Cariello *et al.* used a set of some 414 compounds to compare the capabilities of the DfW and TOPKAT systems.<sup>129</sup> Of these 414 compounds, approximately 20% gave a positive response in the Ames assay. Their results indicated that DfW achieved overall concordance of 64.5% whereas TOPKAT achieved a concordance of 73.3%. The authors noted, however, that 26% of the 414 compounds were considered to be outside the prediction space for the TOPKAT model, and therefore the predictions for these compounds were considered unreliable and removed from the analysis.

Similarly, Pearl *et al.* looked at a set of 123 pharmaceutical compounds, of which 49 were Ames-positive, to compare the abilities of DfW, TOPKAT, and MCASE at predicting the results for compounds in the Ames assay.<sup>130</sup> The authors found the overall concordance for each system was 61%, 67%, and 72%, respectively, with DfW having the lowest false-negative rate at 8%. The authors suggest that by combining one or more of these predictive models it is possible to improve upon the concordance of the individual systems. The authors comment that using MCASE to confirm a DfW-positive call produced a combined system with a high overall concordance at 75% while maintaining coverage at 97%. While using all three systems did result in the highest overall concordance at 86%, the coverage of this approached dropped dramatically to 46%.

**Table 6** Summary of the performance characteristics of MCASE, DfW, and TOPKAT

|                       | <i>Sensitivity</i> | <i>Specificity</i> | <i>Concordance</i> |
|-----------------------|--------------------|--------------------|--------------------|
| <i>MCASE</i>          |                    |                    |                    |
| Ames                  | 13/27 (48.1%)      | 307/330 (93.0%)    | 320/357 (89.6%)    |
| In vitro cytogenetics | 10/47 (21.3%)      | 174/184 (95%)      | 184/231 (79.7%)    |
| MLA                   | 7/23 (30.4%)       | 78/82 (95.1%)      | 85/105 (80.9%)     |
| In vivo cytogenetics  | 6/25 (24.0%)       | 245/267 (91.7%)    | 251/292 (85.9%)    |
| <i>DfW</i>            |                    |                    |                    |
| Ames                  | 14/27 (51.9%)      | 260/346 (75.1%)    | 274/372 (73.6%)    |
| In vitro cytogenetics | 15/47 (31.9%)      | 139/206 (67.5%)    | 154/253 (60.8%)    |
| MLA                   | 8/24 (33.3%)       | 50/85 (58.8%)      | 58/109 (53.2%)     |
| In vivo cytogenetics  | 10/30 (33.3%)      | 194/276 (70.2%)    | 204/306 (66.7%)    |
| <i>TOPKAT</i>         |                    |                    |                    |
| Ames                  | 10/23 (43.4%)      | 267/316 (84.5%)    | 277/339 (81.7%)    |
| In vitro cytogenetics | 11/48 (22.9%)      | 150/172 (87.2%)    | 161/220 (73.1%)    |
| MLA                   | 3/24 (12.5%)       | 67/76 (88.1%)      | 70/100 (70%)       |
| In vivo cytogenetics  | 8/28 (28.5%)       | 219/260 (84.2%)    | 228/288 (79.2%)    |

White *et al.* in their comparison of TOPKAT, DfW, and MCASE used a set of some 520 proprietary pharmaceutical compounds that had been tested in the Ames assay.<sup>29</sup> This test set contained approximately 15% Ames-positive compounds, and therefore would favor systems that had a high false-negative rate. In their analysis they found that TOPKAT had an overall concordance of 74%, MCASE, 81%, and DfW, 72%. Interestingly, though, MCASE could only make predictions on 213 compounds (41%). Similarly, TOPKAT could only make predictions for 319 (61%) of the compounds, whereas DfW made predictions for all compounds in the set. The authors note, however, that when the predictions of all three systems are combined and all three agree, the concordance with the Ames assay rises to 95% but the number of compounds for which predictions are made drops to only 15% of the data set.

In their analysis, Snyder *et al.* looked at the genotoxicity of a set of 394 pharmaceutical compounds that are currently on the market.<sup>28</sup> The data for these compounds were collected from the Physicians Desktop Reference (PDR). The final set comprised 7.2% bacterial reverse mutagenesis (Ames) positives (27/375), 18.7% in vitro cytogenetics (primarily chromosome aberration) positives (47/251), 22% MLA positives (24/109), and 10.1% in vivo cytogenetics (primarily rodent micronucleus) positives (31/305). DfW, MCASE, and TOPKAT were used to make predictions, and their respective results are listed in [Table 6](#).

Snyder concludes that the relative insensitivity of these computational models to predict Ames and, for that matter, genotoxicity in general may be due to both our incomplete understanding of genotoxic mechanisms and an insufficiency of structural coverage in these test systems. It is important, therefore, to consider the limitations of each system and make appropriate decisions when using the commercial in silico models.

### 5.39.5 Summary

The use of in silico models to predict toxicity offers some significant advantages over traditional in vitro and in vivo approaches. The models are generally much cheaper and faster on a per compound basis, and capable of providing an assessment of toxicity within a matter of seconds. They also do not require any physical chemical matter, and can

therefore be employed even before the compounds have been synthesized. These advantages make the use of computational approaches very attractive to the chemical industry and regulators alike.

However, the identification of toxicity is a complex task, often not being revealed until humans are exposed to a compound. Nevertheless computational methods are able to predict individual toxic endpoints, which, when combined with information on likely exposure (e.g., duration of treatment, dose, and route), can provide useful information to assist in risk assessment.<sup>131</sup>

There are a number of areas in the drug discovery process where predictive techniques may be applied, but the nature of the method will normally define its appropriate use. For instance, methods for genotoxicity prediction may be applicable to screen out compounds from a virtual library with a high probability of toxicity. However, prediction of other toxicological endpoints, such as hepatotoxicity, may be more appropriately placed in the drug optimization stages of the discovery process. Needless to say, methods that are available for large-scale screening must be rapid, computer-based, and able to screen large numbers of compounds in a single run.

It is, however, crucial to know the limitations of *in silico* techniques and avoid applying them blindly to every instance. In this respect, it is advantageous to use techniques that present the rationales for their predictions in a traceable manner, and that indicate the limitation of their predictions clearly (e.g., compounds that fall beyond the applicability domain of the model or inconclusive evidence for predictions). In the case of unreliable predictions, it is better to perform additional biological experiments to clarify these issues than to trust *in silico* predictions implicitly.<sup>132</sup>

Significant improvements in the predictive ability of computational models for toxicological endpoints are unlikely to come from improvements in methodology alone, such as the use of better descriptors or new algorithms. The reality is that there is not a simple set of 'Lipinski-like' rules that will answer all questions concerning toxicity. An adverse event can be the culmination of an incredibly complex series of physical, biochemical, and physiological processes. This mechanistic complexity of toxicity coupled with incomplete knowledge is too fundamentally limiting to allow accurate predictions across all chemical space through the use of a single model. Simplistic modeling of such phenomena will only result in trivial models with limited utility.

All computational systems for toxicity prediction, whether rule or QSAR based, are limited by the availability of toxicity data on which to develop, evaluate, and validate models. Indeed, the whole area of predictive toxicology is blighted by the paucity of publicly available, high-quality data for modeling. Much toxicity data are, of course, held within industry archives, and while it is always easy to call for the release of corporate data, unless forced by legislation, large-scale public data release is highly unlikely. However, it should be remembered that commercially sensitive data might be used internally within individual companies to assist in the evaluation, validation, and further development of models.

Improvements in the prediction of toxicity will ultimately come from the more challenging and difficult task of improving our understanding of the mechanisms, and better integration of quantitative modeling QSAR, empirical association, biological mechanisms, and chemical reactivity considerations toward the goal of building mechanistically relevant and valid models across a wide range of mechanisms and chemical classes.<sup>133</sup>

In the future, the use of computer-aided toxicity prediction looks set to expand in the chemical industries and their regulation by government agencies. However, the use of predictive techniques must be tempered by the realization and appreciation of their limitations, and these points require transparency of models and expertise in their application. A more holistic approach to toxicity prediction is required that may include an integrated assessment of absorption, distribution, metabolism, and excretion (ADME), route of exposure, dose, etc. Data used to make an informed assessment may come from a variety of sources, including QSARs, expert systems, and knowledge of the effects of 'similar' chemicals (however similarity may be defined), as well as genomic level *in vitro* and *in vivo* experiments. To best address the challenge of structure-based toxicity prediction, we should seek a convergence of modeling approaches toward a more unified approach for the future, one that includes elements of hypothesis generation, data base exploration, statistical association, and existing knowledge. The ideal toxicity prediction method will ultimately be one that builds upon existing data and knowledge using the full range of human and machine capabilities for processing relevant information.<sup>134</sup>

## Biography

**Nigel Greene** received his BSc in chemistry and computational science from the University of Leeds in the UK in 1991. He was awarded his PhD also from the University of Leeds in 1994, where his work focused on the synthesis of organophosphorus ligands and transition metal complexes for the catalysis of acetic acid production. Following on from his PhD, Greene worked at Lhasa Ltd in the UK, promoting the use and development of the DEREK for Windows computer program for toxicity prediction and METEOR for metabolite prediction. In 1999, after 5 years with Lhasa Ltd, he then moved to Tripos Inc., where he promoted the use of the SYBYL molecular modeling software suite within the pharmaceutical industry. Since February 2001, Greene has worked for Pfizer Inc. in their World Wide Safety Sciences Department, heading a computational toxicology group whose aim is to use in silico methods for the early identification and screening of new molecular entities in drug discovery and development.

## 5.40 In Silico Models to Predict QT Prolongation

### 5.40.1 Introduction

Recent years have witnessed a revolution in philosophical approaches to drug discovery. Spiraling R&D costs along with higher failure rates of clinical candidates have contributed to the growing recognition by the drug discovery community that undesirable drug properties and toxicity are two of the major contributors to pipeline attrition. Owing to this awareness, many organizations have moved to incorporate predictive absorption, distribution, metabolism, excretion, and toxicity (ADMET) into early discovery programs under the slogan of ‘fail fast, fail cheap.’ By identifying and removing undesirable leads early, the research organizations should be able to prevent more costly failures downstream. Wider availability of commercial libraries, internal combinatorial chemistry capabilities, and ever-increasing throughput of high-throughput screening (HTS) campaigns have been providing medicinal chemists

with multiple potential starting points, and the application of predictive ADMET is seen as a way to narrow the scope of lead exploration.

Originally the domain of experimentalists, ADMET began to change in the late 1990s, embracing the use of computational tools for predicting ADMET properties of compounds. As broader and higher quality proprietary data sets became available, computational approaches have advanced from 'first-generation' models, such as Lipinski's Rule of Five,<sup>1</sup> and in a broader sense drug-likeness<sup>2,3</sup> and lead-likeness,<sup>4,5</sup> to 'second-generation' models that focus primarily on predicting pharmacokinetic parameters, such as solubility, intestinal permeability, oral bioavailability, and blood-brain barrier penetration.<sup>6,7</sup> The 'third-generation' models<sup>6</sup> have taken aim at major determinants of metabolic fate of xenobiotics (cytochrome P450s)<sup>8</sup> and factors that induce them (pregnane X-receptor),<sup>9</sup> drug transport proteins affecting compound PK profile (P-glycoprotein),<sup>10</sup> and, more recently, ion channels implicated in QT interval prolongation (hERG).<sup>11</sup> It is this predictive cardiotoxicity screening that is the focus of this chapter.

It would be impossible to incorporate all of the information regarding QT prolongation in a single review chapter, and this was not the intended goal. The primary focus in this review is on in silico tools for predicting drug-induced QT prolongation, and structural lessons that have been derived in an effort to bias newly synthesized ligands away from the undesirable side effect of cardiotoxicity. The field of hERG modeling is very young and active, with most articles on the topic published since 2002. The most recent reviews published on the general topic of QT prolongation are by De Ponti *et al.*<sup>12</sup> and Abriel *et al.*,<sup>13</sup> while Redfern *et al.*<sup>14</sup> is required reading for anyone interested in the acceptable historical safety windows for QT prolongation. Reviews by Mitcheson and Perry<sup>15</sup> and Sanguinetti and Mitcheson<sup>16</sup> cover the biomolecular underpinnings of hERG blockade. Finally, the chemical nature of hERG blockers is discussed by Pearlstein *et al.*,<sup>17</sup> Aronov,<sup>18</sup> and Recanatini *et al.*<sup>19</sup>

#### 5.40.2 Human Ether-a-go-go Related Gene (hERG)-Related Cardiotoxicity

Sudden death as a side effect of the action of non-antiarrhythmic drugs is a major pharmacological safety concern facing the pharmaceutical industry and the health regulatory authorities.<sup>20</sup> In recent years, at least five blockbuster drugs (Figure 1) have been withdrawn from the market due to reports of sudden cardiac death, and a number of others were forced to carry strong 'black box' warning labels.<sup>11,17,20</sup> In all cases, long QT syndrome (LQTS), an abnormality of cardiac muscle repolarization that is characterized by the prolongation of the QT interval in the electrocardiogram, was implicated as a predisposing factor for torsades de pointes, a polymorphic ventricular tachycardia that can spontaneously degenerate to ventricular fibrillation and cause sudden death.

**Figure 1** Drugs withdrawn due to QT prolongation concerns. (Reproduced with permission from Aronov, A. M. *Drug Disc. Today* 2005, 10, 149–155 © Elsevier.)

### 5.40.2.1 QT Interval and QT Prolongation

Cardiac action potential consists of four distinct phases (Figure 2a). In phase 0, upstroke occurs due to rapid transient influx of  $\text{Na}^+$ . Later,  $\text{Na}^+$  channels are inactivated, combined with a transient efflux of  $\text{K}^+$ . In phase 2, also known as the plateau phase, the efflux of  $\text{K}^+$  and the influx of  $\text{Ca}^{2+}$  are counterbalanced. At the end of the plateau, sustained repolarization occurs due to  $\text{K}^+$  efflux via the delayed rectifier  $\text{K}^+$  channels exceeding  $\text{Ca}^{2+}$  influx; this constitutes phase 3 of the action potential. Finally, as part of phase 4, resting potential in myocytes is maintained.

In the clinical setting, the QT interval is measured from the beginning of the QRS complex to the end of the T wave (Figure 2b). The QRS complex of the electrocardiogram corresponds to the action potential depolarization, while the T wave is associated with ventricular repolarization. Torsades de pointes is associated with the twisting of the QRS complex around the isoelectric line on the electrocardiogram. Since QT interval depends to a large degree on the heart rate, it is typically reported as QTc, a value normalized for a heart rate of 60 bpm. Bazett's formula<sup>21</sup> is frequently used to introduce the heart rate correction. For reasons that are as yet unknown, QTc in adult females is about 20 ms longer than that in males. The normal limits of QTc in adults are 430 ms in males and 450 ms in females.<sup>13</sup> An increase of up to 20 ms is considered borderline, while longer QTc values correspond to prolonged QT interval.

### 5.40.2.2 Molecular Basis of QT Prolongation

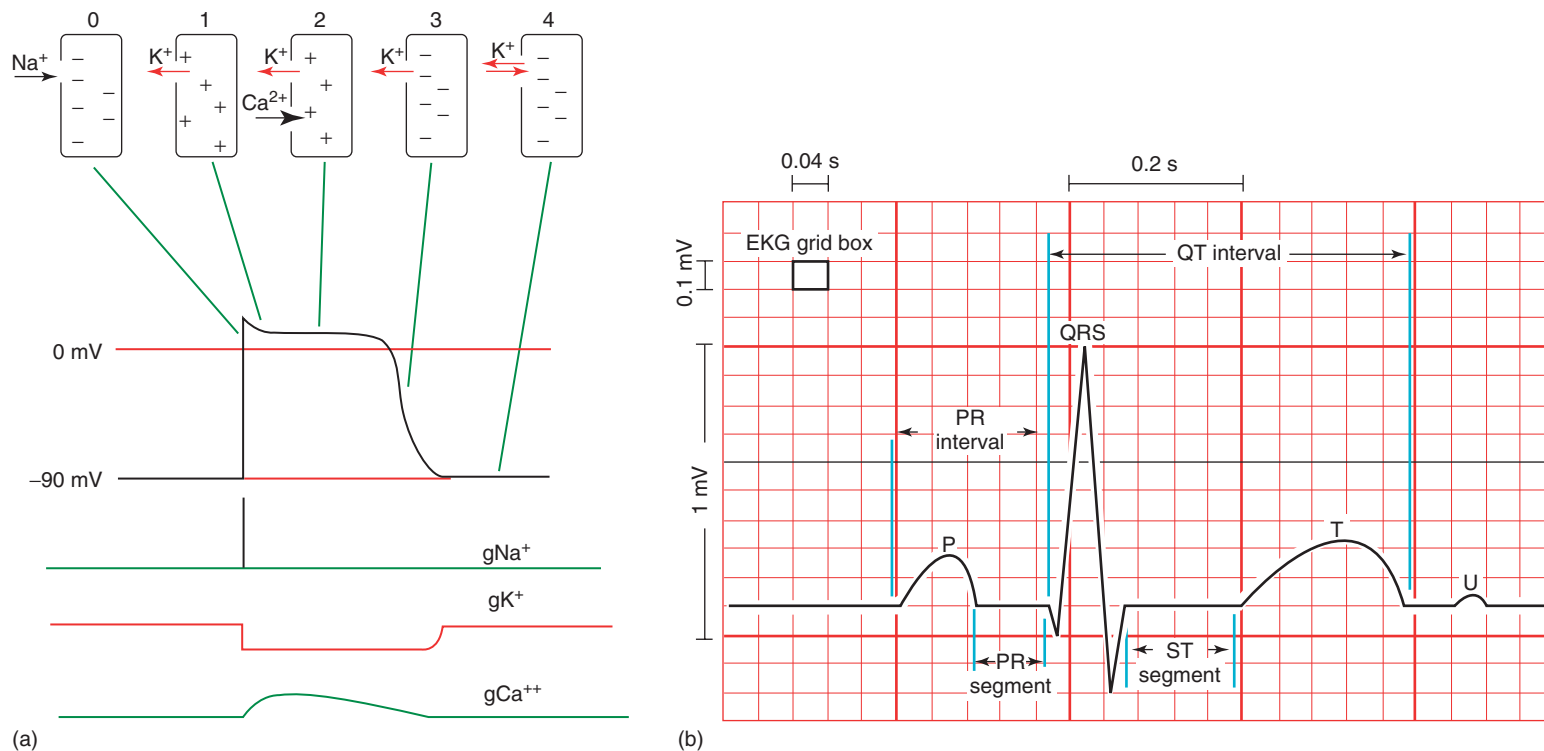

Congenital LQTS can be traced back to a number of possible mutations resulting in defects in sodium channels, and two different potassium channels – the rapidly activating delayed rectifier  $I_{\text{Kr}}$  and the slowly activating delayed rectifier  $I_{\text{Ks}}$ .<sup>22,23</sup> The primary effect the mutations have on the length of the QT interval is due to the role many  $\text{K}^+$  channels play in terminating the plateau phase of the action potential. Any delay in phase 3 repolarization manifests itself in QT interval prolongation. Mutations occur both in genes encoding  $\alpha$ -subunits (KvLQT1, LQT1; hERG, LQT2; SCN5A, LQT3, etc.) and  $\beta$ -subunits (KCNE1, LQT5; KCNE2, LQT6) of ion channels.<sup>13,16,23,24</sup> Mutations in these genes are estimated to occur in  $\sim 1$  in 5000 individuals worldwide and cause an estimated 3000 deaths annually in the US.<sup>16</sup>

### 5.40.2.3 Role of Human Ether-a-go-go Related Gene in QT Prolongation

Virtually every case of a prolonged duration of cardiac action potential related to drug exposure (acquired LQTS) can be traced to one specific mechanism – blockade of  $I_{\text{Kr}}$  current in the heart.<sup>17</sup> This current, a major contributor to phase 3 repolarization at the end of the QT interval, is conducted by tetrameric pores with the individual subunits encoded by the human ether-a-go-go related gene (hERG).<sup>15</sup> Not all hERG channel blockers induce torsades de pointes as they can also modulate other channels that counteract the effect of hERG blockade. However, the blockade of hERG  $\text{K}^+$  channels is widely regarded as the predominant cause of drug-induced QT prolongation and an important indicator of potential pro-arrhythmic liability, making early detection of compounds with this undesirable side effect an important objective in the pharmaceutical industry.

Perhaps owing to the unique shape of the ligand-binding site and its hydrophobic character, the hERG channel has been shown to interact with pharmaceuticals of widely varying structure, often at concentrations similar to the levels of on-target activity of the respective compounds. While risk tolerance for QT prolongation may vary significantly depending on indication, development stage, etc., the documented hERG-blocking activity reduces the intrinsic value of the molecule, as it increases risk of clinical failure. Among the indications least tolerant of hERG blockade by the candidate compound are antivirals and antibacterials where high plasma concentrations of the drug are necessary to suppress resistance, and pain management drugs and antipsychotics where overdosing is likely. In addition, drug–drug interactions (e.g., via inhibition of P450 metabolism) may lead to unexpectedly high plasma levels of a drug, which are sufficient to prolong the QT interval. As a general rule, a safety window of greater than 30-fold has been recommended for the ratio of hERG  $\text{IC}_{50}$  to the expected compound  $C_{\text{max}}$  adjusted for its unbound fraction.<sup>14</sup> This ratio could be used as a ‘go-no go’ decision point in early discovery.

In recent years, a number of in silico approaches have attempted to mitigate the safety concern represented by hERG channel blockade. Some of these approaches have been aimed primarily at filtering out potential hERG blockers in the context of virtual libraries, while others have involved understanding structure–activity relationships governing hERG–drug interactions. This chapter summarizes the most recent efforts in this emerging field.

**Figure 2** Cardiac action potential. (a) Voltage changes in the heart as a function of changes in ion currents into and out of the cell. (b) Schematic of an ECG tracing. Parameters derived from the ECG are depicted. QT interval is determined as the length of time separating the beginning of the QRS complex and the end of the T wave.

### 5.40.3 Screening for Human Ether-a-go-go Related Gene Blockers

Any discussion of predictive modeling approaches would be incomplete without mention of the type of data used to build predictive in silico models. Two excellent reviews in *Drug Discovery Today* have summarized the types of test systems and assays currently available for cardiotoxicity screening.<sup>25,26</sup>

#### 5.40.3.1 In Vitro Telemetry

In vivo telemetry experiments in nonrodents (typically in conscious or anesthetized dogs) are the ultimate preclinical test for cardiotoxicity, with data generated under physiological conditions and related to the pharmacokinetic profile of the drug. However, its high cost severely limits its use at the earlier discovery stage.<sup>25</sup> In vitro electrophysiology in primary cardiac tissue, such as Purkinje fibers, is sometimes used, but is relatively low throughput and variability precludes its widespread application.

#### 5.40.3.2 Patch Clamp Techniques

Voltage clamp techniques represent the ‘gold standard’ in the field and provide real time mechanistic information on ion channels.<sup>26</sup> The experiments are performed in mammalian cells (e.g., Chinese hamster ovary (CHO) cell line or human HEK293) transfected with the gene for hERG. The overwhelming majority of predictive hERG models have been built using mammalian patch clamp data. Electrophysiology data from experiments performed in *Xenopus* oocytes can be found in the literature. Unfortunately, the highly lipophilic environment in the oocytes appears to limit access of the drug to its site of action, leading to IC<sub>50</sub> values being increased by as much as 100-fold.<sup>26,27</sup> While this could be tolerated in a classification model, quantitative structure–activity relationship (QSAR) approaches have tended to avoid using data collected in the oocytes.

#### 5.40.3.3 High-Throughput Assays

Owing to the moderate throughput of patch clamp experiments, many companies have been willing to compromise on data quality to increase assay throughput. Techniques such as fluorescence-based assays with cells stably transfected with hERG and radioligand binding assays<sup>25</sup> have been successfully used to tune out hERG channel activity in lead series.<sup>28,29</sup> Radioligand binding assays typically utilize known hERG blockers, such as [<sup>3</sup>H]dofetilide, [<sup>35</sup>S]MK-499, or [<sup>3</sup>H]astemizole to measure the extent of radiolabel displacement by compounds in question.<sup>30</sup> While it is thought that most hERG blockers bind at the intracellular region of the pore,<sup>15,17</sup> radioligand binding assays have a potential to produce false negatives in case a ligand binds to hERG elsewhere.<sup>30</sup> Fluorescence-based assays utilize voltage-sensitive dyes to monitor the membrane potential of the cell in response to a changing electrochemical gradient across the membrane. Another option is a rubidium flux assay, in which the rubidium gradient is characterized with atomic absorbance spectrometry. Unfortunately, the variation in potency obtained in these higher throughput experiments from patch clamp data and the frequent occurrence of false negatives due to a lower sensitivity of the assays<sup>26,30</sup> makes the data sets derived by these techniques less amenable to consistent model building.

#### 5.40.3.4 Planar Patch Clamp

A new and exciting development in ion channel screening has been the recent introduction of automated high-throughput patch clamp machines (e.g., planar patch technology).<sup>26</sup> Most planar patch instruments utilize silicon-based plates with holes etched into them. Suction brings cells close to the hole, thus removing the need for a manually operated patch pipette. Several correlations to manual patch clamp data have been reported, but further validation is necessary. The approach suffers from problems typically associated with automated screening procedures, such as compound insolubility in buffer leading to false-negative results. If successful, this approach could revolutionize cardiac safety testing by increasing the rate of data acquisition by approximately 100-fold, ultimately providing larger and more diverse data sets for in silico modeling.

#### 5.40.3.5 Whole Organism Approaches

Another recent innovation in cardiotoxicity screening is the use of zebrafish for whole organism compound testing.<sup>31</sup> Zebrafish provide scalability due to their rapid growth, making assays in multiwell plate format possible. In addition, they are tolerant to dimethyl sulfoxide (DMSO), typically used to store liquid compound samples in screening

collections, and readily absorb compounds from the water. In the case of hERG gene, 99% amino acid identity between zebrafish and human sequences has been shown for the key S6 and pore domains.<sup>32</sup> Several known QT-prolonging drugs were shown to elicit arrhythmia in zebrafish embryos.<sup>32</sup> More validation of the zebrafish system is ongoing, but preliminary results appear to indicate its potential use in early toxicity screening. Zebrafish can be viewed as a powerful sieve, and while further compound attrition upon going from zebrafish to humans is expected, the attrition rate should be significantly lower.<sup>31</sup>

#### 5.40.4 Predictive Modeling of Human Ether-a-go-go Related Gene Blockers

Of the variety of hERG modeling approaches that have appeared in the literature, most can be broadly divided into three categories: homology modeling, QSAR models, and classification methods.

##### 5.40.4.1 Homology Modeling of Human Ether-a-go-go Related Gene

At least two groups<sup>33,34</sup> have reported hERG homology models using available atomic resolution structures of bacterial K<sup>+</sup> channels KcsA<sup>35</sup> (closed) and MthK<sup>36</sup> (open). These channels contain only two transmembrane domains (equivalent to helices S5/S6 in **Figure 3**), and the models therefore only cover the predicted structure of the hERG pore. The basic architecture of hERG channel is expected to be similar to that of other voltage-gated K<sup>+</sup> channels, such as KvAP (**Figure 3**).<sup>37</sup> The channel pore domain is formed by tetramerization from helices S5 and S6, as well as the pore helix P and the selectivity filter loop. The selectivity filter lies on the extracellular side of the membrane. The movement of S6 helices with respect to each other in a crossover fashion renders the channel closed, with the water-filled cavity isolated from cytosol. The voltage-sensing paddles formed by helices S3b and S4 are responsible for the voltage dependence exhibited by KvAP. The debate about the exact position of the S4 segment and the details of voltage sensing at the molecular level is ongoing.<sup>38,39</sup> While the structure and location of the paddles with respect to the membrane may be different in hERG, the basic structure of the pore is likely to be reasonably conserved.

Two bands of aromatic residues are predicted to line the cavity, with each monomer contributing Phe656 and Tyr652 (**Figure 4**).<sup>15,33,34</sup> These residues are both located on the S6 helix, with the tetrad of Phe656 situated closer to the mouth of the channel, and the four Tyr652 residues further toward the pore helix. The homology model is corroborated by earlier mutagenesis data. Sanguinetti and co-workers used alanine scanning to identify key residues responsible for hERG blockade by potent inhibitors terfenadine, cisapride, and MK-499.<sup>33</sup> Phe656 and Tyr652 appeared to be the primary interaction points. The current consensus implicates Phe656 in  $\pi$ -stacking interactions with the ligands, while Tyr652 is thought to participate in a cation- $\pi$  interaction with the protonated basic nitrogen present in most of the reported hERG blockers. Recently, the potency for hERG blockade by these three drugs was shown by systematic mutagenesis to correlate well with measures of hydrophobicity of residue 656, such as its side chain van der Waals

**Figure 3** Structural model of hERG channels. Key elements of hERG channel topology illustrated using the x-ray structure of KvAP.<sup>37</sup> Two of the four subunits comprising the tetrameric channel are shown. (Reproduced with permission from Aronov, A. M. *Drug Disc. Today* **2005**, 10, 149–155 © Elsevier.)

**Figure 4** Model of the pore portion of hERG channel. The P-S6 fragment is shown for a dimer. Aromatic residues Phe656 and Tyr652 are critical for hERG block by most known small molecule ligands. Polar residues Thr623 and Ser624 modulate the binding potency for a number of reported hERG blockers. An hERG blocker is represented schematically based on published evidence. One or two hydrophobes interact with Phe656, a positive charge is stabilized by cation- $\pi$  interaction with Tyr652, and the generally hydrophobic tail contains an acceptor able to interact with the polar residues on the loop that connects the pore helix to the selectivity filter. (Reproduced with permission from Aronov, A. M. *Drug Disc. Today* **2005**, 10, 149–155 © Elsevier.)

**Figure 5** Structure of ibutilide.

hydrophobic surface area.<sup>24</sup> In the case of residue 652, the presence of an aromatic residue in this position is required for high-affinity hERG blockade, consistent with the importance of the cation- $\pi$  interaction predicted by ligand-based models.

Additionally, residues Thr623 and Val625, located near the pore helix, were implicated in hERG binding to MK-499, but the effect was moderate in the cases of terfenadine and cisapride.<sup>15</sup> Both Thr623 and neighboring Ser624 (**Figure 4**) have been shown to have pronounced effects on hERG block by vesnarinone, clofilium, and ibutilide (**Figure 5**). These polar residues may be able to interact with the polar tails present in many of the potent hERG blockers.<sup>15,17,34</sup> A recent study of the structural determinants of hERG channel block by clofilium and ibutilide provided further evidence that residues at the base of the pore helices, which also face into the central cavity, can form interactions with drugs that may facilitate high-affinity binding.<sup>40</sup> Mutation of T623A and S624A resulted in approximately 90- and 60-fold increases in

ibutilide IC<sub>50</sub> values, respectively. It is the specific interaction with Ser624 that appears to be responsible for the slow-off rates that characterize clofilium block of both wild-type and mutant D540K hERG channels. Based on the docking model of clofilium within the inner cavity of the hERG homology model, Perry and co-workers invoke polar interactions between the side chain hydroxyl of Ser624 and the chlorine atom in clofilium as the interaction that contributes to stabilization of clofilium binding.<sup>40</sup> The proposed orientation of both clofilium and ibutilide within the hERG channel includes aryl groups pointing toward the selectivity filter, a cation- $\pi$  interaction of Tyr652 with the positively charged amine, and a hydrophobic contact of the fatty side chains of the drugs with Phe656. The role of Val625 in interactions with hERG blockers is less well understood, primarily because according to K<sup>+</sup> channel crystal structures,<sup>35,36</sup> the corresponding valine side chain is buried in the hydrophobic core surrounding the selectivity filter, and does not point into the inner cavity of the channel. Thus, the reason for the sensitivity of hERG block to the V625A mutation could lie in the allosteric effect of this residue on the conformation of neighboring side chains of Thr623 and Ser624.

A combination of structural features is thought to be responsible for the ‘binding promiscuity’ of hERG relative to other K<sup>+</sup> channels. The aromatic residues critical for binding to structurally diverse drugs are missing in channels of the Kv1–4 families, replaced by Ile or Val in positions equivalent to Tyr652 and Phe656.<sup>15,17,24</sup> The exact positioning of the aromatic residues is also of critical importance for binding. Structurally related EAG channels were made sensitive to the hERG blocker cisapride by moving the Tyr residue by one position along the S6 helix.<sup>41</sup> Finally, the hERG channel lacks the Pro-Val(Ile)-Pro motif on the S6 helix, which is present in Kv1–4 channels and is thought to decrease the size of the inner cavity by inserting a kink in the inner helices.<sup>15,24</sup>

The only published example of the use of homology models for quantitative prediction of hERG blockade is the study by Rajamani and colleagues.<sup>42</sup> The method described uses a two-state homology model to represent the flexibility of the channel. Two hERG homology models were built based on the crystal structure of the closed state of KcsA.<sup>43</sup> The lower resolution structure of MthK<sup>36,37</sup> in the open state was used as a guide providing insight into the movement of the S6 helix in going from the open to the closed states of the channel. As a result, two models of hERG channel were built – the partially open state (10° translation away from the KcsA reference state) and the fully open state (19° translation, closely corresponding to MthK). IC<sub>50</sub> values for 32 ligands assembled by Cavalli and co-workers<sup>44</sup> (hERG pIC<sub>50</sub> ranging between 4 and 9) were used to derive the linear interaction energy (LIE) correlation. The ligand set was docked to the homology models, the best poses (one for each ligand) were energy minimized, and used to derive the van der Waals and electrostatic contributions to the binding energy. Models derived for the two homology models separately resulted in poor fit (e.g.,  $r^2 = 0.24$  for the partially open state). However, when a preference of each compound for a particular state was established by comparing the estimated interaction energy for each ligand in both states, separate better fits were obtained, with 21 ligands preferring the open state and 11 ligands the partially closed state of the channel. The final combined model:

$$\text{pIC}_{50} = -0.163(\Delta\text{vdw}) + 0.0009(\Delta\text{ele}) \quad [1]$$

produced  $r^2 = 0.82$  (rmse = 0.56) for 27 ligands, with five compounds identified as potential outliers.<sup>42</sup> The study highlighted the difficulty of using hERG homology models for quantitative predictions of hERG blockade and the need for modeling techniques that can capture the flexibility of the K<sup>+</sup> channel.

#### 5.40.4.2 Quantitative Structure–Activity Relationships

Ligand-based approaches have been extensively applied to understanding SARs of hERG channel blockers. One of the earliest SAR studies performed on a series of compounds that cause QT prolongation is by Morgan and Sullivan.<sup>45</sup> In an overview of Class III antiarrhythmic agents, the authors proposed a general structure of Q-Phenyl-A-NR<sub>1</sub>R<sub>2</sub>. R<sub>1</sub> and R<sub>2</sub> are preferentially hydrophobes, R<sub>1</sub> as alkyl or phenylalkyl (R<sub>1</sub> = H is also acceptable for inclusion in the class), and R<sub>2</sub> as alkyl, arylalkyl, or heteroalkyl. Linker A is a 1–4 atom chain that may contain heteroatoms or be part of a ring. This linker chain was noted as one of the more variable regions in the molecule. Finally, *para*-substituent Q is an electron-withdrawing group, such as nitro, cyano, *N*-imidazole, or *N*-methylsulfonamide.

The first example of hERG pharmacophore modeling appears to be the work by Matyus and co-workers<sup>46</sup> on elucidation of the pharmacophore for blockers of *I*<sub>Kr</sub> current as Class III antiarrhythmic agents. Eleven ligands were divided into two sets. The first set included the six most active agents, spanning a 1.5 log activity range, and the second set contained the less active compounds. Starting structures were obtained by energy minimization in the Tripos force field.<sup>47</sup> Sets of conformations were generated by the Multisearch option in DISCO interface (*see* 4.06 Pharmacophore Modeling: 1 - Methods; 4.19 Virtual Screening),<sup>47</sup> up to a maximum of 100 conformations per ligand. As part of the conformation generation process, various energy minima were sampled by random perturbation of torsions, followed by

**Figure 6** Pharmacophore for hERG blockers. (Reprinted from Matyus, P.; Borosy, A. P.; Varro, A.; Papp, J. G.; Barlocco, D.; Cignarella, G. *Int. J. Quant. Chem.* **1998**, 69, 21–30, with permission of John Wiley & Sons, Inc.) Colored features correspond to donor atom (blue), receptor-associated acceptor site (red), aromatic moieties (green), and aliphatic chain (orange).

minimization and elimination of duplicates. Perturbed torsions were limited to those that have the potential to change the internal geometry of atoms that determine the DISCO features. A new feature definition was added to the hydrophobic class in DISCO to recognize hydrophobic aliphatic chains. DISCO was forced to consider five-point pharmacophores containing one donor atom, one receptor-associated acceptor site, and three hydrophobes, with dofetilide chosen as the reference. Fifty-three pharmacophores from DISCO were analyzed, and the best model was chosen (Figure 6). The basic nitrogen donor was within 5.19, 5.63, and 2.37 Å from the two aromatic features and the aliphatic feature, respectively. The less potent five-compound set was shown to satisfy only four points in the five-point pharmacophore, with one of the three hydrophobes missing.

The first hERG pharmacophore published since the renewed interest in predicting  $I_{K_r}$  blockade was described by Ekins and co-workers using 15 molecules from the literature.<sup>48</sup> The conformers were generated using BEST mode in Catalyst, up to a maximum of 255 conformations per ligand. Hydrophobic, ring aromatic, donor, acceptor, and positive ionizable features were selected for possible inclusion. Ten Catalyst hypotheses were assessed, and the lowest energy cost hypothesis was deemed the best. It contains four hydrophobes, one positive ionizable feature, and produced an  $r^2$  value of 0.90. Proposed distances between the positive center and the hydrophobes are 5.2, 6.2, 6.8, and 7.5 Å. The model was further applied to predict  $IC_{50}$  values for a test set of 22 mostly antipsychotic compounds known to inhibit hERG ( $r^2 = 0.83$ ). More recently, the initial training set was expanded to include 66 molecules, resulting in an observed-versus-predicted correlation of  $r^2 = 0.86$ .<sup>49</sup> This model produced a correlation of  $r^2 = 0.67$  on an additional 25 molecules from the literature.

Cavalli and colleagues<sup>44</sup> constructed a hERG pharmacophore based on a training set of 31 carefully selected QT-prolonging drugs from the literature. The conformational space was sampled by means of Monte Carlo analysis as implemented in the MacroModel software.<sup>50,51</sup> All of the dihedral angles of single linear bonds were allowed to move freely, and an unusually large  $100 \text{ kJ mol}^{-1}$  energy window was used to filter conformers. The procedure generated hundreds of conformers per ligand, which were then clustered using  $1 \text{ Å}$  root mean square displacement cutoff. A ‘constructionist’ approach to pharmacophore generation was employed, whereby astemizole was used as the template onto which other ligands were sequentially superimposed by means of the commonality of geometric and spacial characteristics. The proposed pharmacophore contains three aromatic moieties connected through a nitrogen function that is a tertiary amine throughout the whole set of molecules. The nitrogen and the aromatic moieties are separated by distances of 5.2–9.1, 5.7–7.3, and 4.6–7.6 Å (Figure 7). Comparative molecular field analysis (CoMFA) performed on the training set produced a correlation with  $r^2 = 0.95$  ( $q^2 = 0.77$ ), and its predictive ability was tested on a set of six additional compounds ( $r^2_{\text{pred}} = 0.74$ ).

Pearstein and co-workers<sup>34</sup> reported a comparative molecular similarity indices analysis (CoMSIA) (see 4.23 Three-Dimensional Quantitative Structure–Activity Relationship: The State of the Art) model built using in-house patch clamp data for 28 compounds, 18 of them sertindole analogs ( $q^2 = 0.57$ ). Conformational searching was performed using the MMFF94 force field. Ring centroids and the basic nitrogen were used as landmarks for superimposing the compounds onto sertindole using least-squares fitting (see 4.05 Ligand-Based Approaches: Core Molecular Modeling). According to the model, decreasing the positive charge on the central nitrogen and increasing the steric bulk on the hydrophobic end of the molecule are two potential ways to reduce hERG blocking activity. The model was tested on a holdout set

**Figure 7** Four-point pharmacophore for hERG blockers. (Reprinted with permission from Cavalli, A.; Poluzzi, E.; De Ponti, F.; Recanatini, M. *J. Med. Chem.* **2002**, 45, 3844–3853. Copyright (2002) American Chemical Society.) Colored features correspond to positively charged nitrogen (blue) and aromatic rings (green).

containing four sertindole analogs with widely varying potency for hERG. In addition, the authors constructed a homology model of the tetrameric pore region of hERG from the MthK template<sup>36</sup> and qualitatively docked the set of aligned inhibitor structures into the inner cavity of the channel (see Section 5.40.5.1 for the ligand-binding mode).

Keseru<sup>52</sup> used literature data on 55 compounds to train a QSAR model based on calculated descriptors. Five descriptors were used: ClogP, calculated molar refractivity (CMR), partial negative surface area, and the Volsurf W2 (polarizability) and D3 (hydrophobicity) descriptors. A model of acceptable quality was obtained ( $r^2=0.94$ , SSE=0.82) and tested on a 13 compound holdout set ( $r^2=0.56$ , SSE=0.98). A hologram QSAR (HQSAR; see 4.23 Three-Dimensional Quantitative Structure–Activity Relationship: The State of the Art)<sup>53</sup> model was then created that made use of 2D fragment fingerprints (threshold hERG IC<sub>50</sub> = 1  $\mu$ M).<sup>52</sup> In HQSAR, each molecule is divided into structural fragments that are counted in the bins of a fixed-length array to form a molecular hologram. These structural descriptors encoding compositional and topological molecular information are then used to derive a partial least squares regression model that correlates variation in structural composition with variation in experimental data. The best HQSAR model was validated on a holdout set of 13 compounds ( $r^2=0.81$ , SSE=0.67).

In a study of Class III antiarrhythmics, Du and co-workers<sup>54</sup> selected a set of 34 compounds from the literature spanning a broad range of IC<sub>50</sub> values. Using the features previously proposed to be important in characterizing hERG blockers,<sup>46</sup> the authors turned to HypoGen module in Catalyst. Models were allowed to contain at least one and at most two instances of every feature. The best pharmacophore hypothesis contained a positive ionizable feature, two aromatic rings, and a hydrophobic group. It was then applied to a test set of 21 compounds, which was split into three groups based on the hERG activity level (<1, 1–100, and >100  $\mu$ M). The model predicted the activity of test ligands with  $r^2=0.713$ , with all highly active (<1  $\mu$ M) compounds predicted correctly.

A simple two-component QSAR model for hERG blocking potency was proposed by Aptula and Cronin.<sup>55</sup> A set of 150 descriptors were calculated for 19 structurally diverse hERG blockers from the literature. The calculated variables included physicochemical parameters, topological indexes, and quantum chemical descriptors. Multiple linear regression produced a relationship between hERG blocking potency and two descriptors –  $\log D$  (at pH = 7.4) and  $D_{\max}$  (the maximum diameter of molecules):

$$\text{pIC}_{50}(\text{hERG}) = 0.58 \log D + 0.30 D_{\max} - 0.36 \quad [2]$$

with a reasonable correlation ( $r^2=0.87$ ,  $q^2=0.81$ ). A further analysis of 81 chemicals from Redfern and colleagues<sup>14</sup> was described, but no results were shown. The authors suggest the maximum diameter cutoff of 18 Å for cases where hERG blocking activity is undesirable, and  $D_{\max} > 18$  Å for antiarrhythmics. The relationship described<sup>55</sup> is rather intuitive, with hERG activity correlating with both hydrophobicity and ligand size. More lipophilic ligands that have a large diameter are capable of binding in the hERG channel and engaging most of the residues implicated in hERG blockade.<sup>15,18</sup> While the overall findings with regard to lipophilicity are generally in agreement with earlier studies,<sup>56</sup> the QSAR equation based on a study of only 19 ligands that contains no additional size constraints (e.g., a reasonable  $D_{\max}$  limit beyond which the compound would be unable to enter the channel pore) appears a gross generalization.

One of the larger hurdles for building QSAR models using literature data has been the large discrepancy observed for hERG IC<sub>50</sub> values determined in different laboratories. Interlaboratory variability of greater than 10-fold is not uncommon, even in cases where inhibition was measured using the same cell line. Additional efforts in generating internally consistent hERG data sets that could be made available to the broad scientific community are sorely needed to propel the field forward.

### 5.40.4.3 Classification Methods

While QSAR methods aim to predict absolute compound activity, classification methods attempt to bin compounds by their potential hERG inhibition. The earliest example of a hERG-based classification was reported by Roche and co-workers.<sup>57</sup> A total of 244 compounds representing the extremes of the data set ( $<1$  and  $>10\text{ }\mu\text{M}$  for actives and inactives, respectively) were modeled with a variety of techniques such as substructure analysis, self-organizing maps, partial least squares, and supervised neural networks. The descriptors chosen included  $\text{pK}_a$ , Ghose-Crippen,<sup>58</sup> TSAR,<sup>59</sup> CATS,<sup>60</sup> Volsurf,<sup>61</sup> and Dragon<sup>62</sup> descriptors. The most accurate classification was based on an artificial neural network. In the validation set containing 95 compounds (57 in-house and 38 literature  $\text{IC}_{50}$  values) 93% of inactives and 71% of actives were predicted correctly.

In a decision tree-based approach to constructing a hERG model using calculated physicochemical descriptors, Buyck and co-workers<sup>56</sup> used three descriptors – ClogP, calculated molar refractivity (CMR), and the  $\text{pK}_a$  of the most basic nitrogen – to identify hERG blockers within an in-house data set. With  $\text{IC}_{50} = 130\text{ nM}$  as a cutoff, factors suggestive of hERG activity were determined to be  $\text{ClogP} \geq 3.7$ ,  $110 \leq \text{CMR} < 176$ , and  $\text{pK}_a \text{ max} \geq 7.3$ .

A combined 2D/3D procedure for identification of hERG blockers was proposed by Aronov and Goldman.<sup>63</sup> A 2D topological similarity screen utilizing atom pair<sup>64</sup> descriptors and an amalgamated similarity metric termed TOPO was combined with a 3D pharmacophore ensemble procedure in a ‘veto’ format to provide a single binary hERG classification model. A molecule flagged by either component of the method was considered a hERG active. In the course of 50-fold cross-validation of the model on a literature data set containing 85 actives (threshold hERG  $\text{IC}_{50} = 40\text{ }\mu\text{M}$ ) and 329 inactives, 71% of hERG actives and 85% of hERG inactives were correctly identified. The model utilizing the TOPO metric was shown to be superior to a number of other 2D models using the receiver operating characteristic metric. Additionally, five of eight (62.5%) hERG blockers were identified correctly in a 15 compound in-house validation set. Most of the statistically significant pharmacophores from the ensemble procedure were three-feature [aromatic]–[positive charge]–[hydrophobe] combinations (Figure 8a–b) similar to those reported by Cavalli and colleagues<sup>44</sup>; however, a novel three-point pharmacophore containing a hydrogen bond acceptor was also proposed (Figure 8c). The presence in hERG blockers of the acceptor functionality pointing toward the selectivity pore agrees with the previous observations<sup>15,40,44</sup> of a potential for polar interactions with the side chains of Thr623 and Ser624 to stabilize the hERG–ligand complex.

Testai and co-workers<sup>65</sup> evaluated a set of 17 antipsychotic drugs, all of them associated with reports of torsadogenic cardiotoxicity. The search for a common molecular feature that may be a requirement for hERG blockers focused on measuring several different distances between atoms that could constitute a hERG-active template. The authors hypothesized that such a template for hERG-active ligands consists of a hydrocarbon chain, three or four atoms long, serving as a spacer between a basic sterically hindered nitrogen atom, and a second, more variable, moiety. Focusing on the distance between the basic nitrogen and this second moiety, Testai and co-workers observed that for all of the compounds in the data set the distance converged in the range between 4.32 and 5.50 Å (average = 4.87 Å).

**Figure 8** Three three-point pharmacophores (a–c) for in silico hERG block prediction (from Aronov, A. M.; Goldman, B. B. *Bioorg. Med. Chem.* **2004**, *12*, 2307–2315). Colored features correspond to positive charge (blue), hydrogen bond acceptor (red), and hydrophobic (green). (Reproduced with permission from Aronov, A. M. *Drug Disc. Today* **2005**, *10*, 149–155 © Elsevier.)

**Figure 9** Acceptor-containing three-point pharmacophore mapped onto the structure of cisapride, a known potent hERG blocker. (Reproduced with permission from Aronov, A. M.; Goldman, B. B. *Bioorg. Med. Chem.* **2004**, *12*, 2307–2315 © Elsevier.) Feature colors are same as in **Figure 8**. Matching features are also shown mapped onto the 2D structure of cisapride.

Three-dimensional structures of the antipsychotics were generated starting from known small molecule x-ray structures followed by solvation and minimization. Interestingly, the variable moiety present in 14 of the 17 ligands is a hydrogen bond acceptor, either a carbonyl oxygen or a heteroaromatic nitrogen.<sup>65</sup> This is in agreement with the high information content seen for the acceptor-containing pharmacophore by Aronov and Goldman.<sup>63</sup> Indeed, the acceptor functionality can be seen not only in antipsychotic agents, such as risperidone and droperidol,<sup>63</sup> but also for other known hERG blockers, such as prokinetic agent cisapride (**Figure 9**). In the case of risperidone, the two groups pointed to different hydrogen bond acceptors that, incidentally, are located approximately the same distance from the basic nitrogen – the oxygen of the benzisoxazole<sup>63</sup> and the carbonyl of the pyrimidine.<sup>65</sup>

Bains and colleagues<sup>66</sup> described the application of genetic programming (GP) to building a predictive hERG model. GP, an evolutionary computing technique, ‘evolves’ an algorithm in silico that matches input variables with desired output, and performs both selection of relevant descriptors and algorithm building without human intervention. The data set comprised endpoints from the public domain with proprietary data, totaling 124 compounds. Three types of descriptors were utilized: general molecular descriptors (such as molecular weight), topological fragments, and experimental parameter descriptors. The largest set, topological fragments, was generated automatically and exhaustively from the data set by application of a maximum common subgraph-based algorithm. Only fragments containing at least four heavy atoms and present in two or more ligands were kept. Experimental parameters, a rather unusual addition, were abstracted from experimental sections in the literature. A total of 618 descriptors were used in the GP runs. GP algorithms were trained on a training set, selected for their ability to make predictions on a generalization set, and finally were tested on an independent validation set, their performance judged using Akaike fitness criterion and receiver operating characteristic. The best models achieved 85–90% accuracy in predicting on the validation set when  $IC_{50} < 1 \mu M$  was used as a threshold for hERG-active ligands, which is consistent with the results of previously published classification studies.<sup>57,63</sup> Analysis of correlations between topological descriptors and hERG  $IC_{50}$  revealed that  $IC_{50}$  is:

- positively correlated with the presence of secondary or tertiary basic amines;
- positively correlated with the presence of at least one aromatic ring system;
- positively correlated with the presence of a five-membered nitrogen-containing heterocycle (including fused heterocycles, e.g., benzimidazole);
- negatively correlated with the presence of carboxylates; and
- negatively correlated with the presence of hydrogen bond acceptors.

While it is hardly possible to organize the topological fragment observations noted above into a stand-alone pharmacophore model, the authors pointed out that their results are broadly consistent with earlier publications.<sup>15,17,33,34</sup>

#### 5.40.4.4 Incorporating Human Ether-a-go-go Related Gene Models into the Drug Discovery Process

With a variety of modeling approaches to the hERG problem that are aimed at various endpoints, the issue of incorporating the pertinent model(s) into the drug discovery process becomes essential. It is readily apparent that model utility is as much a function of how a model is being used as of how accurate the predictions are. For example, a model that is good at predicting hERG nonblockers (high ratio of true negatives to false negatives) may be useful in pointing out compounds that almost certainly do not block hERG. Low recovery of true hERG blockers would mean that it should be applied before the compounds are selected for in vitro screening, while a high recovery rate would make the model potentially competitive with the in vitro methods.

Another aspect critical to model deployment is its incorporation into the corporate database. Ideally, a link exists that allows for the model to make predictions on both the existing corporate collection and prophetic (virtual) compounds. The new hERG screening data made available in the course of medicinal chemistry programs can then be fed into the cycle, enabling constant expansion of the original training sets, as well as continuous model validation on an ongoing basis, which is made accessible to the medicinal chemists on the project. The data feedback loop helps address the malaise that most global models tend to suffer from – inadequate performance in the context of local predictions. Constant replenishment of the training set contributes to continuous model improvement in a local, as well as in a global sense, which can be monitored as new data arrives.

An example of one such approach is shown in [Figure 10](#). The hERG model based on the publication by Aronov and Goldman<sup>63</sup> was incorporated into the VERDI chemoinformatics suite at Vertex Pharmaceuticals, Inc. A compound loaded as part of a search ([Figure 10a](#)) can be submitted for hERG prediction, which produces a set of most similar compounds based on which such a prediction is made ([Figure 10b](#)).

#### 5.40.5 Understanding Structure–Activity Relationship of Human Ether-a-go-go Related Gene Blockers

As various in silico methods are being brought to bear on the problem of hERG, some understanding of the SAR relevant to hERG block is starting to emerge.

##### 5.40.5.1 Ligand-Binding Mode

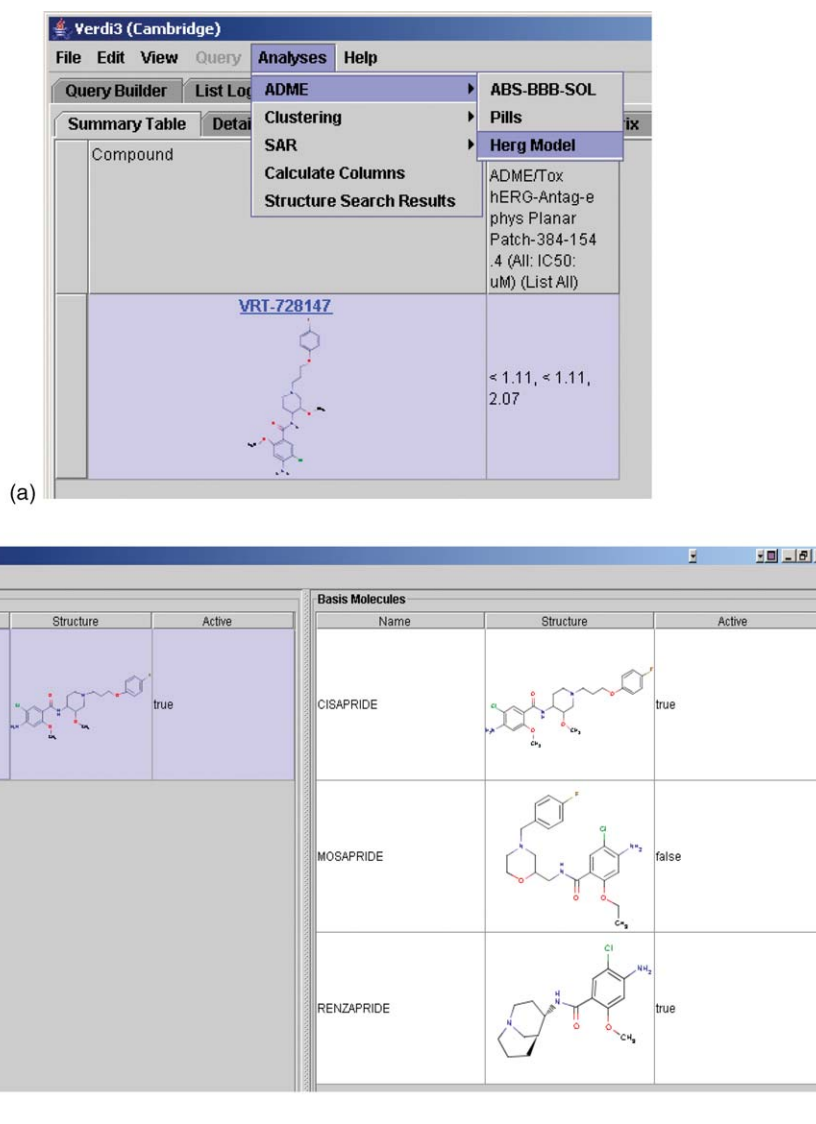

The current consensus<sup>34,36,66</sup> view of the proposed binding mode of hERG blockers within the channel pore is shown in [Figure 4](#). The inhibitor orients itself along the pore axis, with the lipophilic end facing the opening to the cytosol and the polar tail facing the selectivity filter. One or two hydrophobic moieties interact with Phe656 side chains, likely via  $\pi$ -stacking. The basic nitrogen is involved in cation– $\pi$  interaction with Tyr652 residues. While most known hERG blockers contain a basic nitrogen center that is expected to be protonated under biological conditions, some possess an aromatic ring in its place. The aromatic linker may be able to participate in favorable  $\pi$ -stacking with Tyr652 in lieu of a cation– $\pi$  interaction. The tail end of the molecule appears in many of the potent hERG blockers. It is thought to extend deep into the pore and form a hydrogen bond between the acceptor feature<sup>63</sup> ([Figure 8c](#)) and the side chain hydroxyls of hERG, which may be able to explain ligand-dependent attenuation of hERG binding affinity by T623A and S624A mutations.

An important caveat to this discussion is a clear possibility that multiple ligand binding sites exist on hERG that are capable of modulating channel activity. The ability to locate and describe these alternative sites is likely to come from a concerted effort in radioligand competition assays, mutagenesis, homology modeling, and ultimately x-ray crystallography.

##### 5.40.5.2 Structural Lessons Learned

Mapping the chemical space of known hERG blockers has shed some light on the structural aspects of ligands consistent with an hERG blocker profile:

1. Physicochemical property profiling of hERG actives and inactives clearly points to the fact that the likelihood of hERG block decreases significantly for polar low-molecular-weight ligands. As seen in [Figure 11](#), few of the known hERG blockers have  $\text{ClogP} < 1$  or  $\text{MW} < 250$ . This is in agreement with the  $\text{ClogP} \geq 3.7$  limit for potent hERG blockers from Buyck and colleagues,<sup>56</sup> and may be due to the large pore size in hERG as well as the lipophilic character of the pore lining. Unfortunately, for a variety of reasons, which include target-binding

**Figure 10** hERG model as incorporated into the VERDI chemoinformatics suite at Vertex Pharmaceuticals, Inc. (a) A compound (cisapride) loaded as part of a search in the process of being submitted for hERG prediction. (b) A set of most similar compounds produced based on which the prediction is made are displayed. Predictions on both real compounds from the corporate database and virtual compounds are enabled.

affinity, absorption, and clearance considerations, few of the discovery compounds that move into the clinic fall into this category.

2. The presence of a basic solubilizing group or a positively charged nitrogen in general increases the likelihood of hERG block. Conformational analysis of a number of hERG blockers from the literature led to the observation that shielding of the protonated form of the ligands decreases the amount of deprotonation, thus contributing to the increased potency for blocking hERG.<sup>67</sup> Tertiary amines, which form ammonium ions shielded by two structural fragments, block hERG more potently than compounds containing amines at the molecular periphery. Decreasing the  $pK_a$  of the basic amine may lower hERG activity by destabilizing the protonated species. Another useful strategy for attaching solubilizing groups to a molecule of interest may involve identification of multiple suitable substitution sites, thus increasing the odds of finding ligands devoid of hERG activity.
3. A large number of hERG blockers, both basic and neutral, contain flexible linkers that connect various molecular fragments. Flexibility appears to help the ligands find conformations compatible with the large binding site on hERG. Ligand rigidification may lead to removal of undesired hERG activity.

**Figure 11** Reducing the risk of hERG interaction. ClogP and molecular weight distributions for hERG actives and inactives (data set from Aronov, A. M.; Goldman, B. B. *Bioorg. Med. Chem.* **2004**, *12*, 2307–2315 and references therein). Compounds with MW < 250 and ClogP < 1 are significantly less likely to block hERG. (Reproduced with permission from Aronov, A. M. *Drug Disc. Today* **2005**, *10*, 149–155 © Elsevier.)

**Figure 12** Molecular shapes more likely to result in a potent hERG interaction. Ellipses and squares symbolize rings of any size. Pentagons and hexagons symbolize five- and six-membered ring systems, respectively. Linear topology consistent with *meta-/para-* attachments is seen less frequently in hERG active sets than V-shaped geometry stemming from *ortho-*substitution patterns. The role of the basic group in the ligand–hERG interaction can be played by an aromatic ring. The placement of the solubilizing group, if present, may have a strong impact on the hERG profile of the molecule. (Reproduced with permission from Aronov, A. M. *Drug Disc. Today* **2005**, *10*, 149–155 © Elsevier.)

- Some general observations of the topology of ring-linker arrangements versus the potential for hERG blockade are shown in [Figure 12](#). Linear topology consistent with *meta-/para-* attachments is seen less frequently in hERG active sets than V-shaped geometry stemming from *ortho-*substitution patterns. The role of the basic group in the ligand–hERG interaction can be played by an aromatic ring. The placement of the solubilizing group, if present, may have a strong impact on the hERG profile of the molecule.

**Figure 13** Structure of sertindole. See Pearlstein *et al.*<sup>34</sup> for modeling of sertindole analogs.

### 5.40.5.3 Successful Approaches to Reducing Human Ether-a-go-go Related Gene Activity within a Chemical Series

#### 5.40.5.3.1 Reducing lipophilicity

One of the earliest observations regarding ligand propensity to inhibit  $I_{Kr}$  was that the likelihood of hERG block decreases significantly for polar low-molecular-weight ligands. This effect can be achieved through either introduction of polar functional groups or elimination of hydrophobic functionality. The challenge in  $\log P$  management is due to the fact that for most receptor binding sites compound potency often correlates with ligand lipophilicity, and the search for an optimal balance of on-target activity versus hERG potency is typically not trivial.

Pearlstein *et al.*<sup>34</sup> published a rather comprehensive hERG SAR for a series of sertindole analogs that provides a glimpse into the arsenal of modifications that can lead to a drop in hERG activity of a lead compound. For sertindole (Figure 13), the following modifications were successful:

- removal of either of the two halogen atoms;
- introduction of a polar substituent in the phenyl ring;
- saturating the phenyl moiety to cyclohexyl;
- saturating the indole to indoline;
- removal of the alkyl urea substituent in the piperidine ring; and
- removal of the alkylpiperidine.

A series of selective 5HT<sub>2A</sub> receptor antagonists possessing hERG activity was described by Rowley and colleagues.<sup>68</sup> The original 2-phenyl-3-piperidylindoles were potent hERG blockers as measured by the radioactive dofetilide displacement assay (Figure 14a). Removal of the *N*-phenethyl moiety led to a  $\sim 70$ -fold decrease in hERG binding, and the subsequent modification of 4-piperidine to 3-piperidine (not shown in Figure 14a) restored target activity.

Replacement of a phenyl ring with a methyl group, coupled with a switch from a difluoromethyl substituent to a cyclobutyl, and from pyridine to thiazole (Figure 14b) decreased the lipophilicity of the molecule by nearly a log unit, resulting in a greater than 50-fold drop in hERG blocking activity in a tertiary alcohol series of phosphodiesterase-4 inhibitors.<sup>28</sup>

A drop of nearly 10-fold in hERG blocking activity as determined by an in vitro electrophysiological assay using Cos7 cells was achieved in a series of 2-cyclohexyl-4-phenyl-1*H*-imidazoles designed as potent and selective neuropeptide Y Y5-receptor antagonists.<sup>69</sup> This result came from introducing a *gem*-dimethylglycinol amide functionality into the lead molecule (Figure 14c), which led to a large drop in lipophilicity of the compound with a concurrent nearly threefold increase in its polar surface area.

A phenolic hydroxyl was incorporated into the benzylpiperidine benzimidazoles (Figure 14d) active as antagonists of the NR2B subtype of the *N*-methyl-D-aspartate (NMDA) receptor.<sup>29</sup> A concomitant decrease in hERG activity of the ligands as measured in the MK-499 displacement assay was a modest twofold.

#### 5.40.5.3.2 Reducing lipophilicity and basicity

In cases when lowering lipophilicity alone may not result in a sufficient drop in hERG blocking activity, an accompanying reduction in basicity (typically lowering the  $pK_a$  of the basic nitrogen) may prove successful. Bilodeau *et al.*<sup>70</sup> have recently disclosed a series of aminothiazole KDR inhibitors (Figure 15a), which contain a basic amine solubilizing group likely responsible for observed hERG blockade. The  $pK_a$  of the basic nitrogen was reduced by approximately three log units by converting pyrrolidine to *N*-acetylpiperazine, providing a 10-fold drop in hERG

**Figure 14** Lowering hERG liability : reduction in lipophilicity. (a) From Rowley, M.; Hallett, D. J.; Goodacre, S.; Moyes, C.; Crawford, J.; Sparey, T. E.; Fernandes, C.; Gibbs, J. B.; Heimbrook, D. C. *et al. J. Med. Chem.* **2004**, 47, 6363–6372 © American Chemical Society; (b) from Fletcher, S. R.; Burkamp, F.; Blurton, P.; Cheng, S. K.; Clarkson, R.; O'Connor, D.; Spinks, D.; Tudge, M.; van Niel, M. B.; Patel, S. *et al. J. Med. Chem.* **2002**, 45, 492–503 © American Chemical Society.

activity, measured as radioactive MK-499 displacement. A further reduction in lipophilicity of the molecule by substituting a cyano group for the phenyl ring resulted in an additional nearly 40-fold drop in hERG binding.

In order to lower hERG activity in a series of 4-(phenylsulfonyl)piperidines<sup>71</sup> as selective 5HT<sub>2A</sub> receptor antagonists, the spirocyclic sulfone was initially replaced with an acyclic sulfone moiety (Figure 15b). While lowering the log*P*, this structural change increased the pK<sub>a</sub> of the basic amine, leading to a modest twofold drop in hERG binding, as measured in the dofetilide displacement assay in HEK293 cells, and later confirmed in vivo in the anesthetized ferret model. However, when the phenethyl fragment was converted to the acetophenone, the increase in polar surface area resulted in a lower log*P*, and the piperidine pK<sub>a</sub> fell 1.4 log units due to the electron-withdrawing effect from the carbonyl. The result was a further sevenfold change in hERG binding.

#### 5.40.5.3.3 Reducing flexibility

In addition to managing lipophilicity and basicity of the ligand, another potential avenue to modulating hERG activity within a series is by reducing the flexibility of a molecule. It appears that more flexible ligands as defined by the higher rotatable bond count tend to show higher hERG blocking ability as compared to their more rigid counterparts. The reason for this could lie in the greater ability of flexible ligands to adapt to the spacial constraints of the otherwise promiscuous binding site of hERG.

Drugs that activate the serotonin receptor subtype 5HT<sub>4</sub> are widely used to facilitate or restore motility in the gastrointestinal tract.<sup>72</sup> Cisapride, one such 5HT<sub>4</sub> agonist, was marketed in the US from 1993 until its withdrawal in 2000 following multiple reports of heart rhythm disturbances including QT prolongation, syncope, torsades de pointes, and 80 reports of death. Potet and co-workers<sup>72</sup> have reported comparative studies of K<sup>+</sup> currents in hERG-transfected COS-7 cells as affected by structurally similar 5HT<sub>4</sub> agonists cisapride, renzapride, prucalopride, and mosapride. While cisapride was confirmed as a submicromolar hERG blocker, mosapride was shown to be devoid of the hERG side effect. Currently marketed for gastritis in the Far East, mosapride has the potential to be widely utilized as a safe alternative to cisapride. The lower hERG activity in mosapride was partially achieved by decreasing its lipophilicity and basicity in

**Figure 16** Lowering hERG liability: reduction in flexibility. (a) From Potet, F.; Bouyssou, T.; Escande, D.; Baro, I. *J. Pharmacol. Exp. Ther.* **2001**, 299, 1007–1012; (b) from Collins, I. *et al. J. Med. Chem.* **2001**, 44, 2933–2949 © Elsevier; (c) from Bell, I. M.; Gallicchio, S. N.; Abrams, M.; Beshore, D. C.; Buser, C. A.; Culberson, J. C.; Davide, J.; Ellis-Hutchings, M.; Fernandes, C.; Gibbs, J. B. *J. Med. Chem.* **2001**, 44, 2933–2949 © American Chemical Society.

utilizing a morpholine core in place of piperidine (**Figure 16a**). ClogP decreased by 0.37 log units, and the  $pK_a$  of the basic nitrogen dropped by 0.5 log units. Another pronounced difference is that the flexibility of cisapride is partially addressed in mosapride, which has two fewer rotatable bonds. Following the replacement of the highly flexible propoxyphenyl moiety, mosapride affinity for hERG relative to cisapride decreased by more than 100-fold.

A similar approach to engineering out hERG activity was taken by Collins and co-workers<sup>73</sup> in a series of human dopamine  $D_4$  receptor antagonists (**Figure 16b**). The original 3-(4-piperidinyl)-5-arylpyrazole scaffold was rigidified to produce fused partially saturated indazole analogs, and the piperidine moiety was replaced with a piperazine to lower the  $pK_a$  of the molecule. Indeed, the  $EC_{25}$ , estimated in vitro by the measurements made in ferret papillary muscle, increased by greater than 75-fold.

In the 3-aminopyrrolidinone series of farnesyltransferase inhibitors, the original *N*-benzyl-pyrrolidinones were shown to have  $I_{Kr}$  blocking activity in the submicromolar range.<sup>74</sup> By moving the carbonyl out of the ring, the team was able to reduce hERG activity by 13-fold (**Figure 16c**). The resulting *N*-benzamidopyrrolidines were more rigid than the starting series.

**Figure 17** Lowering hERG liability: moving the basic center. (Reproduced with permission from Fraley, M. E.; Arrington, K. L.; Buser, C. A.; Ciecko, P. A.; Coll, K. E.; Fernandes, C.; Hartman, G. D.; Hoffman, W. F.; Lynch, J. J.; McFall, R. C. *et al. Bioorg. Med. Chem. Lett.* **2004**, 14, 351–355 © Elsevier.)

**Figure 18** Lowering hERG liability: introducing a zwitterion. (Reproduced with permission from Paakkari, I. *Toxicol. Lett.* **2002**, 127, 279–284 © Elsevier.)

#### 5.40.5.3.4 Moving the basic center

One of the approaches to tuning out hERG activity is to evaluate a number of different attachment sites for a basic solubilizing group (*see* Section 5.40.5.2). The same result can often be achieved through variations in linker length, which effectively moves the charged center with respect to the rest of the ligand. A recent example of the success of this strategy is the optimization of solubilized indolyl quinolinones as KDR kinase inhibitors.<sup>75</sup> Owing to the presence of an internal hydrogen bond between the quinolinone carbonyl and the NH of the indole moiety, the scaffold is essentially flat, and requires a pendant-solubilizing group to improve its properties (Figure 17). One of the early compounds in the series, a linked acetylpiperazine, showed an inflection point of 520 nM in the MK-499/hERG displacement assay. Shortening of the linker and the transfer of the basicity to the terminal nitrogen of the piperazine produced the desired effect, reducing hERG inflection point to 10.8  $\mu$ M, or greater than 20-fold.

#### 5.40.5.3.5 Zwitterions

The best known example of the use of zwitterions to reduce hERG activity is the case of terfenadine.<sup>76</sup> A potent antihistamine, it was first reported to be cardiotoxic in 1989, and was later shown to block the hERG channel K<sup>+</sup> current. The QT prolongation effect was most pronounced when terfenadine was co-administered with CYP3A4 blockers such as ketoconazole. In contrast, fexofenadine, terfenadine's main metabolite, is devoid of hERG-blocking activity (Figure 18). The carboxylate in fexofenadine renders the molecule uncharged in solution, decreasing the potency of hERG blockade by over three orders of magnitude, and making fexofenadine (Allegra) a best-selling antihistamine.

### 5.40.6 Conclusions

How useful have most of the in silico methods for predicting hERG blockade been so far? Indeed, the publications described in this review have spawned a variety of commercially available models aimed at predicting which ligands may interact with hERG channel. Unfortunately, the impact of these predictive methods on drug discovery to date has been rather limited. Part of the challenge lies in the fact that none of the approaches tried so far can be considered universal. Homology modeling has been able to narrow the scope of mutational data required to characterize hERG, and has been rather successful in providing the rational for the effect these mutations have on channel function. Despite that, docking of prealigned hERG blockers into the homology models has so far only led to qualitative predictions of the importance of certain structural features present in potent hERG blockers. While useful to overall understanding of

the problem, the utility of the 3D receptor-based approaches for rapid prediction of hERG liability in a set of ligands is currently rather low. The emergence of QSAR approaches as applied to hERG liability has produced models better suited to make ligand predictions. The drawback has been that, as is rather typical for QSAR, these models have been trained on rather small sets of known hERG blockers, and while highly predictive in local models, they tend to fail when confronted with broad SAR that is more global in nature. Yet another trend, ligand-based machine learning methods, has shown promise in the ability to discriminate between known hERG blockers and compounds devoid of hERG liability. However, this approach typically yields the prediction as a 'black box' calculation, making efforts to interpret the prediction difficult. Ultimately a widely adopted predictive tool for hERG should be able to make reliable and rationalizable predictions linked to interpretable features, such as presence or absence of certain molecular fragments.

At this point it appears that various hERG predictive methods have contributed to better understanding of the general SAR features implicated in hERG interactions. Many can be used as tools for the prioritization of compounds to be tested for hERG block due to their better performance in identifying hERG inactives. The main reason for that may lie in the data sets available for modeling. Naturally, they have tended to be global snapshots of structures associated with hERG activity, covering "broad but shallow regions of chemical space."<sup>17</sup> In other words, there is more known about nonblockers than blockers. This has rendered current in silico approaches less useful in making accurate predictions for each molecule, such as in the case of an ongoing medicinal chemistry optimization program. The drive toward better computational models may get a boost in the near future from increasing availability of high-throughput hERG channel assays, such as planar patch. While more work is needed to validate the results from these assays versus the 'gold standard' of the patch clamp, these techniques are providing a window into local structure-activity data sets not available previously. Current computational methods do, however, identify trends, which may be sufficient to permit in silico identification of potential scaffold-based QT liabilities in the course of whole library screens, internal as well as commercial, and real as well as virtual. It has been hypothesized that anywhere up to 25–30% of all compounds proceeding from screening to medicinal chemistry optimization have hERG blocking activity.<sup>66</sup> This observation may provide a further impetus to in silico approaches to identifying hERG blockers. These approaches have the potential to provide cost-saving tools that will be applied in combination with in vitro assays to facilitate the discovery of QT prolongation potential early in the drug discovery process, thus improving downstream attrition rates and ultimately the cardiac safety of medications.

## Biography

**Alex M Aronov** is Senior Research Scientist in the Applications Modeling Group at Vertex Pharmaceuticals, Cambridge, MA. His research interests include ways to capture chemical intuition as it relates to drug discovery, structure-based design, and ADMET modeling. Prior to coming to Vertex in early 2001, he was Postdoctoral Fellow in the laboratories of Irwin 'Tack' Kuntz, Paul Ortiz de Montellano, and Ching Ching Wang at the University of California–San Francisco, working on chemogenomic target validation of parasitic targets through structure-based design of novel antiparasitic agents. Originally trained in bioorganic and medicinal chemistry, he received his Doctor of Philosophy degree in 1998 from the University of Washington under the direction of Mike Gelb and Wim Hol, where he was involved in the design and synthesis of novel antitrypanosomal agents.

### 5.41.1 Introduction

In a recent article, Lombardino and Lowe<sup>1</sup> described changes in the way medicinal chemistry and indeed drug discovery are performed today compared to a decade or more earlier. They describe the much wider range of tools to help overcome the numerous hurdles in the drug discovery process (advances in synthetic, analytical, and purification technology, such as transition metal-catalyzed carbon–carbon bond-forming reactions, high-field nuclear magnetic resonance) as well as computer-assisted literature and data retrieval and analysis. The radical changes mentioned are combinatorial chemistry and high-throughput screening (HTS). Combinatorial chemistry allows chemists to generate rational, focused libraries of compounds that allow access to lead material and then potentially define structure–activity relationships (SAR) rapidly. They also identify an Achilles heel with the technology with the statement: “many companies are struggling to triage the large number of screening hits to viable lead compounds that can support a successful drug discovery project. In this struggle, costs can escalate significantly as the generation of large amounts of data is not the same as generating viable, quality leads.” Taking this further, when combinatorial chemistry is used to generate SAR and aid lead development, the screening costs are multiplied even further. The logic of human genome-derived targets and subsequent in vitro screening of compounds against these specific molecularly defined targets is sound to derive specific agonists or antagonists. This is particularly true now as compound files have become more drug-like and project targets are defined by knowledge about the potential binding site as druggable. Selectivity is also readily and rapidly screened for against close neighbours or proteins associated with adverse events (e.g., the rapidly activating delayed rectifier potassium current channel ( $I_{Kr}$ ) in cardiac tissues (hERGK<sup>+</sup>, K<sub>v</sub>11.1)). In vivo the slowing of repolarization, by compounds inhibiting this channel, leads to QT interval prolongation and the appearance of potentially fatal arrhythmias (torsade de pointes). Again, reflecting on a problem often encountered in the past, where discovery programmes concentrated on target potency, with the exclusion of other properties, humanized in vitro screens have been developed that relate to human pharmacokinetic performance. Such screens are termed generically ADME screens and generally address the key pillars of a compound’s in vivo performance (drug-like). The pillars are illustrated in [Figure 1](#).

**Figure 1** Schematic illustrating the key pillars that influence the dynamics of drugs.

#### 5.41.1.1 In Vitro Screens for Oral Absorption

Absorption can be divided into dissolution and permeability phases. Solubility is a key parameter for dissolution of compounds following oral administration. The process depends on the surface area of the dissolving solid and the solubility of the drug at the surface of the dissolving solid. Solubility is inversely proportional to the number and type of lipophilic functions within the molecule and the tightness of the crystal packing of the molecule. Rapid, robust methods reliant on turbidimetry to measure solubility have been developed.<sup>2,3</sup>

Currently, in vitro methods such as Caco-2 or Madin–Darby canine kidney (MDCK) cell monolayers are widely used to make permeability estimates.<sup>4–6</sup> Both these cell lines form monolayers of polarized cells. These cell lines express drug transporters like P-glycoprotein (P-gp). They can be used in 24- and 96-well plates, but this is possibly the limit for these cell-based screens in their current form. The main advantage of MDCK cells is their shorter culture time. Artificial membranes such as parallel artificial membrane permeability assay (PAMPA) have been advanced for high-throughput permeability assessment. The original PAMPA method<sup>7</sup> involved creating a filter-immobilized artificial membrane by infusing a lipophilic microfilter with 10% (weight/volume) egg lecithin dissolved in *n*-dodecane. The filter membrane separated an aqueous solution containing the compound of interest from aqueous buffer. Microtiter plate technology allows rapid screening and the capacity can exceed the 96-well limit of cell-based assays. The use of nonbiological material and microtiter plates greatly increases speed and lowers cost.

The artificial membranes obviously lack transporters and other proteins, and the results generated are analogous to intrinsic membrane permeability. This produces a dilemma since ideally both pure membrane permeability and the influence of drug transporters would be desired to provide data that could be deconvoluted. Reliance on the cell-based systems generates complex SAR output that can be partially addressed by measuring flux in both directions or over a range of concentrations. Ultimately, these solutions lead to even more pressure on the in vitro screening systems.

#### 5.41.1.2 In Vitro Screens for Clearance

The metabolic stability of compounds can be assayed in a high-throughput or semi-high-throughput screening system using recombinant enzymes, human liver microsomes, or human hepatocytes.<sup>8</sup> The use of mass spectrometry provides near-universal detectors for many of these in vitro systems, and separation systems are continually evolving to allow more and more direct introduction of sample. The choice of reagent governs the breadth of metabolic processes examined. The recombinant enzyme, normally CYP3A4, obviously only studies reactions performed by that enzyme. However some 60–70% of all drugs are cleared predominantly by CYP3A4, so screening against this isoenzyme will provide useful SAR. Microsomal systems with the appropriate cofactors provide a comprehensive screening reagent for oxidative metabolism by the liver. The cytosolic oxidation systems are absent such as aldehyde oxidase but these generally play a minor role. In most cases, screening is run using the microsomes fortified with NADPH (via a regenerating system) to study P450 metabolism (and flavin monooxygenases). Broad screening for metabolic stability is best accomplished with hepatocytes, which provide a system containing all the enzyme systems: oxidative, conjugative, and hydrolytic. In terms of ease of use the hierarchy is reversed as hepatocyte systems are more difficult to obtain, difficult to cryopreserve, and generally show limited linearity against cell concentration. This means, in terms of measuring stability, hepatocytes have a lower dynamic range. Human systems also suffer from the inter-subject variability of the donors and even when pooled into fairly large batches show differences in metabolic rate across batches. Screening results are normally percentage remaining or described by disappearance half-life. This is convertible into intrinsic clearance using appropriate scaling, a parameter that has direct pharmacokinetic significance in terms of in vivo pharmacokinetics. Intrinsic clearance ( $CL_i$ ) relates to hepatic extraction ( $E$ ) and hence systemic

clearance  $CL_s$  and hepatic first-pass effect ( $F$ ):

$$E = f_u \cdot CL_i / (f_u \cdot CL_i + Q_H) \quad [1]$$

where  $f_u$  is fraction unbound in blood and  $Q_H$  is liver blood flow.

$$CL_s = Q_H \cdot E \quad [2]$$

Bioavailability is also dependent on the fraction absorbed through the gut (permeability and gut metabolism, partially estimated by screens in [Section 5.41.1.1](#) above).

$$F = 1 - E \quad [3]$$

### 5.41.1.3 In Vitro Screens for Volume of Distribution

Various methods of prediction of the volume of distribution of a compound have been advanced. Very few are utilized in a high-throughput mode. These rely on looking at partitioning into tissue sections or pieces and then extrapolating that data using known values such as tissue volume and weight. The number of tissue types examined may be broad, like that described by Ballard *et al.*<sup>9</sup> (adipose, brain, heart, intestine, kidney, liver, lungs, muscle, pancreas, skin, spleen, stomach, testes, and thymus). Other prediction methods<sup>10</sup> have simplified the number of tissue-partitioning experiments, which need to be conducted and suggest that only two tissue types (adipose and muscle) are required.

### 5.41.2 The Obvious Solution

All these screens and others are high-value, but, as stated above, are very costly to maintain and run. If a number of discovery programmes are advanced using combinatorial chemistry, and there are compelling reasons to do this, the burden on compound control, formatting multiwell plates, robotic screening equipment, and reagent provision becomes unsupportable.

The immediate answer to the above is the use of *in silico* techniques. This approach offers none of the restrictions referred to once a model or system is developed and validated. These models could be used for prioritization: selecting which synthesized compounds to put into the expensive screening cascade referred to above or, more attractively, actually to guide synthesis. The latter could lower the number of compounds needed to develop the SAR necessary to achieve a drug candidate and save both chemistry and screening resources.

There are numerous *in silico* approaches to attempt to model both the output of screens and actual human pharmacokinetic performance. The number of publications for the last decade describing aspects of ADME screening are shown graphically in [Figure 2](#). There is an obvious upward trend for publications around *in silico* approaches and many reviews appear on this topic, summarizing the various attempts and approaches.<sup>11,12</sup>

The vast majority of these papers conclude with apparently successful methods that should be directly applicable to solving the pillars shown in [Figure 1](#) to an acceptable level of accuracy. Despite this huge and clear strategic drive to achieve the obvious solution, screening is still the method of choice and *in silico* methods have done little to change this.

### 5.41.3 The Solution Is Murky

Stouch and co-workers<sup>13</sup> produced a somewhat unusually titled paper that begins to unravel why the *in silico* revolution has not happened despite the promise of the literature. Their paper, 'In *silico* ADME/Tox: why models fail' describes several case examples which actually apply very often generically.

#### 5.41.3.1 Data Quality

To gain a large enough data set literature data are employed. Such data will span many laboratories and will have been collected under varying experimental protocols and conditions. The data set therefore is worthless. Even in a single laboratory, data collected over time will often show variation. An example would be human microsomal or hepatocyte clearance. It is common practice to pool these reagents to try to lower variations; individual human samples show huge variation in certain enzymes.<sup>14</sup> For example, the major human P450 (CYP3A4) shows up to 80-fold variation across a

**Figure 2** Graphical representation of the increasing publication of in silico approaches compared to in vitro screening and 'drug metabolism' in general.

series of human livers ( $n = 45$ ).<sup>15</sup> Despite pooling, substantial variation can be seen between pooled batches. Even with the appropriate positive controls it is difficult to build a large data set from such screens. The commonly used Caco-2 cell line system shows variation in result due to cell passage numbers, culture time, type of support, and medium.<sup>4,6</sup> Hou *et al.*<sup>5</sup> in describing the correlation of Caco-2 permeation with simple molecular properties, highlight the variation in laboratory data. In their training data set the  $P_{\text{eff}}$  for mannitol, often used as a quality standard, showed 10-fold variation across referenced studies ( $-6.75$  versus  $-5.49$ ). Their approach in 'curating' the published data indicates the difficulty in literature-derived training sets. The authors also point out the somewhat more surprising ranges encountered in measured lipophilicity descriptors such as  $\log D_{7.4}$ . They note again a near-10-fold variation in values for compounds, as exemplified by atenolol ( $-1.29$  versus  $-2.14$ ).

Other aspects can also be added in that certain data are very hard to obtain. Whilst human bioavailability data are readily available, these data are a composite of fraction of the drug absorbed, gut first-pass metabolism, and liver first-pass metabolism. To obtain human absorption per se as a true permeability value and relate that to Caco-2 or replace such screens is thus highly problematic. Likewise, most of the data on blood-brain penetration is derived from animal experiments comparing whole blood or plasma with total brain. Such data are only of limited use compared to cerebrospinal fluid or extracellular fluid concentration data. Whole-brain partitioning actually represents partitioning into the lipid of the brain, and not actually access to drug receptors. The apparent dramatic differences in brain distribution described for total brain, as shown above (3–4 orders of magnitude), collapse to a small ratio when free (unbound) concentration of drug in plasma is compared to cerebrospinal fluid or extracellular fluid concentration.<sup>16</sup>

### 5.41.3.2 Compound Space

Almost invariably, any model will fail. No matter how many compounds are employed to build a data set, chemists will innovate and make structures dissimilar to those used to build the model. In the example quoted by Stouch *et al.*,<sup>13</sup> the model was based on 800 marketed drugs. These compounds showed only a very low similarity (less than 0.3 on a scale of 0–1) to those being investigated as putative drugs.

### 5.41.3.3 Accuracy around Critical Decision Points

Many screening cascades have a cut-off point to either test the compound further or to seek an alternative compound. These cut-off points are based on project wisdom and sometimes pragmatism. Many models can show a general trend, but fail to have any predictive value around a go/no-go value. Stouch *et al.*'s example<sup>13</sup> is a decision of CYP2D6 inhibition. Although the model was 90% predictive, the go/no-go point was 10  $\mu\text{M}$ . Here the model predicted correctly 60% of the time and falsely 40% of the time.

In a similar vein, the paper includes a description of a solubility model where, even if accuracy had been achieved, the dynamic range did not address the key areas of interest. In this model the lowest limit was 1  $\mu\text{M}$  for poorly soluble

compounds. With potent molecules solubility below this value may be adequate. Moreover, progress in improving solubility from very low levels could not be predicted.

Lombardo and colleagues<sup>17</sup> also question the progress made with in silico modeling. They concluded from a critical review of work in the field of in silico ADME published during the period 2000–2002 that not much progress had been made in developing robust and predictive models. In agreement with the statements above, they also concluded that the lack of accurate data, together with the use of questionable modeling endpoints, had greatly hindered real progress in defining generally applicable models. They also refer to the complex nature of ADME phenomena, in which a single desired property such as absorption is actually a complex outcome of several biological processes. Local models refer to the concept of small more focused data sets that could be a single project, therapeutic area, or even a research site (as discussed later, in adaptive in combo models, in practice other definitions of ‘local’ can be applied). ‘Local’ will probably mean that the training set is more likely to reflect future compounds for which predictions are needed and also that the data used for training are comparable and consistent for each compound. They also state that the empirical nature of quantitative structure–activity relationship (QSAR)/quantitative structure–permeability relationship (QSPeR) approaches may ultimately dictate the use of ‘local’ models, since it would be hard to extrapolate predictions outside the parameters dictated by the training set.

#### 5.41.4 Physicochemistry Provides a Model and a Link

Despite the apparent lack of progress, intrinsically ADME data have a strong relationship with the physicochemistry of the compound. Physicochemical properties should be predictable from consideration of the chemical structure. Many of the screens provide data that can only be rationalized by an understanding of the physicochemical properties. This relationship is illustrated in [Table 1](#).

Lipophilicity is the key physicochemical parameter linking solubility, membrane permeability, and hence drug absorption and distribution with route and rate of clearance (metabolic or renal). Measured or calculated lipophilicity of a compound is readily amenable to automation at low cost and high throughput. Many of these calculation approaches rely on fragment values, where the model is broken down into fragments. The existing measured values of compounds form the basis for the values assigned to each fragment as well as various correction factors that correct for the proximity of certain groupings. These measured values determine to a large degree the accuracy of the method. De novo calculations often have inaccuracies due to missing fragments or that the core template expresses a combination of properties that the fragmental approach misses (e.g., internal or external hydrogen bonding). The accuracy of the calculation can be significantly improved by actual measurement of some representatives of the core template and/or compound containing or missing the fragment not in the original measured values. This can be likened to the exact approach we will discuss in more depth in [Sections 5.41.5–5.41.7](#): that is, predictions on compounds that have properties (sufficiently) different to those studied previously not to allow the investigator to predict their properties from previous values (can be likened to a training set).

To understand when properties are sufficiently different to change the behavior of a molecule in a biological system, the concept of chemical space has been advanced and developed.<sup>18</sup> The huge number of compounds that can be synthesized represents the universe. Within that compounds can be mapped (chemography) against chemical descriptors of physicochemical and topological properties creating two-dimensional (2D), three-dimensional (3D), or

**Table 1** Physicochemical properties and the relationship to key disposition (pillars) processes. Number of ticks indicates relative importance and the arrow indicates how an increase in the physicochemical property affects the ADME property, e.g., dissolution is decreased by increasing lipophilicity

|  | <i>Lipophilicity</i> | <i>Molecular size</i> | <i>Hydrogen bonding</i> | <i>Ionization</i> |
|--|----------------------|-----------------------|-------------------------|-------------------|
| Dissolution  | √√√ ↓                |                       |                         | √√                |
| Absorption gastrointestinal tract permeation, lipoidal | √√√ ↑                | √√                    | √√                      | √                 |
| Absorption gastrointestinal tract permeation, aqueous  |                      | √√√ ↓                 |                         |                   |
| Metabolism   | √√√ ↑                |                       |                         | √                 |
| Renal clearance  | √√√ ↓                |                       |                         |                   |
| Volume of distribution                                 | √√√ ↑                |                       |                         | √√                |

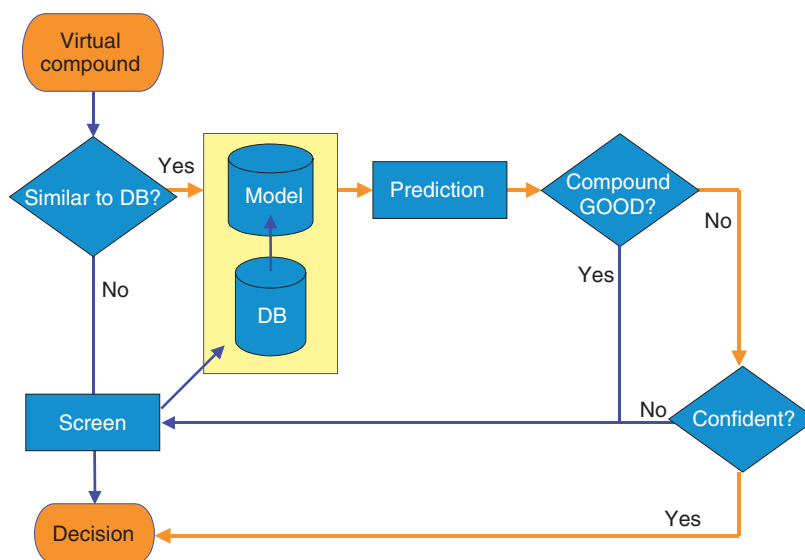

multidimensional space. The hydrogen-bonding capacity of a drug solute is now recognized as an important constituent of the concept of lipophilicity. Initially  $\Delta\log P$ , the difference between octanol/water and alkane/water partitioning was used as a measure for solute hydrogen bonding, but this technique is limited by the poor solubility of many compounds in the alkane phase. Computational approaches to this range from simple heteroatom counts (O and N), division into acceptors and donors, and more sophisticated measures such as free energy factors<sup>19</sup> (used in programme Hybot), to polar surface area.<sup>20</sup>

### 5.41.5 Fixed or Adaptive in Combo Models

In [Section 5.41.3](#), the statement was made that invariably any model will fail. The often suggested answer in computational terms is, to overcome failure, a bigger and better data set is required or that more or better descriptors are employed.

Despite the much larger data set used for training, new compounds explore chemistry space that has not been explored in the original training set. The chemical space is almost infinite. It has been calculated that  $10^{60}$  different molecules could be made from a combination of just 30 C, N, O, and S atoms. It seems highly unlikely that a training set will ever exist that covers the 'space' of this dimension.<sup>21</sup> Whilst this may sound dramatic in terms of structural differences, creating an internal hydrogen bond in a molecule that masks a previously 'exposed' hydrogen bond can have dramatic effects on the biological behavior of a molecule (e.g., gut or cell penetration). The much larger data set allows a model to be built but the lack of precision in estimating parameters for a new molecule makes the use of the model of little value in filtering compounds for screening or guiding synthesis.

An alternative is to turn the cause of failure into an alternative strategy. The simple concept described in [Section 5.41.7](#) – that of making the model adaptive, that is, it grows with new chemical space – should address a major cause of failure. Once a predictive model is constructed it is, by definition, restricted to the chemical space which built the model. To include new chemical space, new data are needed. This is provided by further data from in vitro screens. This interactive process is illustrated as [Figure 3](#). Such an approach requires that all new compounds are examined for similarity to the original model training set. Those that fall outside chemical space need to be screened in vitro (e.g., singleton compounds). Those compounds that do fall within the chemical space of the model can be screened in silico, and then those that are predicted to be highly positive or negative of the screening scale results (e.g., metabolically

**Figure 3** Scheme of an ideal adaptive in combo approach. The process starts with the design of a virtual compound. 'DB' represents the database used to train the in silico model and, if it exists within the compound space of the data base, a prediction on its ADME properties is made. Synthesis of the compound is triggered by a prediction of good ADME properties or it being outside the compound space of the training set, resulting in a low confidence in prediction. The compounds with low confidence in prediction are screened in the appropriate ADME screens and the data then add to the database. The combination of in silico and in vitro techniques provides the necessary information to make the decision faster and at a lower cost than a purely in vitro approach, and with more reliability than a purely in silico derivation of information. Since 'DB' is constantly growing in this combined approach, the model is constantly being updated to cover the evolving chemical space.

stable or labile, *see* [Section 5.41.6](#)) can be withdrawn from the in vitro screening routine with a high degree of confidence. If a more aggressive strategy needs to be addressed in order to reduce costs, then the number of screened compounds could be limited to those that are not within the chemical space of the model. The earlier this method is applied in the drug discovery and development pipeline, the further the costs are reduced – if a compound is identified by the in silico model as a failure and discarded when it is still virtual, then the savings derived from an unnecessary synthesis can be added on top of the screening savings. However, in order to adopt this strategy, the error associated with the in silico predictions should compare the error of the in vitro experiments, and a very robust method to measure the similarity of the compounds to the chemical space of the model training set must be put in place. The screened data are obviously available to medicinal chemists to guide synthesis. More importantly, perhaps the new data allow the model to be retrained with a data set that now covers the new chemical space (represented by ‘DB’ in [Figure 3](#)).

It is appropriate at this point to define further the concept of a compound’s similarity or its position in chemical space, since it is key to the success of the in combo approach. Several recent examples in the literature use this concept to evaluate the quality of in silico QSAR models, either to study systematically the best approach for different kinds of training sets,<sup>22</sup> or to introduce new concepts like the dimension-related distance (DRD),<sup>23</sup> or to explore alternative approaches to linking similarity measures and model quality based on a residuals classification.<sup>24</sup> The bottom line is that the measure of similarity or diversity is context-dependent. Despite the intuitively simple idea of placing a compound in a chemical space and measuring its proximity to its nearest neighbors, there are several aspects of this process that need to be considered:

1. The kind of molecular descriptors that will be used to describe the chemical space and how many should there be: should they be the same descriptors used to develop the in silico model? Or should they invariably be structure-related (e.g., fingerprints)? Can we reduce the number of descriptors to latent variables (e.g., via principal component analysis, PCA) without losing significance in the measure of similarity?
2. How do we measure the distances in the chemical space? The most widely used metric for fingerprint-based chemical spaces is the Tanimoto coefficient, but when other types of descriptors are involved, then the choice of distance metrics expands: Euclidian, Manhattan, Mahalanobis, Pearson, etc.<sup>25</sup>
3. How many neighbors should our molecule have in the training set chemical space so that we can apply the model with confidence? It is clear in the case of a singleton that the number of neighbors will be zero or one at the most, but to choose a criterion for compounds embedded in the whole training set region is not trivial.

Eventually, any chosen strategy to evaluate a compound’s similarity to the modeling chemical space will require optimization, so that the best descriptor space, distance metrics, and number of nearest neighbors can provide the best measure of the in silico model reliability. Recent examples that relate specifically to ADME are discussed in [Section 5.41.8](#).

The adaptive in combo concept becomes even more attractive in today’s environment. Combinational chemistry, applied these days to medicinal chemistry, relies on a common scaffold (or linking group). This scaffold is amenable to rapid parallel reactions at a number of sites to allow the rapid creation of new molecules. These scaffolds tend to be designed around core-privileged structures that begin to match the knowledge surrounding the various drug targets (e.g., aminergic and nonaminergic G protein-coupled receptors). Active compounds from a high-throughput screen can be rapidly exploited, as described above. Such programmes by definition occupy similar chemical space. Indeed, even in the absence of combinational techniques, the final compound selected in development or successful drug programmes shows high similarity to the original lead matter. An adaptive model, therefore, built on a smaller data set from a common scaffold will not fail due to being dissimilar in 2D or 3D chemical space, when new compounds from the same series are tested. The difference with combinational chemistry is that enough molecules are rapidly synthesized early in the programme to form a training set. As new scaffolds are adopted, so the model can be retrained, growing with the increasing chemical space.

Adaptive in combo models should have the maximum chance of fulfilling the three basic requirements of the training data set: (1) accuracy of the data; (2) diversity in terms of occupying the chemical space of the compounds for which predictions are made; and (3) quantity, in that there is sufficient density around the chemical space of the compounds for which predictions are made.

An adaptive in combo model, thus created, should have advantages beyond covering the expected chemical space. It is again conceivable that such models can be based on simplified descriptors, chosen not simply to ‘fit’ the data, but ones that can be directly applied to target new chemical synthesis, that is, to guide drug design. The section on physicochemistry links the pillars of drug behavior to properties that are directly in control of the medicinal chemist. They are easy to understand and to visualize. For instance, albeit with literature-derived training and test sets, Hou *et al.*<sup>5</sup> describe a model based on simple molecular properties correlating well ( $r^2 = 0.67$ ) with Caco-2 permeation. Four

molecular descriptors were found crucial to Caco-2 permeation:  $\log D_{7.4}$ , high-charged polar surface areas based on Gasteiger partial charges, the radius of gyration, and the fraction of rotatable bonds. All of these easily relate to medicinal chemistry and modifications that can be performed on subsequent molecules. Moreover, as the authors describe, these four descriptors give a meaningful physical picture of the mechanism of Caco-2 permeation. A lipophilic molecule penetrates the Caco-2 monolayer easier, but above a  $\log D_{7.4}$  value of 2.0, the influence of lipophilicity reaches a maximum. Larger polar surface areas make a negative contribution to permeability, but this is mainly limited to those atoms with high-charge densities. In addition, larger and more rigid molecules have lower permeability than smaller or flexible ones. Other descriptors of lesser value include number of all atoms, number of aromatic atoms, number of hydrophobic atoms, number of all bonds, fraction of rotatable bonds, mass density, dipole moment, heat of formation, Wiener index, Zagreb index, Hosoya index, and solvation free energy.

Definitely the data that are used to generate the model will not suffer from data quality, although by definition the data will be limited to the in vitro absorption, distribution, metabolism, excretion, and toxicity (ADMET) screens (e.g., [Figure 1](#)). Data quality will be ensured as the assays will be from a single source in a single laboratory with standardized reagents and conditions. The limitations are that these are in vitro results which then have to be extrapolated to the clinical situation, rather than a model based on human data. However, as outlined above, such global models invariably fail with new compound series that are removed in chemical space.

#### 5.41.6 Limitations on What Can Be Achieved

An additional problem with many ADME parameters is the degree of precision attached to them. For instance, if in silico approaches allowed the in vitro pharmacological potency of a molecule to be determined from the structure of the ligand and some information on the target, then one or two orders of magnitude error is permissible. Such predictions would be of use in areas such as lead-finding or even compound optimization. Such error is not useful in ADME prediction, since it would often span the entire range of properties a molecule can possess.

A key difficulty with adaptive models is that the prediction is limited to in vitro properties: few compounds will progress to in vivo testing, and even fewer will be advanced to the clinic. In vitro tests are very good at predicting the extremes of the ranges of compound properties, particularly the positive end (the term ‘positive’ refers to the test and not the potential of the compound). Thus, high Caco-2 flux will invariably mean good absorption. Likewise, very fast metabolism by human liver microsomes or hepatocytes will lead to low bioavailability and high clearance. When the results move from the extremes, the systems are less predictive about eventual in vivo performance. This uncertainty has led to the ‘binning approach,’ where the ranges of the assay are divided into three or four segments. This limitation of the in vitro tests invariably means a compounded error in predicting in vivo performance by in silico methods. An example of this is provided by Shen *et al.*<sup>26</sup> The authors used a k-nearest neighbor approach, which relies on the assumption that chemically similar compounds possess similar physical and biological properties; a hypothesis strongly supported by [Table 1](#). A four-‘bin’ model was developed to predict metabolic stability in human liver homogenate. The model was reasonably predictive of stable compounds; however, it was much less predictive of compounds in the intermediate stability ‘bins’. Considering that the prediction of in vivo performance is most problematic from in vitro data in the intermediate range, the in silico output is likely to be even more uncertain.

Another variation of some of the problems on data quality and drift in assays is exemplified by solubility. Chemists expect a single right answer rather than a range. Even something as apparently simple as solubility does not have a single answer. A particular problem in drug discovery is that solubility is not constant. When a newly synthesized compound is first isolated, it is often as the amorphous form. In this form solubility is invariably at its highest. This is usually the stage at which solubility assays are run to guide new compound synthesis. Subsequent isolation will be in a crystalline form and a decrease in solubility is seen. As purification (crystallization) conditions are further improved, polymorphs are isolated, each representing the thermodynamically most stable form. Polymorphs are different crystalline forms which, although chemically identical, result from a different ordered arrangement of molecules within the crystalline lattice.

#### 5.41.7 Adaptive in Combo Models in Practice

There should be no particular limit to the amount of chemical space covered in any particular model provided it has adequate distribution of structural types and data on the training set. Whilst we have stressed that combinational chemistry scaffolds around privileged structures may be a powerful tool in confirming the need for wide chemical space, we recognize the narrowness of this approach. This is particularly true in the early period of a project, when insufficient data will be available to train a model and early impact on the formative period, including behaviors (in silico–in project),

will be lost. To begin to examine when the SAR of a few projects would be diluted by the diversity of many, we have examined the performance of a metabolic stability model constructed using data derived from projects on two sites. All the projects had diverse targets but some overlap in therapeutic area. One of the sites has excelled in traditional medicinal chemistry whilst the other is renowned for structure-based drug design. Both sites synthesize compounds using singleton and library approaches.

The results of this analysis are summarized in [Table 2](#).

The models used experimental data derived from human microsomal systems optimized for oxidative metabolism to train a naive Bayesian classifier for each site (La Jolla (LJ) and Sandwich (SND) models) and for both sites (Global model). Several descriptor sets were used to build several models, and the best performers were kept as final models for each data set. The procedure to derive and evaluate the models was identical for both sites: 80% of the data available was used to train the model, whilst a test set was derived with the remaining 20% and used to evaluate the performance of the model (1 and 4 in [Table 2](#)). The chemical space of the test set is most likely covered by the training set. Each of these test sets was then run with the model developed for the other site to investigate the probable impact of compounds being outside the chemical space of the model (2 and 5 in [Table 2](#)). As expected, the performance of these models fell, although they still carried some predictive value. A further dimension of deviation from chemical space was examined by the 'external set' (3 and 6 in [Table 2](#)). These comprised the data points from newly synthesized compounds at each site. The global model was built with a merge of both training sets, and also evaluated with a merged test set (7 in [Table 2](#)). This represents an adaptive model since it has been trained to cover the compound space with the new data points from both sites.

The concordance values shown in [Table 2](#) represent the percentage of compounds correctly predicted. Sensitivity and specificity are the ratios of correctly predicted 'stable' and 'unstable' compounds, respectively. The positive and negative predictive values indicate respectively which proportions of 'stable' and 'unstable' predictions are consistent with the experimental data. It can be seen that the combination of both data sets yields a good model, since all the parameters relative to the global test set are  $\geq 80\%$ . This can be contrasted with the performance of the site model's performance on compounds from the other sites. However, the most remarkable result is the higher prediction power of the global model with respect to the external validation sets (8 and 9 in [Table 2](#)): the percentage of captured positives amongst the La Jolla data set increases from 5% to 23%, and both the positive and the negative predictive values also increase for this site. At the same time, the predictions for the Sandwich compounds do not seem to improve or worsen with the inclusion of the La Jolla compounds into the training set, since the sensitivity increases from 16% to 55% at the expense of the negative predictive value, which decreases from 57% to 29%.

**Table 2** Comparative performances, in the prediction of metabolic stability, of two local models (La Jolla (LJ) and Sandwich (SND)) versus a global model that combines La Jolla (LJ) and Sandwich (SND) data. The models are built from training sets exclusive to these research sites; these training sets are then combined to create the global model. The concordance values represent the percentage of compounds correctly predicted. Sensitivity and specificity are the ratios of correctly predicted 'stable' and 'unstable' compounds, respectively

|    | <i>Model</i>                       | <i>Validation set (number of molecules)</i> | <i>Concordance (%)</i> | <i>Sensitivity (%)</i> | <i>Specificity (%)</i> | <i>Positive predictive value (%)</i> | <i>Negative predictive value (%)</i> |
|----|------------------------------------|---|------------------------|------------------------|------------------------|--------------------------------------|--------------------------------------|
| 1  | La Jolla                           | LJ test set (408)                           | 86                     | 89                     | 85                     | 49                                   | 98                                   |
| 2  | La Jolla                           | SND test set (446)                          | 50                     | 32                     | 81                     | 74                                   | 41                                   |
| 3  | La Jolla                           | LJ external set (117)                       | 81                     | 5                      | 99                     | 50                                   | 82                                   |
| 4  | Sandwich                           | SND test set (446)                          | 86                     | 87                     | 85                     | 91                                   | 80                                   |
| 5  | Sandwich                           | LJ test set (408)                           | 46                     | 42                     | 72                     | 90                                   | 17                                   |
| 6  | Sandwich                           | SND external set (80)                       | 60                     | 16                     | 100                    | 100                                  | 57                                   |
| 7  | Global                             | GLB test set (854)                          | 85                     | 83                     | 86                     | 80                                   | 89                                   |
| 8  | Global                             | LJ external set (117)                       | 83                     | 23                     | 97                     | 63                                   | 84                                   |
| 9  | Global                             | SND external set (80)                       | 61                     | 55                     | 92                     | 97                                   | 29                                   |
| 10 | Sandwich with 80% SND external set | 20% SND external set (13)                   | 77                     | 40                     | 100                    | 100                                  | 73                                   |

These results lead to the conclusion that, as more chemical space is covered, the larger model performs better than the smaller dedicated models in dealing with new compounds, even from a local environment. The probable explanation is that, as soon as the two local models are combined, the chances of a new data set being predicted by interpolation rather than extrapolation are higher, hence the higher chances of obtaining correct predictions.

Another way of achieving interpolation rather than extrapolating predictions is to enrich the models with data from a chemical space adjacent in time, rather than in space, to the original training set of the model. That would be the case for the adaptative model represented in [Figure 3](#). To illustrate this, 80% of the SND external set was randomly selected to generate an enriched Sandwich model, and the remaining 20% was used to test its performance. The results, included in row 10 of [Table 2](#), show how the predictions for the SND external set have significantly improved when a representative fraction of its chemical space was incorporated in the Sandwich model: all the statistical indicators have either improved or remained unchanged relative to the results shown in row 6.

Of course, this result might apply to the particular endpoint modeled, or to the particular external tests used for the evaluation, but at least it provides evidence that the adaptive model is a sound strategy and can incorporate considerable chemical space and still be predictive.

#### 5.41.8 Mapping Chemical Space and Absorption, Distribution, Metabolism, and Excretion

Sun<sup>27</sup> has focused attention on the data sets used in the models rather than the models themselves, in a manner analogous to our analysis of the problem, paying particular attention to their size and diversity and to the intrinsic quality. His belief is that data-driven methods, such as quantitative structure–activity/property relationships (QSA/PR), project complicated properties like ADME prediction on to the chemical space defined by compounds in the training set and that this projection simplifies the problem by avoiding the need to define and apply specific mechanisms. Thus, absorption or metabolism processes are complex but can be simplified in these models to a single output. This output is only useful if the training set is relevant in terms of chemical space to the chemical space occupied by the compounds for which predictions are desired.

How to define the need to retrain or adapt the model requires a knowledge of the chemical space occupied by the compounds used to train it. This map of chemical space needs to be specific enough to identify when new compounds, for which predictions are required, fall outside that chemical space.

There are a number of methods for estimating drug space and mapping it. One method (ChemGPS),<sup>28</sup> which has already been applied to ADME,<sup>29</sup> is to borrow from geography and utilize a system like the Mercator convention. Rules are established that are equivalent to dimensions such as longitude and latitude, while structures are equivalent to objects (e.g., cities and countries). Selected rules include size, lipophilicity, polarizability, charge, flexibility, rigidity, and hydrogen bond capacity. Selected objects include a set of ‘satellite’ structures and a set of representative drugs (‘core’ structures). Satellites, intentionally placed outside drug space, have extreme values in one or several of the desired properties, while containing drug-like chemical fragments found in drugs. ChemGPS (chemical global positioning system) is a tool that combines these predefined rules and objects to provide a global drug space map. Novel structures are placed in drug space via principal components analysis score prediction, providing a mapping device for the chemical space. ChemGPS scores are comparable across a large number of chemicals and do not change as new structures are predicted, allowing new compounds to be compared with existing compounds used in the model. Moreover, a record is provided for all previously explored regions of the chemical space, which may allow existing or new models to be assembled with excellent chemical space coverage and thus high predictivity for novel compounds. The principal properties can be translated into interpretable chemical descriptors, as shown in [Figure 4](#).

#### 5.41.9 In Silico–In Project

The examples provided above by Stouch *et al.*<sup>13</sup> highlighted critical decision points of projects. If in silico approaches are to succeed, they have to be seen as an integral part of the project decision process. This is a chicken-and-egg situation, since the in silico approach will not be trusted unless highly validated and trusted – to date something it has failed to do. Screens are often constructed to give decision point readouts such as the cut-off outlined for CYP2D6 inhibition (10  $\mu\text{m}$ ). Similar cut-off values are often used for metabolic liability (percentage remaining in a microsome or hepatocyte system after a given time) and gut permeability (flux value above a certain value, efflux ratio below a certain value). Being on the correct side of such values allows the compound to progress. This is an easy way of evaluating compounds as the screens can have a single assay point and the data lead to clear decisions. Such data may not be the best way either to construct or to use in silico models.

**Figure 4** Principal properties translated into chemical descriptors, illustrating the three most significant dimensions of chemical space.

In fact the application of in silico techniques to drug discovery projects<sup>30</sup> has suffered from a disconnect between those doing the in silico modeling and those synthesizing the compounds. The disconnect can be summarized by the three lacks: (1) lack of alignment; (2) lack of inclusion; and (3) lack of enthusiasm to make change happen. What is needed is:

1. the project at the outset to adopt an in combo philosophy
2. to ensure the data from screens is in an appropriate form for in silico model development (e.g., dynamic range addresses all or the vast majority of compounds with real values and not greater or less than)
3. to ensure in synthesis plans that new chemical space is adequately addressed early to provide modeling substrate
4. the output of the model is in a form that the project team can use and will guide synthesis
5. that the in silico approach of the in combo paradigm is used fully to guide synthesis and that the project does not gradually move back to full reliance on in vitro data.

## 5.41.10 Conclusion

The adaptive model represents a future refinement of in silico techniques. What is needed is not better modeling techniques of the ADME data, but better ways of defining chemical space. Robust definition of chemical space will allow retraining of the model in a timely manner, triggered by the design of new compounds outside the chemical space and their subsequent screening. Pragmatic methods, such as limiting each model to a lead series, an individual project, or a cluster of projects around similar enzymes or receptors may offer a simple 'entry' solution, but, unless the models are adaptive, will begin to fail at some stage as new chemical templates are explored. Ultimately, with better measurement of ADME space, models that encompass many projects of diverse nature may be achievable.

## Biographies

**Dennis A Smith** has worked in the pharmaceutical industry for the past 30 years since gaining his PhD from the University of Manchester, UK, following research on the metabolism of diacetylmorphine. For the last 18 years he has been at Pfizer Global Research and Development, Sandwich, where he is Vice President – Pharmacokinetics, Dynamics and Metabolism. Prior to Pfizer he was head of the Metabolism and Pharmacokinetics Unit at Fisons Pharmaceuticals, Loughborough. During this 30-year span he has helped in the discovery and development of seven marketed NCEs, with hopefully several more to come. His 90 research publications include a number of seminal review papers on the impact of pharmacokinetics and drug metabolism on drug discovery, the role of physicochemical measurement in drug metabolism, species differences in metabolism, the substrate structure requirements of cytochrome P450 enzymes, the interpretation of animal pharmacokinetic and pharmacodynamic data in drug safety assessment, the role of high-throughput screening, and metabolites in safety and efficacy testing. He is active in a teaching role, holding appointments as Visiting Professor at the University of Liverpool and Honorary Senior Lecturer at the University of Aberdeen.

**Lourdes Cucurull-Sanchez** joined the in silico ADME modeling group in Pfizer in 2004, where she currently develops several in silico ADME models for end-points relevant to pharmacokinetics, dynamics, and metabolism. She was previously appointed as a postdoctoral research associate at the University of Cambridge, UK. Sponsored by

Unilever, she applied in silico modeling techniques to several ADME problems, including oral bioavailability and absorption mechanisms. She obtained her PhD in Chemistry in 2000 at the Universitat Autònoma de Barcelona, Spain, where she carried out several ab initio and molecular calculations to assist the bioinorganic chemical modeling of copper proteins. In 1995 she obtained an MPhil in Chemistry at the University of Newcastle upon Tyne, UK, after 1 year of research on x-ray structures of metal complexes with thiolates and related ligands.

### 5.42.1 Introduction

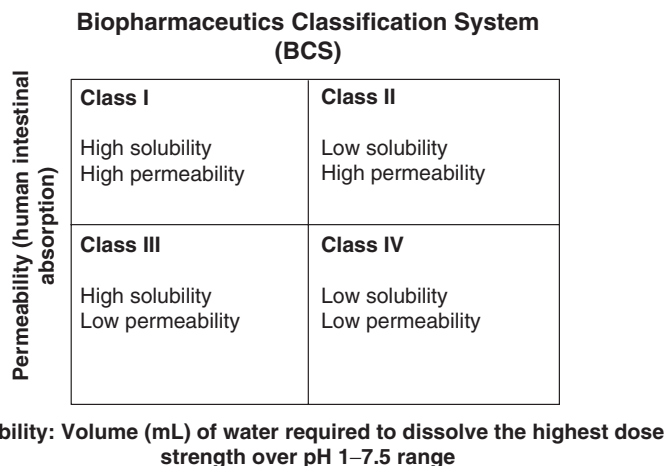

In modern pharmaceutical product development bioavailability (BA) and bioequivalence (BE) have been the subject of repeated studies. Presently, BE studies are being conducted for New Drug Applications (NDAs) of new chemical entity, in supplementary NDAs for new medical indications and product line extensions, in Abbreviated New Drug Applications (ANDAs) of generic products, and in applications for scale-up and post-approval changes. For example, NDA BE studies may be required comparing different formulations in pivotal clinical trials and products intended for market. The complexity and number of studies required are often driven by the fact that several dose strengths may be included in the development process. In addition, BE documentation may also be needed comparing blind and original comparator products in clinical trials. Thus, an NDA typically contains a multitude of in vivo BE studies and the biopharmaceutics classification system (BCS) may be a scientific and a regulatory tool to decrease the number of in vivo BE studies and replace them with BCS based biowaiver (as schematically described in [Figure 1](#)) which also includes nonregulatory applications.

The BCS has been developed to provide a scientific approach for classifying drug compounds based on solubility as related to dose and intestinal permeability in combination with the dissolution properties of the oral immediate release dosage form.<sup>1–3</sup> Additional considerations are pH, chemical and enzymatic stability in the gastrointestinal lumen, membrane transport mechanism, and therapeutic index. The aim of BCS is to provide a regulatory tool for replacing certain BE studies by accurate in vitro dissolution tests. It should be noted that permeability and solubility are substance-specific properties whereas dissolution is product-specific. Thus, it is only dissolution testing that is relevant as surrogate for in vivo BE tests while the BCS classification is a tool to select the compounds suitable for this approach. Presently, it is only high-solubility/high-permeability drugs (class I) for which this approach is acceptable. This is a minimal risk approach because BA of immediate release formulations of class I drugs is insensitive to product dissolution whereas for drugs with low permeability/solubility (classes II–IV) subtle differences in in vitro dissolution could translate into significant differences in BA. Thus, in the regulatory context the BCS classification is used as a risk management tool.

The BCS will certainly reduce costs and time in the drug development process, both directly and indirectly, and reduce unnecessary drug exposure in healthy volunteers, which is normally the study population in BE studies. For example, it has been reported that an application of a BCS strategy in drug development will lead to significant direct and indirect savings for pharmaceutical companies. The BCS is today only intended for oral immediate release products

**Figure 1** Where in the drug development process is the biopharmaceutics classification system (BCS) applied? BCS characterizations are *primarily determined* during preclinical phase and confirmed in phase I. Comparative dissolution tests of drug products as surrogate for in vivo BE studies are mainly performed during phase III and a biowaiver can be obtained. Several nonregulatory applications of BCS in drug development are also shown.

**Figure 2** The BCS provides a scientific basis for predicting intestinal drug absorption and for identifying the rate-limiting step based on primary biopharmaceutical properties such as solubility and effective intestinal permeability ( $P_{eff}$ ). The BCS divides drugs into four different classes based on their solubility and intestinal permeability (defined as more than 90% of the dose absorbed). Drug regulation aspects related to in vivo performance of pharmaceutical dosage forms have been the driving force in the development of BCS. Guidance for industry based on BCS mainly clarifies when bioavailability/bioequivalence (BA/BE) studies can be replaced by in vitro bioequivalence testing.<sup>127</sup>

that are completely absorbed throughout the intestinal tract (>90% of the given dose), and accordingly have an absorption kinetics similar to an orally given solution with the same compound. Furthermore, the BCS has been shown to be very useful for identifying the rate-limiting step and predicting intestinal drug absorption based on primary biopharmaceutical properties such as solubility and effective intestinal permeability ( $P_{eff}$ ).<sup>1–3</sup> A schematic drawing of the biopharmaceutics classification system (BCS) is shown in [Figure 2](#).

BCS has primarily been developed for regulatory applications of oral immediate release products. However, it has also several other implications in the drug discovery, preclinical, and clinical drug development processes and has gained wide recognition within the research-based industry.<sup>3–5</sup> The importance of drug dissolution in the gastrointestinal (GI) tract and intestinal permeability in the oral absorption process has been well known since the 1960s, but the research carried out to constitute the BCS has provided new quantitative data of importance for modern drug development, especially within the area of clinical investigations and determinations of drug permeability with a single-pass perfusion of the human jejunum.<sup>6–8</sup> Another merit of the BCS is that it provides very clear and easily

applied rules for determining the rate-limiting factor in the sometimes very complex GI drug absorption process. In this way the BCS framework can provide guidance in many situations during drug development, for example, to aid in lead optimization and developability risk assessment at clinical candidate drug (CD) selection, to assess feasibility of animal models for in vivo absorption studies, to predict and elucidate food interactions, to support determination of transport mechanism, to aid choice of formulation principle, including suitability for oral extended release (ER) administrations, and to open the possibility of in vitro/in vivo correlations in dissolution testing of solid formulations and risk assessment prior to in vivo BE studies.<sup>5,9</sup> BCS could thereby contribute to more rational decision-making both in screening for candidate drugs and in full development.

The aim of the present chapter is to discuss the past, the present, and the future application of BCS in pharmaceutical drug discovery, preclinical, and clinical product development for oral pharmaceutical products. It is important to realize that oral dosing is the most preferred drug administration route in the clinical usage of drugs: the majority (84%) of the 50 most-sold pharmaceutical products in the USA and European markets are given orally.<sup>4</sup> An extension of the BCS regulatory guideline is considered to be essential for widespread use in all development phases as the current version limits the broad use of BCS since class I drug substances today belong to a minority in pharmaceutical pipelines. For instance, the proportion of class I compounds in the development phase for oral immediate release formulations at AstraZeneca was less than 10% in 2001.<sup>4</sup> By contrast, among well-established drugs on the market, as represented by the 123 WHO oral drugs in immediate release dosage forms, about 25–30% were class I drugs.<sup>10</sup> An example list of drug BCS classification based on human permeability and solubility are given in [Table 1](#).

**Table 1** BCS classification based on human permeability<sup>6</sup> and dose number<sup>10</sup>

| <i>Drug</i>                | <i>Human permeability (<math>\times 10^4 \text{ cm s}^{-1}</math>)</i> | <i>Dose number<sup>a</sup></i> | <i>BCS class</i> |
|----------------------------|--|--------------------------------|------------------|

| Valacyclovir hydrochloride | 1.66   | 0.02                           | I                |
| Verapamil                  | 6.80   | 0.004                          | I                |

<sup>a</sup> Dose number = (highest dose strength/gastric volume (250 mL))/solubility.

<sup>b</sup> High permeability due to carrier-mediated absorption; currently not included in BCS class I.

## 5.42.2 Definition of Relevant Pharmacokinetic Variables

Bioavailability ( $F$ ) is the most useful pharmacokinetic variable for describing the overall quantitative role of all processes influencing the absorption ( $f_a$ ) and first-pass metabolism and excretion ( $E_G$  and  $E_H$ ) in the gut and liver.<sup>11</sup> This pharmacokinetic variable is used to illustrate the fraction of the dose that reaches the systemic circulation, and relate it to pharmacological and safety for oral pharmaceutical products from several different pharmacological classes. To summarize, bioavailability is mainly dependent on three general processes, the fraction dose absorbed ( $f_a$ ), and the first-pass extraction of the drug in the gut wall ( $E_G$ ) and by the liver ( $E_H$ )<sup>1,6,12,13</sup>:

$$F = f_a \cdot (1 - E_G) \cdot (1 - E_H) \quad [1]$$

There are different factors that might affect the fraction dose absorbed (i.e.,  $f_a$ ) and gut wall metabolism (i.e.,  $E_G$ ) of drugs. In general, these can be divided into three general categories: (1) pharmaceutical factors such as choice of excipients and method of manufacturing, (2) physiochemical factors of the drug molecule itself such as solubility and lipophilicity; and (3) physiological, genetic, biochemical, and pathophysiological factors in the intestine.<sup>1,6,12,13</sup> The  $f_a$  is the fraction of the dose transported (absorbed) across the apical cell membrane into the cellular space of the enterocyte according to scientific and regulatory definitions.<sup>1,2,6,12–14</sup> Accordingly, the rate (mass/time) and extent of drug absorption ( $f_a = \text{mass/dose}$ ) from the intestinal lumen in vivo are influenced by: dose/dissolution ratio, chemical degradation or metabolism in the lumen, luminal complex binding, intestinal transit, and effective permeability ( $P_{\text{eff}}$ ) across the intestinal mucosa. The fraction dose absorbed ( $M(t)/\text{dose}$ ), i.e., the fraction of drug disappeared from the intestinal lumen during a certain residence time, assuming no luminal reactions, at any time  $t$  is<sup>1</sup>

$$\frac{M(t)}{\text{dose}} = \int_0^t \int \int A \cdot P_{\text{eff}} \cdot C_{\text{lumen}} \cdot dA dt \quad [2]$$

where  $A$  is the available intestinal surface area,  $P_{\text{eff}}$  is the average value of the effective intestinal permeability along the intestinal region where absorption occurs, and  $C_{\text{lumen}}$  is the free reference concentration of the drug in the intestinal lumen.<sup>1,4,6</sup> From eqn [2] it is obvious that the  $P_{\text{eff}}$  and the dissolved and free drug concentration are the key variables controlling the overall absorption rate and extent, and it is possible to use this regardless of the transport mechanism of the drug.<sup>1,6</sup> Once the drug has reached the intracellular site in the enterocyte, it may be subjected to cytochrome P450 metabolism, predominantly CYP3A4, as well as other enzymatic step such as phase II conjugation by glucuronides, sulfates, and/or glutathione. The enzymatic capacity of the small intestine to metabolize drugs can in pharmacokinetic terms be expressed as the extraction ratio of the intestine ( $E_G$ ).<sup>1,6,12,13</sup> It is important to realize that CYP3A4 is not expressed in the colon.<sup>15–17</sup> The heterogeneity of CYP3A4-mediated gut wall metabolism is crucial to consider, especially for the assessment of interactions with other drugs and/or diet as well as development of ER dosage forms. Instead, drug metabolism by colonic microflora may play a crucial role in colonic drug absorption, especially with regard to drugs given in ER dosage forms, which may be subjected to predominantly hydrolytic and other reductive reactions.<sup>18</sup> The fraction that escapes metabolism in the small intestine ( $1 - E_G$ ) may undergo additional metabolism and/or biliary secretion in the liver ( $E_H$ ) before reaching the systemic circulation. The  $E_H$  is dependent on the blood flow (QH), the protein binding ( $f_u$ ), and the intrinsic clearance of the enzymes and/or transporters ( $CL_{\text{int}}$ ).<sup>11</sup> Recently, it has also been recognized that membrane transport into as well out of the hepatocyte has to be included in the models for predicting and explaining liver extraction.<sup>19,20</sup> These membrane transporters might influence uptake into the hepatocyte and canalicular transport into the bile. These processes are expected to play a crucial role for the local concentration–time profile in the vicinity of the intracellularly located enzyme in the liver.

## 5.42.3 The Biopharmaceutics Classification System

### 5.42.3.1 Present Regulatory Applications

Presently, the BCS is primarily used as a regulatory tool for identifying which drug substances in oral immediate release formulations are suitable for in vitro BE testing and a possible biowaiver. Additional criteria that must be verified for a biowaiver besides solubility, product dissolution, and permeability include drug stability in the GI fluids, therapeutic index classification (narrow or non-narrow), absence of effect of pharmaceutical excipients on the rate and extent of intestinal permeability, and lack of absorption of the parent drug from the oral cavity. If these criteria are met, test and reference products can be compared by in vitro dissolution testing and deemed bioequivalent if sufficiently similar results are obtained. In vitro dissolution testing should be done at three different pH values within the physiological range, typically pH 1.2, 4.5, and 6.8. Product dissolution must be complete (>85%) within 30 min in order to utilize

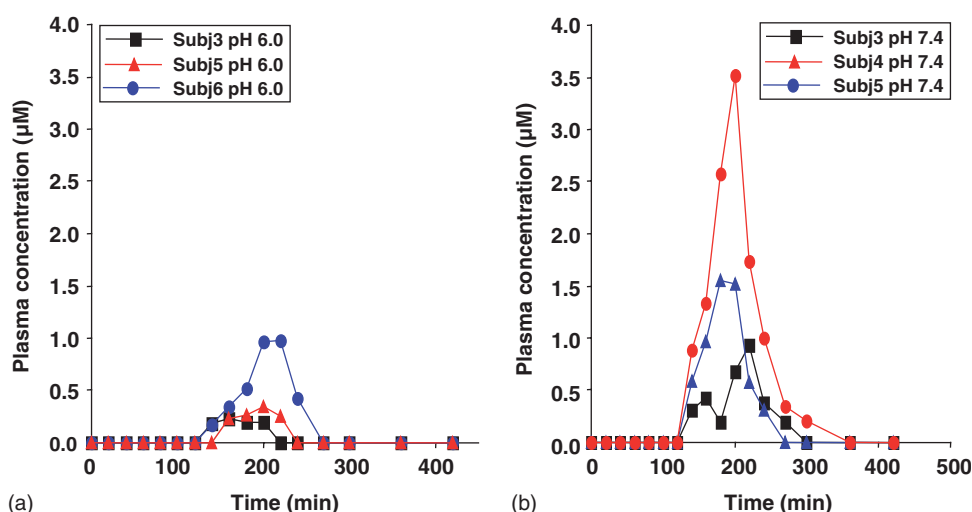

the in vitro BE route. The underlying rationale for this requirement for product performance is to ascertain that drug dissolution is fast enough so as not to become the rate-limiting step in the overall intestinal absorption. It is assumed that gastric emptying will control the onset and rate of intestinal absorption for class I drug substances in products with such a rapid dissolution and no effect on BA will be obtained for different in vitro dissolution profiles within acceptance limits. This has also been verified in vivo by studying metoprolol tablets (a class I drug) with different in vitro dissolution release profiles.<sup>21</sup>

The difference in dissolution rate between a test (*T*) and a reference (*R*) product should be investigated by use of the  $f_2$ -test (see eqn [3] below) where  $f_2 > 50$  is the required limit for equivalence. This limit corresponds to an average difference in amount dissolved at different times (*t*) of less than 10%. If the dissolution is very rapid, i.e., complete dissolution within 15 min, the  $f_2$  testing is not necessary.

$$f_2 = 50 \log \left[ \left( 1 + \frac{1}{n} \sum_{t=1}^n (R_t - T_t)^2 \right)^{-0.5} \cdot 100 \right] \quad [3]$$

In addition to in vitro testing, the test and reference products must not contain excipients that could modify drug absorption in any way except for dissolution effects. For example, the potential for permeability-enhancing effects by surface-active agents, sometimes included in solid formulations, has been identified as one potential concern. However, the reported effects of formulation excipients on efflux inhibitors are not clearly defined, especially not in vivo.<sup>5</sup> Just recently it was reported by Bogman *et al.* that an in vivo intraduodenal perfusion study showed for the first time that low luminal concentrations of the dissolution enhancing vehicle tocopheryl polyethylene glycol succinate (TPGS) slightly enhanced (39%) the intestinal absorption of the P-glycoprotein (P-gp) substrate (ABCB1) talinolol. The concentration of TPGS used was close to the in vitro IC<sub>50</sub> value.<sup>22</sup> We have also in an in vivo perfusion study in humans investigated the influence of a penetration enhancer, sodium caprate (C10), on the rectal absorption of phenoxymethylpenicillin (PcV) and antipyrine (Figure 3). Based on the plasma pharmacokinetics of PcV we showed a slightly increased rectal absorption at pH 7.4 in subjects where C10 was transported into the rectal tissue (absorbed) (Figure 4). However, the increased rectal  $P_{\text{eff}}$  for PcV was too small to detect from the outlet perfusate, which suggests that C10 alone has a limited effect on the in vivo permeability across the rectal epithelium when it is exposed in a solution.<sup>23</sup> These two studies provide an example of the maximum possibility for an interaction since they are perfused through a specific segment. Finally, the effect on GI transit by large amounts of sugars has been highlighted as another issue, especially for liquid formulations where large amounts of such excipients may be included.<sup>3,24,25</sup>

The present regulatory implications of a class I drug are not limited only to BE bridging for generic versus originator products or to different clinical trials versus commercial formulations but are also applied in postapproval manufacturing changes and in the justification of product quality control dissolution methods.<sup>26,27</sup>

**Figure 3** The plasma concentration of phenoxymethylpenicillin during an in vivo rectal perfusion in humans at (a) pH 6.0 and (b) pH 7.4. During 0–100 min and 100–200 min the rectum was perfused without and with caprate respectively at both treatment 1 (a) and treatment 2 (b).<sup>23</sup> Caprate was added to the perfusion solution at 100 min in both treatments 1 and 2.

**Figure 4** Single-pass intestinal perfusion of human duodenum, jejunum, and rectum in vivo. (a) The total Loc-I-Gut concept. To the left is shown a perfusion system of the duodenal segment. The tube system with double balloons (in the middle) allows a segmental single-pass perfusion of jejunum. To the right a perfusion system of the small intestinal stomi is presented. (b) Loc-I-Gut is a perfusion technique for the proximal region of the human jejunum.<sup>7,8</sup> The multichannel tube is 175 cm long and is made of polyvinyl chloride with an external diameter of 5.3 mm. It contains six channels and is provided distally with two 40 mm long, elongated latex balloons, placed 10 cm apart each separately connected to one of the smaller channels. The two wider channels in the center of the tube are for infusion and aspiration of perfusate. The two remaining peripheral smaller channels are used for the administration of marker substances and/or for drainage. At the distal end of the tube is a tungsten weight attached in order to facilitate passage of the tube into the jejunum. The balloons are filled with air when the proximal balloon has passed the ligament of Treitz. Gastric suction is obtained by a separate tube. <sup>14</sup>C-PEG 4000 is used as a volume marker to detect water flux across the intestinal barrier. (c) A schematic presentation of the perfusion tube with three balloons delimiting the segment located in the mid-upper part of the rectum or in a stomi patient.<sup>23</sup> Two balloons located on either side of the anal canal control the position of the tube. The central channel is used for the introduction of the tube by the endoscope, and decompression of gas and fluids during perfusion. The smaller channels are used to deliver air into the balloons and perfusion fluid to and from the rectal segment. The length of the perfused rectal segment is 8 cm.

#### 5.42.3.2 Biopharmaceutics Classification System in Drug Discovery and Preclinical Development

Pharmacokinetic (absorption, distribution, metabolism, and excretion – ADME) parameters are today considered to have a crucial role in the selection process of oral candidate drugs for product development.<sup>28–30</sup> This understanding has also most probably contributed to significantly reduce the number of developmental failure due to pharmacokinetic factors during recent years.<sup>31</sup> Fundamental BCS parameters, such as permeability, solubility, and fraction dose absorbed, are among those ADME parameters and therefore it has been suggested that these fundamental BCS parameters should be useful in both the discovery and early development process.<sup>1,32</sup> For instance, it is clear that new compounds with a very low permeability and/or solubility/dissolution will certainly result in low and highly variable bioavailability, which may limit the possibilities that a clinically useful product can be developed. It is obvious that a selection of candidates that fulfil the BCS requirement of high permeability/high solubility (class I) almost guarantees the absence of failures due to incomplete and highly variable GI absorption. However, these BCS limits are generally too conservative to use as acceptance criteria in drug screening since many useful drugs can be found in classes II–III and even class IV.<sup>10</sup>

First of all, a class I drug is expected to provide complete absorption whereas a certain reduction in bioavailability due to permeability or solubility, as well as due to other reasons (e.g., first-pass metabolism), is generally acceptable. A summary of the different factors that have to be taken into account when defining more relevant acceptance criteria follows:

1. Acceptability of a low and highly variable bioavailability depending on
  - medical need
  - width of therapeutic window
  - potency
  - substance manufacturing costs.
2. Potential for poor in vivo predictability of early permeability and solubility characterizations, due to, e.g.,
  - active transport across the gut wall
  - high paracellular transport through gut wall
  - in vivo solubilization by bile salt micelles.
3. Opportunity to use formulation approaches that improve bioavailability, e.g.,
  - dissolution and solubility enhancement
  - permeation enhancers.

Thus, BCS points out some important variables in the screening of drug candidates whereas the proposed limits are less useful as acceptance criteria in a drug discovery context.

Experimental methods and relevant acceptance criteria regarding permeability and solubility are needed in the early drug discovery process.<sup>33–36</sup> Such procedures have also been introduced in the industry, including solubility screens using turbidimetric measurements and automatic permeability screens in cell-based systems (such as Caco-2 cell model). There appears to be a good correlation between *in vitro* and *in vivo* permeability for drugs with passive diffusion as the main transport mechanism, but there is a significant deviation for drugs absorbed through transporters.<sup>36–39</sup> It is also considered that the interpretation of the importance of efflux carrier on intestinal absorption process is overrated based on results obtained in tissue cell cultures (e.g., Caco-2 cells).<sup>3,4,6,20,40,41</sup> For instance, based on only cell culture data (Caco-2 cells), it was shown that the *in vitro* permeability of fexofenadine in the absorptive direction increased by approximately 200–300% in the presence of various P-gp inhibitors (such as verapamil, ketoconazole, and GF 120918) and that low passive diffusion was the main reason for the incomplete and variable intestinal absorption.<sup>41</sup> Interestingly, an *in vivo* perfusion of the proximal part of jejunum with our Loc-I-Gut technique showed that the *in vivo* permeability was affected by neither ketoconazole nor verapamil at clinical doses (Figure 3).<sup>20,42</sup> It clearly shows that the cell monolayer is too poorly defined to quantitatively predict drug–drug interactions at the transporter level. These cell models can only provide quantitative *in vivo* predictions of drug transport if an extensive mapping of the expression of functional activity of these membrane transporters is done. Therefore, there is a need to develop *in vitro* techniques with functional expressed transporter activities that are better correlated to the various regions of the human intestinal tract.<sup>36,39,41,43,44</sup> These *in vitro* permeability data need to be accurately compared with the corresponding *in vivo* data. We have over the past 15 years determined the human *in vivo* jejunal permeability with a single-pass perfusion technique (Figure 3) for a number of structurally different drugs, as illustrated in Figure 5. In addition, a critical interpretation and extrapolation of the *in vivo* relevance data of intestinal transport are crucial for a meaningful use of these improved cell monolayers.

**Figure 5** Human *in vivo* permeability values ( $P_{\text{eff}}$ ) can be determined by the use of a single-pass perfusion technique (Loc-I-Gut) in the human jejunum.<sup>7,8</sup> These human jejunal  $P_{\text{eff}}$  values have an excellent correlation to the percentage absorbed (A%). The human  $P_{\text{eff}}$ -values were originated from.<sup>6–7,37,42,56,58,89,111,123–125</sup>

It is well known that the intestinal absorption potential of drugs that are mainly transported by passive diffusion maybe be predicted from molecular properties, such as polar surface area, hydrogen bonding,  $\log P$ ,  $\log D$ , and molecular weight.<sup>33</sup> Accordingly, the fundamental BCS parameters are suggested to be based on theoretical descriptors in the future and computational approaches have also been developed for permeability and solubility determinations.<sup>1,10,32,45–49</sup> If further refinement can be achieved for such methods, such as quantitative structure–activity relationship (QSAR) models to optimize ADME properties, it may be possible in the future to displace cell-based permeability screens and solubility estimates in screening for new drug molecules.<sup>33,36</sup> However, simple physicochemical descriptors of solubility and permeability must probably be assembled into and validated in more physiologically based models to be able to accurately predict human intestinal absorption.<sup>50–52</sup> Recently Lindahl *et al.* demonstrated that in vitro permeability values could be used to simulate the absorption from various intestinal segments in humans.<sup>53</sup> An intermediate approach for permeability determinations, between physicochemical and physiologically based methods, is the use of artificial membranes.<sup>54,55</sup> Such techniques provide a pure estimate of transcellular permeability without influence from transporters or the unstirred water layer present in cell-based models, which could provide useful feedback to chemists in the screening phase. Finally, it is important to understand that even if absorption properties are acceptable the drug may have a limited clinical use due to an extensive first-pass extraction in the gut and/or liver that is outside the topic of the present chapter.

In drug discovery there is a strong demand for early information on drug properties such as ADME variables. Several in vitro ADME screens have significantly increased the amount of experimental data generated in the early drug discovery process. In addition to these experimental techniques, there is a need for different in silico methods that can predict ADME variables with fairly high accuracy. For instance, ADME filters that can sort out drugs with undesirable ADME properties can be applied in virtual screening or drug design so as to reduce compound attrition rates. The basis for constructing these predictive models is the existence of high-quality experimental data. Several data sets exist in the literature and have been used for building models that predict ADME-related variables such as  $P_{\text{eff}}$ ,  $f_a$ , and solubility.<sup>29,33,45–50</sup> Unfortunately, many of these data sets have been compiled from different sources and not with the same experimental conditions, making a direct validation of the different models difficult. Another shortcoming with the existing data sets is that different sets of drugs have been used for modeling different properties. This makes it difficult to construct robust and more complex quantitative models, of for example, drug absorption that would be based on  $\log P/\log D$ , solubility, intestinal permeability, metabolic stability, and carrier-mediated membrane transport data. In this case a relevant and common data set is essential that represents the available ADME space. New experimental tools are also constantly being developed that aim to complement in vitro and/or in vivo experiments. Many data sets in the literature contain high-quality experimental ADME-related data. Unfortunately, many of these include compounds that are not commercially available. Others are not structurally diverse, which is an important property when attempting to build predictive models of ADME properties.

In the later phases of preclinical development, various animal models are often used to evaluate the absorption potential of new drugs. The predictive value for humans of various models can be guided by BCS. For example, the rat is considered an appropriate model that predicts permeability-limited human intestinal absorption well.<sup>56–63</sup> In contrast, another very common model, the dog, has been shown to provide faster intestinal permeability and increased absorption compared to humans of low-permeability drugs whereas high-permeability drugs seem to be rapidly and completely absorbed in dog similarly to human.<sup>36,64</sup> In case of solubility limitations of drug absorption, the similarity in basic GI physiological conditions will be the primary determinant for the usefulness of an animal model. The key aspects are GI volumes, pH, and presence of solubilizing agents like bile acids. Several comparisons of these properties have been published for dog, rat, and human as well as other animal models.<sup>65–67</sup> Generally, the dog has been proposed to a reasonable model for BCS class II drugs due to the similarities in relevant aspects of GI physiology. Fairly similar drug solubility has also been shown (Figure 6) for a number of drugs in human and dog intestinal fluid obtained both under fasting and fed conditions in a recent study.<sup>68</sup> Thus, usefulness of animal models in drug absorption studies is dependent on the BCS characteristics of the drug compound.

### 5.42.3.3 Biopharmaceutics Classification System in the Product Development Phase

#### 5.42.3.3.1 Approaches to overcome absorption limitations

BCS may be used to make the normally time-constrained pharmaceutical development process more efficient. If a drug is classified as having low solubility, it is obvious that the rate and extent of absorption may be improved by the use of formulation principles that increase the dissolution rate and/or drug solubility. There are several different formulation principles of varying complexity, ranging from selecting a suitable solid-state form or salt to the use of technologically more advanced formulation principles. Although their application could be limited by several practical factors, such as

**Figure 6** Solubility of four poorly soluble drugs in small intestinal fluid from human (HIF) and dog (DIF) obtained under fasting and fed conditions. Similar drug solubility was observed for human and dog intestinal fluid obtained both under fasting and fed conditions.<sup>68</sup>

poor drug stability, excessive size due to the need for large amounts of excipients in relation to the dose, technical manufacturing problems, and the high cost of goods, it is believed that many poorly soluble compounds with good pharmacological properties could be ‘saved’ by such approaches. One of the most recent advances in this area is the utilization of nanoparticles that can be obtained both by milling or precipitation methods.<sup>69,70</sup> One favorable feature of this approach is the relatively small amount of additional excipients needed, and very significant improvements in oral BA has been reported.<sup>71</sup> Microemulsions and cyclodextrin complexes are examples of other formulation approaches that have proven to increase BA several times for low-solubility drugs.<sup>72</sup>

Low-permeability compounds are less suitable for formulation improvements of BA. Despite extensive research in the area of permeation enhancers, very few products using such principles have entered the market. Significant increases in drug permeability found in *in vitro* models have often not provided the corresponding *in vivo* responses.<sup>23,73–77</sup> Another limitation of the enhancers used has been their unspecific nature, leading to a risk of increased permeability of toxins and other undesirable molecules.<sup>78</sup>

The use of prodrugs has proven to be a more successful approach to increase BA of low-permeability compounds.<sup>79</sup> Melagatran, a direct thrombin inhibitor, is a recent and illustrative example of how intestinal permeability has been increased and with it the developability of a drug.<sup>80,81</sup> It is produced by adding protecting chemical groups to its prodrug xi-melagatran (H376/95), which results in greater BA and less interindividual variability in the pharmacokinetics of melagatran. The two protecting groups change the  $pK_a$  values, producing a prodrug which is uncharged when its pH is above 6.2. Accordingly, the partition coefficient between octanol and water and *in vitro* permeability increased by 170 and 80 times, respectively.<sup>80,81</sup> The BA of melagatran increased from 5% to 20% with significant less interindividual variability when xi-melagatran was given orally instead of melagatran itself.

Targeting the carrier-mediated transport process is another successful prodrug strategy that has been shown to enhance the intestinal absorption.<sup>79,82,83</sup> For example, oligopeptide transporters are responsible for the active absorption of  $\beta$ -lactam antibiotics, the angiotensin-converting enzyme inhibitor enalapril, valaciclovir, and valganciclovir. The BA of valaciclovir was five times higher than that of aciclovir itself due to transport by the intestinal oligopeptide transporter PEPT1.<sup>84–86</sup>

#### 5.42.3.3.2 Feasibility of extended release drug delivery

A successful development of oral ER formulations requires a strategy where BCS today could provide guidance. It is well known that not all drugs would clinically benefit from being given in an ER formulation due to unfavorable absorption properties along the human intestine. For clinical advantages to be obtained, the ER formulation most often requires drug release between 12 and 24 h. Thus, since the small intestinal transit of formulations is only 3–4 h, a significant part of the dose in an ER product will be delivered to the colon, which means that the absorption has to be

**Figure 7** Mean relative bioavailability ( $F_{rel}$ ) after administration to different sites in the GI tract of different high-permeability drugs to humans by use of intubations or remote control capsules. The amount of drug absorbed was similar over the entire GI tract also including the colon.

classified as high in the entire intestine. Class I drugs should therefore be the best candidates for ER development, which also is confirmed as several ER formulations are based on class I compounds.<sup>62</sup> The regional drug absorption in humans has been studied for several drugs by use of specialized techniques such as intubations or remote control capsules; results from such studies for highly permeable drugs are shown in **Figure 7**. The amount of drug absorbed was similar over the entire GI tract including the colon. Consequently, complete fraction absorbed seems to be maintained also after administration to the more distal parts for highly permeable drugs. It is our experience that if passive diffusion is the dominating membrane transport mechanism, an intestinal permeability equal to or higher than for metoprolol is an indication of a useful ER candidate. On the contrary, a low-permeability drug will not be completely absorbed in the small intestine given as a solution or an immediate release tablet, and accordingly the amount absorbed in the colon region will be even lower. This statement is based on experimental data demonstrating that the colonic membrane has an even lower permeability for drugs already classified as low-permeability drugs in the small intestine. For instance, human and rat intestinal specimens mounted in the Ussing chamber model (in vitro) have shown that the permeability of class III–IV drugs is even slower in the colon than the small intestine, whereas class I–II drugs show a slightly higher permeability in the colon when passive diffusion is the dominating membrane transport mechanism.<sup>16,59,62,87</sup> Consequently, it will not be possible to control the rate of absorption by an ER formulation for low-permeability drugs. In addition, a large part of the dose will not be absorbed, leading to a low and uneven variability, and no increased effect duration will be achieved. This is exemplified in ER tablets of amoxicillin. This high-solubility drug ( $4.0 \text{ mg mL}^{-1}$ ) is classified as a low  $P_{eff}$ , even if it is transported across the intestinal barrier via the oligopeptide carrier (PEPT1).<sup>88,89</sup> Essentially, no absorption occurred for an ER tablet when it entered the colon as determined by intubation technique and gamma scintigraphy, which is also in accordance with its slow passive permeability due to hydrophilic properties (polar surface area (PSA) =  $154.4 \text{ \AA}^2$ ,  $\log D_{6.5} = -1.7$ ).<sup>45,90,91</sup> However, recent advances in the area of gastric retention formulations hold some promise that ER formulations of low-permeability compounds may be possible in the future, i.e., the need for colonic drug absorption is no longer critical since the product stays in the upper GI tract during the entire period of drug release.<sup>92</sup>

Class II drugs are also frequently used in ER formulations. Felodipine ER tablets provide an example where a low-solubility compound is included in a useful ER product. It has been possible to administer felodipine, which has water solubility in the physiological pH range of about  $1 \text{ } \mu\text{g mL}^{-1}$ , as a once-daily product in doses up to at least 20 mg without any reduced BA compared to an oral solution.<sup>93</sup> This successful absorption is indeed dependent on the use of a dissolution-enhancing formulation principle where the drug is given in a solubilized form. Other class II compounds, such as nifedipine ( $10 \text{ } \mu\text{g mL}^{-1}$ /doses up to about 100 mg), is absorbed from the colon when released as a micronized drug.<sup>94</sup>

A special consideration may be made regarding classification of low-solubility compounds in ER forms. The standard classification is based on the idea that the drug should be completely dissolved in the gastric fluids, which has been estimated to be 250 mL<sup>1</sup>; this way of classifying drugs may be less relevant for ER formulations since only a very small part of the dose is made available for dissolution in the stomach. The dose is generally spread over the entire GI tract, making the effective water volume available as a dissolution medium for the drug probably larger than the 250 mL used in the original BCS. Furthermore, the drug permeability of these compounds is often much faster than the drug release, further preventing solubility limitations for class II drugs in ER formulations.<sup>95</sup> Thus, increased understanding of total available intestinal fluid volumes and influence of factors other than pH on colonic drug solubility/dissolution are needed before scientifically based solubility criteria can be proposed in the future. The dynamic processing of lipids and bile acids along the small intestine is also a challenging area, which needs to be further considered for understanding and prediction of drug solubility limitation of absorption along the intestine.<sup>96,97</sup>

#### 5.42.3.3.3 In vitro/in vivo correlation (IVIVC)

In vitro dissolution tests are important for the successful development of solid pharmaceutical products and in batch quality controls. BCS is useful for predictions when in vitro/in vivo correction (IVIVC) could be expected for solid immediate release products. These in vitro dissolution tests can only model the release and dissolution rates of the drug and it is only when these processes are rate-limiting in the overall absorption that IVIVC can be established. In the case of class I drugs, the complete dose will already be dissolved in the stomach and, provided that the absorption in the stomach is negligible, the gastric emptying will be rate-limiting and therefore IVIVC is not expected. Thus, in vitro dissolution testing can be expected to be 'overdiscriminating' for those drugs, i.e., tablets showing different in vitro dissolution profiles will provide the same rate and extent of BA.<sup>21</sup>

Class II drugs are expected to have a dissolution-limited absorption and an IVIVC should be possible to establish using a well-designed in vitro dissolution test. One way to investigate and establish such a correlation is to study formulations containing drug particles with different surface areas. For example, the different peak plasma levels in a human BA study obtained between candesartan cilexetil (water solubility  $< 1 \mu\text{g mL}^{-1}$ ) tablets (8 mg), containing drug particles with an average diameter of 4 and 9  $\mu\text{m}$ , respectively, was predicted by a difference in in vitro dissolution in the standard US Pharmacopeia II (USP II) paddle method containing a buffer medium with addition of a surfactant. Examples of other composition/process factors of relevance for establishing IVIVC for immediate release formulations of class II drugs could be variations in solid-state form, effects of granulation conditions leading to different disintegration times of primary particles or tablets, variations in mixing leading to differences in wetting properties, and variations in pH of excipients.

Two cases could be identified for class II drugs when the establishment of simple IVIVCs is not feasible. First, there are a number of formulation principles that could enhance the dissolution rate and solubility of low-solubility compounds. It may be possible to achieve such a rapid and complete dissolution of a class II drug that the gastric emptying becomes rate-limiting, i.e., the BA of the solid dosage forms equals that of an oral solution. Thus, in such a case, the prerequisites for IVIVC will be identical to the situation for class I drugs, i.e., no correlation will be obtained as long as the dissolution rate is significantly faster than the gastric emptying. It has also been discussed that these drug and drug products should fall into a special intermediate class II, where a biowaiver should be applicable. This issue has also recently been discussed.<sup>3,5</sup> The second case in which IVIVC is not likely for class II drugs is the situation where the absorption is limited by the saturation solubility in the GI tract rather than the dissolution rate. In this situation, the drug concentration in the GI tract will be close to the saturation solubility, and changes of the dissolution rate will not affect the plasma concentration profile and the in vivo BA. Standard in vitro dissolution tests are carried out under 'sink conditions,' i.e., at concentrations well below the saturation solubility. Thus, only effects related to the dissolution rate can be predicted in vitro. If more physiologically relevant dissolution media are used, which do not necessarily provide sink conditions, the possibility for IVIVC could be improved as indicated by recent work using a simulated intestinal medium.<sup>98</sup> It has also been reported that, provided an appropriate composition is chosen for the dissolution test, the USP paddle apparatus can be used to reflect variations in hydrodynamic conditions in the upper GI tract.<sup>99</sup>

The absorption of class III drugs is limited by their intestinal permeability and no IVIVC should be expected. However, when the drug dissolution becomes slower than the gastric emptying, a reduction of the extent of BA will be found at slower dissolution rates since the time when the drug is available for transport across the small intestinal barrier will then be reduced.

#### 5.42.3.3.4 Food-drug interactions

Food intake may affect the plasma exposure of a drug, which might influence the efficacy of a drug, and it is therefore crucial from a safety aspect to predict such effects at an early stage. However, an accurate prediction model is a

challenge since several factors are involved in food–drug interactions including physicochemical effects such as increased solubility, binding to secretory or food components; physiological effects in the GI tract such as altered flow rates and gastric emptying; mechanical effects on formulations due to different motility patterns; permeability effects due to interactions with active transporters or effects on the membrane and altered first-pass metabolism. An extensive review of different mechanisms for food–drug interactions can be found elsewhere.<sup>9</sup>

The BCS can be used to predict the mechanisms and magnitude for food effects related to solubility, dissolution, gastric emptying, and permeability. The clinically important interaction with grapefruit juices and other food components that affect the first-pass metabolism is not possible to predict and describe with the use of BCS.<sup>100</sup> The most severe cases of food–drug interactions due to factors considered in BCS are generally found in the group of poorly soluble compounds (class II and IV drugs) given in high doses, as they approach the saturation solubility in the GI lumen. The BA of griseofulvin (class II or class IV) has been reported to be increased up to five times by food, and dosing recommendations requiring concomitant intake of the drug with a meal is often used in these cases.<sup>101</sup> The saturation solubility will be significantly improved by food due to solubilization in mixed micelles, including bile acids, lecithin and monoglycerides obtained from the dietary fat intake, and dissolution into emulsified nutritional lipids, and accordingly the amount of drug available for absorption will significantly increase.<sup>97</sup> An additional effect to the increased plasma exposure might be the relatively large fluid volume available in the stomach after a meal. The effect of just increasing the volume of water administered with a tablet from 200 to 800 mL increased the extent of BA by 50% in a human study of danazol (water solubility  $0.001 \text{ mg L}^{-1}$ ) tablets 250 mg.<sup>102</sup>

Protolytic drugs with a  $pK_a$  within the physiological pH range will also be affected by the food-mediated pH changes in the stomach. A protein-rich meal could increase the pH from the fasting level of pH about 1.5–3 to a close to neutral pH.<sup>103,104</sup> Basic drugs, which are often freely dissolved in the acidic stomach, could thereby experience a reduced BA with food whereas it may be the other way around for low-solubility acids.

For class II drugs given in lower doses, the dissolution rate rather than the saturation solubility is the limiting factor. An increase in dissolution rate due to *in vivo* solubilization mediated by food intake could theoretically be obtained but this is not always found *in vivo*. For example, food does not affect the rate and extent of BA for candesartan cilexetil, a very poorly soluble compound given in a low dose.<sup>105</sup> An *in vitro* dissolution and solubility study of this compound in simulated intestinal media provided a potential explanation. It was revealed that the solubility was increased as a function of bile concentration as expected whereas the dissolution rate was not increased by the higher bile concentrations being representative for the fed state. The slower gastric emptying of dissolved drug might also counterbalance increases in dissolution rate in the fed state. Thus, although intestinal solubility most often will be increased in the fed state for class II drugs, this will not always lead to a more rapid dissolution.

For class I drugs, a slower rate of absorption could be expected after concomitant food intake (reduced  $C_{\max}$  and prolonged  $t_{\max}$ ) due to the decreased gastric emptying rate induced by a meal. Gastric emptying is totally controlled by the two patterns of upper GI motility, i.e., the interdigestive and the digestive motility pattern. The interdigestive pattern, termed the migrating motor complex (MMC), dominates in the fasted state and is organized into alternating phases of activity and quiescence.<sup>106</sup> Gastric emptying in the fed state varies significantly depending on the motility pattern and meal composition, including factors such as energy content, osmolality, and pH. A gastric emptying half-life of about 10 min is obtained in the fasting state whereas a half-life of approximately 45 min has been reported for fluids when measured under nonfasting conditions.<sup>107,108</sup> It was also clearly shown that a smaller volume (50 mL) was more sensitive to the motility phase than large volumes (200 mL). Even during phase I of the MMC, the emptying rate was faster for the 200 mL volume.<sup>107</sup> In addition, it is important to understand that drugs with a shorter half-life will be more sensitive to changes in gastric emptying. Recently, it was reported that *in vivo* results appear to support the hypothesis that rapidly dissolving immediate release solid oral products containing a BCS class I drug are likely to be bioequivalent under fed conditions.<sup>109</sup>

Class III drugs are perhaps the least sensitive to food intake. None of the effects induced by food such as slower gastric emptying and increased solubilization capacity will be of any relevance. It is also well established that the transit from the main absorption region for a class III drug, i.e., the small intestine, would not be affected by food and, generally, no effect on drug permeability is expected by food.<sup>16,59,110</sup> For example, no interaction with food was obtained for the low permeability compound ximelagatran.<sup>80</sup> In addition, Yu *et al.* have confirmed this by suggesting that BCS class III drugs may have the potential to be bioequivalent under fed conditions.<sup>109</sup>

A plausible mechanism for interactions between food and drugs could occur for drugs that have carrier-mediated transport in the intestine, especially if nutritional carriers are involved. The two most important nutrient absorption

carriers for drugs are the oligo-peptide carrier (hPEPT1) and the amino acid transport family. These carrier proteins have a high transport capacity in the human small intestine, and they seem less likely to be involved in direct food–drug interactions, unless high doses are given together with a protein-rich meal. For instance, it has been reported that a protein-rich meal does not affect the BA of levodopa, a drug that is transported by the several amino acid carriers in the human intestine, and this has been interpreted that the amino acids are absorbed rapidly and the risk for interaction is reduced and that the nutritional transporter has a high capacity.<sup>111</sup> Intestinal function depends on the presence of luminal nutrients and is altered during starvation and refeeding. The nutritional status could also cause transcriptional activation of the PEPT1 gene by selective amino acids and dipeptides in the diet.<sup>112</sup> It has also been reported that the integrated response to a certain stimulus may increase PEPT1 activity by translocation from a preformed cytoplasm pool.<sup>113</sup> This short-term regulation of drug transport requires further research. Amino acids are essential for enterocytes, but the luminal supply is compromised with changes in dietary intake. Howard *et al.* found that the removal of luminal nutrition increases the expression of amino acid and peptide transporter messenger RNAs (mRNAs) in the small intestine.<sup>114</sup>

#### 5.42.4 Potential Future Extensions

Class I drug substances today are quite rare in pharmaceutical development, which limits the broad use of the BCS in the drug development. It has also been recognized that the present application represents a deliberately conservative approach, and proposals for extensions have been discussed since original publication of BCS.<sup>1,3</sup> For example, in a recent paper it was suggested that the requirement of highest pH for the solubility measurements could be changed from 7.5 to 6.8 since the latter is more relevant for the pH in the upper GI tract.<sup>3</sup> This revision would thus somewhat relax the requirements for basic drugs. It has also recently been suggested that for acidic drugs the boundaries for solubility are too restrictive (pH 1.0–7.5) and might be narrowed down to pH 5.0–7.4.<sup>115</sup> Yazdani *et al.* reported that, based on the current definition, 15 of 18 acidic nonsteroidal anti-inflammatory drugs (NSAIDs) were classified as class II compounds. If only a neutral pH was used, 15 of the NSAIDs were classified as class I drugs, which may suggest the boundaries are too restrictive for solubility. Based on these findings, the authors suggested that there might be a need for an intermediate solubility classification for highly permeable ionizable compounds, especially when given in low doses.<sup>115</sup> Another proposal in the paper by Yu *et al.* was to reduce the high-permeability definition from 90% to 85%  $f_a$  based on observations that many drugs that are considered completely absorbed provide experimental values below 90%, i.e., 90% seems to be a too rigid criterion considering the precision of the experimental methods.<sup>3</sup> Other more radical relaxations of criteria, such as including class III drugs or class II drugs using simulated intestinal media with bile acids or increase volumes and further reducing the pH interval in solubility measurements, will most probably require further research and analysis of past experiences.<sup>95,97,116,117</sup> For instance, to better predict food effects on the BA/BE of drugs and drug products from in vitro data, a dissolution medium that simulates the initial composition of the postprandial stomach has been developed.<sup>118</sup> Furthermore, it has been suggested by Blume and Schug that the waiver of in vivo BE studies be extended to class III drugs.<sup>119</sup> For immediate release formulations of class III drugs (high solubility–low permeability), it is considered that the handling of the dosage form in vivo be similar to an oral solution. Accordingly, intestinal membrane permeability is expected to be rate-limiting in the overall drug absorption process. Therefore, the rate and extent of intestinal absorption are expected to be controlled by drug molecule properties and physiologic factors, rather than by properties related to the pharmaceutical formulation, given that none of the pharmaceutical excipients used in the formulation has a relevant influence on gastrointestinal transit and permeability of drug.<sup>3</sup> However, what kind of in vitro dissolution requirements should be set to ensure that the drug release has no significant impact on in vivo BA is still unknown, and data available for supporting biowaivers of class III drugs are still limited.<sup>120</sup> In a recent study by Cheng *et al.*, a biowaiver was suggested by the in vitro dissolution profiles and was justified by the in vivo BE data. The demonstration of BE between two immediate release tablets of class III drug metformin in healthy Chinese subjects serves as an example for supporting biowaivers for such cases.<sup>121</sup> Yu *et al.* also showed that a BCS class III drug, hydrochlorothiazide, had a much narrower 90% confidence interval than BCS class II drugs and therefore may be a better candidate for biowaiver. However, important concerns for BCS class III drugs are the effect of excipients on GI transit and permeability (both passive and carrier-mediated uptake and/or efflux transport).<sup>109</sup> Further support for biowaiver of BCS class III drugs is available from Vogelpoel *et al.*, who showed recently that atenolol is a candidate for biowaiver, provided that the formulation contains well-known excipients.<sup>122</sup>

It has also been proposed that dissolution rate should be a more relevant variable than saturation solubility for BCS since the in vivo absorption process is rather a dynamic, rate-controlled process than a process at equilibrium

conditions.<sup>109</sup> The rotating disk method, where the pure drug is compressed into a rotating disk holder to provide a constant area exposed to the dissolution medium, is the method of choice for such investigations (USP). It was shown in a limited set of drug substances that at a rotation speed of 100 rpm class I and III drugs had a dissolution rate faster than  $0.1 \text{ mg min}^{-1} \text{ cm}^{-2}$ .<sup>120</sup>

Extensions of BCS beyond the oral immediate release area have also been suggested, e.g., to apply BCS in the ER area. However, this will provide a major challenge since the release from different formulations will interact in different ways with in vitro test conditions and the physiological milieu in the GI tract. For example, the plasma concentration–time profile differed for two felodipine ER tablets for which very similar in vitro profiles had been obtained, despite the fact that both tablets were of the hydrophilic matrix type based on cellulose derivatives.<sup>93</sup> This misleading result in vitro was due to interactions between the test medium and the matrix forming polymers of no in vivo relevance. The situation for ER formulations would be further complicated by the need to predict potential food effects on the drug release in vivo. Although the present use of BCS is limited, extensions of applications should clearly be made without jeopardizing the quality of products on the market. This would more likely be achieved within the area of oral immediate release than for ER formulations.

The crucial role of membrane transporters in the ADME of drugs has only been fully recognized in the past decade. A new classification system having its origin in BCS has also recently been proposed that should be useful not only in predicting effects of dissolution and permeability on drug absorption but also allow for predictions of overall drug disposition, including routes of drug elimination.<sup>126</sup> It was noted that high-permeability compounds, i.e., BCS class I and II, are highly metabolized whereas low-permeability drugs are preferentially excreted unchanged through the biliary and/or renal route. It was also proposed that a relationship between disposition and permeability determination would be possible to establish, and would form the basis for a Biopharmaceutic Drug Disposition Classification System (BDDCS). However, the proposed application of BDDCS as a tool to predict the effect of carrier-mediated membrane transport on absorption, first-pass liver extraction, distribution, and elimination is not established, since the exact in vivo transport mechanisms and their relevance for many drugs that are transport substrates are far from completely understood. In order to establish this, further validation of their in vivo relevance is needed as well as a significantly improved knowledge of the correlation between the in vitro and in vivo characteristics. In the present genomics and proteomics era, a wealth of detailed information has become available on their structure, function, and topological expression. At the same time, a wide variety of advanced cell biological methodologies have been introduced to study their substrate specificity, the driving forces for membrane translocation, and potential interactions with other drugs and/or endogenous agents during cellular transport. Yet, although our knowledge in this field has been much deepened and our instrumentation amazingly sharpened, somehow an integral view on the practical implications of the related findings for ADME research seems to have been blurred by the multitude of molecular data, the uncritical use of, especially, in vitro methods, and the relative lack of human in vivo data. In other words, the ‘black box’ was filled up so rapidly that we did not even begin to perceive its functional organization. In particular, clinical data in various diseases are scarce and one seems to be at a loss as to which transporters to address first. Despite these difficulties lying ahead of this research, the proposed BDDCS may be developed into a thinking tool and classification system that should be very useful in the multidisciplinary field that is characteristic of drug discovery and development.

## 5.42.5 Conclusion

In the present chapter the importance of the fundamental variables in BCS, solubility and intestinal permeability for oral drug absorption has been scrutinized. The main regulatory impact today is the use of BCS as a framework for identifying drugs for which in vitro dissolution testing could replace in vivo studies to determine BE. Extensions of this approach to cases other than immediate release formulations of the relative rare class I drugs would significantly enhance the impact of BCS. Some drugs that fall into class II and III could be regulated by BCS rather than traditional BE testing.

The future application of BCS is most likely increasingly important when the present framework gains increase recognition, which will probably be the case if the BCS borders for certain class II and III drugs are extended. The future revision of the BCS guidelines by the regulatory agencies in communication with academic and industrial scientists is exciting and will hopefully result in an increased applicability in drug development.

Finally, we emphasize the great use of BCS as a simple tool in early drug development to determine the rate-limiting step in the oral absorption process, which has facilitated communication between different experts involved in the overall drug development process. This increased awareness of a proper biopharmaceutical characterization of new drugs may in the future result in drug molecules with sufficiently high permeability, solubility, and dissolution rates, and that will automatically increase the importance of BCS as a regulatory tool over time.

## Biographies

**Hans Lennernäs** has been a full professor of biopharmaceutics at Uppsala University, Sweden, since, 1 July 2000, and been adjunct professor of Biopharmaceutics at the Royal Danish School of Pharmacy in Copenhagen, Denmark, since 2000. His research interest is the clinical significance of mechanisms and regulation of membrane transport and metabolism of drugs/metabolites in the gastrointestinal tract, hepatobiliary system, and cancer tissues. Based on these findings, he is trying to develop novel strategies of tissue drug targeting and delivery in disease states, such as metabolic and cancer diseases. He has been the Principal Investigator in an extensive collaboration between the US Food and Drug Administration, the University of Michigan, USA, and the Medical Product Agency, Sweden, over several years to develop new guidelines for the Biopharmaceutics Classification System. He has established an extensive human permeability database (45 compounds) that is today widely used in academia and the pharmaceutical industry. He serves as reviewer for several scientific journals. His work has led to more 125 publications, 145 invited lectures, and more than 250 submitted presentations at scientific meetings. He has supervised 12 doctoral theses and acted as cosupervisor for two neurologists. He has obtained several national and international research grants. Dr Lennernäs has received the Glaxo Wellcome Achievement Award 1997, the Annual Award 1998 from the Industrial Pharmacy Section, Fédération Internationale Pharmaceutique (FIP), an Honourable Mentions at Eurand Award 2000. He was elected Fellow of the AAPS in 2004 and received the AAPS Meritorious Manuscript Award 2004. He is on the board of the nonprofit Drug Delivery Foundation, which promotes research and education in this area all around the world. He is also one of the innovators of a novel sublingual drug delivery system for the treatment of various acute pain conditions. He has invented five patent/patent applications, which have resulted in drug products in preclinical phase and in phase I and III clinical trials. His research team is currently composed of seven PhD students, and he has an extensive national and international interdisciplinary collaboration.

**Bertil Abrahamsson** has a broad experience of industrial drug development for more than 20 years within Astra and AstraZeneca. During this period he has held various project management positions, including overall responsibility for all aspects of a project during launch and life cycle management phases. Presently he is managing the biopharm group at AstraZeneca in Mölndal, Sweden, and is, as a Senior Principal Scientist, the most senior biopharmacist globally within AstraZeneca. His responsibilities include biopharmaceutical assessment prior to candidate drug selection as basis for the decision to progress compounds into development. In addition, his group provides biopharmaceutical input and testing, in vitro and in vivo, during product development as well as for biopharmaceutical NDA documentation. His expertise includes absorption pharmacokinetics in vivo predictive/in vitro dissolution and other gastrointestinal processes and functions, oral controlled-release drug delivery, in vivo imaging, and regulatory biopharmaceutics.

Bertil Abrahamsson has published 22 original papers, 6 reviews or book chapters, and more than 50 abstracts in the biopharmaceutical area. He has been invited as a speaker 15 times to international pharmaceutical and biopharmaceutical conferences and workshops. He is presently an adjunct Associate Professor in Biopharmaceutics at Uppsala University, Sweden. He has a large network globally within the scientific community and has managed research collaborations with several key universities in Europe and the USA. He also teaches at the university and supervises PhD students. Finally, he is frequently a referee for the most established journals in pharmaceutical science.

Bertil Abrahamsson has been active for many years in the board of Pharmaceutics and Biopharmaceutics department within Swedish Academy of Pharmaceutical Science, and he has organized and chaired several national and international scientific meetings.

### 5.43.1 Introduction

Genomics, proteomics, and metabonomics represent a triumvirate of approaches that may aid our understanding of biological processes in cells, organs, and the whole organism at the biomolecular level. Recent advances in analytical technologies, coupled with the increasing availability of genome sequences, have led to intense interest in the application of these 'omics' technologies to obtain a greater understanding of the biological events leading to the onset and development of disease. Equally important to those engaged in pharmacological research is the response, both pharmacological and toxicological, of animals or human subjects to the therapeutic agents designed to combat or prevent these diseases. Outside this area there is also a need to assess the effects of the so-called functional foods as well as pesticides and other chemicals where there is likely to be environmental or industrial exposure to human populations.

A better understanding of the effects of xenobiotics, including drugs, on any biological system requires information on events and processes occurring at all levels of biomolecular organization within the organism, including genes, proteins, and metabolism. So while knowledge at the genome level will be of great value in studying disease or toxicity, it must be recognized that there are many environmental factors that will modulate the potential outcomes encoded in the genome. These factors include things such as diet, age, gender, strain, lifestyle, and even the gut microflora that live symbiotically within higher organisms but whose presence and contribution cannot be deduced from the genome sequence of the host. All of these, in combination, will affect the phenotype, and can have a very significant influence on outcomes. As result of this complexity the complementary 'omics' platforms of proteomics and metabonomics are also

becoming widely employed (either singly or in combination) in so-called systems biology approaches to the study of disease and toxicity. Metabonomics, defined as “the quantitative measurement of the dynamic multiparametric response of a living system to pathophysiological stimuli or genetic modification,”<sup>1,2</sup> thus determines changes in the organisms complement of low-molecular-weight organic metabolites in biofluids and organs (in the related field of metabolomics, the aim is to determine the total small-molecule complement of the cell<sup>1</sup>). As such, metabonomics provides information on the endpoints of the various processes going on within the organism in response to change. Like all ‘omics’ approaches, metabonomics is a ‘hypothesis-free’ means of investigating metabolic systems and discovering biomarkers (insofar as there is a hypothesis, it is that “something metabolic may have changed; let’s see if we can find out what!”). These biomarkers may then be used to monitor the responses of the system under examination and, perhaps more importantly, for the development of hypotheses that can advance mechanistic understanding.

### 5.43.2 Analytical Platforms for Metabonomics

The ideal characteristics of analytical techniques for metabonomic studies are that they should provide as comprehensive a metabolic fingerprint as possible in a reasonably short analysis time (so as to enable moderate to high throughput). Such an ideal technique would be unbiased toward particular classes of metabolites and be equally sensitive to all of the components in mixture. It should, in addition, possess a wide dynamic range, in order to cover the whole range of concentrations of endogenous molecules that might be present, and be able to provide quantitative data on all of the components present. Equally important, the technique should provide sufficient structural data to enable the investigator rapidly and unambiguously to identify the marker, or markers, detected. Not surprisingly, no such technique is currently available that can fulfill all of these criteria, and it is rather difficult to envisage any single methodology that could match up to this analytical challenge. Currently, the two major analytical methods used for obtaining metabolic profiles data are based on either high-resolution proton nuclear magnetic resonance spectroscopy (<sup>1</sup>H NMR)<sup>3–5</sup> or, more recently, high-performance liquid chromatography coupled with mass spectrometry (HPLC-MS),<sup>6</sup> with a few examples of the use of gas chromatography (GC-MS)<sup>7</sup> and capillary electrophoresis-MS (CE-MS).<sup>8,9</sup> As well as these methodologies, others have advocated the use of less discriminatory techniques, such as HPLC-ultraviolet (UV),<sup>10</sup> HPLC-electrochemical detection (EC),<sup>11</sup> or infrared-spectroscopy,<sup>12</sup> but it is difficult to support the application of these approaches as they provide only a limited coverage of the molecules likely to be present in any biological sample, with minimal chances of full characterization and identification. So, while not entirely fulfilling the characteristics of the ideal detection and identification system described above, the NMR and separation MS-based methods provide the best compromise currently available and are described in more detail below.

#### 5.43.2.1 Sample Types and Sampling

No matter how sophisticated the analytical technique used in the study, the key to any metabonomics investigation is the sample, and careful sample collection and treatment are essential if good results are to be obtained. The sample types that can be analyzed by the current techniques encompass all of those that might be required for biomedical or toxicological analysis, including urine, bile, blood plasma, intact tissues, and tissue extracts. When combined with chemometric techniques such as principal component analysis (PCA), particular metabolites, or groups of metabolites that provide specific markers for a particular condition (e.g., toxicity, disease, physiological variation) can be identified. In many ways urine provides an ideal method for the noninvasive study of the effects of such conditions on endogenous metabolic pathways. Samples can be taken over the duration of the study and provide a time course of effects that can be used to pinpoint onset and severity of toxicity, and determine the best times for other more invasive investigations. In addition, unless small rodents such as mice are involved, there are usually few restrictions on the size of the sample obtained. Blood plasma provides a more direct ‘window’ on the organism under study, but clearly requires more invasive procedures. There are also well-defined limits on the amounts of sample (and the number of sampling times) that can be taken in any given study. Tissue samples obtained from target organs clearly require surgical intervention, which in animal studies are usually only obtained on autopsy. In the case of humans the removal of, e.g., tumors or diseased organs as part of therapy affords the possibility of the direct study of these tissues.

However, when considering sampling, great care must be taken in all metabonomic studies to ensure both integrity and validity of the study design as there are numerous pitfalls for the unwary. Many factors can result in changes to sample composition and, for good results to be obtained, these must be controlled. Perhaps the most obvious is that biofluid samples provide ideal growth media for bacteria and, unless steps are taken, for example, to preserve urine being collected from animals in metabolism cages, the metabolic profile observed may be more indicative of fermentation than a response to an experimental treatment. More subtle factors such as the time of day of collection,

and the gender, age, strain, and diet of the animals (or humans), as well as stress, exercise, and physical activity, can have very significant effects on global metabolite profiles.<sup>13–17</sup> If not carefully controlled there will be apparent study-related changes in metabolite profiles that are simply artefacts due to poor experimental design and no amount of advanced analytical technology can compensate for a badly designed study.

### 5.43.2.2 Nuclear Magnetic Resonance (NMR) Spectroscopy

#### 5.43.2.2.1 Liquid samples

NMR spectroscopy has many of the ideal characteristics required for the nontargeted analysis of liquid samples for endogenous metabolites. There is thus no need for the preselection of the analytical conditions in the case of biofluid samples such as plasma, urine, and bile, as these can be analyzed without the need for any form of sample pretreatment (other than adding *c.* 10% by volume of D<sub>2</sub>O to act as a field frequency lock for the spectrometer and buffering to minimize chemical shift variation). Currently, analysis at 600 MHz (for <sup>1</sup>H NMR) is the most popular method, requiring about 600  $\mu$ L of sample in total, and taking *c.* 5–10 min per sample depending upon the sample and technique used. Higher-field-strength spectrometers are available, and probes with smaller sample requirements can be used. More recently the so-called cryoprobes have been introduced which combine high sensitivity with even more modest sample requirements. The resulting NMR spectra have very high information content, enabling the rapid detection and identification of analytes present in the sample. Another favorable feature of NMR spectroscopy is that it is nondestructive, permitting the subsequent reanalysis of the sample by other methods (e.g., HPLC-MS, GC-MS). A unique feature of NMR is that it readily allows equilibria between molecules in the sample to be observed. Against NMR spectroscopy as a bioanalytical tool for metabonomics is the criticism that it is relatively insensitive compared to mass spectrometry, for example. In answer to this criticism there is the argument that this disadvantage is more than compensated for by the fact that, unlike techniques such as MS and UV spectroscopy, NMR is equally sensitive for all proton-containing analytes. Also, as indicated above, the sensitivity of NMR spectrometers is constantly improving as a result of advances in field strength and probe design and currently lies in the ng range. The subject of the practice of NMR spectroscopy for metabonomics has been reviewed.<sup>3–5</sup> Typical spectra for control human plasma, bile, and urine samples are shown in [Figure 1](#).

**Figure 1** Partial <sup>1</sup>H NMR spectra (600 MHz) of control human plasma, bile, and urine.

#### 5.43.2.2.2 Solid and semisolid samples

NMR spectroscopy can, in addition to biofluid samples, also be used to obtain metabolic profiles of solid and semisolid tissue samples by employing the technique known as magic angle spinning (MAS). High-resolution (HR) MAS has been used for the investigation of a range of tissue types, including kidney,<sup>18</sup> lymph node,<sup>19</sup> and prostate<sup>20</sup> tumors, as well as liver tissue,<sup>21</sup> and has recently been reviewed.<sup>22</sup> HRMAS provides a complementary method for the analysis of tissues compared to making extracts, with the advantage that intracellular compartmentation, which is lost during tissue homogenization and solvent extraction, is maintained. In a study of the toxicity of acetaminophen (paracetamol), liver samples from mice were analyzed both as extracts using conventional solution  $^1\text{H}$  NMR spectroscopy and intact via HR  $^1\text{H}$  MAS spectroscopy.<sup>22,34</sup> The MAS results clearly demonstrated significant perturbations in the profile of the liver tissue, with a rapid loss of glucose and glycogen combined with increased lipid content. These studies were complemented by transcriptomic<sup>24</sup> and proteomic<sup>25</sup> studies and the combination revealed a picture showing that the drug caused a global energy failure in the livers of mice receiving a toxic dose. More recent studies<sup>26</sup> on the hepatotoxin methapyrilene, administered to the rat at 0, 50, and 150  $\text{mg kg}^{-1} \text{ day}^{-1}$  show a similar pattern of changes in the liver, as illustrated in the HRMAS NMR spectra shown in Figure 2. HRMAS NMR spectroscopy is not limited to tissues but can also be used to study the effects of various treatments on isolated organelles such as mitochondria.<sup>27</sup>

#### 5.43.2.3 Mass Spectrometry

As discussed above, NMR spectroscopy can be performed directly on biofluid samples, but this approach is much less practicable for MS-based systems. This is because of problems due to ion suppression, which result in irreproducible and highly variable responses for analytes, while often ignored, currently present insurmountable difficulties for complex

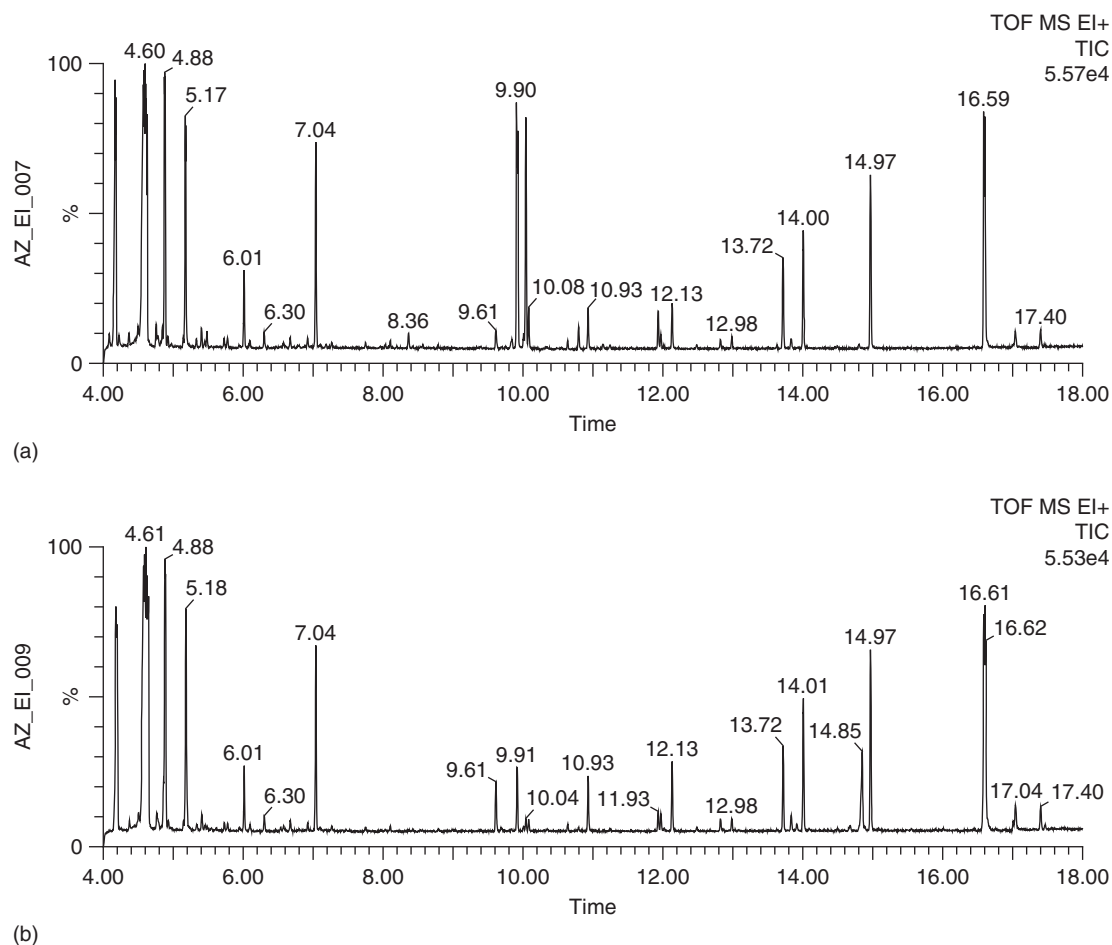

**Figure 2** Average standard  $^1\text{H}$  HRMAS NMR spectra of liver samples obtained from male rats dosed with 0, 50, and 150  $\text{mg kg}^{-1} \text{ day}^{-1}$  of methapyrilene, showing dose-related changes in fatty acids, trimethylamine *N*-oxide (TMAO), glucose, and glycogen levels as a result of hepatotoxicity.<sup>26</sup>

samples such as urine and bile. This view is based on our unpublished studies comparing data obtained by the direct infusion of urine into the ion source of the MS versus HPLC-MS, which showed advantages for the latter. In our opinion, therefore, approaches employing MS for metabonomics that use a combination of MS with a separation technique, such as HPLC, GC, or CE, will give the best results by spreading out the components of a biological sample mixture, thus reducing the potential for ion suppression. These 'hyphenated techniques' are described in more detail below.

#### 5.43.2.3.1 Gas chromatography-mass spectrometry

Although GC-MS, with HR capillary columns, has been widely applied to the metabolomic analysis of microorganisms and plants,<sup>7</sup> there are fewer published applications in mammalian systems. There is, however, considerable potential for GC-MS in this area, and it would be very surprising if many more examples did not appear in the future. An illustration of the potential of GC-MS for metabonomic analysis is shown by the example of the analysis of plasma from Zucker fa/fa and normal Wistar-derived animals given in Figure 3. The total ion current (TIC) traces shown are for both GC-MS with electron impact ionization (EI) (Figure 3) and chemical ionization (CI) (Figure 4). EI techniques provide mass spectra that contain diagnostic fragments that can enable much structural identification to be carried out (especially when combined with the extensive searchable databases). CI, on the other hand, gives mostly molecular ion information, enabling the confirmation of the molecular mass of the unknown. GC provides a highly developed, stable, selective, sensitive, and HR separation system. This capability is continually being enhanced and, with the introduction of GC-GC separations, combined with ever more powerful MS detectors, including time-of-flight (ToF) and ToF-ToF instruments, the comprehensive analysis of very complex samples should be possible. The use of ToF enables accurate masses to be obtained, with the benefit that atomic compositions can be deduced, providing further useful information for structure determination. The major disadvantage of

**Figure 3** Typical TICs obtained from GC-EIMS analysis of plasma obtained from 20-week-old male animals corresponding to (a) Wistar-derived Alderley Park and (b) Zucker fa/fa rats.<sup>106</sup> (Reproduced by permission of the Royal Society of Chemistry.)

**Figure 4** Typical TICs obtained from GC-CIMS analysis of plasma obtained from 20-week-old male animals corresponding to (a) Wistar-derived (AP) and (b) Zucker (+ / +) rats.<sup>106</sup> (Reproduced by permission of the Royal Society of Chemistry.)

GC-based techniques is the need for a fair amount of sample processing prior to analysis. Thus, the direct injection of biofluids samples on to capillary GC columns is not technically viable and, even if it were, the bulk of the components in most biological fluids is relatively involatile. It is normal to analyze extracts of the sample after derivatization to provide volatile analytes.<sup>7,28</sup> The degree of sample preparation required, together with the relatively long run times currently associated with GC, means that the technique is relatively low-throughput compared to some other technologies.

#### 5.43.2.3.2 High-performance liquid chromatography-mass spectrometry

HPLC-MS has begun to be employed in metabonomic studies only relatively recently.<sup>6</sup> However, given the very widespread availability of such systems in laboratories, and the compatibility of reversed-phase separations with many of the components in biofluids, a rapid increase in applications can be anticipated. Studies published to date cover areas such as rodent toxicology,<sup>29–35</sup> metabotyping (metabolic phenotyping) such as the study of strain, gender, and diurnal variation in mice,<sup>14</sup> and disease models.<sup>36</sup> A particular advantage of HPLC-MS over GC-based methods is that, for samples such as urine, it requires relatively little sample preparation, other than the removal of particulates, prior to analysis. For samples such as plasma or serum, proteins must be removed if the integrity of the HPLC column is to be protected, but this is easily done by precipitation with 2 or 3 volumes of acetonitrile. In general, gradient reversed-phase HPLC separations have been performed in preference to isocratic ones as these allow the separation of the maximum number of components in a given analysis time. The samples can be analyzed using a variety of ionization methods (e.g., electrospray ionization (ESI) or CI), with the current practice being to perform HPLC with ESI using both positive and negative ionization modes (usually in separate analytical runs).<sup>7</sup> In Figure 5, typical TICs are shown for the gradient HPLC of mouse urine in both positive and negative ionization mode. As alluded to above for GC-MS, using HPLC in combination with a ToF instrument to obtain accurate mass data from which atomic compositions can be determined greatly enhances the utility of the technique for the identification of unknowns. As well as HPLC-MS on conventional systems using 4.6 or 3.0 mm internal diameter (i.d.) columns packed with 3–5  $\mu$ m packing materials, alternatives such as narrow-bore *c.* 2 mm i.d.), microbore (0.5, 1.0 mm i.d.) and capillary HPLC column formats can be employed.<sup>7</sup> More recently chromatography on 1.7  $\mu$ m columns has been introduced in the form of ultra-performance

**Figure 5** Reversed-phase gradient HPLC-MS analysis of a sample urine obtained from a male black mouse using (a) positive and (b) negative ESI modes.

LC (UPLC)-MS,<sup>33,78</sup> offering a substantial improvement in separation performance over conventional HPLC for complex mixture analysis. A typical example of the UPLC-MS of mouse urine is shown in the TIC in [Figure 6](#). The improved resolution and increased number of peaks detected in UPLC-MS compared to conventional HPLC-MS are clear when these results are compared to those shown in [Figure 5](#).

#### 5.43.2.3.3 Capillary electrophoresis-mass spectrometry

The other major separation technique currently used to obtain metabolite profiles is capillary zone electrophoresis (CZE or, more commonly, CE), usually coupled with MS. To date the bulk of the applications in this area have been to bacterial samples using ‘targeted’ analyses against a panel of up to *c.* 1700 metabolite standards.<sup>8,9</sup> Like HPLC, CE methods have the advantage of requiring little or no sample preparation for samples such as urine. As an electrophoretic method it provides a different separation mechanism to HPLC or GC, based on charge, and CE-MS enables the HR separation and detection of metabolites. As a microbore separation technique CE requires only very small amounts of sample.

#### 5.43.2.4 Data Processing and Model Building

The various analytical techniques described above all have one thing in common. They generate vast amounts of data, with typical metabolite profiles containing hundreds to thousands of components. While manual examination of such data sets is possible in a few cases, it is extremely time-consuming and cannot be advocated as a strategy. Instead, various multiparametric statistical approaches have been developed, of which the most widely applied is PCA. This is a well-known ‘unsupervised’ approach whereby the data from the various groups in the study are examined for differences without the introduction of bias by the investigator.<sup>39</sup> A typical example of a PCA scores and loadings plot for the <sup>1</sup>H NMR spectroscopic data obtained from normal and Zucker rats is given in [Figure 7](#). The scores plot reveals the differences between the two experimental groups while the signals responsible for these differences can be found in the loadings plot. Any initial examination of the data generated by a metabolic profiling investigation should be based on such an unsupervised approach in the first instance. Supervised methods, where the investigator uses prior knowledge, such as which animals or subjects were controls and which dosed/diseased, can be used to construct models for the prediction of the class to which a sample belongs. One such supervised approach is ‘projection to latent structures’ by means of partial least squares (PLS), which can be described as the regression extension of PCA.<sup>40,41</sup> With PLS, unlike PCA, instead of describing the maximum variation in the data (*X*), what is attempted is to derive latent variables, which are analogous to principal components, that maximize the co-variation between the measured data (*X*) and the response variable (*Y*) regressed against. PLS discriminant analysis (PLS-DA) applies the PLS algorithm to classification of the data using a ‘dummy’ *Y* matrix that comprises an orthogonal unit vector for each class.<sup>42</sup> Other methods of supervised data analysis, such as soft independent modeling of class analogies (SIMCA),<sup>43</sup> have also been widely used for determining class in metabonomics studies. The various chemometric methods used for metabonomics have been reviewed.<sup>44,45</sup>

#### 5.43.2.5 Metabolite Identification

Once detected, the biomarker, or biomarkers, have to be identified and strategies for this type of investigation have been described.<sup>46</sup> In the case of NMR-detected metabolites the simplest, and least time-consuming, method for accomplishing this is to use the structural information contained in the spectrum of the biofluid sample itself. Most of the common metabolites found in urine, for example, are now known, and many have characteristic <sup>1</sup>H NMR spectra.<sup>47</sup> Confirmation of identity can then be performed by overspiking with an authentic standard (this is particularly important where resonances can be affected by small variations in sample pH).

However, where it is not possible to assign unknowns directly from the standard one-dimensional (1D) <sup>1</sup>H NMR spectrum, then two-dimensional (2D) spectra can be obtained to aid the identification. Total correlation spectroscopy (TOCSY) is widely used for this, as protons within a spin system, especially when there are overlapping multiplets or there is extensive second-order coupling, are readily observed as off-diagonal peaks in the TOCSY spectrum. TOCSY gives both long-range and short-range correlations and is especially useful when coupling constants are small. Clearly all of the other standard NMR-based structure determination techniques can also be used.

The use of HPLC-MS for metabolite profiling is still in a state of rapid development and exhaustive databases of metabolites and retention time data are still being produced: similar comments can be made about CE-MS. In the case of GC-MS, extensive databases are currently available, although the coverage of analytes likely to be detected in metabonomics experiments is by no means complete. Typically the retention time and mass spectral data obtained for the unknown marker can be compared with those of known metabolites and, as with NMR spectroscopy, overspiking can be used to confirm identity. For complete unknowns a detailed examination of the mass spectral data and, where accurate

**Figure 6** Reversed-phase UPLC-MS (positive ESI) of urine obtained from a sample of urine obtained from a male black mouse.

administration of acetaminophen at 1% by weight of the diet.<sup>49</sup> Based on the chemical shifts and relative intensities of the signals detected in the urine it was possible to deduce the presence of a methylene group, adjacent to a carbonyl function, coupled to two other, strongly coupled highly nonequivalent methylene protons. These protons were also coupled to a single methine proton that had a chemical shift similar to that of an  $\alpha$ -CH proton of an amino acid that formed the X of an ABX spin system. Despite these data the compound remained unidentified. However, SPEC,<sup>49</sup> followed by <sup>1</sup>H NMR to monitor the fractions, and then fast atom bombardment (FAB)-MS obtained the essential information that the unknown had a molecular mass of 129 Da and therefore contained, in addition to two methylene and a methine, at least 1 nitrogen. Based on these findings the unknown was tentatively identified as 5-oxoproline, which was then confirmed by comparison with an authentic standard. Similarly, SPEC was used on samples of urine from rats for the identification of 3-hydroxyphenylpropionic acid (3-HPPA),<sup>50</sup> derived from dietary chlorogenic acid via the gut microflora. Once again the 3-HPPA was partially characterized from the urinary <sup>1</sup>H NMR spectrum which showed four aromatic multiplets between 7.3 and 6.7 ppm and two triplets at 2.84 and 2.48 ppm integrating to two methylene and four aromatic protons respectively. This was consistent with a 1,3-disubstitution pattern on the aromatic ring, while the chemical shifts suggested the presence of a phenolic OH and the chemical shifts for the methylene groups suggested the presence of a carboxylic acid. SPEC was used to obtain a purified concentrate for <sup>13</sup>C NMR, which indicated that the unknown contained nine carbon atoms. These data led to a putative structure which was then confirmed as 3-HPPA by comparison to a standard.

#### 5.43.2.5.2 High-performance liquid chromatography-nuclear magnetic resonance (HPLC-NMR) spectroscopy and high-performance liquid chromatography-mass spectrometry-based methods of identification

When low-resolution techniques prove to be unsuited to providing sufficiently pure material, then either preparative chromatographic isolation followed by spectroscopy or online methodologies such as HPLC-NMR and HPLC-MS must be performed.<sup>46</sup>

Although an efficient use of resources, HPLC-NMR is relatively insensitive and, where low-concentration analytes are encountered, the identification strategy must be formulated accordingly. Currently, a number of different modes of HPLC-NMR can be employed depending upon the problem. Where the sample (or extract) is concentrated, analysis can be performed on-flow, with the required spectra obtained as the sample elutes through the probe. If the analytes are present at lower concentrations, then stopped-flow techniques can be used where the peak corresponding to the analyte (observed using UV, MS, or some other conventional HPLC detector) is held stationary in an NMR-flow probe until a suitable spectrum is obtained. We have found this to be quite efficient in practice and shown that stopped-flow HPLC-NMR can be performed on several peaks in a single run without degrading the separation.

As the analyte is stationary in the flow probe quite complex (and time-consuming) NMR experiments can be performed in addition to simple 1D NMR spectroscopy, including 2D experiments such as TOCSY and correlation spectroscopy (COSY). Even if the peak contains several incompletely separated metabolites, techniques such as 'time slicing' can be used to obtain good-quality spectra. Here flow is restored for a few seconds to edge the peak a little further through the flow probe and this is then followed by the acquisition of a further spectrum. By taking a number of such spectra across the peak it is often possible to obtain spectra of the individual components. An extremely powerful approach, though somewhat time-consuming, is when the whole separation is subject to examination using the time-slicing method (alternatively, very low flow rates can be used).

As well as stopped-flow HPLC-NMR, the peaks of interest can be collected as they elute from the column in sample loops ('peak parking' or 'peak picking'), after which they can then be transferred from the sample collection loops into the NMR flow probe for spectroscopy. It is also possible to collect peaks via an online SPE where, if required, several runs can be performed, collecting and combining several samples of the unknown to provide a concentrate. The analyte may then be recovered using a fully deuterated solvent and directed into the NMR flow probe for spectroscopy.

An example where HPLC-NMR has been used in metabonomics studies concerns the identification of certain aromatic metabolites present in rat urine that separated two separate populations of the same strain.<sup>51</sup> Reversed-phase gradient HPLC combined with <sup>1</sup>H NMR spectroscopy allowed the identification of three of these peaks as hippuric acid, 3-HPPA, and 3-hydroxycinnamic acid. This enabled the conclusion to be reached that the observed differences between the two groups of rats resulted from differences in the respective populations of gut flora and this affected the metabolism of dietary aromatics such as chlorogenic acid.

Similarly, HPLC-MS-based approaches can be very useful in the identification of markers and, for example, xanthurenic and kynurenic acid (both metabolites of tryptophan) were detected as being correlated with nephrotoxicity in the rat.<sup>32</sup> Following detection by HPLC-Orthogonal acceleration (oa)ToF-MS a tentative identification was made based on the use of accurate mass and atomic composition data which was confirmed by the use of authentic standards.

### 5.43.3 Applications of Metabonomics

The applications of metabonomics have covered a very wide range of investigations, from basic studies in biology through more specific applications such as the investigation of disease models, toxicology, clinical investigations, and epidemiology. Typical examples of these studies are described below.

#### 5.43.3.1 Metabotyping

The ‘metabotype’<sup>15</sup> is a term coined to describe the metabolic phenotype presented by samples obtained from a particular population. An example of this might be the differences observed between the metabonomic profiles of, e.g., urine samples of different strains of rodents, or resulting from diurnal variation, diet, age, and gut microflora. Such differences are often by no means trivial, and if not properly understood can represent a confounding factor in metabonomic (or indeed other ‘omic’) investigations as changes may be seen in the profile that have little to do with the experimental treatment and everything to do with normal biology. Thus, using either <sup>1</sup>H NMR spectroscopy or HPLC-MS, it is relatively easy to distinguish between male and female rats or indeed mice of the same strain,<sup>13–15,52</sup> based simply on urine. Similarly, in the case of rodents, the age of an animal significantly modifies the urinary profile,<sup>53,54</sup> and this can be true over even relatively short periods. No doubt similar effects will be seen with other species. In **Figure 8** the effect of age on the profile of male Wistar-derived rats for a 16-week period, from 4 to 20 weeks of age, is shown.<sup>54</sup> The time of day when samples are collected is also important and if 24-h collections of urine are not obtained then the importance of carefully controlling sampling time to ensure that the same period is used for collection can not be overemphasized, as sample composition can change dramatically.<sup>13–15</sup> Similarly, diet can affect the urinary metabolite profile, as can the composition of the gut microflora, which can change during the study.<sup>50,55–57</sup> Thus every effort should be made to use a single batch of diet for the duration of a study, something which may not be easy if dosing over several years is contemplated. Clearly, before undertaking any series of metabonomic experiments it is important to try to establish the baseline conditions for the system under study and obtain an idea of the inherent biological variability in the system. However, as these studies show, metabonomics can provide useful and informative means of investigating the influence of normal physiological processes on the composition of biofluids.<sup>58</sup>

#### 5.43.3.2 Metabonomics and the Study of Toxicity

A major area for the exploitation of metabonomics has been the study of toxicity and this area has been the subject of many publications and reviews (see <sup>59–62</sup> for some recent examples). An example of this type of application is provided by the work of the consortium for metabonomic toxicology (COMET), where a number of pharmaceutical companies and Imperial College have combined to look at a wide range of toxins in rodents.<sup>63</sup> This work was performed with the

**Figure 8** Age profile obtained from the urine of male Wistar-derived rats using <sup>1</sup>H NMR spectroscopy and PLS regression: cross-validated age predictions were obtained by a PLS model with three components. Data expressed as mean  $\pm$  standard deviation.<sup>54</sup> (Reproduced by permission of the Royal Society of Chemistry.)

aim of building metabolic databases of responses to well-characterized 'typical' toxins to which the effects of new chemical entities could be compared to better predict their organ-specific toxicity and mechanism of action. In rodent studies, largely using  $^1\text{H}$ -NMR-based sample analysis of urine or plasma, metabonomics has been demonstrated to be capable of classifying organ-specific toxicity in animals in tissues such as kidney,<sup>64–80</sup> liver<sup>23,24,81–92</sup> (including peroxisome proliferation<sup>93,94</sup>), testes,<sup>95–97</sup> phospholipidosis,<sup>30,98,99</sup> and vasculitis.<sup>100,101</sup> Of course, while it is possible to detect toxicity that is directed specifically to a particular organ, or indeed to a specific region within it, it is often the case that more than one organ can be affected,<sup>92</sup> and that the focus of the toxicity can change with time, so results from such studies need careful interpretation. In addition, as toxicity progresses, feeding may be reduced and this will also affect the metabolite profile.<sup>102</sup>

While the bulk of the metabonomics studies in toxicology have been conducted using NMR spectroscopic methods, more recently HPLC-MS-based analysis, either alone or together with NMR spectroscopy, has begun to be performed.<sup>29–38</sup> The combination of NMR and HPLC-MS techniques is particularly powerful as the different sensitivities and specificities of the two spectrometers enable a more complete metabolic profile to be generated. Indeed, a series of studies on a number of model nephrotoxins has shown the complementary nature of NMR and HPLC-MS.<sup>32–34</sup> In the first of these studies the effect of the administration of a single dose of mercuric chloride to male Wistar-derived rats on the urinary metabolite profiles of a range of endogenous metabolites was studied.<sup>32</sup> Urine was collected for the 9 days of the study and both HPLC-*oa*-TOF/MS and  $^1\text{H}$  NMR spectroscopy revealed marked changes in the pattern of endogenous metabolites as a result of the  $\text{HgCl}_2$ -induced nephrotoxicity. The greatest disturbance in the urinary metabolite profiles was detected at 3 days postdose, after which the metabolite profile gradually returned to a more normal composition. The urinary markers of toxicity detected using  $^1\text{H}$  NMR spectroscopy included increases in lactate, alanine, acetate, succinate, trimethylamine, and glucose, together with reductions in the amounts of citrate and  $\alpha$ -ketoglutarate. In contrast, the HPLC-MS-detected markers (in positive ESI) included decreased kynurenic acid, xanthurenic acid, pantothenic acid, and 7-methylguanine concentrations, while an ion at  $m/z$  188, possibly 3-amino-2-naphthoic acid, was observed to increase. In addition, unidentified ions at  $m/z$  297 and 267 also decreased after dosing. Negative ESI revealed a number of sulfated compounds such as phenol sulfate and benzene diol sulfate, both of which appeared to decrease in concentration in response to dosing, together with an unidentified glucuronide ( $m/z$  326). One conclusion from this study was that both NMR and HPLC-MS (positive and negative ESI) gave similar time courses for the onset of toxicity and recovery. However, the markers seen were quite different for each technique, clearly suggesting a role for both types of analysis. Similar conclusions about the complementary nature of NMR and HPLC-MS were confirmed in an investigation of the nephrotoxicity of the immunosuppressant cyclosporin A.<sup>33</sup> In this instance HPLC-MS analysis was complicated by the presence of ions derived from cyclosporin, its metabolites, and the dosing vehicle which had to be eliminated from the data prior to analysis by PCA. There was, however, once again, excellent concordance between the observed time course of toxicity whichever technique was used. However, as with the mercuric chloride example given above, the markers were different depending upon whether NMR or HPLC-MS was examined. A similar conclusion was reached when the effects of gentamicin on urinary metabolite profiles were examined by HPLC-MS and NMR spectroscopy.<sup>35</sup>

The complementary data provided by the combination of  $^1\text{H}$  NMR and HPLC-MS suggest that, wherever possible, both techniques should be used to analyze samples. Similarly, a future role for GC-MS metabonomic studies of toxicity seems highly likely.

### 5.43.3.3 The Investigation of Disease Models

As well as metabotyping and providing organ-specific biomarkers of toxicity, metabonomics has great potential to aid in the characterization of animal disease models. This characterization is important as the extent to which the model actually mirrors human disease is, self-evidently, critical to the success of the drug discovery process. In addition, if the animal model does have some concordance with human disease, a detailed metabolic analysis may result in the detection of novel biomarkers that can be extended to the clinic to monitor efficacy.

An example of such studies examining disease models is provided by investigations of the urinary and plasma<sup>103–106</sup> metabolite profiles of Zucker (fa/fa) obese rats, which are used as a model of type 2 diabetes. Some of this work involved the collection of samples of urine from male rats at fortnightly intervals from weaning (4 weeks of age) until the animals were 20 weeks of age. These samples were compared with those of a control group of Wistar-derived animals. The urinary NMR and HPLC-MS profiles showed obvious age-related differences between conventional 20-week-old Wistar-derived and Zucker rats. In the  $^1\text{H}$  NMR spectra these differences were evident as, e.g., decreased taurine and increased urinary glucose in the urine of Zucker compared to Wistar-derived rats. These differences are illustrated in [Figure 9](#) for 20-week-old animals. While the appearance of glucose in the urine of diabetic rats might easily have been

**Figure 9**  $^1\text{H}$  NMR spectra for urine samples obtained from (a) 20-week-old male Wistar-derived and (b) 20-week-old Zucker fa/fa rats.<sup>106</sup> (Reproduced by permission of the Royal Society of Chemistry.)

predicted, the meaning of the reduction in taurine excretion is not at all clear. The HPLC-MS data also revealed a similar progression with time. A mean trajectory for these animals, comparing the Zucker (fa/fa) obese and the control group, is shown in [Figure 10](#). The two groups begin to diverge at *c.* 10 weeks of age, and by 20 weeks they occupy quite different areas of metabolic space.

#### 5.43.3.4 Metabonomic Studies in Humans

The use of  $^1\text{H}$  NMR spectroscopy for obtaining metabolic profiles for the diagnosis of metabolic diseases and inborn errors of metabolism is a long-standing application of the technique, with examples including such diseases as ‘maple syrup urine’ and 5-oxoprolinuria.<sup>107–111</sup>  $^1\text{H}$  NMR spectroscopy has also been used to monitor toxicity in the case of drugs such as the anticancer agent ifosfamide. In this study the maximum kidney toxicity effects of ifosfamide were observed by the fourth treatment cycle.<sup>112</sup>  $^1\text{H}$  NMR has also been used to examine the effects of phenol poisoning.<sup>113</sup>

However, studies undertaken to aid clinical development in human subjects, either to monitor treatment or discover new biomarkers, pose much greater difficulties compared to similar investigations in inbred strains of rodents. In particular, humans are much more diverse, and live in much less well-controlled environments than the laboratory animals used for toxicological studies. Thus the animals in metabonomic studies are housed in uniform, and carefully controlled, environmental conditions, and are similar genetically, the same age, usually the same gender, in the same weight range, and eat a controlled diet. In comparison humans, especially patients, in addition to not being housed in uniform environmental conditions are, by their very nature, often ill and subject to considerable variability in virtually all of the things that are carefully controlled in animal studies, and may also be on a range of medications. Even when such factors are controlled to some extent by performing the study on a small number of volunteers of the same gender in a clinical trials unit, there is large interindividual variability.<sup>114</sup> The effects of diet can be very significant and we have found unexpected dietary components (ethanol and ethyl glucoside) associated with the probable use of rice wine in cooking (or saki consumption) appearing in the urine.<sup>115</sup> Similarly, we have detected differences in betaine concentrations in urine between Swedish and British subjects that were sufficient to separate the two groups. This difference was most likely due to a higher consumption of fish by the Swedish population rather than any underlying genetic difference.<sup>116</sup> In the same study we noted dramatic effects on the urinary metabolite profile as a result of dietary changes by a female subject. Two samples were supplied by this individual, some months apart, the first of which was obtained when the subject was following a high-meat Atkins-style diet. This diet resulted in the excretion of large quantities of the amino acid taurine (often seen as a result of hepatotoxicity in rodents). However, when the second sample was analyzed the subject had reverted to a ‘normal’ pattern of food consumption, with the consequent absence of large amounts of taurine (and instead evidence of ethanol consumption).

**Figure 10** Mean metabolic trajectories for male Wistar-derived and Zucker fa/fa rats ( $n=6$ ) derived from  $^1\text{H}$  NMR of urine. Samples were obtained every 2 weeks from 4 to 20 weeks. Bold numbers indicate the mean position for the group while the smaller numbers show the position of individual animals.<sup>106</sup> (Reproduced by permission of the Royal Society of Chemistry.)

Such variables in human studies can result in a large amount of ‘metabolic noise,’ and these factors need to be recognized and, in clinical trials, careful collection of data on diet and medication is needed in order to be able to make confident interpretations of the metabolic data.

As well as monitoring toxic effects, clinical applications of metabonomics for diagnosis have been illustrated by a number of studies. In the case of cardiovascular disease,  $^1\text{H}$  NMR spectroscopy of blood plasma was able to assess accurately the level of coronary atherosclerosis,<sup>117</sup> which is currently only possible with invasive techniques such as angiography. This represents an important potential application as coronary heart disease (CHD) is a major disease in developed nations, where as many as 1 in 3 individuals may develop the condition before the age of 70. In this study serum or plasma samples from subjects with well-characterized disease were analyzed by  $^1\text{H}$  NMR and the data were then subjected to pattern recognition techniques (in particular the orthogonal signal correction (OSC) data filter).

Simple visual comparison of the spectra of human sera from patients with severe triple-vessel CHD patients and normal coronary artery (NCA) subjects showed few systematic differences. However, PCA showed that, while there was overlap between the CHD and normal subjects, some clustering was evident, due mainly to lipids, particularly very-low-density lipoprotein, low-density lipoprotein, and choline. The class separation was then optimized using OSC to improve subsequent multivariate pattern recognition. This enabled the triple-vessel disease and NCA groups to be well separated in the scores plot of principal component 1 (PC1) and PC2. A PLS-DA model was then constructed using data from *c.* 80% of the samples, selected at random, to predict the class membership of the remaining 20% of samples. The resulting model was then used to predict the class membership of the samples not included in the training set, successfully predicting CHD with a sensitivity of 92% and a specificity of 93%, based on a 99% confidence limit for class membership. Indeed,  $^1\text{H}$  NMR-based metabonomic analysis could also distinguish the severity of the CHD, enabling those with single-, double-, and triple-vessel disease to be distinguished, while the conventional risk factors (including age, blood pressure, low-density lipoprotein, and high-density lipoprotein cholesterol, total cholesterol, total triglyceride, fibrinogen, plasminogen activator inhibitor 1 (PAI-1), white blood cell count, creatinine, or history of cigarette smoking) were unable to do this.  $^1\text{H}$ -NMR-based metabonomics was therefore substantially better at distinguishing the severity of CHD using a single blood sample than any of the conventional risk factors yet identified.

Other areas where metabonomics has been applied to human disease include the use of  $^1\text{H}$  NMR spectroscopy for the analysis of plasma from subjects with epithelial ovarian cancer, where it was possible to use  $^1\text{H}$  NMR-based analysis of serum and multivariate statistical analysis to detect a characteristic metabolic fingerprint of the disease.<sup>118</sup>

As well as biofluids, the technique of HRMAS has been used in the investigation of tumor biochemistry, for example with studies on prostate cancer-derived samples<sup>20</sup> (and more recently a larger study with *c.* 200 subjects also investigated this tumor type<sup>119</sup>). Breast tumor extracts have also been studied.<sup>120</sup> These studies demonstrated that it was not only possible to show large metabolic differences between malignant and healthy tissues, but also between different grades of tumor (e.g., more and less aggressive tumors) and it seems clear that metabonomics will have a significant part to play in the diagnosis and mechanistic understanding of tumor biology in the future.

#### 5.43.4 Outlook

Metabonomics, via the multicomponent analysis of biological fluids and tissues, provides a well-established methodology for addressing the differences in global metabolite profiles that characterize different physiological states. As such, metabonomics has much to offer drug discovery as part of a strategy for understanding the test system, investigating human disease, detecting and identifying novel biomarkers, and monitoring therapy to evaluate efficacy or toxicity. In the future, as part of efforts to speed drug discovery and development, the drive will be to increase the throughput of samples, both via improvements in the analytical methodology, and via advances in chemometric techniques to tease out the metabolic differences that characterize samples. It is also possible to predict that there will be a much greater application of metabonomics to the study of human disease. In addition there will undoubtedly be increased emphasis on combining metabonomics data with that obtained from the other 'omics' technologies (genomics/transcriptomics and proteomics) in order to try to obtain a deeper understanding of the systems under investigation. Combining such different data sets in a meaningful way requires new statistical tools and methods for data visualization.

## Biographies

**Ian D Wilson**, BSc, MSc, PhD, DSc, CChem, FRSC, EurChem FChrom Soc, FRES, is a Senior Principal Scientist in the Department of Drug Metabolism and Pharmacokinetics at the AstraZeneca Research site at Alderley Park in Cheshire, UK. He trained as a biochemist at the University of Manchester Institute of Science and Technology, from

where he received both BSc (1974) and MSc (1975) degrees. Subsequently, he obtained a PhD (1978) and more recently a DSc (1998) from Keele University. He is the author or co-author of some 300 papers or reviews, and has received a number of awards in separation and analytical science from the Royal Society of Chemistry, including the SAC Silver Medal for Analytical Chemistry (1990), the Analytical Separations Medal (1996), the Analysis and Instrumentation Medal (2002) and the SAC Gold Medal for Analytical Chemistry (2006). He has also received the Jubilee Medal of the Chromatographic Society (1994) and gave the inaugural Desty memorial lecture for innovation in separation science (1996). As well as being on the editorial boards of a number of journals, he is Editor of the *Journal of Pharmaceutical and Biomedical Analysis* and Editor in Chief of the *Encyclopaedia of Separation Science*. He is currently visiting professor at the Universities of York, Keele, Sheffield Hallam, Manchester, and Imperial College. His research is presently directed toward the further development of hyphenated techniques in chromatography and their application to problems in drug metabolism and metabonomics.

**Jeremy K Nicholson**, BSc, PhD, CBIol, FIBiol, FRSA, FRC Path CChem, FRSC, obtained his BSc from Liverpool University (1977) and his PhD from London University (1980) in biochemistry working on the application of analytical electron microscopy and the applications of energy dispersive x-ray microanalysis in molecular toxicology and inorganic biochemistry. He was appointed Lecturer in Chemistry (Birkbeck College, London University, 1981–83) and Lecturer in Experimental Pathology at the London School of Pharmacy (1983–85) returning to Birkbeck as a Senior Lecturer in Chemistry, then Reader (1989) and Professor of Biological Chemistry (1992). Since 1998 he has been Professor and Head of Biological Chemistry at Imperial College London. Professor Nicholson is the author of over 500 scientific papers, patents and articles on the development and application of novel spectroscopic and chemometric approaches to the investigation of disturbed metabolic and physicochemical processes in cells and biofluids and their relationship to disease processes. His work has been recognized by the award of several scientific prizes, including: the 1992 Royal Society of Chemistry SAC Medal for Analytical Science; the 1997 Royal Society of Chemistry Gold Medal for Analytical Chemistry; the 1994 Chromatographic Society Jubilee Silver Medal; the 2002 Pfizer Prize for Chemical and Medicinal Technologies and the 2003 Royal Society of Chemistry Medal for Chemical Biology. These awards cover various aspects of the development of NMR, LC-NMR, and LC-NMR-MS approaches for biofluid analysis, drug metabolism studies, and for the development and application of metabonomic technologies for toxicological and clinical diagnostics. Research interests include: biological NMR spectroscopy, novel LC-MS and chemometric approaches to bioanalysis, metabolic modeling and studies leading to understanding the molecular basis of disease and toxic processes. Professor Nicholson holds visiting and honorary professorships in several countries and is on the editorial board of 10 international science journals, including Consulting Editor of the *Journal of Proteome Research*. He is also an honorary professor at six universities and a consultant to many pharmaceutical companies in the UK, continental Europe, and the US and is a founder director of Metabometrix, an Imperial College spin-off company specializing in molecular phenotyping, clinical diagnostics, and toxicological screening via metabonomics.

### 5.44.1 Introduction

This chapter aims at illustrating the various objectives of a prodrug strategy, as well as the biochemical pathways involved in prodrug activation (i.e., hydrolysis, oxidation or reduction, or even conjugation). More detailed information can be found in a number of reviews.<sup>1–15</sup> What makes prodrugs different from other drugs is the fact that they are devoid of intrinsic pharmacological activity. Thus, the simplest and clearest definition, in this writer's view, is that given by Adrien Albert in 1958,<sup>16</sup> who coined the term. In modified form, the definition reads:

Prodrugs are chemicals with little or no pharmacological activity, undergoing biotransformation to a therapeutically active metabolite.

Another reasonable but abandoned proposal is that of 'latent drugs' by Harper.<sup>15</sup>

The complete opposites of prodrugs are thus drugs that have no active metabolite (e.g., paracetamol). However, prodrugs should not be confused (as is too often the case), with drugs that are intrinsically active, yet are transformed into one or more active metabolites. In this case, two or more active agents will contribute to the observed clinical response in proportions that depend on differences in pharmacological activities, in compartmentalization, and in time profiles. Examples include cisplatin (which is chemically transformed to the monoaqua and diaqua species), morphine and its 6-*O*-glucuronide, diazepam (which is *N*-demethylated to nordiazepam), and codeine (which is *O*-demethylated to morphine). The search for pharmacologically active metabolites is thus an active topic in drug discovery.<sup>17</sup>

**Figure 1** Two historical examples of prodrugs once in use, namely hexamine (**1**), an intentional prodrug of formaldehyde, and Prontosil (**2**), a fortuitous prodrug of sulfanilamide. (Reprinted from Testa, B. *Biochem. Pharmacol.* **2004**, 68, 2097–2106, copyright (2004), with the permission from Elsevier.)

A number of criteria are available to classify the various types and subtypes of prodrugs. Chemical criteria (e.g., carrier-linked prodrugs versus bioprecursors) are central in our presentation, and will be covered extensively in [Section 5.44.4](#). A historical discrimination can be made between intentional and fortuitous prodrugs. As the name indicates, the former are designed prodrugs obtained by chemical derivatization or modification of a known active agent. Many prodrugs in clinical use are of this type, and they were developed to improve the pharmaceutical and/or pharmacokinetic properties of an active agent, be it a lead candidate, a lead compound, a clinical candidate, a drug candidate, or a marketed drug. A historically interesting example is that of hexamine (**1**, [Figure 1](#)), an intentional prodrug of formaldehyde introduced over a century ago and used for decades as a throat disinfectant.

Whereas fortuitous prodrugs are few compared to intentional prodrugs, the discovery of the active agent they generate will contribute significantly to the understanding of the mechanism of action of the (pro)drug, and may even lead to the discovery of a new therapeutic class. The antibacterial medicine Prontosil (sulfamidochrysoidine) (**2**, [Figure 1](#)) offers a dramatic illustration of this phenomenon, since the discovery in 1935 of sulfanilamide as its active metabolite<sup>18</sup> was the milestone that led to the creation of all antibacterial sulfonamides.

### 5.44.2 A Look at Soft Drugs

It is essential to distinguish prodrugs from soft drugs, which are defined as “biologically active compounds (drugs) characterized by a predictable and fast in vivo metabolism to inactive and nontoxic moieties, after they have achieved their therapeutic role.”<sup>19,20</sup> On the one hand, soft drug design resembles prodrug design since they both involve the introduction of a functional group of predictable metabolic reactivity, for example an ester linkage, to achieve metabolic promotion. On the other hand, prodrugs must be contrasted with soft drugs, which are active per se and yield inactive metabolites. And in a more global perspective, prodrugs and soft drugs appear as the two extremes of a continuum of possibilities where both the parent compound and the metabolite(s) contribute in a large or small proportion to the observed therapeutic response.

In practical terms, soft drugs (1) are bioisosteres of known drugs, (2) contain a labile bridge (often an ester group), and (3) are cleaved to metabolites known to lack activity and toxicity. In other words, soft drugs bear a close stereoelectronic analogy to the target drugs, but a rapid breakdown to inactive metabolites is programmed into their chemical structure.<sup>21</sup>

A typical example is succinylcholine (**3**, [Figure 2](#)), although the discovery of this agent predates by decades the concept of soft drugs. In most individuals, this curarimimetic agent is very rapidly hydrolyzed to choline and succinic acid by plasma cholinesterase, with a half-life ( $t_{1/2}$ ) of about 4 min.<sup>22</sup>

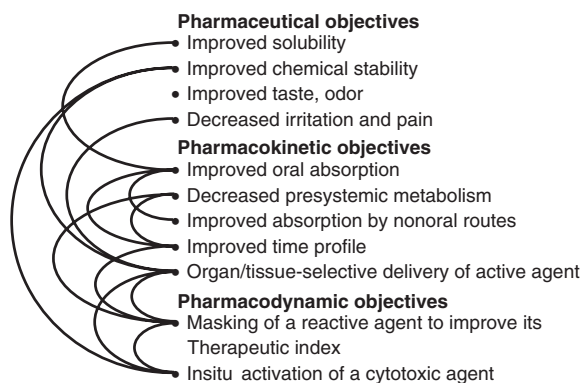

**Figure 2** A few illustrative soft drugs, namely succinylcholine (**3**), whose hydrolysis yields choline and succinic acid; bioisosteres of atropine (**4**), whose hydrolysis of the  $\text{-COOR}$  moiety yields inactive acids; soft  $\beta$ -blockers (**5**), having an ester bridge in the R substituent, as exemplified by esmolol ( $\text{R} = \text{CH}_2\text{COOCH}_3$ ), whose hydrolysis renders the side-chain too polar for receptor affinity; and quaternary ammonium antimicrobial agents (**6**), shown in order of decreasing stability under neutral conditions, with  $\text{N}^+$  being the quaternary ammonium group, and R being an alkyl chain (for references see the text).

Ad hoc designed soft drugs may be found in a variety of therapeutic classes, e.g., soft anticholinergics, soft  $\beta$ -blockers and soft antimicrobials. Thus, a number of potential soft anticholinergic agents (**4**, **Figure 2**) were prepared as bioisosteres of atropine, the  $\text{-CH}_2\text{OH}$  group being replaced by a labile  $\text{-COOR}$  group.<sup>23</sup> In vitro, the most active analog in the series was the isopropyl ester. The rates of chemical and enzymatic hydrolysis were found to decrease with the size of the R substituent. For example, the  $t_{1/2}$  values in rat liver homogenates at  $37^\circ\text{C}$  were approximately 3.5, 7, and 19 min for  $\text{R} = \text{ethyl}$ ,  $\text{isopropyl}$ , and  $\text{cyclohexyl}$ , respectively, while the corresponding  $t_{1/2}$  values in human plasma were much longer (about 80, 190, and 270 h, respectively), suggesting preferential and rapid hydrolysis by carboxylesterases.

A valuable class of soft  $\beta$ -blockers are aryloxypropanolamines, having an ester group in the *para* position (**5**, **Figure 2**).<sup>24,25</sup> In this series, the *para* substituent has an intermediate polarity compatible with good receptor affinity, but hydrolysis unmasks a carboxylic group whose polarity is too high for receptor binding. A promising compound in this series appears to be esmolol (**Figure 2**), whose ester bond is hydrolyzed by an esterase in the cytosol of red blood cells. The  $t_{1/2}$  of esmolol in whole blood is about 1, 2, 13, and 23–27 min in guinea pigs, rats, dogs, and humans, respectively. In humans in vivo, the plasma  $t_{1/2}$  of the drug is approximately 9 min, the recovery from beta blockade beginning 2 min after discontinuation of infusion and being complete at 18 min.<sup>26–28</sup>

Recent results suggest promising applications of soft drugs in the field of topical corticoids, calcium antagonists, and antimicrobial agents.<sup>4,10</sup> Antimicrobial agents deserve a special mention in the context of environmental safety ('green' chemistry). Thus, an extensive quantitative structure–activity relationship study was undertaken to assess the compared activity and stability of various quaternary ammonium antibacterials of interest as disinfectants and in environmental sanitation.<sup>29</sup> Whereas antimicrobial activities were comparable, large differences were seen in stability at neutral pH, allowing the authors to derive a safety index (hydrolytic rate constant divided by minimum inhibitory concentration) of clear environmental interest. As illustrated in **Figure 2** (**6**), stability in the four ester series decreased with increasing proximity between the carbonyl group and the quaternary nitrogen; the same was true in the two amide series. In fact, the effect appears so marked that the ester series with the carbonyl at the  $\epsilon$  position had a higher stability than the more labile amide series. Such simple rules should be of clear interest to soft drugs and prodrugs designers.

For the sake of fairness, it must also be mentioned that the design of soft drugs is not without limitations. Indeed, caution is needed with the definition given at the beginning of this section, specifically with such terms as 'predictable manner' and 'controllable rate' used in the definition. What can indeed be predicted and controlled is, in qualitative terms, the site of cleavage, and, in semi-quantitative terms, the approximate lability of this site. What cannot be predicted and controlled in a quantitative manner is the actual in vivo rate of breakdown. This is due to the many biological factors that influence their biotransformation, in particular the nature, distribution, and levels of the inactivating enzymes, as well as the disposition of the soft drugs themselves, for example the extent of their binding to plasma proteins. A similar limitation also applies to many prodrugs, as discussed in the following sections.

**Figure 3** A schematic list of objectives in prodrug research, together with their overlaps. (Reprinted from Testa, B. *Biochem. Pharmacol.* **2004**, 68, 2097–2106, copyright (2004), with the permission from Elsevier.)

### 5.44.3 Objectives of Prodrug Design

The prodrug concept has found a number of useful applications in drug research and development, as summarized in [Figure 3](#) and discussed in this section. However, it should be clear from the onset that such a view is too schematic, prodrug objectives being intertwined. Thus, an improved solubility can greatly facilitate oral absorption, while improving the chemical stability of an active agent can allow tissue-selective delivery and even lead to its in situ activation.

#### 5.44.3.1 Pharmaceutical Objectives

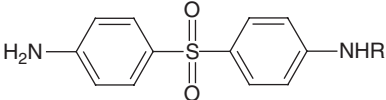

Pharmaceutical scientists are often faced with serious formulation problems resulting from poor solubility, insufficient chemical stability, or poor organoleptic properties. While pharmaceutical technology can solve such problems in favorable cases (e.g., by improving the solubility of cyclosporine), success is not guaranteed and may be time-consuming to achieve. Rather than to wait for an uncertain and delayed pharmaceutical solution to a problem of solubility or stability, project leaders may prefer to take advantage of a prodrug strategy, and hope on an early solution.

A representative example of a prodrug solution to a solubility problem is afforded by dapsone, a drug still used in combination to fight lepra. In a project aimed at improving the water solubility of this drug, a number of prodrugs were prepared by creating an amido bridge between dapsone and an amino acid ([Table 1](#)).<sup>30</sup> Good water solubilities were indeed contributed by the more polar pro-moieties (i.e., glycyl, alanyl, and lysyl). The half-lives of hydrolysis in human blood and plasma were very promising.

Two recent examples illustrate different chemical strategies to achieve better water solubility. Thus, buparvaquone (**7**, [Figure 4](#)) is an effective antileishmania drug belonging to the class of hydroxynaphthoquinones, but its oral and topical availability suffers from poor water solubility. Two prodrugs were therefore prepared and examined for their solubility, rates of hydrolysis, and permeation properties.<sup>31</sup> As shown in [Table 2](#), water solubility was markedly increased in the neutral and acidic pH range. The rates of chemical hydrolysis were rather slow in the acidic pH range, whereas enzymatic hydrolysis was fast except for compound **8** in human skin homogenates ( $t_{1/2}$  about 9 h). Of great pharmacokinetic relevance are also the fluxes through human skin measured under steady state conditions, which suggest an excellent potential for topical (and oral) bioavailability. As a note of caution, however, it must be stated that the hydrolysis of prodrug **9** will liberate formaldehyde, a potentially toxic breakdown product (see [Sections 5.44.4 and 5.44.5](#)).

A second example of chemical interest is that of isotaxel (**10**, [Figure 4](#)), a prodrug of the potent antitumor agent paclitaxel (**11**).<sup>32</sup> Paclitaxel has a very poor water solubility (about  $0.25 \text{ mg L}^{-1}$ ), which necessitates co-injection of a detergent. Taking advantage of the well-known mechanism of intramolecular nucleophilic transacylation, Hayashi *et al.*<sup>32</sup> prepared an analog of paclitaxel with the benzoyl group located on the  $\alpha$ -hydroxy group rather than on the amino group (estimated  $\text{p}K_a$  about 8). As a result, what is an amido function in paclitaxel becomes a basic amino group in isotaxel, and solubility is greatly improved by protonation (water solubility of  $10 \cdot \text{HCl}$  is  $0.45 \text{ g L}^{-1}$ ). *O,N*-Migration of the benzoyl moiety yields the active paclitaxel; as expected, the rate of *O,N*-trans-benzoylation increases with increasing pH (i.e., decreasing proportion of protonation). Thus, transbenzoylation occurred at pH 7.4 and  $37^\circ\text{C}$  with a  $t_{1/2}$  of  $15.1 \pm 1.3 \text{ min}$ , but with a  $t_{1/2}$  of 250 min at pH 4.9. In other words, the nonenzymatic activation of isotaxel to paclitaxel was fast under physiological conditions but slower under pharmaceutically compatible conditions. This study has recently been extended to other *O,N*-migrating acyl groups, leading to valuable structure–reactivity relations.<sup>33</sup>

**Figure 4** Illustrative prodrugs developed for improved water solubility, namely two phosphate prodrugs (**8** and **9**) of buparvaquone (**7**), and isotaxel (**10**), a successful prodrug of paclitaxel (**11**).

As will be discussed later, increasing solubility is not only a pharmaceutical but also a pharmacokinetic objective. Indeed, and as made explicit in the Biopharmaceutical Classification Scheme,<sup>34</sup> solubility is one of the main factors influencing oral absorption (*see* 5.42 The Biopharmaceutics Classification System).

Improving bad taste is well exemplified by erythromycin A, an important antibiotic administered as enteric coated tablets or capsules to adults, but as a suspension to children. To prevent its bad taste causing rejection in children, erythromycin A is normally administered to children as its 2'-ethyl succinate, a taste-free prodrug, which, however, undergoes slow but non-negligible hydrolysis in the medicine bottle. A far more stable pro-prodrug has recently been developed, consisting in 9-enol ether of erythromycin B 2'-ethyl succinate.<sup>35</sup> This double prodrug is very poorly soluble in water, and thus remains stable in solution. In the acidic stomach, however, it converts rapidly to erythromycin B 2'-ethyl succinate, to be further hydrolyzed to erythromycin B (which is equiactive with erythromycin A) in the neutral condition of the small intestine.

#### 5.44.3.2 Pharmacokinetic Objectives

Pharmacokinetic objectives are currently the most important ones in prodrug research. Foremost among these is (1) a need to improve oral bioavailability, be it by improving the oral absorption of the drug, and/or by decreasing its presystemic metabolism (see [Figure 3](#)). Other objectives are (2) to improve absorption by parenteral (nonenteral, e.g., dermal, ocular) routes, (3) to lengthen the duration of action of the drug by slow metabolic release, and, finally, (4) to achieve the organ/tissue-selective delivery of an active agent. Some of these objectives are exemplified below with clinically successful prodrugs.

Achieving improved oral absorption by a prodrug strategy is a frequent rationale in marketed prodrugs.<sup>5</sup> An apt illustration is found within the neuraminidase inhibitors of therapeutic value against type A and B influenza in humans.<sup>36–38</sup> Here, target-oriented rational design has led to highly hydrophilic agents that are not absorbed orally. One of the two drugs in current clinical use is zanamivir (**12**, [Figure 5](#)), a highly hydrophilic drug administered in aerosol form. The other active agent is Ro-64-0802 (**14**), which also shows very high in vitro inhibitory efficacy toward the enzyme but low oral bioavailability due to its high polarity. To circumvent this problem, the active agent was derivatized to its ethyl ester prodrug, known as oseltamivir (**13**). Following intestinal absorption, oseltamivir undergoes rapid enzymatic hydrolysis, and produces high and sustained plasma levels of the active agent. As demonstrated by this example, the prodrug concept may thus be a valuable alternative to disentangle pharmacokinetic and pharmacodynamic optimization (see the conclusion, [Section 5.44.6](#)).

Absorption by nonoral routes includes topical, pulmonary, nasal, rectal, and vaginal delivery, but these routes are of rather limited impact compared with oral administration. This may explain why so few prodrugs have been marketed for nonoral routes. Thus, the many examples listed in an extensive review on prodrugs for topical delivery<sup>39</sup> are rich in scientific information but of modest clinical interest.

Pharmaceutical formulation is the most frequent method used to achieve slow release and prolong the duration of action of a given drug. However, a prodrug strategy can also be useful, as exemplified by depot formulation of esters of steroid hormones. A conceptually different and particularly elegant approach to slow metabolic release has been achieved with bambuterol (**15**, [Figure 6](#)), a prodrug of the β<sub>2</sub>-adrenoreceptor agonist terbutaline (**16**).<sup>40,41</sup> Compared with terbutaline 5 mg taken three times daily, bambuterol 20 mg taken once daily provides smooth and sustained plasma levels of terbutaline, and a greater symptomatic relief of asthma with a lower incidence of side effects.<sup>42</sup> Similar results were obtained when comparing a slow-release formulation of terbutaline 10 mg with bambuterol 0.085 mg kg<sup>-1</sup>.<sup>43</sup> The two preparations elicited a comparable bronchodilating effect, but that caused by bambuterol appeared to be more sustained. The plasma levels of terbutaline were markedly more constant after bambuterol than terbutaline, but they were also significantly lower. This higher effect-to-plasma concentration ratio is another valuable feature of this prodrug, and it results from a marked uptake of bambuterol by the lung, where activation occurs in part.<sup>41</sup>

**Figure 5** Two neuraminidase inhibitors in current use against type A and B influenza in humans, namely the drug zanamivir (**12**) and the prodrug oseltamivir (**13**), whose active agent is Ro-64-0802 (**14**).

**Figure 6** Structure of the useful prodrug bambuterol (**15**) and its active metabolite terbutaline (**16**). (Reprinted from Testa, B. *Biochem. Pharmacol.* **2004**, 68, 2097–2106, copyright (2004), with the permission from Elsevier.)

Indeed, bambuterol is activated to terbutaline by cholinesterase (butyrylcholinesterase, EC 3.1.1.8) in blood serum, and by monooxygenase-catalyzed oxidation in the liver, lung, and other tissues. Following a first burst of terbutaline release, cholinesterase is inhibited by covalent attachment of the dimethylcarbamate moiety ( $\text{Me}_2\text{NCO}-$ ), resulting in a high inhibitory capacity ( $\text{IC}_{50} = 17 \text{ nM}$ ) with very slow reactivation of the enzyme. As a result, the inhibition of cholinesterase by bambuterol is of long duration but fully reversible, 2 days or more being necessary for complete recovery.

The last pharmacokinetic objective discussed here is the organ- or tissue-selective delivery of a given drug, also known as the search for the ‘magic bullet.’ This strategy is receiving ever-increasing interest in the tumor-selective delivery of anticancer agents.<sup>44,45</sup> A recent and clinically very significant example is that of capecitabine (**17**, [Figure 7](#)), a multistep, orally active prodrug of 5-fluorouracil (**20**).<sup>46–48</sup> Capecitabine is well absorbed orally, and undergoes three activation steps, resulting in high tumor concentrations of the active drug. It is first hydrolyzed by liver carboxylesterase, the resulting metabolite being a carbamic acid that spontaneously decarboxylates to 5'-deoxy-5-fluorocytidine (**18**). The enzyme cytidine deaminase, which is present in the liver and tumors, then transforms 5'-deoxy-5-fluorocytidine into 5'-deoxy-5-fluorouridine (**19**). Transformation into 5-fluorouracil is catalyzed by thymidine phosphorylase, and occurs selectively in tumor cells.

Capecitabine is of great interest in the context of this chapter. Clinically, it was first approved for the co-treatment of refractory metastatic breast cancer. Its therapeutic spectrum now includes metastatic colorectal cancer, and there are hopes that it might broaden further as positive results of new clinical trials become available. Capecitabine thus affords an impressive gain in therapeutic benefit compared with 5-fluorouracil, due to its oral bioavailability and a relatively

**Figure 7** The stepwise activation of the successful prodrug capecitabine (**17**) to the antitumor drug 5-fluorouracil (**20**), intermediate metabolites being 5'-deoxy-5-fluorocytidine (**18**) and 5'-deoxy-5-fluorouridine (**19**). Note that the last activation step is tumor-selective. (Reprinted from Testa, B. *Biochem. Pharmacol.* **2004**, 68, 2097–2106, copyright (2004), with the permission from Elsevier.)

selective activation in and delivery to tumors. This has been demonstrated in a number of studies, which have shown that the levels of 5-fluorouracil in tumors are clearly much higher after oral or intravenous capecitabine administration than after 5-fluorouracil intravenous administration. But even more impressive are the tumor-to-blood and tumor-to-gastrointestinal tract ratios achieved after capecitabine administration.<sup>48</sup>

#### 5.44.3.3 Pharmacodynamic Objectives

Pharmacodynamic objectives can be understood as being synonymous with decreasing systemic toxicity. Two major cases are illustrated here, namely the masking of a reactive agent to improve its therapeutic index, and the in situ activation of a cytotoxic agent.

The masking of a reactive agent to improve its therapeutic index is aptly exemplified by the successful anti-aggregating agent clopidogrel (**21**, **Figure 8**). This compound, whose molecular mechanism of action was poorly understood for years, is now known to be a prodrug. However, it is of interest among prodrugs in that its major metabolic route in humans (about 85% of a dose) is indeed one of hydrolysis, but this reaction leads to the inactive acid. In contrast, clopidogrel is activated by cytochrome P450 3A in a two-step sequence. First, the cytochrome P450-catalyzed reaction oxidizes clopidogrel to 2-oxoclopidogrel (**22**). This is followed by a spontaneous and rapid hydrolysis of the cyclic thioester to a highly reactive thiol metabolite (**23**), which irreversibly antagonizes platelet ADP receptors via a covalent S–S bridge.<sup>49,50</sup> Interestingly, the same activation mechanism appears to account for the potent and irreversible inhibition of human cytochrome P450 2B6 by clopidogrel,<sup>51</sup> again demonstrating the high reactivity of the thiol metabolite.

In situ activation to a cytotoxic agent is part of the well-known mechanism of action of the antibacterial and antiparasitic nitroarenes such as metronidazole. Here, we examine this concept as currently intensively applied in the search for more selective antitumor agents.<sup>44,52</sup> Given that tumor cells have a greater reductive capacity than normal cells, various chemical strategies are explored to design bioprecursors activated by reductive enzymes to cytotoxic agents, such as platinum(IV) complexes or *N*-oxides.

**Figure 8** Major metabolic reactions of the successful prodrug clopidogrel (**21**) in humans. Most of a dose is inactivated by hydrolysis to the free carboxylic acid, whereas a smaller part is activated by cytochrome P450 3A to 2-oxoclopidogrel (**22**), followed by spontaneous hydrolytic ring opening to the active agent, a highly reactive thiol metabolite (**23**). (Reprinted from Testa, B. *Biochem. Pharmacol.* **2004**, 68, 2097–2106, copyright (2004), with the permission from Elsevier.)

The latter case is aptly illustrated by the hypoxia-activated, bioreductive antitumor agent tirapazamine (**24**, [Figure 9](#)),<sup>53</sup> seemingly the best-studied drug candidate in this class.<sup>52</sup> Early evidence has shown that tirapazamine is activated to a cytotoxic nitroxide (**25**) by a one-electron reduction catalyzed by NADPH-cytochrome P450 reductase. More recent evidence, however, has implicated this activation to multiple reductases in the nucleus under hypoxia conditions, resulting in DNA single-strand and double-strand breaks.<sup>54</sup> The inactivation of tirapazamine is by two-electron reduction steps catalyzed by quinone reductase, and perhaps mainly by back-oxidation of the nitroxide radical by molecular oxygen in aerobic cells.<sup>55</sup> The metabolism of this bioprecursor is further complicated by spontaneous dismutation. In other words, cellular toxicity will depend first and foremost on oxygen levels in the cells. Of interest is also the fact that simple monosubstitution of tirapazamine can alter its lipophilicity enough to markedly improve extravascular transport and activity against target cells.

#### 5.44.4 Prodrug Classes and their Metabolic Reactions of Activation

##### 5.44.4.1 Chemical Criteria

Besides the criteria of classification discussed above, it is also useful from a pharmacochemistry perspective to examine prodrugs using chemical arguments. Thus, medicinal chemists find it useful to distinguish between four major classes of prodrugs, namely:

- carrier-linked prodrugs (*see* [Section 5.44.4.2](#)), where the active agent (the drug) is linked to a carrier (also known as a promoiety), and whose activation occurs by hydrolysis (esters, amides, imines, etc.), oxidation, or reduction (e.g., prontosil (**2**) *see* [Figure 1](#));
- bioprecursors (*see* [Section 5.44.4.3](#)), which do not contain a promoiety yet are activated by hydration, oxidation, or reduction<sup>7</sup>;
- drug–polymer conjugates (*see* [5.45 Drug–Polymer Conjugates](#)), where the carrier is a macromolecule such as a polyethyleneglycol<sup>56,57</sup>; and
- drug–antibody conjugates and enzyme-directed prodrug therapies (*see* [Section 5.44.4.4](#)), where the carrier is an antibody raised against tumor cells.<sup>4,58,59</sup>

Here, we begin with carrier-linked prodrugs and bioprecursors, which remain by far the largest groups of prodrugs in use. Indeed, of 1562 different active substances marketed in Germany in 2002, 6.9% are prodrugs, with one-half of

**Figure 9** Pathways of activation and inactivation of the hypoxia-selective antitumor agent tirapazamine (**24**). Activation is by a one-electron reduction step catalyzed by cytochrome P450 reductase, occurs selectively in tumor cells, and produces a cytotoxic nitroxide (**25**). Inactivation is by two-electron reduction steps catalyzed by quinone reductase.

these being activated by hydrolytic cleavage of a promoiety, and one-quarter being bioprecursors.<sup>2</sup> Readers interested in a far more comprehensive treatment of carrier-linked prodrugs and bioprecursors are invited to consult the several relevant chapters in a recent book.<sup>4</sup>

#### 5.44.4.2 Carrier-Linked Prodrugs

The carrier strategy remains the most common in prodrug design, although reductive bioprecursors are attracting an ever increasing interest, as [Section 5.44.4.3](#) will show. Here, we illustrate and discuss a number of common and innovative promoieties classified according to the functional group in the active drug to which they are linked.

##### 5.44.4.2.1 Prodrugs of acids

A carboxylic acid group, being ionized in the physiological pH range, will contribute significantly to reducing the lipophilicity of compounds containing this moiety. As a result, a large number of pharmacologically active carboxylic acids may display unfavorable pharmacokinetic properties such as low bioavailability, a problem of particular concern for compounds containing other moieties or a skeleton of high polarity. Thus, a major aim of prodrug design is to improve the pharmacokinetic behavior of active carboxylic acids, explaining why the majority of marketed or experimental prodrugs are derived from such acids. [Table 3](#) lists a number of common and less common carrier groups linked to a carboxylic group in drugs of the type R-COOH. In some cases, prodrugs of this type were developed to correct some pharmacokinetic defect(s) of established carboxylic drugs (post hoc prodrugs). In other cases, the problem was identified during development and ad hoc prodrugs were designed.

##### 5.44.4.2.1.1 Ester prodrugs of carboxylic acids

The simplest carriers in this group are obviously alkyl promoieties, as exemplified by oseltamivir (**13**, [Figure 5](#)) discussed above. Another important therapeutic group illustrating ad hoc prodrug design is that of angiotensin-converting enzyme (ACE) inhibitors.<sup>60</sup> Captopril, the first marketed drug in this class, contains one carboxylate group, while more recent agents contain two carboxylate groups as important features of the pharmacophore. However, the polarity of these groups prevents good gastrointestinal absorption following oral administration. As a result, most dicarboxylate ACE inhibitors in the literature have been developed as prodrugs, being in fact ethyl monoesters, for example benazepril (**26**, [Figure 10](#)) and enalapril (**27**).

**Table 3** Examples of common and less common carrier groups linked to a carboxylic group in drugs of the type R-COOH

| <i>Prodrug types</i>  | <i>Generic structure(s)</i>   |
|---|---|
| Esters of simple alcohols or phenols  | $R^1COOR^2$   |
| Esters of alcohols containing an amino or amido group, or another functionality | e.g., $R^1COO(CH_2)_nNR^2R^3$ or $R^1COO(CH_2)_nCONR^2R^3$ or $R^1COO(CH_2)_nNHCOR^2$ |
| (Acyloxy)methyl or (acyloxy)ethyl esters  | $R^1COOCH_2OCOR^2$ or $R^1COOCH(CH_3)OCOR^2$  |
| Hybrid glycerides formed from diacylglycerols                                   | e.g., $R^1COOCH(CH_2OCOR^2)_2$  |
| Esters of diacylaminopropan-2-ols   | e.g., $R^1COOCH(CH_2NHCOR^2)_2$   |
| <i>N,N</i> -Dialkyl hydroxylamine derivatives                                   | $R^1COONR^2R^3$   |
| Amides of amino acids   | $R^1CONHCH(R^2)COOH$  |

**Figure 10** The structure of ester prodrugs in use, namely benazepril (**26**), enalapril (**27**), and mycophenolate mofetil (**28**).

Benazepril is illustrative of the metabolism and disposition of ACE inhibitor prodrugs.<sup>61</sup> The compound is rapidly and well absorbed perorally in rats, dogs, baboons, and humans, in contrast to its active metabolite known as benazeprilate. The hydrolysis of benazepril to benazeprilate occurs very rapidly, and is catalyzed by carboxylesterases (EC 3.1.1.1). The latter enzymes are found in mammalian liver and in rat plasma, but are almost absent from the plasma of humans and other mammals. This difference might explain some interspecies variations in the rate of activation of ACE inhibitors.

Needless to say, many different *n*-alkyl, branched alkyl, cycloalkyl, alkylaryl, and aryl promoieties have been used in prodrug design. Here, we present a few functionalized alkyl groups whose properties are of interest. A comparison between the rates of activation of two types of prodrugs of nonsteroidal anti-inflammatory drugs (NSAIDs) will illustrate the influence of both the drug and carrier moieties.<sup>62</sup> As shown in [Table 4](#), the (*N,N*-diethylcarbamoyl)-methyl esters were hydrolyzed in human plasma about two to four orders of magnitude faster than the methyl esters. When considering the influence of the acyl (i.e., active) moiety, differences of between 30- and 500-fold are apparent. In other words, both the drug and (mainly) the promoiety influence the rate of activation by human plasma hydrolases, but no structure-metabolism relation is apparent.

Basic promoieties are of interest since they maintain a sufficient water solubility and often afford improved oral absorption. This is nicely illustrated with mycophenolate mofetil (**28**, [Figure 10](#)), an orally effective prodrug of the immunosuppressant mycophenolic acid.<sup>63</sup> The latter is of value in the suppression of acute allograft rejection following cadaver renal transplantation, but it is not absorbed orally. Esterification of the acid with the moderately basic ( $pK_a$  estimated around 8) 2-morpholinoethyl carrier resulted in a rapid and full oral absorption, followed by extensive presystemic de-esterification, presumably by serum cholinesterase. Whereas numerous basic promoieties have been

**Figure 11** The general structure of (oxodioxolyl)methyl esters (daloxates) (**29**) and the mechanism of their base-catalyzed hydrolysis.

used in prodrug design, it is worth remembering that a too close proximity between the ester and amino groups may result in very fast chemical hydrolysis due to intramolecular catalysis.<sup>4,64</sup>

Fragmentable promoieties are another type of carriers, as exemplified by acyloxymethyl (–CH<sub>2</sub>OCOR) and alkoxy-carbonyloxyalkyl (–CH<sub>2</sub>OCOO–alkyl) groups. The hydrolytic pathways by which these prodrugs are activated cleave their promoiety in two or three fragments, respectively.<sup>4</sup> The release of formaldehyde may account for some side effects of such prodrugs. This is certainly the reason why a 1-ethyl bridge should be preferred by medicinal chemists over a –CH<sub>2</sub>– bridge, despite somewhat greater synthetic difficulties.

A fragmentable promoiety of value in prodrug design is the (2-oxo-1,3-dioxol-4-yl)methyl group, yielding prodrugs known as daloxates (**29**, [Figure 11](#)). The interest of this moiety was first documented with prodrugs of antibiotics. Available evidence supports the clean reaction of the base-catalyzed hydrolysis shown in [Figure 11](#), although the actual mechanism may be more complex and/or condition-dependent.<sup>4</sup> Briefly, hydrolysis liberates the pro-moiety as an unstable carbonate monoester, which decarboxylates and generates a diketone. Enzymatic hydrolysis may also be involved, at least in some cases.

#### 5.44.4.2.1.2 Amide prodrugs of carboxylic acids

Compared with esters, few amide prodrugs of carboxylic acids have been investigated. A well-known prodrug of this type is the tuberculostatic agent pyrazinamide (**30**, [Figure 12](#)). In vivo hydrolysis results in its inactivation, with the rate of the reaction determining its apparent half-life. Yet the tuberculostatic activity of pyrazinamide also implies its hydrolysis, since only the prodrug can penetrate into *Mycobacterium tuberculosis*, where it is hydrolyzed by pyrazinamide amidohydrolase to ammonia and the active pyrazinoic acid. The resistance to pyrazinamide can in most cases be explained by mutation(s) in pyrazinamide hydrolase and/or a pyrazinamide-selective transporter.<sup>65</sup>

Pyrazinamide **30**Amino acid amides of 5-aminosalicylic acid **31****Figure 12** The structure of pyrazinamide (**30**) and amino acid amides of 5-aminosalicylic acid (**31**).

Prodrugs of clodronic acid

**32**

Prodrugs of etidronic acid

**33**Adefovir (R = H)  
Tenofovir (R = Me)**34****35****Figure 13** The structure of various phosphonate drugs (and prodrugs) discussed in the text: clodronic acid (**32**,  $R^1 = R^2 = R^3 = R^4 = H$ ), etidronic acid (**33**,  $R^1 = R^2 = R^3 = R^4 = R^5 = H$ ), adefovir (**34**,  $R = H$ ), tenofovir (**34**,  $R = Me$ ), and S-acyl-2-thioethyl phosphate esters of mononucleotides (**35**).

The drug 5-aminosalicylic acid (5-ASA) is of value in long-term maintenance therapy to prevent relapses of Crohn's disease and ulcerative colitis, yet it is absorbed rapidly in the upper intestinal tract and hardly reaches the colon. Prodrugs have therefore been designed with a view to achieve colon-specific delivery (i.e., activation in the colon), for example amino acid amides (**31**, [Figure 12](#)). When incubated with rat cecal content, the glycine amide released 80% of 5-ASA, whereas the aspartic and glutamic amides released 37% and 8%, respectively.<sup>66,67</sup> Oral administration to rats showed that most of 5-ASA-Asp was delivered to the small intestine, and about half of the administered dose was activated to liberate 5-ASA. In contrast, more than 80% of a dose of 5-ASA was recovered from urine, indicating extensive gastrointestinal absorption and negligible colon delivery.

#### 5.44.4.2.1.3 Prodrugs of phosphoric acids

A number of phosphates and phosphonates are of value as drugs, for example bisphosphonates used in the treatment of various bone diseases, and antiviral mononucleotides.<sup>3</sup> Because of the very high polarity of their ionized phosphate moiety, such drugs tend to suffer from limited oral bioavailability, and efforts are being directed toward prodrugs with improved pharmacokinetic properties.

Two typical bisphosphonates are clodronic acid (**32**,  $R^1 = R^2 = R^3 = R^4 = H$ , [Figure 13](#)) and etidronic acid (**33**,  $R^1 = R^2 = R^3 = R^4 = R^5 = H$ ), with oral bioavailabilities in the range of 1–2% and 3–7%, respectively. Two types of acyloxyalkyl esters of clodronic acid were prepared and evaluated for their rate of release of the drug, namely pivaloyloxymethyl esters (**32**,  $R^1 = R^2 = R^3 = R^4 = -CH_2OCOC(CH_3)_3$ ) and benzoyloxypentyl esters (**32**,  $R^1 = R^2 = R^3 = R^4 = -CH_2CH_2CH_2OCOPh$ ).<sup>68</sup> In vitro, the di-, tri-, and tetrabenzoyloxypentyl esters of clodronic acid did undergo some enzymatic hydrolysis at the carboxylate ester, but the resulting 3-hydroxypropyl phosphate esters were stable, and did not release clodronic acid. In contrast, the di-, tri-, and tetrapivaloyloxymethyl esters readily released clodronic acid by enzymatic hydrolysis of the carboxylate ester groups and spontaneous hydrolysis of the hydroxymethyl phosphate groups. It should be noted that the latter reaction liberated formaldehyde, an unwanted feature.

Etidronic acid (**33**,  $R^1 = R^2 = R^3 = R^4 = R^5 = H$ , [Figure 13](#)) represents a more complex case due to the presence of a hydroxy group on the bridging carbon atom. A variety of potential prodrugs were prepared and examined, with the most promising results being shown by the two derivatives having  $R^1 = -COCH_3$ , plus three or four pivaloyloxymethyl promoieties on the phosphonate groups.<sup>69</sup> The postulated mechanism involved enzymatic hydrolysis of the

pivaloyloxymethyl promoities, and chemical hydrolysis of the acetyl ester group. But here again, liberation of formaldehyde occurred during hydrolytic cleavage of the pivaloyloxymethyl promoities.

Analogous approaches also appear of interest in the search for prodrugs of antiviral agents such as the pseudonucleotides adefovir (**34**, R = H, **Figure 13**) and tenofovir (**34**, R = Me).<sup>3,70</sup> A different strategy is based on the use of SATE (*S*-acyl-2-thioethyl) promoities (**35**), as applied in the preparation of prodrugs of medicinal phosphates and phosphonates. Mono- and bis-SATE derivatives have shown promising intracellular delivery, rates of activation, and antiviral activities in cell cultures.<sup>71,72</sup>

#### 5.44.4.2.2 Prodrugs of alcohols and phenols

Prodrugs of active alcohols and phenols have received practically as much attention in the literature as prodrugs of active carboxylic acids. This symmetry may not extend to prodrugs in clinical use, since the improvement in pharmacokinetic properties is generally greater when masking a highly polar carboxylate group than a hydroxy group. However, it is clear that a number of active alcohols and phenols are gainfully used in therapy as ester prodrugs. This section considers a selection of the common and less common promoities that are being used or have been examined in the design of prodrugs of active alcohols or phenols (**Table 5**).

##### 5.44.4.2.2.1 Simple and functionalized acyl esters

The simplest and most common strategy to reversibly derivatize hydroxy groups is obviously with acyl groups, be they simple or functionalized ones. Thus, a number of acetate ester prodrugs are characterized by favorable pharmacokinetic properties and rates of activation. A large number of linear, branched, and cyclic alkanolic acids, as well as aromatic acids, can be found in the literature.<sup>4</sup>

The results with esters of di-acids appear difficult to rationalize. This can be seen with metronidazole, a drug which has attracted marked attention for prodrug design (**36**, R = H, **Figure 14**). At 37 °C and pH 7.4, the hemisuccinate ester (R = -COCH<sub>2</sub>CH<sub>2</sub>COOH) hydrolyzed with *t*<sub>1/2</sub> of 600–700 h in phosphate buffer and in human plasma, indicating the absence of enzymatic catalysis in this biological medium. Under the same conditions, similar results were obtained with the hemimaleinate (R = -COCH-CHCOOH), with *t*<sub>1/2</sub> of approximately 250–350 h. In contrast, the hemiglutarate (R = -COCH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>COOH) was hydrolyzed much faster in human plasma (*t*<sub>1/2</sub> about 16 h) than in phosphate buffer (*t*<sub>1/2</sub> about 800 h). This provides valuable information on the substrate selectivity of human plasma hydrolases, but further studies on a variety of other hemiglutarates as compared to hemisuccinates are required.<sup>73</sup>

##### 5.44.4.2.2.2 Esters of amino acids

Most published examples of esters of amino acids contain an  $\alpha$ -amino acyl moiety. A number of reasons may explain this fact, such as the lack of toxicity of these natural compounds, the large differences in lipophilicity and other properties between amino acids, and the variability afforded by N-substituents. Interesting examples are provided by salicylic acid and metronidazole. Thus, a number of  $\alpha$ -amino acyl prodrugs of metronidazole (**36**, R = -COCH(R')NH<sub>2</sub>, **Figure 14**) were compared for their chemical and serum-catalyzed hydrolysis.<sup>74</sup> The amino acids used for esterification included

**Figure 14** The structure of anti-infective agents whose hydroxy group has been derivatized to yield acyl ester or carbonate ester prodrugs.

alanine, glycine, isoleucine, leucine, lysine, phenylalanine, and valine. Under physiological conditions of pH and temperature,  $t_{1/2}$  of hydrolysis in human serum ranged from 4.5 min for the Phe ester to 96 h for the Ile ester. A good linear relationship was established between the log of the rate constant of enzymatic hydrolysis and the log of the rate constant of hydroxyl-catalyzed hydrolysis of the protonated prodrugs. In other words, the rate of chemical hydrolysis was a good predictor of the rate of enzymatic hydrolysis. This renders the involvement of a plasmatic enzyme such as cholinesterase unlikely, but could suggest an albumin-mediated reaction.

Other types of amino acids have also been reported, as again exemplified for metronidazole by N-substituted glycine derivatives, 3-aminopropanoic acid ( $\beta$ -alanine),  $\gamma$ -amino-butyric acid (GABA), and the two promoieties **37** and **38** shown in Figure 14.  $t_{1/2}$  for hydrolysis in buffer under physiological conditions ranged from 1 to 31 h, and between 8 min and 9 h in 80% human plasma.<sup>75</sup>

The use of amino acyl promoieties is of particular interest in view of recent results demonstrating that prodrugs of this type are substrates of intestinal peptide transporters such as PEPT1, resulting in enhanced intestinal absorption. Such results are of particular value for HIV protease inhibitors and antiviral nucleosides.<sup>76,77</sup> Thus, valaciclovir, the L-valyl ester of acyclovir (**39**,  $\text{R} = \text{H}$ , Figure 14), showed encouraging pharmacokinetic results in the rat and monkey. Indeed, the oral bioavailability of acyclovir following valaciclovir administration was  $67 \pm 13\%$  in the monkey, a significant improvement over the limited availability of the drug administered as such.

#### 5.44.4.2.2.3 Carbonate and carbamate esters

Carbonate esters (alkoxycarbonyl derivatives) are diesters of general formula  $\text{R}^1\text{OCOOR}^2$ . A single mechanism operates in the hydroxyl anion-catalyzed (and presumably also in the enzyme-catalyzed) hydrolysis of carbonate esters, namely a rate-determining addition of the base to the carbonyl carbon, forming an intermediate whose breakdown yields the drug ( $\text{R}^1\text{OH}$ ),  $\text{CO}_2$ , and an alcohol ( $\text{R}^2\text{OH}$ ). A number of carbonate prodrugs have been reported for the opioid antagonist naltrexone, whose phenolic group was esterified to yield a small series of alkyl *O*-carbonates (alkyl = methyl,

ethyl, *n*-propyl, isopropyl, *n*-butyl, and *n*-pentyl).<sup>78</sup> All prodrugs hydrolyzed to the parent drug when passing through sheets of human stratum corneum, with the methyl carbonate providing the highest drug flux, apparent permeability coefficient, and stratum corneum vehicle partition coefficient.

To return to antivirals, promising applications of the carbonate prodrug strategy have been reported for zidovudine and penciclovir, and their analogs. Encouraging results have thus emerged for prodrugs of penciclovir (**40**, Figure 14). This antiherpes agent has a poor oral bioavailability, which has led to the development and US Food and Drugs Administration approval of famciclovir (**41**,  $R^1 = R^2 = -\text{COCH}_3$ ), a pro-prodrug of penciclovir activated by hydrolysis of its acetate groups and xanthine oxidase-mediated oxidation at the 6 position. Attempts to further improve the bioavailability of penciclovir have led to a variety of alkyl monocarbonate esters of 2-amino-9-(3-hydroxymethyl-but-1-yl)purine (**41**,  $R^1 = \text{H}$ ,  $R^2 = -\text{COO-alkyl}$ ) together with the cyclic carbonate **42**.<sup>79</sup> The rates of chemical hydrolysis in a pH 7.4 phosphate buffer at 37 °C ranged from about 3 h to 60 days, and they decreased in the order **42** > methyl > ethyl = *n*-pentyl > *n*-propyl > *n*-butyl = isopentyl > isobutyl > isopropyl. Interestingly, urinary recovery of penciclovir in mice and rats ranged from about one-third to one-half after oral pro-prodrug administration, whereas urinary recovery was 3–9% after penciclovir administration.

A variety of carbamate promoieties have also been attached to a hydroxy group and, particularly, a phenolic group, a good example being bambuterol, the prodrug of terbutaline (**15** and **16**, see Figure 6). The potential of carbamate ester prodrugs ( $R^1\text{OCONR}^2R^3$ ) is well established by a number of studies on their stability and metabolism.<sup>4</sup> Upon hydrolysis, they liberate the active agent ROH and the carbamic acid  $R^2R^3\text{NCOOH}$  which, being unstable, breaks down to the amine  $R^2R^3\text{NH}$  and  $\text{CO}_2$ . The mechanism of hydroxyl-catalyzed hydrolysis of carbamate esters is more complex than that of carbonate esters. In the case of *N,N*-disubstituted carbamates ( $R^1\text{OCONR}^2R^3$ ), the only possible mechanism is as for carbonates (nucleophilic attack at carbonyl carbon by hydroxyl anion to form a tetrahedral intermediate), which is presumably also the mechanism of enzyme-catalyzed hydrolysis of all carbamates.

In the case of *N*-monosubstituted carbamates ( $R^1\text{OCONHR}^2$ ), where RO– is a good leaving group (i.e., having a  $\text{p}K_a < c.12$ , in practical terms a phenol), *N*-deprotonation does occur. The conjugate base then splits spontaneously in a rate-determining step to give the phenolate RO– and an isocyanate  $R^2\text{N}=\text{C}=\text{O}$ ; the latter hydrates rapidly to the carbamic acid, which in turn breaks down to an amine and  $\text{CO}_2$ . This mechanism is thus characteristic for the nonenzymatic hydrolysis of aromatic *N*-monosubstituted carbamate, and it is usually several orders of magnitude faster than the mechanism of hydroxyl addition discussed above.

Thus, there will be a major difference in the design of carbamate prodrugs of phenols and alcohols. In the case of alcohols, both *N*-monosubstituted and *N,N*-disubstituted carbamates will a priori be chemically stable. Why so few carbamates of alcohols were reported as potential prodrugs might be due to enzymatic stability, which can be found to be uselessly stable.

For phenols, their *N,N*-disubstituted carbamate esters will also be high toward chemical hydrolysis, whereas their *N*-monosubstituted carbamates will as a rule be more labile. In addition, many other factors beside chemical stability can strongly influence the bioavailability and pharmacokinetic behavior of a prodrug, mainly enzymatic hydrolysis and lipophilicity. In concrete terms, this implies that careful design (and some luck) may lead to useful carbamates. That bambuterol is not an isolated example of success is demonstrated by the successful antitumor prodrug irinotecan (**43**, Figure 15). The story begins with the isolation of the natural compound camptothecin. Its antitumor activity proved highly promising, but its use was hampered by poor water solubility. Systematic studies led to the discovery of irinotecan, which combined high activity and good water solubility, and which was later shown to be a prodrug whose activity depends on the release of its active metabolite 7-ethyl-10-hydroxycamptothecin (**44**). Several human and rodent carboxylesterases were shown to hydrolyze irinotecan, but the overall activity varies from enzyme to enzyme. A highly active carboxylesterase was isolated from mouse liver and kidney.<sup>80</sup>

**Figure 15** The structure of the successful antitumor prodrug irinotecan **43** and its active metabolite **44**.

#### 5.44.4.2.2.4 Glycosides as prodrugs

Most glycosides reported as potential prodrugs are glucuronides, as illustrated below. Yet other sugars have also been used as promoieties, and it is worthwhile noting here that some natural glycosides are in fact prodrugs. This is the case for arbutin, the *O*-glucoside of hydroquinone. This conjugate is contained in some herbal medicines used as urinary antiseptics; its hydrolysis under the relatively acidic conditions prevailing in urine liberates the active hydroquinone. In other words, arbutin is a natural prodrug undergoing site-selective activation. Another example is afforded by the sennosides, which have been used since ages as laxatives; intact sennosides taken orally are hydrolyzed by colonic microflora, to liberate the active rhein anthrones.

Given the high activity of the gut microflora in various glycosidases, a number of synthetic glycosides were examined as potential colonic delivery systems, in particular corticoids.<sup>66</sup> The same is true for synthetic  $\beta$ -D-glucuronides. Note that glucuronides produced as conjugates ('phase II' metabolites) of drugs and excreted in the bile may also undergo intestinal hydrolysis, resulting in enterohepatic cycling. Hence, it is not surprising that the most promising application of glucuronide prodrugs appears to be in intestinal targeting, for example to treat ulcerative colitis and the irritable bowel syndrome. The same strategy was applied to the colon-specific delivery of corticosteroids used to treat inflammatory bowel disease.<sup>81</sup> Indeed, budesonide- $\beta$ -D-glucuronide and dexamethasone- $\beta$ -D-glucuronide underwent ready hydrolysis in the luminal contents of rat colon and cecum. Rat mucosal homogenates were less active, and hydrolysis in human fecal samples was quite low. Based on these and other studies, the prodrugs were found to be suitable candidates to deliver corticosteroids to the large intestine.

#### 5.44.4.2.2.5 Phosphates and sulfates

A number of phosphate monoesters have been examined as potential prodrugs of active alcohols or phenols, the added phosphate promoiety contributing water solubility and being cleaved with relative ease by enzymatic reactions. A recent example of phosphorylation in prodrug design involves the endocannabinoid noladin ether (**45**,  $R^1 = R^2 = H$ , **Figure 16**). This cannabinoid CB1 receptor agonist reduces intraocular pressure, but its pharmacological profiling and pharmaceutical development are hindered by a poor aqueous solubility. Its mono- and diphosphate esters increased the water solubility of noladin ether more than 40 000-fold. They showed high stability against chemical hydrolysis, yet were rapidly hydrolyzed by alkaline phosphatase and liver homogenates ( $t_{1/2}$  of a few minutes).<sup>82</sup> Hydrolysis in 4% cornea homogenates at 37 °C were also fast ( $t_{1/2}$  of 17–18 min). When tested in vivo in rabbits, the monophosphate ester was very effective in reducing intraocular pressure.

Aryl monophosphates can also be found in the literature, as the phosphorylation of a phenolic group to produce potential prodrugs appears as a strategy of continued interest in medicinal chemistry. For example, the phenolic group of the chemically complex antitumor agent etoposide was monophosphorylated to increase water solubility and chemical stability.<sup>83</sup> After parenteral administration to patients, rapid and quantitative conversion to the parent drug was observed. Besides its pharmaceutical advantages, the prodrug proved to be bioequivalent to etoposide, and its administration resulted in a comparable efficacy.

A note of warning appears appropriate here, since Heimbach and colleagues have shown that a number of phosphate prodrugs may fail to be well absorbed orally due to the liberation (followed by precipitation) of the parent drug by intestinal alkaline phosphatase. Enzyme-mediated precipitation was found to depend on apparent supersaturation ratios, parent drug dose, solubility, and solubilization by the prodrug.<sup>84</sup>

Sulfate esters have but a modest importance as prodrugs, yet a few examples can be found in the literature. Such examples pertain to sulfate esters of phenols and secondary alcohols. A medicinal example is found with 5-ASA *O*-sulfate (**46**, **Figure 16**). As discussed earlier, 5-ASA is an agent for the treatment of ulcerative colitis and Crohn's disease of the large intestine, but it is unstable in the gastric juice. 5-ASA *O*-sulfate was therefore developed as a prodrug able to reach its site of action (the colon) following oral application.<sup>85</sup> In healthy human subjects, the prodrug

**Figure 16** The structure of phosphate (**45**;  $R^1 = \text{phosphate}$ ,  $R^2 = H$ ; or  $R^1 = R^2 = \text{phosphate}$ ) and sulfate ester prodrugs (**46**).

was almost completely metabolized in the colon to the active agent. A high fecal and a low urinary excretion of the active metabolite 5-ASA was observed. Taken together, literature results suggest that sulfate esters can serve as valuable prodrugs for colon-specific delivery, since they avoid absorption in the small intestine and release the active compound by the action of microbial sulfatase in the colon.

#### 5.44.4.2.3 Prodrugs of amines and amides

A number of active amines and amides have shown defects as such poor solubility or poor absorption. As a result, various prodrug strategies have been investigated, several of which are summarized in [Table 6](#).

##### 5.44.4.2.3.1 Amides of active amines

Derivatizing active amines to amides results in loss of basicity and increased lipophilicity. This is may be desirable in some cases, yet it is not a common strategy in the literature, perhaps because amides are inherently more stable than esters toward hydrolases. Yet valuable or promising prodrug amides do exist, particularly having an amino acid or short peptide as promoity.

A fit example of the potential interest of prodrugs of this type is provided by dapsone derivatives presented in [Section 5.44.3.1](#) and [Table 1](#), which as explained were aimed at improving water solubility. An example of targeting a peptide transport system is found in recent carbapenem antibiotics.<sup>86</sup> A series of aminomethyl tetrahydrofuran-1- $\beta$ -methylcarbapenems (**47**, R = H, aminomethyl side-chain in position 2 or 5 ([Figure 17](#))) having excellent in vitro broad-spectrum antibacterial activity exhibited only modest efficacy against acute lethal infections in mice following oral administration. In an effort to improve oral efficacy, a peptide-mediated transport strategy was investigated by substituting the amino group with a variety of amino acids. The peptidic prodrugs containing an L-amino acid were well absorbed and rapidly hydrolyzed, producing high plasmatic levels of the parent drug. Simultaneously, a 3–10-fold increased efficacy was shown by the Ala-, Val-, Ile-, and Phe-substituted prodrugs against acute lethal infections in mice. Median effective doses of  $<1 \text{ mg kg}^{-1}$  against infections caused by *Staphylococcus aureus*, *Escherichia coli*, *Enterobacter cloacae*, or penicillin-susceptible *Streptococcus pneumoniae* were obtained after the administration of single oral doses. In sharp contrast to these results, the D-forms were consistently less active than the parent drug. These results suggested an active absorption process with marked stereoselectivity for the prodrugs prepared from an L-amino acid. This hypothesis is further supported by the fact that the parent drugs demonstrated greater efficacy than the prodrugs following subcutaneous administration.

The oral absorption of an entirely different class of drugs, namely bisphosphonates, has also been improved by a peptide prodrug strategy.<sup>87</sup> The drugs pamidronate (**48**,  $n = 2$ , [Figure 17](#)) and alendronate (**48**,  $n = 3$ ) were derivatized with the Pro-Phe dipeptidyl unit to yield the prodrugs Pro-Phe-pamidronate and Pro-Phe-alendronate (**49**,  $n = 2$  and 3, respectively). The objective of this investigation was to target carrier systems in the intestine, particularly the intestinal peptide carrier system human oligo-peptide carrier for di- and tripeptide (hPEPT1), as well as cytosolic peptidases. In situ single-pass perfusion studies revealed competitive inhibition of transport by Pro-Phe, suggesting

**Table 6** Examples of common and less common carrier groups linked to an amino or amido group in drugs of the type  $\text{RNH}_2$  or  $\text{R}^1\text{R}^2\text{-NH}$  or  $\text{R}^1\text{R}^2\text{R}^3\text{N}$

| Phosphoramidates  | $\text{R}^1\text{R}^2\text{NPO}_3\text{H}_2$  |
| Azo conjugates  | $\text{R}^1\text{-N} = \text{NR}^2$   |

**Figure 17** The structure of various amines, amides and prodrugs thereof.

peptide carrier-mediated transport. Prodrug transport in the Caco-2 cell line was significantly better than that of the parent drugs, and the prodrugs exhibited high affinity to the intestinal tissue. Oral administration of the dipeptidyl prodrugs in rats produced a threefold increase in drug absorption, and the bioavailability of Pro-Phe-alendronate was 2–3 times higher than that of the parent drug. The results indicate that the oral absorption of bisphosphonates can indeed be improved by a peptidyl prodrug strategy targeting hPEPT1 and other transporters.

#### 5.44.4.2.3.2 Carbamates of active amines and amides

Carbamate prodrugs of active phenols and alcohols have been discussed in [Section 5.44.4.2.2.3](#). The same principles operate when an active amine or amide is derivatized to a carbamate prodrug of the general formula  $R^1R^2NCOOR^3$  (*N*-alkyloxycarbonyl derivatives), where  $R^3$  can be an alkyl, arylalkyl, aryl, or a more complex promoiety. Interestingly, this strategy can operate for cyclic amides as well as for amines of strong to weak basicity. A successful example has already been presented earlier in the text, namely capecitabine (**17**, see [Figure 7](#)).

Phenytoin (**50**,  $R = H$ , [Figure 17](#)) is an antiepileptic drug whose poor water solubility and irregular bioavailability justify the development of prodrug forms. The simplest among these are alkylcarbamates. Thus, the ethyl- and isopropyl-*N*3-carbamates (**50**,  $R = -COOEt$  and  $-COOPr^i$ ) were extensively investigated for their pharmacokinetic behavior in rats.<sup>88</sup> The two compounds appeared stable in buffers of pH 2 and 7.4; in rat plasma at 37 °C, they yielded phenytoin with a  $t_{1/2}$  of 2.5 and 4.3 min, respectively. The oral bioavailability of phenytoin increased 8.5- and 6-fold, respectively, after administration of the two prodrugs. Such results, together with the lack of toxicity of the fragments, render these carbamates quite promising.

The derivatization of a basic function is exemplified by the amidine peptidomimetic **51** ( $R^1 = R^2 = H$ , [Figure 17](#)), an antagonist of the platelet membrane glycoprotein GPII<sub>b</sub>III<sub>a</sub> aimed at decreasing thrombotic vascular stenosis and myocardial infarction.<sup>89</sup> The compound is a zwitterion at physiological pH, and showed limited oral bioavailability. A double prodrug approach was examined, with  $R^1 =$  alkyloxycarbonyl and  $R^2 = Et$ . The rates of hydrolysis of the carbamate function in buffers increased only slightly from pH 2 to 7, and then sharply in the alkaline range. In the small series investigated, the rate of hydrolysis increased sharply from  $R^1 = -COOEt$  to  $R^1 = -COSEt$  to  $R^1 = -COO$ -phenyl, that is, with increasing acidity of the leaving group (ethyl  $-OH <$  ethyl  $-SH <$  phenyl  $-OH$ ). These results are of interest since they suggest that the nonenzymatic activation of carbamate prodrugs of basic compounds may be tailored to desired values.

## 5.44.4.2.3.3 Mannich bases

Mannich bases are compounds containing the  $\text{NCH}_2\text{X}$  moiety, where the central carbon atom is rendered electrophilic by two flanking heteroatoms, one of which is nitrogen. Mannich bases examined as potential prodrugs are generally *O*-Mannich bases ( $>\text{NCH}_2\text{OR}$ ) or *N*-Mannich bases ( $>\text{NCH}_2\text{NR}^1\text{R}^2$ ). Such moieties usually undergo rapid nonenzymatic hydrolysis, for example

As shown, the reaction releases formaldehyde. This is an unfavorable feature, given that formaldehyde may be a health hazard, depending on the amounts produced, and on the location and kinetics of its release.

A useful *N*-Mannich base is rolitetraacycline, i.e., *N*-pyrrolidinemethyltetraacycline.<sup>90</sup> This highly water-soluble prodrug of tetracycline is of value for parenteral administration following ex tempore dissolution. The rate of breakdown of the prodrug was found to vary only slightly in the pH range of 1–10. At 21 °C, the limit of stability (10% breakdown) was 1.6 h, whereas the  $t_{1/2}$  at 37 °C and pH 7.4 was 43 min.

*O*-Mannich bases are exemplified by a number of prodrugs of phenytoin.<sup>4</sup> Thus, the 3-(*N,N*-dimethylglycyloxymethyl) and 3-(diethyl- $\beta$ -alanyloxymethyl) derivatives of phenytoin (**50**,  $\text{R} = -\text{CH}_2\text{OCOCH}_2\text{N}(\text{CH}_3)_2$  and  $-\text{CH}_2\text{OCOCH}_2\text{CH}_2\text{N}(\text{CH}_2\text{CH}_3)_2$ , respectively (Figure 17)) appear of interest. At neutral pH, their solubilities were about 4000 and 40 times higher, respectively, than that of phenytoin. The  $t_{1/2}$  values of the conversion to phenytoin in human plasma at pH 7.4 and 37 °C were 23 s and 6.8 min, respectively. After oral administration of the prodrugs to dogs, plasma levels of phenytoin were several times higher than after administration of the drug itself.

A promising approach of broad potential is that of *O*-Mannich prodrugs of tertiary amines. Indeed, a number of poorly water soluble medicinal amines were quaternarized to *N*-phosphonooxymethyl derivatives of the general formula  $\text{R}^1\text{R}^2\text{R}^3\text{N}^+\text{CH}_2\text{OPO}_3\text{H}_2$ .<sup>91</sup> These derivatives showed a considerably increased water solubility over the parent drug, which was regenerated in near-quantitative amounts by alkaline phosphatase-catalyzed dephosphorylation followed by spontaneous breakdown of the *N*-hydroxymethyl intermediate. Shelf life and in vivo studies were also very encouraging.

There exist also Mannich bases with the  $\text{NCH}_2\text{N}$  or  $\text{NCH}_2\text{O}$  fragment enclosed in a five-membered ring. These are exemplified by oxazolidines as potential prodrugs of  $\beta$ -amino alcohols such as  $\beta$ -blockers and ephedrine, and imidazolidin-4-ones as potential prodrugs of peptides.<sup>4</sup>

## 5.44.4.2.3.4 Imines

The literature contains a number of examples of imines (i.e., Schiff bases) of medicinal interest, including prodrugs and drug metabolites. These compounds may undergo metabolic hydrolysis as described below:

Such a reaction is reversible, since the condensation of a carbonyl compound and a primary amine yields the imine under dehydrating conditions. In fact, acidic conditions usually tend to favor hydrolysis, whereas neutral or slightly alkaline conditions will deprotonate the amine, and allow it to behave as a nucleophile toward the carbonyl.<sup>4</sup>

Azomethine prodrugs of (*R*)- $\alpha$ -methylhistamine (**52**, Figure 18) offer an apt illustration on the interest of this approach. (*R*)- $\alpha$ -Methylhistamine (**53**) is a potent and selective histamine  $\text{H}_3$  receptor agonist, but its medicinal use is severely limited by its insufficient peroral absorption, poor brain penetration, and rapid metabolism in humans, especially by histamine *N*-methyltransferase. To circumvent these problems, potential prodrugs were prepared by reacting the drug with variously ring-substituted 2-hydroxybenzophenones.<sup>92</sup> Most compounds proved readily hydrolyzable in aqueous solution, with conversion yields at room temperature ranging from approximately 0.2% to 80% at pH 1, and from 1% to 34% at pH 4. Monohalogenation (i.e.,  $\text{R}^1$  or  $\text{R}^2 = \text{X}$ ) favored hydrolysis, and dihalogenation

**Figure 18** Imine prodrugs (**52**) of (*R*)- $\alpha$ -methylhistamine (**53**), and the structure of the GABA-ergic agent progabide (**54**).

(i.e.,  $R^1$  and  $R^2 = X$ ) increased it further. The majority of the compounds appeared to hydrolyze slightly faster in acidic than in neutral solutions, whereas for others the rates were approximately equal or somewhat faster in neutral solutions.

Following oral administration to mice ( $24 \mu\text{mol kg}^{-1}$ ), the plasma 'area-under-the-curve' concentration (AUC) of (*R*)- $\alpha$ -methylhistamine varied from not detectable (**52**,  $R^1 = 5\text{-OMe}$ ,  $R^2 = \text{H}$ , **Figure 18**) to  $1200 \text{ ng h mL}^{-1}$  (**52**,  $R^1 = 4\text{-F}$ ,  $R^2 = \text{H}$ ). For several of the compounds (e.g.,  $R^1 = \text{H}$ , 4-F or 4-Cl;  $R^2 = \text{H}$ , 4-F or 4-Cl), the plasma AUC was around  $300 \text{ ng h mL}^{-1}$ . Only compounds having the highest plasma AUC produced measurable brain AUC, which varied from about 1% ( $R^1 = 4\text{-F}$ ,  $R^2 = \text{H}$ ) to 22% ( $R^1 = R^2 = 4\text{-Cl}$ ) of the plasma AUC. These pharmacokinetic studies have been complemented by in vivo pharmacological investigations demonstrating anti-inflammatory and antinociceptive properties.<sup>93</sup> Taken together, the results clearly document the potential of this type of prodrugs to improve the pharmacokinetic profile of some primary amines.

The above prodrug candidates show an analogy with the well-known GABA-ergic agent progabide (**54**, **Figure 18**), a brain-penetrating analog or prodrug of the neurotransmitter GABA. Metabolic studies in the rat revealed two hydrolytic reactions. The major one was hydrolysis of the terminal amide group to form the corresponding carboxylic acid, whereas a less important reaction was hydrolysis of the imine link to liberate GABA and gabamide (i.e., the amide of GABA). The detection of GABA and gabamide in the brain of rats dosed with progabide implies slow in situ generation of these active metabolites.<sup>4</sup>

#### 5.44.4.2.3.5 The case of triazenes

*N,N*-Disubstituted triazenes (**55**, **Figure 19**) have been developed as chemically stable triazene prodrugs capable of enzymatic hydrolysis under physiological conditions to liberate a cytotoxic *N*-methyltriazene antitumor agent (**56**). The latter then spontaneously releases the methyldiazonium cation (**57**), which acts by methylating DNA and RNA, most significantly the O-6 position of guanosine residues.

**Figure 19** Mechanisms of activation of *N*-methyl, *N*-acyl, and *N*-acyloxymethyl derivatives (**55**) of *N*-methyltriazenes (**56**), the active antitumor agents which act by releasing the methyldiazonium cation **57**. In some of the cases discussed in the text (e.g., the double prodrug **58**), the aromatic amine released is also active. Compound **59** is the well-known antitumor drug temolozomide.

*N,N*-Dimethyltriazenes (**55**, R = Me, **Figure 19**) can undergo cytochrome P450-catalyzed *N*-dealkylation to *N*-methyltriazenes, but most investigations have focused on *N*-acyl-*N*-methyltriazenes and *N*-acyloxymethyl-*N*-methyltriazenes (**55**, R =  $-\text{COCH}_3$  and  $-\text{CH}_2\text{OCOCH}_3$ ), respectively.<sup>94–96</sup> Such prodrugs were found to hydrolyze in isotonic phosphate buffer and in human plasma. Thus, a  $\beta$ -alanyl derivative (**55**, R =  $-\text{CH}_2\text{CH}_2\text{NH}_2$ , aryl = 4-cyanophenyl) was more stable in phosphate buffer ( $t_{1/2} = 180$  min) than in plasma ( $t_{1/2} = 53$  min).<sup>94</sup> More recent studies report the promising profile of *N*-acyltriazene derivatives of pharmacologically active compounds, in other words, double prodrugs releasing both the methyl diazonium cation and another antitumor agent. This strategy is exemplified by *N*-acyltriazene analogs of the antiresistance drug *O*-benzylguanine,<sup>95</sup> and by compound **58**, which liberates 4-(3'-bromophenylamino)-6-aminoquinazoline, an inhibitor of the epidermal growth factor receptor tyrosine kinase.<sup>96</sup> It thus appears that *N*-acylation or *N*-acyloxymethylation of the triazene terminus is an effective and simple mean of reducing the chemical reactivity of *N*-methyltriazenes while retaining a rapid rate of activation. A look at the structure of the very successful antitumor drug temolozomide (**59**) reveals that it is a cyclized *N*-acyltriazene.

#### 5.44.4.3 Bioprecursors and Bioreductive Agents

As defined above, bioprecursors are prodrugs containing a functional group whose biotransformation generates the active agent without release of any promoity.<sup>1,6,7</sup> As for carrier-linked prodrugs, the bioactivation of bioprecursors can involve a reaction of oxidation, reduction, or hydrolysis/hydration. But while hydrolysis is by far the most frequent mechanism of activation of the carrier-linked prodrugs, a majority of known bioprecursors are activated by reduction. A further difference involves a very few cases of bioprecursors activated by conjugation (e.g., minoxidil sulfate).<sup>97</sup>

##### 5.44.4.3.1 Bioprecursors activated by hydration

Bioprecursors activated by hydrolysis without loss of a promoity imply a lactone ring opening. Here, the term 'hydration' appears preferable to 'hydrolysis,' given that the molecule is not split into two.<sup>4</sup> Some among the successful statins (i.e., HMG-CoA reductase inhibitors) exemplify this case.

Lactone ring hydration unveils the active hydroxy acid, a reaction accompanied by a marked decrease in lipophilicity. An argument of this type would suggest the value of lactone prodrugs in improving bioavailability and/or distribution, but other factors must also be considered, which only complicate any evaluation of the relative pharmacokinetic merits of a lactone prodrug compared with a hydroxy acid drug. The reversibility of lactone hydrolysis has been demonstrated at gastric pH and temperature (pH 2.0, 37 °C); for the prodrug lovastatin (**60**, **Figure 20**), reversible lactone hydrolysis to its active hydroxy acid occurred with an approximate  $t_{1/2}$  of 1 h and an equilibrium constant close to one.<sup>98</sup> Similar results were obtained for some closely related compounds. In contrast, this reversible hydrolysis was much slower under the near-neutral pH conditions of the intestine.

Enzymatic hydration also occurs, in particular by serum paraoxonase. Thus, lovastatin was hydrolyzed at 37 °C in undiluted plasma at rates that were highly species-dependent but seemingly always faster than nonenzymatic hydrolysis (about 0.4% per minute in human plasma, about 0.8% for dogs and monkeys, and about 10% and 50% rats and mice, respectively).<sup>99</sup> In addition to oral absorption and enzymatic hydrolysis, hepatic extraction (passive or active) is also a major factor influencing the therapeutic activity of statins. This organ selectivity, together with the efficiency of enzymatic hydrolysis, does make some lactones useful prodrugs of HMG-CoA reductase inhibitors. However, additional factors may also influence the therapeutic response, in particular the extent and rate of metabolic reactions that compete with or follow hydrolysis, such as cytochrome P450-catalyzed oxidations,  $\beta$ -oxidation, and taurine conjugation.

**60**

**Figure 20** The reversible hydrolytic ring opening of the lactone prodrug lovastatin (**60**) to its active hydroxy acid.

As a result of these various factors, some HMG-CoA reductase inhibitors are used in the lactone prodrug form (e.g., lovastatin, simvastatin, and dalvastatin), while others are used as the active hydroxy acids (e.g., pravastatin and fluvastatin).<sup>4,100</sup>

#### 5.44.4.3.2 Bioprecursors activated by metabolic oxidation

The number of oxidation-activated bioprecursors is limited, and no general rule can be proposed to help in their design. Yet some examples are of high interest, if only for the variety of situations they illustrate. Below, we examine one failure, one success, and one promising case.

A particularly informative, even if all but forgotten, example is provided by ethynylbiphenyl derivatives (**61**, **Figure 21**), investigated as potential bioprecursors of anti-inflammatory biphenylacetic acids. Indeed, it has been known for some decades that ethynylbiphenyl derivatives undergo fast and practically quantitative acetylenic oxidation to the corresponding arylacetic acid, but the detailed mechanism of the metabolic sequence was not fully understood. A few ethynylbiphenyls were thus investigated as potential bioprecursors until severe toxicity problems interrupted their development.<sup>101</sup> Since then, it has been clarified that cytochrome P450-catalyzed oxygenation of the arylethynyl group generates an oxirene that isomerizes to a highly unstable ketene (**62**); the latter in turn reacts with nucleophiles to form adducts, and with water to form the target biphenylacetic acids (**63**).

A therapeutically highly useful example is provided by the biguanide drug proguanil (**64**, **Figure 21**), a major antimalarial agent.<sup>102</sup> Although proguanil might have some specific activities of its own, it is in fact the fortuitous bioprecursor of cycloguanil (**66**). The latter is not useful as a drug, since it shows rather unfavorable pharmacokinetics in contrast to the well-absorbed and well-tolerated proguanil. It is now known that proguanil is a substrate of cytochrome P450 2C19. As shown in **Figure 21**,  $\alpha$ -hydroxylation of the isopropyl substituent yields a carbinolamine intermediate, which *N*-dealkylates to the inactive primary amine **65** (minor route) or cyclizes to cycloguanil by an intramolecular nucleophilic substitution–elimination. Recent studies have taken benefit of this metabolic reaction to design, prepare, and evaluate analogs of proguanil, with promising profiles.<sup>103</sup>

**Figure 21** Examples of bioprecursors activated by metabolic oxidation. Ethynylbiphenyls (**61**) are failed bioprecursors of anti-inflammatory biphenylacetic acids (**63**), due to the intermediate formation of highly toxic ketenes (**62**). Proguanil (**64**) is a fortuitous and well-known bioprecursor of the antimalarial agent cycloguanil (**66**). Hexahydronaphthalen-1-one derivatives (**67**) are promising bioprecursors of dopaminergic catecholamines (**68**).

Our last example in this type of bioprecursor is 6-(*N,N*-disubstituted)-3,4,5,6,7,8-hexahydro-2*H*-naphthalen-1-one derivatives (**67**, [Figure 21](#)).<sup>104</sup> These enones were found to undergo metabolic oxidation and aromatization to the corresponding catechols (**68**). While this metabolic sequence does not appear to have been fully elucidated in terms of intermediates and enzymes, it seems that it begins with 2-hydroxylation followed by aromatization. What has been demonstrated, however, are the in vivo dopaminergic effects of some of these compounds (e.g., with  $R^1 = R^2 = n\text{Pr}$ ;  $R^1 = \text{Me}$ ,  $R^2 = n\text{Pr}$ ;  $R^1 = \text{Et}$ ,  $R^2 = n\text{Pr}$ ) in a rat model of Parkinson's disease.

#### 5.44.4.3.3 Bioprecursors activated by metabolic reduction (bioreductive agents)

Most (but not all) therapeutic applications of bioreductive agents are in the chemical targeting of antitumor agents. Such compounds are also called tumor-activated prodrugs (TAPs), and they belong to a few well-defined chemical classes such as aromatic *N*-oxides, aliphatic *N*-oxides, quinones, nitroaromatics, and metal complexes.<sup>44</sup> Some of these are exemplified below.

The case of *N*-oxides is eloquently illustrated by tirapazamine (**24**, see [Figure 9](#)), and will not be discussed further, except to mention that the utility of such compounds depends on a number of factors such as substrate affinity to one- versus two-electron reductases, redox potential, and cellular permeability.<sup>44,105</sup>

Antitumor nitroaromatic prodrugs are generally used in antibody-directed enzyme prodrug therapy (ADEPT) and gene-directed enzyme prodrug therapy (GDEPT). Also, interesting investigations are also in progress in different therapeutic areas using amidoximes (*N*-hydroxyamidines) as prodrugs of active amidines.<sup>106</sup>

An important class of TAPs is represented by quinones, particularly indolequinones and naphthoquinones, whose prototypal natural compound is the antitumor antibiotic mitomycin C (**69**, [Figure 22](#)). Such compounds undergo bioreductive activation to reduced metabolites, probably hydroquinones, but the mechanism of cytotoxicity of the latter is not fully understood. Oxygen-based radical species generated by the auto-oxidation of these reduced metabolites are prime candidates for the cytotoxicity of quinones.<sup>107</sup>

**Figure 22** Structure of some antitumor bioprecursors activated by reduction. Compounds **69–72** are quinones, and compounds **73** and **75–77** are platinum(IV) complexes. The conversion of **73** to **74** illustrates the reductive bioactivation of platinum(IV) to platinum(II) complexes.

Many studies have focused on the substrate selectivity of potential antitumor quinones in being reduced by DT-diaphorase (NAD(P)H:quinone oxidoreductase, NQO1), an enzyme over-expressed in some tumor types. And, indeed, sufficiently fast reduction by purified NQO1 and in NQO1-rich cells is a criterion of screening. However, bioreduction under hypoxic conditions also appears as a favorable feature. Good substrate selectivity toward NQO1 is exemplified by two compounds of structure **70** in [Figure 22](#) ( $R^1 = -CH_2OH$ ,  $R^2 = H$ ;  $R^1 = H$ ,  $R^2 = -CH=CHCH_2OH$ ). Good capacity to be reduced in hypoxic cells was shown by two compounds of structure **71** ( $R^1 = -CH_2OCONH_2$ ,  $R^2 = iPr$ ;  $R^1 = -CH_2OCONH_2$ ,  $R^2 = cPr$ ).<sup>108</sup> Good in vivo pharmacokinetics such as a relatively long half-life and high AUC values are obviously additional criteria. A promising compound meeting all these criteria was reported as the naphthoquinone **72**.<sup>109</sup>

The last class of TAPs to be presented here are the platinum(IV) complexes.<sup>110</sup> Compared with the traditional platinum(II) complexes, these have a higher lipophilicity and a decreased reactivity, allowing some of them to be administered orally. Efficacy against some platinum(II)-resistant cell lines has also been reported. In fact, several investigations suggest that anticancer activity of platinum(IV) complexes requires bioreduction to the platinum(II) state (see the conversion of **73** to **74** in [Figure 22](#)).<sup>111,112</sup> Platinum(IV) complexes have two axial ligands in addition to the four equatorial ones characteristic of platinum(II) complexes. The axial ligands determine to a large degree the rate at which platinum(IV) complexes are reduced, with chlorine ligands allowing the fastest reduction, and hydroxy groups a slow reduction.

Iproplatin (**73**, [Figure 22](#)), tetraplatin (**75**), and JM216 (**76**) were highly promising candidates in the preclinical phases, but they failed in clinical trials, due to lower activity compared with cisplatin, neurotoxicity, and variable uptake, respectively. Yet active research continues in this field, with, for example, excellent in vitro results being reported for comparatively simple platinum(IV)-ethylenediamine complexes (**77**,  $R = Cl, OH$ ).<sup>112</sup>

#### 5.44.4.4 Principles of Directed Enzyme-Prodrug Therapies (DEPT)

[Sections 5.44.4.2 and 5.44.4.3](#) above contain examples of prodrugs or bioprecursors targeted toward specific tissues and/or enzymes, and whose activation occur selectively around or in the target tissues. Note that prodrugs containing a polymer promoiety also show great promise in this context (see [5.45 Drug-Polymer Conjugates](#)).<sup>113</sup>

Below, we briefly examine prodrug strategies targeting specific enzymes (directed enzyme-prodrug therapies, DEPT). Such strategies fall into a few categories, and by far their most important applications are in antitumor treatment. The first case is the targeting of endogenous enzymes over-expressed by the target tissues. A second case is seen when exogenous enzymes are imported to the target tissues by antibodies (ADEPT). A third case is seen when exogenous enzymes are produced from genes transferred to the tumor cells (GDEPT).

##### 5.44.4.4.1 Targeting of over-expressed enzymes

Enzymes over-expressed in specific tissues allow their targeting by ad hoc designed prodrugs. This strategy offers great promises in tumor therapy and is illustrated here a glucuronide prodrug of doxorubicin, a well-known and highly active cytotoxic agent ([Figure 23](#)). This prodrug is made of the active agent (the 'warhead'), a linker, and glucuronic acid.

To avoid rapid renal and biliary excretion, the methyl ester (DOX-mGA3) was prepared and tested. Its hydrolysis (reaction [1] in [Figure 23](#)) occurred with a  $t_{1/2}$  of 0.5 min and 2.5 h in mouse and human plasma, respectively,<sup>114</sup> strongly suggesting the involvement of carboxylesterases. The glucuronide prodrug so generated (DOX-GA3) is a good substrate of human  $\beta$ -glucuronidase (reaction [2]), liberating  $CO_2$  and the drug linker molecule. The later is unstable, and will undergo a 1,6-elimination process (reaction [3]). This process releases the anthracyclin drug,  $CO_2$ , and iminoquinone methide, which spontaneously hydrates to 4-aminobenzyl alcohol. Incubation of an ovarian cancer cell line with DOX-mGA3 in combination with an excess of human  $\beta$ -glucuronidase resulted in similar growth inhibition to that of doxorubicin. Intravenous administration of DOX-mGA3 to mice resulted in an AUC of DOX-GA3 in tumor and most normal tissues that was 2.5- to 3-fold higher than after the same dose of DOX-GA3 itself. In tumor tissues, this was accompanied by a 2.7-fold increase in the AUC of doxorubicin compared with an administration of DOX-GA3.<sup>114</sup>

##### 5.44.4.4.2 Antibody-directed enzyme prodrug therapies

In the straightforward form of antigen-targeted therapy, a drug is coupled to an antibody raised against tumor cells. Activation occurs by cleavage of the drug-antibody conjugate after its localization on target cells.<sup>59</sup>

ADEPT is different and more complex. Here, an exogenous enzyme is coupled to a monoclonal antibody (mAb) targeted to tumor cells. This enzyme-mAb conjugate is administered, and allowed sufficient time to localize on tumor cells and clear from the circulation. In a second step, a prodrug is administered, which, being a selective substrate of the exogenous enzyme, will be selectively activated at the tumor site. A schematic representation of this strategy is

**Figure 23** The activation pathway of DOX-mGA3, a multiple prodrug of the antitumor agent doxorubicin made of the drug, a linker, and glucuronic acid methyl ester as the pro-promoiety. Following systemic hydrolysis of the methyl ester group (reaction [1]), cleavage of the promo moiety (reaction [2]) is catalyzed by human extracellular  $\beta$ -glucuronidase released in necrotic tumor areas. Spontaneous 1,6-elimination (reaction [3]) then liberates the drug.<sup>114</sup>

shown in **Figure 24**, with the enzyme-mAb conjugate binding selectively to tumor cells and activating the prodrug near their surface.<sup>4,44,58,115,116</sup>

Two relevant examples of ADEPT using carboxypeptidases are presented below. Other peptidases investigated in ADEPT projects include aminopeptidases, human lysosomal  $\beta$ -glucuronidase, and bacterial enzymes such as  $\beta$ -lactamases, penicillin amidases, and nitroreductases.<sup>4</sup>

Carboxypeptidase G2 (EC 3.4.17.11, CPG2, glutamate carboxypeptidase) is a bacterial enzyme unknown in mammalian cells. It has been used with promising success to target cytotoxic alkylating agents to tumor cells.<sup>117,118</sup> In a series of studies, a CPG2-monooclonal antibody conjugate was targeted to a human choriocarcinoma cell line and a human colorectal cell line. The compounds investigated were prodrugs of benzoic acid mustards designed as selective substrates of CPG2, namely 4-(bis(2-chloroethyl)amino)benzoyl-L-glutamic acid (**78**, **Figure 25**) and two analogs. And, indeed, the two tumor cell lines labeled with the CPG2-mAb conjugate effectively activated prodrug **78** to the anticancer agent 4-(bis(2-chloroethyl)amino)benzoic acid (**79**, **Figure 25**), eliciting a strong cytotoxic response. Promising results were obtained in athymic mice with transplanted choriocarcinoma or colorectal xenografts. In a subsequent clinical study, an antibody-directed enzyme prodrug therapy using prodrug **78** met conditions for effective antitumor therapy, and gave evidence of tumor response in colorectal cancer.<sup>117</sup>

Using an exogenous enzyme such as CPG2 is certainly an attractive idea, but it presents the danger of eliciting an immune response in the patient. This is one of the reasons why another approach has been explored, namely the use of artificial mutants of human carboxypeptidases hCPA1 (EC 3.4.17.1) and hCPA2 (EC 3.4.17.15).<sup>119</sup> The drug used was methotrexate (**80**,  $R = H$ , **Figure 25**), an important agent in the treatment of solid malignancies, but one whose lack of cell selectivity is responsible for very serious toxicity to bone marrow and the gastrointestinal tract.

Molecular modeling studies followed by experimental verification had shown that bulky methotrexate prodrugs were good substrates of mutated hCPA1 and hCPA2, having an enlarged substrate-binding pocket obtained by site-directed mutagenesis of Thr268 or Ala268, respectively. Based on these promising results, the cytotoxic efficiency of hCPA1-T286G was tested in an *in vitro* ADEPT model. Here, hCPA1-T286G was chemically conjugated to ING-1 (an antibody that binds to the tumor antigen Ep-Cam) or to Campath-1H (an antibody that binds to the T and B cell

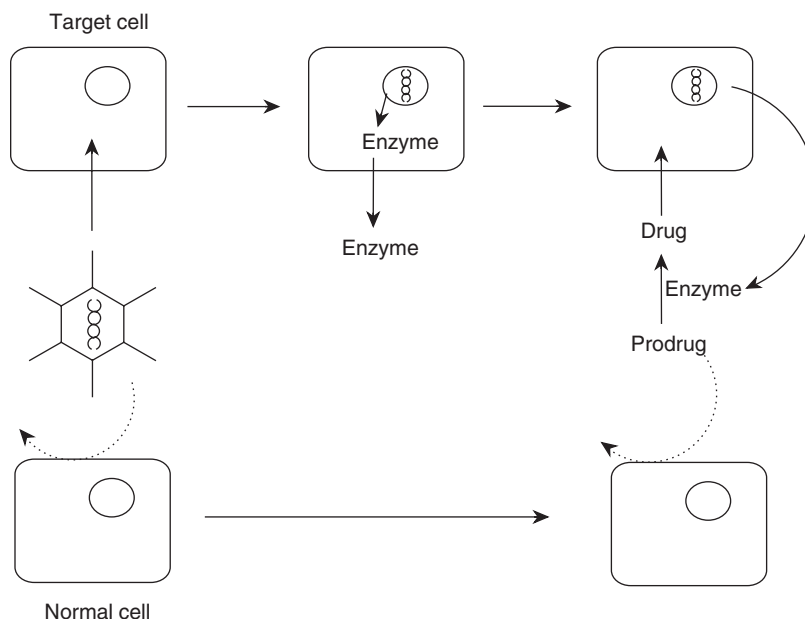

**Figure 24** Schematic representation of a selective delivery obtained by ADEPT. An exogenous enzyme is coupled to the antibody mAb, targeted for tumor cells. In a second step, a prodrug is administered, which, being a selective substrate of the exogenous enzyme, will be selectively activated at the tumor site. (Reproduced from Testa, B.; Mayer, J. M. *Hydrolysis in Drug and Prodrug Metabolism – Chemistry, Biochemistry and Enzymology*; Wiley-Verlag Helvetica Chimica Acta: Zurich, Switzerland, 2003, with permission from Verlag Helvetica Chimica Acta.)

**Figure 25** Examples of prodrugs used in ADEPT and GDEPT and discussed in the text.

antigen CDw52). These conjugates were then incubated with HT-29 human colon adenocarcinoma cells (which express Ep-Cam but not Campath-1H), followed by incubation of the cells with some of the in vivo stable methotrexate prodrugs. As expected, the ING-1:hCPA1-T286G conjugate produced excellent activation of the methotrexate prodrugs to kill HT-29 cells as efficiently as methotrexate itself. In contrast and again as expected, the enzyme–Campath-1H conjugate did not bind to the HT-29 cells (which as stated do not express Campath-1H) and was without effect on the prodrugs.

**Figure 26** Schematic representation of a selective delivery obtained by GDEPT. The gene encoding an exogenous enzyme is transferred to tumor cells, where it is to be expressed. In a second step, a prodrug is administered, which is selectively activated at the tumor site by the exogenous enzyme expressed by the tumor cells. (Reproduced from Testa, B.; Mayer, J. M. *Hydrolysis in Drug and Prodrug Metabolism – Chemistry, Biochemistry and Enzymology*; Wiley-Verlag Helvetica Chimica Acta: Zurich, Switzerland, 2003, with permission from Verlag Helvetica Chimica Acta.)

#### 5.44.4.4.3 Gene-directed enzyme prodrug therapies

In GDEPT, the gene encoding an exogenous enzyme is transferred to tumor cells, where it is to be expressed. Two gene vectors are available, namely viral vectors (virus-directed enzyme prodrug therapy) and non-viral vectors composed of chemical gene delivery agents.<sup>59,116,120</sup> In a second step, a prodrug is administered that is selectively activated by the exogenous enzyme expressed by the tumor cells, as schematized in Figure 26.

As an example, this strategy was also used to activate methotrexate-Phe (**80**, R = Phe, Figure 25) and other methotrexate- $\alpha$ -peptides in the vicinity of tumor cells.<sup>121</sup> Carboxypeptidase A is normally synthesized as a zymogen that is inactive without proteolytic removal of its propeptide end by trypsin. To adapt this system to GDEPT, a mutant form of the enzyme (CPA<sub>ST3</sub>) was engineered. This mutant did not require trypsin-dependent zymogen cleavage but was activated by ubiquitously expressed intracellular propeptidases. All evidence indicated that mature CPA<sub>ST3</sub> was structurally and functionally similar to the trypsin-activated, wild-type enzyme. Furthermore, tumors cells expressing CPA<sub>ST3</sub> were sensitized to the MTX prodrugs in a dose- and time-dependent manner.

To limit diffusion of CPA<sub>ST3</sub>, a cell surface-localized form was generated by constructing a fusion protein between CPA<sub>ST3</sub> and the phosphatidylinositol linkage domain from decay accelerating factor (DAF). After retroviral transduction, both CPA<sub>ST3</sub> and CPA<sub>ST3</sub>-DAF exhibited a potent bystander effect, even when <10% of the cells were transduced, because extracellular production of MTX sensitized both transduced and nontransduced cells.

#### 5.44.4.4.4 Antibody-directed enzyme prodrug therapies and gene-directed enzyme prodrug therapies: concluding remarks

In summary, ADEPT and GDEPT greatly expand the chemical space open to prodrug designers by allowing the use of promoieties and linkers entirely resistant to human enzymes. The activation of potential prodrugs by a promising exogenous enzyme can indeed be optimized computationally and experimentally. In a second stage, the enzyme or its gene is imported into the target tissue. A recent work with novel benzoic acid mustards is mentioned here as a concluding example.<sup>122</sup> A series of polyfluorinated analogs (**81**; X = Cl, Br or I; R<sup>1</sup> and R<sup>2</sup> = F or H; Figure 25) were prepared and screened. The di- and trifluorinated prodrugs were cytotoxic to human breast carcinoma cells (MDA MB361) engineered to express the bacterial CPG2, but were inactive against control cells that did not express the enzyme. Two difluorinated prodrugs (**81**; X = Br or I; R<sup>1</sup> = R<sup>2</sup> = H) were effective substrates for the enzyme, and showed excellent therapeutic activity in CPG2-expressing MDA MB361 xenografts, either curing or greatly extending the life of the animals.

The examples given above may not be the ones ultimately cleared for cancer therapy. They were selected here simply to illustrate the principles of the ADEPT and GDEPT strategies relevant to our context.

#### 5.44.5 Challenges in Prodrug Research and Development

A number of challenges await medicinal chemists and biochemists carrying out prodrug research. These include the additional work involved in synthesis, physicochemical profiling, metabolic and pharmacokinetic profiling, and toxicological assessment.<sup>4,6,8</sup> Such challenges, indeed, may range from fair to prohibitive and can occur at all stages of the R&D process:

- Careful prodrug design is required to minimize the number of proposed candidates and maximize the explored space of physicochemical and pharmacokinetic properties. The ability to predict target properties (e.g., solubility, extent of absorption, and rate of activation) is a major need in rational prodrug design. At present, prodrug designers can rely on some local models or rules to make semiquantitative or even quantitative predictions. This situation should improve in the coming years for the prediction of physicochemical properties, absorption, and distribution, as discussed throughout this volume. In contrast, quantitative predictions of rates of biotransformation remain an elusive goal.
- One or several additional synthetic step(s) are needed for each prodrug candidate being prepared. This implies additional work and effort from chemists, and increased production costs, which may not be considered worthwhile.
- As far as molecular properties are concerned, a first issue is the physicochemical profile of the prodrug candidates and its adequacy with the goals of the project. Some physicochemical properties can be calculated or estimated at the design stage (see above), but experimental verification cannot be omitted. Except for the extra work involved, this is a comparatively straightforward issue.
- A truly critical difficulty is the pharmacokinetic behavior (absorption, distribution, etc.) of prodrug candidates and its adequacy with the goals of the project, first in vitro and ultimately in vivo. High-throughput methods are necessary to rapidly assess the in vitro pharmacokinetic profile of many prodrugs candidates, and to verify or falsify the predictions of the prodrug designers. As with drug candidates, the problem is extrapolation to humans. The danger is real, indeed, that prodrug candidates selected in in vitro pharmacokinetic screening programs may prove disappointing in vivo.
- The truly critical difficulty is the metabolic behavior and, particularly, the rate of activation of prodrug candidates. As discussed elsewhere in this volume (see 5.05 Principles of Drug Metabolism 1: Redox Reactions; 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions; 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues), the huge diversity of drug-metabolizing enzymes and the large interspecies variations that exist make rational optimization of the rate of activation in humans an impossible task. Human liver microsomes have become a common tool in metabolic profiling, but even results so obtained may give a misleading preview of in vivo metabolism. Chemically activated prodrugs may offer the most viable alternative in a few cases.
- Another problem is toxicity relative to the underivatized active agent. By influencing the distribution and tissular concentrations of the active agent they deliver, prodrugs may elicit toxic effects not displayed by the active agent itself. Furthermore, the carrier moiety may generate toxic fragments (e.g., formaldehyde). Additional and careful in vitro (in the presence of activating enzymes) and in vivo toxicological investigations are therefore unavoidable and costly steps in prodrug development, whatever the lack of toxicity of the active agent.

The above problems appear to be the major sources of difficulty in prodrug R&D, not to mention possible complications in registration. No wonder, therefore, that so many medicinal chemists are critical of prodrugs. However, a lucid view cannot ignore the sunny side, in this case the mere existence of a number of successful prodrugs.<sup>2</sup> Several examples have been singled out in this chapter. They demonstrate that prodrug design may indeed achieve satisfy pharmaceutical, pharmacokinetic, and/or pharmacodynamic objectives that would be impossible to achieve otherwise.

#### 5.44.6 Conclusion: What Therapeutic Benefit can Prodrugs Afford?

The gain in therapeutic benefit provided by prodrugs relative to the active agent is a question that knows no general answer. Depending on both the drug and its prodrug, the therapeutic gain may be negligible, modest, marked, or even significant. Nevertheless, a trend is apparent from innumerable data in the literature and when comparing marketed drugs and candidates in R&D.<sup>2,12</sup> In the case of marketed drugs endowed with useful qualities but displaying some

unwanted property that a prodrug form should ameliorate (post hoc design), the therapeutic gain is usually modest yet real, but it will be negligible when the drug defect is tolerable or barely improved by transformation to a prodrug. In contrast, it will be marked or significant when much improved targeting is achieved, as exemplified by capecitabine.

In the case of difficult candidates showing excellent target properties but suffering from some severe and intractable physicochemical and/or pharmacokinetic drawback (e.g., high hydrophilicity restricting bioavailability), ad hoc design may lead to a marked or even significant benefit. Here, indeed, a prodrug form may prove necessary, and its design will be integrated into the iterative process of lead optimization. This is a case aptly illustrated by oseltamivir. In other words, well-designed or even fortuitous (e.g., clopidogrel) prodrugs allow the achievement of medicinal objectives that remain out of reach of the active drug.

In conclusion, a prodrug approach is most fruitful when optimization of a traditional lead candidate fails because the structural conditions for activity (i.e., the pharmacophore) are incompatible with the preset pharmaceutical, pharmacokinetic, or pharmacodynamic properties. In such cases, the gap between activity and other drug-like properties may be of such a nature that only a prodrug strategy can bridge it.<sup>1</sup>

## Biography

**Bernard Testa** studied pharmacy because he was unable to choose between medicine and chemistry. Because he was incapable of working in a community pharmacy, he undertook a PhD thesis on the physicochemistry of drug–macromolecule interactions. Because he felt himself to be not gifted enough for the pharmaceutical industry, he applied for a postdoctoral research position at Chelsea College, University of London, where he worked for 2 years under the supervision of Prof Arnold H Beckett. And because these were easy times, he was called upon to become assistant professor at the University of Lausanne, Switzerland, becoming full professor and Head of Medicinal Chemistry in 1978. Since then, he has tried to repay his debts by fulfilling a number of local and international commitments, e.g., Dean of the Faculty of Sciences (1984–86), Director of the Geneva-Lausanne School of Pharmacy (1994–96 and 1999–2001), and President of the University Senate (1998–2000). He has written four books and edited 29 others, and (co)-authored 450 research and review articles in the fields of drug design and drug metabolism. During the years 1994–98, he was the Editor-Europe of *Pharmaceutical Research*, the flagship journal of the American Association of Pharmaceutical Scientists (AAPS), and he is now the co-editor of the new journal *Chemistry and Biodiversity*. He is also a member of the Editorial Board of several leading journals (e.g., *Biochemical Pharmacology*, *Chirality*, *Drug Metabolism Reviews*, *Helvetica Chimica Acta*, *Journal of Pharmacy and Pharmacology*, *Medicinal Research Reviews*, *Pharmaceutical Research*, and *Xenobiotica*). He holds Honorary Doctorates from the Universities of Milan, Montpellier, and Parma, and was the 2002 recipient of the Nauta Award on Pharmacochimistry given by the European Federation for

Medicinal Chemistry. He was elected a Fellow of the AAPS, and is a member of a number of scientific societies such as the French Academy of Pharmacy, the Royal Academy of Medicine of Belgium, and the American Chemical Society. His recently granted Emeritus status has freed him from administrative duties and gives him more time for writing, editing and collaborating in research projects. His hobbies, interests, and passions include jogging, science fiction, epistemology, teaching, and scientific exploration.

## 5.45 Drug–Polymer Conjugates

### 5.45.1 Introduction

Proteins and peptides have always been seen as potent and specific therapeutic agents, either to rescue the activity of native biomolecules or to treat important diseases like cancer. Insulin and growth hormone are the most well-known examples of the former group,<sup>1–4</sup> while in the latter group some microbial enzymes used as anticancer drugs, such as asparaginase or methioninase,<sup>5,6</sup> have been reported to deplete essential nutrients for cancer cells. Despite the interesting opportunity that these therapeutic agents offer, unfortunately they have intrinsic limitations ascribed to low stability in vivo, a short period of residence in the body, and immunogenicity, the last being common for nonhuman proteins. In the case of low-molecular-weight drugs, a short in vivo half-life (due to rapid clearance by the kidneys or enzyme degradation) is often observed and sometimes there are physicochemical drawbacks, like low solubility or instability.

Several drug delivery systems have been developed in the last few years to improve the pharmacokinetic and pharmacodynamic profiles of many drugs<sup>7</sup> with high or low molecular weight and with different chemical structure. These approaches can be based on tailor-made formulation of the drug, such as liposomal preparation or controlled release formulations, or on a covalent modification of the drug molecule itself, such as polymer conjugation. When modified in this way, the drug can often achieve a prolonged body residence, an increased resistance to degradation, and decreased side effects, and there is generally improved patient compliance. In this chapter we will focus on the area of polymer conjugation to drugs, a technique that is growing fast and that has already resulted in several products available in the marketplace<sup>8</sup> (Table 1).

**Table 1** Several polymer conjugates grouped according to the molecular weights of the conjugated drug

| <i>Conjugates</i>  | <i>Indication</i>   | <i>Year to market or status</i> | <i>Company</i>            |

Many classes of therapeutic agents are amenable to polymer conjugation; however, almost all of the conjugated drugs so far available on the market are proteins, since these were the first to be studied with this technology. A number of different diseases can be treated with conjugated proteins, hence polymer conjugation is not limited to a small number of therapeutic areas. Several compounds produced by conjugation of polymers with nonpeptide drugs with low molecular weight are currently under clinical evaluation and are expected to be on the market in the near future. These are mainly antitumor drugs, as such drugs have the most side effects and limitations that might, at least in part, be solved by polymer conjugation. Recently, this technology has been applied in the field of gene delivery and antisense nucleotides. Polymer conjugation conveys several advantages to drugs (**Table 2**) by deeply changing their *in vitro* and *in vivo* properties. By conjugating drugs with hydrophilic polymers, it is possible to achieve: (1) an increased solubility of the conjugated drug, even for those with very low solubility (e.g., taxol); (2) an enhanced drug bioavailability, which is the result of reduced kidney clearance due to the increased hydrodynamic volume of conjugates; (3) protection from degrading enzymes; (4) prevention or reduction of several drawbacks such as aggregation, immunogenicity, and antigenicity; and (5) specific targeting in organs, tissues, or cells, or exploitation of the ‘enhanced permeability and retention (EPR) effect’ of solid tumor tissues. One limitation of this technology involves patient compliance; conjugates cannot be orally administered because their size prevents absorption through this route, and they have to be parenterally administered.

Research in the field of low-molecular-weight drug–polymer conjugation moved up a gear in the 1950s and 1960s when Peptamin was conjugated to the blood plasma expander polyvinylpyrrolidone.<sup>9</sup> Before then, the research in this area mainly involved the chemistry of conjugation. In the 1960s the first clinical trials of the polymeric anticancer agent divinylethermaleic anhydride/acid copolymer (DIVEMA) were conducted; unfortunately, a severe toxicity was demonstrated, which prevented its use.<sup>10</sup> Since then the concept of a polymer–drug conjugate has been better rationalized<sup>11</sup> and many interesting derivatives have been developed to enhance the activity of various drugs–peptides and proteins in particular, but also molecules such as oligonucleotides or chelating agents for diagnostic purposes.

The first studies on protein–polymer conjugation appeared in the 1960s and 1970s when dextran was investigated as a coupling polymer.<sup>12</sup> However, the real breakthrough came when other synthetic polymers were employed, and poly(ethylene glycol) (PEG) emerged as the best candidate for protein modification.<sup>13</sup> Its superiority is reflected in the fact that there are a number of interesting products already on the market containing PEG, and there are many more in advanced clinical trials (**Table 1**). Other synthetic polymers investigated for polymer conjugation include poly(styrene-co-maleic acid/anhydride) (SMA) and poly(*N*-(2-hydroxypropyl) methacrylamide) copolymers (HPMA), and polyglutamic acid (PGA).

The first application of PEG as a bioconjugation polymer was proposed in the late 1970s by Professor F. Davis and A. Abuchowski at Rutgers University.<sup>31,32</sup> Following his pioneering study a large number of drugs with different structure (proteins, peptides, low-molecular-weight drugs, polynucleotides) have been PEGylated, thus creating a new class of drugs,<sup>13</sup> some of which rapidly became blockbuster products.

The first polymers studied for drug delivery had a linear structure and were composed of one monomer, but polymer chemistry was soon expanded yielding a selection of interesting new structures such as dendrimers,<sup>14–16</sup> dendronized polymers,<sup>17</sup> graft polymers,<sup>18,19</sup> block copolymers,<sup>20</sup> branched polymers,<sup>21</sup> multivalent polymers,<sup>22</sup> stars,<sup>23</sup> and hybrid glycol<sup>24</sup> and peptide derivatives (**Figure 1**).<sup>25</sup>

## 5.45.2 Polymeric Conjugates

### 5.45.2.1 Conjugates with Low-Molecular-Weight Drugs

The term ‘low-molecular-weight drugs’ is used here to describe not only the nonpeptide drugs but also small peptides and oligonucleotides.

**Figure 1** Different polymer structures: (a) dendrimers, (b) dendronized polymers, (c) graft polymers, (d) block copolymers, (e) multivalent polymers, (f) branched polymers, and (g) stars.

An important milestone in the development of these conjugates was the rationalization of the polymeric carrier proposed by Ringsdorf in 1975.<sup>11</sup> According to his model (Figure 2), the drug is linked to a polymeric backbone (biodegradable or not), directly or through a spacer; a targeting residue and eventually a solubilizing group may also be present. The spacer between the polymer and drug may control the release rate or target the release to certain cellular compartments. This may be achieved by the use of spacers cleavable under special conditions, such as acidic medium or lysosomal enzymes. The increased hydrodynamic volume of the conjugate generally extends the blood residence time since the kidney clearance rate is reduced and less frequent administrations are therefore needed. Moreover, hydrophobic drugs can be easily solubilized in water by coupling with hydrophilic polymers, which helps the formulation. The high hydrodynamic volume of the macromolecular carriers offers a passive targeting to solid tumor by the known ‘enhanced permeability and retention (EPR) effect’<sup>26</sup> due to the anatomical and physiological modifications in such tissues, in particular the increased vascular density (the result of highly active angiogenesis), the presence of vessels with both wide fenestrations and lack of smooth muscle layer, and finally a decreased lymphatic drainage. In solid tumor there is also extensive production of vascular mediators, which again leads to increased vascular permeability. The EPR effect can therefore lead to concentrations of a macromolecular carrier in tumor tissue 5–10-fold higher than those in blood plasma, a situation that is difficult to reach with unmodified low-molecular-weight drugs. In addition, the polymeric prodrug can enter cells only through endocytosis,<sup>27,28</sup> a process that is increased in tumor cells, further enhancing drug specificity.<sup>29</sup>

In the last few years active targeting has been receiving great attention for the improvements that may come from a selective therapy toward selected cells, tissues, or organs.<sup>30</sup> An important requirement for drug-polymer conjugates is the absence or limited presence of free drug as impurity (1–2% with respect to the total amount of drug), which otherwise might lead to an overestimation of the conjugate’s potency in a biological evaluation.

**Figure 2** Ringsdorf's small drug-polymer model.

**Figure 3** Protein surface protection offered by conjugated polymer chains.

#### 5.45.2.2 Polymer-Protein Conjugates

Although successful results have been obtained in the clinic using streptokinase or neocarzinostatin conjugates, coupled to oxidized dextran and poly(styrene-co-maleic acid/anhydride), respectively, the research on protein-polymer conjugation really took off following two reports on the modification of bovine serum albumin and bovine liver catalase with PEG.<sup>31,32</sup>

Polymer-protein conjugates have all the benefits described above for low-molecular-weight drug conjugates, but some additional advantages can be achieved, namely the protection of sites of proteolysis and the reduction or prevention of immunogenicity and antigenicity (Figure 3).<sup>33–35</sup> These are the result of the shielding effect of polymer chains on the protein surface, which prevents the approach of other proteins or enzymes by steric hindrance. In general this also influences the activity of conjugated protein, which is lower compared to the native protein in *in vitro* tests, but is more than compensated for *in vivo* thanks to the great improvement of pharmacokinetic parameters.<sup>36,37</sup>

#### 5.45.3 Polymers for Bioconjugation

Many polymers have been investigated as candidates for drug delivery,<sup>38</sup> for example, in the modification of a protein or as a carrier for low-molecular-weight drugs, with linear or branched structures of natural or synthetic origin. These include:

- synthetic polymers: PEG, HPMA copolymers, poly(ethyleneimine) (PEI), poly(acrololmorpholine) (PacM), poly(vinylpyrrolidone) (PVP), polyamidoamines, divinylethermaleic anhydride/acid copolymer (DIVEMA), poly(styrene-co-maleic acid/anhydride) (SMA), polyvinylalcohol (PVA);

- natural polymers: dextran, pullulan, mannan, dextrin, chitosans, hyaluronic acid, proteins; and
- pseudosynthetic polymers: PGA, poly(L-lysine), poly(malic acid), poly(aspartamides), poly((*N*-hydroxyethyl)-L-glutamine) (PHEG).

A short description is given below of most of these polymers because of their limited application, while PEG is described in more detail.

### 5.45.3.1 Vinyl Polymers

These polymers are prepared by radical polymerization of the respective vinyl monomer or by copolymerization of two or more different monomers, to modulate the properties of the final product. Copolymerization in fact allows a tailor-made polymer that is better at responding to the specific requirements of drug delivery to be designed. This kind of carrier can reach high levels of drug loading since, in theory, it is possible to prepare a polymer in which each monomer can carry a drug molecule. Vinyl polymers are not biodegradable and therefore must be limited in size to allow body clearance, mainly by kidney filtration, thus avoiding accumulation in the body. Usually, their molecular weight needs to be below the limit for renal filtration (40–50 kDa). Among all synthesized vinyl polymers, HPMA emerged as the best candidate and led to a number of important conjugates.<sup>39–41</sup> The most studied HPMA conjugate is its derivative with the antitumor agent doxorubicin (FCE28068). The drug was linked to the polymeric backbone through a peptidyl spacer (Gly-Phe-Leu-Gly) specifically designed to be cleaved by lysosomal cathepsin B,<sup>42</sup> yielding a conjugate known as PK1 (Figure 4a).<sup>43</sup> PK1 was optimized to have certain features such as: (1) a molecular weight of 30 000 Da to ensure body clearance and, at the same time, to allow tumor targeting<sup>44</sup>; (2) a spacer sequence that was selected to be stable in plasma, but promptly released in lysosomes; and (3) an amount of bound drug ( $\sim 8.5$  wt%) was required to reach therapeutic concentration in tumor cells.

From the PK1 studies the PK2 conjugate was produced (FC28069, Figure 4b), which, like the pure drug, possesses an *N*-acylated galactosamine residue as the targeting group.<sup>45</sup> This molecule conveys targeting to the liver thanks to its interaction with hepatocyte asialoglycoprotein receptors. PK2 has a molecular weight of 25 000 Da, a doxorubicin content of  $\sim 7.5$  wt%, and a galactosamine content of  $\sim 1.5$ – $2$  wt%. PK1 reached phase II clinical trials for the treatment of breast, colon, and small-cell lung cancer, and it was the first HPMA conjugate to be administered to patients.<sup>46,47</sup> PK2 was the first targeted polymer to enter clinical trials, and it was used for the treatment of primary and secondary liver cancer.<sup>48</sup> PK1 and PK2 showed a two- to five-fold reduction in anthracycline toxicity, and despite the high cumulative doses of doxorubicin administered, no cardiotoxicity was observed.

HPMA copolymer was studied as a potential carrier for two other anticancer drugs apart from anthracyclines, namely, camptothecin (MAG-CPT<sup>49</sup>; Figure 4c) and paclitaxel (PNU166945<sup>50</sup>; Figure 4d). Both these drugs suffer from low solubility in water; polymer conjugation provides a solution to this problem while allowing the EPR effect for solid tumor targeting to be exploited. Camptothecin is linked to HPMA copolymer through a H-Gly-NH-(CH<sub>2</sub>)<sub>6</sub>-NH-Gly-OH spacer that forms an ester linkage with the C-20 hydroxyl group of the drug. The conjugate has a molecular weight ranging from 20 000 to 30 000 Da depending on the drug loading (5–10 wt%). Paclitaxel, on the other hand, is conjugated at the level of the C-2 hydroxyl group (drug loading  $\sim 5$  wt%) by an ester bond with the spacer Gly-Phe-Leu-Gly. The drug solubility in water is increased from  $0.0001$  mg mL<sup>-1</sup> of the free drug to  $2$  mg mL<sup>-1</sup> of the conjugate. Both HPMA conjugates entered phase I clinical trials, but the results indicated the need for optimization of the derivatives' design, in particular regarding the stability of the linkage between the polymer and the drugs (ester) and the drug loading. In this case, the products showed the toxicity of the respective free drugs due to the rapid hydrolysis of the ester bond. Another intensively studied and promising conjugate is the HPMA-platinate conjugate (AP5280, Access Pharmaceuticals, Figure 4e), where the metal is chelated by a malonate molecule, which is linked to a 25 000 Da HPMA chain by a Gly-Phe-Leu-Gly spacer. The loading of platinum is about 7 wt%. To be effective platinum has to be released from the conjugate and the malonate derivatives showed the best rate of hydrolysis. The conjugate has now entered phase II clinical trials.<sup>51,52</sup>

Many studies were carried out to investigate the potential toxicity of the HPMA copolymer alone or as a conjugate. For example, it was found that PK1 could be administered in clinical trials up to cumulative doses of  $>20$  g<sup>-2</sup> without problems of immunogenicity or toxicity.<sup>46,53,54</sup>

### 5.45.3.2 Poly(Amino Acids) and Analogs

PGA, poly(L-lysine), poly(aspartamides), poly(*N*-hydroxyethyl-L-glutamine) (PHEG), are easily synthesized and possess a peptidyl structure. They are biodegradable when obtained from the natural L-amino acids but are not if

**Figure 4** Several polymer conjugates of low-molecular-weight drugs: (a) HPMA copolymer-doxorubicin (PK1; FCE28068), (b) HPMA copolymer-doxorubicin-galactosamine (PK2; FCE28069), (c) HPMA copolymer-camptothecin (MAG-CPT; PNU166148), (d) HPMA copolymer-paclitaxel (PNU166945), (e) HPMA copolymer-platinite (AP5280), (f) polyglutamate-paclitaxel (XYOTAX; CT-2103), and (g) PEG-camptothecin (PROTHECAN).

**Figure 4** Continued

prepared from the D-enantiomers. The drug loading of these polymers, similarly to HPMa, is high since any monomer possesses a side reactive group (amine, carboxyl, or hydroxyl) that can be derivatized for drug coupling.

Of this class of polymers, the conjugate PGA-paclitaxel (CT-2103, XYOTAX,<sup>55–58</sup> Figure 4f) from Cell Therapeutics is at the most advanced clinical stage (phase II/III). In this case, a PGA with ~40 000 Da molecular weight was linked to paclitaxel through an ester bond reaching a loading of ~37 wt%. An interesting property of this polymer is its biodegradability by cathepsin B to form glutamyl-paclitaxel.<sup>59</sup> In early trials it was administered every 3 weeks in the treatment of mesothelioma, renal cell carcinoma, nonsmall cell lung cancer, and a paclitaxel-resistant ovarian cancer disease. A significant number of patients with partial response or stabilized disease was observed. Phase II confirmed its efficacy in patients with recurrent ovarian cancer, but in this case the conjugate displayed a more frequent neurotoxicity than predicted from phase I trials, probably related to the fact that the patients were heavily pretreated with platinates. Further investigations are ongoing.<sup>60</sup> PGA was also conjugated to camptothecin through an ester bond leading to the product CT-2106 (Cell Therapeutics) containing 33–35 wt% of drug and a molecular weight of 50 000 Da. The conjugate has entered a phase I trial.<sup>61</sup>

### 5.45.3.3 Polysaccharides

Several polysaccharides have been used in pharmaceutical applications. In terms of pharmacokinetics of the carriers themselves, molecular weight, electric charge, chemical modifications, and degree of polydispersity and/or branching largely determine their fate in vivo. Generally, large molecular weight (> 40 kDa) polysaccharides have low clearance and relatively long plasma half-life, resulting in reticuloendothelial or tumor tissue accumulation. As with other

macromolecular carriers the tumor accumulation is due to the EPR effect, but through the additional linking to the polymer of targeting molecules it is possible to reach specific cells. The most important application as polymeric carrier has been for the preparation of macromolecular prodrugs that are inactive as such, but after release of the free drug at the site of interest they perform their action.<sup>62</sup> Polysaccharides have also been used in the preparation of protein conjugates that, while still maintaining the activity of the starting proteins, increase the duration of effect and decrease the immunogenicity.<sup>62</sup>

The most commonly used polymer of this class was dextran<sup>38</sup> (mainly 1,6 poly  $\alpha$ -D-glucose with some 1,4 branching links), which was first approved as a plasma expander. Its conjugate with doxorubicin (AD-70; mol.wt. dextran  $\sim 70\,000$  Da) entered phase I clinical trials, but displayed a toxicity attributed to uptake of dextran by the liver reticuloendothelial cells.<sup>63</sup> Dextran was also used as a carrier of proteins, in particular to improve the pharmacokinetics. The most important results were obtained with streptokinase (Streptodekase),<sup>64</sup> but superoxide dismutase was also studied.<sup>65</sup> For the coupling the polymer was oxidized by periodate yielding aldehyde groups that in turn were reacted with protein amino groups, mainly from lysines. This method, however, was abandoned due to the fact that the multiplicity of binding groups in the polymer might yield to undesirable cross-linking in the reaction with the protein, beyond the high heterogeneity of the products.

### 5.45.3.4 Proteins

Among all proteins, albumin and transferrin are the most studied as macromolecular carriers. Although the tissue distribution of these proteins is influenced by their functional role in the body, a series of investigations have shown that the anatomical and physiological characteristics of tumors can promote, by the EPR effect, the uptake in these tissues of drugs conjugated to serum proteins. Antitumor and antiviral agents have been conjugated to serum proteins and early clinical trials have been performed with transferrin conjugates of cisplatin and doxorubicin,<sup>66</sup> with adenine arabinoside monophosphate conjugated to lactosaminated albumin,<sup>67</sup> and with methotrexate bound to albumin.<sup>68</sup> Clinical trials with an albumin-doxorubicin prodrug and a long-acting opioid component are under way.<sup>69</sup> A limitation for the use of proteins is their structural complexity with several groups having different functionalities (amino, carboxylic, hydroxyl, and thiol groups). This may be an advantage where they are linked to simple drugs, since high loading is possible, but it also presents a great problem when conjugating to peptides or proteins, since the presence of many reactive sites may lead to cross-linking and heterogeneous products. The use of albumin as a carrier of therapeutic proteins was exploited 20 years ago with good results being achieved in the case of superoxide dismutase.<sup>70</sup>

However, in the case of albumin, it is possible to overcome the problem of the reactive group multiplicity by exploiting the lone thiol group,<sup>71</sup> which can react with specific thiol-reactive molecules. Thanks to the great potential of genetic engineering it is now possible to obtain the desired protein or peptide fused with albumin,<sup>72</sup> avoiding the risks of cross-linking.

### 5.45.3.5 Poly(Styrene-co-Maleic Acid/Anhydride)

The protein neocarzinostatin (NCS), which exhibits cytotoxicity against mammalian cells and Gram-positive bacteria at concentrations as low as  $0.01\,\mu\text{g mL}^{-1}$ , was conjugated to SMA: two small polymer chains (1.6 kDa) were linked to the amino group of Lys-20 and Ala-1. The conjugate, named SMANCS, showed a half-life 10–20 times higher than the native protein and by the EPR effect the accumulation in tumor was 30-fold that of muscle.<sup>73</sup> Thanks to its increased hydrophobicity, SMANCS can be solubilized in lipid media such as Lipiodol and administered intra-arterially for treatment of tumors. The derivative was marketed in Japan in 1993 (Zinostatin Stimalamer) for the treatment of hepatocellular carcinoma.<sup>74</sup> SMA conjugation, however, did not become a general method for protein coupling because, like dextran and HPMA, it possesses many sites of attachment along the polymer backbone, which can give rise to complex mixtures of products.

### 5.45.3.6 Poly(Ethylene Glycol)

As a modifying polymer PEG has the benefit of three decades of studies littered with important milestones, which has already resulted in seven products on the market (Table 1). This polymer is chosen for: (1) the lack of immunogenicity, antigenicity, and toxicity; (2) its high solubility in water and in many organic solvents; (3) the high hydration and flexibility of the chain, at the basis of the protein rejection properties; and (4) its approval by the FDA for human use. PEG is synthesized by ring opening polymerization of ethylene oxide. The reaction, which is initiated by methanol or water, gives polymers with one or two end chain hydroxyl groups termed monomethoxy-PEG (mPEG-OH)

or diol PEG (HO-PEG-OH), respectively. The polymerization process produces a family of PEG molecules with a wide range of molecular weights. In this form PEG is not suitable for use in drug conjugation, although it is largely employed in pharmaceutical technology as excipient. As with any polymer, the biological properties of PEG, such as kidney excretion or protein surface coverage, are based on its size, so it is necessary to use samples that are as homogeneous as possible. Fractionation techniques (e.g., gel filtration chromatography) need to achieve narrow polydispersity and must also exclude the presence of the diol form (formed from traces of water in the polymerization reaction) as an impurity in monomethoxy PEG batches. A wide series of activated PEGs have been developed to address different chemical groups in the drugs. Furthermore, PEGs with various shapes (branched, multifunctional, or heterobifunctional) are now available. Monofunctional polymers (mPEG-OH), linear or branched, are most suitable for protein modification since the diol or multifunctional polymers can give rise to cross-linking. Those with multiple reactive groups on the chain are useful to obtain an increased drug to polymer ratio. Increased loading is particularly needed in therapeutic agents with low biological activity, which would otherwise require the administration of a large amount of conjugate with consequent high viscosity of the solution.

The optimization of both the polymerization procedure and the purification process is now allowing the preparation of PEGs with low polydispersity,  $M_w/M_n$  ranging from 1.01 for PEG with molecular weights below 5 kDa to 1.1 for PEG as big as 50 kDa.

PEG has unique solvation properties that are due to the coordination of 2–3 water molecules per ethylene oxide unit.<sup>75</sup> This, together with the great flexibility of the molecule backbone, is responsible for the biocompatibility, nonimmunogenicity, and nonantigenicity of the polymer;<sup>31</sup> it also possesses an apparent molecular weight 5–10 times higher than that of a globular protein of comparable mass, as verified by gel permeation chromatography.<sup>76</sup> Owing to this large hydrodynamic volume, a single PEG molecule covers a large area of the surface of the conjugated protein, preventing the approach of proteolytic enzymes and antibodies.<sup>77–79</sup>

In vivo PEG undergoes limited chemical degradation and the body clearance depends upon its molecular weight: below 20 kDa it is easily secreted into the urine, while higher molecular weight PEGs are eliminated more slowly and the clearance through liver becomes predominant. The threshold for kidney filtration is about 40–60 kDa (a hydrodynamic radius of approximately 45 Å<sup>80</sup>), which represents the albumin excretion limit. Over this limit the polymer remains in circulation and mainly accumulates in liver. Alcohol dehydrogenase can degrade low-molecular-weight PEGs, and chain cleavage can be catalyzed by cytochrome P450 microsomal enzymes.<sup>81</sup> Some branched PEGs may also undergo a molecular weight reduction when the hydrolysis and loss of one polymer chain is catalyzed by anchimeric assistance.<sup>82</sup> However, regarding safety concerns when choosing the PEG's molecular weight in the design of a new drug-polymer conjugate 'it is commonly accepted to use PEGs below 40 kDa' to avoid accumulation in the body. This is the molecular weight employed in two successful products, Pegasys and Macugen (Table 1) belonging to the PEG-protein and PEG-small drug conjugate classes, respectively. Finally, several years of PEG use as an excipient in foods, cosmetics, and pharmaceuticals, without toxic effects, is clear proof of its safety.<sup>76</sup>

The first generation of PEG conjugates was based on low-molecular-weight polymers ( $\leq 12$  kDa), most commonly in their linear monomethoxylated form (mPEG). Batches of this polymer often contained a significant percentage of PEG diol, an impurity that, once activated, could act as a potential cross-linking agent. Furthermore, the chemistry employed in mPEG synthesis often resulted in side reaction products or led to weak and reversible linkages. The drugs PEG-adenosine deaminase (Adagen)<sup>83</sup> and PEG-asparaginase (Oncaspar)<sup>84</sup> belong to this generation of PEG conjugates.

The second generation of PEGs is characterized by improved polymer purity (reduction of both polydispersity and diol content for high-molecular-weight PEGs) and by a wide selection of activated PEGs that allow selectivity of reaction toward different protein sites. The availability of several new PEGs is now widening the opportunities in PEGylation technology. Second-generation PEGs currently on the market include:

- PEG-propionaldehyde, also in the form of the more stable acetal: the reaction with the amino group leads to a Schiff's base that, once reduced by sodium borohydride, yields a stable secondary amine that maintains the same net charge of the parent drug.
- Several PEG-succinimidyl derivatives: highly reactive toward amino groups. The reaction rate of these derivatives may significantly change depending upon the length and the composition of the alkyl chain between PEG and the succinimidyl moiety.<sup>85</sup>
- 'Y' shaped branched PEG<sup>86</sup> (see Figure 1f): provides a higher surface shielding effect and is more effective in protecting the conjugated protein from proteolytic enzymes and antibodies (Figure 5). Moreover, proteins modified with this PEG retain higher activity than the same enzyme modified by linear PEGs. This effect is probably due to the branched polymer that prevents the PEG from entering the enzyme active site cleft or other sites involved in biological activity (Figure 6).

- PEGs reactive toward thiol groups: PEG-maleimide (MAL-PEG), PEG-vinylsulfone (VS-PEG), PEG-iodoacetamide (IA-PEG), and PEG-orthopyridyl-disulfide (OPSS-PEG) have been specifically developed for this conjugation, but only the last one strictly reacts with the thiol groups, avoiding any amino modification that might occur with the other three (Figure 7).
- Heterobifunctional PEGs<sup>87,88</sup>: these derivatives have different reactive groups at the two polymer ends that allow two different molecules to be linked separately to the same PEG chain. It is therefore possible to obtain conjugates that carry both a drug and a targeting molecule. Among the proposed and commercially available heterobifunctional PEGs, the most commonly used are H<sub>2</sub>N-PEG-COOH, HO-PEG-COOH, and H<sub>2</sub>N-PEG-OH.
- Multiarm or 'dendronized' PEGs (Figure 1b and g): the former are prepared by linking a linear PEG to a multimeric compound, whereas the latter are linear PEGs with a dendritic structure at one or both chain ends.<sup>89,90</sup> The aim of both derivatives is to increase the drug/polymer molar ratio, overcoming problems of high viscosity that may occur with solutions of monofunctional drug-polymer conjugates. This is particularly true for drugs that require a high amount of product for the therapeutic treatments.

Most of these PEGs, also in the activated form, are now commercially available.

**Figure 5** Shielding effect of different PEG structures – linear and branched. The higher steric hindrance of branched PEG compared with linear PEG explains its enhanced capacity to reject the approach of other proteins (e.g., degrading enzymes) or cells. (Reproduced with permission from Pasut, G.; Guiotto, A.; Veronese, F. M. *Exp. Op. Ther. Patents* **2004**, 14, 859–894.)

**Figure 6** Effect of PEG hindrance on the enzyme active site access. The high steric hindrance of branched PEG, which makes it difficult for the active site cleft to be accessed, may explain the lower inactivation of enzymes as compared to linear PEG of the same size. (Reproduced with permission from Pasut, G.; Guiotto, A.; Veronese, F. M. *Exp. Op. Ther. Patents* **2004**, 14, 859–894.)

**Figure 7** Examples of activated PEG molecules reactive toward thiol groups: (a) PEG maleimide, (b) PEG orthopyridyl-disulfide, (c) PEG iodoacetamide, and (d) PEG vinylsulfone.

Several protein bioconjugates derived from this second generation of PEGs have reached the market, such as linear PEG-interferon  $\alpha$ -2b (PEG-Intron),<sup>91</sup> branched PEG-interferon  $\alpha$ -2a (Pegasys),<sup>36,92</sup> PEG-growth hormone receptor antagonist (Pegvisomant, Somavert),<sup>93</sup> and PEG-granulocyte colony stimulating factor (G-CSF) (pegfilgrastim, Neulasta).<sup>94</sup> More recently also a PEG conjugate of a 24-mer oligonucleotide, a branched PEG-anti-VEGF aptamer (pegaptanib sodium injection, Macugen)<sup>95</sup> is also marketed, while many other peptide, protein, and oligonucleotides products are under clinical trials and hopefully will be available in the near future.

In PEGylation of low-molecular-weight drugs, PEG faces the limit of low drug loading since in its standard form the polymer can be derivatized only at the two chain extremes. However, several derivatives have been prepared and the most advanced is the PEG-camptothecin conjugate (PROTHECAN or Pegamotecan, Enzon), obtained by linking two drug molecules (using C-20 hydroxyl group) at the termini of a 40 000 Da polymer chain (Figure 4g). The drug loading corresponds to 1.7 wt%, which is rather low if compared with other multivalent polymers (i.e., PGA, HPMA copolymers). The product passed phase I trials<sup>96</sup>; the maximum tolerated dose is 100 mg m<sup>-2</sup> (camptothecin equivalent) and the recommended dose for phase II studies is 7000 mg m<sup>-2</sup> administered for 1 h i.v. every 3 weeks. Phase II studies are ongoing and preliminary data shows Pegamotecan to be a promising treatment for adenocarcinoma of the stomach and gastroesophageal (GE) junction. The conjugate appears to be well tolerated, with a low incidence of toxicities. Grade 2 cystitis, a known toxicity of camptothecin, was observed in 2 out of 15 patients.<sup>97</sup>

PEG-camptothecin conjugates with tri- or tetrapeptide linkers, to exploit the drug release inside the cell only, have been shown to be highly stable in plasma but rapidly hydrolyze in the presence of lysosomal enzyme cathepsin B.<sup>98,99</sup> In vitro and in vivo results are encouraging and indicate that the polymer bound camptothecin derivative SN-392 (10-amino-7-ethyl camptothecin) is less toxic than the free drug and the camptothecin analog CPT-11, but is still highly effective against Meth A fibrosarcoma cell lines. From pharmacokinetic studies it was immediately evident that the maximal plasma concentration ( $C_{\max}$ ) after administration of 10-amino-7-ethyl camptothecin is eightfold higher than that after PEG-SN392 injection, although AUC data are comparable. The mean residence time (MRT, a dose-independent measure of drug elimination expressing the average time a drug molecule remains in the body after intravenous injection) after PEG-peptide-camptothecin injection is threefold higher than that after injection of both forms of 10-amino-7-ethyl camptothecin. The data indicate that the conjugate acts as a circulating reservoir of the antitumor agents, since the conjugate itself it is not active until it enters the cells and the drug is released, by lysosomal enzymes, to exploit its action. This method of release, often employed for antitumor drugs, is discussed further in Section 5.45.5.

An interesting study reports the preparation of PEG-doxorubicin conjugates where several parameters, such as polymer molecular weight (5 000–20 000 Da), the structure of PEG (linear or branched), and the sequence of a peptide linker between drug and carrier (i.e., H-GFLG-OH, H-GLFG-OH, H-GLG-OH, H-GGRR-OH, or H-RGLG-OH),

were taken into consideration.<sup>100</sup> Surprisingly, the conjugate with the greatest antitumor activity in rats had the lowest molecular weight PEG (mPEG<sub>5000</sub>-GFLF-doxorubicin). Apparently, this contradicts the need to have conjugates with molecular weights above 20–30 kDa for a blood residence time long enough to allow accumulation in tumors by the EPR effect. It was demonstrated by light scattering that this low-molecular-weight PEG-doxorubicin conjugate forms micelles in solution, and consequently its apparent molecular weight rises to 120 000 Da, which ensures an effective EPR effect and explains the antitumor activity.

Enzon researchers also studied the preparation and optimization of PEG-paclitaxel conjugates using several PEG molecular weights.<sup>101</sup> In this case, the authors reported the importance of a molecular weight  $\geq 30$  kDa in order to prevent rapid elimination of the conjugates by the kidneys. A PEG derivative of this drug entered phase I clinical trials and preliminary data are encouraging; however, neutropenia, as with the free drug, is a predominant hematological toxicity.<sup>102</sup>

#### 5.45.4 Considerations for PEGylation

To obtain conjugates with improved pharmacological properties several parameters of the polymer must be taken into consideration. In PEGylation the mass of the PEG chain and the binding site on the protein or drug are important parameters to be considered, as well as the chemistry of linkage and the use of a proper spacer. In the modification of proteins it is better to use few high-molecular-weight chains than a higher number of low-molecular-weight ones. A multipoint attachment of PEG or the use of too large a PEG is expected to reduce or prevent a protein's bioactivity by interfering with receptor binding; however, a low total mass of bound PEG cannot ensure protection from degradation and results in poor pharmacokinetic profiles. The effect of both number and mass of linked PEG chains on recognition and pharmacokinetic parameters are well documented in the literature.<sup>103,104</sup> The site of PEGylation is also critical since when this resides in, or close to, the protein recognition area or active site of enzymes, the polymer affects the biological activity. Furthermore, the modification of certain residues may cause conformational changes ending in denaturation or exposure of buried amino acids, which may lead to aggregation or facilitate proteolytic degradation.

#### 5.45.5 Controlled Release of Conjugated Proteins or Drugs

In general, with nonprotein drugs a stable bond between the polymer and drug is not convenient since many molecules exploit their activity only in the free form. A chemical bond that releases the native molecule is therefore welcome, especially if the release can be triggered under specific controlled conditions. The polymeric prodrug of antitumor agents or substances that possess systemic toxicity should be stable in the bloodstream, but release the drug from the carrier in the desired tissue or cell. The only way to obtain such controlled release is by the use of a proper spacer or linkage between drug and polymer that can be hydrolytically or enzymatically cleaved. Examples of how to achieve a prompt or retarded release of conjugated drugs include:

- Linkers that respond to pH changes.<sup>105</sup> Following cell internalization by endocytosis the conjugates are exposed to the acidic pH of endosomes and lysosomes; furthermore, the pH of tumor tissue is slightly more acidic than that of healthy tissues.<sup>106</sup> This situation can be exploited using acid-labile spacers, such as *N*-*cis*-aconityl acid, which was the first approach used to reversibly link daunorubicin to aminoethyl polyacrylamide or poly(D-lysine).<sup>107</sup> In this case a prompt drug release was evident at pH 4 or lower, while in blood or at pH 6 the linker was stable. A hydrazon linkage can also take advantage of the fact that a low pH is needed to free the drug; this linker was exploited in several conjugates to release adriamycin<sup>108</sup> or streptomycin<sup>109</sup> from the carrier.
- Exploitation of lysosomal enzymes. In this case the macromolecular carriers enter the cell by endocytosis and the newly formed endosome fuses with the lysosome, exposing the polymer–drug to a series of degrading enzymes. A spacer (usually an oligopeptide) that is specifically designed to be cleaved by the lysosomal enzymes allows a lysosomotropic drug delivery. This strategy also takes advantage of the fact that lysosomes are overexpressed in tumor cells where cathepsins B or D and other metalloproteinases play a role in tumor growth. Examples of such oligopeptide linkers include those studied by Duncan and Kopecek for optimization of PK1; among these H-Gly-Phe-Leu-Gly-OH and H-Gly-Leu-Phe-Gly-OH appear to be the most effective.<sup>42,110</sup>
- Drug release by anchimeric-assisted hydrolysis. This sophisticated strategy uses linkers that are designed to form a double prodrug system. The drug-linker is first released from the polymer by hydrolysis (first prodrug), which triggers the linker (second prodrug) that finally releases the free and active drug. Examples of these double drug delivery systems include the 1,6-elimination reaction or trimethyl lock lactonization (Figure 8).<sup>111,112</sup>

**Figure 8** Controlled release of active molecules from PEG based on the (a) 1,6-elimination system and (b) trimethyl lock lactonization system.

### 5.45.6 PEGylation Chemistry for Proteins

To appreciate the potential of PEGylation in drug delivery, it is important to understand the chemistry involved in the linking. A brief description is given below.

#### 5.45.6.1 Amino Group PEGylation

PEGylation at the level of protein amino groups may be carried out with PEGs having different reactive groups at the end of the chain and often, although the coupling reaction is based on the same chemistry (for instance acylation), the obtained products are different. The difference may reside in the number of PEG chains linked per protein molecule, in the amino acids involved, and in the chemical bond between PEG and drug. The most common methods for random PEGylation are reported here, while procedures for site-direct modification will be discussed later.

Products available on the market so far mainly come from random PEGylation (Adagen, Oncaspar, PEG-Intron, and Pegasys) since Food and Drug Administration (FDA) authorities approve these conjugate mixtures upon demonstration of their reproducibility. The activated PEG for amino linking can be chosen from a range of commercially available polymers, the most common being PEG succinimidyl succinate (SS-PEG), PEG succinimidyl carbonate (SC-PEG), PEG *p*-nitrophenyl carbonate (pNPC-PEG), PEG benzotriazolyl carbonate (BTC-PEG), PEG trichlorophenyl carbonate (TCP-PEG), PEG carbonyldiimidazole (CDI-PEG), PEG tresylate, PEG dichlorotriazine, PEG aldehyde (AL-PEG), and a branched form of PEG (PEG<sub>2</sub>-COOH) (Figure 9).

The difference between these PEGs lies in the kinetic rate of amino coupling and in the resulting link between polymer and drug. The derivatives with slower reactivity, such as the carbonate PEGs (pNPC-PEG, CDI-PEG, and

**Figure 9** Examples of activated PEG molecules reactive toward amino groups: (a) PEG succinimidyl succinate, (b) PEG succinimidyl carbonate, (c) PEG *p*-nitrophenyl carbonate, (d) PEG benzotriazol carbonate, (e) PEG trichlorophenyl carbonate, (f) PEG carbonylimidazole, (g) PEG tresylate, and (h) PEG dichlorotriazine, and (i) PEG aldehyde (AL-PEG). (Adapted from Pasut, G.; Guiotto, A.; Veronese, F. M. *Exp. Op. Ther. Patents* **2004**, 14, 859–894.)

TCP-PEG) or the aldehyde PEGs, allow a certain degree of selective conjugation within the amino groups present in a protein, according to their nucleophilicity or accessibility.<sup>35</sup> An important difference in reactivity is usually observed between the  $\epsilon$ -amino and the  $\alpha$ -amino group in proteins due to their  $pK_a$ : 9.3–9.5 for the  $\epsilon$ -amino residue of lysine and 7.6–8 for the  $\alpha$ -amino group. This was exploited for the  $\alpha$ -amino modification reached by a conjugation at pH 5.5–6.0, as is the case for G-CSF with PEG-aldehyde.<sup>94</sup> The  $\epsilon$ -amino groups of lysine, which possess high nucleophilicity at high pH, are instead the preferred site of conjugation at pH 8.5–9.

It is noteworthy that the conjugation performed using PEG dichlorotriazine, PEG tresylate, and PEG aldehyde (the latter after sodium cyanoborohydride reduction) maintains the same total charge on the native protein surface, since these derivatives react through an alkylation reaction, yielding a secondary amine. In contrast, PEGylation conducted with acylating PEGs (i.e., SS-PEG, SC-PEG, pNPC-PEG, CDI-PEG, TCP-PEG, and PEG<sub>2</sub>-COOH) gives weakly acidic amide or carbamate linkages with loss of the positive charge.

The PEG derivatives described above may sometimes give side reactions involving the hydroxyl groups of serine, threonine, and tyrosine and the secondary amino group of histidine. These linkages, however, are generally hydrolytically unstable yielding the starting residue. The reaction conditions or particular conformational disposition may enhance the percentage of these unusual PEGylations; for example,  $\alpha$ -interferon was found to be conjugated by SC-PEG or BTC-PEG also at His34 under slightly acidic conditions<sup>113</sup> (the  $pK_a$  value of histidine is between those of the  $\alpha$ - and  $\epsilon$ -amino groups). PEG was found to be linked to the hydroxyl groups of serine in the decapeptide antide or those of tyrosine in epidermal growth factor (EGF).<sup>114,115</sup>

Two examples of random amino PEGylation are reported here.

#### 5.45.6.1.1 Random PEGylation of asparaginase

Asparaginase was one of the first PEGylated enzymes; it catalyzes the hydrolysis of asparagine to aspartic acid and ammonia. The resulting depletion in asparagine is fatal to leukemic lymphoblasts and certain other tumor cells, which by lacking or having very low levels of asparagine synthetase are unable to synthesize asparagine de novo and rely on asparagine supplied in the serum for survival. The free enzyme, however, is cleared too quickly from the body and it is immunogenic, which limits its therapeutic use. When asparaginase from *Escherichia coli* was modified with a PEG of 5000 Da the conjugate was shown to cause tumor regression in transplanted mice and to possess less immunogenicity than the native *Escherichia coli* form.<sup>116–118</sup> PEGylation also improves the enzyme chemical stability and the resistance to plasma proteases.<sup>119</sup> PEG-asparaginase first entered clinical trials in 1984 and since then it has been administered to thousands of patients with acute lymphoblastic leukemia (ALL).<sup>120</sup> The PEG-conjugated enzyme can be safely administered to most patients, even in cases where there is an allergic reaction to *E. coli* or *Erwinia* asparaginases. The longer serum half-life of PEG-asparaginase allows a longer interval between administered doses. PEG-asparaginase was developed by Enzon and was approved by the FDA in 1994 for the treatment of patients with ALL who are hypersensitive to native forms of the enzyme. It is now available commercially from Enzon as Oncaspar. The mean serum half-life of PEG-asparaginase is about 15 days as opposed to the 24 h of the nonmodified *E. coli* enzyme and the 10 h of the *Erwinia* form. The rate of total clearance of PEG-asparaginase was found to be 17-fold lower than that of the unmodified enzyme, whereas the volume of distribution was similar for the two preparations. L-Asparagine levels were undetectable immediately following the 1-h infusion of peg-asparaginase and remained low during the 14-day interval between doses. Interestingly, a recent pharmacoeconomic study<sup>121</sup> demonstrated that despite the higher cost of PEG-asparaginase versus the unmodified enzymes, the overall expense of treatment is comparable to that of unmodified enzymes.

Since FDA approval in 1994, drug monitoring has been performed by several phase IV clinical studies and detailed recent reviews are available in the literature.<sup>84,122</sup> Recent studies have been carried out on the rational basis that immunological, pharmacokinetic, and pharmacodynamic factors have a considerable impact on the efficacy of asparaginase therapy. Therefore, investigations are now aimed at defining the optimum dose and dosing schedule of the different asparaginase preparations that are used in the clinic<sup>123</sup> or correlating antibody levels with pharmacological response.<sup>124</sup>

#### 5.45.6.1.2 Random PEGylation of interferon $\alpha$ -2a

Interferon  $\alpha$ -2a (IFN $\alpha$ -2a) was modified with an *N*-hydroxysuccinimide activated PEG having a branched structure. A high-molecular-weight PEG (PEG<sub>2</sub>, 40 kDa) was chosen on the basis of several preliminary studies disclosing the fact that: (1) the protein surface protection achieved with a single, long and hindered chain PEG is higher than that obtained with several small PEG chains linked at different sites<sup>13</sup>; (2) branched PEGs have lower distribution volumes than linear PEGs of identical molecular weight, and the delivery to organs such as liver and spleen is faster;<sup>125</sup> (3) proteins modified with branched PEG possess greater stability toward enzymes and pH degradation.<sup>86</sup>

**Table 3** Pharmacokinetic properties of interferon  $\alpha$ -2a and its PEGylated form in rats<sup>92</sup>

| <i>Protein</i>                        | <i>Half-life (h)</i> | <i>Plasma residence time (h)</i> |
|---------------------------------------|----------------------|----------------------------------|
| Interferon $\alpha$ -2a               | 2.1                  | 1.0                              |

The 40 kDa branched succinimidyl PEG (PEG<sub>2</sub>-NHS) was linked to interferon  $\alpha$ -2a using a 3:1 PEG:protein molar ratio in 50 mM sodium borate buffer pH 9 yielding a few protein isomers.<sup>34</sup> PEGylation under these conditions led to a mixture containing 45–50% monosubstituted protein, of 5–10% polysubstituted protein (essentially dimer), and 40–50% unmodified interferon. Identification of the major positional isomer within the mono-PEGylated fraction was carried out by a combination of high-performance cation exchange chromatography, peptide mapping, amino acid sequencing, and mass spectroscopy analysis. It was demonstrated that this branched PEG, thanks to its more hindered structure, was attached mainly to one of the following lysines: Lys-31, Lys-121, Lys-131, or Lys-134.<sup>36</sup> Even though the in vitro antiviral activity of PEG2-IFN $\alpha$ -2a was greatly reduced (only 7% was maintained with respect to the native protein) the in vivo activity, measured as ability to reduce the size of various human tumors, was higher than that of free IFN $\alpha$ -2a. The positive result could be related to the extended blood residence time of the conjugated form as shown in [Table 3](#). These studies resulted in the release of the interferon conjugate Pegasys, which has a long period of residence in the blood and is effective in eradicating hepatic and extrahepatic hepatitis C virus (HCV) infection.<sup>92</sup>

#### 5.45.6.2 Thiol PEGylation

The presence of a free cysteine residue represents an optimal opportunity to achieve site direct modification because it rarely occurs in proteins. PEG derivatives having specific reactivity toward the thiol group, i.e., MAL-PEG, OPSS-PEG, IA-PEG, and VS-PEG ([Figure 7](#)), are commercially available and allow thiol coupling with a good yield; however, differences among these polymers in terms of protein-polymer linkage and reaction conditions. Even if the thiol reaction rate of IA-, MAL-, or VS-PEGs is very rapid, some degree of amino coupling may also take place, especially if the reaction is carried out at pH values higher than 8. On the other hand, the reaction with OPSS-PEG is very specific for thiol groups, but the obtained conjugates may be cleaved in the presence of reducing agents as simple thiols or glutathione (present in vivo). PEGylation at the level of cysteine allows easier purification of the reaction mixture since the presence of only one or a few derivatizable sites (free cysteines) avoids the formation of a large number of positional isomers or products with different degrees of substitution, this being a common problem for amino PEGylation. The potential of thiol PEGylation may be further exploited by genetic engineering, which allows the introduction of an additional cysteine residue in a protein sequence or the switching of a nonessential amino acid to cysteine.

The use of this strategy with human growth factor was extensively studied. To overcome the common problems of random amino PEGylation, cysteine muteins were synthesized by recombinant DNA technology. The cysteine addition at the C-terminus of hGH leads to a fully active mutein that allows a site-specific PEGylation using the thiol-reactive PEG-maleimide (PEG-MAL, 8 kDa). It was necessary to treat the rhGH mutein with 1,4-dithio-DL-threitol (DTT) before the coupling step, to maintain the C-terminal cysteine in the reduced form and to prevent the formation of scrambled disulfide bridges. After removal of DTT excess by gel filtration, the conjugation leads to a mono-PEGylated derivative with a yield of over 80%.<sup>126</sup>

Hemoglobin (Hb) is another important example of thiol conjugation; in fact, PEGylation of this protein prevents the vasoactivity as a consequence of its extravasation.<sup>76</sup> After several unsuccessful attempts through random PEGylation, a site-specific modification was performed at Cys-93 (of the  $\beta$ -chain) with maleimidophenyl PEG (MAL-Phe-PEG; 5, 10, and 20 kDa), leading to PEGylated Hb carrying two polymer chains per Hb tetramer.<sup>127</sup> This product was found to be more efficient than polymerized Hb, the Hb-octamer, or Hb-dodecamer.

#### 5.45.6.3 Carboxy PEGylation

PEGylation at the level of protein carboxylic groups needs their activation for the reaction with an amino PEG. This procedure, however, is not without its limitations since undesired intra- or intermolecular cross-links may occur by reaction with the amino groups of the protein itself.

**Figure 10** Staudinger ligation leading to a C-terminal mono-PEGylated protein by reaction of a mutated protein, containing a C-terminal azido-methionine, with an engineered PEG derivative, methyl-PEG-triarylphosphine.

To circumvent this problem it is possible to use PEG-hydrazide (PEG-CO-NH-NH<sub>2</sub>) instead of the usual PEG-amino and to carry out the coupling at pH 4–5 thanks to the low p*K*<sub>a</sub> of PEG-hydrazide. In this case, the protein's COOH groups, activated by water-soluble carbodiimide, do not react with the protein amino groups, which at low pHs are protonated, but with the amino group of PEG-hydrazide only.<sup>128</sup>

An alternative method for specific C-terminal PEGylation is based on the Staudinger ligation.<sup>129</sup> The protocol, using a truncated thrombomodulin mutant,<sup>130</sup> begins with the expression by *E. coli* of a mutated protein containing a C-terminal azido-methionine. This reacts specifically with an engineered PEG derivative, methyl-PEG-triarylphosphine, leading to a C-terminal mono-PEGylated protein (Figure 10). This method, however, involves the preparation of a gene encoding a protein with a C-terminal linker ending with methionine. Expression in *E. coli* is induced when the transformed bacteria are suspended in a medium where methionine is replaced by the azido-functionalized analog. Unfortunately, this method is applicable only to the rare case of proteins lacking methionine in the sequence; otherwise a methionine in the middle of the protein sequence will stop the protein transduction because the azido-analog does not permit the linking of the following amino acid.

### 5.45.7 Strategies in Protein PEGylation

To better exploit the potential of PEGylation several strategies have been developed with the purpose of: (1) obtaining homogeneous products; (2) forming PEGylated conjugates with high retention of activity; and (3) performing PEGylation under gentle conditions that are compatible with easily degradable proteins.

Site-selective conjugation is always preferred as it allows easy purification and characterization of products and, most importantly, better retention of biological activity. As described above, selective PEGylation may be achieved taking advantage of a free cysteine, but this is possible only when this amino acid is present in the native protein or is introduced by genetic engineering. Alternatively, it is possible to take advantage of the lower p*K*<sub>a</sub> value of the α-amino group at the N-terminus with respect to the p*K*<sub>a</sub> of ε-amine of lysines; in fact, performing the reaction under neutral or mildly acidic conditions, prevents the PEGylation at the level of lysine, but leaves the N-terminal amino group reactive.<sup>131</sup> The most successful example of this strategy is the alkylation of r-metHuG-CSF with PEG-aldehyde, proposed by Kinstler. The reaction was carried out at pH 5.5 in the presence of sodium cyanoborohydride to reduce the Schiff's base initially formed.<sup>94,132</sup> The conjugate obtained with a molecule of a 20 kDa PEG showed an improved pharmacokinetic profile due to the reduced excretion by the kidneys. The PEG-G-CSF conjugate Pegfilgrastim has been on the market since 2002.

Site-specific PEGylation can also be achieved by exploiting the different accessibility of protein amino groups, as reported for a truncated form of growth hormone-releasing hormone (hGRF<sub>1–29</sub>). It was demonstrated that by using an appropriate solvent it is possible to alter the accessibility and reactivity of the three available amino groups. Nuclear magnetic resonance (NMR) and circular dichroism analysis indicated that the percentage of α-helix in hGRF<sub>1–29</sub>, which

is only 20% in water, rises to 90% in structure-promoting solvents such as methanol/water or 2,2,2-trifluoroethanol (TFE), thus facilitating a region-selective modification. When PEGylation was performed in TFE the monoPEGylated conjugate at the level of Lys-12 reached 80% for all PEGylated isomers;<sup>133</sup> however, the same reaction conducted in DMSO yielded an almost equimolar mixture of mono-PEGylated Lys-12 and Lys-21 isomers.<sup>134</sup>

Alternatively, specific PEGylation may be performed by blocking some of the reactive groups with a reversible protecting group as reported for insulin. This protein is formed by two polypeptide chains, A and B, and its three amino groups (Gly-A1, Phe-B1, and Lys-B29) are all candidates for PEGylation. Hinds proposed a site-directed PEGylation procedure involving the preliminary preparation of N-BOC (*tert*-butyl carbamate)-protected insulin.<sup>135</sup> As an example, in order to synthesize  $N^{\alpha B1}$ -PEG-insulin the intermediate  $N^{\alpha A1}$ ,  $N^{\epsilon B29}$ -BOC-protected insulin was prepared prior to conjugation with PEG-SPA at the level of free  $N^{\alpha B1}$ . The final conjugate was obtained upon BOC removal with TFA treatment, forming the  $N^{\alpha B1}$ -PEG<sub>2000</sub>-insulin conjugate with 83% of the native insulin activity.

In general, in the PEGylation of an enzyme a requirement for high retention of the activity is that the PEG chains do not modify or obstruct the active site. Many strategies have been developed to achieve this goal: (1) the use of branched PEGs that, thanks to their higher hindrance with respect to linear polymers, have reduced accessibility to the active site (Figure 6); (2) to perform PEGylation in the presence of a substrate or an inhibitor that blocks polymer access to the active site; and (3) to conduct the modification after the enzyme is captured on an insoluble resin by substrates or inhibitors linked on it. In the last case, the obtained conjugate is eluted from the resin by changing the pH or adding denaturants, thus leading to a derivative that does not have linked PEG chains at the level of active site and its closer surroundings (Figure 11).<sup>136</sup>

A problem that may occur during protein PEGylation is the production of a low yield, especially when the modification is directed toward a buried or less accessible amino acid. This inconvenience is enhanced when the reaction is performed with high-molecular-weight PEGs due to the high steric hindrance. In the case of interferon beta (IFN- $\beta$ ), conjugation at cysteine 17 could only be achieved with a low-molecular-weight OPSS-PEG oligomer, but not with a high-molecular-weight polymer.<sup>137</sup> Modification with high-molecular-weight PEGs could be successfully attempted via a two-step procedure: in the first reaction, the protein is modified with a short-chain heterobifunctional PEG oligomer, while in the second, the obtained conjugate is linked to a higher molecular weight PEG, possessing specific reactivity toward the terminal end of the first oligomer (Figure 12). The heterobifunctional PEG oligomer had

**Figure 11** PEGylation strategy for the protection of an enzyme active site from polymer conjugation: firstly the enzyme is loaded into an affinity resin functionalized with the appropriate ligand. The enzyme's active site binds the ligand, thus protecting the active site itself and the area close to it from PEG modification. After reaction under heterogeneous conditions the modified enzyme is eluted from the column.

**Figure 12** Two-step tagging PEGylation strategy for a buried SH group in a protein. Smaller PEG molecules are more reactive than high-molecular-weight PEGs toward the buried cysteine. (Reproduced with permission from Pasut, G.; Guiotto, A.; Veronese, F. M. *Exp. Op. Ther. Patents* **2004**, 14, 859–894.)

**Figure 13** Reaction catalyzed by Tgase between a glutamine residue in a protein and an alkyl amine. (Reproduced with permission from Pasut, G.; Guiotto, A.; Veronese, F. M. *Exp. Op. Ther. Patents* **2004**, 14, 859–894.)

a thiol reactive group at one end of the chain and a hydrazine group at the other (OPSS-PEG-Hz, 2 kDa). As mentioned above, hydrazine is still reactive at low pHs when a protein's amino groups are usually protonated and not reactive, thus preventing unwanted amino PEGylation of the protein. The INF-SS-PEG-Hz conjugate could therefore be selectively modified with PEG-aldehyde (30 kDa) by reductive alkylation. The overall yield was higher than 80%.

A recent study demonstrated that specific PEGylation at the lone, but not accessible, thiol groups of G-CSF could be achieved upon its exposure to partially denaturant conditions. After modification with OPSS-PEG, the native conformation of G-CSF was recovered by removal of the denaturant.<sup>138</sup>

#### 5.45.8 Enzymatic Approach for Protein PEGylation

Recently, as an alternative solution to obtaining homogeneous PEG-protein conjugates under mild reaction conditions, some researchers have been investigating the possibility of exploiting the specificity of enzymes to catalyze PEGylation, which might preserve the protein activity better than with chemical methods. Since the first report, proposed by H. Sato involving the enzyme transglutaminase (Tgase),<sup>139</sup> other researchers have developed interesting approaches with different enzymes. From the data obtained so far it is predicted that these procedures will lead to further results of great interest and applicability.

Sato studied two methods for interleukin-2 (IL2) PEGylation using transglutaminases (Tgase) from guinea-pig liver (G-Tgase) or from *Streptovorticillum* sp. strain s-8112 (M-Tgase). Both enzymes catalyze the transfer of an amino group from a donor (for example PEG-NH<sub>2</sub>) to a glutamine residue present in a protein (Figure 13). The two enzymes differ

**Table 4** Comparison of IL2 conjugate activities between random PEGylation and site-directed PEGylation by Tgase<sup>139</sup>

| Proteins  | % Activity <sup>a</sup> |
|---|-------------------------|
| rhIL2   | 100                     |
| PEG10-rhIL2 (random PEGylation)                       | 74                      |
| (PEG10) <sub>2</sub> -rhIL2 (random PEGylation)       | 36                      |
| rTG1-IL2 (chimeric protein for enzymatic PEGylation)  | 72                      |
| PEG10-rTG1-IL2 (enzymatic PEGylation)                 | 69                      |
| (PEG10) <sub>2</sub> -rTG1-IL2 (enzymatic PEGylation) | 72                      |

The rTG1 abbreviation represents the N-terminal fused Pro-Lys-Pro-Gln-Gln-Phe-Met sequence introduced as Tgase substrate.

Adapted from Sato, H. *Adv. Drug Delivery Rev.* **2002**, 54, 487–504.

<sup>a</sup>The amount of activity was expressed as the per cent residual bioactivity as compared to the rhIL2.

in the required amino acid sequence neighboring the glutamine of the substrate. Several tailor-made linear PEGs, differing in molecular weight and type of alkylamine present at the polymer end, have been synthesized, the best reactivity being shown by polymers terminating with a  $-(CH_2)_6-NH_2$  group. IL2 contains six glutamines, but none of them is a suitable substrate for the more specific G-Tgase. The problem was overcome by preparing chimeric IL2 proteins that had at the N-terminus a peptide sequence that is a good G-Tgase substrate, like the Pro-Lys-Pro-Gln-Gln-Phe-Met (derived from Substance P<sup>140</sup>) or the Ala-Gln-Gln-Ile-Val-Met (derived from fibronectin<sup>141</sup>). In the former case, a mono-PEGylated conjugate was obtained while a mixture of mono- and di-PEGylated forms resulted in the latter case. The enzymatic coupling was carried out under mild conditions: 0.1 M Tris-HCl buffer, pH 7.5 at 25 °C for 12 h in the presence of CaCl<sub>2</sub> 10 mM.<sup>136</sup> The derivatives maintained almost the same activity of the native protein, whereas the classical chemical conjugation with mPEG-NHS yielded products with decreased activity (Table 4). Using the less specific M-Tgase, mPEG<sub>12000</sub>-(CH<sub>2</sub>)<sub>6</sub>-NH<sub>2</sub> could be directly incorporated into rhIL2 at the level of Gln-74.<sup>142</sup> Compared to others site-specific chemical PEGylation, such as cysteine coupling or N-terminus modification at acidic pHs, the enzymatic method produces less undesired products, i.e., protein-protein dimers (due to cysteine oxidation) or εNH<sub>2</sub> lysine PEGylation.

A two-step enzymatic PEGylation, called GlycoPEGylation, was developed by Neose Technologies. In this case, *E. coli*-expressed proteins were glycosylated at the level of specific serine and threonine with *N*-acetylgalactosamine (GalNAc) by in vitro treatment with the recombinant O-GalNAc-transferase. The obtained glycosylated proteins were subsequently PEGylated using the O-GalNAc residue as the acceptor site of the cytidine monophosphate derivative of a sialic acid-PEG, a reaction selectively catalyzed by a sialyltransferase.<sup>143</sup> The great advantage of this technology is the possibility of PEGylating proteins produced in *E. coli* in order to mimic the mammalian ones, since the PEG chains replace the native sugar moiety at the precise site of glycosylation, forming conjugates that retain the correct structure for receptor recognition and an extended plasma half-life. This method, however, is still awaiting large-scale application.

### 5.45.9 PEGylated Protein Purification and Characterization

Theoretically, in a conjugation reaction conducted with an excess of PEG, one could expect all of the reactive groups of the protein to be modified, thus yielding mainly a single product. However, in order to avoid loss of biological activity, a smaller amount of PEG is generally employed even if this gives rise to a mixture of positional isomers.<sup>144</sup> Often the mixture can be fractionated by ionic exchange chromatography<sup>145</sup> due to the suitable differences in isoelectric point of each isomer. Reverse-phase chromatography was found to be less efficient in this respect, and gel filtration separates only species with different masses.

Once the isomers are separated it is necessary to identify the PEGylation site in the primary sequence. The usual approach involves enzymatic digestion of the conjugate, purification of the peptides, and their identification by mass spectroscopy or amino acid analysis. A good example is reported in the characterization of PEGylated interferon α-2a,<sup>146</sup> where the comparison of the peptide fingerprint of the conjugated protein with that of the native protein allowed the region of PEGylation to be identified on the basis of the disappeared peptide signal. Besides the lengthy procedure, the conjugated polymer may interfere by steric hindrance with the proteolytic enzymes, resulting in an incomplete cleavage that complicates the interpretation of the peptide finger printing. An alternative procedure exploits the use of

**Figure 14** Use of PEG-Met-Nle-OSu or PEG-Met- $\beta$ Ala-OSu to introduce a reporter amino acid at the PEGylation site: PEG conjugation and release of PEG by CNBr. Nor-leucine (Nle) or  $\beta$ -alanine ( $\beta$ Ala) can be identified on the protein by enzymatic digestion of the protein and mass spectrometry analysis of the obtained peptides.

PEG-Met-Nle-COOH or PEG-Met- $\beta$ Ala-COOH in the conjugation step. These possess a chemically labile bond in the peptide spacer at the level of methionine, which can be cleaved by treatment with CNBr (Figure 14) leaving only nor-leucine or  $\beta$ -alanine tags on the protein. The amino acid tagged peptides can be easily identified by standard sequence methods or by mass spectrometry analysis in the enzymatically digested mixture.<sup>147</sup>

### 5.45.10 Conclusion

In this chapter only a few drug conjugates out of the many described in the literature or patents have been discussed. The intention was to give examples of the potential of the method and how different problems were identified and solved. Polymer conjugation is often employed not only to improve the pharmacokinetic profiles of drugs, but also to give new properties to the modified drug, such as a higher solubility and stability, specific targeting, and for proteins removal or reduction of immunogenicity.

Many different polymers have been used in this field, both from natural or synthetic sources. Multifunctional polymers are preferred for low-molecular-weight drugs, since higher loading can be achieved, while monofunctional polymers are the essential choice for proteins to avoid unwanted cross-linking.

Among all polymers, PEG emerged as the most successful, and it has already led to several marketed products (Table 1). In fact, PEGylation, which was initially used to improve the therapeutic value of peptide and protein drugs, has now been extended to nonprotein compounds and, more recently, oligonucleotides. PEG has several useful properties that are finding application in other therapeutic approaches, such as the surface modification of liposomes (stealth liposome<sup>148</sup>), micro- and nanoparticles,<sup>149</sup> and, last but not least, cells,<sup>150</sup> making them biocompatible when implanted in vivo.

At the basis of this technology lies an in-depth understanding of the chemistry of polymers, which despite the number of advances made over the years is still open to new advancements.

## Biographies

**Francesco M Veronese** has a degree in Pharmacy from the University of Padova, Italy. In 1962–1970 he was a researcher for the Italian National Council of Researches, 1971–1972 an Associated Research Professor at the Department of Biochemistry, University of California-Los Angeles, CA, 1973–1981 an Assistant Professor of ‘Pharmaceutical Industry,’ University of Ferrara, and of ‘Applied Biochemistry,’ University of Padova, Italy, and from 1982 Full Professor of ‘Applied Pharmaceutical Chemistry,’ School of Pharmacy, University of Padova. His past research activities have included: specific chemical modification of peptides and proteins for structure–activity relationships; induction, purification, sequence, enzymatic, and structural properties of glutamate dehydrogenases; structural and

enzyme activity investigation of thermostable enzymes; drug-protein interaction: covalent and noncovalent linkage between furocoumarins and proteins; covalent modification by amphiphilic polymers of polypeptides and proteins to improve their therapeutic potential and their use in biocatalysis; entrapment of bioactive substances by nonbiodegradable matrices (acrylate polymers obtained by  $\gamma$ -ray induced polymerization) or polyvinyl alcohol, and by biodegradable polymers (polyphosphazenes) for controlled release; and polymeric prodrugs with targeting properties. Currently, Prof Veronese is carrying out research in the following areas: covalent binding of polymers to low-molecular-weight drugs, peptides, and proteins for improved delivery and increased therapeutic index; modification of enzymes with amphiphilic polymers for biocatalysis in organic solvents; and noncovalent entrapment of drugs by insoluble nonbiodegradable or biodegradable polymers for slow and controlled release of bioactive compounds. He was chairman of the PhD program in Pharmaceutical Sciences at the University of Padova 1983–2003; Director of the ‘Seminar of Pharmaceutical Sciences’ 1982–2000; co-organizer of the ‘Advanced School of Pharmaceutical Chemistry’ 1980–1992; co-organizer of the ‘National Seminars in Pharmaceutical Sciences’ 1980–1992; and Past President of the ‘Controlled Release Society,’ Italian Chapter, since 2004. Author of over 190 peer research papers, 15 reviews, 11 book chapters, and 19 US or European patents.

**Gianfranco Pasut** has a degree in Pharmaceutical Chemistry from the University of Padova, Italy. He spent some time as an exchange student at the University of Pennsylvania, PA before becoming a researcher at the School of Pharmacy, University of Padova, in 2006. Dr Pasut's research activities have included: studies on doxorubicin conjugated to PEG and macromolecular carriers; modification of cis platinum and Ara-C with PEG; synthesis and characterization of dendronized PEGs as a high-loading carrier for low-molecular-weight drugs and development of a new labeling method with technetium of PEGylated chelating agent for diagnostic application.

Currently, Dr Pasut is carrying out research in the following areas: modification of proteins with PEG; preparation of specific targeted macromolecular molecules for diagnostic and therapeutic purposes; and synthesis of PEG drugs releasing nitric oxide.
