

Comprehensive Medicinal Chemistry II

Volume 2 : Strategy and Drug Research

Elsevier, 2006

Editors-in-Chief: John B. Taylor and David J. Triggle
ISBN: 0-08-044513-6

Introduction

2.01 The Intersection of Strategy and Drug Research, Pages 1-84, W.H. Moos

2.02 An Academic Perspective, Pages 85-97, D.J. Triggle

2.03 An Industry Perspective, Pages 99-135, W. Wierenga

Organizational Aspects and Strategies for Drug Discovery and Development

2.04 Project Management, Pages 137-158, Y. Nakagawa and L. Lehman

2.05 The Role of the Chemical Development, Quality, and Regulatory Affairs Teams in Turning a Potent Agent into a Registered Product, Pages 159-172, S.A. Munk

2.06 Drug Development, Pages 173-202, P. Preziosi

2.07 In-House or Out-Source, Pages 203-223, R.D. Connell

2.08 Pharma versus Biotech: Contracts, Collaborations, and Licensing, Pages 225-238, D. Cavalla

2.09 Managing Scientists, Leadership Strategies in Science, Pages 239-252, A.M. Sapienza

2.10 Innovation (Fighting against the Current), Pages 253-264, R. Root-Bernstein

2.11 Enabling Technologies in Drug Discovery: The Technical and Cultural Integration of the New with the Old, Pages 265-287, M. Williams

2.12 How and Why to Apply the Latest Technology★, Pages 289-557, A.W.

Czarnik and H-Y Mei

2.13 How and When to Apply Absorption, Distribution, Metabolism, Excretion, and Toxicity, Pages 559-572, R.J. Zimmerman

2.14 Peptide and Protein Drugs: Issues and Solutions, Pages 573-601, J.J. Nestor

2.15 Peptidomimetic and Nonpeptide Drug Discovery: Receptor, Protease, and Signal Transduction Therapeutic Targets, Pages 603-647, T.K. Sawyer

2.16 Bioisosterism, Pages 649-711, C.G. Wermuth, P. Ciapetti, B. Giethlen and P. Bazzini

2.17 Chiral Drug Discovery and Development – From Concept Stage to Market Launch, Pages 713-736, H.-J. Federsel

2.18 Promiscuous Ligands, Pages 737-752, S.L. McGovern

Targets

2.19 Diversity versus Focus in Choosing Targets and Therapeutic Areas, Pages 753-770, D.A. Giegel, A.J. Lewis and P. Worland

2.20 G Protein-Coupled Receptors, Pages 771-826, W.J. Thomsen and D.P. Behan

2.21 Ion Channels – Voltage Gated, Pages 827-875, J.G. McGivern and J.F. Worley

2.22 Ion Channels – Ligand Gated, Pages 877-918, C.A. Briggs and M. Gopalakrishnan

2.23 Phosphodiesterases, Pages 919-957, D.P. Rotella

2.24 Protein Kinases and Protein Phosphatases in Signal Transduction Pathways, Pages 959-992, T.K. Sawyer

2.25 Nuclear Hormone Receptors, Pages 993-1036, N.T. Zaveri and B.J. Murphy

2.26 Nucleic Acids (Deoxyribonucleic Acid and Ribonucleic Acid), Pages 1037-1052, E.E. Swayze, R.H. Griffey and C.F. Bennett

2.27 Redox Enzymes, Pages 1053-1087, J.A. Dykens

2.01.1 Overview

In this overview, readers will find a preview of what follows. We will start with one of the fundamental issues facing the industry today. As may be evident from even a cursory reading of the daily newspaper, drug research is a complicated, time-consuming, and expensive process. It is the proverbial high-risk, high-payoff industry. Alarming, the capitalized, out-of-pocket, pre-approval costs for new drug development have increased by a factor of 3–4 over estimates at the end of the 1980s and nearly six times that of the 1970s. Yet, even with increased spending, industry productivity has dropped. Given these financial and other issues, the sustainability of the industry has been called into question, with the need for each major pharmaceutical company to produce a blockbuster at least once a decade to remain healthy financially, and in the face of continuing safety issues and withdrawals of major marketed drugs. Can the drug discovery process be redirected to provide a stronger pharmacoeconomic future?

If ever there were an industry in need of a better, faster, cheaper strategy, the pharmaceutical industry would be it. Despite this somber picture, the 1990s were quite prosperous for many pharmaceutical companies, and many biotechnology and pharmaceutical companies are doing exceedingly well today financially and otherwise. Venture capital funded biotechnology companies represent an increasing proportion of new drugs entering the marketplace. Indeed, the term biotech is often a misnomer, since many biotech companies focus on small molecule drugs rather than on protein biologics.

Safety has been a major issue in the new millennium, with failures of selective cyclooxygenase inhibitors such as rofecoxib (Vioxx) commanding attention. Even without safety issues, drugs face continued hurdles once marketed. For example, despite demonstrated clinical significance in treating Alzheimer's disease, certain regulatory bodies have decided that the benefits of cholinesterase inhibitors such as donepezil (Aricept) are not sufficient to justify their costs.

How does one take into account today's major issues – including attrition, productivity, efficiency, success rates, costs, and shots on goal – and make things better? The answer is not clear, but most would agree that the expected acceleration in drug discovery and development with the advent of new technologies such as combinatorial chemistry and genomics has, unfortunately, been slow to materialize. In reality, it may simply take more time for the results of recent advances to become more tangible.

Pharmaceutical R&D can be organized in various ways, taking into account line versus matrix considerations, departments versus teams, decision points, interfaces, and transitions. Before embarking on a new project, and as part of periodic project reviews, many groups evaluate the project from a number of perspectives. Decision making of this sort is important in almost any profession, albeit less complicated in many other industries. Successfully managing the interface of drug discovery and drug development requires a clear target product profile that team members and management have agreed upon. With each successive stage of drug discovery and development, new groups must interface to advance the project. For example, as a drug moves into early development, scale-up is usually required, in order to prepare enough material under controlled conditions to proceed with toxicology and other studies.

Internal research must be coordinated within and without, including with contract organizations, to which work may be outsourced. Whether a company is a giant pharmaceutical corporation or a small biotechnology firm, it may be resident at more than one site. Even the largest companies will contract out certain work. Small companies with only a few people may contract out most or all of their laboratory studies. Preclinical development and clinical and regulatory tasks are commonly conducted by contract research organizations specializing in such areas. Perhaps contrary to expectations, basic research is also frequently outsourced. Most of the large biotech-pharma alliances are essentially outsourcing arrangements, with the biotech company contributing new technologies and approaches while big pharma provides the funding and later stage resources required to take a product through preclinical and clinical development to marketing and sales. Though the First World has dominated these arenas historically, the Pacific Rim has positioned itself to capitalize on many of these opportunities in the future, with substantial growth in biotechnology and pharmaceutical R&D. Southeast Asia, including China, India, Singapore, and Taiwan, as well as other countries, represents growing competition for the future, and offshoring of high technology jobs from the US and Europe has become a topic of discussion and concern.

What about the people who drive this industry? How does one recruit and manage the human resources required to be successful in medicinal chemistry and pharmaceutical R&D? There are, as one might expect, many factors to consider. Research laboratory management requires paying attention to both the forest and the trees – the big picture as well as the details. It requires finding ways to stay informed without micromanaging. Managing well requires many leadership skills, including an appreciation for and a knack for leveraging different styles, the ability to communicate effectively on many different levels, ways of addressing conflict and change constructively, comfort (or if not comfort then a productive disharmony) with the corporate culture, and an understanding of motivation.

Companies go through several stages as they develop, moving from start-up through focus, integration, optimization, and finally reaching maturity. Management practices must evolve during these progressions, or crises and even business failures will result. Thus, whereas the management profile in early business stages is often vision-driven and planning is ad hoc, later-stage companies require more structured processes and formal planning. Similarly, business goals evolve from being flexible and entrepreneurial to being more consistent, integrated, and measurable.

Innovation is often discussed but rarely practiced, and even more rarely studied with rigor. In fact, many people fight innovation as it moves through the several stages of a revolution. In the end, most new science needs to be hyped to have a chance. New technologies are always greeted with skepticism, many people have vested interests in competing old approaches, and people do not like change in general. Moreover, the timeframe to develop practical applications of new technologies is always longer than expected.

The latter part of the twentieth century witnessed the birth of numerous technologies that advanced the state of the art in drug research. Technological advances often spawned a new cadre of start-up ventures. That trend was quite evident in the combinatorial chemistry field in the 1980s and 1990s. However, as is common with these waves of change, many of the original companies were acquired, failed, or changed directions, becoming unrecognizable or untraceable over a few short years.

Many technologies critical to today's medicinal chemistry (and pharmaceutical R&D in general) were developed starting in the 1980s. These include combinatorial chemistry, high-throughput screening, genomics, and proteomics. The development of combinatorial chemistry is a particularly interesting case study in the biotechnology and pharmaceutical industries. One might trace its formal beginnings to the development of solid-phase peptide synthesis by Merrifield in the early 1960s, though other developments including natural products chemistry may also be considered seminal events. Nanotechnology (or nanobiotechnology) is the latest platform to employ the skills of the medicinal chemist. The concept of targeted therapeutic nanoparticles is being tested in a number of academic and industrial laboratories around the world. Much of this work is being done in the cancer field.

While the beginnings of quantitative structure–activity relationships (QSARs) in medicinal chemistry have roots that date back to the 1940s and 1950s, drawing heavily on linear free energy relationships and physical organic chemistry, methods advanced remarkably once computers became commonplace. Still, sometimes the best techniques – back of the envelope calculations – are the simplest. Advances in computing have allowed the development of molecular modeling and other tools for structure-based design, sometimes referred to as computer-aided drug design. While this can be a very technical discipline, practical guides exist for those who are interested in learning more or even becoming practitioners. The thousands of three-dimensional structures of macromolecules that have been solved provide a good basis for drug design.

Chemical space, nearly infinite, is a continuum, with pockets of biologically relevant properties. Various strategies have been used to calculate this n -dimensional physicochemical property space. Evaluating the diversity of a given set of compounds from first principles may utilize one of a number of different approaches, such as clustering, receptor site interaction simulation, similarity, and other techniques.

What other considerations should be mentioned? Even if one had a large and diverse library of drug-like molecules, it is conceivable that some of the biological targets of interest would not be druggable – that is, it might not be possible to modulate some targets through interactions with orally available small molecules. Others have tried to devise new ways of screening libraries virtually – by computer – before proceeding to laboratory work.

In the old days, chemists, biochemists, and pharmacologists worked together in pharmaceutical companies to identify promising new drug leads by a slow, iterative process, often driven principally by data in animals. What has happened to the old ways with the advent of novel technologies and new scientific disciplines? For one, molecular biologists became a major part of drug discovery teams in the 1980s and 1990s, developing molecular assays to prioritize compounds for animal testing. The basics have not changed, but many new technologies have been added to the medicinal chemist's armamentarium, including combinatorial chemistry.

While there have been major advances in many of the early stages of drug discovery, a bottleneck remains in preclinical development – in absorption, distribution, metabolism, excretion, and toxicity (ADMET) – both in vitro at a high-throughput level, or with high content assays, and in vivo in animals for screening and for formal drug development tasks. Addressing this part of drug development requires different thought processes and procedural rigors because of regulations. Various methods have been developed to predict or optimize drug absorption and pharmacokinetics.

Successful drug hunters persevere, have a whatever-it-takes mindset, and occasionally use tips and tricks that others miss. The key can be as simple as determining when it is time to move on – proceeding to the next stage of evaluation even if the molecule is not ideal, since more questions will be answered by going forward than have been answered to

date. Drug hunting can require fighting against the current, for example, working on dirty drugs or polypharmacy when others are focused on very selective drugs.

Drug discovery targets fall into various classes and families. Many are receptors or enzymes. One analysis of drug targets concluded that there were more than 400 in total, based on drugs that had reached the marketplace, including enzymes, ion channels, receptors, and other targets. The largest percentage, about one-third, were targets associated with synaptic and neuroeffector junctions and the central nervous system.

Some have tried to assess the genome from the standpoint of druggability. They estimate that only about 3000 druggable targets exist in the human genome. G protein-coupled receptors and kinases figure prominently in this analysis. Considering only the currently marketed drugs, G protein-coupled receptors account for almost one-third of this group, with ion channels a distant second. Another evaluation suggests that there are no more than 1500 exploitable drug targets based on the intersection of druggable targets and genes linked to disease.

Selecting the right target is more an art than a science. The process to select a target requires consideration of corporate, business, and R&D strategy, as well as portfolio balance, in addition to scientific and medical arguments for or against. It must also consider the interplay of stakeholders, consumers, and the drug firm, with attendant factors, including those that are technical, legal, economic, demographic, political, social, ecological, and infrastructural. Unfortunately, it is frequently the case that marketing projections used to prioritize drug opportunities are not anywhere close to actual sales.

There is an old saying: The difficult we do immediately; the impossible takes a little longer. In some ways, this is the challenge in front of us. The health and well being of the world rests on our success in tackling these challenges and opportunities. Wish us luck!

2.01.2 Organizational Aspects

2.01.2.1 Introduction

Drug research is a complicated, time consuming, and expensive process^{1,2} – high risk with a potentially high payoff (Table 1). PhRMA (Pharmaceutical Research and Manufacturers of America) estimates that it takes an experimental drug an average of 10–15 years to advance from early-stage laboratory research to US patients. (For purposes of illustration, the pharmaceutical R&D process leading to commercialization will be outlined here as if the intended path is with the US Food and Drug Administration (FDA)). During these dozen or so years, thousands of compounds are evaluated in discovery and preclinical testing, just five enter human clinical trials, and only one is approved by the FDA.³ (Company and R&D statistics can be found in various industry compilations, such as those prepared by PAREXEL.⁴)

The capitalized, out-of-pocket, pre-approval costs for new drug development have recently been estimated to exceed \$800 million (MM), an increase of 3–4 times over estimates at the end of the 1980s and 6 times that of the 1970s (Figure 1). Thus, it should be no surprise that major pharmaceutical companies invested more than \$30 billion in R&D in 2002, a number that has doubled every 5 years since 1970 (Figure 2).⁵ Increased spending is also evident at the National Institutes of Health (NIH). It should also be no surprise that drug prices can be high, given the astronomical costs to develop each drug, the long timelines, and the major risks of failure. Nonetheless, the debate over drug pricing rages on in an effort to contain healthcare costs, including arguments that patients are double charged for drugs – once via tax dollars and a second time when they need a drug.^{6–9} This debate began in the 1950s, and continues to this day.¹⁰

Even with increased spending, the number of regulatory applications for new therapeutics has dropped (Figure 3). Success rates for approval of investigational drugs, in particular, have been studied extensively. If one looks at the period from 1963 to 1999, the number of investigational new drug applications (INDs) for new chemical entities (NCEs) has not changed much, but the duration of the clinical and approval phases has gone up by more than 50%, from just over 4 years to almost 7 years. The time from synthesis to approval of NCEs went up from 8.1 years in 1963–1969 to 14.2 years in 1990–1999. In the latter period, cancer drugs took the longest, at 16.2 years, while anti-infectives took 12.3 years. Interestingly, during the 1980s these studies showed a reduction in clinical approval rates for self-originated drugs, but an increase in clinical approval rates for acquired compounds, suggesting that companies found it more productive to develop other companies' products than their own.^{11,12} Overall, despite the passage of several legislative acts in recent decades (e.g., Prescription Drug User Fee Act of 1992 (PDUFA) and FDA Modernization Act of 1997 (FDAMA)) that could have speeded the development of new drugs, overall approval times for new therapeutics in the US are little changed, though there have been apparent temporary improvements from time to time at one stage or another in drug development.^{13,14}

Add to these concerns the projection that the compound annual growth rate of large pharmaceutical companies may not support their valuations. For example, predicted growth rates for 2003–2008 range from 1.1% to 11.3% among the

Table 1 Pharmaceutical R&D and approval process, timeline, and costs

	<i>Preclinical</i>		<i>Clinical</i>			<i>Postmarketing</i>		
	<i>Discovery & early development</i>	<i>IND</i>	<i>Phase I</i>	<i>Phase II</i>	<i>Phase III</i>	<i>NDA</i>	<i>FDA</i>	<i>Phase IV</i>
Years	6.5		1.5	2	3.5		1.5	
Test subjects	In vitro, in vivo, animal studies		Healthy volunteers	Patient volunteers	Patient volunteers		Review process	Surveillance
			20–100 subjects	100–500 patients	1000–5000 patients			Up to millions of patients
Purpose	Bioactivity, safety, pharmaceutical properties		Safety & dose	Efficacy & side effects	Efficacy, adverse reactions, longer term use		Approval	Other studies per FDA
Success rate	≥ 5000 compounds evaluated		5 drugs enter clinical trials				1 drug	approved
Cost	\$335 million		—	\$467 million				\$95 million

IND, Investigational New Drug Application; NDA, New Drug Application; FDA, Food and Drug Administration.

Figure 3 Decreases in new drug and biologic submissions in the US.

top 13 pharmaceutical companies. At the other end of the scale, the sometimes unrealistic wishes of company founders may not support the valuations of small biotech companies.¹⁵⁻¹⁶

Given these financial and other issues, the sustainability of the industry has been called into question, with the need for each major pharmaceutical company to produce a blockbuster at least once a decade to remain healthy financially, and in the face of continuing safety issues and withdrawals of major marketed drugs. Can the drug discovery process be redirected to provide a stronger pharmacoeconomic future? Major drugs continue to be withdrawn from the

market for safety reasons, such as astemizole (Hismanal), cisapride (Propulsid), fenfluramine (Pondimin), and terfenadine (Seldane) for cardiovascular problems, phenylpropanolamine for stroke risk, and troglitazone (Rezulin) for liver toxicity.¹⁷ Pharmaceutical and biotechnology companies have never faced so many challenges, including financial, technical, regulatory, social, and ethical issues.^{18,19} If ever there were an industry in need of a better, faster, cheaper strategy, the pharmaceutical industry would be it. Some, however, have questioned whether it will ever get better without radical changes, yet major changes are hard to enact in such a heavily regulated industry.²⁰

Despite this somber picture, the 1990s were quite prosperous for many pharmaceutical companies. A look at more than 40 drugs that have changed the world has been published, from aspirin to sildenafil (Viagra) and more.²¹ The 1990s were dominated by antiulcer drugs such as ranitidine (Zantac) and omeprazole (Prilosec). Various case histories can be found on these subjects.^{22–24} Given that treatment options for high levels of gastric acidity were rather limited only 30 years ago, the gastrointestinal field has made great strides forward, first with histamine H₂ blockers, and later with proton pump inhibitors. This field has seen the gamut: the rise of billion dollar products, prescription (R_x) to over-the-counter (OTC) switches, and the development and commercialization of single enantiomers (e.g., esomeprazole (Nexium) from omeprazole). Of recent great interest has been the so-called magic bullet for certain cancers, namely, imatinib (Gleevec or Glivec). The history of imatinib has also been summarized as a case history, in both journal article and book form. It is a story that started around 1990, with initial leads identified in a protein kinase C (PKC) screen, continuing to 1992, when imatinib was first synthesized, to 2001, when imatinib was approved by the FDA to treat chronic myelogenous leukemia (CML).^{25,26} Imatinib has been a great success story for Novartis and its employees, target-based therapies and kinase inhibitors, cancer research and cancer patients, and drug development in general, but it still took 9 years from first synthesis to regulatory approval. Moreover, the drug industry had been working on PKC inhibitors for many years prior to the discovery of imatinib.

The US is the largest market for pharmaceuticals in the world. Based on an analysis in mid-2004, it represented nearly \$230 billion in sales, which was 46% of global sales. Japan was second largest, at 11.1%. Germany, France, Italy, Spain, and the UK taken together accounted for 20.8% of global sales. Antiulcer drugs have for a long time occupied the top spot, as noted above, with antidepressants not far behind, but no longer. Agents that reduce cholesterol and triglycerides now hold first place with nearly \$30 billion in global sales. The recent market leader has been atorvastatin (Lipitor), sold for hypercholesterolemia. However, possibly as many as 20 recent top drugs will lose their patent protection in the period between 2000 and 2010, and thus their sales will likely fall precipitously as generic competition grows and new drugs are introduced. In the face of this blockbuster mania, it is interesting to note that while some companies have grown largely on their own (e.g., Roche), others have grown through mergers. An example is Pfizer, which today encompasses Agouron, Gödecke, Jouvénal, Monsanto, Pharmacia, Searle, Upjohn, and Warner-Lambert/Parke-Davis, among others.²⁷

Though many reviews focus on sales as the index worth measuring when it comes to top drugs, another measure is the total number of prescriptions. Table 2 shows a comparison for 2003. Returning to sales, the numbers are staggering – each of the top 48 drugs in the US sold \$1 billion or more in 2003. Moreover, every drug in the top 200 sold \$200 MM or more in the US in 2003.

Table 2 Top drugs in 2003 by number of prescriptions and sales in the US²⁸

<i>Top drugs by number of prescriptions</i>	<i>Top drugs by sales</i>
Hydrocodone with acetaminophen	Lipitor (\$6.3 billion)
Lipitor	Zocor
Synthroid	Prevacid
Atenolol	Procrit
Zithromax	Nexium
Amoxicillin	Zyprexa
Furosemide	Zoloft
Hydrochlorothiazide	Celebrex
Norvasc	Epogen
Lisinopril	Neurontin

Venture capital (VC) funded biotechnology companies account for an increasing proportion of new drugs entering the marketplace. However, 'biotech' is often a misnomer, since many biotech companies focus on small molecule drugs rather than on protein biologics. In recent years, almost 25% of new drugs, both new molecular entities (NMEs or NCEs) and new biological entities (NBEs), came from the biotech industry.²⁹ The Hatch-Waxman Act benefited drug development significantly in the US, especially for big pharma, providing for patent term extensions, among other things.³⁰ It has also led to many patent challenges, which could in the long run be detrimental to all concerned.³¹ The 1980 Bayh-Dole act was even more important, especially for the academic sector and for the creation of a strong biotechnology industry. It put patents issued based on government-funded research in the hands of the universities and other institutions where the work was conducted. From the standpoint of technology transfer and the creation of new companies, products, and personal wealth, this regulatory act has been a major success. It may be the prime reason for continued US dominance of biotechnology and related areas. However, not everyone has been pleased with the results, since material transfer agreements (MTAs) that keep rights in check can slow and hinder research, and some have complained about a growing corporate for-profit mentality among university administrators and researchers.³²

The Cohen and Boyer patent on recombinant deoxyribonucleic acid (DNA) techniques signaled a turning point for pharmaceutical research and the creation of the biotechnology industry. Granted in 1980, the processes represented by this patent underpinned much of the industry's early growth and the influx of major sums of venture capital in the two decades leading up to the twenty-first century.³³ Thus, it should be no shock how important patent protection is to this industry. Patentability is determined based on novelty, inventive steps, enablement, and support.³⁴ Of course, patents provide legal monopolies over new therapies, which has led to concerns about monopolistic drug pricing, as alluded to above.

Biotechnology companies have had a number of banner years in recent times. The year 2000 is the record holder for monies raised in initial public offerings (IPOs), with over \$8 billion. In 2004, another good year, more than \$2 billion was raised. VC investments were in excess of \$5 billion in 2004, even higher than in 2000.³⁵

This is indeed an industry that counts time in decades and even centuries. Consider for illustration the case of nonsteroidal anti-inflammatory drugs (NSAIDs). It has been known for centuries that the bark of willow trees and other plant substances have medicinal effects. On hydrolysis, the active antipyretic ingredient in willow bark, salicin, yields salicylic alcohol. Based on this discovery, salicylates including aspirin came into use as pure drugs in the mid to late 1800s. Many years later, in the early 1960s, the project that produced piroxicam (Feldene) was initiated, building on the knowledge of other NSAIDs, including aspirin. Piroxicam was first launched by Pfizer in 1980, 18 years after the project began, and well over 100 years since the discoveries relating to salicin had been made. Aspirin and other NSAIDs are now known to exert many of their actions (analgesic, anti-inflammatory, antipyretic) through the inhibition of prostaglandin biosynthesis, this in turn being effected through the inhibition of two forms of cyclooxygenase, COX-1 and COX-2. Based on the differential expression patterns of cyclooxygenases, a number of companies sought COX-2-selective agents to minimize the gastric toxicity that is so problematic with chronic NSAID use. This work ultimately yielded COX-2-selective agents such as celecoxib (Celebrex), which became billion dollar drugs before it was realized that marketed COX-2 inhibitors increased cardiovascular risk.^{36,37} The chemical structures of representative NSAIDs are shown in Figure 4.

Indeed, the fate of COX-2 inhibitors is under debate at the time of this writing. The recall of rofecoxib (Vioxx), a billion dollar product for inflammatory pain, led to an immediate collapse of Merck stock. Whereas Merck had been the darling of the industry for many years, and was widely respected for high-quality research, its star fell almost overnight. Will Merck be able to survive alone, or will it be forced to merge with another entity to weather the storm, given adverse market forces and public perceptions?³⁸

Is a drop in new drug application (NDA) approval times the reason for an increase in drug withdrawals from the marketplace, as with COX-2 inhibitors? Though some have suggested this to be the case, it is not clear. However, it is a fact that NDA approval times have dropped considerably in the last 20 years, from 1986, when median approval times for all NDAs were approximately 33 months, to 2003, when priority reviews were accomplished in under 7 months and standard reviews in about 23 months.³⁹ COX-2 inhibitors are not the only therapeutics to come under fire in recent years. Deaths of multiple sclerosis patients following therapy with natalizumab (Tysabri, formerly antegren, approved in 2004) has led to further scrutiny of the FDA early approval process. Other drugs that have received accelerated approval include indinavir (Crixivan, human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS), 1996), Gleevec (imatinib, leukemia, 2001), gefitinib (Iressa, lung cancer, 2003), and bortezomib (Velcade, multiple myeloma, 2003).⁴⁰

The failure of major COX-2 inhibitors postmarketing should be a wake-up call for the importance of monitoring the safety of new drugs⁴¹ – and importantly for personalized medicine – diagnostics, prognostics, biomarkers, surrogate markers, pharmacogenetics, and pharmacogenomics. Whether suitable application of the latest technologies could have

Figure 4 Representative NSAID chemical structures.

prevented such a fiasco is unknown, but the future will (or at least should) demand application of the tools of personalized medicine. To say this in a different way to drive the point home, the variation of drug responses between individuals and populations can be significant, quite literally meaning a difference of life or death.^{42–44}

Even without safety issues, drugs face continued hurdles once marketed. For example, despite demonstrated clinical significance in treating Alzheimer's disease (AD), certain regulatory bodies have decided that the benefits of cholinesterase inhibitors such as donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) are not sufficient to justify their costs.⁴⁵

While the basic research that underpins drug discovery may start years or even many decades earlier, the discovery and preclinical testing phase of pharmaceutical research is generally regarded as lasting 6–7 years. In this phase, a large number of compounds are studied *in vitro* and *in vivo* to evaluate their biological effects, safety, and formulations. Roughly 1 in 1000–10 000 (or even millions!) of these compounds advance to filing of an IND with the FDA (Table 1 and Figure 5). An IND typically describes the discovery and preclinical testing of the drug candidate, the clinical plans, and various chemical and biological data, including manufacturing details, presumed mechanism of action, and toxicology. In addition, institutional review boards (IRBs) must review and approve all clinical trials at each clinical site. If the FDA does not disapprove an IND or put it on hold within 30 days, human testing may begin.

Clinical trials include three phases of testing prior to filing of an NDA with the FDA (Table 1). In Phase I, which takes about 1.5 years to complete, up to 100 healthy human volunteers are studied to determine safety and dosage

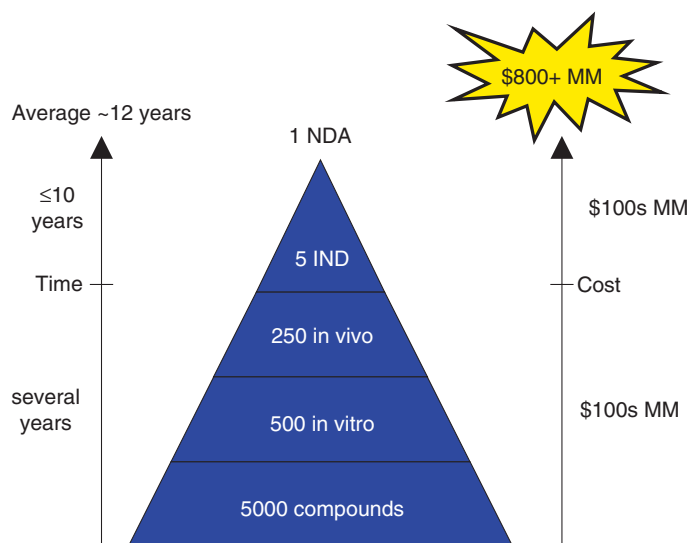

Figure 5 The drug development pyramid – long timelines, high costs, heavy attrition. IND, Investigational New Drug Application; NDA, New Drug Application. (Reprinted with permission from Moos, W. H. Introduction: Combinatorial Chemistry Approaches the Next Millennium. In *A Practical Guide to Combinatorial Chemistry*; Czarnik, A. W., DeWitt, S. H., Eds.; American Chemical Society: Washington, DC, 1997, pp 1–16. Copyright 1997 American Chemical Society.)

parameters. In Phase II, which may take 2 years to complete, up to 500 patients are studied to evaluate drug efficacy and side effects. In Phase III, thousands of patients are studied to confirm efficacy and monitor adverse reactions with longer term use. Approximately one in five of these compounds progress through an NDA to FDA approval. An NDA describes all of the information that a company has amassed, and may amount to more than 100 000 pages of reports. (Fortunately, FDA filings are increasingly electronic, rather than hard copy.)

Of course, there are exceptions. For instance, in some diseases, such as cancer, in which the drugs may be very toxic, initial human testing is conducted in patients rather than normal individuals, and preclinical testing may be abbreviated.⁴⁶ In orphan diseases, defined in the US to be diseases with fewer than 200 000 patients, smaller numbers of patients may be studied.⁴⁷

Congress first signed the Orphan Drug Act into law in 1983, recognizing that there are many life-threatening or very serious diseases and conditions that have not received attention because of their small market size. Developing drugs for these indications would not be profitable without financial and other incentives. This group includes such diseases as amyotrophic lateral sclerosis (ALS; Lou Gehrig's disease), Huntington's disease, and muscular dystrophy, which affect small numbers of individuals. Incentives are now in place in the US, Europe, and elsewhere for orphan diseases, providing facilitated interactions with regulatory bodies, grants and other financial incentives, and marketing exclusivity for a period of years, when certain conditions are met.

Once a drug is approved, and physicians begin prescribing it, the FDA may require further testing. This postmarketing surveillance period is sometimes referred to as Phase IV (Table 1). During this period, companies must continue to submit regular reports to the FDA describing adverse reactions and other relevant records.

Given all of these circumstances, many of which may be incomprehensible to lay persons, how does the public view the pharmaceutical industry? Medicinal chemists and their employers should be pleased to hear that 78% of adults say that ethical drugs make a big difference, and 91% believe that drug companies make significant contributions to society through R&D.⁴⁸ Despite this positive view, one can find a number of unflattering (and some would say unfair) assessments of the industry and its players.⁴⁹

And what about the media? Though the media serves an important role in society, sometimes it works at cross purposes with pharmaceutical and biotechnology R&D, in part by promoting sensationalism and fear mongering at its worst. Both reporters and scientists can be at fault when this relationship and its checks and balances fail.^{50–52} It is hoped that this chapter, and the other chapters in this volume and series, will in some small way aid in making the relationship between the media and scientists practicing this art one of honesty and mutual understanding. May the next scientific breakthrough be viewed with a new perspective of comprehension and reported in a balanced manner.

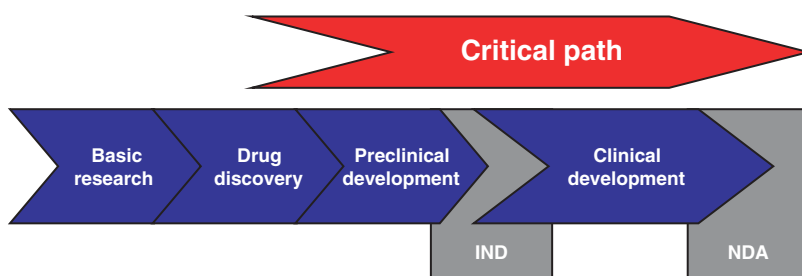

Figure 6 The FDA critical path for medical product development.

2.01.2.2 Major Issues Including Attrition

How does one take into account today's major issues – including attrition, productivity, efficiency, success rates, costs, and shots on goal – and make things better? The acceleration expected in drug discovery and development with the advent of new technologies such as combinatorial chemistry and genomics has, unfortunately, been slow to materialize. This delay has led to much discussion in academic, government, and industry circles, with various proposals resulting. For example, the FDA has analyzed the so-called pipeline problem and published a white paper on its assessment of the challenges and opportunities in the critical path to new medical products.⁵³ During the last decade, both the total budget of NIH and US pharmaceutical R&D spending have more than doubled (Figure 2). Despite these increases in spending, the total number of NCEs and NBE license applications (BLAs) submitted to the FDA has dropped by roughly a factor of two (Figure 3). While most stages and phases of drug discovery and development appear to have slowed and become more expensive, it is in what FDA calls the critical path (Figure 6) – from preclinical development to product launch – that the changes are most evident. The critical path investment required for one successful product launch has increased by more than \$500 MM since 1995. A new product development tool kit has been proposed to address the pipeline problem, including modernized scientific and technical methods in several areas. Areas of focus in the new product development tool kit include animal models, computer-based predictive models, biomarkers for efficacy and safety, and clinical evaluation techniques, including the following.⁵³

2.01.2.2.1 New product development tool kit for the critical path

Efficacy:

- Quantitative metrics and surrogate markers correlating mechanism of action with efficacy
- Imaging technologies
- Pharmacogenomic strategies for optimal patient selection

Safety:

- Proteomic and toxicogenomic approaches
- Predictive in silico toxicology
- Accurate assessment of cardiovascular risk, including QTc interval prolongation

What causes attrition? The average clinical success rate, from first-in-man studies to registration, was only 11% from 1991 to 2000 among the 10 largest drug companies. In the clinic, a lack of efficacy or safety concerns each account for about 30% of the failures. While pharmacokinetics and bioavailability have been cited as the reasons for around 40% of attrition in prior years, more recent estimates show that these factors account for less than 10% of the failures. In recent years, cardiovascular drugs have had the highest success rate (20%), whereas oncology and women's health drugs have had the worst success rates (no more than about 5%). Some authors have proposed that one can reduce attrition by paying attention to various factors, such as the following⁵⁴:

The following factors may influence attrition:

- strong evidence supporting mechanism of action and links to specific disease pathways;
- elimination of leads with mechanism-based toxicity using modern tools such as gene knockouts;
- identification of biomarkers for dosing and efficacy;

- early proof-of-concept studies in humans;
- more appropriate animal models such as transgenics; and
- earlier resolution of potential commercial issues, including alignment of R&D and sales and marketing and more accurate forecasts of changes in medical best practices and competitive products.

It may be possible to achieve the desired output by brute force. The larger the number of drugs in development, the greater the chance that drugs will be approved – this is a quantity argument that ignores quality in calculating the potential for success. Nonetheless, is it possible that some of the largest drug companies, such as Pfizer, will in fact become large enough that they will have enough shots on goal to be successful almost regardless of the odds.

2.01.2.3 **Project Management Including Teams**

Pharmaceutical R&D can be organized in various ways, taking into account line versus matrix considerations, departments versus teams, decision points, interfaces, and transitions. Some companies have developed strong line management-based departments, such as chemistry, biological sciences, pharmacokinetics and drug metabolism, and toxicology. In these organizations, projects may be driven by individuals within a department, who on their own find collaborators in other departments to move projects forward (department-driven projects, [Figure 7](#)). In others, matrix teams are in control, though departments based on scientific discipline provide a home for team members (matrix-driven projects, [Figure 8](#)). Team leaders in a matrix organization report directly to the head of research, as well as reporting to their department heads. A hybrid of these two approaches places all of the necessary resources for each project under one person’s control, regardless of scientific discipline (self-contained projects, [Figure 9](#)). In these organizations, there is no scientific discipline-based department. The project is the department, with the necessary chemistry, biology, and other scientific disciplines all self-contained. The choice of organizational structure is based more on personal preference and experience than on clear evidence that one system works better than another. In the matrix-driven project model,

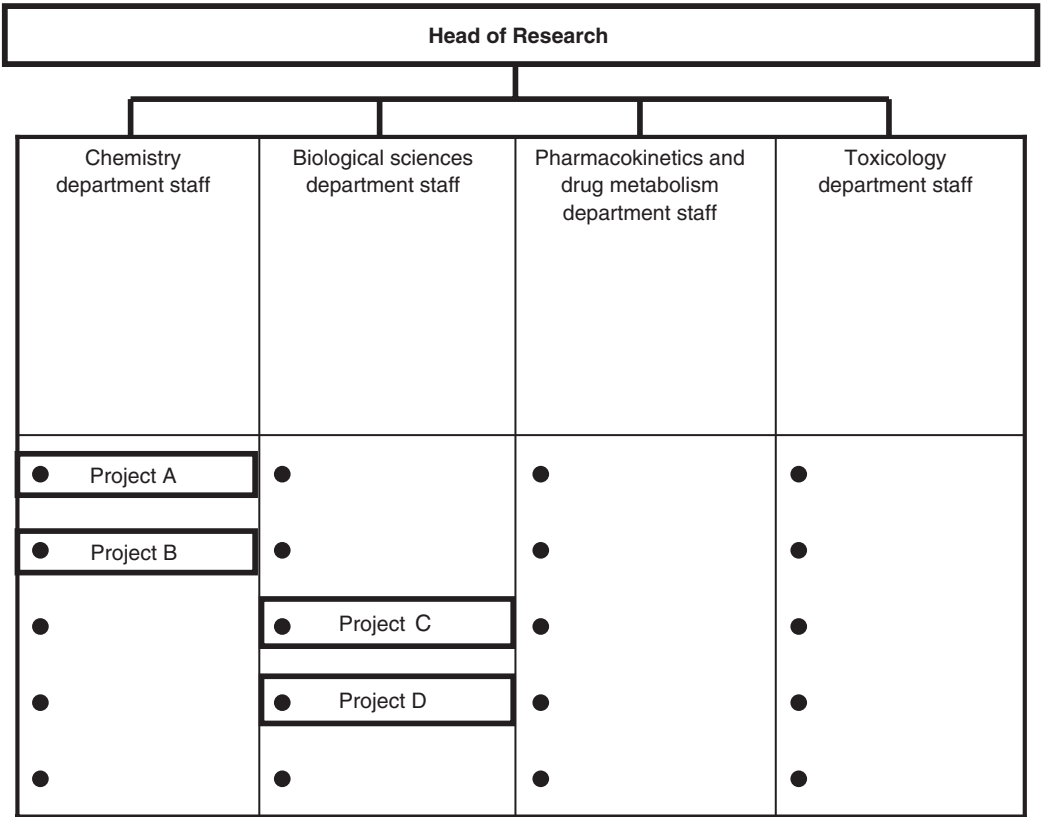

Figure 7 Department-driven projects.

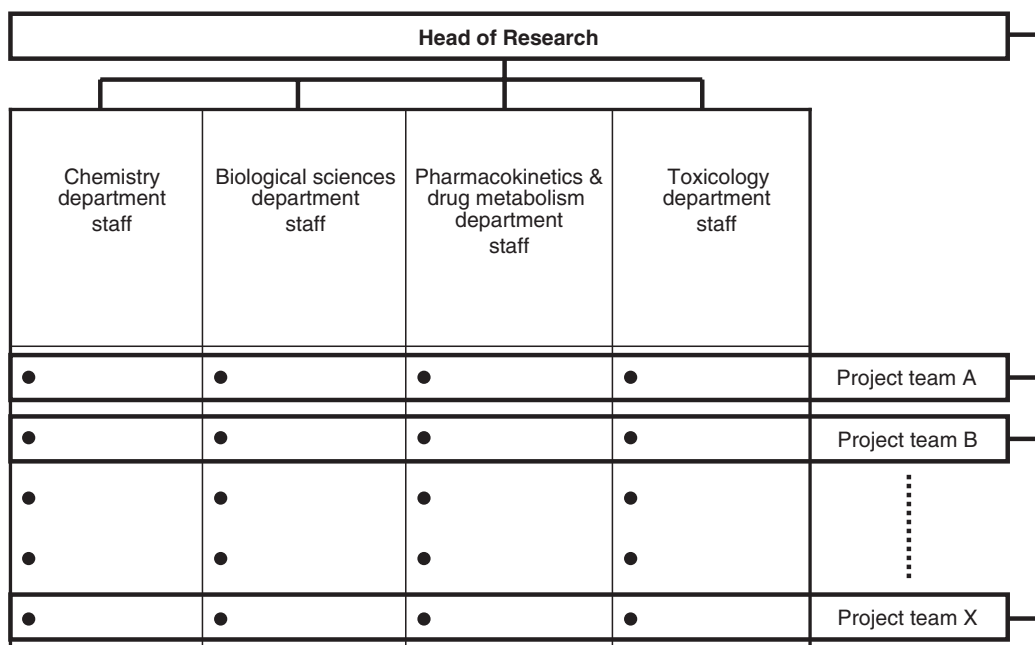

Figure 8 Matrix-driven projects.

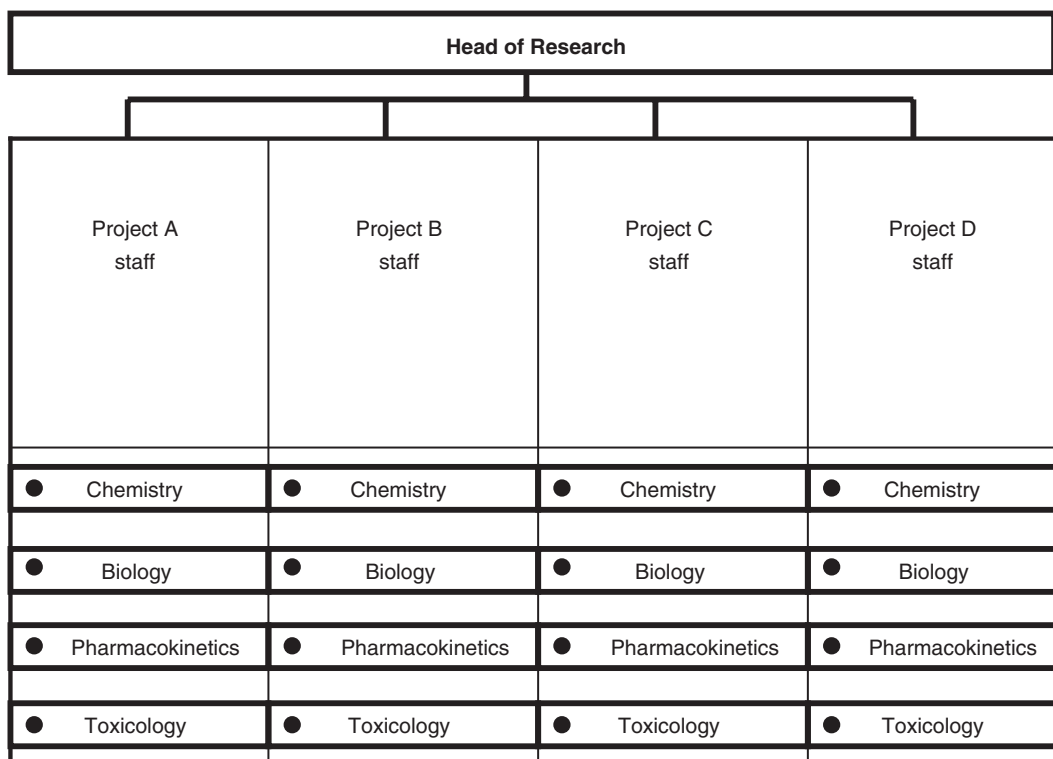

Figure 9 Self-contained projects.

one may have the best of all worlds, but significant coordination is required, necessary resources may not always be available, and leaders may have more than one boss. In self-contained projects, all of the resources necessary to be successful are under project control, but the quality of the science may suffer because there is no larger home for each scientific discipline.

Table 3 Project team members are selected to represent different departmental mixes at different stages of development

<i>Scientific members</i>	<i>Other team members</i>
Biochemistry	Business development
Chemical development	Contracts
Clinical development	Intellectual property
Core facilities	Project management
Drug metabolism	Regulatory
Medicinal chemistry	Sales and marketing
Molecular biology	
Pharmacokinetics	
Pharmacology	
Toxicology	

Project team members are drawn from various departments to address the needs of a project at different stages (Table 3). Thus, medicinal chemistry and discovery biology are critical in the early stages of the project, whereas chemical development, clinical and regulatory, are more important as one enters the clinic. A project team might range in size from a few people to two or three dozen members.

Project team chairpersons are responsible for the success of their projects. The chair provides overall leadership for the project from a scientific and management perspective. The chair should push the project forward to ensure that state-of-the-art (SOTA) technologies are being applied, group cohesiveness is maintained, and progress is being made toward team goals. Ultimately, the team leader is responsible for communicating the project's successes and failures to management. Team vice- or co-chairs assist the chairs in all aspects of the project. The vice-chair assumes responsibility for the project in the chair's absence. In addition, the vice-chair is responsible for recording the team's progress, or lack thereof, and disseminating this information as appropriate.

Before embarking on a new project, and as part of periodic project reviews, many groups evaluate the project from a number of perspectives. Some companies refer to this as a SWOT analysis – Strengths, Weaknesses, Opportunities, and Threats. The questions asked might include the following:

- What is the overall objective, and over what time period?
- Is this an area of major unmet medical need?
- Is the market large enough to warrant the time and cost required to develop a new drug?
- How are you and your competitors approaching the problem, and how will you win this race or competition?
- What are the clinical, regulatory, and other hurdles that you need to surmount?
- What constitutes proof-of-concept, and how will you know when you reach your objective?
- What are the resources you need to be successful?

Decision making of this sort is important in almost any profession, albeit less complicated in many other industries. Managing the interface of drug discovery and drug development successfully requires a clear target product profile that team members and management have agreed upon.⁵⁵ Some groups start by constructing a hypothetical package insert for the product they would like to develop.

2.01.2.3.1 Overall project assessment scheme

Executive summary:

- Synopsis of R&D program
- Objectives, including timeframes

Medical need:

- Disease incidence/prevalence
- Demographics/geographical distribution

Strategies to meet objectives:

- Current industry/medical dogmas
- What is your primary approach?
- What constitutes proof-of-concept?
- Rationale for choosing these approaches
- What are the alternatives?

Competitive assessment:

- Competitive technologies and approaches
- Status of top products already marketed or in clinical trials

Market assessment:

- Overall business/commercial potential
- Potential impact of disease trends
- Potential impact of new drugs reaching market within 5–10 years

Regulatory position:

- Pharmacogenomic opportunity?
- Nonclinical R&D issues (pre-IND)
- Clinical R&D issues (pre-NDA)

Resources:

- Team chairs and champions
- Resources, including staffing plans and other major expenses
- Major consultants

Proposed goals/milestones:

- Project history
- Plans for next 12 months
- What does success look like 5 years hence?

One of the basic decisions to consider at the earliest stage of drug discovery is which scientific or therapeutic area a given team of people should focus on. Once a group is operational, targets need to be validated, and decision points and transitions need to be considered.

2.01.2.3.2 Target validation

- Are the targets relevant to the disease?
- What is the desired profile of a drug acting against a given target, and how should one screen for this activity?
- Once hits have been identified, and improved leads have been prepared, when are the leads good enough to proceed to exploratory development, such as rising-dose, range-finding toxicology?

2.01.2.3.3 Selected decision points and transitions from discovery to new drug application

- Therapeutic area choice
- Target validation
- From screening hits to optimized leads
- Entry into exploratory preclinical development
- Advancement to full-scale preclinical development
- IND preparation and submission
- Conduct and review of clinical Phases I–III
- NDA submission

With each successive stage of drug discovery and development, new groups must interface to advance the project. As a drug moves into early development, scale-up is usually required, in order to prepare enough material under controlled conditions to proceed with toxicology and other studies

Despite these never ending complications, a very large number of drugs have made it to the finish line, being marketed in many countries around the world. Several books provide details on these drugs and their properties from the perspective of medicinal chemistry or from other pharmacological and medical perspectives.^{56–59}

2.01.2.4 Recruitment and Management of Human Resources

How does one recruit and manage the human resources required to be successful in medicinal chemistry and pharmaceutical R&D? There are, as one might expect, many factors to consider:

- How many people are needed?
- What mix of talents and personalities will be most functional?
- Who is the right boss for various occasions?
- How does one provide for career growth and training?
- What about other factors that fall under categories such as morale, management, and leadership?

Research laboratory management requires paying attention to both the forest and the trees – the big picture as well as the details.⁶⁰ It requires finding ways to stay informed without micromanaging.⁶¹ Managing well requires many leadership skills, including an appreciation for and a knack for leveraging different styles, the ability to communicate effectively on many different levels, ways of addressing conflict and change constructively, comfort (or if not comfort, then a productive disharmony) with the corporate culture, and an understanding of motivation.⁶² A terrific scientist and friend once described to me what makes for a successful scientist in Biotech or Pharma (paraphrased below)⁶³:

Often the scientists who are most successful in industry have an in-depth knowledge of some specific area within their discipline, and, to the extent that they are vocal promoters of such a subdiscipline, could be viewed as *prima donnas*. The major question for such an individual is not whether this type of attachment should be readily abandoned, but rather whether other approaches are viable, respectable, and supportable as practiced by colleagues with different expertise. The scientist who believes that s/he has the only solution to any problem does not fit well into a biotech or pharma setting because s/he sends others clear signals that they have no value except to serve as acolytes to his/her vision and technical approach. The true *prima donna* is so self-centered and intolerant of others' ideas that s/he causes too much collateral damage to justify his/her limited success. The super subspecialist who values others' approaches is, on the other hand, a potentially fine colleague who can make substantial contributions to a multidisciplinary organization. For the manager of such a person, the challenge is to prevent that individual from becoming isolated and evolving a program that does not employ alternative practices. Though one could focus on examples of failures, this is perhaps less productive than highlighting successes. Successes can arise from proper contextual use of subspecialty expertise, such as combinatorial chemistry as one avenue of drug discovery, while separately evaluating specialty libraries related to biological target families, and also using scaffolds derived from specialty libraries to enable new combinatorial approaches. As another example, rational drug design approaches, which are usually employed only in a convergent fashion – to advance from lead to preclinical candidate – can also be employed in a divergent fashion to suggest novel scaffolds for novel combinatorial programs.

While the importance of interviewing can be lost on busy technical people in companies both large and small, hiring new researchers who have the ability to make both intellectual and emotional contributions to an organization (especially small organizations) can mean the difference between self-destruction and success.⁶⁴ How do you judge a candidate for a job? Can and will s/he do the job? What about compatibility with the current team? What are the candidate's values, work ethic, motivations, hot buttons, etc.? How do you make sure to avoid legal pitfalls during the interview, possibly related to age, race, religion, sex, sexual persuasion, or marital status? If the job candidate had a problem at their prior employer, will that problem repeat itself at your place of work? There are some desirable characteristics to look for when recruiting⁶⁵:

- role awareness and loyalty;
- high and focused energy levels;
- inner motivation and good reasons to want the job;
- emotional maturity and compatibility;
- fire in the belly (but not a rebel without a cause); and
- drive to complete tasks that have been started.

As one progresses up the management ladder, there are many factors that may influence successful transition from technical jobs to management, as outlined below⁶⁶:

- treating time as a most precious asset;
- dealing well with aggravations;
- selling yourself versus the competition;
- mentorship (for you and for your staff);
- leveraging strengths;
- understanding and compensating for one's weaknesses (possibly more important than having great strengths);
- teaming and collaboration;
- confidentiality and corporate obligations; and
- the art and science of negotiation.

After reading a memo on completed staff work in a military journal, an early head of a major pharmaceutical company summarized his thoughts as follows.⁶⁷ He certainly offers something to consider:

1. It is your job to advise your chief what he ought to do, not to ask him what you ought to do.
2. Your views should be placed before him in finished form so he can make them his views simply by signing his name (... 'or by making very minor corrections').
3. ...[A] draft needn't be neat but ought to be complete.

Setting expectations can be important from many perspectives – to maximize performance and to minimize frustrations, amongst others. In this context, what does one tell aspiring medicinal chemists just starting out in their careers? Perhaps they need to know, at a very basic level, their missions, the keys to success, and their responsibilities, as outlined below – points that might be only rarely taught to those who end up practicing medicinal chemistry, if at all.⁶⁹ The exact origins of this listing of overview and responsibilities are unclear, but it is something that the author has used and developed in various forms over the years.

2.01.2.4.1 Guidelines for medicinal chemists early in their careers

2.01.2.4.1.1 Overview

2.01.2.4.1.1.1 Mission of a medicinal chemist To use all techniques and knowledge available to the modern organic chemist, combined with a sound understanding and application of medicinal principles, in order to discover innovative, safe, and efficacious new drug candidates in a timely and efficient manner.

2.01.2.4.1.1.2 Keys to success Highly intelligent, skilled, and motivated scientists whose contributions, individually and as part of a team, both in ideas and in the synthesis of compounds, are absolutely essential to novel drug discovery and development, to the company, and to the ultimate beneficiaries of new medicines.

2.01.2.4.1.2 Responsibilities

2.01.2.4.1.2.1 Literature work Appropriate literature searches should be conducted to evaluate possible synthetic routes and to determine whether target compounds or analogs are known. Knowledge of current literature is important. Independent reading of relevant scientific literature during off hours is essential for optimum performance.

2.01.2.4.1.2.2 Synthesis of known compounds You should know if the compounds you are making are known. It makes little sense to reinvent the wheel – in the long run you will get farther by consulting the literature first. If a compound is known but not fully characterized, then you should complete the characterization. Where physical data have been reported, you must compare some but not necessarily all data. Application of appropriate and thorough chemical expertise is essential. After appropriate literature work has been done, new compounds should be prepared by the best possible route. Preparation involves setting up and carrying out reactions, monitoring reaction processes, working up reactions, and purifying and isolating the desired products. Full chemical characterization ideally implies at least the following: nuclear magnetic resonance (NMR) spectroscopy and other spectra to ascertain structure, mass spectrometry and/or elemental analysis to determine composition, and chromatography to show the degree of purity. Where desirable, other data should be obtained. Careful interpretation of these spectral and analytical data is expected.

2.01.2.4.1.2.3 Submission of compounds for biological evaluation Appropriately characterized target compounds should be submitted for biological evaluation as directed, with inclusion of as much relevant information as possible on submission forms (which are increasingly electronic). The forms may include information regarding solubility, project classification, synthetic routes, and references.

2.01.2.4.1.2.4 Maintaining accurate and well-documented experimental records Research notebooks should be kept orderly and up-to-date, with cross-references wherever necessary. Experimentals should include starting reagents, a description of the experiment (setup through isolation), references where appropriate, cross-references to spectra, analyses, and the like, and an overall assessment of mass balance and yield.

2.01.2.4.1.2.5 Invention records Significant ideas for new target structures, modifications to existing leads, or new methods of compound use should be recorded in a full and timely manner. To ensure the maximum value of invention records, new ideas should be investigated, developed, and exploited with diligence.

2.01.2.4.1.2.6 Safe laboratory conduct General safe laboratory conduct is essential. This includes maintaining clean and organized work areas, and proper disposal of wastes. Safety glasses must be worn at all times in the laboratory, and no food or drinking material should be present in the laboratory. Water awareness is expected – to reduce the chance of floods – with hoses clamped and unused water lines turned off.

2.01.2.4.1.2.7 Oral and written reports Reports should be completed in a neat, concise, and timely manner whenever requested. Clear reports at various meetings summarizing recent personal work are expected. Again, preparation of invention records, patents, and manuscripts should be done in a timely fashion.

2.01.2.4.1.2.8 Careful treatment of laboratory equipment Equipment should be treated with respect. This includes maintaining instruments, keeping equipment clean, and not abusing equipment. For example, vacuum pump oil should be changed regularly, glassware breakage should be kept to a minimum, stirrers and hot plates should be wiped off periodically, cracked or frayed electrical cords should be replaced, and glassware should be cleaned thoroughly and soon after use.

2.01.2.4.1.2.9 Independence and initiative A certain degree of independence should be demonstrated in the completion of assigned tasks. Similarly, initiative should be taken to design and implement synthetic routes to unknown compounds. Routine purifications, isolations, and characterizations should be carried out without intervention. Supplies of important intermediates should be monitored, and when low, further supplies should be synthesized or purchased. An appropriate range of alternatives should be considered prior to making decisions.

2.01.2.4.1.2.10 Personal interactions Personal interactions should be handled professionally. Interpersonal problems should be confronted in a constructive and positive manner. Diplomacy, consideration, and the ability to compromise (when appropriate) are important traits.

2.01.2.4.1.2.11 Monitoring biological activity The activity of compounds should be monitored carefully. A good understanding of the biomedical underpinnings of the project is necessary for optimum performance. New compounds should be suggested for synthesis based upon sound medicinal reasoning. Where appropriate, computer-assisted methods should be employed. Knowledge of compound numbers, names, and structure–activity relationships (SARs) is expected.

2.01.2.4.1.2.12 Awareness of goals An awareness of corporate, department, group, and personal goals is important.

2.01.2.4.1.2.13 Timeliness The importance of developing, implementing, and maintaining effective plans should not be underestimated. Deadlines should be adhered to; even better, complete the task ahead of schedule. Potential problems should be anticipated. The status of tasks and assignments should be reviewed periodically to ensure successful completion.

2.01.2.4.1.2.14 Management Assigned personnel should be managed effectively. This requires the use of appropriate leadership styles for the circumstances at hand, and administering relevant policies, practices, and procedures.

Additional words to the wise for thought processes, decision making, and related topics have been summarized elsewhere.⁷⁰ It is important to develop, maintain, and where possible record, the institutional memory of organizations. This tacit knowledge can be a significant strategic advantage – or a troublesome stumbling block.⁷¹

Scientists may not be as focused on money as people in other professions, but money can still be a factor in medicinal chemistry, as in any other profession – for recruitment, retention, and job satisfaction. Though the media and the general public often complain about the compensation paid to pharmaceutical and biotechnology executives, is their compensation truly out of line with leaders in other professions? (This is always a hotly debated topic.) In recent years, salaries for biotech executives have trended upward. The salary range generally depends on company size, from small companies with market capitalization below \$50 MM with executives paid \$275 000 annually, to large companies with billion dollar market capitalization with executives paid \$500 000 annually. A bonus based on performance is often granted on top of the salary, as are stock options (see below).⁷² As one comparison, consider professional baseball, with average salaries greater than \$2 MM, versus biotechnology chief executive officers (CEOs), with average salaries (base plus bonus) of \$310 000. Successful mortgage and real estate brokers, as well as those involved in various segments of the financial industry, are routinely compensated well above biotechnology company CEOs. At the top end, while the CEO of Pfizer made almost \$17 MM in 2004, including stock-related compensation, and the CEO of Genentech made \$23 MM, many professional athletes, radio, television, and movie stars, and real estate moguls made the same or more. Thus, if one sets aside the debacles of Enron, ImClone, Tyco, WorldCom, and a few others, healthcare and other corporate executives are in fact underpaid versus other professions, especially given the importance of healthcare.^{73–80}

2.01.2.5 Multiple Sites Including Outsourcing

Internal research must be coordinated within and without, including with contract organizations, to which work may be outsourced. Whether a company is a giant pharmaceutical corporation or a small biotechnology firm, it may be resident at more than one site. Large multinational companies often have R&D sites in several countries. For example, Warner-Lambert's Parke-Davis Pharmaceutical Research Division (now part of Pfizer) had R&D sites in France, Germany, the UK, and the US (California, Michigan, and New Jersey) at various points in time. Even small biotechnology companies may have sites in more than one country. The small, privately held biotechnology company MitoKor (now part of Migenix, based in British Columbia, Canada) at one time had sites in Massachusetts and California in the US and also in Australia.

With size and multiple sites, though, come difficulties in managing a large and far-flung empire. The concept of making each site more or less self-contained is one that some companies have gravitated toward, with what GlaxoSmithKline calls Centers of Excellence (as in Centers of Excellence in Drug Discovery (CEDD)). This approach makes a given site more like a biotechnology company, with all of the resources necessary to take drug candidates into early clinical development, and ideally through human proof-of-concept.^{81–83} Johnson and Johnson (J&J) claims to take this approach as well, with various acquisitions historically operating rather independently (e.g., ALZA, Centocor,

and Janssen). Warner-Lambert also followed this approach, with its UK site focusing on neuroscience, and its California site focusing on structure-based design in areas such as antivirals and anticancer agents.

Having multiple sites can lead to we/us versus they/them issues, lack of coordination, duplication of resources, and many more challenges. If the sites are in distant time zones, there may never be a convenient time to talk, though faxes, emails, and cell phones help in this regard. Some companies have chosen to organize different sites around different therapeutic areas. This structure provides focus and critical mass, which makes sense from a business standpoint. However, it can limit the potentially profitable follow-up of scientific discoveries that lead one outside the site's therapeutic areas, a limitation that makes no sense from the perspective of scientific innovation because it is often the unexpected results that open the door to major opportunities. Unfortunately, the organization of research facilities is only one of many areas where the viewpoints of business and science may differ. Clearly, to apply the principles of portfolio management properly and most successfully, one must consider the elements of both business and science.⁸⁴

Even the largest companies will contract out certain work. Small companies with only a few people may contract out most or all of their laboratory studies. Preclinical development and clinical and regulatory tasks are commonly conducted by contract research organizations (CROs) that specialize in such areas, such as Covance, MDS, PAREXEL, Southern Research Institute, SRI International (formerly the Stanford Research Institute), and others that have preclinical or clinical capabilities. In recent years, both chemical discovery (especially chemical libraries) and chemical development have found outlets in chemistry CROs, including Albany Molecular, ArQule, Array, Ash Stevens, and Discovery Partners, to name a few.

Decisions to outsource R&D may be based on practical business needs, practical scientific limitations of one's organization, or even personal relationships. However, there are often a number of advantages to using CROs. They provide expertise and resources (people, contacts, laboratory space, and equipment) in areas that some firms may not have, and there is no commitment to continue funding the staff or the work beyond a certain point. For small companies, the alternative, namely, recruiting and making a long-term commitment to the necessary staff, outfitting a laboratory, and getting operations up and running, usually would take too long and would commit too much capital to be worthwhile. For a large company, CROs provide additional resources that extend what a firm might be able to accomplish during periods of peak activity.

Even basic research is frequently outsourced. Most of the large biotech-pharma alliances are essentially outsourcing arrangements, with the biotech company contributing new technologies and approaches while big pharma provides the funding and later stage resources required to take a product through preclinical and clinical development to marketing and sales. The need for and the value of such deals have been established since the 1980s through numerous partnerships, though disappointment is not uncommon. One could argue that big pharma should outsource even more of its research, focusing internally on its stronger capabilities in development and commercialization. Indeed, breakthrough products discovered and developed internally at major pharmaceutical companies have become a rarity, even though R&D expenditures at these same companies have roughly doubled every 5 years since 1970. Biotechnology companies, on the other hand, appear to be playing an increasingly important role in generating new therapeutic product candidates – and they are doing this with far less investment than their larger competitors. The factors driving this evolution range from financial to management to scientific, an understanding of which provides a more profitable future. Pharmaceutical and biotechnology companies that place themselves at the center of a cluster of relationships with partners (see [Figure 10](#)) may significantly outpace their more internally focused competitors, by increasing the productivity of their overall R&D efforts, at lower cost, and with less risk. Thus, in the view of some, “the twentieth century... encompassed the rise and decline of major pharmaceutical discovery research laboratories.”⁸⁵

The Pacific Rim has experienced substantial growth in biotechnology and pharmaceutical R&D. Southeast Asia, including China, India, and Singapore, as well as others, represents growing competition for the future, and offshoring of high technology jobs from the US and Europe has become a topic of discussion and concern. Companies such as Bridge Pharmaceuticals have been set up to take advantage of offshore CROs and other opportunities in mainland China, Taiwan, and elsewhere. Government-supported expansion has been especially evident in Singapore since the 1980s, with its Economic Development Board (EDB) and, more recently, the Agency for Science, Technology, and Research (A*STAR). Various companies, large and small, have established significant research efforts in Singapore as a result, including Novartis and MerLion, to name just two.^{86–87}

2.01.2.6 Contrasting Biotech with Pharma and Innovation

Companies go through several stages as they develop, moving from start-up through focus, integration, optimization, and finally reaching maturity. Management practices must evolve during these progressions, or crises and even business

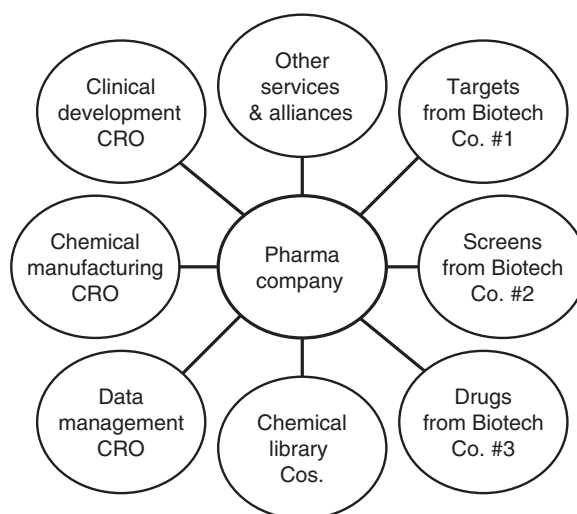

Figure 10 A pharma-biotech cluster model.

failures will result. Thus, whereas the management profile in early business stages is often vision-driven and planning is ad hoc, later-stage companies require more structured processes and formal planning. Similarly, business goals evolve from being flexible and entrepreneurial to being more consistent, integrated, and measurable.⁸⁸

Biotech can be contrasted with pharma and innovation in the following ways:

- entrepreneurs versus intrapreneurs;
- planning versus chaos;
- strengths and limitations of each model and individual;
- new frontiers versus me-too products;
- effect of research environment; and
- champions.

Innovation is often discussed but too rarely practiced (and even more rarely studied with rigor, though a few examples can be found in the recent literature⁸⁹). In fact, many people fight innovation as it moves through the several stages of a revolution. The stages of a scientific revolution have been summarized in various ways for centuries. For example, the German philosopher, Arthur Schopenhauer, who lived from 1788 to 1860, has been quoted as follows. “All truth passes through three stages. First, it is ridiculed. Second, it is violently opposed. Third, it is accepted as being self-evident.”⁹⁰ Others have elaborated on the general theme that Schopenhauer stated so clearly and simply. In the first stage of a revolution, your friends tell you that you are wrong, dead wrong. You are not even close to the truth. Some of your friends stop being friends as you continue to pursue your disruptive idea. In the second stage, a few of your colleagues begin to admit that there may be some validity to your hypothesis. Don’t let this lull you into a sense of security, however, because they continue to deride you, discount the value of your new approach, and may even attack you in public. Even worse, they may undermine you and your hypothesis behind your back. In the third stage, the soundness of your concept is at last recognized by a growing majority in your field, but most people still spend their time finding holes in your theorem. Finally, even the opinion leaders – the power brokers of your field – agree that there is significance in your work, and they eventually announce that it was in fact their idea in the first place.⁹¹

In the end, new science usually needs to be hyped to have a chance. New technologies are always greeted with skepticism, many people have vested interests in competing old approaches, and people do not like change in general. Moreover, the timeframe to develop practical applications of new technologies is always longer than expected. However, for those who persevere with a truly valuable new technology, proof-of-concept (PoC) or proof-of-principle (PoP) comes when the eureka moment was so long ago that most people cannot remember the original experiments or who performed them, successful applications are numerous, the new science is fully integrated into everyday R&D, and the approach is referred to by abbreviation (and many can’t remember what the letters in the abbreviation stand for). Finding the right balance – to be cutting edge but not so novel that one’s work is too risky – is a comfort space that can be difficult to find, as many unique enterprises, such as those pioneering mitochondrial medicine, have observed.⁹²

Recognizing the innovative members of your organization, and creating an environment to get the most out of them, is easier said than done.⁹³ Some might even say that creativity has been held hostage by corporate control systems and capitalism, among other forces.⁹⁴ There are many obstacles and inducements to the process of discovery, but there are a series of research strategies that may help.⁹⁵ In the end, there is no one right way to conduct research, and unusual paths can lead to interesting but unexpected results.⁹⁶

Thus, according to Root-Bernstein, there are ten research strategies to facilitate discovery:

- do the unthinkable;
- get as much noise as possible out of the system;
- run controls over and over and over again;
- make analogies from your work and extrapolate;
- test experimental variables over a very wide range of conditions;
- determine the specific criteria you are looking for and then try everything you can think of until you generate the desired results;
- generate theories of existing processes in order to predict new ones;
- work simultaneously on several problems in the hope that one will cross-fertilize another;
- reevaluate an old discovery from the modern perspective; and
- turn problems on their heads and reevaluate.

The promise and disappointments of innovative science of recent decades are manifold. Advances in analytical techniques and separations technologies, especially NMR spectroscopy, mass spectrometry (MS), and high-performance gas and liquid chromatography (GC and HPLC), allowed the SOTA in the pharmaceutical industry to move forward dramatically in the 1960s and 1970s. These advances were followed in the 1980s by the adoption as routine tools of such techniques as computer-aided molecular modeling (structure-based design, SBD) and molecular biology, including the polymerase chain reaction (PCR). In the 1990s, combinatorial chemistry, high-throughput screening (HTS), and genomics took center stage. Several technologies are vying for the spotlight as we start the new millennium, including proteomics and ribonucleic acid (RNA) interference (RNAi). While many of these techniques are now commonplace, the jury is still out on the routineness and value of antisense and gene therapy approaches (Table 4). Will they become widely accepted, or are they destined to be niche plays? In this writer's opinion, it is likely to be the former, but acceptance will clearly take more time. Some examples of pharmaceutically relevant scientific advances of recent decades are given in Table 5.

Technological advances often spawn a new cadre of start-up ventures. That trend was quite true of the combinatorial chemistry field in the 1980s and 1990s. However, as is common with these waves of change, many of the original companies were acquired, failed or changed directions, becoming unrecognizable or untraceable over a few

Table 4 Which technologies have made it, and which have not (yet)

Widely accepted

short years. (They are, at least, hard to remember.) Some of today's largest independent public biotechnology companies didn't exist in the early years of combinatorial chemistry's debut ([Table 6](#)). The path of acquisition for some companies has been long and tortured, ending with their going out of business ([Table 7](#)).

The mantra in many of these new fields has some or all of the elements of doing things better, faster, and cheaper. The paradigm shifts of recent decades have often led to subtle improvements, which are possible only with extra spending, and therefore are certainly not cheaper ([Table 8](#)).

The timeframe for the development and adoption of new technologies is typically several decades. Using combinatorial chemistry as an illustrative case, one can trace its origins to the 1960s and early solid-phase peptide chemistry. If one accepts this starting point, then it took almost 40 years for combinatorial chemistry to become commonplace, and its full impact may not be evident until 2010–2020, given the long timelines of the pharmaceutical industry. Given that Mother Nature had a head start eons ago, it took even longer ([Figure 11](#)).

Innovative science takes time to develop, usually decades ([Table 9](#)).

Table 7 New technologies and start-up companies may take tortured business routes, being acquired, failing, changing directions, or even going out of business^a

Commonwealth Serum Laboratories > CoSelCo Mimotopes > Chiron > Houghton Joint Venture > MitoKor > Fisher Scientific > PharmAus/EpiChem
 Stauffer > Unilever > Cheseborough-Ponds > Imperial Chemical Industries > Zeneca > Oxford/Cambridge Combinatorial > Millennium > Signature > Out of business
 CombiChem > Dupont > Bristol Myers Squibb > Deltagen > Out of business
 Arris > AxyS > Celera > Out of business
 Protos > Chiron > Novartis
 Parnassus > Kosan

Note: The symbol '>' denotes that the previous company became or was acquired by the company after the symbol.

^aThese examples are taken from the field of combinatorial chemistry.

Table 8 Are new technologies better, faster, and cheaper?**Better**

- Often yes
- However, old science is still extremely valuable and new science simply adds to it

Faster

- Often yes
- However, different bottlenecks become rate limiting and speed is still restricted

Cheaper

- Often additive to existing expenses
- Rarely cheaper until many years later

<i>Date</i>	<i>Event</i>
5 billion BC	Earth's formation & first molecular & biodiversity
5 million BC	First human beings
500 BC	Time of Hippocrates, the father of modern medicine
1960 AD	First publications on solid-phase <i>peptide</i> synthesis
1975 AD	First articles on solid-phase <i>organic</i> synthesis (nonpeptide)
1985 AD	First publications on rapid parallel synthesis
1985 AD	First companies devoted to combinatorial chemistry
1990 AD	New drugs approved after 2000 were first studied
2000 AD	Combinatorial chemistry became mainstream

2.01.2.7 Business Development Including Aspects of Portfolio Management

Before one places major resources behind a project, a formal evaluation is required in many organizations. This evaluation may include an assessment of medical need, strategic approach, the competition, regulatory hurdles, market potential, timelines, and resources required, as discussed earlier in this chapter. Many questions arise in the process. For example: How many projects should one work on, in which therapeutic or technological areas? Are you a mile wide and an inch deep, or a mile deep and an inch wide? How should one evaluate internal products versus projects and products that have been acquired or partnered? Where does intellectual property come into play? As in many situations, a fair amount of judgment is required in this area, and colleagues, investors, and other stakeholders may find each other at odds.

One of the most important strategies to balance risk, gain access to cutting edge technologies, and to increase success rate is for larger companies to partner with smaller ones. These alliances are in principle beneficial to both partners. The financial terms of such an arrangement are critical, though probably more so to the smaller partner. Typical deal terms include up-front payments, license fees, equity purchases, staffing costs (full-time equivalents (FTEs) or equivalent full-time staff (EFTS)), and success-based milestone payments and finally royalties after commercialization. There are many factors to analyze when looking at deal terms, as outlined in [Table 10](#).⁹⁷

Because most therapeutic projects fail, it can be better for companies to place multiple bets. That is, taking into account odds of success and failure, a chance to receive 10% each on 10 projects is more likely to yield a payout than 100% on one project. On the other hand, if a company has only one project, it will probably need to keep that project to itself to have a chance of success.

There is a phenomenon sometimes referred to as a U-shaped value curve (which is really an incremental return-on-investment [iROI] curve; [Figure 12](#)). At the earliest stages of a project, such as when a new molecular target has been

Table 10 Deal terms in alliances between pharmaceutical companies and biotechnology firms

	<i>R&D tools</i>	<i>In vitro data</i>	<i>In vivo data</i>	<i>Clinical safety</i>	<i>Clinical efficacy</i>	<i>NDA filed</i>
	<i>Patents, targets, libraries, screens</i>	<i>Lead series</i>	<i>Optimized lead</i>	<i>Phase I</i>	<i>Phase II–III</i>	<i>Approved</i>
Years of work	1 +	2 +	3 +	5 +	6 + +	8 + + +
Deal royalties ^a	0–6%	2–8%	4–10%	6–12%	8–14%	10–20%
Deal value created (\$MM) ^a	\$0–3 each	\$1 +	\$5 +	\$20 +	\$70 +	
Private valuation (\$MM)	\$0–5 each	\$5–30	\$10–60	\$40–120	\$100 + +	
Public valuation (\$MM)	\$1–3 each	\$10–20	\$20–30	\$30–50	\$150 + +	\$400 + +

^a Clinical success milestones (IND, Phases I–III, NDA) typically yield at least \$8–12 MM in addition.

Figure 12 U-shaped project value and investment curve. ROI, return on investment.

Figure 13 Inverted U-shaped value curve for later stage private companies.

identified, the project is often valued very highly. It is new, exciting, and little bad is known about the project. Then, as the project progresses and one learns about limitations or frank problems with the approach, its apparent value (and iROI) may decrease, often hitting a low point in preclinical development, when toxicities begin to appear. Once the drug enters clinical trials, the value (and iROI) increases again, with Phase I/II being a crossover point for deal making. On the other hand, a project may not be partnerable until it reaches a later stage of development, so despite a lower iROI for additional studies, it is critical to spend the money to advance the compound to later stages of development.

There is another phenomenon that produces a U-shaped value curve, but this time it is an inverted U (Figure 13). Later stage private companies that have not yet gone public begin to lose value, ending up in a penalty box for not graduating with their class. Such companies may end up being forced to do down rounds (i.e., reducing the price of their stock, sometimes quite significantly), to merge with other companies, or to go out of business. There may be simply too much baggage from the company's earlier years, too many tired investors, and an over-shopped story, to stand a reasonable chance of pulling out of a downward spiral.

For many early-stage technology companies, the transition to product development is difficult if not impossible. Even in the genomics space, where rich partnering deals and public offerings propelled the industry for several years, companies were forced to forward integrate to clinical stage therapeutic products, often by merger or acquisition, in order to protect their value and viability.⁹⁸ Millennium is a good example, having acquired LeukoSite and COR Therapeutics to get where it is today with products in the clinic or on the market. The standard model, where pharmaceutical companies have been strongly in control of the product outcomes of partnerships with smaller biotechnology firms, is evolving to one where biotechnology companies retain much more control over their targets and resulting drug candidates.⁹⁹

At the core of a project's value is the intellectual property that surrounds it. Intellectual property includes patents, trademarks (TMs) or service marks (SMs), and copyrights.¹⁰⁰ Other confidential information such as manufacturing processes might be maintained as trade secrets. For R&D, patents are usually of most interest, as they give the inventors or their assignees the ability to exclude others. Once filed, patents generally have a 20-year lifetime. Patents start with an invention, recorded as an invention record in many companies, followed by filing of a provisional or full patent application. Patents are usually filed in more than one country, and are valid only in those countries where they issue. To be patentable, an invention must be novel, among other things. If someone tries to make, use, or sell an invention in a country where you hold a patent, they are said to be infringing, and various legal remedies exist. Once a product composition is commercialized, TMs or SMs become more interesting. It is the ability to have a legal monopoly on a given product or its use for a period of time that makes it worthwhile for companies to invest in novel research. Interestingly, certain large companies worry more about freedom-to-operate than being able to exclude others from R&D. They assume that they can out-muscle anyone who invades their territory, provided they have freedom to operate.

2.01.2.8 Drug Development

Drug development, whether chemical or biological, is a complicated but well-documented and heavily regimented process.^{101–102} There are many interesting aspects to this stage of R&D, and chemistry has a major impact at many points along the path toward commercialization. Consider, for example, the switch to predominantly one enantiomer

that has occurred in the last decade or so. Curiously, as recently as the late 1980s, industry information sources were still uncertain as to which drugs were single isomers and which were not.¹⁰³

The representative stages of drug development in which chemistry has significant impact are as follows:

- chemical development;
- process research;
- chirality;
- formulations (especially novel approaches such as liposomes and other nanoparticles, nanosuspensions, etc.^{104,105});
- clinical stages and novel strategies and approaches thereto; and
- commercialization and cost of goods.

Practical aspects of drug development include determining the best salt form and formulation, characterization of the active pharmaceutical ingredient (API), and defining purity requirements. Salt forms can influence bioavailability, manufacturing, purification, solubility, stability, and even toxicity.¹⁰⁶ Salts are often chosen empirically, and systematic approaches to choosing salts have been proposed.¹⁰⁷ Hydrochlorides have been the most common salts historically, representing >40% of the FDA-approved commercially marketed drug salts in 1974. Other common anionic salts include acetates, bromides, chlorides, citrates, hydrobromides, iodides, maleates, mesylates, phosphates, sulfates, and tartrates (Table 11). Calcium, potassium, and sodium are common metallic cation salts.¹⁰⁸ For injectable products, one needs to be wary of potential toxicity resulting from co-solvents and excipients. Certain intravenous solutions may, for example, cause hemolysis.^{109–112}

Purity is also critical. One might target 95–98% purity for early preclinical studies, with no single impurity at levels greater than 1%. Any impurity present at a level of 1% or higher should be characterized both chemically and biologically. (Why is this important? Consider the case where a 1% impurity is 100 times more potent than the main product – its effects thus being equal to that of the main product despite much lower levels.) As development progresses, full-scale toxicology and clinical studies should generally use material that is at least 98% pure, with no single impurity at levels greater than 0.5%.

As development progresses, one must adhere to Good Laboratory and Good Manufacturing Practices (GLP and GMP). Ultimately, a drug manufacturing process can be codified as a Drug Master File (DMF), allowing reference to its contents and general approvals for subsequent use by others.

Thus, there are many challenges in the transformation of research laboratory methods to process R&D at scales suitable for manufacturing and under conditions that meet regulatory guidelines. The low profile of process R&D in past years has become a much higher profile with more complicated molecules entering development (e.g., discodermolide). Ignoring total quantities that might be required, it is clear that dealing with amoxicillin, with an API cost of about \$40/kg, is less of an issue than dealing with paclitaxel, at \$200 000/kg, and drugs such as discodermolide would be off the charts (see below).¹¹³

Novartis successfully carried out a 39-step synthesis to provide tens of grams of discodermolide, a potent tumor cell growth inhibitor, for clinical testing. While the compound subsequently ran into trouble, the Novartis achievement

represents a synthetic tour de force.¹¹⁴ Discodermolide is a polyketide lactone containing 13 stereogenic centers, a tetra-substituted lactone, two multisubstituted alkenes, a carbamate, and a terminal diene. It was originally isolated in small quantities from a Caribbean sponge, *Discodermia dissoluta*, and exhibits potent immunosuppressive and cytotoxic effects. The activity of discodermolide is typical of certain natural products that affect microtubules and the mitotic spindle, including cancer drugs such as epothilone and paclitaxel (Taxol) – see Figure 14. To prepare enough discodermolide for clinical trials, Novartis resorted to chemical synthesis using fragments produced by fermentation, since biological production of the molecule as a whole had not been successful by the time scale-up was required. With an overall yield of up to 10%, and at least 35 total synthetic steps, 60 g of material were prepared.¹¹⁵

Prior to the initiation of each phase of human clinical trials, animal toxicity studies that support the planned doses must be completed (Table 12). These animal studies are typically done in two species, rodents and nonrodents, with the intent of providing adequate safety data to support uninterrupted human clinical trials. Among various exams that are conducted, observations are made regarding the animals' eating and other behaviors, body weights and metabolism, liver and kidney function, and blood parameters.¹¹⁶ A number of studies have evaluated from a regulatory perspective the proper conduct and duration of toxicology studies, including carcinogenicity testing, and considerations for specific therapeutic areas, including respiratory drugs and anticancer agents.^{117–120} This preclinical R&D process, taken (1) from idea to target discovery and validation, (2) through drug discovery, pharmacokinetics (PK), absorption, distribution,

**Figure 15** The process from idea to IND.

metabolism, and excretion (ADME), and toxicity (ADMET), as well as formulation, among other steps, (3) to filing of an IND, requires the interplay of many different groups and disciplines (Figure 15).

If suitable data have been obtained to support human clinical testing and all regulatory hurdles have been cleared, the drug enters clinical pharmacology studies – first in man (FIM) or Phase I. FIM may be conducted in normal volunteers or in patients, depending on the disease target, with rising dose PK and tolerability (safety), and occasionally with biomarker endpoints.

To accelerate the entry of new drugs into clinical trials, as well as to select the best lead for advancement, microdosing or Phase 0 studies have been devised to determine human metabolism data on very small quantities of material. Accelerator mass spectrometry (AMS) has been used to provide pharmacokinetic data, and positron emission tomography (PET) has been used to generate pharmacodynamics information.¹²¹

There are various types of clinical trial design, each with its own set of strengths and weaknesses (Figure 16). Some of the common terms used to describe clinical studies are given in Table 13. For example, a nonrandomized intervention study using historical controls ensures that every patient receives therapy (no one receives placebo). It can be easier to recruit patients into these studies and less expensive to run the trial. However, the lack of a concurrent control can lead to incorrect conclusions, particularly when the current patient population differs from the historical population or when disease management has evolved to a new standard of care. While different diseases and special circumstances may sometimes dictate otherwise, for most Phase III trials the gold standard is a double-blind,

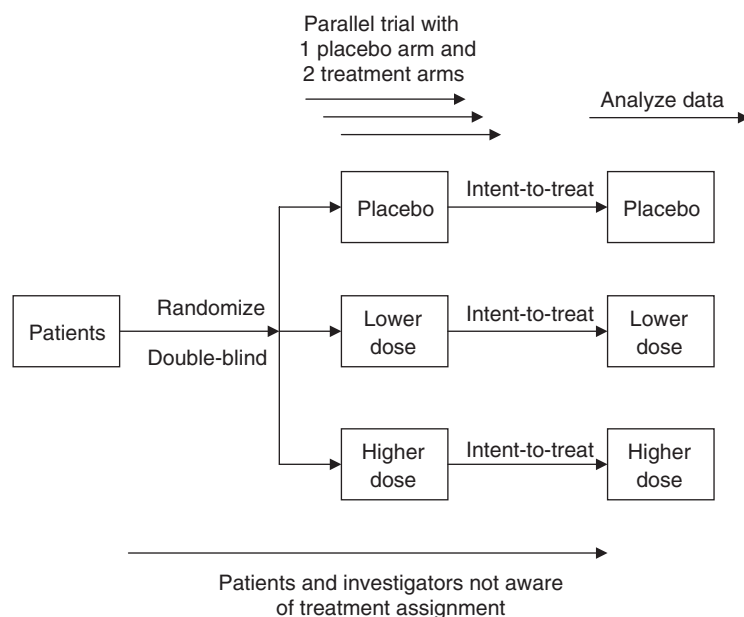

Figure 16 Schematic of a parallel, randomized, double-blind, placebo-controlled clinical trial using an intent-to-treat analysis.

Table 13 Some of the common terms used to describe clinical studies

Cohort	Groups exposed to the therapy of interest are followed for a period of time and then compared with unexposed groups using outcome measures specified up front
Crossover	Subjects to be treated are divided into at least two treatment groups. Each group receives all treatments sequentially after random selection of the first treatment, usually with a washout period between treatments
Cross-sectional	Treatment exposures and outcome measures are determined at a single time point
Double-blind	Neither investigators nor subjects know whether subjects have been assigned to drug or placebo
Intent-to-treat analysis	All randomized patients are analyzed in the groups to which they were originally assigned, regardless of compliance – even if they fail to adhere to the protocol or withdraw from the study
Meta-analysis	Statistical analysis of a combination of separate clinical trials of the same drug
Multicenter	Studies conducted at more than one site
Open-label	Nonblinded study – both investigators and subjects know if subjects have been assigned to drug or placebo
Parallel-arm	Subjects receive one or two different treatments throughout the study
Prospective	Looking forward from a given starting point to assess drug effects
Randomized	Subjects allocated to treatment groups randomly

randomized, parallel-arm study, with the aim of demonstrating statistically significant superiority over placebo. Such a design reduces potential biases from affecting trial outcomes and is less affected by issues such as missing data.¹²² One alternative to a superiority trial is a noninferiority or equivalency trial, with the endpoint being either effectiveness or safety.¹²³ Occasionally, trials will be stopped in midstream for interim analyses. The pros and cons of such an approach must be weighed carefully at the outset, and statistical parameters must be carefully considered.¹²⁴

For any selected design, one must guard against false-positives (type I or α errors) or false-negatives (type II or β errors). To avoid false-positives in analyzing clinical data, a significant outcome is usually considered to be only those results that reach statistical significance at the level of $p = 0.05$ or better. To avoid false-negatives, the sample size (number of patients) is adjusted (powered) based on the targeted difference between treated and control arms so that the study is likely to show statistical significance.¹²⁵ Biomarkers or surrogate endpoints are being used increasingly to help guide clinical trials. Thus, while the definitive endpoints in renal transplantation are several, one of the definitive

endpoints is acute rejection, and creatinine serves as a straightforward surrogate endpoint. In prostate cancer, the definitive endpoints are mortality and disease progression, but prostate-specific antigen (PSA) levels have been used as a surrogate endpoint (though not without controversy).¹²⁶ In targeted cancer therapies, a number of changes have been made to the standard clinical protocols. For instance, instead of looking for a maximum tolerated dose and dose-limiting toxicities in Phase I, the desired outcome might instead be the optimal biological dose with no toxicity.^{127,128} Ultimately, substantial evidence of efficacy must be demonstrated to gain approval of an NCE, which may require multiple adequate and well-controlled clinical trials, using prospectively determined assessment variables for major outcomes and both a global clinical improvement rating and a specific quantitative assessment related to the disease that is accepted to be valid and reliable.¹²⁹

Ultimately, the path to drug approval is not always a straight line – far from it in many cases. Tacrine, an aminoacridine, was the first drug approved by the FDA to treat Alzheimer's disease, in 1993, just a few years after gaining notoriety in a controversial 1986 publication on studies in Alzheimer's patients.¹³⁰ Yet, it was originally identified as an antibacterial agent in 1945.¹³¹

2.01.3 Drug Discovery

2.01.3.1 Introduction

The latter part of the twentieth century witnessed the birth of numerous technologies that have advanced the SOTA in drug research.¹³² The search for new approaches was in part propelled by the prosperous 1990s. As discussed earlier in this chapter, the 1990s were a period dominated by antiulcer products, with ranitidine surpassing the first billion dollar drug, cimetidine,^{133,134} and holding the top spot in the first part of the decade, after which it was unseated by an antiulcer agent acting by a different mechanism, omeprazole.¹³⁵ In the 1990s, the number of billion dollar drugs rose from six to 35. During this period, worldwide sales of the top drug increased from \$2 billion to almost \$6 billion, and by 1999 the 100th largest selling drug raked in almost \$500 MM. However, although antiulcer drugs dominated the top spots, there were more cardiovascular drugs in the top 10 in the 1990s than any other drug class. While no company had multiple top 10 drugs in all of the 1990s, Merck came closest, missing only 1990.¹³⁶ (And yet, what will happen with Merck after the rofecoxib debacle?)

There are multiple hit identification strategies (Figure 17), and new drugs come from many sources, both rational and brute force.¹³⁷ The exploitation of drug prototypes has been reviewed extensively.¹³⁸ Some have argued that starting with an old drug is the best way to find a new drug. This has been called selective optimization of side activities (SOSA). Thus, one starts with a diverse collection of marketed drugs in order to find and then optimize hits against new pharmacological targets. Because the starting points have already proved useful in man, the hits are guaranteed to be drug-like. A number of successful SOSA examples have been reported starting from sulfonamides, calcium channel blockers, beta blockers, antidepressants, neuroleptics, and so on.¹³⁹ Despite the power of combinatorial chemistry and HTS, natural products still provide unique structural diversity. Natural molecules have intrinsic advantages, of course, having evolved alongside biological systems. Mother nature had eons of a head start versus medicinal chemists (Figure 11). Thus, it might have been predictable that a large percentage, almost 30%, of the NCEs approved by the FDA between 1981 and 2002 were natural products or compounds derived from natural products. Natural products (or derivatives) with important therapeutic uses today include the antibiotic vancomycin, the anticholinergic scopolamine, and the opiate morphine, to name just a few.¹⁴⁰ However, in recent years, natural products have gone out of favor in some circles, in part because they have been less compatible with other new technologies, such as HTS.¹⁴¹

New drugs come from many sources including:

- focused synthesis of new chemical structures;
- modification of old drugs (new analogs);
- new uses for old drugs (repositioning or repurposing)¹⁴³;
- endogenous substances found in humans;
- natural products from nonhuman sources; and
- random screening.

Though the field of combinatorial chemistry is still evolving, it has already made a mark on the industry. It has asked lofty questions such as: How high is up? That is, the vastness of chemical space is not easy to fathom, and a vanishingly small proportion of this space has been studied by medicinal chemists. The challenge of harnessing this space, defining

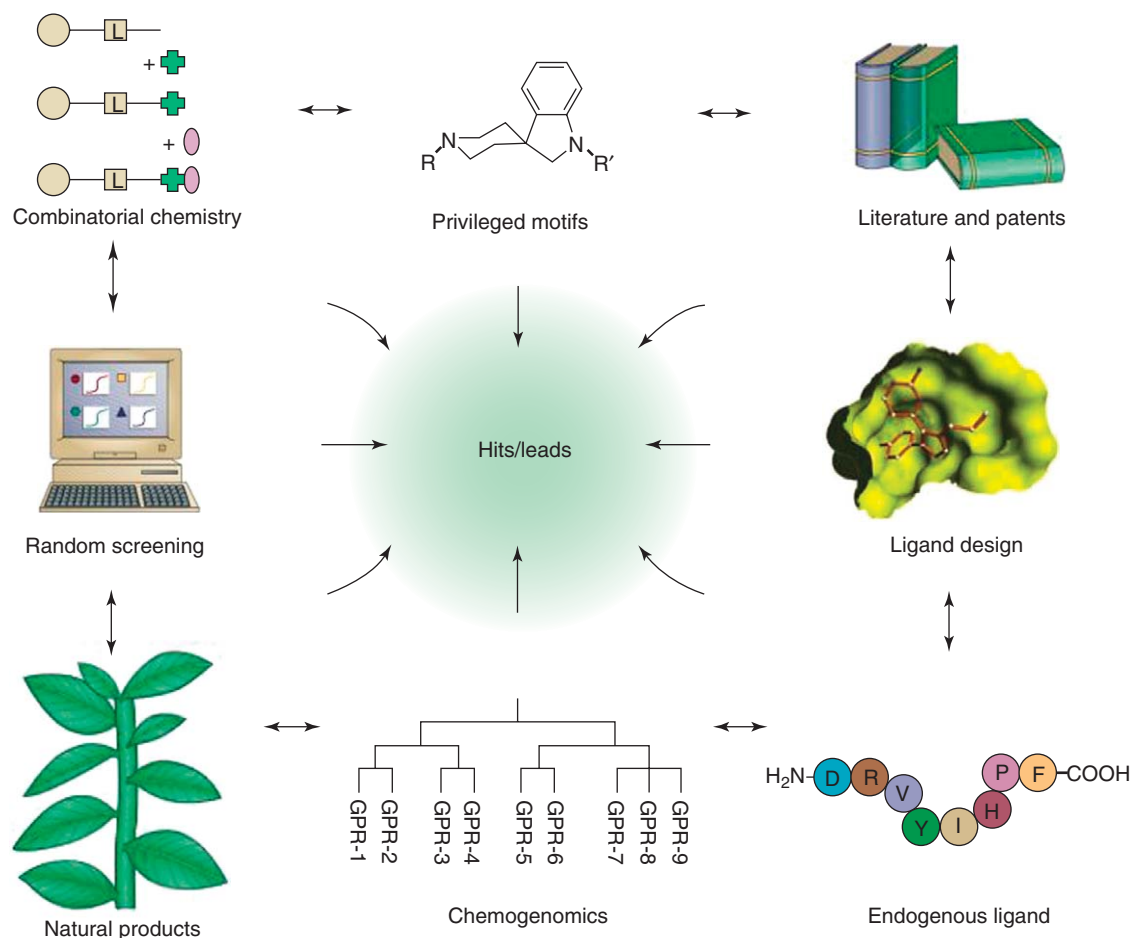

Figure 17 Hit identification strategies. The most commonly applied hit identification strategies today range from knowledge-based approaches, which use literature- and patent-derived molecular entities, endogenous ligands or biostructural information, to the purely serendipity-based ‘brute force’ methods such as combinatorial chemistry and high-throughput screening. The amalgamation of both extremes is anticipated to deliver more high-content chemical leads in a shorter period of time. (Reprinted with permission from Bleicher, K. H.; Böhm, H.-J.; Müller, K.; Alanine, A. I. *Nat. Rev. Drug Disc.* **2003**, 2, 369–378. Copyright 2003 Nature Publishing Group.¹⁴²)

what parts are biologically relevant in order to create improved pharmaceuticals, is being tackled by many scientists around the world.¹⁴⁴ The rapidity of change in this new field has manifested itself in various ways. Totally new ways of thinking about and visualizing the problem were required, such as flower plots (Figure 18). As another example, during the preparation of one recent book on combinatorial chemistry, nearly 60 chapter authors had changed jobs, moved, joined new companies, or been involved in a merger or acquisition.¹⁴⁵

The pharmaceutical paradigm *c.* 2000 is a marriage of the old and the new, in many cases driven by advances in chemical and biological technologies. Whereas the old pharmaceutical model was low-tech trial and error, taking 10–20 years and \$800 MM or more to reach the marketplace, the new model is high tech and information rich (Figure 19). Drug discovery is a subset of this complicated paradigm. It combines targets, HTS, compound libraries, and informatics to produce leads that are evaluated iteratively for biodisposition parameters, safety, and efficacy (Figure 20).

2.01.3.2 Technologies

Many technologies critical to today’s medicinal chemistry were developed starting in the 1980s.¹⁴⁶ These include combinatorial chemistry, HTS, genomics, and proteomics. The development of combinatorial chemistry is a particularly interesting case study in the biotechnology and pharmaceutical industries. One might trace its formal beginnings to the

Figure 18 Flower plots as a way of analyzing molecular diversity. Structures and ‘flower plots’ of 18 side chains from a biased NSG peptoid combinatorial library based on the tyramine submonomer. (a) The top row side chains are from tyramine and its five closest available analogs. The 12 side chains in the lower rows were chosen by D-optimal design from a pool of 721 amines. (b) Corresponding flower plots each represent all 16 properties for a single side chain. Petals for positive values point outward, and negative petals point toward the center. The radius is 3 standard deviations, and the center has been colored by similarity to tyramine. (Reprinted with permission from Martin, E. J.; Blaney, J. M.; Siani, M. A.; Spellmeyer, D. C.; Wong, A. K.; Moos, W. H. *J. Med. Chem.* **1995**, 38, 1431–1436. Copyright 1995 American Chemical Society.)

development of solid-phase peptide synthesis by Merrifield in the early 1960s,¹⁴⁷ though other developments including natural products chemistry may also be considered seminal events.

Perspectives on the application of combinatorial technologies to drug discovery have been published by various groups,^{148–151} and several books have appeared on the subject.^{152–155} As reviewed by Furka, three main methods were developed starting in the late 1980s. These included mixed reactant, portioning-mixing, and light-directed synthesis methods.¹⁵⁶ The early work by Geysen and co-workers,¹⁵⁷ Houghten and co-workers,¹⁵⁸ and the group at Chiron (Geysen, Moos, Rutter, Santi, and the former Mimotopes and Protos) is noteworthy. Personal perspectives on the early days of this field have been reported by Lebl. Much of the early work was performed on libraries of peptides and nucleotides (e.g., containing phosphodiester, phosphorothioate, methylphosphonate, phosphoramidate, guanidine, or peptide nucleic acids [PNAs], antisense oligodeoxynucleotides¹⁵⁹). While each group contributed significantly to this revolution in synthesis, it was probably the Parke-Davis group that first showed how broadly organic syntheses could be conducted on solid-phase supports. Their work commanded attention because it focused on heterocycles, the bread and butter of big pharma, rather than the peptides and nucleotides that biotech companies emphasized. Thus, the fledgling field of combinatorial chemistry finally got the pharmaceutical industry’s attention.¹⁶⁰ Academic groups also joined the fray, preparing libraries of benzodiazepines using the multipin method.¹⁶¹

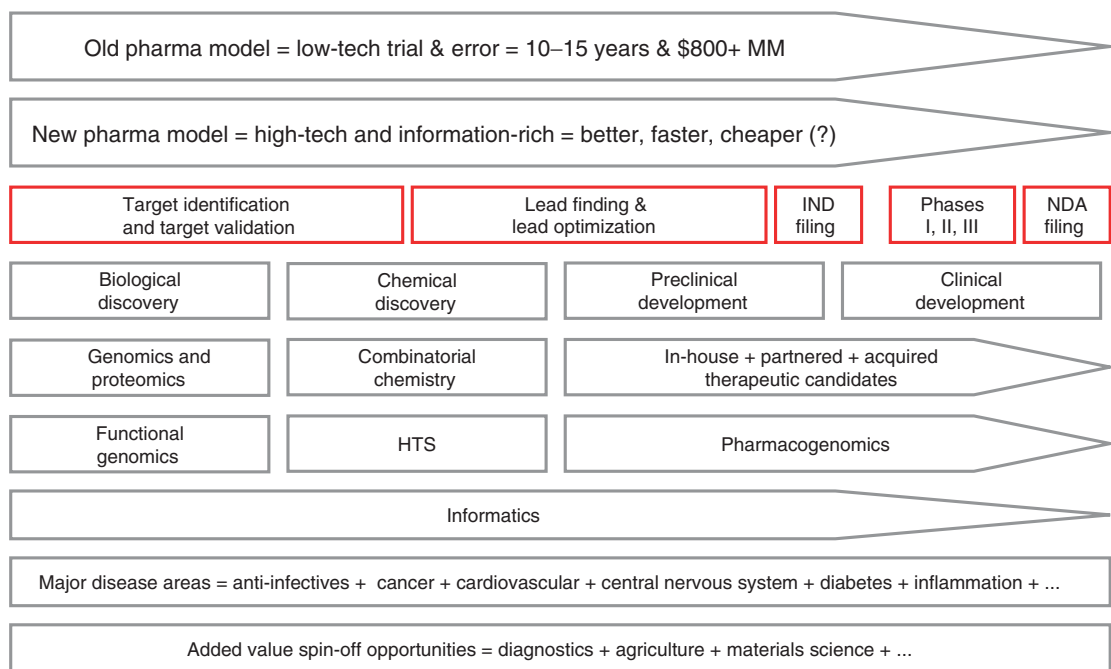

Figure 19 Today's elaborate biotechnology-driven pharmaceutical paradigm is a marriage of the old and the new.

H., Eds.; American Chemical Society: Washington, DC, 1997, pp 1–16. Copyright 1997 American Chemical Society.)

The use of natural and unnatural nucleic acids as tools to study biological processes has blossomed in recent years. Whether antisense, small interfering RNAs (siRNAs, part of the RNAi revolution), or other oligonucleic probes, these readily prepared and highly specific molecules are not only useful as tools for research, but also have utility as diagnostic probes and therapeutic agents. Current and emerging approaches with nucleic acids and analogs include¹⁶²:

- triplex-forming oligonucleotides;
- ribozymes that alter DNA sequences;
- siRNAs;
- messenger RNA (mRNA) cleavage and repair using ribozymes or deoxyribozymes;
- riboswitches;

- RNA and DNA aptamers; and
- nucleoside analog therapeutics.

While their potential applications are broad, finding a magic bullet antisense therapeutic has been slower than some might have expected, requiring easy synthesis in bulk, in vivo stability, and the requisite cellular efficacy, half-life, safety, and selectivity.¹⁶³ The medicinal chemistry of this class of compounds had already been extensively studied in the early 1990s (Figure 21).¹⁶⁴ However, economically viable large-scale synthetic processes for antisense compounds took a long while to develop.¹⁶⁵ Fomivirsen (Vitravene) was the first antisense product to gain clearance for marketing. It is used to treat cytomegalovirus (CMV) retinitis in AIDS patients, and was approved approximately 20 years after oligonucleotide therapeutics were first proposed.¹⁶⁶

The task of converting bioactive peptides into stable, orally available small molecule drugs has been the focus of much work. A new understanding of proteases in the 1980s served as a catalyst for a large number of companies and laboratories to tackle proteases as targets and peptides as drugs (Table 14).¹⁶⁷ This work was facilitated by growing datasets of structural information on which molecular modeling could be performed. Improved technologies for the synthesis of peptides and peptidomimetics also aided this work, often in the areas of cardiovascular and antiviral research.

Perspectives on how to bridge the gap between peptides and peptidomimetics and peptoids were addressed regularly starting in the 1980s, at a time when many other advances were being made in the understanding of endogenous

peptides, especially neuropeptides.^{168,169} Numerous obstacles stood in the way of making the leap from peptides to peptidomimetics, however. For example, because food and proteins are digested and absorbed in the intestine, peptides and peptide-based drugs are attacked by numerous enzymes. Progress has been made, however, in a number of areas. Some of the early work focused on angiotensin-converting enzyme (ACE) inhibitors, renin inhibitors, and cholecystokinin (CCK) antagonists. CCK regulates the secretion of pancreatic enzymes, contractility of the gall bladder, and gut motility. It is commonly found in the gut (and the brain) as an octapeptide (8-mer). Screening of fermentation broths for CCK antagonists led to a breakthrough with the discovery of asperlicin, the initial lead around which a number of orally active analogs were developed. Of course, Mother Nature had already devised her own peptidomimetic stories, including that of the naturally occurring morphine and the later discovered endogenous opiate peptide enkephalins, originally termed morphinomimetics. See [Figure 22](#) for two pairs of endogenous substances and their mimics. Drug delivery approaches have also been tried, including novel formulations, penetration enhancers, and intranasal delivery.¹⁷⁰

Common obstacles in the development of peptidomimetic drugs have included:

- poor intestinal absorption;
- alternative routes of administration, other than intravenous (IV), also lead to poor blood levels;
- rapid metabolism, including hydrolysis (proteolysis) at peptide amide bonds; and
- rapid excretion.

Though the term peptoid was first used more broadly, it found regular use to describe a family of N-substituted glycine (NSG) oligomers ([Figure 23](#)). Subsequently, a number of novel biopolymer systems were proposed or reported. This includes β -peptide oligomers, oligocarbamates, oligosulfones, and vinylogous oligopeptides – far from a complete list ([Figures 24 and 25](#)^{171–172, 173–175}).

Figure 22 The structures of some biologically active endogenous peptides and their corresponding peptidomimetics.

Figure 24 Various biopolymer systems that have been proposed or reported to be of interest in drug discovery or combinatorial chemistry, including peptides and NSG peptoids.

Figure 25 Additional biopolymer systems that have been proposed or reported to be of interest in drug discovery or combinatorial chemistry.

How were these new backbones developed? Oligo-NSG-peptoids were originally conceived as a new class of diverse peptide-like molecules able to be prepared using combinatorial methods. Initial studies showed NSG peptoids to be resistant to proteolysis and to have activity as protease inhibitors and as binders to nucleic acid structures.^{176–178} The development of a breakthrough submonomer method of synthesis made the preparation of diverse peptoid libraries straightforward using automated and robotic synthesizers.¹⁷⁹ Further work showed that carefully designed peptoid libraries allowed the discovery of a wide variety of bioactive molecules through mix-and-split and deconvolution strategies, yielding compounds with nanomolar potency at G protein-coupled receptors (GPCRs), including adrenergic and opiate receptors,^{180–181} and also uncovering novel antibiotics^{182–183} (see **Figures 26 and 27**). The easy preparation of small oligopeptoids led to the study of larger polypeptoids. Polypeptoids with diverse side chains have been synthesized dozens of residues in length, and some have been shown to have stable secondary structure despite the achirality of the peptoid backbone. For example, peptoid 5-mers show properties similar to peptide α -helices,¹⁸⁴ and

Figure 27 Mix-and-split combinatorial synthesis used in the discovery of NSG peptoid antibiotics. A one-mix library. A total of 13 amines were attached through the C-terminus to Rink type resin. The amine resin was then mixed and the population containing 13 different resins was split into 13 tubes. To each mixed resin-containing tube a defined second position amine was added. Each of the 13 tubes was then split into five tubes so that five different defined N-terminal amines could be added to each pool. This protocol results in 65 pools of 13 compounds, in which the N-terminal and middle positions are defined. (Reprinted from Ng, S.; Goodson, B.; Ehrhardt, A.; Moos, W. H.; Siani, M.; Winter, J. *Bioorg. Med. Chem.* **1999**, 7, 1781–1785, with permission from Elsevier.)

libraries of 15-mers have uncovered molecules that show helical behavior.¹⁸⁵ Ligation is possible to create dimers of oligopeptoids, allowing the synthesis of even larger polypeptoids.¹⁸⁶ Cationic peptoid oligomers and conjugates have been demonstrated to facilitate gene transfer.¹⁸⁷

The shift from screening fully characterized single pure compounds, synthesized in solution, to assaying mixtures of large numbers of compounds, often prepared using solid-phase supports, required a sea change in thinking. Given the entrenched views of the pharmaceutical industry at that time, it is perhaps not surprising that much of this work was pioneered in small entrepreneurial companies and at academic laboratories or research institutes. Even for the latter, moving beyond natural building blocks was a difficult early step in combinatorial chemistry (Figure 28). The game of building blocks and numbers that combinatorial chemistry became in the 1990s has evolved into a higher level game in the twenty-first century, though the numbers were quite impressive even in the beginning (Table 15).¹⁸⁸

In the early days of combinatorial chemistry, there was perhaps more emphasis on quantity than quality – large numbers of compounds were prepared, but arguably these libraries were not very interesting from a small molecule drug discovery perspective. The general concept was a good one – more data, less effort, more successful choices (Figure 29). As the field developed, and researchers developed combinatorial methods to prepare libraries of more complicated and more drug-like molecules, and as people became more sophisticated at analyzing molecular diversity parameters, there was a clear shift toward library quality.¹⁸⁹ Today, libraries of more complex molecules can be prepared using one or more of a variety of solid-phase or solution methods (Figure 30).¹⁹⁰

With new libraries of compounds, often mixtures of compounds, new HTS methods had to be developed (Figure 31). Making HTS more efficient has been the goal of many groups. Doing so requires development of the right assays, selection of the right compound sets, and methods to filter out unwanted hits including promiscuous hitters. Assays may be homogeneous, using techniques such as fluorescence, or separation-based, using techniques such as filter-binding. A hybrid method for selecting the right compounds has been referred to as rapid elimination of swill (REOS), which uses simple counting schemes to weed out molecules that are too large or too reactive, among other features.¹⁹¹

What if one could put all known drug targets and all known drug candidates in a test tube, allow the highest affinity pairs to self-assemble, and then separate the bound pairs? While not possible today at such an extreme, this approach, known as affinity selection, has been demonstrated on a much smaller scale. Thus, compound libraries have been

Figure 30 Evolution from amino acid-like combinatorial building blocks to true drug-like scaffolds took time, but eventually diverse drug libraries were being prepared using readily available common intermediates. (Reprinted with permission from Moos, W. H. Introduction: Combinatorial Chemistry Approaches the Next Millennium. In *A Practical Guide to Combinatorial Chemistry*; Czarnik, A. W., DeWitt, S. H., Eds.; American Chemical Society: Washington, DC, 1997, pp 1–16. Copyright 1997 American Chemical Society.)

mixed with purified proteins, size-exclusion chromatography has been used to separate bound from free, and the resulting receptors with bound ligands have been separated and the ligands then detected by mass spectrometry (a process called affinity selection mass spectrometry, ASMS); see [Figure 32](#). The method has been used successfully to study ligands for both receptors and enzymes.^{192–196}

Technologies may also take the form of cellular compartments or drug classes. Thus, companies such as Cytokinetics have focused on cytokinetic pathways, Idun on cell death and caspases, Isis on antisense, MitoKor on mitochondria,

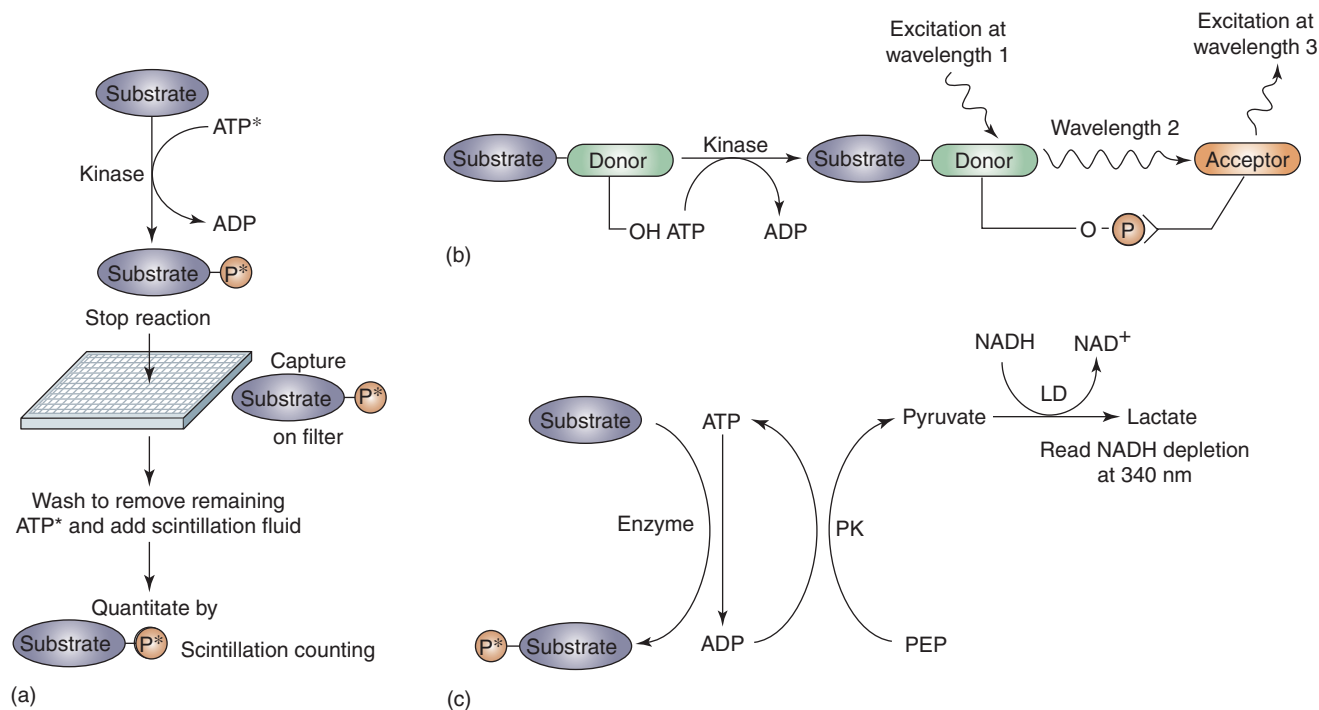

Figure 31 Several examples of screening assays used in HTS paradigms. This figure outlines the principles behind three assay types used for screening. The examples illustrate their application to kinase assays, but in all cases the methods are applicable to other target types. A standard separation-based assay is depicted in (a), in which radiolabeled ATP transfers a labeled phosphate moiety from ATP to substrate. The substrate is subsequently captured on a membrane, and separated from the ATP substrate by filtration. The signal is measured by addition of scintillate and quantitated by counting. (b) An outline of the general principles of FRET, a homogeneous assay format. In this case, a labeled substrate is phosphorylated allowing it to bind to a second molecule labeled with an acceptor group. The proximity of the two groups allows energy transfer between the donor and acceptor. This causes a shift in wavelength for the signal emitted from the assay and detection of the product without separation from the substrate. (c) Another homogeneous assay format in which the conversion of ATP to ADP is coupled to the conversion of NADH to NAD using two enzymes, pyruvate kinase (PK) and lactate dehydrogenase (LD). This decreases the A340 of the assay, which is used to monitor the progress of the reaction. (Reprinted with permission from Walters, W. P.; Namchuk, M. *Nat. Rev. Drug Disc.* **2003**, 2, 259–266. Copyright 2003 Nature Publishing Group.)

Figure 32 Affinity-selection mass spectrometry as a means of screening compound libraries to identify agents that bind to targets of interest, such as receptors.

X-Ception on nuclear hormone receptors, and so on. Such foci can lead to fascinating developments; consider mitochondria, for example. Mitochondria are cytoplasmic organelles involved in calcium regulation, cell death, energy production, free radicals, and metabolism. They are cellular powerhouses, functioning as the batteries, generators, and engines of cells. Almost all cellular activity involves mitochondria, so they are essential to human life. In many ways, mitochondria function like a cell within a cell, and they house proteins derived from two genomes, the nuclear genome, inherited from both the mother and the father, and a small mitochondrial genome, inherited in almost all cases only from the mother. Whereas the mitochondrial genome has only 37 genes, nuclear DNA encodes thousands of mitochondrial proteins. Mitochondria play a critical role in human health and disease, and mitochondrial dysfunction has been linked to more than 75 diseases, including major diseases of aging.^{197–199} Because of the central role of mitochondria in so many cellular events, many drug discovery groups ultimately work on this organelle directly or indirectly.

Which provides a segue to genomics... Subsequent to the combinatorial chemistry revolution, genomics took hold. When applied to drug discovery and development, genomics generally refers to the study of genes associated with or implicated in human diseases, and the set of technologies that enables such work.²⁰⁰ Since the start of the Human Genome Project in 1988 and its completion in draft form in 2001, and for the foreseeable future, genomics has commanded and will command the attention of countless researchers. Though a number of initial estimates predicted around 100 000 genes in the human genome, many were surprised when this number had to be rounded down to something closer to 20 000–30 000 genes.

Exploring genome space requires bringing together geneticists, computer scientists, biochemists, cell biologists, structural biologists, and physiologists in order to understand gene function. Medicinal chemists can help to validate these potential new drug targets and their function by discovering ligands that prove the point.²⁰¹

Completing the human proteome, being more challenging, has lagged developments in genomics. Yet a map of all human proteins was discussed as early as 1981,²⁰² and a human protein index was considered by the US Congress long before the Human Genome Project was conceived. However, because of its much greater complexity – probably at least two orders of magnitude more complex than the human genome – human proteomics is in many ways still in its infancy.²⁰³ Proteomics was advertised as the next genomics, but as suggested above, while the human genome may have only 20 000–30 000 genes, the total human proteome is no doubt millions of proteins when one takes into account posttranslational modifications and other diversity enhancing changes. At a very basic level, proteomics researchers must sequence peptides, typically via mass spectrometry. At a more complicated level, and critical to its use in personalized medicine, proteomics must be extrapolated from the bench to the bedside,²⁰⁴ applying proteomics to early diagnosis, to disease-tailored therapeutic targets, and finally to personalized medicine. Taking cancer as the example, full exploitation of proteomics requires, ideally, knowledge of or access to protein signaling pathways, tumor-host interactions, mass spectrometry, laser capture microdissection, and microarrays. To break down the problem into smaller parts, certain groups have chosen to focus on organellar proteomics, including mitochondria, in order to establish a beach head in this area.^{205–207} Others have directed their attention to epigenetic phenomena, such as DNA methylation.²⁰⁸

Interestingly, whereas drug discovery scientists are used to working in the range of millimolar (10^{-3}) to femtomolar (10^{-15}) concentrations, genomics and proteomics have added to our vocabulary because they deal with concentrations in the attomolar (10^{-18}), zeptomolar (10^{-21}), and even yoctomolar (10^{-24}) ranges. Given the deluge of information flowing from both genomics and proteomics, bioinformatics has become a new focal point for both education and R&D.²⁰⁹

What is the potential impact of genomics and related technologies on the pharmaceutical and biotechnology industries? It is expected to be quite broad, including small molecule drugs, gene and protein therapies, and diagnostic tool kits. It is not without its challenges, however, including questions about data overload, who owns the data, who pays for what, ethical objections to certain uses, and so on.²¹⁰

Potential genomics opportunities in healthcare include:

- gene therapy;
- protein therapy;
- small molecule drugs; and
- diagnostics.

2.01.3.3 Chemical Biology and Chemical Genomics

Chemical biology and chemical genetics are at their core all about interfaces and boundaries with other scientific disciplines, including biochemistry, pharmacology, and genomics. It is often said that the action in science is at the interfaces, and this has never been more true of chemistry, biology, and physics, with chemistry at the center of the action, of course (Figure 33).²¹¹ Whereas NMR revolutionized organic chemistry in the 1960s and 1970s, and became a common in vivo diagnostic imaging methodology in the 1980s and 1990s, its recent use to view chemical processes and protein conformations within living cells may herald yet another major step forward for biochemical and pharmacological applications of medicinal chemistry post-2000.²¹²

Phrases with the word ‘chemical’ followed by biology, genetics, or genomics have cropped up in recent years, particularly from the work of Schreiber.^{213–217} One may think about applying medicinal chemistry to controlling pathways and systems at various levels, including genetic manipulations (Figure 34). Such applications have been accomplished with cell-cycle machinery, for example.²¹⁸ Powerful manipulations of cellular pathways can be effected by bridging different protein subunits with small molecules. Such manipulations have been accomplished through chemical inducers of dimerization in systems such as the immunophilins with drugs based on cyclosporine and FK-506 (Figure 35).²¹⁹ Chemistry-to-gene assays have also been established in model organisms such as *Caenorhabditis elegans*,²²⁰ and reporter-gene based mouse models are being developed,²²¹ all of which may make chemical genomics more useful in the future.

Combinatorial biosynthesis has been exploited for many years through natural products. More recently, a number of academic and industrial groups have managed to harness some of these processes to produce new collections of related molecules. Progress is particularly evident in the production of classes of polyketides and nonribosomal peptides that have proven useful in pharmaceutical and agricultural products. Examples include antibiotics such as erythromycin, penicillin, rifamycin, and vancomycin, as well as anticancer drugs, cholesterol-lowering agents, and other important classes of pharmaceuticals. Now it is possible to exploit controlled biological manipulations to effect Claisen-like condensations, cyclizations, decarboxylations, dehydrations, epimerizations, reductions, and other chemistries in order to produce new analogs that would otherwise be very difficult to prepare synthetically (Figure 36).^{222–223}

Both hybrid enzymes and catalytic antibodies have been used to synthesize or modify complex molecules.²²⁴ Applying the power of the immune system by using antibodies to facilitate transformations such as metallation, pericyclic, and redox reactions has allowed the synthesis of molecules that might be hard to prepare in other ways.²²⁵

Synthetic biology is another variation on the theme. One group of synthetic biologists uses unnatural molecules to mimic or create artificial life. Another group studies natural systems and then applies these functions to unnatural systems. Through these approaches, diagnostics have been created, as have a variety of devices.²²⁶ For example, the standard 20 amino acids are used as building blocks by essentially all organisms to generate the peptides and proteins of

Figure 33 Leveraging the interfaces of science.

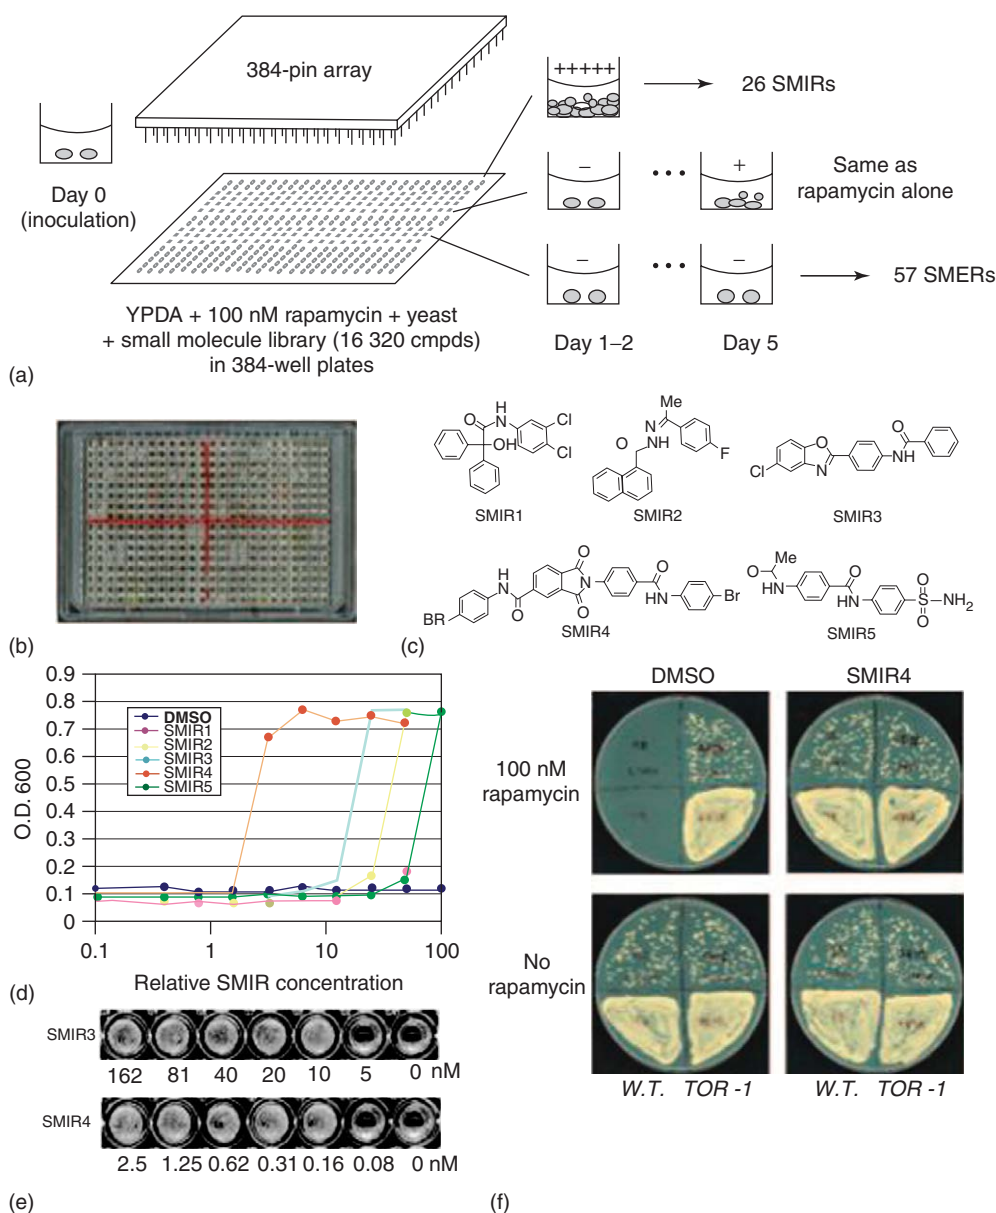

Figure 34 A chemical genetic screen for small molecules that modulate rapamycin's antiproliferative effect in yeast. (a) Schematics of the screen. Compounds were transferred from library plates to assay plates (containing growth medium, rapamycin, and yeast cells) by using 384-pin arrays. SMER, small-molecule enhancers of rapamycin. (b) Retest of SMIRs in a 384-well plate. White wells indicate compound-induced yeast growth in the presence of rapamycin; black (transparent) wells indicate no growth. (c) Chemical structures of the fast-acting SMIRs (yeast growth identifiable on day 1, same as the 'no rapamycin' control). (d) Dose-response curves for SMIRs in wild-type (rapamycin-sensitive EGY48) cells inoculated in YPDA containing 100 nM rapamycin. (e) Minimal concentrations of SMIR3 and SMIR4 required for yeast growth in YPDA containing 20 nM rapamycin. (f) SMIR4 treatment and the TOR1-1 (S1972R) mutation both confer rapamycin resistance. Cells were plated at two different densities on the upper versus lower halves of the plates (1:1000). (Reprinted with permission from *Proc. Natl. Acad. Sci. USA* **2004**, *101*, 16594–16599. Copyright 2004 National Academy Sciences, USA.)

life. Additional diversity is generated through posttranslational modifications. However, it is only in the last few years that scientists have devised ways to add novel amino acids and to expand the genetic code directly. Using unique codons, over 30 novel amino acids have been incorporated through genetic manipulations, including azido, fluorescent, sugar, keto, metallo, polyethyleneglycol (PEG), and unsaturated alkyl moieties.^{227,228} For example, one can incorporate alkyne residues into proteins in *Escherichia coli* bacteria.²²⁹ These changes may ultimately allow the routine production

Figure 35 Structures of representative immunophilin ligands that inhibit the cell cycle.

Figure 36 Examples of natural product antibiotics that are polyketides or nonribosomal peptides.

of new and improved biomolecules and even new life forms.²³⁰ This approach also provides new routes for labeling proteins in a site-specific manner for NMR studies.²³¹ It has further been used to modify viral combinatorial peptide systems such as phage display.²³²

Overcoming certain obstacles in stem cell biology, such as large-scale production, will be required for broader use of stem cells for healthcare purposes. Chemistry can play a role in advancing this field too, for example, through the use of small molecules that regulate the fate of stem cells. This includes simple solvents such as dimethyl sulfoxide (DMSO), steroids such as dexamethasone, and anticancer drugs such as imatinib.²³³

Nanotechnology (or nanobiotechnology) is the latest platform to employ the skills of the medicinal chemist. Heterocyclic peptide nanotubes have been prepared.²³⁴ The concept of targeted therapeutic nanoparticles is being tested in a number of academic and industrial laboratories around the world. Much of this work is being done in the cancer field. Thus, a particle of perhaps 10 nm diameter can be derivatized on its surface with a ligand that

preferentially targets cancer cells; the particle itself is sized to allow enhanced penetration into cancerous tissues, and inside the particle is a payload of a therapeutic agent to kill the cancer cells. These nanoparticles are approximately the size of an antibody, and may provide a platform that allows one to detect, image, and treat all at once.^{235–236}

2.01.3.4 From Small Molecules to Macromolecules

Small molecule drugs, typically less than 500 Da in molecular weight, have been the mainstay of pharmaceutical R&D for the last century. Earlier sections of this chapter discuss peptides, peptoids, peptidomimetics, and the use of new technologies to advance the SOTA in drug discovery. From these sections, it should be evident that the promise and reality of applying biotechnology to pharmaceutical applications is a relatively recent phenomenon.^{237–238} What about proteins and other biological macromolecules – drugs that weigh tens to hundreds of thousands of daltons? The routine chemical synthesis of peptides was limited to relatively short peptides of up to about 50 amino acids until the 1990s. However, methods such as chemical ligation now allow the synthesis of proteins of 100 amino acids or longer, with the chemical synthesis of the 99-residue HIV-1 protease being a major event in this field (Figure 37). These new methods provide access to hitherto unreachable analogs and in some cases higher purity than is available using biological means of production.²³⁹ For both short and long sequences, various protecting groups and solid phases have been employed to prepare peptide analogs, including Rink and Wang resins.^{240–242}

It was 1975 when Milstein and Köhler discovered how to isolate monoclonal antibodies (MAbs) using hybridomas. This discovery helped to start the UK biotech industry and led to the first MAb diagnostic product in 8 years and the first FDA-approved MAb therapeutic product in 11 years. By the end of 2004, 18 MAb products were approved for therapeutic use in the US, and half this number in Europe. Many of these MAbs have been approved for cancer therapy, and some have achieved billions of dollars in sales. Drug discovery has benefited from advances in the use of MAbs as research tools, and it is conceivable that selective targeting strategies will require substantial help from medicinal chemistry as the field progresses.^{243–244}

RNAi was discovered in the 1990s, and is finding increasing applications in drug discovery and as therapeutics. Specific inhibition of mRNA reduces protein levels in a cell, sometimes essentially silencing a given transcript (> 75% knockdown). By using siRNAs, one can determine the relevance of certain proteins to disease pathology, thus aiding studies to define the druggable human genome.^{245–246}

We have only scratched the surface in the potential tools, applications, and products that will result from these arenas. Blocking protein:protein interactions continues to be a challenge for small molecules, but new methodologies are cropping up regularly, including the targeting of susceptible domains.²⁴⁷

2.01.3.5 Computational Approaches

The structural requirements for receptor binding that lead to agonism can be exceedingly tight. In the case of the muscarinic cholinergic agonist, arecoline, the addition of a single methyl group reduces affinity and/or agonism by a factor of 10 or more (Figure 38).²⁴⁸ However, most interactions are more forgiving than this example, and thus amenable to a wide variety of structure-based design and other computational approaches, including quantitative structure–activity relationships (QSAR).

While the beginnings of QSAR in medicinal chemistry have roots that date back to the 1940s and 1950s,²⁴⁹ drawing heavily on linear free energy relationships and physical organic chemistry,²⁵⁰ methods advanced remarkably once computers became commonplace. Sometimes the best techniques are the simplest. For example, a study of various central nervous system (CNS)-active drugs yielded a common phenethylamine pharmacophore.²⁵¹ This pharmacophore is evident in opiate analogs²⁵² and many other classes of CNS drugs. Operational schemes such as the Topliss Tree can be powerful yet simple ‘back-of-the-envelope’ approaches to deciding which analogs to synthesize in a medicinal chemistry program (Figure 39).²⁵³ Manual methods for Hansch-type applications have also been proposed,²⁵⁴ and the contributions of various functional groups to binding interactions have been calculated.²⁵⁵

Analog	R ₁	R ₂	R ₃	R ₄	R ₅	R ₆	IC ₅₀	Relative agonism ^a
1	Me	H	H	H	H	H	>100	–
2	H	H	Me	H	H	H	50	39
3 (arecoline)	Me	H	Me	H	H	H	10	100
4	Me ₂ +	H	Me	H	H	H	50	93
5	Et	H	Me	H	H	H	350	8
6	Me	H	Et	H	H	H	10	10
7	Me	Me	Me	H	H	H	>100	–
8	Me	H	Me	Me	H	H	1800	1
9	Me	H	Me	H	Me	H	>100	–
10	Me	H	Me	H	H	Me	>100	–

Copyright 1972 American Chemical Society.)

Though QSAR analyses are not as common as they once were, they can be very helpful in understanding and guiding analog programs.²⁵⁶ However, one must be careful not to analyze too many variables in QSAR studies, as the risk of a chance correlation increases with the number of variables considered.^{257–258} Occasionally, almost perfect correlations have been found between biological activity and parameters such as lipophilicity (log *P*).²⁵⁹ Lipophilicity was once determined laboriously by partitioning experiments. It was facilitated greatly when HPLC techniques became available to estimate octanol-water partition coefficients.²⁶⁰ Today, most medicinal chemists use calculated log *P* (ClogP) values.²⁶¹ After these many years, the field of QSAR has generated considerable data of utility in drug discovery. For example, the Hansch group has entered nearly 12 000 equations into its database, representing over 40 years of work. This work has been summarized as a collection of human chemical–biological interactions, including taste, odor, metabolism, absorption, excretion, and toxicity, among others.²⁶²

Advances in computing have allowed the development of molecular modeling and other tools for SBD, sometimes referred to as computer-aided drug design (CADD).²⁶³ While this can be a very technical discipline, practical guides exist for those who are interested in learning more or even becoming practitioners.^{264–265} The thousands of three-dimensional structures of macromolecules that have been solved provide a good basis for drug design. This approach has been used to develop novel inhibitors in many systems, some of the first being inhibitors of matrix metalloproteases, HIV protease, and renin.²⁶⁶ Despite shrinking budgets in many institutions, structural biology has been picking up the pace lately. More than 600 unique structures have been solved and entered into the Protein Data Bank (PDB),²⁶⁷ though most proteins cluster into just four classes of structures.²⁶⁸ While current SBD approaches can be very sophisticated, the field began with physical models, which were followed by hand-drawn models and small molecule x-ray crystal structures, which led to various conformational and charge-based modeling techniques, and ultimately many other strategies were employed to yield technical insights via molecular modeling (see Figure 40).

A more recent approach, fragment-based lead discovery, has been used successfully by several groups, often utilizing crystallography or NMR techniques, together with molecular modeling. In these methods, small molecular fragments are allowed to interact with targets of interest, and different binding elements are then linked together or tethered to increase the potency and specificity of the binding interaction.^{270–272} Figure 41 shows an early example of the results obtained by using an NMR-based approach on an FK-binding protein (FKBP) target. In this and other SBD-related areas, in some cases the approaches have evolved from traditional lock and key systems to induced fit models and the stabilization of conformational ensembles.²⁷³ Even membrane-bound targets are being studied at a structural level using solid-state NMR.²⁷⁴

With these and other computational technologies in place, the stage was set for applying computers to thinking about and calculating the diversity space that combinatorial chemistry could in theory tackle.^{275–278} Thus, combinatorial chemistry was described as a molecular diversity space odyssey as we approached 2001.²⁷⁹ Consistent with the space odyssey theme, others have made analogies between mapping biological activity space and exploring uncharted territories amongst the stars.²⁸⁰ For most intents and purposes, chemical diversity space is infinite. However, there are subsets of this vast space that represent preferred characteristics of drug classes and families of molecules that interact with gene superfamilies, such as the GPCRs. There are also subsets that one might consider to contain drug-like or druggable chemical series.²⁸¹ (The term ‘druggable’ may also refer to drug targets, namely, those targets that can be readily attacked with small organic molecules.) At this point in time, many approaches to determining criteria for drug-likeness have been proposed.^{282–283} Moving beyond drug-likeness to the design of libraries with specific properties, such as CNS activity, has been the subject of some studies as well,²⁸⁴ though other principles such as blood–brain barrier (BBB) transport are also important in such an analysis.²⁸⁵ With any screening program, one needs to watch out for false positives. For instance, it turns out that some types of molecule are promiscuous, perhaps resulting from aggregation phenomena.²⁸⁶

Chemical space, whether infinite or not, is a continuum, with pockets of biologically relevant properties, and various strategies have been used to calculate this *n*-dimensional physicochemical property space (Figure 42).²⁸⁷ Evaluating the diversity of a given set of compounds from first principles may utilize one of a number of different approaches, such as clustering, receptor site interaction simulation, similarity, and other techniques.^{288–290} The vastness of this space is exemplified by the following: there may be a larger number of drug-like compounds that could in theory be synthesized than there are particles in the universe.

What other considerations should be mentioned? Even if one had a large and diverse library of drug-like molecules, it is conceivable that the biological target of interest would not be druggable – that is, it may not be possible to modulate some targets through interactions with orally available small molecules.²⁹¹ Others have tried to devise new ways of screening libraries virtually – by computer – before proceeding to laboratory work. While much heralded in the 1980s, this SBD technique has yet to live up to its full potential.^{292–293} In the face of these many powerful new technologies, it can be easy to forget the power of simple thought paradigms that can be exploited on the back of an

(b)

Figure 40 Example of an early structure-based design approach, with phosphodiesterase inhibitors studied as potential new drugs for congestive heart failure: (a) five-point model for cAMP PDE inhibition and inotropic effects, use of x-ray crystal structures to better understand small molecule structures, and revised five-point model based on cAMP; (b) comparing molecular frameworks and electrostatic potentials of PDE inhibitor (imazodan) and cAMP. Figure 41 Fragment-based lead discovery of high-affinity ligands for proteins using SAR by NMR.

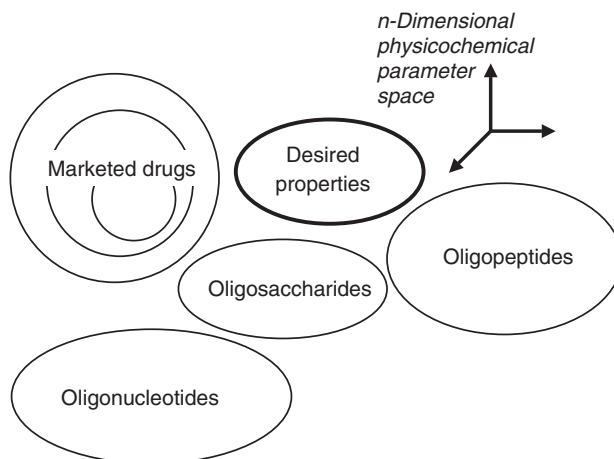

Figure 42 Chemical diversity space representation.

envelope. Lipinski's rule of five fits this rubric.²⁹⁴ The rule of five predicts poor absorption or permeation to be more likely when certain thresholds are surpassed.

Some common characteristics of drug-like molecules are²⁹⁵:

- molecular weight $\sim 250\text{--}500$;
- oral bioavailability $\sim 1\text{--}100\%$;
- lipophilicity (as calculated by ClogP) $\sim 1\text{--}5$;
- elimination half-life $\sim 1\text{--}5$ h;

- plasma protein binding up to >90%;
- soluble in water and alcohol; and
- one or more rings and a basic nitrogen.

In the midst of all of this new diversity that is being synthesized and calculated, a recent review of all oral drugs approved from 1937 to 1997 showed that, despite small trends in physical properties, there has been little substantial change over the years, except for molecular weight. Molecular weight increased from generally below 300 to often above 400 during this period. Only 2% of these drugs have molecular weights greater than 500 and more than three hydrogen-bond donors. Fewer than 5% have more than four hydrogen-bond donors.²⁹⁶ Another study showed that the average molecular weight of oral drugs decreases as they progress through clinical trials, converging on the average molecular weight of marketed drugs.²⁹⁷

2.01.3.6 Evolution of Preclinical Research over Several Decades

In the old days, chemists, biochemists, and pharmacologists worked together in pharmaceutical companies to identify promising new drug leads by a slow, iterative process, often driven principally by data in animals. What has happened to the old ways in the face of SOTA technologies and new scientific disciplines? For one, molecular biologists became a major part of drug discovery teams in the 1980s and 1990s, developing molecular assays to prioritize compounds for animal testing. The basics have not changed,²⁹⁸ but many new technologies have been added to the medicinal chemist's armamentarium, including combinatorial chemistry.

Solid-phase chemistry in the pharmaceutical industry was very rare, except in areas such as peptide synthesis, until the 1990s. Yet the field took off, and by 1997 well over 150 different types of solid-phase-based chemical products had been described,²⁹⁹ and more than 80 different compound libraries had been prepared.³⁰⁰ Only a few years later, hundreds of compound libraries had been reported.³⁰¹

Opinions vary on the success of new drug discovery technologies, such as combinatorial chemistry and HTS.³⁰² However, it is hard to contest that combinatorial chemistry has led a revolution in medicinal chemistry – the world of synthetic chemistry has been changed forever – and it is getting better with each new generation of approaches, including that of the latest natural products-based, diversity-oriented libraries.³⁰³ While the costs of what has been called big dumb science are not insignificant, applying these new processes in a focused and rational manner has begun to show real benefits in the time it takes and the quality of the leads that are progressing into the clinic.³⁰⁴ Genomics is being applied increasingly to identifying molecules that affect targets of interest. For example, a genome-wide screen in yeast has been used to identify small molecules that inhibit the activity of kinases.³⁰⁵ Some argue that microarrays and other molecular profiling techniques will revolutionize the way we develop drugs (Figure 43).^{306,307}

A case study that displays some of the points of interest in the never-a-dull-moment evolution of preclinical research over several decades can be found in aging research and CNS diseases such as AD.³⁰⁸ The number of centenarians per million people in the US increased from 15 in 1950 to 263 in 2000.³⁰⁹ Though the US government declared the 1990s the Decade of the Brain, progress has been slow given the complexity of this organ. Nonetheless, at various points in time, roughly 10% of the drugs in development globally targeted CNS indications. The CNS space is an interesting example, highlighting some of the many issues that face drug hunters today in studies of the brain and other physiological systems. Whether the issues faced in this field and others will trigger a return to the fundamentals seems doubtful, even if such a change would address the current ailments of the industry – the seemingly poor productivity, the 30 years that it takes to move from scientific discovery to marketed products, megamergers that underperform, infatuation with new technologies long before their time, major failures postmarketing, and so on. There are multiple opinions on this subject, as one might expect.^{310–314} A list of the major classes of CNS drugs is given in Table 16.

The representative issues facing CNS drug hunters today are:

- the complexity of the brain and our limited understanding;
- incomplete information regarding the pathophysiology of major diseases;
- relegation of behavioral pharmacology to a secondary role versus molecular neuroscience, starting in the late 1980s; and
- biases against funding what some consider to be more difficult, costly, and time-consuming hurdles in CNS clinical study (biases that are not always correct).

Possibly no other area has seen such major advances in the late twentieth century as AD. This curious ailment of old age was first reported by Alois Alzheimer in 1907.^{315,316} The field of AD and related disorders has given rise to many classifications of age-related cognitive decline, from age-associated memory impairment (AAMI) to the more recent mild

cognitive impairment (MCI).^{317,318} About 10% of Americans in a community setting over age 65 have probable AD, ranging from a few per cent in the 65–74 age group, to nearly half of all subjects over 85. Given the high percentages of AD in older persons, the public health impact of this disease will continue to rise with increasing longevity.³¹⁹

This is a field full of dogmas, where some people equate β -amyloid with AD, and researchers take to their pathophysiological dogmas like religions, whether it be the β -amyloid Baptists, the τ protein Taoists, or the mitochondrial dysfunction Mitochondriacs. It is also a field that ignores studies that don't fit the latest schema. Thus, even in the face of numerous studies reporting positive data in one or more measures, large, politically charged, government-funded studies carry more weight, biasing medical practice in directions that may not be correct. Witness the dramatic decline in estrogen use for dementia or cognitive decline (and for menopause symptoms) after the results of the Women's Health Initiative Memory Study (WHIMS) were published.³²⁰ The conclusions of WHIMS authors are not, however, fully accepted by all estrogen researchers.³²¹ Notwithstanding the WHIMS results, finding new drugs from old drugs (described earlier as SOSA) is an approach that has borne fruit in the estrogen field. Here, less feminizing or nonfeminizing estrogens are finding utility as neuroprotectants, possibly via mitochondrial mechanisms.^{322–323} These include components of estrogen therapies that have been administered to humans for more than 60 years, such as the less hormonal (less feminizing) 17α -estradiol, an isomer of the most potent natural feminizing hormone, 17β -estradiol.³²⁴ The activity of compounds like these has been reported in transgenic models of AD.³²⁵

Figure 44 Assessing permeability of drugs using Caco-2 cell monolayers and filter-well setups.

2.01.3.7 Transition from Research to Development, Including Absorption, Distribution, Metabolism, Excretion, and Toxicity

While there have been major advances in many of the early stages of drug discovery, a bottleneck remains in preclinical development – in ADMET – both in vitro at an HTS level, or with high content assays (HCAs), and in vivo for screening and for formal development. Addressing this part of drug development requires different thought processes and procedural rigors because of regulations. Various methods have been developed to predict or optimize drug absorption and pharmacokinetics.^{326–328} Properties that influence oral bioavailability have been studied extensively.³²⁹ One popular system uses human colon epithelial (Caco-2) cell lines. In this system, permeability is typically assessed using monolayers of Caco-2 cells on filter wells (Figure 44).^{330,331} Physicochemical measurements and plasma protein binding data have been used to predict volume of distribution values.³³² Molecular modeling has been used to predict cytochrome P450 (CYP)-mediated drug metabolism.³³³ Pharmacokinetics has become more integrated into the drug discovery process over time.³³⁴

Many groups have worked to reduce attrition rates via ADME profiling earlier in the drug discovery process. These efforts include studying a wide variety of parameters.³³⁵ Similarly, the chemistry of metabolism and toxicology as it relates to safety and toxicity profiling, prediction, and analysis has been reviewed. Modern techniques and approaches include the following:

- solubility and solubilization;
- permeability and active transporters;
- ionization or dissociation constants;
- lipophilicity;
- chemical integrity and stability;
- metabolic stability and clearance;
- CYP inhibition and other metabolism-related drug interactions;
- safety and toxicity threshold concepts from the perspective of adverse effects in general, carcinogenicity in particular, and individual human variation³³⁶;
- mechanistic insights into idiosyncratic toxicities, including reactive metabolites, immune-mediated responses, low levels of infections accompanying disease, and mitochondrial damage³³⁷;
- in silico predictive toxicology and ADME, including PK and phenotyping, using molecular modeling, expert systems, and data-driven systems, which of course still need to be validated and accepted by regulatory bodies^{338–340};
- prediction of drug interactions, focusing on CYP, kinetics, genetic variability, and computational methods^{341,342};
- designing against metabolic activation and analytical methods for metabonomics (also referred to as metabolomics or metabolomics), such as has been used in the design of leukotriene antagonists and PDE inhibitors^{343–344};
- drug delivery and BBB models, including in silico methods, endothelial cell monolayers, co-cultures of endothelial cells and glia, dynamic flow-based systems, and other models of permeability including multidrug resistance³⁴⁵; and
- model organisms like the zebrafish and cell signaling networks, including developmental toxicology, toxicogenomics, proteomics, xenobiotic metabolism, and toxicity of various systems, such as cardiovascular, CNS, and the immune system, and mapping drug and gene function relationships.^{346,347}

2.01.3.8 The Perspective of Successful Drug Hunters

Annual Reports in Medicinal Chemistry is a good, concise, annual summary of the latest success of the industry's drug hunters.³⁴⁸ Successful drug hunters persevere, have a whatever-it-takes mindset, and occasionally use tips and tricks

that others miss. The key can be as simple as determining when it is time to move on – proceeding to the next stage of evaluation even if the molecule is not ideal, since more questions will be answered by going forward than have been answered to date. Success can require fighting against the current, such as working on dirty drugs or polypharmacy when others are focused on very selective drugs. Multicomponent therapeutics is a recent example of the latter,³⁴⁹ though Janssen apparently espoused this approach decades ago.

The following are a few thoughts that might go through a drug hunter's mind:

- research and development can be very different, requiring different temperaments;
- breaking the rules creatively in research (innovative chaos) may lead to the next breakthrough;
- following the rules exactly – competence, pure and simple – may be the only viable path through highly regulated phases of development;
- key experiments should be run as soon as possible to get to proof-of-concept;
- from a portfolio and media standpoint, a drug's development in the clinic should not be halted until you have a suitable replacement ready to go;
- if possible, go/no-go decisions on safety should be made as early as possible, but decisions on efficacy should be delayed until Phase III; and
- a decision should not be revisited unless there is new information.

The push for personalized medicine became more forceful in the 1990s with major advances in genomics and proteomics, and personalization will definitely affect the drug hunters' game in this century. However, the regular use of pharmacogenomics to guide clinical trials and choice of therapy remains a distant goal, given the complexities of the human genome, first sequenced in 2001.^{350–354} Nonetheless, marrying diagnostic advances with the latest therapeutics to enable the next generation of personalized therapies could be just over the horizon. Once personalization is achieved regularly as the norm, industry-wide economic effects can be expected. Will large companies be at a disadvantage to smaller ones if personalized medicine decreases the market size of each new therapeutic to only those individuals who will benefit most? At the time of this writing, we can only speculate.

Some of the thorny issues faced by drug hunters at the more than 1000 biotech companies that exist today can be summarized as follows³⁵⁵:

- rising costs in R&D;
- a weak economy following the 'froth' of 2000;
- capital formation difficulties;
- Prescription Drug User Fee Act of 1992 (PDUFA);
- FDA heads, staff, and appropriations (turnover, vacancies, and insufficient funds);
- stem cell research and gene therapy;
- medical records confidentiality;
- generic biotechnology products;
- animal rights activism;
- pricing and controls, including Medicare and reimportation of drugs; and
- intellectual property and technology transfer issues.

With all of these issues, what's a drug hunter to do? A few additional comments from experienced drug hunters follow regarding the yin and yang of pharmaceutical research and development^{356–359}; though not obviously related, some of the same thought patterns can be helpful in running a company³⁶⁰:

- Decisions, once made, must be acted upon promptly and communicated well.
- A decision should be made when you have enough information to make a good one, or if you don't have time to delay; once it is made, never look back (e.g., because someone or something may be gaining on you!).
- What are the 'key' experiments? Many of the killer questions can be asked up front, but are never answered until it is too late – when the issues are about to kill the project.
- With analogy to football, research is often a passing game, lots of razzle-dazzle excitement, where you want to fail early and often, whereas development is the ground game, with success often the result of grit, determination, and sheer competence.
- Never waver in development.

- Don't avoid risk, especially in pharmaceutical research, where over 90% of everything you do will fail – try something new rather than following the pack.
- Many companies have done well with me-too products, so taking a risk is not always the best move from a development or financial perspective.

2.01.4 Targets

At the end of this volume are a series of chapters that introduce strategy and drug research in the context of several important classes of drug targets. While the present volume does not endeavor to present an all encompassing review of major drug targets, it sets the stage for a more detailed consideration of therapeutics and their targets in later volumes (see in particular Volumes 6 and 7 in this reference work – for example, chapters that cover drugs for attention deficit hyperactivity disorder (ADHD), anxiety, cancer, depression, infectious diseases, and neurodegeneration). In considering how to evaluate drug targets from the perspective of medicinal chemistry, one is generally less interested in the information that might be found in molecular biology or pharmacology texts. Rather, one should be more interested in information concerning gene classification, protein structure, localization, physiological function, second messengers (if any), prototypical pharmacology and therapeutic or other products, association with diseases, genetic defects, and future directions – all with the intent of serving as a sound and understandable introduction to someone entering a new area. Thus, it is hoped that this brief introduction will provide the chemist or other interested readers with sufficient background to understand and interpret more comprehensive and detailed experimental and theoretical works.

It is with the above in mind that we now introduce target strategy and drug research. This introduction will be even less complete than those chapters that conclude this volume, and the subsequent volumes in this reference work, but such a layered approach, at greater and greater levels of detail, should serve to lead everyone, from beginner to expert, to their most appropriate entry points into the literature.

We will begin with transporters, a popular set of CNS targets, especially in the last couple of decades, and also a broad class of proteins with a significant role to play in both drug discovery and preclinical development, including ADMET properties (*see* Volume 5). A brief discussion of other targets will follow.

2.01.4.1 Transporters as an Example of an Important Class of Targets

Transporters, pumps, and ion channels have evolved to move ions, proteins, and other molecules across membrane barriers.⁴⁶¹ Transporters are membrane proteins that actively or passively control the influx and efflux of organic and inorganic molecules in all organisms. This flux may be the primary site of action for certain drugs, or it may modulate the efficacy or toxicity of others. Transporters also play a role in drug absorption and disposition. Unlike channels, which are typically on or off and may form pores in membranes, transporters participate more intimately in the movement of drugs, ions, and other substrates across membranes, often requiring a conformational change to perform their function. As such, their transfer rates are usually much slower than that of channels. Transporters may also be called pumps, reuptake sites, and translocases, among other names.

Drug transporters are expressed widely – in brain, intestine, kidney, and liver, for example – and play a key role in both drug action and in ADMET, as introduced above. Given such a central role in cellular physiology, it should be no great revelation that a significant percentage of human genes have been surmised to encode transporters or related proteins.⁴⁶¹ In the initial sequencing of the human genome, more than 500 genes were identified as putative transporters,³⁵³ though this number may be an underestimate because many genes whose molecular functions were not known at the time may ultimately be found to encode transporter functions. Approximately 4% of marketed small-molecule drugs act via transporter targets, which is on a par with drugs working via nuclear hormone receptors. Except for the dominance of GPCRs and enzymes, which respectively account for 30% and 47% of the targets through which marketed small molecules act, only ion channels (7%) are more common than transporters in this respect.³⁶²

Serotonin (5-hydroxytryptamine, 5HT) reuptake (serotonin transporter, SERT) inhibitors used in treating depression, such as fluoxetine (Prozac, [Figure 45](#)), represent a common class of drugs acting at transporter targets. Fluoxetine heralded a breakthrough in treating depression when it was approved by the FDA in 1987, some 13 years after it was first described in the scientific literature as a selective serotonin (re)uptake inhibitor (SSRI). SSRIs subsequently became one of the most widely used drugs for CNS disorders. Particularly worth reading are a case history of fluoxetine and a recent review on neurotransmitter transporters and their impact on the development of psychopharmacology.^{363,364} Since the original discoveries were made, fluoxetine and other SSRIs have also been shown to have utility in treating not just depression but also anxiety, obsessive compulsive disorder, and other diseases.³⁶⁵ In recent years, several transporter

Figure 45 Chemical structure of fluoxetine, a prototypical selective serotonin reuptake inhibitor.

Figure 46 Chemical structures of selected small-molecule monoamine neurotransmitters.

inhibitors achieved a billion dollars or more in sales, among these being citalopram (Celexa, Forest), fluoxetine (Prozac, Lilly), paroxetine (Paxil, GlaxoSmithKline), sertraline (Zoloft, Pfizer), and venlafaxine (Effexor, Wyeth).³⁶⁶

The dopamine transporter (DAT) – a Na^+ and Cl^- -dependent neuronal transmembrane protein – was first cloned in the early 1990s, and is involved in locomotor control, including functions lost in Parkinson's disease. DAT is also involved in reward systems, and thus in addiction to drugs such as amphetamine and cocaine, and in ADHD and Tourette's syndrome, among other illnesses.^{367–371} Indeed, the actions of many small molecule neurotransmitters containing a basic amine are modulated through transporter sites, including those of adrenaline and noradrenaline (epinephrine or norepinephrine), dopamine, histamine, and serotonin (Figure 46). That is, transporters serve to modulate synaptic neurotransmitter levels through reuptake into nerve terminals, and once inside they are taken up into vesicles via different transporters (Figure 47). These effects lend themselves to being studied via in vivo imaging techniques, as outlined later.

Multidrug and drug-specific transporters are involved in the efflux of anticancer and antibiotic chemotherapeutics, which leads to significant resistance in cancer cells and a variety of pathogenic organisms, including bacteria, fungi, and parasites.³⁷² This is often referred to as multidrug resistance (MDR), with P-glycoprotein (P-gp) being a common MDR site in cancer cells. P-gp first generated interest when it was discovered in the late 1980s to be overexpressed in cancer cells. Some drugs, including verapamil (Figure 48), a calcium channel blocker, have been found to inhibit MDRs.³⁷³ While such inhibitors might eventually prove useful in dealing with resistance in cancer and infectious diseases, success to date has been limited.

Transporters have also been exploited in drug delivery. The use of Pluronic block copolymers to modulate P-gp-mediated BBB drug efflux has been studied. These polymers have been demonstrated to enhance BBB penetration.³⁷⁴ The choline transporter has also been proposed as a BBB vector for drug delivery.³⁷⁵ Other drug delivery examples are described below.

The transporter arena has proved so important that biotechnology companies have been founded to exploit the effects of transporters on drug absorption. Consider, for example, XenoPort.

2.01.4.1.1 Current nomenclature

Several superfamilies of transporters have been identified. Most notably, these include ATP-binding cassette (ABC) and solute carrier (SLC) transporters (Table 17).

ABC transporters are also known as the major facilitator superfamily (MFS). There are seven subfamilies of MFS (denoted A through G). Many ABC transporters work to actively pump substrates across membranes using energy derived from ATP hydrolysis. The ABC transporters, including MDR and P-gp proteins, are of interest not only in studying drugs used in cancer and infectious disease but also in studying the transmembrane conductance regulator in cystic fibrosis (CFTR, an ABC transporter that functions like a chloride channel⁴⁶²), the sulfonyl urea receptor (SUR)

Figure 49 Chemical structures of chloroquine and tolbutamide.

ion channels in diabetes. (Note that KATP channels are made up of Kir6, part of the Kir channel family, and SUR, which has been called an ion channel but is an ABC transporter family member.⁴⁶³) P-gps have been compared across several species.⁴⁶⁴ Though it is true that well-studied transporters such as MDR play an important role in drug resistance, new transporters with potential relevance to drug resistance are still being discovered, such as Pfert, which is responsible for resistance to chloroquine (Figure 49) in malaria, and the hexose transporter, which may be a worthy new drug target in malaria.^{376–378}

Neurotransmitter transporters are part of the SLC transporter family, and include biogenic amine transporters of two types, the first comprising DAT, the norepinephrine transporter (NET), and SERT, and separately the vesicular monoamine transporters (VMATs), a distinct proton-dependent gene family (Table 18). Excitatory and inhibitory amino acid neurotransmitters also have transporters. Many neurotransmitter transporters retain the predicted 12 transmembrane spanning domains of this broad family, and range from about 500–800 amino acids in length.³⁷⁹

2.01.4.1.2 Gene/molecular biology classification and protein structure

The ABC and SLC superfamilies of transporters are multi-membrane-spanning proteins.

We will consider for structural illustration one family of SLCs, namely the SLC22 transporter family, which includes transporters for organic anions (OATs) and organic cations (OCTs), as well as zwitterions and cations (OCTNs).

Examples of SLC22 substrates include:

- α -ketoglutarate;
- cAMP;
- cGMP;
- choline;
- L-carnitine;
- prostaglandins; and
- uric acid salts.

These generally polyspecific transporters contain 12 predicted transmembrane α helices and one large extracellular loop between the first and second transmembrane domains (Figure 50). SLC22 transporters function as co-transporters (as with Na⁺ and L-carnitine), exchangers, and uniporters. From the cloning of the first SLC22 in 1994, the rat OCT1, a number of SLC antiporters, symporters, and uniporters have been cloned. SLC22 genes have been found on a number of chromosomes, including 1, 3, 5, 6, 11, and 14.³⁸⁰ Related proteins include organic anion transporting polypeptide transporters (OATPs), which are involved in drug disposition.³⁸¹

The gene organization and other features of the human DAT in neuropsychiatric disorders have been reviewed.³⁸² DAT functional groups have been analyzed in detail at the level of amino acid topography. From these studies it has been ascertained that drug–DAT binding occurs at multiple distinct sites. An atlas of these functional groups has been published.³⁸³ Structure–function studies of the DAT have shown that it can operate in normal and reverse or efflux modes.³⁸⁴ Promiscuous inhibitors have been reported that affect DAT, NET, and SERT to significant but varying degrees, which has provided insight into designing more selective monoamine neurotransmitter transporter inhibitors.³⁸⁵

Because transporters are membrane proteins, which are difficult to crystallize, bacterial proteins that can be expressed at high levels have been most amenable to x-ray crystallography. Successful structures to date include MsbA, an *E. coli* ABC transporter that is homologous to MDR,³⁸⁶ and LacY, an *E. coli* MFS lactose permease.³⁸⁷ LacY is a proton symporter, co-transporting protons and oligosaccharides, and is encoded by a structural gene in the *lac* operon of *E. coli*. As with other members of the MFS family, LacY causes the accumulation of (in this case) oligosaccharides, which is driven uphill energetically using energy released by the downhill electrochemical proton translocation gradient. The

mechanism of transporters such as LacY, and their hand-off of protons and substrates, may involve inward-facing and outward-facing conformations (Figure 51). Computational models have been developed to identify potential P-gp inhibitors and substrates.^{465,466}

2.01.4.1.3 Physiological function

As one might expect from a very broad and important class of proteins, transporters play a wide variety of roles in physiology. A sampling of the roles they play can be found below.

Transporters act as reuptake sites for neurotransmitters, and the pathophysiology of major depressive disorders is believed to involve serotonergic systems, including SERTs. SERTs, for example, are reduced in depression, and various genetic studies implicate these transporters in the disease.³⁸⁸ Long-term exposure to reuptake inhibitors causes downregulation, as one might expect. However, this effect is reversible in 48 h.³⁸⁹ There is also a remodeling that appears to be necessary for therapeutic utility, as antidepressants such as SSRIs take from 2 weeks to 4 weeks to achieve their full effects.

Adenine nucleotide transporters (ANTs), also called translocases or translocators, are reversible transporters of ADP and ATP, and have been implicated in mitochondrial apoptotic processes (programmed cell death). ANTs are believed

Figure 50 General structure of SLCs.

to participate in a complex of proteins that govern mitochondrial membrane permeabilization, a key assemblage in a number of apoptotic pathways. Mitochondrial dysfunction has been implicated in a wide variety of disorders, ranging as far afield as AD and viral infections.³⁹⁰ Mitochondria, with their inner and outer membranes, also use transporters to move proteins around, such as the translocases of the outer membrane (TOMs) and translocases of the inner membrane (TIMs).³⁹¹

The potential for drug–drug metabolism–transporter interactions has been an increasing worry for the industry and for regulatory bodies because of major drug development failures and safety issues with marketed or late-stage drugs in recent years. This includes interactions between antihistamines and antibiotics, for example. Conferences have been held and articles published to debate how best to deal with these issues.^{392,393}

SLC OATs are critical to the renal elimination of many charged drugs, toxins, and xenobiotics. This role in clearance and detoxification is essential for survival. Moreover, drug–drug interactions may occur and nephrotoxicity may also result from interactions with these transporters.³⁹⁴

Polyamine transporters (PATs) have been identified at elevated levels in tumor cells. There appears to be broad structural tolerance among PATs. The molecular requirements for selective polyamine delivery in cells containing PATs have been defined.³⁹⁵

Cholestasis is the syndrome that results from the impairment of bile formation, which may occur because of autoimmune, genetic, or metabolic disorders. Bile secretion depends on a variety of membrane transport systems, including organic and ion transporters, such as OATP, MDR1, and others. Defects in these transporters are associated with various liver diseases in humans.³⁹⁶

Deficiencies in HLA molecules occur when transporters associated with antigen processing (TAPs) are defective.³⁹⁷

2.01.4.1.4 Prototypical pharmacology and therapeutics

2.01.4.1.4.1 Therapeutics

The activity of drugs against efflux transporters can be assessed readily by using one or more in vitro and in vivo systems. This includes accumulation, efflux, transport, ATP hydrolase or synthase (ATPase) assays in vitro, and behavioral, transgenic, and mutant models in vivo.³⁹⁸ Thus there are many ways to uncover and study drugs that may modulate transporter function. A few examples of therapeutics and their mechanistic classes are given below.

Again, one of the most successful classes of transporter inhibitors are the SSRIs. SSRIs are more selective for neurotransmitter transporters than other classes of antidepressants, but the tricyclic class of drugs also interacts with the transporters (Figures 52 and 53). These various antidepressant classes bind to various neurotransmitter receptors as well, which explains many of the side effects (Table 19). There are a number of thorough reviews of the therapeutic potential of neurotransmitter transporter inhibitors, both in this reference work (*see* 5.01 The Why and How of Absorption, Distribution,

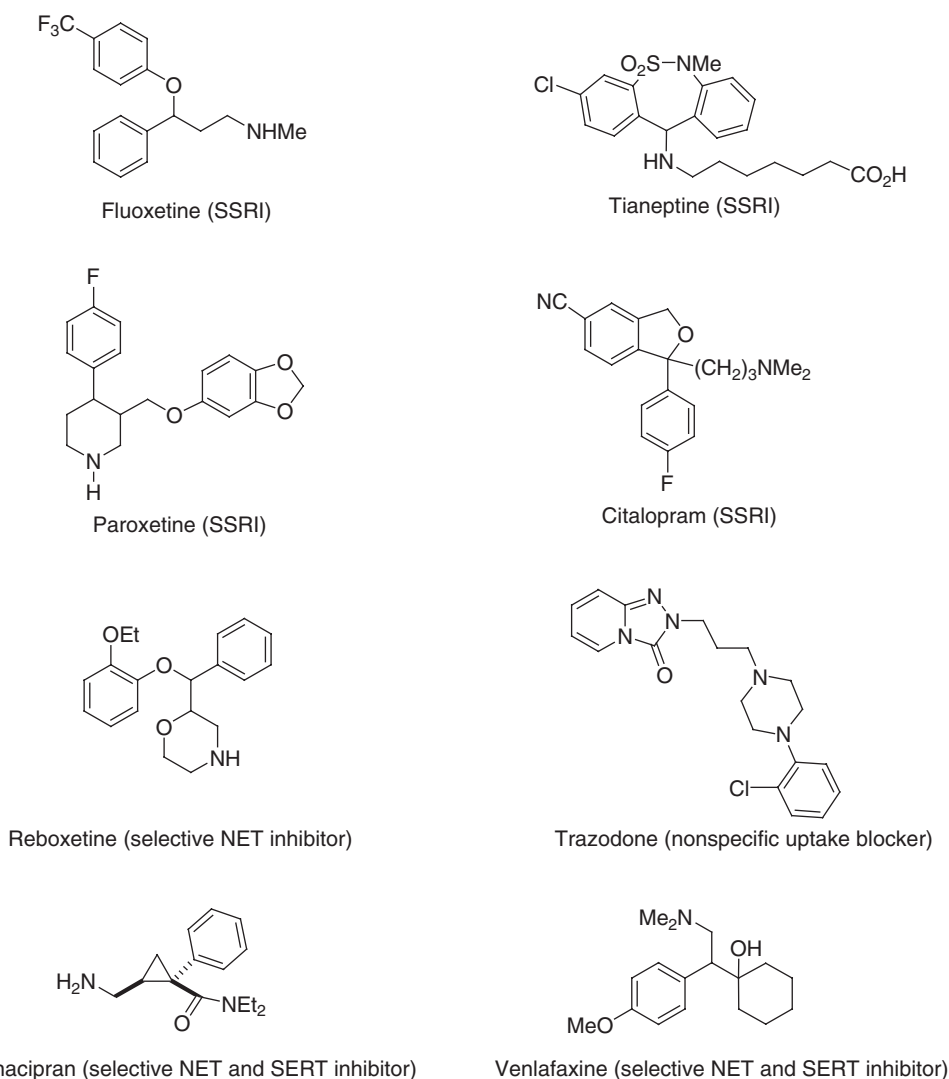

Figure 52 Chemical structures of representative monoamine neurotransmitter transporter inhibitors.

Metabolism, Excretion, and Toxicity Research; 5.04 The Biology and Function of Transporters; 5.32 In Silico Models for Interactions with Transporters; 6.01 Central Nervous System Drugs Overview; 6.03 Affective Disorders: Depression and Bipolar Disorders; 6.05 Attention Deficit Hyperactivity Disorder; 7.01 Cancer Biology; 7.02 Principles of Chemotherapy and Pharmacology; 7.03 Antimetabolites; 7.09 Recent Development in Novel Anticancer Therapies) and elsewhere.^{399,400}

Neurotransmitter transporter sites are the targets of drugs for ADHD, anxiety disorders, and depression, among other diseases. This includes a wide range of structural classes, perhaps most notably SSRIs such as fluoxetine. The SSRIs have also been an interesting area for exploration of chiral substitutions, since drugs such as citalopram and fluoxetine are racemic mixtures, which raises questions around ADME, efficacy, and safety.

SSRIs in some cases have seen expanded use and have challenged anxiety drugs such as benzodiazepines. With fewer side effects, including lesser liability of dependence and withdrawal effects, transporter inhibitors have as a result been able to carve out a worthwhile niche beyond depression. Transporter inhibitors are also finding use in veterinary indications; for example, to treat depressed or nervous pets.

DAT is a key interaction site for cocaine (Figure 54), and may be a critical pathway leading to its liability for abuse.⁴⁰¹ Indeed, novel DAT inhibitors have been studied as potential therapies for drug abuse.⁴⁰²

Drugs such as fenfluramine and 3,4-methylenedioxymethamphetamine (MDMA, ecstasy) cause the neuronal release of serotonin by acting as substrates for SERT proteins (Figure 55). Agents such as these affect appetite, but can lead to neurotoxicity, primary pulmonary hypertension, and valvular heart disease. Their potential in treating psychiatric disorders, such as addiction, depression, and premenstrual syndrome, is predicated on eliminating the side effects.⁴⁰³

Potent and selective inhibitors of the type 2 glycine transporter (GlyT-2) have been described (Figure 56). As glycine is one of the major inhibitory neurotransmitters in vertebrates, it has been proposed that selective inhibitors of GlyTs could have novel effects as analgesics, anesthetics, or muscle relaxants.⁴⁰⁴

One of the largest selling drugs in history, the antiulcer omeprazole (Figure 57), inhibits the secretion of gastric acid. Omeprazole blocks the monovalent inorganic cation transporter activity of $H^+/K^+-ATPase$, also known as the proton pump.^{405,405a}

Sodium-co-dependent bile acid transporter inhibitors (Figure 58) have been studied as potential therapeutics to reduce levels of low-density lipoproteins in atherosclerosis, to prevent coronary heart disease.⁴⁰⁶

Peptide inhibitors of P-gp have been developed based on the structure of the P-gp transmembrane domains in the hope of discovering agents that reduce drug resistance (Figure 59). These peptides sensitize resistant cancer cells to doxorubicin.⁴⁰⁷

Thiazide diuretics (Figure 60) block the Na^+, Cl^- transporter. Diuretics are used to treat patients with edema, including those with cirrhosis, congestive heart failure, nephrotic syndrome, and renal insufficiency.⁴⁰⁸

2.01.4.1.4.2 Imaging

Despite therapeutic successes, imaging studies of SERT and studies of post-mortem brain tissue have not to date yielded unequivocal conclusions about the role of these transporters in depression and suicide.⁴⁰⁹ The use of and challenges in exploiting imaging to monitor disease progression in neurodegenerative diseases such as Parkinson's disease have been reviewed, with a focus on disease-related and drug-induced changes in DAT expression and single

photon emission computed tomography (SPECT).⁴¹⁰ From these and other studies, the turnover rate of DAT protein has been shown to be similar to that of receptor proteins.⁴¹¹ Neuroimaging data suggest that levodopa may modify DAT after chronic use. This is important because levodopa is widely used to reduce the symptoms of Parkinson's disease.⁴¹²

Positron emission tomography (PET) often uses ¹⁸F-fluorodeoxyglucose (FDG) to monitor cellular glucose consumption in patients. FDG is taken up into cancer and other cells via glucose transporters, and its uptake provides information on the consumption or metabolism of glucose, and on glycolysis. Other radiotracers are used in PET, including suitably labeled thymidine and fluorothymidine, which are taken up via nucleoside transporters. In the latter cases, information is generated on DNA synthesis and the proliferation of tumor cells.⁴¹³

Figure 60 Chemical structure of hydrochlorothiazide, a diuretic.

Figure 61 Chemical structures of additional endogenous and xenobiotic substances whose ADMET properties are modulated by transporters.

2.01.4.1.4.3 Drug delivery

Transporters such as the SLCs have been studied as drug delivery targets as well as therapeutic targets and targets for ADMET and drug resistance ([Figure 61](#)). For example, the lipid regulator pravastatin distributes selectively to the liver via SLCs, which reduces side effects in other parts of the body. P-gps can restrict the entry of a variety of endogenous substrates (e.g., estrone sulfate) or xenobiotics (e.g., daunorubicin and methotrexate) into the brain or other tissues.⁴¹⁴ Prodrugs have also been designed to take advantage of transporters involved in transporting amino acids, carboxylic acids, nucleosides and nucleoside bases, and peptides, among others.⁴¹⁵

2.01.4.1.5 Genetic diseases

The high variability in psychopharmacologic drug responses makes pharmacogenetics in areas such as the study of drugs acting at serotonin or other catecholamine transporters complex. Nonetheless, pharmacogenetic studies on a number of drugs have yielded interesting results on phenotypes and response rates, including those with SSRIs such as fluoxetine and citalopram.⁴¹⁶ Indeed, drug development strategies for behavioral disorders in neurodegenerative diseases have

Figure 62 Chemical structure of fexofenadine, an antihistamine.

Figure 63 Chemical structures of carnitine and uric acid.

been discussed in the context of gene polymorphisms associated with several neuropsychiatric diseases or symptoms. For example, a 44 base pair insertion in *SERT* has been associated with psychosis and aggression.⁴¹⁷

The primary site of action of SSRIs is now well known to be *SERT*.⁴¹⁸ As cited earlier, because patients with depression and related illnesses respond so variably to SSRIs, a number of studies have been undertaken to determine whether there is a genotypic explanation for the large differences in clinical response. Current information is not conclusive as a diagnostic tool, but *SERT* *s/s* and *STIM2 10/12* genotypes in Caucasians and Asians, respectively, may be correlated with less favorable responses.^{419,420} Meta-analyses of population- and family-based studies of *SERT* gene polymorphisms and bipolar disorder have concluded that there is a small but detectable effect of the transporter on the odds ratio of the disease.⁴²¹ Other studies have concluded that variants in the long promoter region of *SERT* (5-*HTTLPR*) are associated with transporter efficiency and cytokine and kinase gene expression relevant to treatment outcome, and with lithium treatment outcome in prophylaxis against mood disorders.^{422,423} A broad review of the genes, genetics, and pharmacogenetics of *SERT* has appeared.⁴²⁴ Genetic or acquired deficiencies in another neurotransmitter transporter, NET, have been associated with orthostatic intolerance and tachycardia.⁴²⁵

Though much of the historical work on variations in drug metabolism has focused on CYP enzymes, more recent studies have shown that ABC transporters such as P-gps lead to altered distribution and bioavailability parameters, owing to functional genetic polymorphisms.⁴²⁶ Because such a wide range of molecules are transported by P-gps, the effects of *MDR1* polymorphisms on disease risk, drug disposition, and drug efficacy have been studied extensively.⁴²⁷ Single nucleotide polymorphisms (SNPs) in *ABCB1* have also been shown to affect fexofenadine (Figure 62) concentrations in patients.⁴²⁸

One in three epilepsy patients have drug-resistant epilepsy. It has been reported that specific ABC transporter polymorphisms (i.e., *ABCB1*, which is *MDR1* or *P-gp 170*), which lead to increased expression, may be either causal or linked with a causal variant of drug-resistant epilepsy.⁴²⁹ In addition, mutations in the *ABCA3* gene cause surfactant deficiencies in newborns, which is fatal.⁴³⁰ Defects in the SLC22 class of transporters causes systemic deficiencies (e.g., in carnitine or uric acid (Figure 63)) and changes in drug absorption and excretion.³⁸⁰

Statins and the effects of SNPs on hepatic uptake transporters have been studied, as mentioned above. However, how these SNPs contribute to drug disposition and therapeutic efficacy and safety indices remains to be clarified.⁴³¹

2.01.4.1.6 New directions

The current state of the art in antidepressant therapy dates back in origin to the 1940s and 1950s, with the discovery of serotonin as ‘enteramine,’ and the finding that the antitubercular iproniazid improved the mood of sanitarium patients through a mechanism ultimately defined as inhibition of monoamine oxidase (MAO) (Figure 64). These serendipitous findings helped dramatically to deepen our understanding of monoamines, neurotransmitters, and CNS diseases such as depression.⁴³²

The history of this field has been summarized by several authors. While at most 50–70% of clinically depressed individuals find solace in monoamine therapies and other psychiatric approaches, many patients are poorly served. Thus, newer approaches that are non-monoamine in mechanism are being sought, with limited success to date,

Figure 64 Chemical structures of iproniazid and other MAO inhibitors.

unfortunately. If one considers the first wave of antidepressant drug development as starting with classic pharmaceutical research and resulting in the tricyclic antidepressants, and the second wave starting with clinical observations and yielding SSRIs such as fluoxetine, then the current or third wave would start with pathophysiological, pharmacogenomic, or etiological models and will hopefully yield a new generation of therapies that extend beyond monoamine therapeutics. Representative new approaches are listed below^{433,434}.

- circadian rhythm gene products;
- corticotropin-releasing factor;
- glucocorticoids;
- glutamatergic agents;
- hypothalamic feeding peptides;
- neurokinins;
- neurotrophic factors;
- phosphodiesterase inhibitors; and
- vasopressin receptor antagonists.

Finally for this discussion, with the worldwide increase in illicit drug use (e.g., more than 15 million US citizens over the age of 12 years are estimated to be illicit drug users), the need for addiction therapies continues to grow. Targeting monoamine transporters for such therapies has been the focus of a number of laboratories in recent years.⁴³⁵

2.01.4.2 General Discussion of Targets

Having considered transporters as drug targets, we would be remiss if we did not mention other major classes, such as G protein coupled receptors, ion channels, and so on, since drug discovery targets fall into various classes and families (many are receptors or enzymes). One analysis of drug targets concluded that there were 417 in total, based on drugs that had reached the marketplace, including enzymes, ion channels, receptors, and other targets. The largest percentage, about one-third, were targets associated with synaptic and neuroeffector junctions and the CNS.⁴³⁶

Some have tried to assess the genome from the standpoint of druggability (Figure 65). They estimate that only about 3000 druggable targets exist in the human genome. GPCRs and kinases figure prominently in this analysis. Considering only the currently marketed drugs, GPCRs account for almost one-third of this group (Table 20), with ion channels a distant second (7%). Another evaluation suggests that there are no more than 1500 exploitable drug targets based on the intersection of druggable targets and genes linked to disease.⁴³⁷ Hopefully this is a vast underestimate.

The major drug discovery target classes are as follows:

- GPCRs;
- kinases and phosphatases;

Figure 65 Drug discovery target classes and families, with reference to the druggable genome. Gene family distribution of (a) the molecular targets of current rule-of-five-compliant experimental and marketed drugs, and (b) the druggable genome. Serine/threonine and tyrosine protein kinases are grouped as one gene family (ST/Y kinases), as are class 1 and class 2 G protein-coupled receptors (GPCRs). CYP, cytochrome P450; Cys, cysteine; NHR, nuclear hormone receptor; PDE, phosphodiesterase; Zn, zinc. (Reprinted with permission from Hopkins, A. L.; Groom, C. R. *Nat. Rev. Drug Disc.* **2002**, *1*, 727–730. Copyright 2002 Nature Publishing Group.)

- ligand- and voltage-gated ion channels;
- nuclear hormone receptors;
- nucleic acids (DNA and RNA);
- phosphodiesterases;
- proteases;
- redox enzymes;
- second messenger metabolizing enzymes; and
- transporters (as described above).

Table 20 Selected examples of GPCRs

Adenosine	Interleukin
Adrenergic	Leukotriene

Dopamine	Serotonin
Endothelin	Somatostatin
γ -Amino-butyric acid	Tachykinin
Galanin	Thrombin
Histamine	Vasopressin

Table 21 Key features of drug discovery targets to consider

<i>Key features</i>	<i>Description</i>
Current Nomenclature and Molecular Biology Classification	International unions, societies, etc.
Protein Structure	Protein sequences and 3-dimensional structure
Physiological Function	Role of target family in mediating physiological functions
Second Messengers	Role of biochemical intermediates (cAMP, inositol phosphates, etc.) in mediating physiology and their targets and metabolizing enzymes (cascades and pathways)
Prototypical Pharmacology	Major drugs and classes of drugs associated with target subtypes and the function of agonists, antagonists, and inverse agonists
Prototypical Therapeutics	Major therapeutic applications
Genetic Links to Diseases	Diseases associated with target and mutations
Future Directions	Problems and limitations associated with target, and possible new directions

Selecting the right target is more an art than a science. The process to select a target requires consideration of corporate, business, and R&D strategy, as well as portfolio balance. It must also consider the interplay of stakeholders, consumers, and the drug firm, with attendant technical, legal, economic, demographic, political, social, ecological, and infrastructure factors, in addition to scientific and medical arguments. Unfortunately, it is often the case that marketing projections used to prioritize drug opportunities are not anywhere close to actual sales – examples include tamoxifen (Nolvadex), captopril (Capoten), cimetidine (Tagamet), fluoxetine (Prozac), and atorvastatin. Thus, the research director must evaluate – and discount – all these inputs prior to making the judgment call.⁴³⁸

Various strategies have been proposed to improve decision making in preclinical studies, whether it be hit-to-lead generation or predicting how a compound will behave in humans from the standpoint of pharmacokinetics, metabolism, efficacy, and safety. Other strategies include decision gates regarding target validation, proof-of-concept, and druggability. Given that about 45% of currently marketed drugs target receptors, and 28% target enzymes, clearly these target classes are druggable. Regardless of the target, many approaches end up in the same place, focused on reducing attrition, optimizing multiple properties simultaneously, moving from hit to lead, and arguing about quality versus quantity in chemical libraries.⁴³⁹ Some of the features to consider when evaluating drug discovery targets can be found in [Table 21](#).

GPCRs, also known as 7TMs, 7-spanners, or serpentine receptors, are widely considered the most important class of drug targets, at least historically. However, kinases are gaining ground. Kinases are today implicated directly or indirectly in more than 400 human diseases.

Diseases with inflammatory or proliferative responses in which kinases may play a significant role include

- arthritis,
- asthma,
- cancer,
- cardiovascular disorders,
- neurological disorders, and
- psoriasis.

Kinase activity can be modulated by blocking adenosine triphosphate (ATP) binding, disrupting protein–protein interactions, or downregulating gene expression. These approaches have yielded several small molecule drugs and antibodies on the market or in development (Figures 66 and 67). The first major breakthrough in this area was a Novartis drug, imatinib, a protein-tyrosine kinase inhibitor that blocks ATP binding, discussed earlier in the chapter. Imatinib was first marketed in 2001 for chronic myeloid leukemia (CML), and crossed the billion dollar sales threshold in 2003. Unfortunately, clinical resistance has been observed in the targeted oncogene, the result of mutations. Other examples of kinase inhibitors developed for cancer include gefitinib and erlotinib (Tarceva). To date, clinical studies have focused on cancer – colorectal, nonsmall cell lung, pancreatic, renal – though arthritis, AD, diabetes, diabetic neuropathy, heart disease, inflammation, and Parkinson's disease are also under investigation.^{440,441}

One of the givens with a new class of targets is that the early therapeutic indications may not be where the target ultimately proves useful. Consider the case of the endothelins (ET-1, ET-2, and ET-3) and their receptors (ET_A, ET_B, and ET_C). The first ET receptor ligand was identified in 1988 as a very potent, vascular endothelium-derived vasoconstrictor peptide, 21 residues in length.⁴⁴³ Given the vasoactivity of this substance, many companies originally targeted cardiovascular disease, though the area was believed to represent a major opportunity for many diseases. The wide range of targets is not surprising given that ET receptors are widely distributed in mammalian tissues, and elevated levels of ET-1 have been observed in atherosclerosis, congestive heart failure, hypertension, myocardial infarction, pulmonary hypertension, and renal failure. However, the direction of R&D in this area has changed

Figure 66 Chemical structures of the protein kinase inhibitors imatinib, gefitinib, and erlotinib.

Figure 67 Mechanisms of tyrosine kinase function and drugs acting at various sites. TK, tyrosine kinase; PDGF(R), platelet-derived growth factor (receptor); VEGF(R), vascular endothelial growth factor (receptor); EGF(R), epidermal growth factor (receptor); FGF(R), fibroblast growth factor (receptor); KL, KIT ligand; FL, FLT3 ligand; HGF(R), hepatocyte growth factor (receptor); HER-2, named after its gene *HER2/neu*, also known as *ErbB2* (named based on its similarity to avian erythroblastosis oncogene B), is the protein product of a protooncogene, originally named after human epidermal growth factor receptor, to which it is structurally related; RET, receptor tyrosine kinase; FLT, fms-like tyrosine kinase (fms, Feline McDonough Sarcoma); c-KIT, a member of the PDGFR family, c-KIT is a tyrosine kinase receptor that dimerizes following ligand binding and is autophosphorylated on intracellular tyrosine residues; c-FMS, a tyrosine kinase; c-MET, a tyrosine kinase; JM, juxtamembrane; ITD, internal tandem duplications; BCR, breakpoint cluster region; ABL, Abelson; HSP, heat shock protein; CC, coiled coil; JAK, Janus kinase; ALK, anaplastic lymphoma kinase; NTRK, a tyrosine kinase; ASP, aspartic acid; 17-AAG, 17-allylamino-17-demethoxygeldanamycin; Ph, Philadelphia. (Reprinted with permission from Krause, D. S.; Van Etten, R. A. *N. Engl. J. Med.* **2005**, 353, 172–187. Copyright 2005 Massachusetts Medical Society. All rights reserved.⁴⁴²)

significantly. Speedel announced in 2005 that its oral ET receptor antagonist (SPP301) successfully completed Phase II clinical trials in diabetic nephropathy,⁴⁴⁴ and Abbott is seeking FDA approval for an ET receptor antagonist (atrasentan (Xinlay)) in oncology indications.⁴⁴⁵

2.01.4.3 Project Selection

It is beyond the scope of this introduction to go into detail on all of the techniques that researchers use to validate new targets. It would also be a long discussion, at times philosophical, to cover reasons to diversify one's research versus focusing efforts in certain areas. Small biotech companies face such decisions regularly. For example, a company named 7TM focuses on GPCRs, and as mentioned earlier, MitoKor focused on mitochondria. Other companies focus on therapeutic areas – Kosan and Telik being largely cancer based, for example, though each has its own technological focus as well. Still others focus on technologies or specific approaches, such as SGX (formerly known as Structural GenomiX) and its fragment and crystal SBD strategies. These examples notwithstanding, project selection – including the identification, validation, and prioritization of genes and targets emanating from genomics initiatives – ultimately draws on many technologies. While an enormous amount of data has been generated, we have barely started our journey to exploit these data because of the laborious and time-consuming process of validating new drug targets (Table 22)⁴⁴⁶ and the many challenges surrounding data integration (Figure 68).⁴⁴⁷

2.01.4.4 Other Target Classes

In 1997, Drews and Ryser summarized what they termed classic drug targets.⁴⁴⁸ These targets of marketed drugs were broken down into 11 classes comprising about 500 targets (Table 23). Receptor targets dominated these numbers, being twice as common for marketed drugs as enzyme targets, followed by factors and hormones, channels or unknown targets, and nucleic acid targets. Central nervous system (CNS) and related targets were the most common.

How have we done in various therapeutic and target areas? First, let us consider cancer. Modern chemotherapy started with nitrogen mustards in the 1940s. The NCI began systematic screening for new anticancer drugs in the 1950s. Chemotherapy following surgical removal of cancers was demonstrated to improve cure rates in the 1960s. Major drugs like cisplatin and paclitaxel were approved in the 1970s and 1990s. The tyrosine kinase inhibitor, imatinib, was approved in 2001 by the FDA, representing a new target-based paradigm in the field. Clearly a lot of progress has been made – but also clearly there is a long way to go to achieve the National Cancer Institute's goals.⁴⁴⁹ If you are diagnosed with a serious cancer today, and a cure is discovered for this cancer today, you will probably still die of this cancer because it takes so long to develop new drugs, even for cancer. The war on cancer is thus far from won, but the NCI has stated as its goal to eliminate suffering and death from cancer by 2015.⁴⁵⁰

Moving beyond cancer, new targets in the 1980s included phosphodiesterases (PDE). Who could have predicted that PDE inhibitors, which were studied extensively in the 1980s for heart failure (e.g., inhibitors of type 3 cAMP PDE, like amrinone),⁴⁵¹ and later as antidepressants (e.g., rolipram),⁴⁵² would ultimately yield billion dollar products for erectile dysfunction (e.g., inhibitors of type 5 cGMP PDE, such as sildenafil (Viagra)).^{453,454} This shift in emphasis raises other questions, though. A society that shifts its attention to “desires rather than diseases” is a society gone off track.⁴⁵⁵

The history of calcium antagonists provides an interesting case study in the development of a whole new therapeutic paradigm, one which continues to evolve as new compounds, new targets, and new medical uses are developed. Compounds such as verapamil, nifedipine, and diltiazem showed how widely divergent chemicals could all target similar ion channels (Figure 69).⁴⁵⁶ Ion channels continue to be of great interest as drug targets, beyond traditional therapy for hypertension, anesthesia, anxiety, epilepsy, and insomnia, as new opportunities are uncovered for this well-established therapeutic class in pain, autoimmune disease, cancer, and other areas.⁴⁵⁷

Table 22 Functional genomics technologies leading to new drug targets

Gene-family mining and comparative genomics	Identity and similarity to known gene families
RNA profiling	High-density expression arrays
Proteomics	Gel electrophoresis and mass spectrometry
Oligonucleotides	Knockdowns, RNAi, microRNAs
Systematic analyses	Analysis of gene function in cell culture, cDNAs
Model organisms	Drosophila, zebrafish

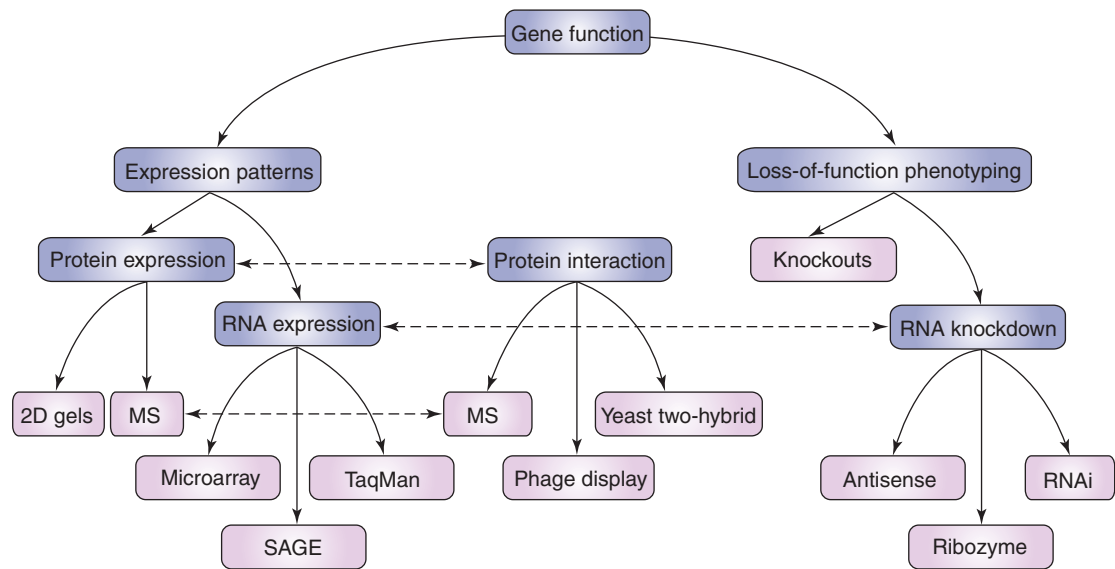

Figure 68 Examples of various domains of drug discovery research data that must be integrated for optimal results. Examples of scientific data domains (by no means exhaustive) relating to gene function, arranged in a taxonomy to indicate their natural nesting from general themes down to specific data-generating technologies (in pink). Such a hierarchy could continue upwards to culminate in an amalgamation of the major domains of biology, chemistry, and medicine. Integration of heterogeneous domains can occur vertically from the bottom up in an initiative to provide comprehensive data access or consolidated data collections; it can also occur horizontally between domains, such as RNA expression and protein interaction, in specific integrative ‘experiments.’ The challenges of integration actually begin with ostensibly homogeneous data, such as various readouts of expression, and even in combining results of several experiments based on the same technology. The dashed arrows connect domains dealing with the same biological entities (proteins and RNA) or with instances of the same method (mass spectrometry), each of which should be related by means of common data standards for naming and formatting so as to ease integration. MS, mass spectrometry; SAGE, serial analysis of gene expression; RNAi, RNA interference. (Reprinted with permission from Searls, D. B. *Nat. Rev. Drug Disc.* **2005**, *4*, 45–58. Copyright 2005 Nature Publishing Group.)

Table 23 Therapeutic targets of marketed drugs

Number	Therapeutic or functional area
137	Synaptic, neuroeffector, or CNS
55	Hormones and their antagonists
50	Inflammation
47	Renal and cardiovascular
39	Neoplastic diseases
38	Blood and bloodforming organs
19	Infectious disease
16	Immunomodulatory
15	Gastrointestinal functions
10	Vitamins
8	Uterine motility

Figure 69 The diverse nature of calcium channel blocker chemical structures.

Table 24 Properties of drug candidates to consider when contemplating full-scale development

<i>Chemistry</i>	<i>Pharmacology</i>	<i>Pharmacokinetics and drug metabolism</i>	<i>Preclinical safety</i>
Novel chemical structure	Validated target	Measurable plasma levels	Low pharmacologic risk (cardiovascular, CNS, gastrointestinal, renal, respiratory)
Strong patent position	Mechanism of action linked to pathophysiology of disease	High oral bioavailability	Negative in mutagenicity tests
Inexpensive synthesis possible on large scale	Potent	Suitable half-life	High therapeutic index based on toxicology studies
Isomers separated (and compared)	Selective versus other targets	Low first pass metabolism	
High purity	Reproducible efficacy in predictive animal model	Limited induction of hepatic enzymes	
Salt form studied and selected	Clear dose response	Limited interaction with other drugs	
	Suitable duration of action		
	Active after repeated dosing (minimal tolerance)		
	Advantages versus competitive agents		

While many companies have exited research on agents for infectious disease, new biodefense initiatives are bringing such work back into vogue.⁴⁵⁸ This renewed interest may yield drug candidates of use both for terrorist attacks and for the more traditional community-acquired infections, bacterial, fungal, or viral, including flu pandemics and the like.

Though many of the new technologies and ways of thinking about molecular targets, druggability, and ADMET are indeed worthwhile advances, one must not lose sight of the principles of classical medicinal chemistry. Indeed, the belief that pharmacokinetics is the major reason for drug development failures is not borne out by the data. Whereas pharmacokinetics was the reason for 39% of drug development failures in a survey of large UK companies from 1964 to 1985, this number drops to 7% if one excludes anti-infectives from the list. Thus, decades of medicinal chemistry experience must be merged with the new technologies to achieve the desired levels of success.⁴⁵⁹ And even the simplest screening methods can be useful, such as using silica gel plates with targets such as cholinesterase.⁴⁶⁰ In the end, a variety of properties must be evaluated the old-fashioned way before advancing a drug into development, whether the target is a good one or a bad one. In closing, Table 24 serves as a reminder of what properties matter in such decisions, including target validation, mechanism of action, dose response, bioavailability, and other pharmaceutical properties.

Biography

Walter H Moos has more than 20 years of experience in the pharmaceutical and biotechnology industries. He is currently Vice President and Head of the Biosciences Division at SRI International. For a number of years Dr Moos served as Chairman and Chief Executive Officer of MitoKor, until it merged with Micrologix to create MIGENIX. Previously, he was employed by Chiron (now Novartis) as a corporate officer, last holding the position of Vice President of R&D – Technologies Division. Dr Moos held earlier positions at Warner-Lambert/Parke-Davis (now Pfizer), last serving as Vice President, Neuroscience and Biological Chemistry. Dr Moos has served on the boards of directors of Alnis, Anterion, Axiom, the Biotechnology Industry Organization, CMPS, MIGENIX, Mimotopes, Oncologic, Onyx, Rigel, and the Keystone Symposia. He is a co-founding member of the CEO Council, Red Abbey Venture Partners. Dr Moos has edited several books, helped to found multiple journals, and has a total of more than 140 manuscripts and issued patents to his name. In addition, he has held adjunct faculty positions at the University of Michigan – Ann Arbor, and since 1992 has been an adjunct professor at the University of California – San Francisco. He has also served on academic and related advisory committees, including the US National Committee at the National Academy of Sciences. Dr Moos holds an AB from Harvard University and received his PhD in chemistry from the University of California – Berkeley.

“The achievements of chemical synthesis are firmly bound in our attempts to break the shackles of disease and poverty”.

Roald Hoffman, 1993
Nobel Laureate Chemistry

2.02.1 Changing Faces, Places, and Directions

A number of recent reviews have discussed at some length the nature of medicinal chemistry education in both Europe and the USA and have also examined the issues of the educational characteristics necessary for medicinal chemists practicing in the pharmaceutical industry.^{1–4} These reviews constitute a useful comparative resource to which reference should be made for details of curriculum recommendations and related matters. Some of these findings and recommendations are presented in **Tables 1** and **2**. Additionally, the Carnegie Foundation for the Advancement of Teaching has published valuable essays by Breslow and Kwiram on doctoral education in chemistry.^{5,6} Extensive discussion on the future of graduate education, albeit solely from a US perspective, may be found at ‘Re-envisioning the PhD,’⁷ which includes links to academic studies of many issues around doctoral education in both the sciences and humanities. This website contains the reports of many studies from which may be drawn some general conclusions, amongst the most important being that the programs are too long, too specialized, and too focused on preparing their students for solely academic careers, which careers will not be available for the overwhelming majority of graduates. A specific report on graduate education in the pharmaceutical sciences was commissioned by the American Association of Colleges of Pharmacy and published in 1999.⁸ Indeed, the output of only a very small number of graduate programs is sufficient to fill new faculty recruiting demand and this creates a very competitive and recruiter-advantaged situation. The most recent study, for example, of faculty recruitment into Departments of Chemistry (and other departments from Colleges of Arts and Sciences) reveals that over 50% of the faculty at the top 25 American research universities obtained their PhD degrees from the top 10 universities (the rankings are those provided annually by *US News and World Report*)⁹.

Finally, and reflecting the well-established observations that increased higher education correlates with higher lifetime income, the Royal Society of Chemistry in conjunction with the Institute of Physics commissioned PriceWaterhouseCoopers to re-examine this with particular reference to graduates of physics and chemistry programs in the UK. Their report found that graduates of these programs will earn on average 30% more than the corresponding high-school graduates.¹⁰ This study was taken in light of the unpopularity of chemistry programs in the UK that has led to the closure of a number of university departments.¹¹ This situation is not unique to the UK. The USA also has serious concerns about its education achievements in general, with overall concerns for literacy, science, and mathematics. Recent reports indicate that not only does the USA rank poorly in science on an international comparative scale, but that there are widespread inequalities within populations¹² and the USA has increasingly depended on non-USA students, particularly science graduates from China and India, to fill its graduate programs in science and engineering.^{13–15} In 2003, non-US students, for example, obtained approximately 40% of science doctorates and almost 60% of engineering doctorates. At the National Institutes of Health some 50% of the doctorate staff and fellows are non-US and

the 2000 US Census indicates that almost 40% of doctoral-level employees are foreign-born. The Business Round Table arguing for a new scientific education initiative has discussed these issues in the United States.¹⁶

And the Western world continues to attract scientifically and medically qualified individuals to its shores, despite the impoverishing effects that this may have on the countries of origin.^{17,18} Whether these demographics reflect actual true shortages of scientifically qualified individuals or simply market-driven efforts to dampen wage and salary expectations and the cost of education remain in question.^{19–24} However, many initiatives are under way with mechanisms designed to make chemistry a more attractive study area.²⁵ Whether these will be productive is questionable, at least in the USA, where new post-Scopes fundamentalist views of science now appear to be endorsed by both the public at large and their political leaders.^{26,27}

In this chapter, however, a rather broader view will be taken in an effort to place medicinal chemistry within the context of ongoing changes in the underlying sciences, in the roles and structures of universities, in the changing social role of science, and of the impact of globalization on science in both the rich and poor worlds.

Science is not a static entity. Consider physics. At the beginning of the twentieth century everything was in its place in Newton's clockwork universe. And there was no reason to suspect that this clockwork precision would not accommodate what little else there was to discover. Yet in a few short years it was all overturned and physics had to start again. That revolution was a catalytic event for other changes in the twentieth century. Biology transformed itself in a

few short years from an essentially descriptive discipline to one largely molecular in nature, in significant part because of the entry of physicists into the field. And that biological revolution is now spreading to other disciplines, notably chemistry.

The underlying paradigms of molecular biology – ‘diversity,’ ‘evolution,’ ‘self-organization,’ and ‘replication’ – are changing the face of chemistry and of medicinal chemistry in particular. Ehrlich’s magic bullet may in the future be, not the laboriously handcrafted molecule of the 1900s, but rather a self-synthesizing, reproducing, evolving, and targeting molecular machine or bioreactor designed to synthesize on demand the appropriate molecule(s) for cellular repair or destruction. These changes will continue to impact both the definition and the content of medicinal chemistry.^{28–31}

Originally a discipline largely grounded in and practicing synthetic organic chemistry and guided in its direction by in vivo and some in vitro pharmacological data, medicinal chemistry has expanded in the past three decades to embrace not merely the dramatically expanded synthetic and technologic advances in organic chemistry, but also to include expanded analyses of structure–activity relationships through detailed knowledge of target structure, and increasingly of structure–property relationships and to be guided in direction by genomics-driven technologies that provide biological data directly from defined human targets. Thus, the medicinal chemist is increasingly dealing with pharmacokinetic, metabolic, genomic, and toxicological inputs all of which also guide the directions of organic synthesis. The influence of these inputs is clearly seen in [Figures 1](#) and [2](#) that demonstrate respectively the old and new pathways of drug discovery.

As synthetic chemistry continues to be further influenced by molecular biology through, for example, template-guided processes there will be increasing need for definitions of molecular biology to expand even further its disciplinary horizons.^{32–35} The IUPAC definition³ of medicinal chemistry of 1998:

“Medicinal chemistry is a chemistry-based discipline, also involving aspects of biological, medical, and pharmaceutical sciences. It is concerned with the invention, discovery, design, identification, and preparation of biologically active compounds, the study of their metabolism, the interpretation of their mode of action at the molecular level and the construction of structure–activity relationships.”

will continue to develop and to expand to include a greater biologic input. In this context, the words of George S. Hammond⁹⁰ in his 1968 Norris lecture to the American Chemical Society assume particular significance:

“The most fundamental and lasting objective of synthesis is not production of new compounds, but production of properties.”

Figure 1 The two pathways of drug discovery that compare the classical (top) and the genomics-driven (bottom) routes.

Figure 2 A comparison of the pathways of drug discovery indicating in pathway B the role of high-throughput and high-information inputs to the process subsequent to molecular input compared to the classical low-throughput pathway A. The implications for medicinal chemistry are the increasing importance of genomics-based disciplines to the total drug discovery process and the necessity for the medicinal chemist to factor these considerations into drug and molecular design.

These changes in disciplinary content and focus mean that the old walls and barriers that have traditionally separated disciplines are eroding rapidly. Biology is no longer confined to Departments of Biology and chemistry is practiced in academic departments from Anthropology to Zoology. These changes impact the teaching and practice of medicinal chemistry and related pharmaceutical disciplines. As Schools of Pharmacy, long the dominant home of Departments of Medicinal Chemistry, focus increasingly on the clinical aspects of their teaching and research so will their basic science disciplines be increasingly found in other departments. Thus, many Departments of Chemistry with their increasing biological emphasis also have strong programs in medicinal chemistry. Similarly, drug delivery is increasingly seen an integral component of bioengineering programs housed in Schools of Engineering, rather than a major activity of Schools of Pharmacy.

Such changes create tension in the faculty, but they are to be welcomed as part of the inevitable maturation of scientific disciplines and as further indications of the progressive integration of scientific knowledge. Nowhere is this to be seen more prominently than in the rapidly emerging discipline of systems biology, a discipline intended to provide through the integrated application of chemical, biological, and physical disciplines a complete understanding and mapping of biological pathways and function.^{32,33} Both the practice and teaching of medicinal chemistry will be influenced significantly by this emerging discipline. The medicinal chemist of the future will thus be an individual

armed with a toolbox of discipline-derived technologies that she will simultaneously use, replace, and replenish as necessary. It is, in fact, one of the great ironies of our twentieth-century reductionist approach to science that we have arrived at a stage where integration of knowledge is an even greater priority than the mere accumulation of new knowledge. The twentyfirst-century will be heavily dependent on the interdisciplinary sciences.³⁴

“The challenge for the university will be how to accommodate the learning necessary to achieve such a skill set within an environment that has a very strong tradition of silo-based disciplinary organization and that is also increasingly assuming some of the properties and characteristics of the market economy.”

The traditional expectation from the pharmaceutical industry has been that the principal training for a medicinal chemist should be in synthetic organic chemistry with the anticipation that biological and related knowledge will be added later through experience or through specific training.²⁻⁴ It remains true today that the medicinal chemist must have a thorough grounding in synthetic organic chemistry – ‘how to put molecules together and take them apart again’ – and to be able to correlate structure and biological activity. However, there have been very significant changes in the drug discovery process during the past two or three decades. Prior to this period the chemist collaborated with the pharmacologist who typically worked with in vivo or in vitro tissue preparations. Considerations of pharmacokinetic and toxicological issues came late in the discovery process and were not of primary concern to the chemist. In the new drug discovery programs there is much more emphasis on biological considerations and the nature and character of the drug target, which may well have been defined from genomic considerations. Additionally, biological assays are often primarily cell-based with cloned receptors, enzymes or channels and ADME (absorption, distribution, metabolism, and excretion) considerations are now part of the molecular design process. Finally, the increasing sophistication of structure-based approaches and the use of in silico technologies necessitate at least a familiarity by the chemist of these computational techniques.³⁵ It is thus possible that the current view of a medicinal chemist as primarily a synthetic organic chemist with grafted-on biological knowledge will be replaced by a broader definition and even the creation of subspecialties of medicinal chemist.³⁶ How this will be achieved is a matter of some current interest.

The university will not, of course, be the sole player in the teaching of any discipline or collection of disciplines in this learning environment. Thus, for medicinal chemistry there are a number of national and international summer schools and similar learning environments designed to provide at least the rudiments of medicinal chemistry, typically to newly trained synthetic organic chemists.³⁷ A broadly representative program from one of these summer schools is presented in [Table 3](#). Valuable as these programs are the major responsibility for education must nonetheless fall on the university. One possible solution will be the creation of ‘certificate’ programs that are created jointly by universities and the pharmaceutical industry and that offer validated knowledge in a variety of medicinal chemistry subdisciplines – molecular modeling, in silico chemistry, ADME, etc.

Similarly, it is plausible to consider some further sharing of the drug discovery enterprise where academia has typically been involved only in the very earliest stages. For example, the Molecular Libraries Initiative of the National Institutes of Health Roadmap for Medical Research will generate a library of small-molecule chemical probes that will be screened through the development of new assay formats and procedures and that will permit predictive ADME/Toxicology.^{38,39} The data from this will be available in a public database, PubChem, and should provide a new stimulus for academic involvement in the early phases of drug discovery.

2.02.2 Academia in a State of Flux

“Today we are at a crossroads
One road leads to hopelessness and utter despair
The other leads to total extinction
Let us pray that we have the wisdom to choose wisely.”

Woody Allen, Address to the Graduates

The preceding discussion, albeit focused primarily on medicinal chemistry, must however be seen as part of a larger set of changes that are affecting the academic environment of the twentyfirst-century. A better understanding of the challenges facing medicinal chemistry may be gained by some consideration of the changing faces and directions of the academy – an organization in a considerable state of flux. In this broader context it should be noted that in this pace of

2. Case histories: II
3. Case histories: III

^aSmall group sessions.

change there is nothing particularly unique to the discipline of medicinal chemistry. Michael Gibbons, a former director of a science policy unit in the UK has argued that much of today's leading science does not consist of the patient process of putting one brick on top of another, but rather of solving complex problems that cross many disciplines. He sees the university in an environment that he calls "a socially distributed knowledge production system" in which the university is but one of many generators of knowledge.⁴⁰ Thus, in this viewpoint the idea of a university as a tidy institution living harmoniously within its own self-defined boundaries may well be dead. Rather, we may need to see the university as an open structure within a cloud of continuously forming and dissolving relationships. This is a pattern that is already common to individual faculty who are long used to being accused of having greater loyalties to their disciplines than to their own institutions.

Universities always appear to be in a state of crisis or at least flux, whether it be the salary of the football coach, the nature of core programs and their lack of funding or, and more simply, some new sex scandal focused on the administration. This apparent universal state of crisis is puzzling since universities are, in fact, our oldest and arguably amongst our most successful institutions. The first true university was founded in Bologna in the eleventh-century and those of Paris, Oxford, and Padua a century later. But universities are really much older and can trace their origin to the library of Alexandria and the Greek protocols of scientific inquiry. These ancient foundations, and thousands like them, continue to grow and prosper. But they are changing – the students are no longer monks, the teachers no longer priests, and the curriculum has long been stripped of Greek, Latin, logic, and rhetoric and even of much philosophy. Over a century ago Cardinal John Henry Newman provided a definition of the university based on his belief that it is necessary to separate the pursuit of truth from mankind's 'necessary cares.' Newman's university would be: "the high protecting power of all knowledge and science, of fact and principle, of inquiry and discovery, of experiment and speculation."^{41,42} Newman had recognized that which Francis Bacon had already announced some 400 years ago that knowledge is power: "knowledge and human power are synonymous, since the ignorance of the cause frustrates the effect, for nature is only subdued by submission."⁴³

The reality is, however, that universities have always been nonstatic entities, but that the pace and nature of change are today both quantitatively larger and qualitatively more distinct than in previous centuries. And these changes are not universally welcomed.^{44–46} The factors generating change include:

1. Exponential increases in scientific knowledge.
2. Fragmentation of scientific disciplines.
3. Increasing cost of scientific research and education.
4. Increasing ethical issues, particularly around biology-based disciplines.
5. Rapid changes in learning technologies.
6. Increased demand – demographics and economic market.
7. Increased general competition.
8. New learning organizations – virtual universities.
9. Proprietary competition – corporations buying or creating universities.
10. Rapidly growing role for education as credentialing.
11. Education as a commodity.
12. Diminishing public funding as demand increases.
13. Expectations of education as an immediate economic benefit.
14. Worldwide competition to Western dominance of knowledge.
15. Privatization of knowledge as part of a neoconservative ‘free market’ economy.

The challenge for universities thus appears to be twofold. First, a dramatic increase in the rate of generation of scientific knowledge and the associated specialization of knowledge and second and increased public and political expectation of universal higher education and of attendant direct economic returns from university-based, publicly funded research. For universities the questions are thus whether to remain true to Newman’s concept and serve as the guardian and generator of knowledge for the public good and how to accommodate to the increasing expectation that knowledge should be treated as a commodity of rapidly translatable economic benefit. But the challenge may be more apparent than real. Although the faculty, particularly those from the humanities, may well dislike the term “The Knowledge Factory,” used by *The Economist*,⁴⁷ applied to their institutions, universities have, at least until comparatively recently, nonetheless navigated quite successfully the competing demands of generating the intellectual commons and of contributing to economic development. This dual role is eminently in line with the concept of the public funding of research as defined by Vannevar Bush in the USA in the immediate post-World War II environment⁴⁸:

“The Government should accept new responsibilities for promoting the flow of new scientific knowledge and development of scientific talent in our youth. These responsibilities are the proper concern of the Government, for they vitally affect our jobs, our health, our security.”

Although the model of scientific support outlined by Vannevar Bush has often been interpreted as a linear description of scientific research that distinguishes ‘basic’ and ‘applied’ research as separate extremes, it was noted by Donald Stokes in *Pasteur’s Quadrant*⁴⁹ that the distinction is in reality far less clear and that much scientific research falls into the category of ‘use-inspired basic research’ (Figure 3). Much biomedical research, including medicinal chemistry falls into this category.

2.02.3 The Ethos of Science

“Nature is often hidden, sometimes overcome, seldom extinguished.”

Francis Bacon, 1625

The traditional role of academic science, and of university function in general, has been to operate as a ‘gift’ economy to which members of this economy contribute intellectual and creative gifts. The rewards in this economy are to those who provide the most and the most valuable gifts and are in the form of academic honors, distinctions, and recognition.^{50–52} This gift economy contrasts with the commodity economy of the market place whereby money constitutes both the price of entry and the recognition of participation. The gift economy model of academic science is entirely consistent with the ethos of science as defined by Robert Merton some 50 years ago.^{50,53,54} Merton defined this ethos based on the values of the free and open exchange of knowledge, the unrestricted pursuit of this knowledge

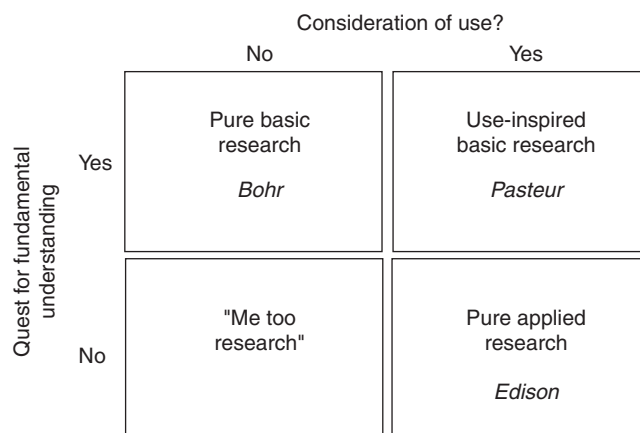

Figure 3 The quadrant model of scientific research. (Reproduced with permission from Stokes, D. E.; *Pasteur's Quadrant: Basic Science and Technological Innovation*; Brookings Institution Press: Washington, DC. 1997.)

Figure 4 The conflict between the traditional and the new 'market' focus of universities.

independent of self-interest, and an acceptance that science is a product of nature and not of politics, religion, or culture. Merton defined four norms that characterized this view of science – “universalism”, “communalism,” “disinterestedness,” and “organized skepticism.” These norms define the intellectual commons of science – a freely generated and freely available pool of “certified knowledge.” It is this environment that has characterized the role of the university and that has stood society well: this role may be changing and it imposes stress on the traditional structure and values of the academy (Figure 4).

From the specific perspective of medicinal chemistry Ralph Hirschmann, who has been long and sequentially associated with both the pharmaceutical industry (Merck Research Laboratories) and academia (University of Pennsylvania) the situation is clear (*see* 1.01 Reflections of a Medicinal Chemist: Formative Years through Thirty-Seven Years Service in the Pharmaceutical Industry):

“Medicinal chemistry has always stood with one foot in the academic world and the other in the industrial world ... The roles of these two sectors need to be profoundly different if their combined efforts are to benefit the patient. It is the responsibility and function of academe to undertake fundamental research, and it is the task of industry to perform the developmental research required if the knowledge generated by the former is to lead to medicines and vaccines...”

Similarly, Sir James Black has written⁵⁵:

“I think that you should understand that at no point have I ever professionally made claims about what I thought that work would achieve, for the simple reason I’ve never thought that it was going to achieve anything other than answer a question. The challenge was to make a molecule which would have the properties of allowing you to answer a physiological question.”

Finally, and to reinforce the previous statements, it is worthy of some note that between 1993 and 2002 only 14 new chemical or biological entities had their origins in academic laboratories out of the total of 355 new introductions (see 1.13 The Role of Small- or Medium-Sized Enterprises in Drug Discovery).

2.02.4 The University in a Market Environment

“There is big pressure on universities now to go into places that are determined politically by the funding councils and I think that this very bad for discovery. There is too much pressure to go into applied areas.”

Robin Ganellin, 2004⁵⁶

There is an increasing awareness that universities are becoming increasingly involved in a variety of commercial activities and that this may change their traditional role of contributors to and keepers of the intellectual commons. To be sure this concern is not new and was expressed almost a century ago by Thorstein Veblen in his volume *The Higher Learning in America*.⁵⁷ And the American land-grant university has always had a significant role in fostering the practical arts.⁵⁸ However, there is a concern well expressed by a number of academic authors that the increasing commercialism may change significantly both the roles and the prestige of universities.^{59–62} This has been well expressed by Slaughter and Leslie⁶²:

“Increased global competition interacted with national and state/provincial spending priorities so that less money was available from government, when measured as a share of higher education revenue or as constant dollars per student. In the 1980’s globalization accelerated the movement of faculty and universities towards the market...began to undercut the tacit contract between professors and society because the market put as much emphasis on the bottom line as on client welfare. The *raison d’être* for special treatment of universities, the training ground for professionals, was undermined.”

The commercialization of universities is not a uniquely American phenomenon, although the USA has certainly led the way. Increasingly, European and other universities are also following suit, driven by arguments that competitive scientific wealth in the global environment can be extracted from university research by commercializing and focusing its research.

Whether such approaches will be as successful as their promoters argue is yet to be determined. The successes of the past that led to the creation of the high technology hubs of San Francisco, Boston, San Diego, and elsewhere are due largely to events that had occurred prior to the Bayh–Dole legislation of 1980 and, in any event, were due only in part to the intellectual achievements of the university.^{61,63,64} The temptation in universities to become increasingly large research institutions may, in fact, diminish their intrinsic creativity. Even in a Viagra-fueled world bigger is not always better, as was recognized by Theodore Schultz as early as 1980⁶⁵:

“We have become enamored of large research institutes and large programmes...but they are difficult to administer and they are subject to what is known in economics as diminishing returns to scale.”

According to Jonathan Cole, former Provost of Columbia University, size brings a corollary set of problems. The increased dependence on industry, government, and business brings increased public exposure and hence the universities are increasingly susceptible to political and public manipulation and control.⁶⁶ This is not, of course, new. American universities have seen this before during the era of Senator McCarthy and their leaders did not stand up to be counted then either.⁶⁷ And prior to that both German and Russian science and their citizens paid an enormous price for the politicization of science by Hitler and Stalin, respectively.

The reflections of Derek Bok, former President of Harvard University, over a two-decade period are of some relevance here:

“Alliances with industry will provide not only an alternative to federal largesse, but also revitalize intellectual life in universities, as corporations inject real world problems.”⁸⁶

“The mounting requirements of the state might prove less onerous than the demands made by the market.”⁸⁷

“I worry that commercialization may be changing the nature of academic institutions in ways which we will come to regret. By trying so hard to capture more money for their work, universities may compromise values that are essential to the continued confidence of the general public.”⁵⁹

But of course Adam Smith knew this almost 250 years ago⁸⁸:

“People of the same trade seldom meet together, even for merriment and diversion, but the conversation ends in a conspiracy against the public.”

2.02.5 Globalization and Science in the Rich and Poor Worlds

“For unto whomsoever much is given of him much shall be required.”

Luke 12: 48

Since 1945 a principal goal of the USA has been to maintain world leadership in the sciences. There is little doubt but that the USA has been enormously successful in science and technology as measured by a variety of indices including Nobel (and similar) prizes received, citations to publications, papers, and patents published, and the launching of technology-based industries, notably biotechnology. However, precise comparisons of scientific wealth in nations is a difficult task, and when citation comparisons are made with reference to both population and GDP, the smaller European countries (Scandinavia, the Netherlands, and Switzerland) all perform more strongly.^{68,69} In significant part, the success of these nations is due to the role of universities. A comparison of the top 500 world universities published by the Shanghai Institute of Education and based on a number of criteria, including Nobel prizes, articles published in *Science* and *Nature*, numbers of publications and numbers of faculty members, shows that in the top 100 institutions there are 58 US and 31 European universities.⁷⁰ However, regardless of these differences it is striking that a mere 31 of the world's 193 countries produce 97.5% of the most cited papers in science.⁶⁹ These figures represent, of course, only one component of a grossly unequal world.⁷¹

More recently, the USA has announced a goal of unchallengeable world supremacy in both military and economic fields.⁷² This goal is neither desirable nor attainable and is, in fact, delusional. It is most unlikely that in a globalized world one nation can maintain such supremacy. Indeed, there are already significant observations that the distribution of scientific wealth is shifting between nations and that the USA is losing its claimed dominance in the sciences.⁷³ In a comparison of science citations China and India are rising rapidly and the citation gap between the USA and the EU is closing.^{74–76} Indeed, some comparisons suggest that in some fields the EU is ahead of the USA.⁷⁷ These changes are part of a global power shift in the making that may well end with a transfer of economic power from the West to the East, or at least a significant reduction of the existing dominance by the West.^{78–82} According to Raghunath Mashelkar, Director-General of the Council of Scientific and Industrial Research of India:

“If India plays its cards right it can become by 2020 the world's number-one knowledge production center.”⁸⁰

2.02.6 Implications for Academic Medicinal Chemistry

“As for the future, your task is not to foresee but to enable it.”

Antoine de Saint-Exupéry⁸⁹

Outside of changes in our knowledge base of medicinal chemistry there are two important implications of the preceding discussions for the practice and achievements of medicinal chemistry in the academic environment. First, the changing nature of university-based science in general with its increasing emphasis on patenting, inventions, and rapid commercialization. As a component of the shift (or reduction) of economic and scientific dominance by the West it may be anticipated that the existing distribution of medicinal chemistry expertise will change at both the academic and industrial levels. Associated with this shift the compulsion by TRIPS (Trade Related aspects of Intellectual Property RightS) for noncompliant countries to shift from copying to creativity in the pharmaceutical (and other) fields will increase the need for medicinal chemistry development at both academic and industrial levels. There is significant evidence that this is already occurring through both outsourcing from the USA and the increase in drug discovery chemistry in both China and India.⁷⁸ Although major pharmaceutical companies have long outsourced components of drug discovery chemistry to US-based companies such as Millennium, Pharmacopeia, Albany Molecular, ArQule, and Discovery Partners, the shift is now to non-US-based companies, notably in India.^{79–85} This dual stimulus of outsourcing and TRIPS will expand both the need and dimensions of medicinal chemistry education in India and elsewhere in Asia and it is to be anticipated that over the next one to two decades the teaching and practice of medicinal chemistry will increasingly be focused and delivered in Asia.

2.02.7 Conclusions

Medicinal chemistry is a discipline firmly grounded in organic chemistry. Traditionally, in fact, a subdiscipline of synthetic organic chemistry, medicinal chemistry has increasingly expanded at both the physical and biological interfaces of organic chemistry. This expansion represents a challenge both to definition as well as to the practice of

teaching and research within an academic environment. Departments of medicinal chemistry have long been associated with schools and colleges of pharmacy, but this association is changing and medicinal chemistry, together with allied pharmaceutical science disciplines, is now increasingly associated with other departmental structures, notably chemistry. Additionally, with the globalization of science non-US and non-European countries are increasingly seen as significant academic and industrial science players and Asia will likely be a major player in both academic and industrial medicinal chemistry by the second and third decades of the twenty-first century.

Biography

David J Triggle, PhD, is the University Professor and a Distinguished Professor in the School of Pharmacy and Pharmaceutical Sciences at the State University of New York at Buffalo. Professor Triggle received his education in the UK with a PhD degree in chemistry at the University of Hull. Following postdoctoral fellowships at the University of Ottawa (Canada) and the University of London (UK) he assumed a position in the School of Pharmacy at the University at Buffalo. He served as Chairman of the Department of Biochemical Pharmacology from 1971 to 1985 and as Dean of the School of Pharmacy from 1985 to 1995. From 1996 to 2001 he served as Dean of the Graduate School and from 1999 to 2001 was also the University Provost. He is currently the University Professor, in which capacity he teaches bioethics and science policy, and is President of the Center for Inquiry Institute, a secular think tank located in Amherst, New York.

Professor Triggle is the author of three books dealing with the autonomic nervous system and drug–receptor interactions, the editor of a further dozen books, some 280 papers, some 150 chapters and reviews, and has presented over 1000 invited lectures worldwide. The Institute for Scientific Information lists him as one of the 100 most highly cited scientists in the field of pharmacology. His principal research interests have been in the areas of drug–receptor interactions, the chemical pharmacology of drugs active at ion channels, and issues of graduate education and scientific research policy.

2.03.1 Business Model

The landscape of what is typically referred to as the life sciences pharmaceutical sector is usually divided into four categories by the investment community and Wall Street. The first two categories are the pure play pharmaceutical businesses and the specialty pharma businesses. A third category is the diversified businesses which typically includes consumer products, chemical or agriculture as part of a pharmaceutical business. The last category is biotechnology. Until about 1980 only three of these four categories coexisted, and, in fact during the twentieth century these categories underwent substantial changes in definitions. The biotechnology sector arose with the advent of recombinant DNA methods in the 1970s, generating, for the first time, the opportunity to make proteins in cell culture in the laboratory in a designed fashion. Of course, prior to that time there were protein-based drugs, such as insulin and growth factors, but these were derived through laborious extraction processes from natural sources. From today's vantage point this landscape of four business models is now well established and likely to extend for some time into future decades. Nonetheless, through the ever-changing consolidation and rebirth of new companies within the overall industry there will undoubtedly be significant changes in populating these categories.

2.03.1.1 Pharmaceuticals

Inherent in the processes of discovering and developing drugs are the fundamental aspects of understanding diseases, their cross-species penetrance, and the capability of modeling these diseases in the laboratory. The utilization of this knowledge predictably led to the development of drugs for both the treatment as well as the prevention of disease or disease progression. In addition, there is knowledge generated to identify the disease in the first instance (diagnostics) and evaluate the progression of the disease in the patient. To the extent that these diseases are similar between animals and humans, the exploitation of this knowledge leads to the development of veterinary products as well. Over the last century the business model for pharmaceuticals has frequently included the development and commercialization of products as treatments for disease, vaccines for the prevention of disease, diagnostics for the detection of disease, and utilization of all three of these in animal models of disease. While the focus of this chapter is not on veterinary medicines per se, a significant business driver in veterinary medicine has been the utilization of drugs in food-producing animals; specifically, the use of antibiotics and hormones for the efficient growth of food-producing animals and the prevention of concomitant disease has revolutionized the animal-products industry. However, over time the business of veterinary medicine has developed more and more in parallel with human medicine, including the treatment of cancers and chronic inflammatory diseases such as arthritis in animals. In addition, the reimbursement side of this business has also begun developing parallels with human medicine with the advent of insurance for payers for treatment of animal diseases. Therefore, we can reasonably expect the pharmaceutical companies will continue to be interested in veterinary medicine as well.

All of the pharmaceutical companies have been involved in therapeutics, and their growth has been driven by success in therapeutic drugs. Some of the companies have also been interested in prevention: vaccines. While vaccines have had tremendous impact on human and animal health in disease prevention, interest was not universal within the industry due, in part, to the special requirements of manufacturing vaccines. In addition, while the return on investment was never as high as therapeutics, it dropped significantly with perceived safety issues and increased litigation in the 1970s. A resurgence of interest has occurred, due to new biotechnology-based approaches, reproducible methods of manufacturing, and increased demand, both on medical need and government support. Biotech companies and large pharmaceutical companies have been coparticipants in this reemergence of interest in vaccines.

In a somewhat analogous fashion, diagnostics has only been part of a subset of the pharmaceutical companies' business interests. The margins have been lower than therapeutics and the product cycle shorter. However, with advances in biotechnologies such as polymerase chain reaction (PCR) and, more recently, genomics and proteomics, there is a resurgence of interest in diagnostics. Furthermore, there is the expectation that many of tomorrow's drugs will be co-marketed with a diagnostic.

From today's vantage point we view the pharmaceutical business as a very complex business that is both capital and time intensive. It has very high thresholds for entry because of the time and capital commitments coupled with the high knowledge-base requirements. The term fully integrated pharmaceutical company (FIPCO) is used routinely today to describe this model. The top 20 pharma companies today are all FIPCOs and possess all the requisite infrastructure for basic research, drug discovery, drug development, and manufacturing for commercialization for their products as well as marketing and sales forces for distribution and sales of their products. The most obvious value driver, and a significant barrier to entry, is the extraordinary resources required for the discovery and development of drugs. [Table 1](#) shows the largest pharmaceutical companies in 2004 and their aggregate R&D spend of nearly US\$40 billion. This translated into about US\$250 billion in revenues for those companies in 2004. The global pharmaceutical sales for 2004 was US\$550 billion.

However, this was not always so. It was not until the 1950s and 1960s that the concept of a fully integrated organization really materialized. R&D spend at that time was not double-digit percentages of sales, as it is today, and the key value drivers were ability to manufacture and penetrate the European, North America, and Japanese marketplaces. This required manufacturing as well as sales in a number of countries and represented the internationalization of the business. The larger pharmaceutical companies of that time outsourced very few of their services and often times included internal services for maintenance, employee activities, and transportation. It is important to recognize however, that the FIPCO model was one that evolved over a number of prior decades. This is perhaps most readily understood by exemplification; the consolidation of a number of companies that led to today's GlaxoSmithKline.

The parentage of GlaxoSmithKline can be traced back to Beecham's Pills in 1842, John K. Smith & Company founded in 1841, Burroughs Wellcome & Company begun in 1880, and McLeans Ltd. founded in 1919.^{1,2} Three of these names have already disappeared from the current GlaxoSmithKline moniker but they were very substantial contributors to today's present GlaxoSmithKline corporation. Beecham's Pills was a laxative business that grew into a

Table 1 Aggregate R&D expenditures of major pharmaceutical companies, 2004

<i>Company</i>	<i>R&D spend (US\$ billion)</i>	<i>Percentage of sales</i>
Pfizer	7.7	15
Sanofi-Aventis	5.2	16
GlaxoSmithKline	4.8	16
Novartis	4.0	14
AstraZeneca (AZ)	3.8	18
Roche	3.8	16
Lilly	2.6	19
Bristol-Myers Squibb (BMS)	2.4	11
Wyeth	2.4	14
Amgen	1.9	20

diversified pharmaceutical manufacturer in the mid-twentieth century and ultimately became a major international pharmaceutical producer of antibiotics in the late twentieth century. In 1989 Beecham merged with the then Smith Kline Beckman. The Beckman name was dropped and Smith Kline Beecham became the name of the new entity. The name Glaxo has its roots in milk powder production back in the late nineteenth century established, originally by Joseph Nathan in Wellington, New Zealand. Glaxo's move into prominence was relatively recent in the timetable of pharmaceutical company maturation and was evident with its blockbuster drug, Zantac, which evolved in the 1970s and 1980s. However, it was the merger with Wellcome in 1995, generating GlaxoWellcome, that really provided a diversified pharmaceutical business. Burroughs Wellcome, founded in London by two American pharmacists, Henry Wellcome and Silas Burroughs in 1880, ultimately straddled the Atlantic between the USA at Research Triangle Park and Wellcome in London, majority owned by the Wellcome Foundation in London. They had substantial competencies in chemotherapies and were one of the early entrants into the production of interferon. In 2000, after a couple of attempts, Glaxo Wellcome merged with Smith Kline (having dropped Beecham from the name) and is now the third largest pharmaceutical company. However, even this brief litany does not do justice to the evolution of becoming a FIPCO, for, within the background of the Beecham history, there is the SE Massengill Company, perhaps (unfortunately) best known for its elixir of sulfanilamide, which included the toxic cosolvent diethyleneglycol. Beecham also acquired McLeans Ltd. (McLeans toothpaste) and Glaxo acquired Meyer Laboratories in 1978.

The big pharma model has been remarkably robust and continues today with more than a half a decade of validation. The model has been the basis for significant earnings flow and growth, probably unsurpassed by any other industry. Undoubtedly the driver for this has been the development of new treatments that have not only extended life but have significantly improved the quality of life of millions of people. Nonetheless, the history of pharma is littered with examples where a successful product itself is not sufficient for sustaining the business model. Examples include ibuprofen from Boots, naproxen from Syntex, and sodium chromoglycate from Fisons. However, even companies with a portfolio of products have ultimately failed to sustain their independence and identity, even though they were FIPCOs. Many of these companies like Squibb, Roussel, Robbins, Miles, Lederle, Kabi, Boehringer Mannheim, Upjohn, and others were acquired with the belief that size and scale are the ultimate drivers to sustaining growth. Complicating this picture, however, is that there has been a strong financial driver for mergers and acquisitions, rather than just size/scale responding to a changing environment. In addition to size and scale there has been the belief that capturing cost synergies is important. Cost synergies have materialized; unfortunately, virtually all pharmaceutical companies that have participated in mergers and acquisition activities have failed to increase market share at the end of the day. It was only a decade ago that the largest pharma company had revenues representing only 4% of the total market. Today, Pfizer has 13% of the global market share, by virtue of its recent acquisitions of Parke Davis/Warner Lambert and Pharmacia. However, 13% share is less than the additive shares of the three companies prior to merger. Further growth of Pfizer is unlikely to occur by more consolidation, if only for antitrust reasons. In large part because of this there have been alternative models for life sciences and pharmaceuticals and these have included diversified, specialty pharma, and biotech.

2.03.1.2 Specialty Pharma

Specialty pharma has arisen as a more prominent sector in the overall pharmaceutical landscape over the last 10–15 years. This is primarily due to the move of big pharma into blockbuster driven sales and marketing with increasing emphasis on primary care sales forces and direct to consumer advertising. Therefore companies with a focus on specialty products have arisen by in-licensing products and investing more focused sales efforts on already marketed products. This sector currently enjoys significant value assessment because of the absence of significant R&D costs together with lower sales costs associated with specialty product opportunities. In parallel there has been a growing resurgence and interest in generic products. During the mid-1990s generic products were plateauing, after a significant rise in the 1980s, and big pharma were selling off their generics businesses to specialty companies focusing on that sector. However, in the first decade of this century the number of large products opportunities that have become generic has mushroomed, and this has precipitated a resurgence in interest in not only the specialty pharma but also big pharma acquiring these products and competing in this landscape. In parallel, some specialty pharma have also moved further back into the value creation paradigm and in-licensed early staged product development opportunities to carry them forward to commercialization. They are back integrating therefore into ultimately becoming FIPCOs. Similarly, several companies in the service sector, that is contract research organizations (CROs), particularly those focusing on clinical services, have also in-licensed development stage compounds to ultimately attempt to commercialize them.

2.03.1.3 Diversified Model

As noted earlier, a number of today's pharmaceutical companies had their roots in a strong chemical business. More recently a number of companies with strength in that area have attempted to enter into the pharmaceutical arena. Companies such as Monsanto, Dupont, Kodak, and Proctor & Gamble, to name a few, have attempted to add pharmaceuticals to their diversified business interests. One of the rationales offered was to balance a cyclic business that has significant peaks and valleys such as pharmaceuticals, with more stable businesses, thus modulating the overall swings in a company's fortunes. However, there is usually only modest synergy, if any at all, between the various businesses. There are different competencies in research, the development areas, and ultimately sales and marketing, and this basically results in multiple companies within the corporation contributing to the bottom line of a corporation in an independent fashion. Companies that have recognized this have been able to manage this diversification. Johnson & Johnson is one such example. The key to success seems to be allowing those various companies to operate with autonomy. However, companies that have attempted to integrate these have rarely been successful and ultimately have lead to deconsolidation. Examples of this include Warner Lambert, Bristol-Myers Squibb (BMS), American Home and, most recently, Bayer.

2.03.1.4 Biotech

Biotechnology began in the 1970s at the commercial level with the formation of Cetus (1971), Biogen (1976), Chiron (1977), and Genex (1977). Shortly thereafter one of the most well-known biotech companies, Genentech, began and this was followed by a substantial increase in biotech start-ups securing funding through venture capital and ultimately proceeding to become public companies. The exclusive focus of these biotechnology companies was the production of protein therapeutics with recombinant DNA technology. Some of these proteins were replacements for already marketed protein therapeutics; many were new. The former category includes such products as insulin, growth hormone, and interferon and the latter category includes such products as tissue plasminogen activator (TPA), erythropoietin (EPO), and granulocyte colony stimulating factor (G-CSF). In the 1980s the breadth of therapeutic opportunities increased particularly as it began to include the development of antibodies as therapeutic proteins. However, the incubation phase for success with antibodies was longer than anticipated, and really did not materialize until the mid-1990s. Even with biologicals as products, it is still a decade of time and investment to the first product (Figure 1).

In the intervening time a new type of biotech company came into being. These new companies were start-ups that focused on small molecules or developing tools for the discovery of small molecules. In essence, these start-ups competed directly in the landscape of big pharma. These neopharma of course had limited funding, staffing, and experience, but were offering new targets, faster, smarter ways of discovering drugs and an entrepreneurial enthusiasm for risk-taking in a very risk-tolerant environment.

Unlike their former biotechnology/biological cousins in the biotech sector, the investment in the small molecule type drug was relatively modest until one proceeded into later stage clinical evaluation. The challenge for developing biologicals was the manufacturing of these biologicals and the investment in costly facilities early in the development

Company	Founded	IPO	Years to IPO	First product launch	Product	Years to first product	First full-year profit	Years to profit from founding	Years to profit from IPO

cycle of the product. This pioneering work in biologicals manufacturing was primarily unique to biotechnology. However, the capability to scale up small molecule drugs, and manufacturing them, of course, had generations of experience in big pharma. It was natural then that the neopharma, small molecule biotech companies would look to partner relatively early on with big pharma to exploit their respective strengths and weaknesses. This paradigm of corporate partnering was in fact happening on a modest scale in the 1980s, but grew to be very substantial in the 1990s and, in fact, represented a validation of the technology of the small biotech company.

Another significant opportunity arose in the mid-1990s in biotech and it revolved principally around two major initiatives. The first initiative was the sequencing of the human genome and the genomes of number of species. The second was the much more diversified but nonetheless significant investment in automation, miniaturization, and informatics. The combination of these two waves of technology development and information development led to a significant paradigm change in the discovery of drugs. This paradigm change was the large-scale adoption of an already evolving philosophy of molecular targets for drugs, irrespective of whether the drugs are biologicals or small molecules. With the initiatives in these two domains being primarily in biotech, this also represented a significant partnering opportunity for big pharma, with their realization that they needed to access this information and these technologies. The scale of this was unprecedented and required in many ways a substantial increase in the investment in R&D for drug discovery and drug development. Furthermore, this changing paradigm likely contributed to the reduction in productivity in the development of new drugs during the 1990s by big pharma and, even to the current time. During this time biotechnology matured and companies such as Genentech and Amgen achieved market capitalizations equivalent to big pharma with even more enviable price/earnings (P/E) ratios. Biotechnology demonstrated not only that proteins could be drugs but that they could have a substantial impact on the treatment of diseases heretofore not treated with small molecules. Often these biologicals were at a higher cost, but the cost–benefit ratio was acceptable. So what was once a chemistry-driven industry has now become appropriately a blend of chemistry and biologicals with a growing emphasis on the molecular understanding of the basis of diseases. Success depended on the integration of the biological and chemical sciences to discover drugs. In 2005 there are at least 500 publicly traded biotechnology companies in the world and they are providing an increasing number of new discoveries and drug development for the overall industry. Eleven of the 80 blockbuster drugs in 2004 originated from biotech companies.

Within the last several years a new type of start-up company has arisen which focuses exclusively on drug development. These have been termed NRDOs (no research, development only). Given the history of biotechnology, it is hard to call these biotech companies, as they are almost the antithesis of biotech. These companies, like specialty pharma, minimize investment in research and find their drugs by in-licensing. They secure presently undervalued assets, perform clinical studies, add value, and then partner with commercial organizations, big pharma, or ultimately build their own sales organizations. Venture capital, at this time, appears to favor this business model as it shortens the time to a product-driven revenue stream over the more traditional biotech model, and presumably reduces risk, although that remains to be seen. In a similar vein is a growing interest in repurposing old drugs and/or resurrecting old drug candidates that never quite made it.

longer-term safety evaluation.) Ultimately, the package of information from the clinical studies, together with much more extensive toxicology studies including up to 2 years evaluation in animals, plus extensive manufacturing data on the active ingredient as well as the final drug product, are assembled into a new drug application (NDA) and submitted to the regulatory authorities. Typically the review period for these NDAs is on the order of 1–2 years and the drug is then approved for commercial distribution. The overall process from project initiation to approval usually extends beyond 10 years. The duration of the various phases are shown as ranges in [Figure 2](#). The activities between lead development candidate and IND are where regulations begin to impact and this regulation continues through approval and beyond. Therefore, the duration of these later phases or stages is more consistent, since many of the activities are common to most drugs. There are exceptions where regulators, such as the Food and Drug Administration (FDA), have allowed for abbreviated toxicology studies in animals or accelerated approval based on a single pivotal clinical study.

Drug discovery and drug development can be described as a process but also as a complex and interdependent array of multidisciplinary competencies. Throughout the history of drug discovery and development an essential competency has been the ability to synthesize organic compounds. While historically some drugs were secured from natural sources, and a few still are today, most drugs are synthesized in a laboratory and then scaled up in much larger reactors and equipment in manufacturing facilities. Therefore, primary prerequisites for drug discovery are the competencies of organic chemistry synthesis and structure determination. These expertises are required at the beginnings of the process of drug discovery and are also required throughout the drug development path to commercialization. However, the primary need is in the earlier stages of drug discovery and drug development. Other competencies, principally in the domain of biology, are required in the earlier stages of drug discovery and are critical to dissecting pathways to understand the etiology of diseases. Similarly, these biological expertises are important for establishing laboratory surrogates for disease pathways, and for generating tools for understanding mechanism of action for drug candidates. These scientific disciplines and expertise are presented in [Table 2](#). Some of the more recent additions to the scientific disciplines and expertises required for an integrated R&D enterprise include computational and informatic technologies, as well as the competencies of genomics and proteomics to better translate laboratory information to the clinic regarding the drug and the disease. This expertise frequently partners with pharmacokinetics to understand exposure response relationships and establish what are termed PK/PD correlations, that is, pharmacokinetics/pharmacodynamics. (PD are surrogate markers that measure the impact of the drug on the patient's disease or on the patient per se (e.g., safety).) Another recent trend has been to establish better models in the laboratory for preclinical predictability of potential clinical findings for safety and ADME (absorption, distribution, metabolism, excretion). For example, laboratory tools and assays to predict potential liabilities due to cytochrome P450 metabolism or inhibition, QTc prolongation, certain liver toxicities, and substrates for unique transporters are now routine in today's modern drug discovery laboratories. The goal for these kinds of activities is to minimize the failure rate that occurs when the drug enters human clinical study, either for pharmacokinetic reasons, safety reasons, or efficacy reasons.

The pharmaceutical value paradigm is depicted in [Table 3](#) and brings together some of these competencies by phase or stage of development and commercialization of a drug. While some of the competencies bridge a number of these areas of expertise in drug discovery, development, manufacturing, marketing and sales, nonetheless there are important differentiating characteristics between some of these stages of the pharmaceutical value paradigm. Many of the activities in drug development, manufacturing and commercialization are readily scalable, and in today's environment, readily outsourced. On the other hand, many of the activities in drug discovery are not readily scalable and require critical, state-of-the-art expertise, but often on a modest scale. Given the complexity of the underlying sciences, many of these activities are collaborative in nature and are often interfaced with academic investigators or scientists in research institutes funded by various government agencies or foundations. Similarly, while the later stages of drug development are capital intensive, the earlier stages of drug development, and indeed drug discovery, are 'human capital' intensive. Typically the proportion of the R&D budget that is allocated to drug discovery is on the order of 25%, while 75% is used for drug development. The more significant contributors to the increasing costs of drug development are increasing regulatory requirements, increasing size and breadth of clinical trials, as well as their inherent cost, and also the scale-up of the drug entity under development to prepare for ultimate commercial scale. In the context of the overall pharmaceutical value paradigm, drug discovery and development represent about 20% of the overall cost, with another 10% incurred for manufacturing, 10% for marketing, and, ultimately, 25% for sales and distribution.

Overall the drug discovery and development process is complex, characterized by many more failures than successes, and is time and capital intensive. It is ultimately characterized by long cycle times and extraordinary efforts at gathering data from diverse sources and assembling usable knowledge into a dossier for a new drug registration.

2.03.2.1 How to Organize for Drug Discovery and Drug Development

As previously noted, the processes of drug discovery and development are complex, highly interdependent, and multidimensional. This complexity has challenged various organizational models over the decades and no single model has evolved as the unifying solution. It is not only the multidimensionality and complexity that challenges organizational models, but also the value drivers that are sought by the company engaged in the business of developing drugs. For example, if one of the value drivers in the organization is scientific excellence in various disciplines and technologies contributing to drug discovery and development, this value is orthogonal to higher-level, multidimensional knowledge across a variety of scientific disciplines and/or disease categories. Furthermore, many drugs are useful in treating more than one disease, and these diseases, while perhaps interrelated, are typically organized in different therapeutic areas. And, lastly, there is the important dimension of project/program evaluation and prioritization. Drug discovery or development programs are categorized by stage of development as well as importance and urgency of development. An organizational model for drug discovery and development therefore, must be able to prioritize across drug development and discovery programs which span stages of development, disease and therapeutic areas, and

Table 3 Pharmaceutical value paradigm

current and future business interests, and which account for the reality of the annual budget and the competitive landscape for that particular program.

With these attributes in mind, most pharmaceutical organizations are either structured around therapeutic areas or functional disciplines. [Figure 3](#) depicts the typical functional disciplines and therapeutic categories of R&D. The categories listed are not meant to be comprehensive but represent the most commonly chosen categories, both therapeutically and functionally. In addition to this listing of therapeutic categories there are also specific diseases within these categories, and some diseases that are not readily captured or segregated into a therapeutic category. Additional complicating factors include diseases that span therapeutic categories. There are many examples of these complications, but to name just a few: is multiple sclerosis, an autoimmune disease, listed under central nervous system (CNS) or under inflammatory or immunopathological diseases? is type 1 diabetes, another autoimmune disorder, listed under endocrine diseases? is inflammatory bowel disease an inflammatory disease or listed in the gastrointestinal category? A third complicating dimension to therapeutic categories is the recognition that a single category can encompass quite a diverse group of diseases and, similarly, a diverse group of drug discovery targets. For example, CNS disorders can include psychiatric diseases such as anxiety, depression, schizophrenia, bipolar disorder, and neurological disorders including epilepsy and insomnia, as well as neurodegenerative diseases, such as Alzheimer's and Parkinson's diseases. It also can include neurotrauma, such as stroke, traumatic brain injury, or subarachnoid hemorrhage. The evaluation of each one of these diseases and disease subcategories is actually quite different in the clinic as well as in the laboratory. Therefore, research into these disease subcategories can have many more unique than common features in a therapeutic area. Each of these disease categories can independently require a substantial number of scientists and clinicians to appropriately discover and develop drugs to treat these disorders.

The alternative R&D organizational option is organization aligned by function. This type of structure attempts to utilize the critical path value and state of the art competency attributes in those functional areas to assure scientific excellence in the quality of the work that is ultimately executed in the laboratory or the clinic. It also facilitates the flexible reallocation of staff to various projects, based on functional needs, with sufficient resources to meet the need of that particular project. These needs can vary frequently from project to project as well as by stage of development.

Not unlike the therapeutic categories, the functional categories also have significant diversity within them. For example, in molecular biology, there are different skill sets for producing proteins in various cell-based systems, particularly between prokaryotic and eukaryotic systems. Physical and analytical chemistry encompasses a diverse array of knowledge and expertise in a variety of instruments including sophisticated techniques such as x-ray crystallography, nuclear magnetic resonance (NMR), and mass spectrometry, as well as specialization in various separation technologies and the detection/identification of minute amounts of samples. Indeed there is even some overlap with biological analysis between the analytical sciences of chemistry and the analytical sciences of molecular biology (gene chips and proteomic chips). A function such as chemical development and chemistry process research involves a cadre of chemical engineers and synthetic chemists involved in novel processes research, as well as synthetic chemists expert in large-scale production. It also includes groups of analytical chemists and experts in environmental assessment for manufacturing and disposal.

Some of these functional areas are common to both drug discovery and development. Typically, information technologies (IT) are required for all phases of drug discovery and development. In addition, PK and ADME,

Table 4 Key factors for organizing R&D

<i>Attributes</i>	<i>Considerations</i>
Scientific/technical competencies/depth	Program funding versus department funding
Disease knowledge	Annual budget
Therapeutic area knowledge	Priorities
Drug discovery knowledge	Speed versus breadth/depth of program
Drug development knowledge	
Commercial/market opportunities	
Competitive/analysis (includes IP)	

toxicology, and pharmacology, both laboratory and clinical, as well as pharmaceutical sciences and product development, are integral to both drug discovery and development. Therefore, any functional-based organization with alignment to drug discovery versus drug development needs to take into consideration the functional overlaps. Table 4 summarizes the key attributes and considerations in organizing R&D.

The R&D organizational model most often utilized by smaller organizations is the functional model. The most compelling factors for this choice are sufficiency and critical mass of these various functions together with the flexibility to reallocate resources to priority programs. In addition, most small organizations usually focus on one or two therapeutic categories, or perhaps more accurately, several different diseases. Therefore, for all practical purposes, they represent a therapeutic category that has functional organizational structure. At the other end of the size spectrum are the large pharmaceutical R&D organizations involving several thousand scientists. The majority of these organizations organize by therapeutic category to capitalize on knowledge of diseases and increased ability to interface with their commercial counterpart organizations, as most commercial organizations are aligned by product and therapeutic category. In addition, this provides for a more focused, team-based approach on particular products in a specialized therapeutic category. Lastly, these organizations are large enough to justify a critical mass of most of these functional areas within a therapeutic category.

There are challenges and deficiencies with this model, however, in the large organizations. One of the challenges is dealing with the stage of development of the project. For example, should a therapeutic category of cardiovascular diseases encompass, as an organizational model, both drug discovery and development? The benefits of collaboration and coordination between clinical and preclinical activities within a therapeutic category spanning both drug discovery and development are maximized. However, the effective management of an organization that spans a 10-year time horizon per project within a therapeutic division is a significant undertaking and challenge. The head of the therapeutic area has to have significant experience and expertise in a number of the diverse functional areas contributing to the ultimate success of their drug discovery and development programs. In addition, the senior management of such an organization has to make priority decisions between different therapeutic areas, as opposed to projects, and translate these into budget and staffing. Furthermore, the present-day realities of the significant global investment in late stage clinical studies, international regulatory review, and manufacturing of product present extraordinary challenges to the therapeutic-based organizational structure, since these cannot economically be replicated in each therapeutic organization. Similarly, there are some technical subspecialties that also cannot be replicated in each therapeutic category. Lastly, therapeutic-area-based organizations are notorious for not sharing resources or drug discovery or drug development programs between therapeutic areas. So the concept of free-standing therapeutic divisions within an R&D organization that span the stages of drug discovery all the way to commercialization is extremely difficult to justify.

One of the larger global pharmaceutical companies, GlaxoSmithKline, has chosen a hybrid model that incorporates some of the elements of both therapeutic categories and functional categories. Several years ago, they established centers of excellence in drug discovery (CEDD) that were organized by therapeutic category. These divisions typically were staffed with anywhere from 300 to 500 scientists and had responsibility for the stages of late drug discovery through clinical proof of concept. This required these CEDDs to staff in areas of medicinal chemistry, analytical chemistry, pharmacology, PK and ADME, clinical pharmacology, and some elements of toxicology and pharmaceutical sciences. Furthermore, they had the biological functions within their organization unique to their therapeutic category. Nonetheless, they were able to tap into (indeed, required in most instances) global functional organizations that included the basic drug discovery technologies as well as global Phases II and III clinical trials, regulatory and chemical

development, pharmaceutical development, and ultimately manufacturing. In addition, GlaxoSmithKline established two external CEDDs through biotech partnerships. This type of organization, therefore, attempts to optimize for the strengths of therapeutic focus and knowledge expertise, and at the same time provide access to those competencies in drug discovery technologies, and drug development that are scalable, typically global in nature, and not unique to any particular therapeutic category or disease-based drug discovery/development. The challenges to this type of hybrid model are the fact that there are now several handoffs in the process from the earliest stages of concept and target validation through to NDA approval. In addition, there are multiple interfaces within the various global drug discovery technology functions and drug development functions. There still exists the challenge of developing a drug that may have applications across therapeutic areas, and lastly, there is the challenge to senior management regarding decision making in therapeutic areas for funding staffing and the relative priorities of areas versus projects.

Another model that has been explored to varying degrees is the business unit. The business unit model evolves from the goal of enhanced coordination and integration of drug development with the commercial organization. This model maximizes input from marketing, marketing research, and sales together with reimbursement policies into the decisions of which drugs to develop and how to develop them. This is basically an R&D organizational model that has the maximal commercial input and responsibility. This type of model has not been utilized very often in modern pharmaceutical R&D organizations. However, as the organizations are getting larger, the appeal of this type of model grows, primarily for specialty sales and marketing. In fact, the specialty pharma business represents an example of this type of model, particularly as specialty pharma is now back integrating by licensing in drugs in earlier stages of drug development rather than only acquiring drugs that are on the market. The challenges for this type of model are inherent in the success or failure of the drugs in late stage development. There are still quantifiable failure rates for drugs in Phases II and III trials and even, for that matter, for drugs recently launched. With the success of the business unit model hinging on perhaps just a couple of products, there could be significant swings in funding, as well as staffing this type of organizational structure. To be successful, this model would have to encompass a significant portfolio of development projects and launched drugs.

Three other very important elements in organizing for drug discovery and development are the practical issues of size and location, together with a centralized or decentralized philosophy of managing the overall organization. Clearly as size increases and extends beyond a core location, centralized decision making and management tends to yield to some elements of decentralized management. Global pharmaceutical R&D enterprises have at least five major R&D centers that are often spread between Europe, the USA, and Japan. It would not be surprising to see a geographic expansion over the next 10–15 years into China and India. The size of the individual R&D site appears to range anywhere from 300 or 400 to several thousand. Behaviorists note that when an organization grows beyond the ability to have daily or weekly contact with people that you know, there is a risk of losing the elements of efficient teamwork and goal-oriented team execution. Growing beyond the size of about 300 or so brings the risk of losing those advantages and of course also requires significant additional investment in other forms of communication to make them as facile as possible. On the other hand, sites that are staffed with fewer than 300 risk the ability to rapidly execute on programs because of deficiencies in resident expertise. Clearly for large sites there is an economy of scale in terms of infrastructure and services and not unimportantly other business interests such as recruiting base and cost of living.

A key element for some R&D organizations is proximity to other centers of excellence, most typically, academic institutions and research institutes. In fact, most pharmaceutical organizations are located close to major academic centers with international reputations. The concept is a simple one, that is, to maximize interaction with academic investigators which are often a source of new ideas, collaborative research, and clinical investigations. In addition, such locations provide an important catchment basin for recruiting the best scientists to an R&D organization. With recruitment being on an international scale, locations close to the top universities have enhanced ability to recruit internationally as well as providing a variety of employment options for dual-career families. One of the challenges however, is these areas tend to be higher cost of living. Companies like Lilly and Pfizer, for example, have chosen to put several of their R&D centers in areas that are not close to academic centers. Both of these R&D organizations tend to have more centralized decision making in management and their R&D centers exceed several thousand people per site.

2.03.2.2 Size (Biotech)

Over their 30-year history biotechnology companies have evolved from small start-ups to companies such as Amgen and Genentech that today rival the market caps of big pharma and also compare favorably with the size of the R&D organizations in big pharma. However, the vast majority of the biotech companies are still relatively modest in size, averaging fewer than 500 in total staff in R&D. The issue of size has already been alluded to relative to both the stages of drug discovery versus drug development, as well as the critical competencies and expertise that are required to

Figure 4 Pharmaceutical industry R&D spending 1970–2003. Pink columns represent unadjusted annual R&D expenditures of Pharmaceutical Research Manufacturers of American (PhRMA) member companies as reported in their annual surveys. Spending is as reported, unadjusted for gross domestic product. An exponential curve (red) has been fitted to these data along with the square of the correlation coefficient. The blue curve represents annual R&D expenditure as a percentage of net sales. (Reproduced with permission from Cohen, F. J. *et al. Nat. Rev. Drug Disc.* **2005**, 4, p 81 © Nature Publishing Group; <http://nature.com/>.)

effectively perform drug discovery and development. It has been demonstrated many times that the process of drug discovery can often involve only a relatively modest team of scientists who are focusing on the translation of basic research into the use of a particular drug candidate to treat a specific disease. Frequently there is also an important link to academic investigators who were involved in the basic concepts to be validated or who provided collaborative insights into a novel model of a particular disease. Size is not a prerequisite for the initial adaptation of the science or even the optimization of the initial discovery to find a drug candidate. Indeed, even a modest-sized organization can effectively utilize CROs to evaluate an initial drug candidate in small clinical trials. It is axiomatic then that size is not a competitive advantage in the early stages of drug discovery but, in fact, could lead to lack of efficiencies and productivity.

Alternatively, those functions that require a considerable capital investment and are readily scaled are competitive advantages if available on a significant size, primarily in areas of drug development. Nonetheless scale has been a critical factor in some areas that involve drug discovery. The sequencing of the human genome is one such example. Additional examples include high-throughput screening (HTS), the genotyping of many human diseases, and the human proteome initiative. None of these would be possible without substantial coordination of many collaborative sites so that the overall effort can be appropriately scaled. Furthermore, systems biology is a new endeavor, which requires scalable technologies to interrogate, in parallel, networks and pathways at the signaling level, in cellular functional output, and ultimately at the anatomic and species level. The output will contribute to drug discovery, but is not the result of hypothesis driven research, the latter of which has historically been the basis for most of drug discovery. This is paradigm shift.

The past 10 years has provided some insights into the lack of correlation with R&D investment, size, and productivity. Productivity, as measured by new molecular entities being launched, has been flat over the last 10 years while R&D investment, together with size of R&D organizations and big pharma, has gone up dramatically. [Figure 4](#) describes the overall productivity as a function of R&D spend over the last several decades. It is evident that the trend of the last 10 years is a continuation of a trend from the two previous decades. In 2001 the major pharmaceutical companies were credited with discovering one-quarter of the new molecule entities (NMEs) approved by the FDA that year, but were responsible for two-thirds of the global R&D spending.^{3,4} Furthermore, in 2005 the in-licensing and partnering activities in big pharma are as significant as their internal R&D efforts. Most of the in-licensing and partnering is done with biotech companies. This provides further evidence that size and productivity are inversely correlated.

2.03.2.3 Philosophy

The various approaches to drug discovery and development can have a significant impact on the ultimate success of the endeavor. The choices described below are presented as either/or but the reader should be cognizant that these

represent ends of a spectrum in every case, and that while choices need to be made, the choices are frequently blends of these various approaches. As in most cases involving options, the position on the spectrum that is chosen has various advantages and disadvantages. These are, at best, qualitative and are very often context and time dependent.

2.03.2.3.1 Target versus disease

A drug is approved by the health regulatory authorities in each country for the treatment of a disease. The labeling and patient package insert for the drug provides information on the dose and duration of administration to provide relief of symptoms associated with the disease or the reduction in disease burden. Most diseases have multiple etiologies and these etiologies may actually take on more or less prominent roles as the disease progresses or regresses. As the molecular basis for the etiologies has unfolded over the last half century, drug discovery has focused on the designing of drugs that would interact with the key molecular targets in an etiologic pathway of the disease. These molecular targets are, of course, primarily proteins or glycoproteins and, for drug discovery purposes, are subdivided into cell surface receptors, intracellular receptors and factors, enzymes, and ion channels.

Small-molecule drugs, much like the organism's own metabolome, interact with these molecular targets in a selective way and usually at unique binding sites. This selectivity in small molecule to macromolecule recognition defines a unique three-dimensional fit. By definition, this fit or recognition is unique to the molecular target as well as the drug or drug class. By extension, therefore, it is difficult to design a drug that can interact with more than one molecular target because of the unique definition of the binding elements. This binding leads to a functional outcome, which is either inhibition of the function of the molecular target or the enhancement of the function of the molecular target. Common terminology includes inhibitors, antagonists, agonists partial agonists, and modulators. The binding of proteins or other macromolecules as drugs to molecular targets follows similar rules, although the binding is usually more complicated, involving a number of points of recognition, some of which may be noncontiguous. This usually translates into greater specificity in macromolecule-to-macromolecule interaction. One caveat is that it is possible to design drugs that recognize members of a class of molecular targets if the binding site/recognition element is common to the members; this is termed 'pan-specific.' In totality, this describes then the mechanism of action of the drug. Given the relative specificity of drugs for molecular targets and the multiple etiologies of diseases, the logical outcome is that more than one drug is used to treat a disease. Indeed the practice of combination therapy is now common, particularly for most chronic and degenerative diseases.

An analysis of the number and type of molecular targets employed by the drug discovery industry, prior to the human genome initiative of the 1990s,⁵⁻⁷ identified about 400 targets. The two major categories of targets were, not surprisingly, enzymes and cell-surface receptors. A more recent analysis disclosed a breakdown of marketed small-molecule drugs by class, showing nearly half of the marketed drugs targeting enzymes and about one-third of the marketed drugs targeting G protein-coupled receptors (GPCRs).⁸ By definition these are druggable targets [Figure 5](#).

Figure 5 Marketed small-molecule drug targets by biochemical class. GPCRs, G protein-coupled receptors. (Reproduced with permission from Hopkins, A. L.; Groom, C. R. *Nat. Rev. Drug Disc.* **2002**, *1*, p 730 © Nature Publishing Group; <http://www.nature.com/>.)

The human genome program ultimately determined that there were about 30 000 unique genes in the human genome, suggesting that there would be a significant new drug discovery landscape of new molecular targets. Indeed, estimates ranged as high as 10 000 new molecular targets based on either the number of disease related genes⁵ or the number of ligand binding domains.⁶ However, a more recent estimate suggests that the drug targets available for small-molecule drugs is probably closer to 1 500.⁹ Figure 6 presents two different ways of discriminating the druggable genome. Figure 6a represents a distribution of molecular targets using a combination of marketed drugs and drugs in development. An extension of this to the druggable genome in Figure 6b describes the available families of drug targets and their relative percentages, based on the sequencing of the human genome. An analysis of the distribution of the gene family populations shows that there are no large, undiscovered protein families, even

Figure 6 Drug-target families. (a) Gene-family distribution of the molecular targets of current rule-of-five-compliant experimental and marketed drugs; (b) gene-family distribution of the druggable genome. CYP, cytochrome P450; NHRs, nuclear hormone receptors; PDEs, phosphodiesterases; ST/Y, serine/threonine tyrosine. (Reproduced with permission from Hopkins, A. L.; Groom, C. R. *Nat. Rev. Drug Disc.* **2002**, *1*, pp 728, 730 © Nature Publishing Group; <http://www.nature.com/>.)

though there is still a significant percentage of proteins expressed by the genome which are functionally unclassified. Therefore, our most current analytics of drug target families would suggest that while the number of families might grow, they will be populated by relatively few numbers of targets and that, for all practical purposes, the druggable genome may expand threefold over the next decade or two. Concomitant with the expansion of the number of druggable molecular targets has been the expansion of the number of diseases. It had been estimated that there were about 100 diseases for which we had drug therapy available prior to the beginning of the human genome project.¹⁰ **Table 5** represents a compilation of diseases newly treated in the last decade and a half that expands this disease treatment universe by at least a third. In addition, there are about 500 new drugs that have come to market over that same time frame that not only provide treatments for these diseases but also give better treatments for previously treated diseases.

A cataloging of the distribution of known molecular targets by therapeutic areas provides some correlation and guidance to the interrelationships of targets and diseases. **Table 6** shows that there are some significant differences in molecular target types depending on therapeutic area. For example, CNS diseases are dominated by GPCRs, whereas infectious diseases and cancer are dominated by enzymes as drug discovery targets. The option to orient drug discovery toward molecular targets versus diseases has a focus on a particular class of targets at one end of the spectrum and a focus on a specific disease or disease category at the other end of the spectrum. The advantages of this focus are obvious and can represent competitive advantages in drug discovery. A focus on a disease category provides in-depth knowledge of that disease category, both at the laboratory as well as at the clinical and marketing levels. However, that specific disease category may require multiple families of drug discovery targets requiring a depth of knowledge unique to these individual families of targets. Alternatively, a focus on a specific class or family of targets may well require a breadth of therapeutic area or disease target applications to fully exploit that drug discovery effort. Furthermore, some of these families of targets represent a significant degree of heterogeneity. For example, enzymes represents a diverse group of proteases, kinases, and phosphatases. GPCRs have enjoyed radically different degrees of success in yielding to drug targeting. Structure-based drug design (SBDD) can much more effectively be applied to enzymes as targets as well as some nuclear hormones and nuclear receptors, whereas integral membrane proteins are much more refractory to SBDD approaches. HTS approaches typically measure only binding as an endpoint and secondary, lower throughput/high content assays are required for determining function. Therefore, the investment in expertise in cellular pharmacology can be different with certain classes of enzymes versus GCPRs versus nuclear receptors. Ion channels

represent a relatively unique expertise requiring electrophysiology and other tools for analyzing ion flux and ligand versus voltage gating functional output. In conclusion, it is important to evaluate the multiple overlap of molecular target classes with diseases and therapeutic areas to maximize for success in drug discovery and development.

2.03.2.3.2 New molecule entity versus life cycle management

A continuing issue in managing R&D is the conflicting choices of investing in NME research versus investing in life cycle management. As projects achieve the stage of commercialization, there is an inevitable continuing investment in these projects to further understand the safety of the product postmarketing, to explore broader indications of the product, and, at times, to explore new formulations and dosing schedules for the product. This work, of course, requires resources that frequently are in the domain of R&D and therefore compete with investment in NMEs at earlier stages of evaluation. Another component of this competition for overall budget spend is a Phase IV clinical trials program for a recently launched product. Phase IV studies are important, and involve evaluation of the product in patients with comorbidities related to the target disease for the product. However, usually the funding and sponsorship of these Phase IV studies is under the commercial organization of a pharmaceutical company and only indirectly competes for R&D resources.

The investment in life cycle management for a recently launched product is usually quite significant, particularly for products that are seeking label expansion to include longer-term morbidity and mortality measurements. The data to support this usually requires large clinical trials. The market forecast and justification for this investment is more readily quantified and much less discounted than a market forecast for a new molecular entity that is in Phase I or Phase II clinical studies. By definition this forecast carries more credibility and provides more assurances on return on investment. However, companies grow the top line by adding new products and this can only happen if R&D organizations are investing sufficiently in NME research. If investment in NME research is coming at the expense of investment in life cycle management, then the organization is likely to suffer the longer-term consequences of these shorter-term views or perspectives. The bottom line is that success is expensive, investment cannot stop at the door of commercialization, and life cycle management is a reality. It is imperative that the organization takes a long-term view and sufficiently invests in NME research and development together with life cycle management. The consequence of underfunding NME research is that the company increases its risk of losing independence within a short time frame.

2.03.2.3.3 Chemical versus biological

The history of the pharmaceutical organization is replete with examples of drug discovery that were dominated by chemistry and medicinal chemistry. As chemists achieved a better understanding of what properties were important for a chemical to be a therapeutic, they also understood the abilities to morph a chemotype or structural motif or chemical core (e.g., benzodiazepine) into a drug that could be useful for other disease pathways. An example of this is the history of sulfanilamides (Figure 7).⁵ The transformation of one of the initial sulfanilamides as an antibiotic to a hypoglycemic, then to a diuretic, and finally to an antihypertensive over a 30-year time span illustrates the medicinal chemistry learnings of these concepts.

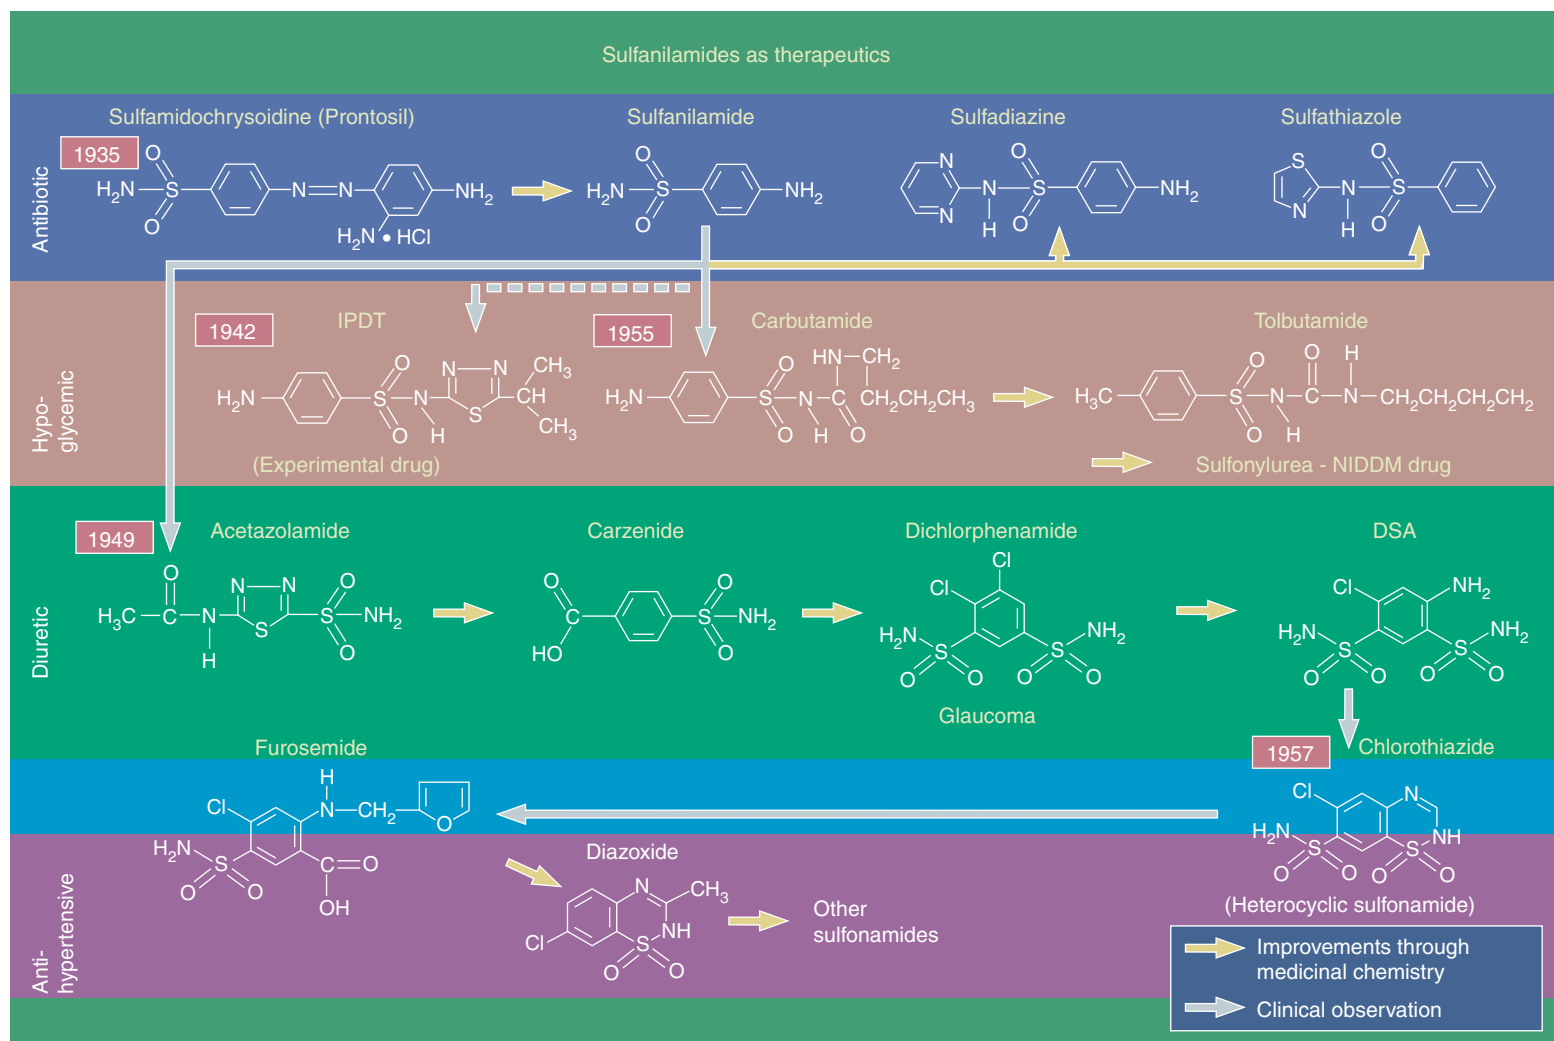

Figure 7 Sons of sulfanilamide. A schematic representation of drugs that originated from sulfanilamide. A single chemical motif gave rise to antibiotics, hypoglycemic agents, diuretics, and antihypertensive drugs. (Reprinted (abstracted/ excerpted) with permission from Drews, J. *Science* **2000**, 287, 1960–1964. Copyright 2000 AAAS.)

Terminology for small-molecule drug properties includes such terms as promiscuous ligands, ‘rule of five,’ bioisosterism, chirality, ADME, biopharmaceutical profiling, and off-target profiling.¹¹ Today’s drug discovery armamentarium is basically multidimensional profiling wherein the chemical is optimized for structure against a number of factors at a very early stage prior to advanced in vivo evaluation. The biggest challenge for small molecules as drugs is, and still remains, safety evaluation. The ability of small molecules to interact with a number of macromolecules in the in vivo milieu can lead to safety issues. In addition, safety issues can arise from extended pharmacology, from extended half-life, variable absorption, or metabolic induction. Our laboratory models for predicting human safety are the least predictive of all of our tools in drug discovery. Most small drugs fail for animal toxicity or human adverse effects. Improvements in this dimension will undoubtedly improve the productivity of developing small molecules as drugs. The merger of these predictable tools with medicinal chemistry will have a dramatic impact.

Biologicals (i.e., proteins) have been used as therapeutics for a number of decades but have been limited by source. The advent of recombinant DNA technology in the 1970s revolutionized our abilities to make proteins in the laboratory and has led to the introduction of a number of proteins onto the marketplace for treatment of various diseases. The challenge in the development of proteins, unlike small molecules, is not from the toxicology or safety perspective, but more from effective drug delivery and manufacturing perspectives. Since the production of biologicals is defined at the regulatory level as ‘the process is the product,’ the process must be well defined when clinical trials are initiated. Since there can be significant changes in the process as it is scaled up, the material that is produced for the key Phase II and certainly pivotal Phase III trials, of necessity, has to be at the manufacturing scale. To accomplish this, the R&D enterprise needs to invest in large-scale facilities for biologicals manufactured early in the process of drug development. This is a significant capital investment and an equally significant investment in time and talent. The delivery of macromolecules as drugs limits their breadth of application. Oral administration is yet to be commercialized in spite of many clever approaches, so parenteral administration is the only route. Inhalation and intranasal approaches are nearing commercialization. A related limitation with biologics as drugs is the difficulty of using a macromolecule for intracellular drug targets.

A third, not inconsequential, issue for developing biologicals is the potential to generate an antibody response in humans that binds and/or neutralizes the biological. Therefore, significant research has gone into engineering proteins and antibodies to minimize an immunological response in humans and optimize for overall efficacy. On the plus side, one of the advantages of developing biologicals is that the antibody response in animal safety studies precludes any meaningful safety findings and therefore longer-term animal toxicology studies are not required. One of the other reasons for biologicals requiring less toxicology is that many are endogenous substances, and thus already well tolerated by patients at physiological levels.

With these relative advantages and disadvantages in mind, most large pharmaceutical companies today are involved in developing both small-molecule drugs and biologicals. Amgen, originally a biologics-only biotech company, has expanded its original biological platform toward small-molecule drug discovery and development. Genentech, on the other hand, has remained consistently with biologicals in drug discovery and development. Most small biotech companies are doing either small-molecule or biological development, not both. Big pharma was late getting into biologicals; however, over the last 7–8 years there has been a considerable increase in commitment (Figure 8).

There have been significant attempts to develop other large molecules as drugs that are not proteins. These include both DNA and RNA based oligonucleotide drugs. Thus far, development of these types of drugs has had very limited

Figure 8 Share of biologicals as a percentage of total late-stage product pipeline. Late-stage products include Phases II and III and preregistration trials. (Reproduced with permission from Windhover’s In Vivo.)

success. The primary difficulty has been delivering these macromolecules to the target organ or target cell type. Achieving sufficient PK, both in the whole organism and also at the cellular level, has been extremely difficult and this has only been one of a number of challenges in developing oligonucleotides as drugs. The initial challenge was simply the ability to synthesize and scale these up. In addition, many of the oligonucleotides presented unique toxicology in animals as well as in humans. These very substantive hurdles have now been largely overcome. However, efficacy has still eluded the pioneers in this area of new drug discovery and development. Lastly, gene therapy has struggled to yield a successful therapeutic, in spite of over a decade of significant time and investment. Delivery of genes in various formats with various vectors has been validated in animals as well as in humans. However, local regional delivery versus systemic exposure remains a challenge and safety continues to define the most significant hurdle yet to be overcome in gene therapy approaches.

2.03.2.3.4 Best in class versus first in class

The debate on best in class versus first in class can be pictured as a pendulum that swings in one direction and then the opposite direction, historically over a 10-year period. The 1980s were characterized by best in class strategies relative to first in class or so-called innovative drugs. For example, better nonsteroidal anti-inflammatory drugs (NSAIDs) were being registered along with better beta blockers, more potent corticosteroids, and H₂ antagonists. Of course angiotensin-converting enzyme (ACE) inhibitors and statins were first introduced in the 1980s with follow-ons coming quickly behind. The 1990s, on the other hand, were characterized by biologicals coming to market as first in class and most R&D centers espousing first in class philosophies. In addition to the advent of biologicals, this swing in philosophy was driven largely by the anticipation of many new molecular targets coming out of the human genome project, as well as the belief that pricing pressures would be continually increasing due to generic competition and only first in class drugs could command premium pricing (Figure 9).

Several retrospective analyses of the relative merits and value of first in class versus best in class have concluded that, at least for blockbuster drugs, best in class has greater value creation¹². The analysis segregates first in class to those drugs targeting unprecedented molecular targets, that is, molecular targets that had not yet been validated with drugs, selective for these targets, in Phase II clinical efficacy studies. The best in class drugs, of course, were defined by precededented approaches and were further subdivided into fast followers, differentiators, and latecomers. This analysis showed that drugs targeting precededented approaches (Figure 9), not only had a higher value creation but also had

Figure 9 Analysis of precededented versus unprecedented drug targets. Drugs targeting precededented approaches create more value with a lower risk of failure (precedented approaches are defined as those which have established clinical effectiveness; as proxy, we use 40 months prior to market entry to designate that status, as Phase III and registration take ~40 months and clinical effectiveness is typically proven after smaller Phase IIa trials). Present values were calculated using sales from 1990 to 2000, adjusted for inflation, and estimated future sales discounted at 10% back to year 2000 dollars; overall development survival rate is the product of phase-specific survival rates from preclinical, Phase I, Phase II, and Phase III + Reg trials. (Source: McKinsey analysis; PBJ Publications Pharmaprojects; FDA/CDER; Company reports; analyst reports.)

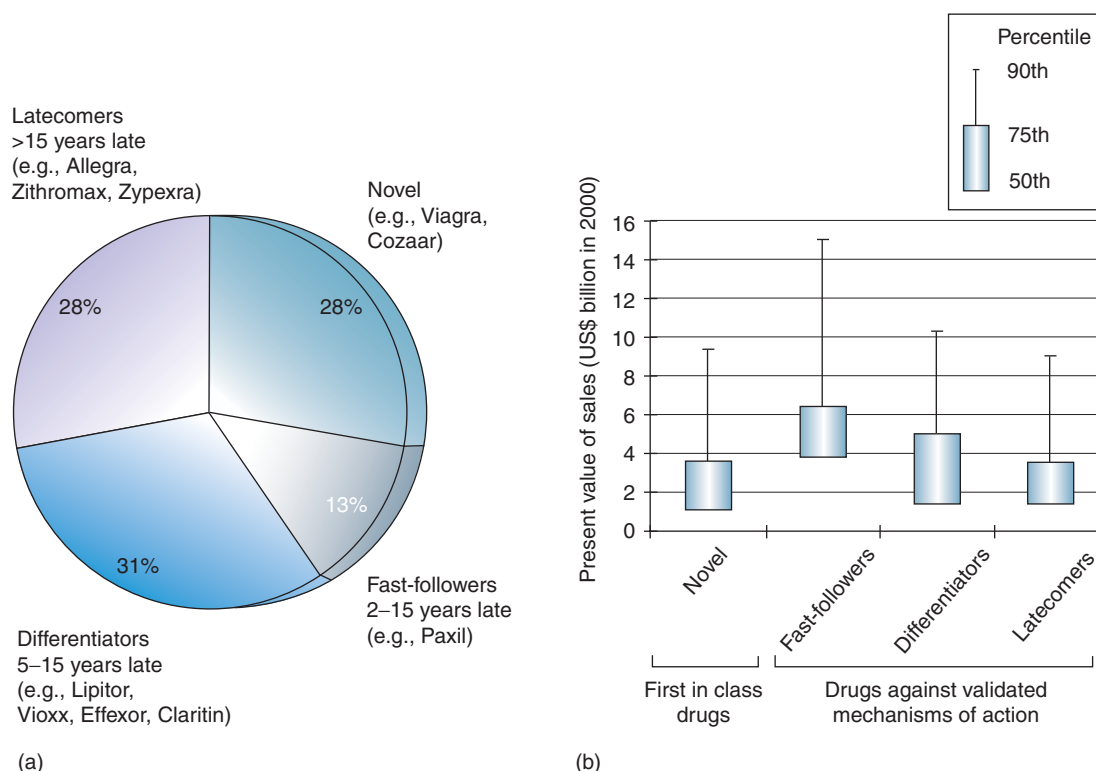

Figure 10 Most blockbusters had established mechanisms of action, and novelty does not always generate value. (a) The 32 blockbusters launched by the top 15 pharmaceutical companies during 1991–2000 and compared their mechanisms of action with presently marketed products. (This analysis was based on multiple data and information sources, including Elsevier Science, PJB Publications Pharmaprojects and the Evaluate Pharma Database). (b) The 189 drugs launched by 15 top Pharmaceutical companies in the period of 1991–2000. Present values were calculated using actual sales, adjusted for inflation, and estimated future sales were discounted at 10% back to year 2000 US dollars; all present value figures showed the same trends as data comparing the sum of the first 4 years of sales. Shown are the ranges in present value of sales from the 90th (top 10%), 75th, and 50th (median) percentiles. (This analysis was based on the data and information from the following sources: Elsevier Science; Evaluate Pharma Database; PJB Publications Pharmaprojects; FDA/CDER; company reports; analyst reports, IMS Health.) (Reproduced with permission from Booth, B.; Zimmel, R. *Nat. Rev. Drug Disc.* **2003**, 2, 838–841 © Nature Publishing Group; <http://www.nature.com>.)

overall higher development survival rate. The breakdown of the best in class versus novel or first in class drugs is shown in **Figure 10a**. The first in class drugs represent only about 30% of the total number of blockbuster drugs launched during that decade. Similarly, **Figure 10b** depicts the relative value creation of the first in class drugs versus best in class, again, secondarily cataloged by fast-followers, differentiators, and latecomers. The largest number of drugs in the best in class were in the latecomer category.

In addition to value creation and overall survival through the development process, other factors to consider are development cost and time, stages at which the respective programs are being derisked, and the competitive landscape. With these considerations, the advantage should usually favor first in class. The competitive landscape should favor first in class. With development cost and time, there may well be a more abbreviated development path to commercialization, assuming it represents breakthrough therapy. Best in class drugs, on the other hand, claim the advantage of a precedented development path to commercialization and a higher likelihood of survival through the clinical phases of development. However, a critical attribute for best in class is differentiation. Differentiation will usually not be evident until the completion of Phase III clinical trials. While improved efficacy is a key differentiator, as important, if not more important, are safety, the breadth of the label claims, and convenience of administration. Safety is much more fully defined in Phase III clinical trials and ultimately in postmarketing analyses. Efficacy and label claims are differentiated also in Phase III clinical trials (**Table 7**).

It would be prudent for R&D management to assess carefully opportunities of best in class and first in class in the therapeutic areas of interest and within the context of molecular targets of interest. Appropriate risk/reward analysis is

Table 7 The relative advantages of best in class versus first in class drugs

<i>Best in class</i>	<i>First in class</i>
Higher value creation	Speed of development
Precedented development and commercialization	Costs of development
Higher survival rate	Physician/consumer interest
	Differentiation
	Novelty

relevant to either category (Table 7). First in class, as higher risk programs against unprecedented targets, should not be justified based on niche market opportunities. Similarly, with best in class differentiation occurring late in the development scenario, research on precededented targets requires an equally substantial market potential. Of course, if the aggregated industry worked only on best in class, there would ultimately be no new novel drug categories. Careful consideration should be given to an analysis of both of these categories as part of an overall R&D philosophy.

2.03.2.3.5 Decision making versus organizational alignment

The differentiation of decision making versus organizational alignment is an increasingly important factor as R&D organizations increase in size. Basically, these two options represent the ends of a spectrum defined by speed. Rapid decision making leads to rapid execution. Of course, if the decision is wrong, it can also lead to rapid failure. On the other hand, organizational alignment is achieved by consensus building, which is generally a slow process, and therefore can lead to a significant delay in execution. A further counterpoint is that the execution phase may be more effective and of higher quality, because of the increase in inherent ownership in the process due to the consensus approach employed to achieve the final decision. So, in addition to speed, there is also quality of execution that is an important factor in decision making versus organizational alignment.

The advantage for small organizations is they can achieve both effective and rapid decision making in concert with organizational alignment. However, as the majority of drug discovery and development programs are in larger organizations, and as noted, organizations that continue to increase in size, the ability to effect rapid decision making with organizational alignment is significantly compromised in larger R&D enterprises.

A large organization can have rapid and effective decision making using a top-down approach. This is an effective management option as is evidenced by its continual utilization in most military forces and in many business models including pharmaceuticals. However, in a diverse, highly technical environment, such as pharmaceutical R&D, it is imperative and essential to have involvement of the technical community in both the planning as well as the execution of the programs. Recognition of this complexity and valuing collective wisdom are important drivers for establishing the right balance of effective decision making and organizational alignment. The decision making process should be clear and transparent to the organization. Transparency is challenging in an environment where decisions are complicated and highly debatable, and where failure is the more frequent outcome. Decisions should be timely and clearly communicated. As importantly, there should be appropriate, periodic monitoring of the execution phase of the program to deal with focus and completion, as well as, mid-course corrections. Assuming high-quality competencies in an organization, the execution of the program is most effective if there is ownership and buy-in on the part of the stakeholders. This can be achieved, indeed highly valued, by soliciting proposals for programs or program changes, establishing peer review of the relative merits of the proposals, and then appropriately resourcing the agreed programs. Ultimately senior management must make these decisions, as R&D cannot be effectively accomplished in a loose federation of individual investigators. High-quality science must be valued not in its own right but for its applications to new medicine discovery and development. Fraud, or incomplete or inaccurate information, cannot be tolerated, for in the end, human safety is jeopardized.

The pace of change is increasing and the competitive environment is expanding both in depth as well as in breadth or globally. Nonetheless, improvements in drug discovery and development over the past several decades have been incremental and will likely continue to be incremental. The time from concept to commercialization will continue to be a decade or more in the foreseeable future. Therefore, an R&D organization must be willing and able to act quickly, but not prematurely. The decisions are complex and multifactorial and the urge to decide in the face of public or investor pressure should not override thoughtful and deliberative decision making.

2.03.2.3.6 Fail fast versus follow the science

The mantra 'fail early, fail fast' rose to prominence in the 1990s, particularly as new molecular targets for drug discovery were highly valued. The rationale for this perspective is quite obvious. Many new targets were being established and evaluated using HTS technologies. Differentiation of 'on target' versus 'off target' binding was readily available. Furthermore, as new predictive laboratory screens and tools for ADME were becoming available, the researcher could make decisions about lead compound quality much earlier in the process than was typically done in the past. In addition, with new targets being the focus, the failure rate for lack of efficacy in the laboratory and/or the clinic seemed to be increasing and of course, the cost of failure much later in the process is higher. Therefore, the logic is to take forward into development only those drug candidates that pass all the prescriptive and preclinical tests and demonstrate acceptable animal safety prior to Phase I evaluation in human subjects. By extension, this philosophy can be extended to early clinical evaluation, as drugs that exhibit a flaw in their early clinical profile can still be taken forward all the way through Phase III clinical studies. Therefore, the 'fail early, fail fast' philosophy exhorts the decision maker to evaluate critically the early clinical findings and discontinue development as soon as feasible. In fact, the philosophy encourages the R&D organization to celebrate program terminations as effective, critical decision making and saving the organization money downstream.

Most researchers in drug discovery and development would agree that the most difficult decision is when to terminate a program or project. Examples abound of drugs that made it to market after being 'killed' several times during their development. In addition, drugs can be deprioritized at various time points due to limited resources and the constraints of the annual budget. However, the discovery and development of a drug, while a tortuous path, with oftentimes several branch points, nonetheless is a path that develops data and new knowledge. This knowledge needs to be evaluated within the context of the significant limitations of our tools to predict human efficacy and safety in various disease categories. These tools are still quite rudimentary, particularly our ability to predict human safety based on animal toxicology studies. Development of new knowledge along the development pathway of a drug is another form of hypothesis driven research. 'Follow the science' means, simply, do appropriate experiments, assess the data, and understand the implications of the conclusions. Early, key milestones in drug discovery include the establishment of preclinical efficacy data on a drug candidate with acceptable biopharmaceutical properties, including the ability to scale up effectively the active ingredient. Toxicological evaluation in animals is not a black-and-white analysis, but in fact, a subjective one, which must be taken within the context of the targeted disease and patient population. The FDA, as one regulatory body, has encouraged sponsors to dialogue with them prior to initial clinical evaluation of a drug candidate. The purpose of this overture is to bring more collective wisdom to bear on the options to evaluate the drug candidate in humans, including both an acceptable safety threshold to proceed, as well as, the best path forward. Subsequent key milestones include Phase I human PK/PD and safety followed by Phase II efficacy (exposure response) in patients. Each one of these milestones generates critical data to extend the working hypotheses, modify them, or disprove them.

The drug discovery/drug development industry is diligently trying to improve the predictabilities of its preclinical tools for human efficacy and safety. However, the decision matrix does not yet readily yield to a box checking exercise with quantitative thresholds for go/no-go decisions. Hypotheses should be critically evaluated, 'the science should be followed,' and success milestones should be celebrated.

2.03.2.4 Culture

Culture is a word that has many connotations. A dictionary might define culture in the first instance as "a particular form of civilization, especially the beliefs, customs, arts and institutions of a society at a given time." The culture of an R&D organization has some parallels to this definition of a civilization or a form of a civilization. However, it is still difficult to describe it fully. But culture certainly includes important attributes such as views and values, practices, geography, and size. Some of these attributes have already been discussed in this chapter, and therefore, the focus of this brief section on culture will be on four additional elements important to drug discovery and development.

Organizations can typically be described as collaborative or insular; again, two ends of the spectrum. To some degree, competitive is another relevant adjective and can be in contradistinction to collaborative, but competitive can also be an integral part of collaborative. Fundamentally, the question is: "What are the advantages or disadvantages of being a collaborative organization?" Viewed in the larger context, 'collaborative' must include both intramural interdepartmental and interlaboratory collaboration as well as extramural collaboration with groups and institutions external to the R&D organization. Given the large number of interfaces in the overall process of drug discovery and development, together with a similarly large number of interdependencies between the various laboratories and disciplines, collaboration has to be the norm rather than the exception for effective drug discovery and development. All aspects of

collaboration should be evident, including communication, in its largest sense, joint planning and execution, shared goals and responsibilities, data sharing, and collaborative analyses. When organizations have planning silos or departmental or decision making silos, both the efficiency and effectiveness of drug discovery and development are compromised. There does need to be an appropriate balance of 'need to know' versus 'nice to know' information access and information analyses. An individual scientist or small group of scientists are responsible for the detailed planning and execution of a particular experiment or study and has responsibility for the integrity of the data. They are, after all, the individuals with the most knowledge to understand and interpret the data. Nonetheless, in the highly interdependent, regulated, and resource-intensive environment of drug discovery and development, all experiments and studies are part of bigger programs with long time-lines. If poorly executed or poorly timed, they can have a serious impact on the value creation for a new drug candidate.

The opportunities for an R&D organization to collaborate with the scientific community in the external environment are multiple. Indeed every R&D organization has collaborations with academic scientists and research institutes on an ongoing basis. However, the philosophies in managing these relationships can vary. One end of the collaborative spectrum is a contractual obligation to the external party to perform certain tasks and, when completed, to deliver the final report. The other end of the spectrum is an agreement for activities that require resources at both institutions, wherein the activities are interdependent, much like an internal program within an R&D organization. Indeed in some cases, three-way collaborations exist. These kinds of collaborations minimize the we/they attitude that can happen with arm's length collaboration and can truly lead to synergies from the joint investment of the scientists and technologies of the two organizations. The collaborations do require careful management, project champions in both institutions, and alignment of strategy and tactics. Since these collaborations often involve a significant culture difference and/or size difference, sensitivities to these differences must be acknowledged up front and their unique features understood throughout the term of the collaboration.

Some R&D organizations have set up competitive collaborations, both internal and external. The rationale is that two approaches to discovering a drug candidate of a certain type are better than one and that competition brings out the best efforts of both parties, since ultimately a winner is defined. However, these strategies clearly establish silos within the organization or silos between two institutions and significantly diminish the collaborative attitudes within the culture of the organization.

Investing in a research program or a drug candidate development program is a long-term investment. Frequently difficult, seemingly intractable challenges arise during these programs that can halt progress, or at a minimum, diminish momentum. It is human nature that ownership defines loyalty. Individual scientists or teams truly invested in a program will exert the extra effort to find ways around problems that arise and to exercise the perseverance necessary for the longevity of the program to ultimately achieve regulatory approval and commercialization. Program champions are prerequisites for real ownership and investment. In the absence of a program or product champion, there is a loss of ownership because ownership and leadership are dispersed amongst committee members. When this is coupled with multiple committee responsibilities for team members and/or frequent turnover of leadership roles for programs, passion is diluted and focus is lost. Concern with product champion roles is that the champion is less than objective in their analysis of the value of the assets and the chance of technical success. These complicated programs, however, cannot be left to autopilot and therefore, a responsible R&D organization should appropriately balance the advantages of product/program champions with periodic objective review of the overall portfolio of programs. This review should address resource adjustments or program terminations to reflect the overall relative chances of success within the business context.

Any R&D organization has a number of programs at any one point in time to manage and resource. Its culture is defined by the objectiveness and transparency of this portfolio management, as well as by the factors that are valued in managing the portfolio. Some organizations discount considerably the value of market forecast in defining various phases of drug discovery and development process, whereas other organizations put considerable emphasis on market assessments for programs, from initiation through to ultimate regulatory approval. Should the absence of a current market preclude the initiation of a drug discovery program? Should the assessment of a limited commercial opportunity define the progression of a drug candidate into Phase I clinical studies? How important is the chance of technical success in defining program initiation or program progression through various stages of discovery and development? Is medical need a surrogate for market assessment? Should a program starting in drug discovery have a well-defined path laid out to ultimate regulatory approval at inception? The answers to these questions define to a large degree the philosophy of a portfolio management for the R&D culture. The realities are that unmet medical needs exist and new markets are created by addressing these needs with new drugs. Good primary and secondary market research can make reasonable estimates about market potential when there is no market. But the challenge remains to define market potential or market opportunity 10 years in advance of when the question is addressed. The medical need as well as

reimbursement opportunities can change dramatically in that time frame. The typical scenario is for market research to impact in a more significant way as programs become more mature and closer to regulatory approval. However, the medical need and the marketing opportunities can and should play a role in even the earliest stages of drug discovery programs. Market research can help define a potential product profile, refine the competitive landscape, and provide one of the several discriminating factors for program prioritization.

The final factor for designing culture in an R&D organization is entrepreneurship. An entrepreneurial environment is one characterized by individual initiatives and exploratory endeavors, frequently involving high risk. An entrepreneurial environment is further characterized by decentralized management and decision making. Alternatively, the more regimented structured environment is characterized by centralized management and decision making. However, appropriate entrepreneurship is not just high-risk activity, but it should also be a program with a credible business plan and opportunity, where rewards can be articulated and quantified, and where failure is linked directly to continued employment. An entrepreneurial environment attracts scientists who are willing to invest themselves in programs with limited validation but with high potential. It is an environment that is likely to be a transforming environment. Nonetheless, to be successful and transforming, the R&D organization needs to assess and manage the risk, provide appropriate freedom to execute programs and demand responsibility for success and failure.

2.03.2.5 Partnering

Partnering between biotech and big pharma has become an industry in its own right. In 2004 Pfizer claimed that it had over 300 active R&D partnerships with biotechnology companies. These partnerships span the spectrum of drug discovery and development including novel technology access, drug discovery partnerships, and preclinical and early clinical phase deal making for products or projects, as well as later stage partnering/licensing arrangements. The change in landscape is not just in the number of deals being struck, but in the fact that the combination of these partnerships as well as traditional licensing now means that half of the products launched by pharmaceutical companies are products from licensing or partnering activities. The management of these interfaces is a critical function within companies and perceived as a competitive advantage.¹³ In spite of the shared reward inherent in the nature of these partnerships, there is still a good return on investment for big pharma as well as biotech, considering the terms of the agreements and business needs and drivers of the companies involved in the partnering. The degree to which big pharma companies partner is dependent on their R&D philosophy but it also dependent on their nearer-term business needs. For example, during the 1990s Merck effected a modest number of partnerships compared to the other top five pharma companies. However, in the first decade of the twenty-first century, Merck has dramatically increased the number of partnerships and in-licensing deals reflecting the anticipated and significant reduction in revenues with products going off patent mid-decade.

2.03.3 R&D Productivity

R&D productivity has declined over the last 20 years, as measured by investment in R&D spend versus new molecular entities approved and launched (Figure 4). Over the last three decades the group at Tufts University Center for the Study of Drug Development in Boston has studied the costs of drug development. Their most recent estimates¹⁴ are based on a number of randomly selected drugs developed by 10 pharmaceutical companies, between the years 1983 and 1994. The reported development costs that were assessed run through the year 2000, and are therefore based on year 2000 dollars. Their calculated out-of-pocket costs per new drug was about US\$400 million. Capitalizing these costs to market approval with appropriate discount rates yields an US\$800 million cost in year 2000 currency. These data, together with earlier studies, suggest an annual rate of increase of drug development costs running at 7.4% above inflation. Therefore, today's cost for the successful development and commercialization of a new molecular entity is well over US\$1 billion.

Many factors have contributed to the increasing costs and time required to discover and develop drugs, some outside of the landscape of R&D. Over the last two decades five critical pieces of legislation have affected the discovery and development of new therapeutics. The Patent and Trademark Amendments of 1980 (Bayh-Dole Act) and the Drug Price Competition and Patent Term Restoration Act of 1984 (Hatch-Waxman Act) have fostered translational research and extended patent lifetime as a function of development time extensions, but have also significantly boosted generic competition. The Orphan Drug Act of 1983 attempted to incentivize for drug discovery and development of treatments for rare diseases. In aggregate, these three pieces of legislation have stimulated continuing investment in R&D for drug discovery and development. During the 1990s the Prescription Drug User Fee Act of 1992 (PDUFA) and the FDA Modernization Act of 1997 (FDAMA) addressed the continuing elongation of drug

development and review times. These two pieces of legislation required user fees for the filing of NDAs and then utilized these user fees to increase the number of reviewers at the FDA. Overall this has reduced review times modestly over the last decade, compared to the previous decade, and stabilized the time spent in the clinical phases of drug development.¹⁵ However, the scope and size of clinical trials has continued to increase concomitantly with increasing costs of clinical studies.

In spite of the decrease in R&D productivity and increasing costs of drug development, the pharmaceutical and biotech industries have continued to grow and deliver new medicines to patients. These industries have been able to do this because they have essentially enhanced the overall value per drug by targeting commercially attractive, unmet needs that can be premium priced, and by expanding established market arenas with improved therapeutics. But the industry can only grow, and indeed survive, by addressing two other fundamental areas of productivity. It must increase efficiency by reducing costs or time or both, and it must decrease the cost of failure by terminating drug candidates sooner or improving the probability of success. The area for greatest impact is the area of decreasing cost of failure. Increasing efficiency will be incremental at best, since reducing time per program is unlikely. Similarly, reducing costs is very unlikely. How do we improve the probability of success and decrease the cost of failure? – focus on drug discovery.

2.03.3.1 Drug Discovery

A survey by Accenture of 15 pharmaceutical companies between 1997 and 2000 showed that the average company utilized 250 full-time employees (FTEs; 1 FTE = 1 year equivalent), or approximately US\$70 million, for each new drug that enters into formal drug development.¹⁶ Furthermore, while times had decreased from target identification to development candidate from 1997 to the year 2000, nonetheless, the average time was still around 5 years. Considering that a top five pharmaceutical company will have to launch six new molecular entities per year in the 2010 year time frame, simply to achieve annual growth targets in the 5% range, the time and financial investment alone for multiple drug discovery programs funded in parallel with the historical attrition rates is simply not feasible.

Key factors in understanding productivity in drug discovery evolve from an analysis of bottlenecks in the overall process (Figure 2). In concert with overall attrition rates, there are a variety of attrition rates that are cited for the various stages of drug discovery. Table 8 is a compilation of data from personal experience in the industry together with a number of different sources over the last 10 years, therefore it must be viewed as an approximation and several years out of date. The overall success rate of 4%, starting with molecular target identification and validation up to IND, underscores the high failure rate of a process that historically has taken 5 years to proceed from target identification to IND. Clearly, only modest improvements in several of these steps can have a dramatic impact on the overall success rate. Therefore, there has been significant time and attention paid to these various stages in reducing the failure rate and, concomitantly, reducing the time. Many R&D organizations today have shaved at least 1 year off this 5-year drug discovery cycle and some have reduced it even further. Researchers are improving the quality of their compound libraries in several dimensions: numbers of compounds, compound diversity, compound stability, compound characteristics (molecular weight, logP, H bonds, polar surface area, etc.).¹⁷ HTS has grown up during the late 1990s into efficient, automated systems by the year 2005 with the capacity to do 384 well-plate screening routinely, with good informatics support, and the ability to cherry-pick samples for primary and secondary screening. Additional investment is being made in high content cell-based screens to evaluate the activity of the early hits for validation and prioritization. Increasing quality is going into the hit to lead process in drug discovery.¹⁸ This is the stage that significant additional investment will be required to optimize the early leads, and this stage is still one of the bottlenecks in modern drug discovery. At this stage, medicinal chemistry is invested in the process and

Table 8 Success rates for stages of drug discovery

<i>Stage</i>	<i>Success rate (%)</i>
Target identification/validation	50
Screen	25
Hit	30
Lead compound	30
Clinical candidate	70
Investigational new drug	50

multidimensional structure–activity relationships (SARs) are explored to find the best compound. Such a compound must meet the clinical candidate profile of potency, selectivity, PK/bioavailability, metabolic stability, as well as key safety thresholds for cytochrome P450 inhibition, QTc liabilities, and genotoxicity. This stage of drug discovery can often take 2 years or more. It is highly iterative and is the most resource-intensive stage of the drug discovery program. It is because of these attributes that significant improvements are sought to reduce the number of compounds made to achieve a clinical candidate and reduce the time required to achieve a clinical candidate. The interested reader is referred to subsequent chapters in this volume which deal with these various activities in much more detail.

Another bottleneck in the drug discovery process is preclinical safety evaluation. A comprehensive perspective on this has to include the pharmacology of the drug in animal models of the disease being studied, together with the pharmacology and toxicology of the drug in rodents and nonrodents in the traditional preclinical safety evaluation. These studies require considerable time and resources to execute, and are often done in a serial fashion. Furthermore, these studies require significant amount of the active ingredient as well as significant support from analytical and pharmaceutical sciences. As a substantial amount of these activities are regulated by the FDA and come under ICH guidelines, there is little opportunity for modification. Nonetheless, there are strategies under investigation for predictive toxicology assays including toxicogenomics. Performing pharmacology and animal safety in a more parallel fashion can shorten time-lines.

There are more publications today describing ways to improve drug discovery productivity than there are actual initiatives to improve productivity. Not to be left out, the author offers the “Top 10 ways to improve drug discovery productivity” in [Table 9](#). Some of these suggestions are more strategic in nature, such as the choice of drug target (precedented versus unprecedented), investment in biologicals as drug targets, and the philosophy of drug targeting selectivity versus specificity. Furthermore, SBDD or computational techniques are important considerations in improving productivity. Recognizing that these techniques are not yet universally applicable to all drug targets, they are however growing in throughput and breadth of application. Lastly, these suggestions include consideration for the earlier prioritization of various screens for drug candidate liability assessment within the overall screening and lead to optimization paradigm.

A very important consideration for improving R&D productivity and impacting both drug discovery and drug development attrition rates is the strategy of parallel development and backup/second generation candidates. To evaluate these options properly, the boundaries need to encompass advance lead in drug discovery through at least proof of concept in early Phase II clinical studies. Furthermore, an analysis has to look at a number of programs together with quantifying the number of compounds within a single program. Similarly, the cycle time for the compounds in serial versus parallel mode development requires specification. It is noted that this analysis is relevant to every medium to large-size organization since it requires no new technologies or unique skill sets.

Keelin and Reeds¹⁹ have used a simulation approach to evaluate serial versus parallel development and utilized four categories of parallel, from light to maximum parallel. [Figure 11](#) describes the input format, which includes phases of development through to launch, numbers of compounds, phase success probability as well as terminal state probability. In addition, the simulation assumes full dynamic downstream decision making, including if and when a target is known to have failed, all development stops, and if and when a lead compound fails, backups are advanced according to the parameters of the strategy. In addition, cost, time, and failure probabilities are phase adjustable by program and a net present value (NPV) analysis of cost and value is presented for each scenario. [Figure 12](#) is one representation of the output of the simulation and shows that parallel strategies are up to 18 months faster to market, and, similarly, result in higher peak sales. Interestingly, significant advantages over serial development are noted with only moderate and evaluate at dose versus efficacy. Phase III clinical trials typically involve a thousand or several thousand patients and

Table 9 Top 10 ways to improve drug discovery productivity

-
- Increase degree of validation of drug targets
 - Include biologics and small molecules
 - Utilize biomarkers
 - Minimize metabolism liabilities early
 - Titrate ‘off-target’ selectivity appropriate to the disease(s) of interest and use more than one screen for ‘on-target’
 - Eliminate compounds with mechanism-based toxicity
 - Prioritize PK/ADME analyses
 - Maximize SBDD
 - Employ ‘rule of five’ or similar guidance and early pharmaceuticals profiling
 - Integrate computational informatics and algorithm for quantitative structure–function relationships and virtual ligand screening (VLS)
-

Phase	Compound					Phase success probability	Terminal state probability	6 phases of development
	1	2	3	4	5			
p0	0	1	1	1	1	60%	40%	
p1	0	0	1	1	1	40%	36%	
p2a	0	0	0	1	1	70%	7%	
p2b	0	0	0	0	1	70%	5%	
p3	0	0	0	0	1	65%	4%	
Launch							8%	
							100%	
5 compounds					Target success			2 states of target success
					1

reaffirm efficacy at a specific dose, but more importantly evaluate safety in a larger population of patients. The design of the Phase III or pivotal trials is usually reviewed with the regulatory authorities and forms the basis for establishing the important dosing and administration information of the drug for regulatory approval.

During the time periods in which drug development projects were analyzed, 1985–95, success rates were generally 1 in 9 or 10 entering Phase I achieving regulatory approval and launch. This has gone up somewhat over the last 10 years to 1 in 7 or 8. Attrition is most significant in Phase II where historically it has been typically greater than 50%. Phase I attrition is less, with Phase III realizing the lowest attrition rate. Clearly, the biggest impact of R&D productivity would be to reduce attrition rates in clinical evaluation. To that end, most of the focus has been on improving the drug candidate profile prior to entering the clinic, although certainly improvements in clinical trial design, particularly proof of concept in early Phase II, has been an area of further scrutiny and concentration. Another factor has been the focus on the correlation of Phase II endpoints with the pivotal Phase III trials. It is not uncommon that the Phase II or proof of concept studies can utilize surrogate endpoints that are different than the registration driven endpoints for Phase III required by the regulatory authorities. Examples of this include clinical studies of new cancer treatments, the evaluation of multiple sclerosis, endometriosis, benign prostatic hypertrophy, and others.

Other important factors affecting attrition rates in drug development include the target selection for the drug candidate under study and also the therapeutic/disease category. In addition, there appears to be a different success rate of biologicals versus small molecules, as well, in Phases II and III. [Figure 13](#) portrays data from one analysis of success rates on late stage parallel activities. Moderate parallel is defined ‘as many as two backups pursued at any one time’ with the first started simultaneously, while the second lags by one quarter. In contrast, maximum parallel involves four backups pursued through Phase IIa with no lag in starting backups after the lead. Therefore, moderate parallel is a resource moderate scenario.

2.03.3.2 Drug Development

The scrutiny of R&D productivity began with drug development. The logic was that drug development was the most significant investment in time and in funding in the overall drug discovery and development process. Secondly, drug development was more predictable and the activities were common across most drug development programs. In addition, it was in drug development that significant increases in time, cost, and regulation were most evident, and, lastly, failure, particularly in late stage drug development, was not only readily visible but also very costly. For example, data from the PhRMA trade association show that in the 10-year period of 1991–2001 R&D spend went from US\$12 billion dollars to US\$30 billion, nearly tripling. In addition, while research/drug discovery spending went from US\$7 billion to US\$12 billion, development spend went from US\$5 billion in 1991 to US\$19 billion in 2001. And while there was a fourfold increase over this 10-year time period in terms of total development spend, there was a fivefold increase in clinical trial costs. The aggregate spend for R&D for 2004 was over US\$50 billion. Obviously, costs continue to rise, and continue to be disproportionate to the number of NME approvals.

Success rates for drugs in various stages of development is typically measured by success in the clinical phases of drug development: Phases I–III. To briefly reiterate, Phase I clinical studies are typically of short duration, involve fewer than 100 subjects, and evaluate dose (concentration) versus safety. More recently, Phase I studies have been used

Figure 12 (a) Parallel strategies: higher peak sales. (b) Parallel strategies: faster to market. (Reproduced with permission from Keelin, T.; Reeds, M. *Points to Light*, 2002 10, 17–18.)

to evaluate PK and PD as well. Phase II clinical studies typically involve 700 patients new molecular entities under study in 1997. This shows that Phase II clinical success is twice as high for precedented or best in class targets versus unprecedented or first in class targets. Furthermore, biological targets show a significant higher success rate than small-molecule or chemical drugs against unprecedented targets. The overall trend is evident as well in Phase III success rates but, the differences are not as dramatic.²⁰ Therefore, the portfolio choices of types of targets, as well as small-molecule versus biological can affect the overall attrition rate in R&D productivity.

Figure 13 Success rates for compounds targeting novel mechanisms of action from Phase II that reach preregistration. (Reproduced with permission from Windhover's In Vivo.)

Similarly, choices of therapeutic areas can affect the attrition rates. For example, while the development of cancer drugs has enjoyed lower regulatory hurdles, both clinically and toxicologically, than other therapeutic categories, nonetheless, it has historically yielded lower success rates. Those therapeutic areas that have the best correlation of preclinical efficacy to clinical efficacy include antibiotics, certain cardiovascular products such as antihypertensives and lipid-lowering agents, and certain categories of the treatment of pain, particularly inflammatory-associated pain. In contrast, preclinical evaluation in animal models of cancer, many CNS disorders, immunopathologies, antivirals, and degenerative cardiovascular disorders have poor correlation with clinical evaluation. [Table 10](#) provides a perspective on various disease categories and the success rates in these categories.

Lastly, even within a therapeutic category, there can be significant differences in success rates depending on the types of drug targets that are chosen. Cancer, by definition, probably represents the highest diversity of types of molecular targets. In large part, because of the diversity of types of cancer and the large phenotypic and genotypic differences in the degree of progression of the stages of cancer, multiple molecular targets can change significantly in their validity as targets by tumor type and overtime. Historically, cancer treatment has been principally cancer chemotherapy where the goal was to utilize cytotoxic drugs to reduce or eliminate the cancer burden. These usually were not cancer or histiotype-specific treatments and acted on common molecular machinery common to different cancer types as well as normal cells. More recently, targeted therapies have arisen which focus on genes or their protein products unique to a type of cancer, often expressed on the surface of the tumor cell. However, there have also been targeted therapies going after unique signaling dysfunction within cancers or the dysregulation of hormonal control within certain cancer types. These have included not only small-molecule approaches but also immunotherapy involving antibody treatment. These more recently introduced targeted therapies have also changed the paradigm of cancer treatment to one involving more chronic therapy and reducing, but not always completely eliminating, the tumor burden. Layered on this complexity is the frequent utilization of combination therapy attempting to enhance overall response by attacking more than one pathway as well as dealing with the frequent resistance development that occurs with many cancer treatments. In conclusion, many factors then impact the success rate in drug development relative to the clinical evaluation of the drugs including the predictability of the preclinical data, the type of molecular target, the therapeutic and disease category, and, lastly, the nature of the treatment.

Again, there are significant differences in acute versus chronic therapy, both in the speed with which one can secure an answer of success or failure, but also in the duration of the clinical studies. Historically, the mix has favored chronic therapies over acute treatments. However, more recently, big pharma have attempted to broaden their perspective in reinvesting in acute therapies and specialty care opportunities. In one respect the upsurge in drug discovery in cancer represents specialty care. Other examples in specialty disease areas, include sepsis, acute congestive heart failure, and severe, hospitalized infections. Finally, broadening the overall drug modality footprint to include biologicals is another component of maximizing success and return on investment.

Table 10 Therapeutic area analysis

Therapeutic area category	Diseases	Degree of difficulty (1–5) ^a	
		Drug discovery	Drug development
<i>Central nervous system</i>			
Neurology	Stroke, traumatic head injury (THI), subarachnoid hemorrhage (SAH)	2	5
	Epilepsy	2	2
Neurodegenerative	Alzheimer's, Parkinson's, Huntington's, multiple sclerosis	3	4
Psychiatric	Generalized anxiety disorder, major depressive disorder (MDD), bipolar, schizophrenia	2	3
Pain	Nociceptive, inflammatory	1	2
	Neuropathic	3	3
<i>Cardiovascular</i>			
Coronary artery disease	Hypertension	1	1/3
	Dyslipidemias, atherosclerosis	2	2/3
	Restenosis	3	3
Congestive heart failure	Acute, chronic	3	3
	Anticoagulants	3	2
<i>Metabolic</i>			
Diabetes	Type 1	5	4
	Type 2	2	2
Obesity	Energy, anorexigenic	4	3
Reproductive	Fertility	2	4
	Endometriosis, fibroids, benign prostatic hypertrophy	3	3
<i>Inflammation</i>			
Pulmonary	Asthma, chronic obstructive pulmonary disease	3	3
Arthritis	Rheumatoid, osteoarthritis	3	3
Gastrointestinal	Inflammatory bowel disease, irritable bowel syndrome	4	4
<i>Gastrointestinal</i>			
Antisecretory/antidiarrheal		3	2
Antiemetic		3	2
Overactive bladder		3	2
Gastroesophageal reflux disease		2	2
<i>Infectious diseases</i>			
Bacterial		1/3	1/3
Viral		2	2
Fungal		2	2
<i>Cancer</i>			
Hematological	Leukemias, lymphomas	2	2
Solid tumors	Colon, breast, lung, etc.	3	3

^a Ranked 1–5, with 1 = low and 5 = high; includes assessment of technical success and duration/cost; split values reflect a subset value due to unique hurdles (e.g., 1/3 for infectious diseases for drug development due to 1 = low difficulty in clinical studies but 3 = moderate difficulty due to recent FDA stipulation of percent confidence intervals for achieving equivalence to standard therapy).

There are other components of drug development that can be improved to impact overall R&D productivity. The two most important ones are long-term toxicology in animals and drug scale-up and manufacture. The potential liabilities here are primarily addressed by timing. For biologicals, it is important to determine the scalability of the product early on before significant downstream investment. For long-term toxicology studies, particularly for unprecedented targets and first in class drugs, it is important to initiate the studies sooner in the paradigm to minimize overall investment in the program before this key finding can be established. A recent example is the requirement by the FDA to complete 2-year carcinogenicity studies in drugs for the treatment of diabetes, that act on peroxisome proliferator-activated receptor gamma (PPAR- γ), before longer-term clinical trials can be initiated. A final factor to consider is discontinuation for commercial reasons. Here again, addressing the commercial fit of the drug development portfolio should be done early on in the drug discovery or early stage drug development process. Alternatively, and exemplified most commonly in biotech companies, if there is no commercial fit, the product can be partnered or out licensed at Phase II, a stage in which significant asset value has been determined and the overall program reasonably derisked.

Efficiencies have been an area of focus as well for drug development. Efficiencies have focused primarily on the bottlenecks in clinical trials. One of the challenges in early phase clinical evaluation is the cost and time in establishing the PK of the drug candidate, or PK/PD. The typical scenario requires considerable investment in drug scale-up (usually Good Manufacturing Practice), 2–4-week toxicology in two species, bioanalytical development, and preparing regulatory submissions. The FDA has recently promoted ‘phase 0’ studies, which allow for microdosing and/or short-term, low doses that might exhibit pharmacology in human subjects, to address PK and PK/PD with a more limited preclinical package. Other bottlenecks have been enrollment, clinical trial execution, and dealing with the tremendous data burden generated by clinical trials, particularly large clinical trials. Significant improvement has been realized in patient recruitment and enrollment in clinical studies. Establishing large databases of patients, extending clinical trials on a global basis, advertising, earlier clinical site qualification, and other techniques have been used to address this bottleneck. The data challenge with clinical trial execution has primarily been addressed by trying to minimize paper and make the overall data acquisition as well as data management electronic. Electronic data capture at sites is now becoming a reality and real-time data acquisition has improved considerably. Undoubtedly, there are additional efficiencies that need to be realized but progress is being made. Lastly, the coordination of clinical trial supplies using interactive voice recognition services and just in time inventories has enhanced the efficiencies of clinical trial execution as well.

2.03.3.3 Infrastructure

Often overlooked in R&D productivity assessments is the role of intellectual property (IP), information technologies (IT), and regulatory affairs. These are critical areas of competency and expertise in drug discovery and development in that they provide the framework for describing and protecting the assets: the drug candidates. Expertise in IP, IT, and regulatory is required at a number of the stages of the drug discovery and development paradigm and therefore, the integration of these competencies is important in enhancing R&D productivity.

2.03.3.3.1 Intellectual property

Patents are essential to the pharmaceutical business model. Since the time from concept to commercialization is frequently more than a decade, some degree of exclusivity of the product is required to justify the extraordinary time, expense, and risk associated with drug discovery and development. Patents have therefore been part of drug discovery and development for many years. Novelty in therapeutics that has been patented has been primarily of two types: composition of matter and methods of use. The most rigorous and defensible patenting of proprietary work has been the composition of matter since it unequivocally describes the drug and its closely related analogs. Furthermore, this type of patent also describes how to make and use the novel entities. In recent times, a challenge to composition of matter patents has been the legalities of patenting genes, gene sequence, vectors with genes as therapies, and the like. Generally, the US Patent & Trademark Office (PTO) has been favorable while the European countries patent offices have not.

Alternatively, methods of use patents have been utilized to describe novel uses of prior art and afford a measure of exclusivity for the innovator. Over the past two decades there has been a significant increase in methods of use patents as it applies to drug discovery tools. These patents have typically described new screening methods and/or key components of screens, such as the molecular target of interest, as a way to identify potential drug candidates. While these types of patents have been more difficult to enforce than typical composition of matter patents, these patents are considered particularly important to small companies business models as this IP represents a potential revenue stream. There is inherent conflict with these patents and the freedom to practice in the domain of ‘research purposes only.’ The FDA has allowed companies that are preparing new submissions for drugs for regulatory approval to utilize the patented art of other companies to generate appropriate safety and efficacy information, for example, as comparators to their own

drug candidate. This represents a second source of inherent conflict between method of use patents regarding drug discovery tools and the drug discovery and development paradigm. Ultimately, these conflicts will be resolved.

The protection of the novel art in drug discovery and development is an ongoing function within R&D, from the genesis of drug discovery through to the commercialization of the product. Patent attorneys with a science and/or medical background are essential for the execution of appropriate patent applications. They must be involved at the conception of a program since the initial drug discovery target could be novel in its own right, as well as, methods of using said target to discover new drugs. Furthermore, the composition of matter of the initial lead compounds should be described as soon as possible. The timing of a patent application takes on additional importance with the change in the American Inventors Protection Act of 1999, which states that any patent filed in 2000 and beyond will be published within 18 months of its application date. Prior to that time point a patent was not published until it was issued. Therefore, the publication of the application within 18 months discloses the intents of the innovating party sooner than has historically been the case. The timing of filing is critical both from the point of view of length of the exclusivity period as well as the protection of art in a highly competitive area of research.

As a program progresses in development, it is not uncommon that new uses for a drug are identified and explored. These also involve additional patent activity. New routes that are uncovered to produce and scale up the active ingredient also merit patent protection. Furthermore, novel forms of the active ingredient such as polymorphs, novel formulations, and/or unique delivery systems should be patented. Another dimension to patent activity is the breadth of filing patent applications. Global pharmaceutical companies usually file in many countries, countries that they have identified as potential commercial markets for their future product. This requires interfacing with the patent offices of many different countries, dealing with the languages unique to those countries as well as the downstream issuance fees. Today many countries, including now China and India, subscribe to the World Trade Organization (WTO) and General Agreement on Tariffs and Trade (GATT). This serves to harmonize some of the regulations on patenting among the many countries.

Patents are, of course, particularly important for small companies in that the value of the company is based on both the drugs in the company's portfolio that under development but also the validity of the exclusivity surrounding these drug candidates. Maintaining that exclusivity is not just a matter of the filing and issuance of patents, but also dealing with patent interferences that arise or lawsuits involving other parties that may be utilizing the innovator company's proprietary inventions. This investment in expertise in patent law within a pharmaceutical company or biotech company is no longer unique to those environments. Most academic institutions and government laboratories now are very aggressive in patent applications and the enforcement thereof. This has become a growing revenue stream for those institutions and furthermore, often represents a basis for spinout companies with tech transfer of the intellectual property discovered at these institutions.

2.03.3.3.2 Information technology

Several decades ago IT was relegated to specialists in computer science siloed in an organization cloistered around a main frame. With the advent of the internet, desktop computers, distributed computing networks, high-speed communications including wireless, IT are now an integral part of day-to-day activities for the drug discoverer and the drug developer. In fact, IT represents the most significant revolution over the last several decades in the life sciences and particularly in drug discovery and development. IT provides the opportunity to generate and analyze extraordinary amounts of data with high efficiency while providing the tools for the individual scientist or scientific teams to perform efficient multidimensional analyses of drug candidates. It does challenge the drug discoverer or developer to extract and utilize knowledge from all of these data. Indeed knowledge management is probably our biggest challenge.

The R&D organization virtually runs on its IT backbone. IT typically represents about 10–15% of the R&D budget in most organizations and includes not only computer scientists but experts in chemoinformatics, bioinformatics, and statistics, and computational scientists involved in simulation and modeling. The colocalization of these scientists with the chemists, biologists, and those scientists involved in drug development is a competitive advantage. Close working relationships are essential between the IT specialist and the scientist utilizing the applications so that effective and efficient research comes from the overall investment. The challenge exists to maintain critical mass and competency in IT centers, such as data management, computational chemistry, and infrastructure while maintaining an appropriate balance between the investment in these core competencies and the distributed nature of IT.

2.03.3.3.3 Regulatory

Regulatory affairs typically refers to that group of scientists who formulate the strategy for interacting with the regulatory authorities in various countries as well as the tactics of securing responses to questions dealing with

submissions and maintaining communication postregistration. Many of the scientists who populate regulatory affairs groups were originally involved in drug discovery or development. They need to understand the processes involved in drug discovery and development to accurately represent the science to the regulatory authorities. They are also involved in the compilation of the information in the form of investigational new drug submissions or new drug applications for final registration. With the evolving landscape of regulatory guidances, they also need to remain state-of-the-art in what the regulatory agencies are thinking and saying.

Organizationally they become involved when preclinical toxicology studies initiate on a drug candidate, as this represents usually the first event in generating data under regulatory guidelines (Good Laboratory Practice (GLP)). From this point on regulatory affairs is involved with nearly every aspect of drug development through to commercialization. They are also involved in postcommercialization activities. For example, activities that involve an expansion of information to modify a current label on a marketed product, submissions for new indications, or new formulations and postmarketing surveillance of safety (pharmacovigilance) are part of regulatory. Regulatory affairs also plays a role in reviewing advertising and other communications that are used to describe the new product during and after an NDA.

2.03.3.4 Technology

In addition to IT, drug discovery and development has been dramatically impacted by new technologies. These technologies have been primarily advances in automation and miniaturization, and secondly in the abilities to sequence DNA in an extraordinarily high-throughput and high-fidelity fashion. These technologies are going to be elaborated in much more depth in subsequent chapters in this volume. As an overview, the areas of principle focus in new technologies are combinatorial chemistry, HTS, and genomics.

Combinatorial chemistry had its genesis with the early efforts in the late 1980s and early 1990s to synthesize rapidly peptides and subsequently small organic molecules in a combinatorial fashion. Varying several different appendages to a core synthetic element allowed a rapid parallel expansion of a library of compounds within this structural core. These resulting combinatorial libraries provided for an explosion of compound inventories. In turn, these libraries provided for the increased chemical diversity as well as increased design for HTS. This technique had its advent in the mid-1990s and incorporated engineering and robotics to screen rapidly for actives or hits in a multiwell format, such as 96, 384, or 1536 well-plates. HTS generated extraordinary amounts of data about binding of compounds in these libraries to a molecular target of interest and therefore served as a starting point for a new drug discovery program. These two technologies have now been incorporated into every drug discovery organization in one fashion or another. They are capital-intensive investments, not only in the hardware, but also in the human expertise required to utilize these technologies, and lastly the IT support for them. Even though it has been a decade since they came into use, it is not yet clear whether they have truly increased R&D productivity.

Genomics describes the multiple technologies involved in high-throughput sequencing and analysis of sequences to provide a gene map for humans and a number of other species. This has been a global effort on a massive scale and has resulted in the complete sequencing of multiple genomes in less than a decade. It has been estimated that over \$15 billion in private capital alone was invested in the human genome project. The vision is that this information will provide for many new molecular targets for drug discovery, and will provide for a molecular understanding of diseases and therefore allow for better diagnostics and personalized medicine. The realization of this vision is however still sometime in the future. There is an extraordinary amount of biology that still needs to be done to understand the function of the gene in the first instance. Then follows the exploiting of this functional information in many dimensions including drug discovery and linkage to human diseases. Proteomics is a technology that has paralleled genomics in its development and describes the analysis of the proteins that are expressed from genes that are under active transcription. Proteomic analysis is now a ongoing technology and business opportunity, allowing for a better understanding of disease pathways, the discovery of new diagnostics, and the establishment of new druggable molecular targets for drug discovery and development. While there may be only a thousand to several thousand new molecular targets that have come out of the genomics efforts, posttranslational modification and compartmentalization of proteins within cell substructures means that there are multiple proteins that come from a single gene. Therefore it is expected that additional definition will be forthcoming about the true number of new druggable molecular targets based on proteomic analyses. Systems biology is the latest new descriptor of frontier efforts evolving from genomics and proteomics. It is the effort to understand the pathways and networks interrelated within the cell for a more global understanding of function. One area of genomics promise and application has been pharmacogenomics. In brief, this is the evaluation of genotypes or genotypic profile for a particular disease in patients using a variety of different techniques for genome location analysis and gene sequencing. Investigators,

and many companies, in this new field are studying how variations in sequences contribute to phenotypic traits such as diseases, disease subpopulations, and/or drug responses. For example, one approach is analysis of millions of single nucleotide polymorphisms (SNPs) in a population that has specific traits or a disease. The applications of this information include molecular targets for drug discovery, diagnostics, biomarkers for drug development, subsetting patient populations that may be more responsive to a particular therapy (personalized medicine), or repurposing known drugs. The potential is extremely exciting, but the promise continues to be well ahead of the deliverables.

It is premature to conclude whether genomics and its related 'omics' technologies have increased or decreased R&D productivity. However, they are essential components of modern-day drug discovery and development and as such, these obligatory tools are being used in the overall drug discovery and development paradigm. Drug discoverers will follow the science whether it is hypothesis-driven or a systems approach. Ignoring the science will be at their peril.

The growing power of reimbursement policies at the federal level in many countries in the pharmaceutical marketplace is having a significant impact on the current business models for big pharma as well as specialty and biotech. For many years, countries in Europe as well as Japan have had prices determined at the federal level and therefore have historically been markets with lower margins relative to the USA. In addition, the Japanese marketplace, which is characterized by higher prices on market entry, has the obligatory, biannual reduction in the price of a pharmaceutical after market entry. Recently, various countries in Europe have introduced the concepts of capitation of total healthcare budgets, reference price listing, and parallel imports between countries. All of these have served to reduce margins even more over the last 5–10 years in these countries for new pharmaceuticals. Furthermore, in the USA at the government and payer level, we are witnessing pressure to cover the uninsured, and pressure for a Medicare drug benefit which has now recently been enacted into law and will be put in place in 2006. As payer economics are suffering and Medicare bankruptcy is looming in the next 10–15 years, and with healthcare costs accounting for about 20% of the federal budget, there is a growing pressure to shift the burden to consumers and employers. These are seen with increasing co-pays and employers requiring employees to bear a greater share of the healthcare burden. We are seeing that employers are bearing about 40% of all costs versus 20% in 1990 and healthcare is the second largest payroll cost, representing between 6–8% of the total operating cost of employers. And, lastly, as the population is aging simultaneously with the uninsured population increasing, there will be greater pressures put on healthcare costs in the future.

With all of this there is also growing competition in major drug classes. Exclusivity periods are declining significantly in the last two decades and the cliff is even steeper for branded drugs when they lose patent, witnessing losses of 90% plus in less than a single quarter. While each one of these elements is not new, they are all trending in a direction that will result in a collision in the not too distant future. If that collision occurs, something will have to yield. Either society will have to be willing to pay more for medical treatment relative to other costs in society or the cost of discovering and developing a drug will have to be somehow be slashed or, lastly, the prices for drugs will have to be significantly reduced. If either of the latter two scenarios materializes, there is a high likelihood that there will be a significant diminution of new drugs becoming available to treat diseases in the next quarter century.

2.03.4 Conclusion

Drug discovery in the pharmaceutical industry has evolved over the last 100 years from serendipitous findings with rapid commercialization to a highly structured, regulated, and complex network of laboratory and clinical activities requiring more than 10 years and US\$1 billion from concept to commercialization. The 'industry' has similarly evolved from a diverse array of companies, most of modest size, with significant proportions of nonpharmaceutical revenues, to a more consolidated landscape today with the largest pharma companies securing more than 10% market share and focusing exclusively on pharmaceuticals. In the last three decades the biotechnology sector, starting from a new technology in designing biologicals as drugs, has matured to an array of over 500 small to large companies heavily invested in the discovery and development of all types of new pharmaceuticals, diagnostics, and products for agriculture.

Revolutionary advances in science, particularly at the interfaces of chemistry, biology, engineering, and IT have led to increasing complexities and costs in the development of new drugs but have also led to new ways to design drugs, new drugs for diseases previously untreated, and much better understanding of the etiology of diseases. The challenge in today's pharmaceutical research environment is the appropriate integration of the requisite multidisciplinary functions at the various stages of drug discovery and development to effectively find, develop, and introduce new drugs. This challenge is exacerbated by the consolidation of the industry resulting in R&D organizations of extraordinary size and literally spanning the globe. The most efficient and effective model for drug discovery and development is the

functional model within a therapeutic area, sized to enjoy critical mass of key functions and outsource other functions, yet compact enough for complete colocation of functional competencies. Size can be a strategic advantage in some drug development functions but is often an impediment to productive drug discovery.

Biotechnology has revolutionized drug discovery and development in several ways. Firstly, it represents the advent of designed biologicals as drugs. Secondly, with venture capital financing, the biotech industry has substantially solved the challenge of starting new companies in a business that is risky and capital intensive. Thirdly, it epitomizes the new biology and new technologies. Lastly, it defines entrepreneurship, a cultural asset largely ignored in larger pharmaceutical companies.

Philosophy matters! Technical competencies and motivated scientists are essential, but not sufficient, for successful drug discovery and development. Important philosophical choices regarding target versus disease, chemical versus biological, best in class versus first in class, and fail fast versus follow the science can significantly affect the success of a pharmaceutical or biotech enterprise. Related issues such as the relative resourcing of life cycle management of drugs on or about to enter the market versus development of new drug candidates are critical decisions for the longer-term building of the business. These choices cannot be generically prescribed, but must be evaluated and appropriately titrated to meet the needs of the organization at any defined state of maturation.

Culture is an often under-appreciated competitive advantage. Those R&D organizations that recognize the values of collaboration, foster an entrepreneurial environment, and balance product champions with good portfolio management usually thrive and exhibit the attribute of excellent execution. Lastly, partnering has become another essential password for growth and success, from the smallest to the largest companies and extending well beyond the private sector to academic and government laboratories.

In spite of the decrease in R&D productivity and increasing costs of drug development, the pharmaceutical and biotech industries have continued to grow and deliver new medicines to patients. A major reason for this is they have enhanced the overall value per drug by targeting commercially attractive unmet needs that can be premium priced, and by expanding established market arenas with improved therapeutics. But the industry can only grow, and indeed survive, by addressing two other fundamental areas of productivity. It must increase efficiency by reducing costs or time or both, and it must decrease the cost of failure by terminating drug candidates sooner or improving the probability of success. The area for greatest impact is the area of decreasing cost of failure. Increasing efficiency will be incremental at best, since reducing time per program is unlikely. Similarly, reducing costs is very unlikely. While significant improvements and efficiencies have been realized in drug development, the focus is on drug discovery. The future will belong to those organizations that develop the tools to dramatically improve success rates in clinical evaluation.

Biography

Wendell Wierenga, PhD is Executive Vice President, Research and Development at Neurocrine Biosciences in San Diego, CA. He joined Neurocrine in September 2003 and is responsible for all aspects of R&D including discovery research as well as preclinical and clinical development, manufacturing, and regulatory affairs. From August 2000 to August 2003, Dr Wierenga was Chief Executive Officer of Syrrx, Inc., a private biotech company specializing in high-throughput, structure-based drug design. Prior to joining Syrrx, from March 1997 to July 2000, he was Senior Vice President of Worldwide Pharmaceutical Sciences, Technologies and Development at Parke-Davis/Warner Lambert (now Pfizer), where he was responsible for worldwide drug development, including toxicology, pharmacokinetics/drug metabolism, chemical development, pharmaceuticals, clinical supplies, information systems, and technology acquisition. From 1991 to 1997 he was Senior Vice President of Drug Discovery and Preclinical Development at Parke-Davis. Prior to Parke-Davis, Dr Wierenga was at Upjohn Pharmaceuticals for 16 years, where his last position was Executive Director of Discovery Research. Dr Wierenga led/participated in the research and development of more than 50 INDs, over 10 NDAs, and over 10 marketed products, including Lipitor and Neurontin. Dr Wierenga earned his BA from Hope College in Holland, MI, his PhD in Chemistry from Stanford University, and an American Cancer Society Postdoctoral Fellowship at Stanford. Dr Wierenga is on the SAB of Almirall and Agilent. In addition, he has been on the boards of directors of four biotech companies and is currently on the boards of CIPHERgen, Onyx, and XenoPort.

2.04.1 Introduction

One of the most important assets to a company is its research project pipeline, and to ensure that the best decisions are made with respect to both advancing and terminating projects, proper oversight and management of the project portfolio are essential. Successful companies are able to translate good science into attractive drug candidates, and ultimately, a therapeutic drug. They are able to make good decisions as quickly as possible based on solid information and data. Successful project teams should be able to provide this information to the key decision-making committees in a succinct and timely manner, and skilled project management support should ensure that project teams are able to deliver on these needs. By making the right decisions, the company increases its probability of success by providing the appropriate resources (which are usually limited) to those projects that are the most promising and have the best chance of advancing into the clinic, and ultimately to the market. This chapter will address several important aspects of research project management: from project teams, leaders and managers, to organizational oversight, collaboration management, and transitioning of projects from research into development. The approaches described in this chapter are commonly utilized in many companies; however, there are other approaches that can be and are used in other organizations, and that may be better suited for their particular research environment and needs.

2.04.2 Pipeline Phases and Appropriate Project Teams

Development of a small-molecule drug is becoming an exceedingly expensive and complex process,¹ and requires the participation of numerous functional areas. The creation of a project team should enable better strategic decisions and operational planning, and cross-disciplinary project teams are essential to ensure that key aspects of candidate advancement are appropriately addressed. A high-performing team will identify and anticipate key issues and make appropriate decisions quickly, thereby keeping critical timelines on track.

Project team composition will evolve over the lifetime of the project, comprising mainly research functions in its early stages, and later including nonclinical, clinical, regulatory, and process development functions as needed. Commercial, business development, and intellectual property (IP) input are also important, and the extent of analysis and input will again be dependent upon the stage of the project. Similarly, project leadership may evolve over time as the key focus and goals of a project change as the project advances through the pipeline. Project leadership will be addressed in the next section.

Different companies have differing philosophies regarding the role and/or need for project management support, especially prior to entry of the project into development. An effective project manager will ensure that there is good communication and sharing of information between team members, that project timelines and budgets are adhered to, and working closely with the project team leader, that the project goals are met, and that senior management is informed of any key deviations from the original plan and/or strategy. If an experienced project team is in place, the need for project management support may be less critical, as the team members will understand the importance of clearly defined goals and open communication, the issues and activities which need to be addressed and implemented, and presumably will have satisfactory organizational skills. An experienced and well-organized research project leader can often serve in the dual role of a Project Leader/Manager. However, once a project enters into development, formal project management support is usually required, as project tracking, resource management, and communication to appropriate management teams become even more critical. Further aspects of project management will be discussed in [Section 2.04.6.4](#).

To address appropriate project team composition at various stages of the pipeline, it is first necessary to describe the general activities and goals for each phase of a project ([Figure 1](#)).

2.04.2.1 Project Phases: Activities and Goals Define Team Composition

2.04.2.1.1 Target identification and validation

Depending on the company strategy and therapeutic area, target identification and validation may or may not be part of the drug-development pipeline. Due to the potential risks of working on clinically yet-to-be-validated targets,

Figure 1 Typical research pipeline stages.

many companies elect to focus their drug discovery efforts on known, validated targets. If a company is interested in identifying novel targets, or in further validating putative targets, this stage is critical as significant resources will eventually be placed on the target of interest. The availability of tool or reference compounds and existing structural data are considerations that can impact the attractiveness of a target. A poorly validated target can result in wasted time and resources, and therefore strict criteria must be established and met before a target is accepted into the pipeline.²

New literature can dramatically affect the validity of a target (both positively or negatively); therefore much diligence must be placed on following the scientific literature at this point of the pipeline. In addition, the project team must be aware of the IP status of the target; freedom to operate considerations surrounding the target (including assay reagents and technologies) are important factors in deciding whether to progress a target of interest. The project team at this initial stage is usually small and comprised primarily of research biologists and bioinformaticists.³ However, input from clinical and commercial groups should also be solicited at this point for a reality check on the downstream development feasibility and commercial attractiveness of the target/indication.

In addition to the target validation biology efforts, protein biochemistry resources may be needed for reagent generation for future activities, including primary and secondary screening, structural chemistry efforts, etc.

2.04.2.1.2 Target development and high-throughput screening (HTS)

Once a target is approved by the appropriate oversight committee, it is necessary for assay development scientists to develop a robust, high-throughput screen for screening the company's compound collection. If only a subset of compounds will be screened based on the target, a lower throughput screen will be acceptable. Many new technologies are being used for high- and medium-throughput screening, and may be addressed in Chapter 2.12, pp 90–95. Hits from the screening effort need to be confirmed for activity and identity. In addition, nascent structure–activity relationships (SARs) from a compound series are often a requirement for advancing a compound or scaffold into the next phase. During this phase, robust secondary assays as well as selectivity screens should be developed. Medicinal chemistry and chemical informatics resources often become involved from this stage to help evaluate the attractiveness of the chemical starting points, as well as to help evaluate all the biological data available on the compounds of interest.

2.04.2.1.3 Hit-to-lead

Once a project has advanced past the screening phase and identified confirmed hits with a discernible SAR, a project team is usually created to take the project to the next phase. It is at the hit-to-lead stage where the project requires dedicated participation from different scientific disciplines. Typically, the biology champion of the project and a medicinal chemist will team to lead the effort to identify a few attractive chemical lead series based primarily on *in vitro* data. It is important for the project team to develop a target product profile (TPP) by this stage, which will define the properties of the ideal drug candidate.⁴ Input from downstream functions such as clinical and commercial groups will be necessary to develop a useful TPP. The TPP defines the required efficacy and side-effect (safety) profile for the drug, the dose regimen and how it will be administered, in which patient populations and for what indication (Table 1). It should target an acceptable cost of goods based on anticipated competitor products. Ideally, it will define the performance requirements of the drug that will enable the commercial organization to assess the market impact upon introduction of the product, and estimate the commercial return.

The project team will also need to develop a screening cascade, which clearly delineates the critical path and criteria that need to be met to advance a compound further down the pipeline. The proposed screening cascade will need to be approved by the Research Management Team, since this allows them to estimate the resources that will be required for moving the project (as well as other projects in the portfolio) forward. Frequent and open communication between project teams and research management is critical from this point on, since significant resources (both people and external dollars) start being deployed at this stage, and any new result could change the strategy of the project. Both the TPP and the screening cascade should be dynamic and flexible; they should be able to reflect changes in new biology and competitive landscape, and frequently be revisited to ensure that they serve to drive decision-making and advance the most promising compounds (Figure 2).

In addition to the *in vitro* primary and secondary assay and selectivity data, it may be appropriate at this stage to better characterize the biochemical mechanism of activity, for example, reversible versus irreversible inhibition, competitive versus noncompetitive or allosteric inhibition. The physicochemical properties of the leads should also be assessed early on. This would include analytical chemistry measurements of compound solubility, stability, and preliminary assessment of potential metabolic liabilities, among others.

Table 1 Example of a target product profile (TPP)

Profile parameter	Target claim
Indication	
In vitro potency/selectivity profile and MOA	
drug metabolism and pharmacokinetics (DMPK)	
Preclinical efficacy and biomarker analysis	
Safety	
Clinical efficacy	
Dose regimen, route	

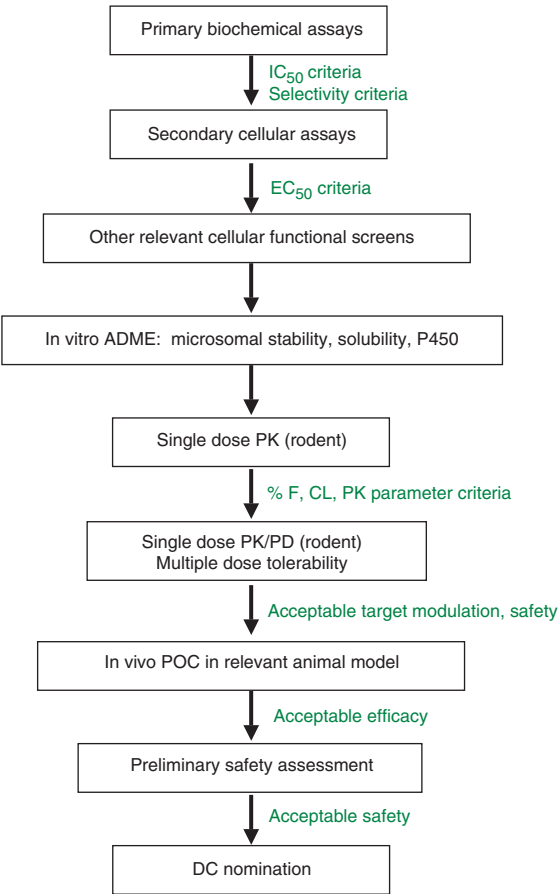

Figure 2 Example of a general screening cascade. F, bioavailability; CL, clearance; PK, pharmacokinetics.

Ideally at this stage, alternative scaffolds will also be identified, in case the lead series should fall out later in the pipeline due to unfavorable physicochemical or biological properties.

2.04.2.1.4 Lead optimization

Once attractive leads that meet all the defined in vitro criteria have been identified, the compounds are optimized based on their in vivo properties. This occurs during the lead optimization phase of a project, and therefore nonclinical

functions of pharmacology, pharmacokinetics (PK), and to some extent, toxicology are integrated into the project team. Companies are increasingly realizing that concomitant optimization of absorption, distribution, metabolism, and excretion (ADME) and safety parameters relatively early in the drug discovery process (lead selection and optimization phases) can help to improve the probability of success, so that fewer candidates fail in development for reasons that could have been predicted in research.^{5,6} Medicinal chemistry resources continue to be critical, not only for generation of new compounds to test, but for initial compound scale-up for the in vivo studies. Projects may also require evidence of target modulation (pharmacokinetics/pharmacodynamics (PK/PD)) using translational medicine approaches to demonstrate that the compounds are exerting their pharmacologic effect via the desired mechanism/target.

Appropriate animal models must be available to assess the activity of the candidates. Attention should be given to ensure that the animal model is relevant, that is, that the observed disease is driven by the targeted mechanism. The clinical development organization should also be consulted to select the relevant testing models as well as clinical dose regimens. The team must revisit its criteria for advancement (efficacy, PK, safety), and at the end of this phase, select a small number (1–3) of promising candidates to advance into the predevelopment phase.

2.04.2.1.5 Predevelopment

The goal of this phase of the drug-discovery pipeline is to identify the Development Candidate (DC) from the 1 to 3 advanced preclinical candidates. Further in vivo evaluation to determine efficacy, optimal dose scheduling, and safety will be conducted. PK studies will need to be conducted in nonrodent as well as rodent species, as will preliminary safety studies. Further benchmarking against competitor compounds should also be performed to assess the relative activity and safety of the possible drug candidates. These studies may provide insights regarding areas of anticipated superiority of the internal candidate. The project team composition will expand to include more involved participation from functional areas which are also important in investigational new drug-enabling and other development activities. In particular:

- Chemical development representation to ensure compound scale-up procedures are feasible.⁷
- Formulation development to perform preformulation work, salt selection, polymorph evaluation, etc.
- Toxicology support since more extensive safety assessment will be needed prior to candidate selection.
- Clinical: preliminary clinical strategy will be required to design appropriate safety studies (with some guidance from Regulatory on any considerations that could impact the clinical development of the candidate).

2.04.2.2 Team Responsibilities

From the previous section, it is apparent that as a project advances through the drug discovery pipeline, the size of the project team will increase due to the increasing number of activities that need to occur. Meetings comprised of large groups of people are rarely effective; therefore a smaller Core Team should be defined. The Core Team is usually comprised of more senior representatives from the key functional areas of the project team. This working group (usually 4–6 people) is responsible for meeting on a regular basis to discuss new project developments, make appropriate decisions, and then to communicate those decisions and action items back to their functional areas. To keep the entire project team informed and engaged, it may be appropriate to hold monthly or quarterly project team meetings where the whole team is invited to hear the latest updates, accomplishments, and key issues the project was facing (mechanisms for sharing project information/data are addressed in [Section 2.04.9](#)). These meetings should be primarily informational in nature; however, there may be times when it is appropriate to include a larger group to discuss data and reach decisions. Functional areas may hold department meetings on a regular basis where all department scientists attend, and at these meetings key issues or developments regarding a particular project may be presented and discussed. It is usually within this forum that younger team members receive exposure to real project-related problems, and how they are addressed. In addition, open project reviews serve to educate and expose less-experienced researchers to real-life drug discovery issues (and solutions).

The project team is also responsible for keeping senior management updated on the status of the project. It is usually the project leader and/or project manager who will communicate both project achievements as well as issues to the management team. It is particularly important that delays or challenges facing the team are brought forward quickly, as they could impact allocation of resources within the organization. If a team does bring forward issues to the management team, they should also be prepared to recommend solutions to the challenge at hand.

2.04.2.3 Metrics and Goals

2.04.2.3.1 Project goals

To keep the team on track, it is imperative to establish project goals and metrics with associated timelines that have been approved by senior management. At the outset of a project, it will be recognized that the timing is a best guess estimate based on previous experience and knowledge. However, as the project progresses, definition of tighter delivery dates should become possible, and it becomes the challenge of the leader, manager, and team to meet the goals and timelines. Nomination and acceptance of drug candidates into development are often highly visible (and easy to measure) metrics.

Examples of key milestones/goals for a project team include:

- Advancement to next project phase
- Identification of advanced preclinical candidate(s)
- Completion of candidate scale-up for toxicology studies
- Completion of the first safety study
- Nomination of DC.

2.04.2.3.2 Individual and project functional area goals

From the high-level team goals, functional area goals for the project can be set. It is critical that the project leader and functional area heads agree upon the functional area goals for each project in the portfolio to eliminate the possibility of conflicting functional versus project metrics. One way to accomplish this is to establish written goals for each team member, which are signed off by both the project leader and functional area head. In this manner, the functional area head is better able to assess all the activities across the entire R&D portfolio for which his/her group is responsible, and can ensure that there are adequate resources available to provide the agreed-upon deliverables. Without this understanding, there is a risk that conflicting priorities (due to limited resources to support both project and functional goals) will result in delays to project progress. This possible conflict is addressed further in [Section 2.04.5](#) on matrix organization.

Senior management will review the organization's portfolio of projects and should ensure that the approved timelines and delivery dates for each project are compatible with available resources – both research and anticipated downstream development resources. Development Candidate nomination dates should be agreed upon by both research and development management teams, because it is important that once approved, the compound advances immediately into investigational new drug-enabling studies. Based on such consideration of resources, if two projects project a DC nomination at similar times and adequate resources are not available to advance both at the same time, a decision may be made to delay one DC nomination date to provide the team more time to identify and nominate the best possible candidate. However, any delay in an anticipated DC nomination may result in idle capacity in the development organization, which was planning to receive the candidate. In understanding the dependence of resource allocation and budgeting upon the meeting of project goals and timelines, the importance of proper project team oversight and management becomes clear.

2.04.2.4 Development Candidate Criteria

In addition to defining the goals for the project team, it is important to define the criteria by which a DC will be selected ([Table 2](#)). As do the timelines, as the project matures, the criteria may become more stringent and better defined. Depending on the nature of the project and the therapeutic indication, the criteria for selectivity, therapeutic index, compound half-life, metabolic liabilities, and other parameters will vary. Each project will have its unique set of criteria, but listed below are parameters that are commonly considered in selecting a DC. Other considerations involved in transitioning projects into development are further addressed in [Section 2.04.8](#).

2.04.3 Project Team Leadership

2.04.3.1 Effective Leadership

Effective leadership is as important to the success of a project team as it is to the overall success of a pharmaceutical or biotechnology company. There does appear to be a paradox, however, between empowered groups of coworkers who

Table 2 Development candidate criteria considerations

<i>Parameter</i>	<i>Required information</i>
In vitro potency	<ul style="list-style-type: none"> • K_i or EC_{50} • Selectivity against relevant off-targets and related targets • Other testing funnel parameters (e.g., MDR cell lines)
Chemistry/physicochemical properties	<ul style="list-style-type: none"> • Efficient, cost-effective route for API production at kg scale (including analytical methods for qualification of API) • Chiral centers • Crystallinity • Solubility • Stability • Acceptable preclinical formulation
Drug metabolism	<ul style="list-style-type: none"> • P450 isozymes (3A4, 1A2, 2C9, 2C19, 2D6), lack of inhibition or activation • Microsomal stability in relevant species (human, rodent, dog) • Plasma stability • Hepatocyte stability • Protein and red blood cell (RBC) binding • Other possible metabolic liabilities • Drug–drug interactions
Pharmacokinetics	<ul style="list-style-type: none"> • Pharmacokinetics in two species (rodent and nonrodent) • % F (> 30%) • $T_{1/2}$ (supports desired dosing regimen) • C_{max}, AUC • V_d, tissue distribution • Clearance • Dose linearity • Permeability (Caco-2), transporter (P-gp) studies if relevant • Major routes of elimination
Efficacy	<ul style="list-style-type: none"> • Efficacy in two animal models, if available • Evidence of target modulation, if applicable
Safety	<ul style="list-style-type: none"> • <i>hERG</i> (negative) (<i>human ether-a-go-go related gene</i>) • Ames mutagenicity (negative) • Micronucleus (negative) • Mouse lymphoma assay • 7-day pilot studies in rodent and nonrodent • PanLabs/other screening tox panel (no significant interactions)

collaborate to achieve team goals and the notion of having a leader who, in traditional terms, directs a team. Project teams need strong leaders who help to drive the effort to define goals and who will motivate, facilitate, and coordinate individual efforts of team members. Project leadership is best embodied in a leader of colleagues rather than a leader of subordinates (supervisor/employee), typical of most functional departments. A project leader must have the scientific experience necessary to lead their team. An effective leader will jointly set goals, use talent effectively, and question and develop each team member, appreciating their value and their contributions. A project leader may also coordinate meetings and agendas and may be responsible for writing meeting summaries and team communications (in the absence of a dedicated project manager). The shaping of project reviews and the updating of senior management, as appropriate, are also the responsibility of a project leader.

Previous leadership experience can be invaluable. Having experienced the drug discovery or preclinical development pathway before and knowing the next steps often can prevent backtracking and can shorten the development pathway. For example, a team might have planned to perform the study that would support recommending a DC, but the leader realized that that particular study would have to be repeated under Good Laboratory Practice (GLP) conditions for an investigational new drug application. It might be more efficient to take the extra time to qualify the active pharmaceutical ingredient (API), rather than repeat the study, saving cost and time. However, sometimes the less experienced can be successful team leaders if they have effective interpersonal skills and are diligently listening and learning from those around them.

2.04.3.2 Interpersonal Skills of Effective Leaders

Interpersonal skills are among the keys to effective leadership. Good communication, in particular, is important. A leader must listen to the team and facilitate the listening between various functional team members. Issues should be addressed and brought to the forefront, not ignored in hopes that they will vanish. It is important to identify gatekeeping issues as soon as possible since they impact the team cross-functionally. No team member should force a path forward over the objections of other team members. For instance, a chemist might want to move a molecule forward because of potency. However, lack of solubility might preclude good bioavailability or limit the options for formulations. A good leader will negotiate with the team on activities and their priorities, maintaining particular focus on activities that lie at the interface of different groups. An effective leader delegates activities, yet checks in to ensure that timelines on deliverables are not slipping. This could have an impact on other team members' activities as well as delay the project team's effort to achieve the goals communicated to senior management. If timelines are slipping, the leader should ensure that the entire team is aware of the changes so that they can adjust their activities accordingly. Lastly, an effective leader will motivate a team to work for the greater good and to transcend the individual functional goals. An example of this might be when the project team leader convinces the core team member that it is more important to have his/her team focus on the mechanism of action of the compound, in support of the project, than to achieve the biology department's goal of setting up a new target for screening.

2.04.3.3 Project Leader Responsibilities

A leader must be willing to assume responsibility for the success or failure of the project. The failure of a project will not be evaluated as a bad outcome if the project was well executed but the science did not support the theory. Terminating a project early saves the company time and money and permits resources to be deployed on more promising therapeutic targets.

A leader can help to develop and motivate a team by providing structure and expectations. Structure takes many forms; regular meetings with consensus agendas, enforcement of teamwork and frank discussions, regular challenging of the team's direction as well as the direction of the individual functional teams. Effective leadership includes challenging the team in a productive manner to think strategically as its information base grows and changes.

It is important that the project team leader, as well as the team, is aware of relevant external events. Awareness of the competitive intelligence and maintaining a liaison with the commercial organization are critical. The leader should keep the team up to date on external and competitive advances and ask the team and the commercial group how this information can impact or change the current TPP of the project team. For instance, if the competitor has identified an effective agent that was dosed as a once daily dose regimen, the team may need to adjust the product profile from twice-daily dosing and focus on other attributes such as no cytochrome P450 (CYP) inhibition to avoid drug-drug interactions, which were a liability of the competitor.

A project leader's role is to orchestrate the moving parts of a project while regularly communicating on a high level with senior management. S/he has the responsibility to keep management informed of progress and issues as they arise. Leaders ensure adequate resourcing to achieve the team's objectives and advocate with senior research management for those resources. Resources include not only full time equivalents, but also equipment, contracts, and collaborations that can facilitate achievement of team goals. The leader must understand the needs and issues at such a detailed level as to offer sufficient justification to senior management.

2.04.3.4 Transitioning Project Leadership

As a team transitions through drug discovery to preclinical development, there may be a need to transition leadership as well. Some leaders are able and willing to lead projects on into early clinical development while some leaders' strengths and interests are better suited to particular stages of a project. Sometimes it is best for the team to transition to leadership that can better lead the cross-functional team through a critical point. An example might be a team whose most significant challenge is the optimization of pharmacokinetic parameters of the lead molecules, but the team leader's strengths focus on the biological mechanism of action. The team needs the leadership of someone who is comfortable driving the team to focus on the drug metabolism and pharmacokinetics (DMPK) experiments and on feedback to medicinal chemists. Additionally, a project leader might not be/feel capable of leading a team in preclinical development and would rather move back onto an earlier staged project team. Different leadership skills are needed at different times in the drug discovery pipeline and research management should be gauging leadership effectiveness at all times, adjusting it as necessary. If a team is not achieving its goals, is it because of less than effective leadership? If so, a change should be made. Although teams do not always embrace change and adjust as quickly as they should,

management should make changes swiftly, reassuring the team that these changes are in the best interest of the team's success. At the earlier stages in the pipeline (hit-to-lead, lead optimization), a co-leadership model (e.g., a biologist pairing with a chemist) is an option which can lead to favorable results.

2.04.4 Effective Project Teams

The definition of a project team is a group of individuals with a common vision, set of performance goals, and an agreed-upon approach for which they hold themselves mutually accountable.⁸ High-performing project teams share some basic features: the project goals are clear and the team has a 'can-do' approach to their work. Project teams must have a sense of urgency and the skills to achieve dependable results.

2.04.4.1 Productive Project Teams

Productive project teams generally exhibit the following characteristics:

- *Strategic thinking*: Action plans are well-conceived and logical, and work plans are adjusted to accommodate various outcomes.
- *Interdependence*: Team members solicit ideas and input from their various colleagues while defining the goals and the implementation of the work plan. A high-performing project team member welcomes the input of his/her colleagues, recognizing that it might help the project team make better decisions, thereby reducing wasted time and effort.
- *Project commitment*: Team members are committed to the success of the project – achievement of the team's objectives being the highest priority of each member. Their individual success is tied to the success of the project.
- *Pragmatic innovation*: Effective teams develop innovative but practical solutions to problems and work through team issues in a pragmatic manner.
- *Diversity*: Diverse skill sets, views and ways of thinking breed novel solutions to unanticipated issues.
- *Thoughtful responsiveness*: Effective teams do not overreact to new problems – they make a clear assessment and develop a solution.
- *Effective communication*: Project team members clearly communicate progress, issues, and obstacles among themselves and within discovery research.
- *Clarity*: Effective teams clearly understand the team goals and each member's responsibilities.
- *Commitment to the team*: Team members are committed to each other's success since successful teams are comprised of successful individuals.
- *Authority and responsibility*: Teams have the authority to make decisions and the responsibility to execute plans to achieve the goals. They are focused and follow through on activities.
- *Empowerment*: Quality teams have the power to make decisions and have clear decision-making processes.
- *Passion*: Team members feel urgency and enthusiasm for the accomplishment of the team's goals. Individuals care about the outcome and the results.
- *Reliability*: Project team members are able to rely on each other. Since project team members are interdependent, the inability of a team member to deliver affects other functions of the team and the team's overall success.
- *Flexibility*: Science can be unpredictable at times. Good teams have the flexibility to deal with unanticipated outcomes.
- *Honesty and trustworthiness*: Team members are honest with each other, trust each other, and operate with integrity.
- *Supportiveness*: The team supports each member's efforts and members are mutually appreciative of each other's efforts. They are good listeners, and they question and challenge each other to achieve.
- *Enjoyment*: Effective teams are composed of talented individuals who enjoy their own work as well as being part of a team.

These are some of the characteristics of effective teams. There is a tendency to call a collection of people who work together a team, but it is the above characteristics that distinguish such a group from a highly productive team.

2.04.4.2 Functional Departments versus Project Teams

Functional departments are usually comprised of researchers with common scientific background and training, and goals for the department are usually focused on improving technologies and efficiencies of the department, as well as

advancing the science in specific areas for which the group may be known. It is critical for department members to keep an update on the scientific literature and competitive landscape to ensure that they remain competitive and are aware of developments that could impact both the department and the projects that the department supports. Within a given functional department, researchers' projects may not be related and people may work independently of each other, but they will have the same supervisor and will be rewarded based on their individual contributions toward meeting the functional area metrics.

Productive teams, on the other hand, have clear common goals and objectives and are rewarded primarily based on the team's performance. Highly effective teams meet to solve problems, resolve issues, and to make decisions. The project team members are interdependent on each other, are skilled at communicating and juggling tasks, and therefore put out enhanced performance, quality decisions and a greater work product than could be achieved if each individual worked alone.

2.04.4.3 High-Performing Project Teams

High-performing project teams utilize team meetings effectively to communicate, coordinate, and cooperate on team activities. Successful meetings are thoroughly planned well ahead of time. Effective leaders will seek input on the agenda and communicate the purpose of every meeting. Occasionally, special meetings will be necessary to deal with unpredicted results or issues. Agendas should be distributed in advance of meetings so that members can be prepared to discuss issues and share new data. During the project meetings, the team will review progress made toward commitments and goals and articulate action items that evolve from each discussion. Brief meeting minutes or summaries should be written after each meeting to capture the discussions, conclusions, and action items. Each team member thereby knows who is responsible for each action item.

2.04.4.4 Rewarding Teamwork

It is critical that the success of teams be rewarded as opposed to individual efforts.⁹ The culture of drug discovery must truly recognize and compensate teamwork. Line managers in pharmaceutical companies are often responsible for the evaluation of individuals. They must seek input from project leaders and other team members. This information can be invaluable in recognizing an individual's contributions and, in providing constructive feedback, to enhancing the individual's value to the team and the effectiveness of his or her teamwork.

Project leaders should provide to the reviewing line manager an assessment of each of their team members. Information provided should include:

- Does the team member fully represent their functional area, providing relevant, high-quality data in a timely manner?
- Does the team member participate in the intellectual development and creative expansion of the project?
- Does the team member always act in the best interest of the team, maintaining good working relationships with other team members and project team leaders, and supporting the project decisions?

Similarly, research senior management must provide an assessment of the project leader's performance. Information provided should include:

- *Leadership skills*: Does the project leader articulate project goals and inspire commitment from the team? Does the leader possess the energy, scientific insight, and the personal commitment necessary to lead the team?
- *Communication*: Does the leader foster an environment in which the team communicates honestly and openly and is information shared through regular team meetings? Does the project leader effectively communicate project issues to senior research management and the scientific advisory board as required?
- *Teamwork*: Does the leader promote collaboration to achieve team goals?
- *Operations*: Does the leader develop project plans and deliverables, have a command of the project issues and make critical decisions? Each project team member and project leader must know that their individual performance and resulting compensation is closely tied to the effectiveness of their performance on the team.

2.04.5 Matrix-Driven Organizations

Matrix-driven organizations exist in various forms across a wide range of R&D organizations.¹⁰ They are the center of a continuum of management possibilities between a purely functional (line) organization and a purely product-based

organization.^{11,12} If the environment of a company is relatively simple (as defined by considering of the following four factors: complexity, diversity, rate of change, and uncertainty), a more traditional hierarchical management structure may be preferred. However, if the environment of a company is complex, as is the nature of most biopharmaceutical or pharmaceutical companies, a matrix organization is probably more appropriate.¹³ The formation of cross-functional project teams by definition involves a matrix organization since it involves bringing two or more usually distinct functional areas together to focus on the common project goals. Team members will therefore have dual lines of authority, responsibility, and accountability that violate the traditional ‘one boss’ principle involved in line management.

One of the primary advantages associated with the formation of formal project teams is the creation of cross-functional (horizontal) communication linkages. Improved communication between functional groups is critical for project success, and therefore this type of team structure emphasizes and values development of communication skills within a team. Improved information flow within project teams allows information to more quickly permeate within an organization, and therefore can lead to improved decision-making and response time.^{14,15} In addition, in a matrix organization, individuals have the opportunity to participate on a variety of projects with different individuals from across the organization, allowing for sharing of ideas, knowledge, perspectives, and experiences. Thus, being a member of a project team should result in increasing the individual’s breadth and awareness of other disciplines and activities within the organization, ultimately contributing to his or her career development.

One of the primary disadvantages of a matrix- or project-driven organization results from the creation of dual/multiple authority and influence.¹⁶ The most common authority conflicts are those between functional and project leaders over project priorities. For example, functional group responsibilities require and encourage individuals to remain current and aware of new technical and scientific developments within their area of expertise, and this could be in conflict with performing more routine studies that the project may require. It is therefore very important that there is agreement between the project and functional leaders regarding the expectations and priorities for each project (as described in [Section 2.04.2.3](#)). It is also critical that the reporting structure for the project teams is clearly defined: the project teams are accountable to the Research Management Team, and the functional heads, as members of the management team must agree upon the priorities of the project versus their functional metrics.

Cross-functional teams force individuals to take more personal initiative in defining their roles and goals, negotiating conflict, assuming responsibility, and making decisions. This increased level of autonomy and responsibility can lead to increased stress among team members; however, if managed properly, the matrix organization can result in a more productive and satisfying work environment.

2.04.6 Research Project Oversight and Decision Points

2.04.6.1 Management Teams

As mentioned in previous sections, proper project oversight is critical to monitor progress and to ensure that projects are resourced appropriately for success, or conversely, to terminate projects and make resources available to other projects if the situation (e.g., scientific data, budget considerations) warrants this. Typically, the Research Management Team will comprised of the Head of Research along with the heads of key functional areas. This group is ultimately responsible for ensuring that the research organization meets the agreed-upon annual metrics. Project teams should report to the Research Management Team to avoid the possibility of conflicting interests or agendas between project goals and functional area goals. The management team must act consistently and transparently in managing department priorities and resources in order to achieve the organization’s goals.

A typical Research Management Team may be comprised of:

- Head of Research
- Head of Biology
- Head of Bioassays
- Head of Chemistry
- Head of Nonclinical (pharmacology, PK, toxicology)
- Head of Research Project Management/Project Mentor (if applicable).

Ad hoc participation by representatives from human resources, operations, finance, legal, and business development is often necessary to address the range of issues the management team is responsible for. Typical responsibilities of the management team include:

- Oversight of research (project) portfolio – ensure scientific rigor of projects
- Definition and oversight of research metrics
- Development and oversight of research budget
- Identification of business development opportunities (in- and out-licensing)
- Career development opportunities
- Staffing considerations (hires and terminations).

Effective decision-making by the Research Management Team should minimize risk and maximize benefit to the research organization.

2.04.6.2 Reviews and Feedback

For all the reasons that have been previously stated, it should be apparent that management teams must be updated regularly on the status of the projects in the research portfolio. There are several mechanisms by which this can occur.

2.04.6.2.1 Written project reports

Formal written reports (using a defined format or template) can provide useful information which is readily available when needed for reference. For projects, either bimonthly or quarterly updates are probably appropriate. Each project should address:

- Progress toward project goals (e.g., on track or delayed)
- Key highlights/achievements
- Issues identified and possible solutions
- Budget
- Next milestones, next steps.

Writing a project report often forces the project leader to stop and assess the status of the project, to review the progress as well as to identify key issues, and to see how well the team performed relative to what was projected in the last report. Many project leaders start out with the view that they have more important things to do other than writing a project report/update; however, they often eventually appreciate that taking the time to critically analyze the project progress, issues and planning the next steps is a valuable exercise and helps them become a more effective leader.

2.04.6.2.2 Formal project reviews

Management teams can use open forum, formal project reviews as a mechanism for receiving updates on a project, as well as a means to educate their research organization. It is also an opportunity to include the development organization in open discussions, allowing personnel to learn more about projects that are in the late research pipeline. By inviting the research organization to regular project reviews, a large audience can be exposed to real drug discovery projects – real issues that are faced, questions that should be considered, projects that are making good progress, and projects that are floundering. Over time, the audience should be able to evaluate which projects are running well and why, and conversely, which projects are not running well and why. Management should be pleased if when making the difficult decision to terminate a project, the organization understands and agrees with the decision. Researchers will also hopefully apply lessons learned from the presentations and discussions to their own projects and areas of research.

2.04.6.2.3 Ad hoc meetings with project teams

In addition to regular project updates (either reports or presentations), the Research Management Team must be able to meet with project teams on an ad hoc basis – either at the request of the team, or when the management team is concerned about certain issues or needs clarification.

It is important that the teams receive feedback from their efforts to update management on the status of their project – both from a technical perspective and to know how effectively their message was communicated. This feedback should be delivered to the team in a timely manner – ideally within 48 h of the presentation or receipt of the

report, but certainly within a week. Teams will be much more motivated to deliver a quality product if they know management is going to take the time to read and review the material and offer thoughtful, useful, and timely feedback. This is probably one of the most important jobs of the management team – to oversee the projects in the research pipeline, educate project teams, and make adjustments where necessary.

2.04.6.2.4 Team member feedback

With matrix-driven project teams, it is important that each team member be evaluated for his/her performance in advancing both functional and project goals. Contributions toward achieving functional goals are usually easier to assess by the direct supervisor, since presumably there is a direct reporting relationship of a team member and functional supervisor. Contributions to the team may be more difficult for the direct supervisor to assess, as the supervisor will not usually be a member of the team, and therefore must rely upon both the project leader and manager for formal feedback on team performance. This is an important consideration, since a team member risks not having an accurate and fair performance evaluation on team performance, especially if most of their time is spent on project-based activities.

2.04.6.3 Project Decision Points

Based on information provided, it is the responsibility of the management team to make decisions on prioritization and resourcing of projects. Typical project decision points include:

- Acceptance of a target for further target development/HTS activities (deployment of assay development, protein biochemistry resources)
- Acceptance of preliminary hits into hit-to-lead activities (e.g., deployment of medicinal chemistry resources)
- Advancement of project into lead optimization (deployment of preclinical resources)
- Identification of 1–3 advanced preclinical candidates for predevelopment activities (deployment of further preclinical resources, process/chemical development)
- Acceptance of DC (transition project from research into development and IND-enabling studies).

2.04.6.4 Project Management

Given the importance of team performance in achieving project (and organizational) goals, it is not surprising that many companies elect to have project managers working in concert with the project lead to ensure coordination and oversight of key team activities. A project manager is usually assigned to a project once it advances to a phase where numerous functional areas are involved (e.g., lead optimization/predevelopment stage), or if there is an external collaboration that needs to be carefully managed (*see* [Section 2.04.7](#)). The vast majority of companies will deploy formal project management support once a compound officially enters development (investigational new drug-enabling activities), due to the numerous activities with critical timelines and regulatory requirements that need to be managed.

2.04.6.4.1 Research project management

Depending on the level of experience of the project teams, management can elect to provide project management support during the later phases in research. If project management support is not provided, the organizational aspects of running a project will fall upon the project leader and other members of the core team. Contrasting roles and responsibilities for project leaders and managers are presented in [Table 3](#), with the caveat that it is also possible for one person to serve both functions. There are traits in common that make a person an effective project leader and/or manager. It has been observed that to be an effective leader, one has to know when to manage; to be an effective manager, one has to know when to lead.

Many of the operational activities of a project (meeting scheduling, developing timelines and budgets, collaboration management, etc.) are not technical in nature, therefore research team members often prefer to have someone on the team whose responsibility is to attend to these important, but nontechnical activities. It is extremely useful, however, for the research project manager to have a scientific background so that she can understand key project issues, and help the team to develop and implement solutions. For a less-experienced team, if the project manager has drug development experience, she can work with the project leader to define the project goals while the team works to achieve them. An experienced project manager will also look to the future and anticipate needs and identify potential issues while the team members are dealing with more immediate activities. If truly all the team needs is advanced organizational and administrative support, the role is probably best filled by a project coordinator, whose scientific

Table 3 Roles and responsibilities of project leaders and managers

<i>Project leader</i>	<i>Project manager</i>
<ul style="list-style-type: none"> ● Key communicator: project status, progress and results/issues <ul style="list-style-type: none"> – Updates and alerts key stakeholders/management and oversight committees, partners as appropriate – Spokesperson/representative of project team internally and externally – Project champion – Surfaces alignment issues between project needs and functional area support ● Leads/monitors technical execution and strategy for project team <ul style="list-style-type: none"> – With team and management, define clear goals and deliverables and timelines – Sets scientific strategy for achieving goals – May have key functional role in project plan – Ensures technical soundness of project implementation and results (data) ● Lead quality decision-making <ul style="list-style-type: none"> – Accountable for quality of decisions – Ensures functional integration and alignment to maximize probability of success (PoS) – Holds team members and functional heads accountable for planning and execution of agreed-upon deliverables 	<ul style="list-style-type: none"> ● Owens overall project plan <ul style="list-style-type: none"> – Works with team to develop project plan and timeline based on agreed-upon project goals – Integrates functional plans and deliverables – Maintains accurate budget/schedule – Forecasts/anticipates possible gaps or events which could impact budget or timeline – Ensures functional area deliverables occur on time and with quality ● Manage project processes <ul style="list-style-type: none"> – Project planning and tracking (Gantt charts, liaison with functional areas) – Budget planning, tracking, and forecasting (interfacing with finance) – Team effectiveness <ul style="list-style-type: none"> ○ Meeting planning and facilitation ○ Team communication ○ Meeting follow-up/action items ○ Identification of key issues/gaps and possible solutions ● Manage support interfaces <ul style="list-style-type: none"> – Ensure communication, alignment, and integration with <ul style="list-style-type: none"> ○ Business development ○ Finance ○ External collaborators ○ IP ○ Noncore team functional areas

experience/expertise would not be as advanced as that of a research project manager. This is a suitable role for an associate level researcher who is looking to move out of a laboratory setting into a more administrative role, but still has interest in being involved in drug discovery. The risk in limiting a research project manager to these activities is the lack of a challenge and the potential resentment of having to perform administrative duties at the expense of keeping up with his or her area of technical or scientific expertise. This can be offset, of course, if there are other challenges associated with the position, such as those described in next paragraph. Depending on the experience of the project manager and the working relationship with the project leader, there may even be times when it is appropriate for the project manager to act on behalf of the project leader. The attractive feature of the project manager position is that it is the central point of the project, and she must know what is happening on all aspects of the project, not just in one particular functional area.

The project manager will often act as the liaison between functional areas, and should be viewed as an ‘objective’ member of the team. His/her job is to ensure that the project is on track, and to identify where interactions can be improved for the benefit of the project. This is possible since the project manager is not a functional area member, and therefore should not be perceived as having any sort of hidden agenda. An effective project manager will know who are the key contacts in each of the relevant functions and establish good working relationships with them. The project manager should at all times be viewing the project from the ‘30 000 foot’ vantage point, rather than on single components of the project, to assess how the various pieces of the project are (or are not) coming together in support of the team’s goals. The working relationship between the project leader and project manager can be compared with that of the Chief Executive Officer (CEO) and Chief Operating Officer (COO) of a company. The leader defines the (technical) strategy and goals for the project, and the manager works from the operational side to ensure that the strategy is executed and the goals are met on time and within the allocated budget. [Table 4](#) provides other examples of the complementarity and potential overlap of the two roles.

Table 4 Duality (and potential overlap) of project leader/project manager responsibilities

<i>Activity</i>	<i>Leader</i>	<i>Manager</i>
Creating the project plan	Establishes direction and strategy, scientific rationale, and project goals	Defines task and develops budget
Developing the team and network to implement the plan	Aligns and directs team with technical expertise and experience	Directs with definition of roles, structures, resources required, and timelines
Execution of the project plan	Motivates, leads, and inspires; communicates across and up	Controls by tracking activities and communicating across and down
Achieving the goals	Produces quality product (target, DC), future opportunities for team members	Produces order and predictability; reduces unforeseen obstacles/delays

Where the project management function resides organizationally varies within different companies. Many companies do not offer formal project management support in research, and individual team members (in particular, the project leader) assume the planning and operational responsibilities. In some organizations, the research project management group resides within research, whereas some companies deploy project management support for the research from out of the development project management department. In the transitioning of a candidate between research and development, project leadership will often change hands and the project management support can provide a continuum during this process.

As mentioned earlier in this section, if project management resides within research, the head of the function will often be a member of the management team, as she can inform the group of project-related issues that may not be readily apparent to individual functional unit heads. In smaller research organizations, rather than having a project management group, a senior level experienced individual (Head of Discovery Team Management, Project Mentor) can function as a resource to all project teams, providing drug discovery/development as well as project management type of advice. This position would have responsibility for the overall performance of project teams, function as team mentor for all teams, integrate with business development and collaborators as appropriate, and create/initiate new project teams once approved by the Research Management Team.

2.04.7 Management of Collaborative Projects

2.04.7.1 Collaboration Initiation

If management makes a decision to collaborate on a project with an external partner, it is critical at the outset that each party's roles and responsibilities are clearly defined, as well as the goals of the collaboration. Typically, this means that the relevant participants meet prior to the execution of the agreement to work out such details, so that once the agreement is executed, people are ready to start immediately working toward the project goals and milestones. Optimally, at the initiation of a collaboration, a clearly delineated research plan will have already been drafted. This plan should detail the project goals and milestones, activities/responsibilities of both parties with target delivery dates, number of full time equivalents in various disciplines, and other anticipated project expenses. At the kick-off meeting, this plan should be further vetted with team members, discussed and formalized, and there should be agreement between the team/project leaders and senior management that the deliverables, resource allocations, and time frames are reasonable.

It will either be the responsibility of the project leader or the project manager to ensure that communication between the parties is frequent and productive. A collaboration will only be successful if the two parties trust and respect each other, and therefore it is often beneficial to ensure that scientists have a chance to meet face to face and interact with each other soon after the collaboration starts, if not before. A sign of a good collaboration is when scientists from each organization feel comfortable contacting and communicating with their colleagues whenever necessary – not just at the scheduled joint meetings. The sooner the team can transition from a 'we versus them' mentality to a 'we are one team' mentality, the more likely it is that a productive and successful collaboration will result.

2.04.7.2 Logistical Considerations

It is important to include chemical informatics and information technology representatives during the initial planning stages of a collaboration, as it will be critical to have easy and secure exchange of information (e-mail, structures, and data)

between the two parties. Details regarding protection/isolation of company databases, project data, samples, etc. must be addressed. There are several 'virtual office' software packages available which allow secure communication both within and between organizations (Flypaper, Groove).¹⁷ This type of software allows team members from both parties to share files, manage meetings, track activities – basically to function as if they were working at one location.

Whatever a project leader or manager can do to encourage open communication between colleagues will ultimately benefit the collaboration. The timing of key discussions and decisions cannot always be coordinated with scheduled joint team meetings, therefore it must be made clear to team members that any material discussions be formally documented and communicated to the project leaders. Given the advances in teleconference capabilities (secure shared databases and e-mail systems, sharing of slides, etc.) – joint project team teleconference meetings can be effective and scheduled on a regular basis. However, one cannot underestimate the value of face-to-face meetings between colleagues as a way to instill the commitment, camaraderie, and trust needed for project success, especially at the outset of the collaboration.

If a project is collaborative in nature, a project manager will often be assigned, as it is recognized that additional organizational and logistical activities are usually involved, and are critical to the success of the project. As trivial as they might seem, details regarding joint teleconference calls and meetings, project-specific confidential databases, routine communication, travel, etc., can significantly impact the quality of the collaboration and should not be underestimated.

2.04.7.3 Collaboration Oversight

Collaboration oversight is typically performed by a Joint Management Team (JMT), which is comprised of an equal number of key representatives from both parties (usually 3–5 from each). Assignment of a Chair for the committee can vary; some collaborations have an assigned member who acts as Chair for all JMT meetings, while others may elect to have the Chair alternate depending on which party is hosting the meeting. The composition of a typical JMT would include from each company:

- Vice Presidents of key functional areas (Biology, Chemistry)
- Project leader
- Core team member/area experts
- Project or alliance manager (or business development representative)
- IP or other legal representative (if appropriate)

The JMT should meet on a regular basis for the duration of the term of the collaboration (usually quarterly or bi-annually). The responsibilities of the joint Research Management Team include:

- Approval of and monitoring of the research plan
- Approval of any modifications to the research plan (including budget)
- Approval of any changes to DC selection criteria

It is critical that the details of dispute resolution are clearly described in the collaboration agreement. If the JMT is not able to reach an agreement on a particular issue, the issue will be addressed by the management representatives identified in the agreement.

By leveraging the capabilities of the two parties, the probability of success for the project is increased. A well-run collaboration will identify and call on the strengths of each organization, but will also recognize that there may be times when resources are limited. Under these circumstances, to minimize delays in the project timeline, a partner may be requested to perform activities normally assumed by the other party.

2.04.8 Transitioning Projects into Development

As a drug candidate meets the criteria of the TPP, the project team must obtain the support of research management, and therefore should schedule a project review with their management. This review should be an oral presentation by the core project team members on the attributes of the molecule which support the team's nomination to move the candidate into clinical development. This review should promote discussion and critical review of the data. If management does not agree with the team's recommendation, they must provide critical feedback to the team on experiments that should be performed, or additional issues that need to be addressed before they can endorse the team's recommendation.

2.04.8.1 Development Candidate Nomination Document

If the Research Management Team supports the nomination of the candidate into development, they will usually need to justify the nomination to a larger strategic body, such as a Development Committee or Strategic Review Committee within the company. It is customary and recommended that the research project team assemble into one document all the information and data generated on the individual DC. This information can be distributed as preread material before the formal discussion and agreement by the larger strategic decision-making body. The document could be called a Development Candidate Nomination (DCN) and should contain as much of the following information as is available:

Development Candidate Nomination

Table of Contents

I. Executive Summary

II. Introduction

- a. Rationale*
- b. Key Distinguishing Product Features*
- c. Competition*
- d. IP Position*

III. Product Profile

- a. Draft Profile*

IV. Chemistry

- a. Name*
- b. Chemical Structure*
- c. Molecular Formula*
- d. Molecular Weight*
- e. Formula Weight*
- f. Physical Appearance*
- e. Melting Point*
- h. Solubility*

V. Pharmacology

- a. Mechanism of Action Statement*
- b. In Vitro*
- c. In Vivo*

VI. Drug Metabolism and Pharmacokinetics

- a. In Vitro Profiling*
- b. In Vitro Metabolism*
- c. In Vivo Profiling*
- d. Drug Interaction Profile*

VII. Toxicology

- a. General Toxicology*
- b. Safety Pharmacology*
- c. Genetic Toxicology*

VIII. Estimated Human Dose

IX. Pharmaceutical Development:

- a. Synthetic Route*
- b. Physicochemical Properties and Salts*
- c. Process (Scale-up) Assessment*
- d. Estimated Costs of Goods*
- e. Analytical Methods*
- f. Formulation*

X. Major Issues, Assumptions, Constraints

XI. Team Recommendation

XII. IND Timeline and Resources

XIII. Project Team Members

Executive Summary: An executive summary should be developed after the rest of the DCN is assembled. It should include the top-line information that supports the advancement of the compound into development, including: therapeutic area, key data, predicted human dose, summary of synthetic process, IP position, and rationale.

Introduction: The introduction provides the background information on the unmet medical need, the market opportunity and the current standard of care and its limitations. It also provide, the project background, origins of leads, and collaborators if applicable.

Product Profile:

- Rationale:* Provide epidemiology and prevalence of the disease which should support the subsequent elaboration of the unmet medical need and limitations of current therapies. Describe the current market and market potential with appropriate citations. This section can be developed with the assistance of the commercial development team. Justify the advancement of the candidate into your company's marketing and commercial strategy. Describe the targeted product attributes and outline the TPP which the team developed early in its life time with the input of the commercial strategy team.
- Key Distinguishing Product Features:* Describe how the product would work, how it could be rationally combined with other molecules within your portfolio or the market or could displace the current standard of care.
- Competition:* Summarize the status of the competition, describing the individual compounds, the stage of development (Phase I, Phase II, etc.), the mechanism of action, the companies and publicly known status on efficacy.
- IP Position:* Have your patent group make a statement on the patentability of the proposed DC. If patents have not been issued, provide an update on the status of all applications.

Chemistry: Include the IUPAC name of the molecule along with the structure and in-house company name. Summarize the molecular formula, the molecular weight, and formula weight. Describe the physical appearance, melting point, and solubility at various pH values.

Pharmacology:

- Mechanism of Action:* Describe the mechanism of action and the studies carried out to support the mechanism.
- In Vitro Activity:* Summarize all in vitro activity of the molecule in enzyme or cell culture systems. Include selectivity versus other cell lines and related targets and cytotoxicity observed. Provide results on experiments that describe the impact of serum shift on efficacy, if relevant.
- In Vivo Activity:* Describe all in vivo efficacy experiments, doses utilized, and results as compared with a known standard.

Drug Metabolism and Pharmacokinetics: Describe the bioanalytical methods developed and applied for the quantification of the drug candidate in the plasma of preclinical species.

- In Vitro Profiling:* Describe the relevant in vitro disposition properties of the drug candidate studies in a variety of tissues from both animal and human origin. These in vitro systems describe aspects of the absorption, metabolic stability, and distribution properties and can be predictive of the in vivo pharmacokinetic properties in preclinical species. Property studies should include: (1) kinetic solubility; (2) absorption in Caco-2 permeability systems; (3) metabolic stability in human and nonhuman hepatic microsomes that can lead to a prediction of in vivo clearance rates; and (4) protein binding in the plasma of human and all nonhuman systems tested in vivo.
- In Vitro Metabolism:* Describe the in vitro metabolism studies on the drug candidate which were utilized to identify the major metabolites and the proposed metabolic pathway. The in vitro data should suggest that the drug candidate would have adequate metabolic stability and free fraction such that it would be reasonable to expect sufficient active pharmacological concentrations in human subjects utilizing the desired route of administration.
- In Vivo Profiling:* Describe the in vivo disposition of the drug candidate in preclinical species, including the clearance, volume of distribution, half-life, and percent bioavailability. Discuss whether the in vivo pharmacokinetic profile data is consistent with and predictable from the in vitro data. Include results of dose proportionality studies and the impact on C_{max} , T_{max} , AUC (area under the curve) and percent bioavailability, as well as the results of salt forms, if applicable, on the fraction of the dose absorbed.
- Drug Interaction Profile:* Describe the CYP inhibition potential against the most prevalent human CYPs. High IC_{50} s relative to the potency at the drug target might suggest the potential for drug-drug interactions is unlikely. The potential for CYP induction should also be examined.

Toxicity: Describe the results of a general 7-day toxicity study in rat or dog. Include clinical observations, effects on body weights and food consumption, hematology and clinical chemistry. Confirm exposure on the first and last day of the study. At the end of the study, describe the macroscopic observations and organ weights. Determine the no observed adverse effect level (NOAEL) for the compound. Safety pharmacology should be investigated in a panel of receptor or enzyme assays to determine if some off-target pharmacology would be predicted. Genetic toxicity potential should be determined in the Ames screening assay.

Estimated Human Dose: Based on the in vitro and in vivo PK correlation presented for the preclinical species, determine the estimated human pharmacokinetic parameters for the drug candidate as determined from the in vitro data from human test systems. A one-compartment model to simulate pharmacokinetics of the drug enables the calculation of total plasma concentrations required to exceed the trough target EC_{50} or IC_{50} . Estimated dosing regimen, quantity and frequency, is important for future preclinical and clinical studies.

Pharmaceutical Development:

- a. **Synthetic Route:** Provide the synthetic route for the synthesis of the drug candidate from commercially available starting materials.
- b. **Process (scale-up) Assessment for Active Pharmaceutical Ingredient (API):** Identify issues which will need to be addressed for the further development of the synthetic process prior to scale-up.
- c. **Estimated Cost of Goods for Active Pharmaceutical Ingredients:** Estimate the full time equivalents and time for process development and for the GLP and GMP campaigns. The cost estimates can then be provided from these estimates.
- d. **Analytical Methods:** Outline the specification and methods for raw materials, intermediates and in-process testing which will need to be developed. Estimate the analytical support necessary for process scale-up and pilot plant manufacturing. In addition, specifications and methods for drug substance and drug product need to be developed and batch analyzed for toxicology and clinical studies. Estimate the resources required for the development and release of materials.
- e. **Physicochemical Properties of the Free Base and Salts, if Appropriate:** Provide pH-solubility profiles and melting point and heat of fusion as determined by differential scanning calorimetry.
- f. **Formulation Assessment of the Pharmaceutical Drug Product:** Outline the activities and resources necessary for preformulation and formulation efforts.

Major Issues, Assumptions, and Constraints: List unresolved major issues and assumptions included in the document that might impact the decision to advance the drug candidate.

Recommendation: The recommendation is usually fairly straightforward. The team is recommending the initiation of IND-enabling activities. The IND timelines with supporting assumptions are outlined in the next section.

IND Timeline and Resources: Include a Gantt Chart and list of assumptions.

Project Team: List project team members and their role on the team, so that individuals can be contacted for additional questions or clarifications. Phone numbers, office location, and other relevant contact information (administrative assistants, e-mail address, etc.) should also be included as appropriate.

References: List references utilized.

Appendix: Additional supporting material if necessary.

Once the document has been generated, it will serve not only as a resource to support the formal declaration as a DC, but also as a reference for the new project team down the clinical development path.

2.04.8.2 Transitioning of Project Team Membership

As mentioned previously, project leadership or project team composition may change as projects mature through the drug-discovery process; through target identification, assay development, high-throughput screening, lead identification, and lead optimization. The most dramatic changes in project team composition occur, however, as projects transition from research into development. At this time, a project team becomes focused on the advancement of a specific drug candidate. It is very important that during this process, the project is handed off in a manner to ensure that critical information is transferred and team efficiency is not lost. It is often recommended to keep a few key individuals from the research project team on the new development project team.

As a research project team realizes that they are close to identifying a DC that meets the desired TPP, it is important to begin to include representatives from process chemistry, clinical research, and development project management in the research project team meetings. The first objective is to familiarize the development organization

with the issues and possible timing of the recommendation of a DC. The second objective is to begin to solicit input from development colleagues; input on decisions and on the required information for the DCN document.

The preclinical and subsequent clinical development of a product requires a more structured and well-defined development process than that occurring in drug discovery. Regulatory requirements by the Food and Drug Administration (FDA) and European Medicines Agency (EMA) agency require that a drug's sponsor must submit data demonstrating that the drug candidate is safe for use in initial Phase I clinical trials. A preclinical team must undertake GLP studies to support the safety of administering the drug candidate to humans. Depending on the therapeutic use, the requirements for preclinical testing may vary. After developing a preclinical plan, it is recommended that a pre-IND meeting or a conference call with the FDA be scheduled to ensure that the team is performing the necessary experiments to support human dosing. Minimally, the FDA will require information on (1) the pharmacological profile of the drug; (2) the acute toxicity of the drug in at least two preclinical species (one nonrodent); and (3) subacute toxicity studies to support the proposed frequency and duration of dosing in Phase I human trials.¹⁸ The data for the FDA must comply with GLP regulations. The regulatory agencies utilize the GLP standards to ensure the quality of the preclinical data.

2.04.9 Project Management Tools

There has been considerable pressure on pharmaceutical research departments over the past decades to become more efficient due to the increased costs of pharmaceutical research and development. As such, the industry has adopted many automated tools to improve productivity. Many of these improvements are early stage research tools for research to help identify new biological targets, synthesize compound libraries, and screen the libraries against the new targets. More recently, there has also been a push to increase the effectiveness of the later stages of drug discovery. There has been an emphasis on integrating these processes to achieve more success, more efficiently with information management and simulation tools. Many companies agree, however, that discovery project management tools have not advanced significantly over the years. Data generated by project teams should be easily accessed by team members on company databases that should be updated nightly. Project team documents meant to be communicated between project teams and research management can be saved into folders that are automatically sent to both parties. These documents might include project team meeting summaries, project reviews or action items generated by research management. The creation of a research information management site on the company intranet provides a common area for all project team information to be stored and accessed by parties with the required access privileges. This type of site would typically be maintained by a Chemical Informatics group, and it is the responsibilities of the team members (or the project manager) to ensure that project information remains update.

A commonly used project management tool is Microsoft Project, which can be used to track and integrate team activities, especially interdependencies and critical path activities. Probably one of the most useful capabilities is the ability to generate a Gantt chart for the project, which serves to clearly represent a timeline of key activities to the team as well as management. The Gantt chart shows the duration for each activity, dependencies, and key decision and delivery dates. It also can immediately recalculate the timeline if one critical path activity is delayed. Although this and other more sophisticated tools are available for development project teams (e.g., OPX2 by Planisware),¹⁹ research project teams often do not use these types of tools until there are clear activities associated with a single candidate (e.g., at the predevelopment stage), or when the team is contemplating recommending a DC and are estimating IND filing dates as part of the DCN documentation.

2.04.10 Conclusion

The discovery and development of quality drug candidates is a complex, cross-functional process. Highly effective teams and project leaders teams can achieve their goals by working cooperatively in a matrix-type organization. Successful project teams have clearly defined goals and objectives and are able to communicate effectively among themselves and with research management. It is important for project leaders and functional area heads to agree upon the project goals and priorities to avoid conflict between line and project metrics. Effective project management can help drive the definition of the project goals, ensure that the project remains on track and is resourced appropriately, as well as anticipate possible issues which could impact project timelines or budgets. Research management is responsible for oversight of the project pipeline, ranging from project resourcing and providing technical advice and mentoring, to portfolio management and making go/no go decisions on projects themselves. Research management should empower project team leaders and their teams, internal or collaborative, as much as

possible to successfully plan, monitor, and execute on team objectives. By instilling the discipline of good project/research management and leadership, companies can improve their probability of success for delivering successful drug candidates into clinical development, as well as creating a stimulating and productive environment in which their scientists can work.

Biographies

Yumi Nakagawa is a Senior Director of Research at Novartis in Emeryville, CA. She received her BS in Chemistry from the University of California, Berkeley, in 1979, and her PhD from the University of California, Los Angeles. Dr Nakagawa was also an NIH Postdoctoral Research Fellow at UC Berkeley from 1984 to 1987. Prior to joining Chiron in 1996, Dr Nakagawa was a Senior Research chemist at Chevron, where she worked in agricultural chemistry and later, in catalyst research. She is the inventor/co-inventor on 31 US patents. At Chiron, Dr Nakagawa managed several large technology transfer and target collaborations, and eventually led the Research Project Management group in Chiron Technologies. In 2003 she became head of Chiron BioPharmaceuticals Research Operations, and later worked in the Office of the Chief Scientific Officer until the acquisition by Novartis in spring 2006.

Lori Lehman is currently Senior Director of Research at Gilead Sciences, Inc. in Foster City, CA. She received her BS in Chemistry and MS in Organic Chemistry from Bucknell University, Lewisburg, PA, in 1979 and her PhD in Organic Chemistry from Duke University, Durham, NC, in 1983. Prior to joining Gilead, Dr Lehman held positions as Senior Scientist at Schering-Plough working in the Departments of Allergy and Inflammation and Cardiovascular Disease; Senior Director of Chemistry at Amylin Pharmaceuticals working in Diabetes; and as Vice President of Research at RiboGene, Inc. working in Infectious Diseases. During her career, Dr Lehman led several research and development projects and managed collaborative relationships with large and small pharmaceutical companies and academic research groups.

2.05.1 Introduction

Organic chemistry is a science practiced by two groups in the pharmaceutical industry who have radically different aims. The first group consists of medicinal chemists who use the tools of organic synthesis to construct unique structures with the aim of identifying interesting biological activity. The only concern of this group is the architecture of the molecule to achieve a predetermined pharmacologic purpose. This group of scientists is relatively unconcerned with the practicality of the synthetic route selected as medicinal chemists typically prepare materials on the gram scale. As a compound moves from discovery through early development and ultimately into the manufacturing arena, the amounts of drug substance required to support the studies and postapproval marketing ranges from kilos to as much as hundreds of metric tons of material. It is at the development stage that the second group of organic chemists becomes involved. In sharp contrast to the medicinal chemist's world, the concern of the chemical development team is a manufacturing route that can be carried out reproducibly and economically while being executed by chemical operators at a large scale.

A 'drug product' consists of a pharmacologically active agent: a 'drug substance' or 'active pharmaceutical ingredient' (API) that has been compounded with appropriate excipients into a system that can effectively deliver that agent to its site of action within the body of a patient. Approval to market a drug product in a timely fashion can mean substantial dollars to the sponsor of a new drug application. If one assumes that the new drug product is a blockbuster, having a market value of one billion dollars per year, every month that an application's approval is delayed costs the sponsor almost one hundred million dollars! This has a substantial effect on the ultimate economic value of the product to the enterprise. It is money that can never be recovered, as the drug patent's lifetime is finite and not related to the time required to answer questions from a regulatory agency.

Regulatory approval to market a drug product from the US Food and Drug Administration (FDA) and other Ministries of Health can be obtained upon successful completion of two important review processes. The first component is the scientific package of toxicology and clinical data that support the safety and efficacy of the drug for its

proposed indication. The chemical development team has no control over that aspect of the approval process. This is an inherent property of the molecule and the quality of biological and clinical evaluation of the molecule. The second component is the scientific review of the chemistry, manufacturing, and controls sections of regulatory package assembled for submission to licensing agencies. This is a property of regulatory compliance. The regulatory approval process is mapped out in a set of regulations promulgated by the FDA as well as other regulatory bodies throughout the world. This chapter deals principally with small-molecule drug substances regulated under Title 21 of the US Code of Federal Regulations (21 CFR), the regulations that resulted from the Food, Drug and Cosmetic Act of 1938 which has been updated from time to time.¹ Regulation of these small molecule drug substances specifically falls under the Center for Drug Evaluation and Research (CDER) of the FDA in the USA. The USA, Europe, and Japan under the auspices of the World Health Organization (WHO) determined that a consistent set of regulatory requirements and format would be to everyone's advantage. They formed the International Conference on Harmonization (ICH) to address this issue. The result of those conferences was to publish a set of principles and issue a set of guidance documents,² collectively referred to as the current Good Manufacturing Practices or cGMPs, which govern the manufacture of drug substances. It is compliance with these regulations that the chemical development team controls and where that team can generate substantial value for its organization. Chemical development is an inherently costly process requiring an investment of many millions of dollars. While it is difficult to compress the overall regulatory approval cycle time, a properly documented, carefully executed development package will generate few questions from regulatory agencies. While almost all chemistry regulatory questions can be answered, the process of clarification and resolution of outstanding issues involves a delay in approval to market as well as an additional investment. It is this aspect of the development process that will be the focus of this chapter.

In addition to the chemical development team's role in securing approval to market a drug, the team has a number of other ongoing material supply requirements that must be met during the development cycle. These responsibilities include supplying materials to support ongoing toxicology studies and formulation development. These studies do not require that the API be manufactured following the requirements of cGMP. In order to ensure that the material fairly represents material that will ultimately be used in clinical trials and subsequently marketed; the development team should provide material that is comparable to that anticipated to be generated from the manufacturing process as well as good documentation of the synthesis methodology employed. The material should have a comparable profile of impurities and be the same particle size and polymorph to ensure that dissolution properties do not change, thus changing availability of the drug to the living system. Materials will also be needed to support ongoing clinical trials in people. Federal law mandates that all materials destined for human use must be manufactured following cGMP requirements.

A term that is often misused is GLP or Good Laboratory Practice. These regulations are not a less stringent version of the GMP requirements; rather these regulations mandate how the analytical laboratory used to evaluate toxicology samples is managed.³

All of the regulatory requirements surrounding the drug product and the API have been mandated to ensure that the pharmaceutical industry's products are safe, pure, and effective. Additionally, these requirements ensure that the manufacturing processes are designed to be consistent from batch to batch and ensure that patients receive the same pharmacologic benefit with each dose of medicine. Defining a chemical process that is consistent is a critical component of process development. Many of the current requirements have been instituted to minimize the opportunity for human error.

2.05.2 Development Chemistry Tasks

A well-established principle in the drug-manufacturing arena is that the quality and purity of the drug substance cannot be ensured simply by analytical evaluation of the API at the end of the manufacturing process. Rather, the purity of the drug substance depends on maintaining proper control of the materials used and proper control of the synthetic process used for the manufacture of the material. Therefore, the task of the chemical development group can be simply stated as the identification of a robust, economically viable, and, most importantly, consistent process. A robust process is required to allow chemical operators to execute the process in large, fixed equipment. The process must be consistent to assure that the patient receives the same product with each dose (*vide supra*). An economical process ensures that the product is viable in the marketplace.

Economics is playing an increasingly prominent role in the pharmaceutical industry and occasionally development of pharmacologically interesting classes of molecules is terminated for reasons of high cost of goods. For example, in the 1980s many major pharmaceutical companies had research efforts to identify compounds to manage hypertension by inhibiting the enzyme renin. Today, there are no renin inhibitors marketed as antihypertensive drugs, even though

many drug candidates of that class of agent were shown to reduce blood pressure in humans. The high cost of goods was a concern in many of those programs. Interestingly, the drug design concepts elucidated in the renin area provided the foundations for many of the currently marketed human immunodeficiency virus (HIV) protease inhibitors.

The first tasks for the team are definition of the synthetic route, reagents, and process parameters. Chemists operating in a medicinal chemistry laboratory have many technical options available to execute a synthesis. Reaction volumes, management of heat, and mass flow are not concerns in a medicinal chemistry setting. These issues become prominent in a plant setting. There are a number of excellent monographs covering these topics in detail. Anderson presents a particularly detailed text covering the chemical operational topics that must be considered.⁴ Additionally, some chemical steps that can be executed in a matter of hours with laboratory equipment can require days in a plant setting. In the discovery setting, one has easy access to temperatures as low as -100°C and a wide variety of chromatographic systems to purify the most challenging reaction mixtures. In the plant setting, one would prefer to employ less technically challenging, costly unit operations. That is not to imply that technically difficult unit operations are precluded. Atorvastatin calcium (Lipitor) is manufactured using low-temperature chemistry.⁵ During scale-up work toward SDZ-NKT343, Prashad *et al.* used chromatography early in the program but successfully eliminated that type of purification upon further process development.⁶ Such operations are costly and, in general, worth avoiding. They must, however, be evaluated on a case-by-case basis.

In addition to the design of an efficient process, the development team must be concerned about reagents selected for production. Certain reagent classes are easy to use in research but pose substantial hazards for production materials destined for consumption by humans. For example, lead- or mercury-containing reagents might prove useful in a discovery laboratory but should be avoided in a process setting.

Medicinal chemists have easy access to a very wide variety of solvents, including chloroform and diethyl ether. When used at production scale, chloroform is a solvent that has serious environmental and operator exposure liabilities. Diethyl ether is a potential fire hazard and can form peroxides rapidly and thus should be avoided in a plant setting. These types of solvent are generally not permitted in a drug-manufacturing process. Regulatory agencies have categorized solvents as class 1, 2, or 3 and have imposed residual solvent limits based on potential hazards to human health (Table 1). Class 1 solvents should be avoided whenever possible. In some instances, they cannot be avoided, for example if benzene is required as a core-starting subunit in a drug synthesis or if the specific reactions fail when conducted with class 2 or class 3 solvents. If they must be used, the residual solvent limits required by the FDA are generally well under 10 PPM. Class 2 solvents have general residual solvent limits in the range of 100–1000 PPM while class 3 solvents have a residual solvent limit of up to 5000 PPM under certain circumstances without any additional justification. Higher limits are permitted with appropriate justification if the process cannot achieve lower levels of the residual solvent. Toxicology studies must be completed to support the safety of the material, and general GMP guidelines must be followed. There are exceptions to these generalities. Methanol has a limit of 3000 PPM, although it is listed as a class 2 solvent. Specific limits for individual solvents can be found in the FDA Guidance.⁷

The tasks that the chemical development team must execute are described below and that discussion is roughly patterned after the current requirements suggested by the ICH guidelines for a common technical document (CTD), summarized in M4Q.⁸ This and related FDA guidance documents provides the framework for assembly of regulatory documents in a format that permits effective review by both US and international agencies of the application for approval to market the drug.

2.05.2.1 Regulatory Tasks for Drug Approval

The major sections of the CTD that concern the chemical development team are those covering ‘drug substance.’ Within that major section are a number of sections and subsections that describe all elements of the chemical process, analytical methods, characterization of materials, and requirements of cleaning processes.

2.05.2.1.1 Drug substance physical and chemical properties

The first section of a CTD covers nomenclature, chemical structure, and physicochemical properties of the drug substance. One is required to provide the International Union of Pure and Applied Chemistry (IUPAC) name of the agent and the US Adopted Name (USAN) as well as any common names for the material. A standard graphical representation of the structure is presented along with general physicochemical information about the material. The properties described should include spectroscopic properties, for example ultraviolet/visible spectrophotometry (UV-Vis), melting or degradation range, and solubility properties. The rotation for optically active substances should be provided as well as pK_a 's if appropriate. The morphology of a solid drug substance must be evaluated for APIs destined for solid dosage forms of drug products. In the case of solution drug products (oral liquids or those destined for

Table 1 Solvent classification for pharmaceutical products

<i>Class 1 solvents</i>	<i>Class 2 solvents</i>	<i>Class 3 solvents</i>
Benzene	Acetonitrile	Acetic acid
Carbon tetrachloride	Chlorobenzene	Acetone
1,2-Dichloroethane	Chloroform	Anisole
1,1-Dichloroethene	Cyclohexane	1-Butanol
1,1,1-Trichloroethane	1,2-Dichloroethene	2-Butanol
	Dichloromethane	Butyl acetate
	1,2-Dimethoxyethane	tert-Butylmethyl ether
	<i>N,N</i> -Dimethylacetamide	Cumene
	<i>N,N</i> -Dimethylformamide	Dimethyl sulfoxide
	1,4-Dioxane	Ethanol
	2-Ethoxyethanol	Ethyl acetate
	Ethylene glycol	Ethyl ether
	Formamide	Ethyl formate
	Hexane	Formic acid
	Methanol	Heptane
	2-Methoxyethanol	Isobutyl acetate
	Methyl butyl ketone	Isopropyl acetate
	Methylcyclohexane	Methyl acetate
	<i>N</i> -Methylpyrrolidone	3-Methyl-1-butanol
	Nitromethane	Methylethyl ketone
	Pyridine	Methylisobutyl ketone
	Sulfolane	2-Methyl-1-propanol
	Tetrahydrofuran	Pentane
	Tetralin	1-Pentanol
	Toluene	1-Propanol
	1,1,2-Trichloroethene	2-Propanol
	Xylene	Propyl acetate

injection), morphology is not a concern. As the API is already in solution, the crystalline form of the solid is irrelevant unless it is a concern for dissolution during the manufacturing of the formulated product. The evaluation should define the crystalline form using optical microscopy and provide information concerning polymorphs – different crystal lattice forms of the same chemical agent. Understanding the polymorphic form of the drug and controlling that precise arrangement of molecules within the crystal during production and storage of the bulk active ingredient aid in an understanding and definition of the rate of dissolution of the drug in the body.⁹ The rate of dissolution has a substantial effect on the rate at which the drug is delivered to the patient. In addition to the role the polymorph of a drug has on the patient, polymorphs are patentable as unique compositions of matter. Thus there are economic reasons to consider polymorphism in addition to safety and efficacy concerns.

In addition to the polymorph of an API having an impact on bioavailability, particle size can also have a tremendous impact on the efficacy of a drug in a human. Different particle sizes dissolve at differing rates, causing the drug to be

delivered to its site of action at different rates. During process development, consideration should be given to the appropriate crystallization conditions as well as the need to modify the bulk particle size.¹⁰ The latter can be accomplished through various milling, micronization, or sieving techniques. As with morphology, particle size is of particular concern for drugs that are to be administered as solids. It is much less important for drugs that are administered orally in solution or parenterally.

The names and addresses of the manufacturer(s) of the drug substance and all subcontractors involved in the work should be provided. Approval to manufacture a given product also mandates the site(s) of manufacture and the specific types of processing equipment that can be used. While these points are at the discretion of the applicant, they must be included in regulatory filings. The sites and type of equipment that are employed can be changed, but most such changes require revalidation of the process, updates to regulatory filings, and approval from regulatory agencies before product incorporating the changes can be sold.

The next section details the manufacturing steps for the drug substance. A flow diagram for the process should be provided along with a written description of the synthetic route. The specific type of equipment used is presented in this section. Examples might include a description of the type of reaction vessels, for example a glass-lined vessel; and isolation equipment utilized, for example, isolation via centrifugation. A critical component of the section is the description of the in-process controls (IPCs) used in the process to assess progress of a reaction or quality of an isolated intermediate. Typically, each step of the process is monitored to assure completion of the step without buildup of untoward impurities or degraded material. Ideal IPCs to monitor reaction progress are information-rich, reproducible, accurate, and easily executed by a chemical operator in a plant setting. A typical IPC to monitor reaction progress might include the conduct of a chromatographic test to assess progress of the reaction. This might be a thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), or gas chromatography (GC) analysis. Visual tests can often be effective tools. For example, a color change might be an indication of reaction completeness (presence of the blue color of Na^0 in liquid ammonia to signify excess sodium in ammonia in a sodium–ammonia reduction). Often spectroscopic methods such as UV or infrared spectroscopy are employed. Occasionally pH can be used as an indication of reaction progress.

The specifications for the quality attributes and manufacturers of the key starting materials should be included in the manufacturing section together with the analytical methods used to evaluate them. In addition to key starting materials, the manufacturing section should provide a discussion of the specifications for reagents, solvents, and ancillary materials.

This section of the CTD also presents the rationale for the definition of the starting materials for the process. The team preparing the filing would generally like to define the starting materials as late in the synthetic sequence as possible. Materials used in the production of an API and which are incorporated as a significant structural fragment into the structure of the API are commonly defined as ‘API starting materials.’ They are often separated from the API by several synthetic steps.

An API starting material should be an article of commerce or it should be well described in the chemical literature. It can be a material purchased from one or more suppliers under contract or commercial agreement, or alternatively, an API starting material might be produced in-house.

The approach of defining starting material as an advanced intermediate in the scheme affords maximum flexibility in sourcing those materials. It further allows changes to be incorporated in the manufacture of that compound without regulatory impact provided that testing demonstrates that no new impurities are generated. In general, it is advisable to define an API starting material and ensure that the position that has been taken is agreeable to the FDA and other regulatory bodies through discussions of the definition with those agencies prior to filing documents for regulatory approval. This approach avoids costly surprises late in the registration process. GMP requirements do not apply to steps prior to the defined API starting material.

Starting materials, reagents, and intermediates, final APIs, as well as packaging materials and processing aids all require well-defined specifications and appropriate analytical evaluation to control the attributes of the materials used to produce drug substances. These specifications and tests should be information-rich and should provide data that assure that the materials introduced into the process are of suitable quality to afford API that meets the clinical requirements. In general, specifications for late-stage intermediates are more critical than for those of early-stage materials or common reagents. The intent is to provide appropriate characterization of the material to determine suitability of the material for the next step in the process.

Setting specifications for the final API requires careful thought. At the stage of toxicology studies, material should be of the minimum level of purity acceptable for evaluation and contain all likely impurities that might be encountered as the process is scaled. The reason for this is that, as a process is scaled, equipment is changed from laboratory glassware to fixed equipment in a plant. With unit operations in a plant often requiring longer times than typically

found in the laboratory, impurities can build up and purification can become an issue. In a medicinal chemistry laboratory, there are many easy-to-manage techniques available to purify an agent. Flash chromatography is a very common laboratory technique, as an example. As noted, these operations become more challenging in the plant setting. Additionally, many plant operations are conducted with technical-grade solvents rather than American Chemical Society (ACS) materials. An ACS-certified material indicates that the reagent meets all of the specifications and requirements found in *Reagent Chemicals*, published and periodically revised by the ACS while 'technical-grade' materials meet less stringent requirements and, as a consequence, are less expensive. Decisions about solvent and reagent requirements should be considered at an early stage of the program. Typically, for toxicology studies, the API should be in the range of 96–98% pure. As the process is refined and more is learned about the material, the purity should be increased to a level above 98% purity. While it might be straightforward to prepare the first few hundred grams at a level of purity of greater than 99% pure, this can prove very limiting, as larger amounts are needed. Bridging toxicology studies are required if new impurities are introduced into the API. Such studies are quite costly, in terms of both time and money.

Critical parameters should be determined by experiment and scientific judgment and typically should be based on knowledge derived from research, scale-up batches, or manufacturing experiences. Prior to validation, the appropriate range for each critical process parameter that will be used during routine manufacturing should be defined.

2.05.2.2 Statistical Evaluation of Process Variables

In the 1920s the British geneticist and statistician Sir Ronald Fisher developed the initial concepts of statistical design of experiments, also referred to as design of experiments or DoE.¹¹ These concepts provide a formal, rigorous framework to rationally design a set of experiments to relate the quantitative effect of variation of specific parameters with the resulting measured response(s) analyzed using statistical methods. The original concepts were put forth to meet the needs of agricultural experimentation with which he and his colleagues were involved. The basic idea was that there is a simple underlying geometric structure to such experimentation. Fisher and his colleagues further developed the statistical methods and analyses that became the standard procedures of the discipline.

Many chemists are unfamiliar with the techniques. Workers at DuPont were instrumental in moving these concepts into the chemical industry and taught these techniques to many outside organizations, beginning in the 1970s.¹² DoE has been shown to be quite useful in the identification of appropriate ranges for critical parameters in a chemical process. The method allows multidimensional space to be probed and considers the effect of variation of one parameter on other parameters in the process. It is also very efficient, using a statistically based mathematical model to generate the interaction of a very large number of parameter interactions through variation of multiple parameters in a single experiment.

Fortunately, there are a number of commercial, off-the-shelf software products available so that the practicing process chemist does not need to become an expert statistician to use these effective techniques. Many in the pharmaceutical industry have used Fusion Pro, developed by S-Matrix, with success. This software is commercially available and parameters such as temperature can be monitored directly by computer. Parameters that might be considered include reaction temperature, mixing rate, cooling rate, and ratio of reagents utilized in the process. While the DoE approach appears complicated at first, that approach proves to afford much more information with fewer experiments than a traditional linear approach where a single variable is explored in a single experiment. When unexpected results are obtained, it is quite probable that some parameters that were not considered critical to the manufacturing process in the initial experimental design are indeed critical.

Parameters that have been determined to be critical process parameters should be controlled and monitored during process validation studies. Process validation should confirm that the impurity profile for each individual lot of API is within the limits set in the specifications and is comparable to, or purer than, the profile of material used for toxicological and pivotal clinical studies.

A written set of documents detailing the strategy planned for process validation should be in place and followed for validating the manufacturing processes for the API. The purpose of the study is to ensure that the manufacturing process that has been developed is reliable and provides product that is consistent and homogeneous, and meets the predetermined set of specifications. Among the attributes of the API that should be considered are purity, qualitative and quantitative impurity profiles, physical characteristics, including particle size, density, and polymorphic form, moisture and solvent content, homogeneity, and microbial load. For drug substances destined for injection, bacterial endotoxin or pyrogen testing is also required.

The protocol should define the scope and purpose of process validation. The number of process validation batches to be prepared should be addressed. The number of complete batches to be prepared under the protocol is typically

three consecutive successful runs. Given the high value of many APIs, it is acceptable to have executed only one run at the time of the FDA preapproval inspection (PAI) with a commitment to complete the subsequent batches successfully prior to launch. This is referred to as 'concurrent validation.' Analytical test methods that will be used are listed. Often, a number of additional analytical tests are performed during validation that might subsequently be eliminated. An example of an analytical test method that might be used during validation but not during routine product release could be an x-ray analysis to examine polymorphic form. These data are collected under protocol, and if the results obtained during validation are consistent, subsequent x-ray analysis of the product would not be required. A detailed discussion of the chemical transformations, unit operations, and a process flow diagram should be included. The description of the unit operations should include all major processing equipment to be used as well as appropriate qualification of the equipment. Equipment qualification can be directly incorporated into the validation protocol or by reference to prior reports. Based on the parametric studies that were executed, the critical process parameters and operating ranges must be described. The protocol should include plans for product sampling. This includes a description of sampling points, frequency of removing samples, quantities of each sample required, and procedures for collecting samples.

The protocol needs to define criteria by which the executed validation will be deemed acceptable. Deviations from the plan must also be documented. The plan should also describe what measures will be taken in the event of a failure. It is wise to execute at least one full-scale batch using the proposed batch production records prior to initiating validation. This is often referred to as a demonstration batch. This affords confidence that the production procedures, test methods, and specifications have been appropriately defined. Validation should be conducted prior to the commercial distribution of an API and when there have been significant changes to the manufacturing procedure.

2.05.2.3 Cleaning of Equipment and Facilities

This is an appropriate juncture to discuss cleaning procedures.¹³ These procedures involve equipment-cleaning as well as facility-cleaning. There are three types of contaminants that can adulterate an API: (1) physical contamination (particulates); (2) biological contamination (bacteria, yeast, and mold; also called 'bioburden'); and (3) chemical contamination (cross-contamination).

The physical facility, including the heating, ventilation, and air conditioning (HVAC) system and associated particulate filtration should be of an appropriate design and be able to be cleaned. The facility should also be monitored to demonstrate that it is reasonably free of microbial contamination. The API itself is also evaluated to insure that it has an appropriately controlled level of bioburden. Subpart C of 21 CFR part 211 details the requirements for facility design.

Cleaning of multi-use manufacturing equipment requires detailed and validated cleaning procedures and analytical methods. The potential limits for product carryover into subsequent batches should be considered when setting limits for the appropriate level of cleaning of the equipment. With the exception of penicillin analogs and other extremely sensitizing agents, which should be manufactured in dedicated facilities, the regulatory agencies offer little firm guidance on an appropriate level of decontamination of facilities and equipment that must occur. Limits that are set for carryover should be 'logical,' 'practical,' 'achievable,' and 'verifiable' according to regulatory agencies. Often, an appropriate approach to setting a limit for permissible amount of carryover is based upon pharmacologic data for a particular material. The limit is set to allow a maximum carryover of 1/1000 of the usual therapeutic dose to be present in a dose of the subsequent product based on the assumption that such a low dose would have minimal effect on a patient.

If the process train, or set of equipment used to produce a material, is to be used to produce the same product multiple times in that process train, a 'minor cleaning' procedure between batches is required. A 'minor cleaning' is also appropriate if the process train is used to conduct the next step in a chemical sequence to produce a product. The cleaning process used in this case should be effective for the removal of process residues. For the purposes of minor cleaning, however, a visual inspection demonstrating that there is no material remaining in the process train is all that is required to insure that the cleaning process has been effective.

Process equipment in a chemical plant is seldom dedicated, as such equipment costs millions of dollars to design and install. Typically, therefore, process equipment will be used for a variety of different products and 'major cleaning' processes must be developed and validated by executing three successful, successive cleaning operations. This includes analytical verification that the process was effective. The procedure might involve aqueous conditions, including a detergent, which is itself a potential chemical contaminant. If detergents are used, their absence after cleaning must be verified using an appropriate and validated analytical method. Organic solvents and physical methods are excellent choices for cleaning. Process equipment for the pharmaceutical industry is designed to have minimal dead

zones where materials can collect; however, there are still some areas where residue can remain. These areas include seams or valves. The cleaning program should include an evaluation of those difficult-to-clean areas. The delineation of hard-to-clean sites can be predicted based on prior experience; however a formal challenge is preferable. Often, equipment will be coated with a nontoxic, surrogate material which is easy to visualize using either visible or UV light. Riboflavin is an example of such a surrogate. The cleaning procedure is executed and the equipment is inspected to assess the effectiveness of the cleaning procedure. Most of the agent will have been removed, but it is not unusual for material to be observed in valves, seals, and other difficult-to-clean areas.

Once a piece of process equipment has been cleaned, the cleanliness must be verified. Equipment can be swabbed; a direct sampling of the surface of the processing equipment, to demonstrate the validity of the cleaning process. It can also be rinsed to evaluate the effectiveness of a given cleaning procedure. The swabs and rinses can then be evaluated by analytical techniques that are preferably specific to the given product to be removed from the equipment. Appropriate analytical methods include HPLC or a UV-Vis analysis. Under certain conditions, an analysis of total organic carbon might be appropriate; however, that type of an analysis is not material-specific and is predicated on the materials to be evaluated being soluble in water. The methods for these analyses must be validated (*vide infra*). As part of the cleaning program, swab and rinse transfer efficiencies and material solubility must be evaluated. Typically, small coupons of the surface being cleaned (Teflon, glass, or stainless steel, for example) can be evaluated in the laboratory to determine the efficiency of the transfer of the analyte to the swab and subsequently from the swab to the analytical medium.

2.05.2.4 Analytical Methods

The analytical techniques used to characterize fully the API are very important topics to address. While simple spectroscopic techniques and elemental analyses are sufficient in a medicinal chemistry laboratory, regulatory agencies require a much more elaborate data set to register a drug. A typical set of analytical methods for full characterization of the material might include IR, nuclear magnetic resonance (NMR) spectroscopy (both ^1H and ^{13}C), elemental analysis, UV-Vis, mass spectrometry (MS), optical rotation, differential scanning calorimetry (DSC), HPLC, GC, residue on ignition/sulfated ash, thermogravimetric analysis (TGA), as well as an analysis of moisture in the product. x-ray powder diffraction (XRPD) for determining polymorphic form and a determination of particle size, often using a laser light-scattering method, of the solid drug substance must also be described. Again, morphology questions are irrelevant issues for APIs destined for a solution formulation but critical issues for solid-dosage forms of drug products.

2.05.2.5 Analytical Method Validation

The analytical group within the chemical development team has the responsibility to demonstrate that the analytical methods developed for a particular drug substance are validated.¹⁴ The methods employed must be shown to be accurate, precise, linear, sensitive, specific for a given material, and reproducible. Analytical methods are progressively optimized throughout the development cycle. For the purpose of the investigational new drug application (IND), a method that has been developed at a rudimentary level is adequate, but the method must be scientifically sound, consistent with ICH Q7A. As with the synthetic process, optimization continues throughout the development cycle. All analytical methods should be fully optimized and validation completed prior to initiation of phase III trials. By completing these activities in advance, the chemical development team minimizes the potential for erroneous results in clinical trials, when many patients are involved and many dollars are at stake.

Prior to each analysis of a drug substance, there must be an evaluation of the analytical system suitability. This is an established procedure that ensures that the equipment, analytical procedure, and samples to be analyzed are working properly at the time of analysis. System suitability parameters should be defined and included as an integral section of the analytical procedure.

As with all validation activities in the pharmaceutical industry, a validation protocol should be developed prospectively after a thorough set of experiments has been executed to define appropriate conditions for the analysis. That protocol details the specifics of the acceptance of successful execution of the validation.

The process of validation of an analytical method generally demonstrate properties of:

- specificity: ability to measure desired product in a complex mixture;
- accuracy: agreement between measured and real value;
- linearity: proportionality of measured value to concentration;
- precision: agreement between a series of measurements;

- range: concentration interval where method is precise, accurate, and linear;
- robustness: reproducibility under normal but variable laboratory conditions;
- limits of detection: lowest amount of material that can be detected;
- limits of quantitation: lowest amount of material that can be measured.

2.05.2.6 Impurities

A detailed discussion of impurities found in the API is also required. This discussion should include a listing of impurities that are introduced from the starting materials, reagents, and solvents, as well as those arising as a consequence of the mechanistic pathway of the reactions utilized in the process. Forced degradation studies of the product are useful guides in this endeavor. In addition to providing access to potential impurities that can be used as standards of the impurities found in the drug substance, forced degradation experiments demonstrate that the stability studies that must be conducted are indeed stability-indicating. By demonstrating that impurities can arise and that they can be detected with the analytical methods used, confidence is gained that those methods are stability-indicating and can be validly used in the stability studies. Modes of forced degradation include subjecting the material to high temperatures, light, or oxidative conditions. The material should also be subjected to hydrolytic conditions employing either acidic or basic conditions. Reference standards of impurities can be isolated using preparative HPLC. Typically, the structure of all impurities present in the product at greater than 0.1% should be elucidated. HPLC, MS, and NMR analyses prove to be a primary set of techniques used for this purpose.

For critical impurities, one often needs authentic materials. One approach to obtain the standards is independent synthesis of the suspected impurities. This can be a time-consuming endeavor. Alternatives that can be employed include using preparative HPLC to isolate the desired impurities from the drug substance. Often, the residual solvents used for precipitation or crystallization of a material that contains the impurities (that supernatant is also called a 'mother liquor') or other operations conducted during the synthesis of the API are rich sources of such materials.

2.05.2.7 Reference Standard of the Drug Substance

The primary reference standard for a drug substance is a sample of the drug substance that is generally the highest-purity material that can be prepared. An independent synthesis route is often used to prepare this standard. It may also be synthesized using the manufacturing route with additional purification steps. If an alternative synthetic strategy was utilized, it must be described in detail. If the usual route of synthesis is employed, the material should be purified by additional crystallizations or by chromatographic purification and these should also be detailed in the CTD. The primary reference standard must be shown to be the desired chemical structure by a very detailed chemical analysis. This involves analytical testing above and beyond the requirements for normal testing and release of material. The reference standard is maintained as the benchmark against which all working standards are qualified.

Working standards of authentic materials are prepared from routine manufacturing batches of material. The purity of working standards is determined by direct comparison with the primary reference standard. This material is used as the standard for testing and release of routine production batches of drug substance. As with the primary reference standard, additional analyses are required to establish the attributes of this material versus routine release.

2.05.2.7.1 Stability of the active pharmaceutical ingredient

Formal, documented studies to provide experimental data to justify all holding times for intermediates as well as to support the proposed API expiration or requalification date must be conducted.¹⁵ Analytical methods should be validated and shown to be stability-indicating prior to initiating stability studies for regulatory filings to ensure that the results of the studies are meaningful. The APIs used in stability studies should be packaged in a comparable fashion to the manner that the bulk API will be stored (*vide infra*). While three representative batches of material must be evaluated in the stability study, the batches do not have to be prepared at full manufacturing scale. Rather, pilot batches produced using the same synthetic procedures and process can be used to provide material to support a regulatory filing. Small-scale batches can be utilized to manage cash flow as manufacturing at full scale is quite costly. Companies often do not want to manufacture a large number of full-scale batches until approval appears imminent. A commitment is made at the time of filing to subject the first three full manufacturing batches to ongoing stability studies as well as an additional batch per year thereafter. Many products are stable under ambient conditions and typical stability studies are conducted under the conditions presented in [Table 2](#).

Some APIs, however, are unstable under ambient conditions and lower temperature storage conditions are required. [Table 3](#) presents standard storage conditions for materials to be stored under refrigerated conditions and [Table 4](#)

Table 2 Typical conditions for ambient stability studies complying with ICH guidelines

<i>Study</i>	<i>Storage conditions</i>	<i>Minimum time period covered with data at time of submission</i>
Long-term	25 °C ± 2 °C/60% RH ± 5% RH or 30 °C ± 2 °C/65% RH ± 5% RH	12 months
Intermediate	30 °C ± 2 °C/65% RH ± 5% RH	6 months
Accelerated	40 °C ± 2 °C/75% RH ± 5% RH	6 months

RH, relative humidity.

Table 3 Typical conditions for refrigerated stability studies complying with ICH guidelines

<i>Study</i>	<i>Storage conditions</i>	<i>Minimum time period covered with data at time of submission</i>
Long-term	5 °C ± 3 °C	12 months
Accelerated	25 °C ± 2 °C/60% RH ± 5% RH	6 months

RH, relative humidity.

Table 4 Typical conditions for freezer storage stability studies complying with ICH guidelines

<i>Study</i>	<i>Storage conditions</i>	<i>Minimum time period covered with data at time of submission</i>
Long-term	− 20 °C ± 5 °C	12 months
Accelerated	25 °C ± 2 °C/60% RH ± 5% RH	6 months

details conditions used for standard freezers. If one requires still lower temperatures, those must be dealt with on a case-by-case basis. Stability studies include ‘accelerated conditions’ to provide an early indication of product instability. Additionally, one should consider the effect of potential temperature excursions that might arise during shipping and design specific experiments to demonstrate that the material is stable during its travels. Stability studies are only required to be long enough to support proposed length of API storage. Typically, 2 years of stability data are adequate; however, for very-low-volume products, stability studies might be extended for up to 5 years.

The frequency of analysis during a stability study should establish the stability profile of the drug substance. For drug substances with a labeled stability of greater than 12 months, analysis of long-term storage samples should be every 3 months during the first year, every 6 months during the second year, and annually thereafter through the proposed length of the study. Evaluation of all attributes for the assigned specification is not necessary at all time points. Rather, a subset of stability-indicating tests is conducted at intermediate time points and the full set of assays is only executed at the initial time point, typically the original release date, and at the end of the study. Intermediate assays might include identity by IR, purity using HPLC, and moisture analysis. Attributes such as microbial load and residue upon ignition are not expected to change during storage and are thus only evaluated at the beginning and the end of the study.

For intermediate and accelerated storage conditions, a minimum of three time points, including the initial and final time points (e.g., 0, 3, and 6 months) for a 6-month study are appropriate. If the material appears to be decomposing, the intermediate and accelerated studies should be extended to define the limits of stability of the API.

2.05.2.7.2 Packaging

Packaging of the API is a detail often taken for granted in a discovery laboratory. Typically, in a research laboratory, one has easy access to a variety of small vials. In a plant setting, however, the quantities stored are substantially larger. While glass bottles might prove acceptable for hundreds of grams or even a small number of kilos of material, generally packaging options for bulk drug substances include plastic or lined drums, or large totes. The materials of construction of packaging material must be compatible with the materials being stored. As noted, the same material of construction,

closure system, and configuration should be used for stability studies as will be used for storage and shipping of the material. As an example, small plastic bags sealed with twist ties in fiber drums might be utilized for the stability study if the packaging configuration for commercial materials is to be plastic bags sealed with twist ties inserted into fiber drums.

2.05.2.8 Reprocess and Rework of Materials

Reprocessing and reworking are not issues that often arise during the development cycle but can become very serious issues postapproval. On presumably rare occasions, a batch of an intermediate or a final API fails to meet the required specifications. Regulatory agencies recognize that there is a tremendous amount of value in each batch and those agencies do permit reprocessing and reworking operations to be executed. These operations are distinct both operationally and from a regulatory perspective.

Reprocessing is defined as resubjecting the material to identical conditions detailed in process description. Reprocessing might involve the addition of fresh reagents or solvents to unreacted material if an in-process test demonstrates that a reaction is incomplete. It could also be the repetition of a purification operation such as a crystallization step or a distillation that are part of the established manufacturing process.

There is a risk for formation of by-products during a reprocessing operation as the material could be subjected to additional warming or oxygen during the operations. Any reprocessing should involve an evaluation by the process, manufacturing, and quality teams to be certain that the quality of the material is not adversely impacted and that the potential formation of by-products is considered.

If reprocessing is required for many batches, the process might in reality be out of control. If the reprocessing always affords material that meets the specification, the reprocessing operation should be incorporated into the standard manufacturing process.

Subjecting out-of-specification material to a process that is not part of the established manufacturing procedure is defined as a reworking process rather than a reprocessing operation. For example, a rework might include a crystallization from a solvent not typically found in the original manufacturing process. Prior to reworking materials, a formal investigation led by the quality team into the origins of the nonconformance should be conducted and the issues causing the problem should be identified. Batches that have been reworked should be tested to demonstrate that the material has the same analytical attributes as material arising from the original process. In particular, a very detailed analysis of the impurity profile of the reworked material is required to demonstrate that no new impurities were introduced and that the material is of the same quality as the material produced by the original, validated process. Stability testing will be required for materials produced through a new, rework process. The new process will also require formal validation. In this case, concurrent validation of the process can occur during the actual execution of the process. As with all validation activities, the generation of a protocol is required, describing the rework procedure and defining the expected results. If there is only one batch to be reworked, a report can be written and the batch released once the material has been shown to be acceptable.

2.05.3 Development Chemistry Timeline

As can be seen from the discussion of the tasks that the chemical development team must execute prior to achieving regulatory approval, there is a tremendous amount of work required. The entire development process, however, takes some years and the tasks can occur in a programmed fashion, which also affords effective management of cash flow.

Figure 1 graphically depicts the critical tasks for the chemical development team and the phases of development at which the tasks should be executed. The timeline from biological concept to approved product is often 10 years or more. The process development team's involvement typically begins at the stage when a novel chemical agent is elevated to the status of a drug candidate. At that time, larger quantities of materials are required for toxicological evaluation. The amount of material required at this point is typically in the range of hundreds of grams to many kilos. The amount of material required is determined by the potency of the candidate, the proposed therapeutic indication, and dosing schedule of the drug.

While the analytical characterization of the material tends to be rudimentary at the stage of toxicology studies, it is very important to understand enough about the molecule and its properties such that the data generated during toxicology studies are meaningful. As such, analytical methods, in particular, HPLC methods used for an assessment of the purity of the drug substance, should be linear, precise, reproducible, and have an established limit of detection. The methods are likely to be refined throughout the development cycle. Therefore, while a fully validated analytical method is not needed at this time, the data must be justified from a scientific perspective. It is also necessary to understand the morphology of the product at this point if the product is to be administered from a solid delivery system.

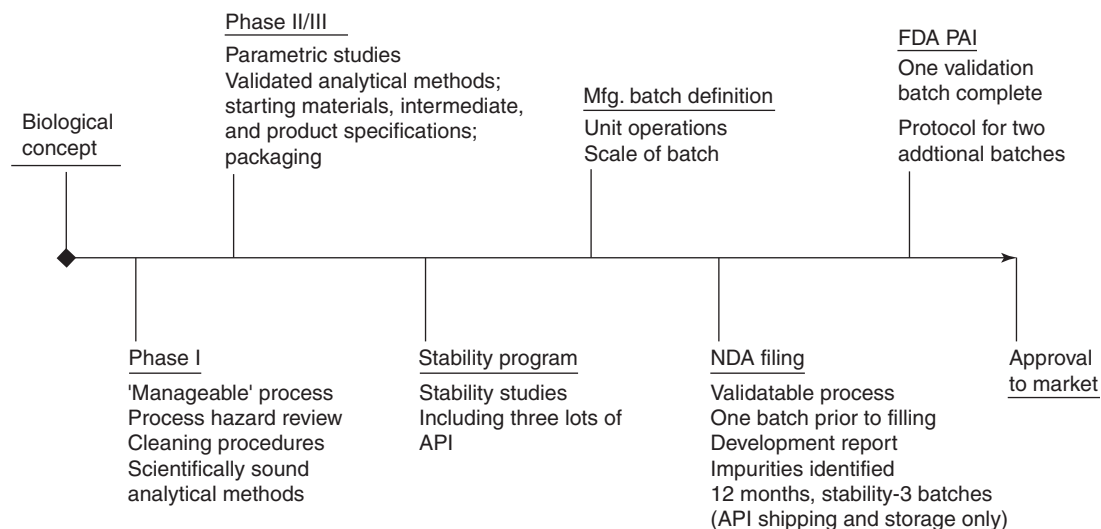

Figure 1 Development chemistry task timeline.

When the compound has been shown to have an appropriate safety profile in animals, human evaluation is set to begin. As one begins human evaluation of the product, a process that is manageable at a multi-kilogram scale is often required. As the scale moves into the range of kilograms, it is an appropriate time to consider in detail the safety of the chemical operations. Under certain conditions, the Occupational Safety and Health Administration (OSHA) mandates that a formal process safety management (PSM) program be implemented, as large quantities of chemicals are used.¹⁶ The regulations provide specific guidelines as to when such a PSM evaluation is required and the rules are dependent on very specific amounts of materials used in a process. For example, a PSM evaluation is required when 100 lb or more of propargyl bromide is to be used, while such analysis for hydrogen chloride is not required until a threshold limit of 5000 lb is to be used in a process. Even when a formal PSM is not required, many elements of the program should be considered as an integral part of good business practices. In particular, an initial process hazard analysis (PHA) should be conducted by a team including representatives from engineering, operations, and individuals who have hands-on experience in executing the process prior to preparing material on the kilo scale. This analysis is a systematic evaluation to identify and analyze the significance of potential hazards associated with the proposed chemical process. Typical factors considered in a PHA are the potential for a fire, an explosion, and various chemical releases. Issues discussed should include an evaluation of the equipment to be used in the process, instrumentation, utilities, and the potential for human error. This analysis also specifically addresses potential failure modes in a proposed synthetic process.

From the perspective of cGMP compliance requirements, at the stage of phase I clinical trials, cleaning procedures must be considered and protocols should be developed; however, the methods need not be validated. As described above, the analytical methods should be sound; however, the final set of cleaning methods and assays has probably not been defined at this stage of the program.

As the clinical data for phase I are analyzed and the candidate is elevated into phase II clinical trials, the process must be refined and should substantially resemble the process proposed for use in the manufacturing setting. Parametric studies should be initiated to defend the proposed ranges for temperature, mode and time for reagent addition, stirring rates, holding times, and any other process parameters that have been deemed critical from the studies by process chemistry and engineering.

As phase III clinical trials are initiated, the process and analytical methods should be locked and preparation for the assembly of the new drug application should be underway. Analytical methods should be validated and formal stability studies should be underway using three separate lots of API. The formal development report covering all aspects of the chemical process and impurities should be assembled. This report will be evaluated by regulatory agencies during the inspection process.

Once the new drug application has been filed, the FDA or foreign regulatory agencies, depending on where regulatory filings have occurred, will typically conduct a PAI of the facilities. At the time of the inspection, regulatory agencies expect that the first batch of API at full scale, manufactured according to the validation protocol, will have been complete and that the material will have been released. The validation protocol must include plans to complete at least three batches according to that protocol. Regulatory agencies understand the expense of executing multiple

batches. Some firms elect to postpone execution of the remaining validation batches until approval appears imminent. More conservative companies will execute all three batches prior to an inspection to assure themselves that no untoward events occur.

As the new drug application review process occurs, the process is typically formally transferred from the process development team into the manufacturing department. Collectively, those teams with input from those responsible for evaluating the size of the market and thus demand for the product postapproval must ensure that enough material is available to support a successful product launch.

While changes to the process, methods, type of processing equipment, and site of manufacture can be initiated at any point, it is important to remember that these changes require a detailed understanding of the regulatory process. It is wise not to initiate such changes during the new drug application approval process. Depending on the scope of the changes involved, new validation studies will be required, as will completion of additional stability testing with the API that resulted from incorporation of those changes. The material incorporating any changes will need to be shown to be equivalent to the original API. Agencies understand product lifecycle management and allow such changes; however, adequate time must be allowed to obtain proper regulatory approval.

In summary, there are many tasks that must be executed for a successful approval of a new drug application. The tasks are logical and follow a scientific progression. Attention to the details and well-executed science will ensure success in the approval process.

Biography

Stephen A Munk, PhD, is the President and CEO of Ash Stevens Inc. (ASI), an organization serving as an API development and manufacturing contractor operating in the state of Michigan. Dr Munk is a member of its board of directors. He has experience in drug discovery, development, and manufacturing, both as a scientist and as a manager.

Prior to joining ASI in 1997, he worked at Allergan, Inc. in the area of drug discovery, focusing on adrenergic agents. Ash Stevens Inc. received nine FDA approvals to manufacture APIs under his leadership through 2005. These include bortezomib, clofarabine and 5-azacitidine during the period of 2003–04. Dr Munk's work has been summarized in a number of publications and patents covering topics in medicinal chemistry and process development. He received his PhD in organic chemistry from the University of California at Berkeley under Henry Rapoport's guidance and he was an American Cancer Society Postdoctoral Fellow, conducting studies in medicinal chemistry and molecular biology, at Purdue University in Dale Boger's laboratory. Dr Munk also serves as an adjunct Associate Professor at Wayne State University. His activities at Wayne State are in the Departments of Chemistry and Medicinal Chemistry.

2.06.1 Introduction

Over the last 50 years, many important new drugs and new classes of drugs have been developed, which have undoubtedly contributed to the battle against serious illnesses, prolonging the average life expectancy and improving quality of life. Nonetheless, there are still several areas of medicine in which new pharmaceutical weapons are needed:

- viral infections (e.g., respiratory tract infections, viral hepatitis, acquired immune deficiency syndrome (AIDS), etc.)
- control of neoplastic growth

- degenerative diseases of the central nervous system (CNS) (e.g., Alzheimer's and Parkinson's disease, multiple sclerosis)
- muscular dystrophies
- infections caused by bacteria resistant to antimicrobials, which are increasing in frequency
- malignant vomiting syndrome during pregnancy (drugs without adverse effects on the pregnancy or embryo/fetus)
- nonaddictive pain control
- rheumatoid arthritis
- control of the side effects of glucocorticoid therapy

Over the past decade, the search for new drugs has become a frantic race to identify biological targets, hits, and leads, and to develop them as rapidly as possible.^{1–5}

The identification of a new chemical entity (NCE), i.e., a medication containing an active ingredient that has not been previously approved for marketing in any form, as a 'lead' requires important decisions. An initial series of preclinical studies will be necessary to define the lead's fundamental characteristics, confirm its validity, and evaluate the prospect of its further development. If the decision is made to proceed, the molecule will be evaluated in preclinical pharmacotoxicological studies, which are a prerequisite for requesting authorization to proceed with additional studies in humans (claimed investigational exemption for a new drug: IND). Development of the NCE then proceeds through phases I, II, and III, and continues, after the new drug application (NDA) has been approved by the US Food and Drug Administration (FDA), with the postmarketing surveillance (PMS) of phase IV (Figure 1).⁶

The pages that follow will provide a detailed analysis of the R&D process and highlight some of the possibilities offered by new technology for accelerating this process and hopefully reducing its costs.

It must be stressed at this point that R&D of an NCE requires a substantial investment of private capital, with the objective of obtaining realistic returns within an acceptable period of time. According to stock market analysts, a drug that can be considered a 'blockbuster' should generate sales exceeding \$1 billion a year,⁵ while costs for the realization of an innovative NCE currently range from \$800 million to \$1 billion (see below). The identification of the target, selection of the lead, and every subsequent step in the development process are thus tied to the producer's strategy – corporate strategy, business strategy, R&D strategy, and portfolio.⁵

There are three basic types of R&D projects, each with its own costs and research commitments:

1. Innovative research: a project that will lead to the development of a drug with greater efficacy (e.g., the statins, which were more effective than earlier lipid-lowering drugs) or greater efficiency (in terms of a more convenient route of administration, less frequent dosing, and/or better tolerability than earlier drugs used to treat the same condition).
2. Innovative improvement (also referred to as 'enlightened opportunism'⁷): these projects produce a drug with higher potency, less frequent dosing, and/or greater selectivity than those currently used for the same purpose (e.g., the selective β_1 -blocker, atenolol, versus nonselective $\beta_1\beta_2$ -blockers like propranolol).
3. Me-too projects (or 'unenlightened opportunism'⁷): these efforts involve justifiable improvement of a drug, a new NCE that can be patented, but no substantial originality.

2.06.2 Discovery and Development of a New Chemical Entity

2.06.2.1 Hits and Leads

Traditionally, drugs were discovered by testing compounds synthesized in time-consuming multistep processes against a battery of in vivo biological screening tests.⁸ Today's environment calls for rapid screening, hit identification, and hit-to-lead development.⁹ The identification of synthetic or naturally occurring molecules as potential drug leads generally involves automated testing of large collections (libraries) of compounds for activity as inhibitors or activators of a specific biological target, such as a cell receptor or enzyme.⁹

Identification of the target is a fundamental step in the R&D of an NCE. Until a few years ago, the target was considered the 'receptor for the drug molecule,' but the term has now been expanded.¹⁰ A recent analysis of current therapeutic targets indicates that, while almost half of drugs presently on the market are directed toward cell membrane receptors (48%), close to one-third (28%) act on enzymes, and 11% target hormones or hormonal factors; the rest are directed against ion channels (5%), nuclear receptors (2%), nucleic acids (2%), or unknown targets (<7%).¹¹ Disease-linked proteins are common targets.⁵

The identification of a 'hit' and the rapid transformation of this molecule into a series of high-content 'leads' are key activities in the R&D process¹¹ (Figure 2). According to Bleicher *et al.*,¹¹ a 'hit' is a primary active compound with nonpromiscuous binding behavior that exceeds a certain threshold value in a given assay. After the hit has been subjected to an identity and purity evaluation, an authentic sample is obtained (or resynthesized), and its activity is confirmed in a multipoint determination. This validated hit is a molecule capable of producing physiologically or pathologically significant modification in a biological substrate. A lead, according to the same authors, is "a prototypical chemical structure, or series of structures, that demonstrates activity and selectivity in a pharmacological or biochemically relevant screen. This forms the basis for a focused medicinal chemistry effort for lead optimization and development with the goal of identifying a clinical candidate. A distinct lead series has a unique core structure and the ability to be patented separately."

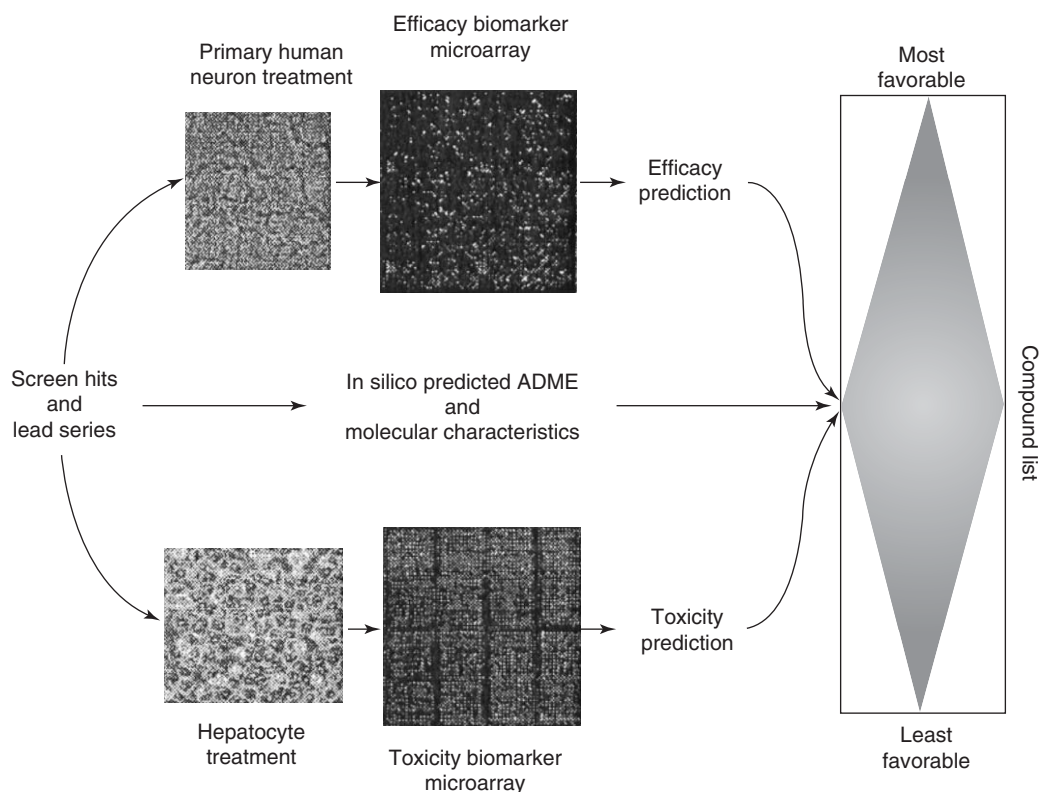

Figure 2 Application of predictive efficacy, toxicogenomics, and molecular prediction to early lead selection. Hits and lead series molecules' characteristics might be evaluated using in vitro assays of efficacy and toxicity biomarker expression, combined with in silico predictions of ADME and drug-like qualities, to prioritize compounds for further development. (Reproduced from Lewin, D. A.; Weiner, M. P. *Drug Disc. Today* **2004**, 9, 976–983, with permission from Elsevier.)

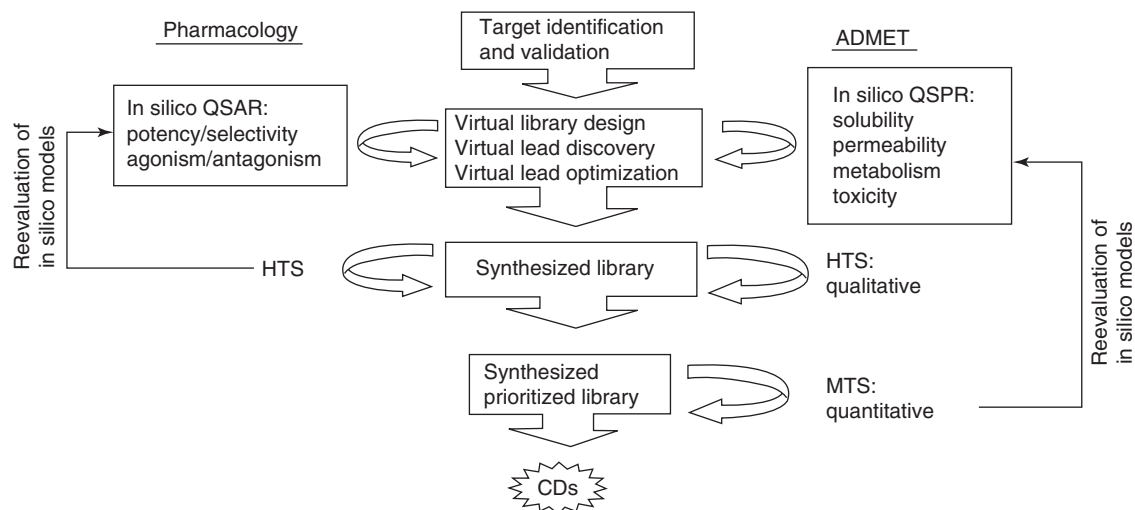

Figure 3 Knowledge-based, parallel drug discovery setting. Computational prioritization of a virtual library is followed by chemical synthesis. In silico and in vitro pharmacological and ADMET screening are performed simultaneously. ADMET, absorption, distribution, metabolism, excretion, and toxicology; CDs, candidate drugs; MTS, medium throughput screening; QSPR, quantitative structure–permeability relationships. (Reproduced with permission from Bergström, C. A. S. *Basic Clin. Pharmacol. Toxicol.* **2005**, 96, 157 © Blackwell Publishing.)

The hit identification strategies most commonly used today range from knowledge-based approaches, which utilize literature- and patent-derived molecular entities, endogenous ligands, or biostructural information, to methods based on ‘pure serendipity’ or ‘brute force,’ such as combinatorial chemistry and high-throughput screening (HTS).¹¹ The latter method involves robotized analysis of enormous libraries of natural and synthetic compounds with the aim of identifying substances potentially capable of interacting with, e.g., binding, activating, or inhibiting, specific biological targets, such as surface receptors or enzymes.^{9,13} Combinatorial chemistry allows the synthesis of large series of closely related chemicals using the same chemical reaction and appropriate reagents. These series, or libraries, can then be subjected to HTS, based largely on assays of binding to target biomolecules, to identify hits, around which more highly focused series are designed and synthesized in a subsequent round.¹³ The amalgamation of both extremes is expected to deliver more high-content chemical leads in a shorter period of time^{11,13} (Figure 3).

Once a target has been identified, its ‘druggability’ must be assessed, that is, its potential to be significantly modified by a small ligand molecule with physicochemical and absorption, distribution, metabolism, and excretion (ADME) characteristics that will allow it to be developed into a candidate drug (i.e., a lead) with the desired therapeutic effects.¹¹

As a rule, the molecular and structural properties of the lead are subjected to relatively minor modifications to produce the launched candidate drug.¹¹ In this process, knowledge of the pharmacophore is also important. Of the various definitions provided for this term,^{9,13,15} the most complete seems to be that furnished by Yamashita and Hashida:¹³ “the steric and electronic features that are necessary to ensure optimal interactions with a specific biological target structure and to trigger (or block) its biological response.”

The protein nature of the target must also be considered. Most targets belong to one of the principal classes of enzymes and proteins noted above, i.e., cell membrane and nuclear receptors, protein kinases, proteases, and protein phosphatases, although structural homologs of these proteins (with > 30% sequence identity) can also be considered as targets.¹⁶ Knowledge of the three-dimensional structure of the target protein or its homolog (especially membrane proteins, which are the most common drug targets) is essential to understand the drug’s mechanisms of action and also for rational drug design. It can be determined by means of x-ray crystallography, NMR spectroscopy, or cryoelectron microscopy.¹⁰ In this context, it is important to consider the process of computationally placing a virtual molecular structure into a binding site located on a biological macromolecule (docking) or rigidly relaxing the respective structure and then ranking (scoring) the complementarity of the fit.¹¹ The process begins with the application of docking algorithms that pose small molecules in the active site. The calculations do not succeed if they do not differentiate correct poses from incorrect ones and if ‘true’ ligands cannot be identified. The pose score is often a rough measure of the fit of a ligand into this site; the rank score is generally more complex and may serve as a substitute for binding assays.

The *in silico* approach for predicting the metabolism of an NCE includes quantitative structure–activity relationship (QSAR) and three-dimensional QSAR studies, protein and pharmacophore models, and predictive database.^{8,16} There have recently been a number of QSAR studies focusing on drugs' ability to cross Caco-2, Madin–Darby canine kidney (MDKC) cells, parallel artificial membrane permeability assay (PAMPA), which are widely used as a model of intestinal absorption.^{13,17} Filters can be installed on computers to allow ADME analysis of computationally designed drug-like molecules before they are actually synthesized. In this manner, synthesis can be reserved for those that have been predicted *in silico* to have acceptable potency and developability.¹⁷ For this type of ADME analysis, there is a need for more rapid high-throughput (HT) technology. Those that are currently available do not come within the two orders of magnitude routinely achieved for these analyses in the industry, e.g., in ligand receptor assays.¹⁸ In addition, none of the *in vitro* systems for ADME analysis has been validated thus far, although some validation is included in the long-term plans of the European Centre for Validation of Alternative Medicines (ECVAM).¹⁸ More information on ADME can be found in Ekins *et al.*¹⁹ and in the fifth volume of Comprehensive Medicinal Chemistry II.

Gene expression microarray analysis can be valuable as the basis for cell-based HTS to identify compounds that alter gene expression patterns in a particular way.²⁰ Gene expression profiling in *in vitro* cell systems, animal models, and clinical settings can all lead to the identification of additional targets that feed back into earlier stages of the drug discovery process.²⁰

Before embarking on the development of a lead, the manufacturer must be reasonably certain that the molecule can be synthesized or otherwise produced (for biological products), in accordance with good manufacturing practices (GMP) at a reasonable cost and that it can be formulated in an appropriate manner for administration to animals and ultimately humans. The drug's stability and measurability in biological matrices must also be ascertained in a preliminary manner.

2.06.2.2 Principles of New Chemical Entity Testing Prior to Human Trials

As the Nobel Prize winner, Sir James Black,²¹ has pointed out, the *nonselectivity* of an NCE may not be detectable until it reaches the development stage involving testing in intact animals. Too much combinatorial chemistry might well come to be seen as a risk factor to the corporate health. The process of preclinical drug discovery and development passes through a number of phases, ranking from the earliest activities when a therapeutic target is identified, through to animal studies preparing for the handover to clinical development and the first dose in humans.²²

According to Greaves *et al.*,²³ preclinical testing of a lead includes the following phases:

- primary pharmacology
- secondary pharmacology
- toxicology
- kinetics and toxicokinetics

Primary pharmacological studies involve a variety of experimental methods and focus on various organs and systems²⁴ depending on the type of lead and its clinical orientation. Depending on the specific characteristics of the NCE, they should include a phase of investigation at the cellular and molecular levels of its *in vitro* receptor binding (to ascertain its affinity and selectivity); its effects on enzymes that play key roles in the function of the neurons of the autonomic, peripheral, and central nervous systems (e.g., acetylcholinesterase, tyrosine hydroxylase, dopamine-3' hydroxylase, monoaminoxidase); its effects on the hepatic cytochrome P450 system (complete with *in silico* ADME modeling, when possible); assays of receptor agonism or antagonism in cultured cells; effects on neoplastic cells, microbial or fungal strains, isolated tissues, blood vessels, heart, lungs, ileum of rats or guinea pigs, diverse types of tumor cells, and antimicrobial effects. *In vitro* approaches can be used to study the concentration of free active drug at the level of the receptor. Studies have shown that a concentration capable of producing a 75% rate of receptor occupation is predictive of therapeutic concentrations for many G protein-coupled receptors,²⁸ although the specific rate required varies depending on the target disease (see later discussion of the *in vitro* therapeutic coefficient).

These activities must be supplemented by *in vivo* studies of the drug's activity in animals with experimentally induced disease, e.g., models of inflammation, neoplastic disease, infections, diabetes, atherosclerosis, depression, and dementia, and, when possible, in animals with natural or spontaneous pathology or those subjected to gene knockout, knockdown, or knockin procedures.

Secondary pharmacological studies include assessments of safety, which should focus on the cardiovascular, respiratory, immune, and central and peripheral nervous systems. The animal species most suitable for these types of studies are listed in [Table 1](#).

Table 1 Animal species suitable for evaluating the various pharmacotoxicological aspects of an NCE

<i>Organ or system affected</i>	<i>Species used for testing</i>
Central nervous system	Dogs and monkeys (better than rats, especially at high doses) ^a
Sensory organs	Rats, dogs, monkeys
Cardiovascular system	Dog (conscious or anesthetized), minipig
Gastrointestinal system	Rodents, dogs ^b better than monkeys (e.g., monkeys are more resistant to vomiting)
Kidneys	Dogs and rodents (concordance is weak)
Endocrine system and metabolism	Rodents, dogs
Bone marrow	All species: concordance is good as long as the dose is calculated in terms of mg/m ² of body surface
Coagulation	Rabbit
Skin	Pig, rabbit
Site of administration	Rabbit, pig (serum creatine phosphokinase activity, histopathology)

Adapted from various authors.^{22,24–26}

^aMice and rats are preferable for evaluating certain CNS effects (degree of sedation, muscle relaxation, motor activity, which is correlated with dizziness in humans, stimulation).

^bThe gastrointestinal tract of the dog is physiologically very similar to that of humans in terms of motility patterns, gastric emptying, and pH, particularly in the fasting state.¹³

Toxicology studies must be performed according to good laboratory practice (GLP)²⁵ and evaluate the effects of single or repeated doses of the drug on the general condition of the animal (it is important to recall that, despite careful checks, 3–5% of the animals are unhealthy at the beginning of any study²⁷), on blood chemistry parameters, blood cell morphology, and autopsy findings. These studies will be followed by in vitro tests that investigate genotoxic endpoints,²⁶ in vivo mutagenic potential,²⁴ effects on reproduction, and carcinogenesis, as summarized in **Table 2**.²⁴

These toxicological studies identify the no-effect dose and the maximum tolerated dose for single-dose administration and for repeated treatment, and the therapeutic coefficient. With reference to the duration of treatment shown in **Table 2**, a month should be sufficient to ascertain most toxic phenomena.²³

An interesting in vitro approach to evaluation of the therapeutic coefficient involves simultaneous assessment, based on measurement of appropriate parameters, of the concentration of the NCE that is sufficient to produce a therapeutic effect (e.g., 75% occupation of the target receptor), the concentration of free drug in the plasma, and the safety threshold for the parameter being considered. For instance, in studies of terfenadine, terolidine, and cisapride, close correlations have emerged between the free drug concentration in plasma, lengthening of the QT segment in dogs and humans (a very important parameter of cardiac toxicity), and the concentrations associated with in vitro blockade of K⁺ human Ether-a-gogo Related Gene (hERG) channels²⁸ (**Figure 4**). The dependence of QT prolongation on free plasma concentrations lent support to the application of a 30-fold safety multiple between therapeutic activity and concentrations causing QT prolongation.²⁸

Drugs known to affect the QT interval in humans have also been shown to affect heart rate in zebrafish embryos.^{29,30} Angiogenesis inhibitors induce specific vascular defects in the patterning of embryonic vasculature.^{29,30} There are marked species differences in the response to peroxisome proliferators: mice and rats are highly responsive, while humans respond poorly or not at all.³¹

Studies of kinetics and pharmacokinetics should verify the presence and the destiny of the drug in organic liquids (maximum plasma concentration attained (C_{\max}), half-life of drug ($t_{1/2}$), area under the plasma concentration–time curve (AUC), apparent volume of distribution (V_d), clearance) of rats, dogs, and monkeys at different times after single and multiple administrations.²³

For small molecules intended for oral administration, several key properties are also required (Lipinski's rule of five): molecular mass < 500 Da; fewer than five donor hydrogen bonds; fewer than 10 acceptor hydrogen bonds; and an octanol–water partition coefficient (an indicator of the NCE's ability to cross biological membranes) less than 5.⁹

All in all, even if studies in the various models are carried out simultaneously, the testing discussed above will require 2–4 years, after which the producer will be able to present an adequately documented application for an IND. For this reason, it is common practice to carry out preliminary explorative pharmacotoxicology studies without strict

Table 2 Safety tests

Type of test	Approach	Comment
Acute toxicity	Acute dose that is lethal in approximately 50% of animals and the maximum tolerated dose. Usually two species, two routes, single dose.	Compare with therapeutic dose.
Subacute toxicity	Three doses, two species. 4 weeks to 3 months may be necessary prior to clinical trial. The longer the duration of expected clinical use, the longer the subacute test.	Clinical chemistry, physiologic signs, autopsy studies, hematology, histology, electron microscopy studies. Identify target organs of toxicity.
Chronic toxicity	Rodent and nonrodent species. 6 months or longer. Required when drug is intended to be used in humans for prolonged periods. Usually run concurrently with clinical trial.	Goals of subacute and chronic tests are to show which organs are susceptible to drug toxicity. Tests as noted above for subacute. 3 dose levels plus controls.
Effect on reproductive performance	Effects on animal mating behavior, reproduction, parturition, progeny, birth defects, postnatal development.	Examines fertility, teratology, perinatal and postnatal effects, lactation.
Carcinogenic potential	Two years, two species. Required when drug is intended to be used in humans for prolonged periods	Hematology, histology, autopsy studies. Tests in transgenic mice for shorter periods may be permitted as one species.
Mutagenic potential	Effects on genetic stability and mutations in bacteria (Ames test) or mammalian cells in culture; dominant lethal test and clastogenicity in mice.	Increasing interest in this potential problem.
Investigative toxicology	Determines sequence and mechanism of toxic action. Discover the genes, proteins, pathways involved. Develop new methods for assessing toxicity.	May allow rational and earlier design and identification of safer drugs. Possibly run at higher compound throughput.

Figure 4 Modeled pharmacokinetic profile of a novel chemical entity with consideration of free drug exposure relative to projected efficacy levels (based on, e.g., receptor occupancy) and safety threshold (based on, e.g., level at which QT prolongation is anticipated). (Reproduced with permission from Walker, D. K. *Br. J. Clin. Pharmacol.* **2004**, 58, 601 © Blackwell Publishing.)

observance of the GLPs. These can provide information on the minimum effective and maximum tolerated doses for single- and multiple-dose administration (from 14 days to 1 month, via two routes of administration and in two species, preferably the rat and the dog), the *in vitro* mutagenic potential of the drug in bacterial and mammalian cells,²³ and fundamental ADME properties. A final focus, especially for larger-molecule drugs, is the molecule's possible effects on the immune system. New technology (such as surface plasma resonance and cell-based bioassays) is available to determine whether antibodies have formed or if immune system biomarkers have changed during toxicology testing.²⁵

Conventional approaches of experimental pharmacology, together with repeat-dose toxicity studies of up to 1 month's duration, can predict adverse events in first-dose-to-human studies with a reasonable level of accuracy, i.e., more than

Figure 5 Percentage concordance between animal and human toxicities, grouped by organ. Similar to data on anticancer drugs, correlation is better for toxicities in the gastrointestinal tract, and hematopoetic and cardiovascular systems. (Reproduced with permission from Greaves, P.; Williams, A.; Eve, M. *Nat. Rev. Drug Disc.* **2004**, 3, 226 © Nature Publishing Group.)

90% of the toxic effects that can be detected in animal models.²³ When there is no prior knowledge of organ toxicity, it is advisable to evaluate the effects of repeat administration of a high dose of the drug for at least a few days, a period that is generally sufficient to permit the development, expression, and identification of organ pathology.²² Figure 5 shows the rates of concordance between toxic effects produced by drugs in animals and humans.²³

The toxicological tests outlined above cannot exclude the risk of milder toxic effects, such as nausea, headache, distortion of the sense of taste, vertigo, or dry mouth.^{23,32,33} They are also no guarantee against idiosyncratic reactions. Unlike the effects that can be predicted based on the results of toxicological testing, idiosyncratic reactions are infrequent adverse responses to a drug characterized by the absence of dose dependence and by variable periods of latency following drug administration despite extensive and essentially negative preclinical testing and large clinical trials (troglitazone,²³ trovafloxacin,³¹ bromfenac,²³ fialuridine²⁴) (see Section 2.06.4.3.6). They can nonetheless be quite serious and in some cases fatal. They are often manifested by severe hepatotoxicity, which some investigators attribute (e.g. fialuridine) to mitochondrial toxicity.^{23,31} In light of the need for first-dose-to-human studies, integrated primary and secondary pharmacology data and repeat-dose toxicity information across the experimental models used are required to provide meaningful data to justify the experiment, to manage diverse events, and to avoid serious organ toxicity.²³

The first dose to humans may be one-fifth to one-tenth of the dose per kilogram that has proved to be effective in 50% of the animals in specific models of the target disease or condition and at least 10–20 times lower than the dose that produces no effect in dogs and one other animal species when administered repeatedly for at least 1 month.

2.06.3 Clinical Testing

A clinical trial is essentially a prospective controlled trial that includes human subjects and is designed to evaluate the efficacy of a therapeutic intervention, diagnostic procedure, or medical/surgical device.³⁴ All clinical trials must be conducted according to the ethical principles contained in the Helsinki Declaration, which is periodically updated. (See versions drafted in Tokyo, Venice, Hong Kong, South Africa, Edinburgh, and a note of clarification added in Washington, 2002.)³⁵ The study protocol is evaluated by the institutional review boards (IRB) and ethical committees, whose establishment and duties are regulated by the Council of International Organizations of Medical Sciences (CIOMS)/World Health Organization/WHO³⁶ and, in the US, by the FDA.³⁷ The investigator must also ensure that the trial will adhere to the basic principles of GLP outlined in the code cited above.

Evaluation of the NCE's efficacy and safety in healthy and diseased humans currently involves phase I trials, which are normally conducted on healthy human subjects, and those of phases II, III, and IV, which are conducted on patients affected by the disease that the NCE is expected to influence.^{24,38–41} Specific experimental methods and techniques have been developed to reduce the risk of problems related to the following factors: (1) the clinical history of the disease; (2) the presence of other risk factors; and (3) placebo and nocebo effects, i.e., positive and negative effects experienced by human subjects that are due exclusively to the administration of a substance identified as a drug. These effects, which can occur in a substantial percentage of trial participants, are manifested by subjectively reported

improvement in a symptom (placebo effects) or adverse effects such as nausea, abdominal pain, and headache (nocebo effects) with no objectively detectable correlates.

The clinical history of the disease should allow one to determine: (1) whether or not its course is sufficiently stable; (2) its type is sufficiently uniform over a period of at least several months; (3) the absence of sudden improvement or worsening; and (4) the nature and (if possible) the timeframe of its outcome.

Potential risk factors include the presence of other diseases, particularly those affecting the liver, lungs, or thyroid, and lifestyle factors, such as smoking, alcoholism, or drug use. The patients treated with the NCE and those receiving the control treatment must be similar in terms of diet and other types of therapy. The agent used to treat the control group can be:

1. the currently available drug considered most effective for treatment of the target disease, e.g., for evaluation of a new antiarrhythmic drug for the control of atrial fibrillation, the control group might be treated with amiodarone, flecainide, propafenone, or quinidine, as the experimenter sees fit. As a rule, the control treatment and the one being evaluated in the trial are administered at fixed doses for the duration of the study
2. a placebo, i.e., an inert compound with no pharmacological action, which has been formulated in such a way that it appears identical to the test drug. In some cases, placebos are designed to produce some of the same adverse effects predicted for the test drug (e.g., dry mouth) since the absence of these effects in a double-blind study could reveal to the experimenter the group origin of control subjects.

The inclusion of placebo treatment in clinical trials is designed to eliminate the risk of biases, on the part of the subject or the researcher or both, in favor of the NCE under conditions of variable disease history. Responses to a placebo are based on the effects of suggestion (administration of any form of therapy is the best way to lead the patient to believe he or she is improving) and those of spontaneous improvement. Many patients seek treatment when they are experiencing symptoms, and many symptoms, such as pain, anxiety, depression, insomnia, diarrhea, and constipation, can regress or subside spontaneously if they are not being caused by a disease that is progressive. Therefore, in any trial designed to assess the effect of a treatment (pharmacological or nonpharmacological) on a symptom, it is appropriate, whenever possible (*see* [Section 2.06.3.1](#)), to include a group of patients who will be treated under double-blind conditions with a placebo.

2.06.3.1 Models and Techniques Used for Clinical Drug Testing

In clinical trials, especially those of phase II, III, or IV, the problems outlined above can be avoided to some extent by:

1. inter- or intraindividual cross-over study designs^{24,46}
2. use of uncontrolled or parallel multiple-arm study design
3. random assignment of trial enrollees to the NCE and control treatment arms^{43–45}

Trials conducted according to an interindividual cross-over design begin with a ‘run-in’ period, in which the patient is allowed to stabilize and vital parameters are evaluated. Thereafter, each randomized group of patients is divided into arms, which are treated with the NCE or the control agent for a predetermined period during which efficacy parameters are periodically assessed. This interval is followed by a second ‘washout period,’ during which all treatment is suspended, and the treatment arms are then reversed: the arm treated with the NCE now receives the control treatment, and vice versa. This second treatment period is identical to the first in terms of duration and patient evaluation. All treatments are administered under blind or double-blind conditions. (In the former design, the patients, but not the investigators, are unaware of which drug they are receiving; in the latter, the investigators are also blinded.) At the end of the study, all data collected in the two cross-over groups will be divided into two pools: (1) those recorded during treatment with the NCE; and (2) those recorded during the control treatment.

In trials conducted according to an intraindividual cross-over design, in which three treatments are being compared – the NCE (A), the standard treatment (B), and a placebo (C) – the randomized patients are divided into three groups. Patients in group I are treated with drug B, then with drug C, and finally with drug A. In the other two groups, the order of the treatments is different (group II: C–A–B; group III: A–B–C). Each treatment is administered for an identical period of time (e.g., 1 week), during which prescribed evaluations are carried out, and the three treatment periods are separated by a week-long washout period. At the end of the trial, data from the three groups are pooled, and values recorded during each of the three treatments are compared and subjected to statistical analysis.²⁴

The methods described above are useful for testing NCEs designed to treat diseases characterized by slow evolution or long periods of stability (e.g., stable angina, type 2 diabetes, moderate hypertension, asthma without crises, rheumatoid arthritis, osteoarthritis).

For drugs that will be used to treat short-lasting conditions (e.g., infectious disease, acute cystitis, seasonal rhinitis), the trial must be conducted in an uncontrolled manner (blind or double-blind) with no form of cross-over. In uncontrolled trials,⁴¹ all eligible patients are treated with the NCE, and its effects are evaluated against the normal course of the disease, which is considered to be well known, and if possible based on the evolution of suitable biomarkers (see below). These trials are unsuitable for drugs used to treat diseases with variable outcomes (e.g., mortality in community-acquired pneumonia,⁴⁷ AIDS,⁴⁸ etc.). They should only be used when: (1) the disease is very likely to be fatal (e.g., coagulopathy caused by Ebola virus infection); (2) the efficacy of the NCE is dramatically evident during the initial observations; (3) the adverse effects are acceptable in light of the expected benefit; (4) there are no alternative treatments for use as a control; and (5) there are plausible biological and pharmacological bases for the NCE's efficacy.

The use of nonrandomized controlled trials with parallel groups is also to be discouraged. In these studies, the NCE and the control treatment are administered to two groups of eligible patients, and their responses are comparatively analyzed. However, treatment assignment is not random, but based on other criteria (e.g., assignment to one arm on odd or even days), which are predictable and thus subject to influence by the investigator's preferences. Consequently, the two treatment groups may not be truly comparable.

In another type of nonrandomized controlled trial, all enrolled patients are given the test drug, and the results are compared with those documented in a historical control group consisting of patients treated in the past with a traditional form of therapy. The control data in these studies are collected retrospectively, usually from hospital charts. One of the major drawbacks of this trial design is that the group treated with the NCE has certain advantages over the historical control group in terms of more modern (and presumably more effective) forms of diagnosis, assistance, and therapy (e.g., computed tomography (CT), magnetic resonance imaging (MRI) or γ -stratigraphy for evaluation of tumor dimensions versus conventional imaging for the historical controls).

In randomized clinical trials (RCTs), the NCE and control drug (or placebo) are assigned to eligible patients in a random manner, and the groups are treated according to a parallel design (or, less commonly, another type of design). Randomization enhances the comparability of the groups.⁴⁴ Each subject is assigned a numerical code; this measure allows researchers to identify a single subject (for any type of problem related to that individual) without interrupting the entire trial. The trial is conducted under double-blind (or, less commonly, single-blind) conditions, with a cross-over design when possible, depending on the characteristics of the disease being treated. The indices and parameters to be evaluated are identified before the study begins, as are the times for their evaluation. The data collected in the groups are subjected to comparative statistical analysis (described in greater detail below).

The discussion above refers to trials with two or three arms, but there may be more than three. This approach is used, for example, when multiple doses of the NCE are being assessed or when the NCE's effects are being compared with those of two or more standard treatments. In these cases, extreme caution is essential to avoid treatment mix-ups, particularly in double-blind studies in which the drugs are identified exclusively by a numerical code. Placebo treatment of the control group can only be justified when all of the following are true: (1) there are currently no effective standard means for treating or preventing the disease being studied; (2) the treated and control groups will be exposed to the same risk; and (3) a controlled trial is absolutely necessary to determine whether or not an NCE is actually effective.

In phase II and III, an alternative method for evaluating the effects of an NCE is the sequential trial approach.^{38,49,50} In the conventional trials used for pharmacological testing during phases II and III, the number of subjects to be treated in each arm – 10, 20, 30, 100, or more – is established before the study begins, whereas in nonrandomized controlled studies, the analysis extends to all eligible subjects enrolled within predetermined intervals of time (for example, on odd or even days of the month or every other month).

In sequential trials, the comparison is made in matched pairs of subjects with disease of the same severity, one treated with the NCE, treatment A, the other with conventional therapy, treatment B. An alternative approach involves consecutive administration of the two treatments in the same subject, who thus serves as his/her own control. (In this case, as in cross-over studies, the patient's disease must be fairly stable.) Based on a predetermined criterion which is evaluated in terms of pre-established endpoints (as hard as possible), a 'preference' is assigned to one of the two treatments, i.e., it is rated as better than the other treatment. Pairs in which no preference can be assigned are excluded from the analysis. Each preference is plotted on a graph, like the one shown in [Figure 6](#), producing a line that extends diagonally upward (if treatment A is truly better) or downward (if the opposite is true). When the number of preferences assigned to one of the treatments exceeds the pre-established statistical limits in the graph, that treatment

Figure 6 Boundary diagram for a sequential trial. Here $1 - \beta = 0.95$, but $\theta_1 = 0.85$. Two boundary diagrams are shown, one for $2\alpha = 0.05$, the other for $2\alpha = 0.01$. Values of α and β at the boundaries are approximate. See text for explanation. (Reproduced with permission from Goldstein, A.; Aronow, L.; Kalman, S. M. *Principles of Drug Action. The Basis of Pharmacology*, 2nd ed.; John Wiley: Chichester, 1974, p 793.)

Figure 7 Sequential analysis of a trial of the effects of atenolol (x) and propranolol (O) versus placebo in hyperthyroid patients using an objective assessment of effects, including heart rate. Both drugs are significantly better than placebo ($P = 0.05$) but a comparison of atenolol and propranolol (Δ) fails to distinguish between them in efficacy. (Reproduced with permission from Rogers, H. J.; Spector, R. J.; Troance, J. R. *A Textbook of Clinical Pharmacology*; Hodder & Strughton: London, 1981, p 169 by permission of Hodder & Stoughton Ltd.)

is declared to be significantly superior to the other (Figures 7 and 8). If this does not occur, the null hypothesis is declared to be true: the two treatments are not significantly different.

Sequential trials offer certain advantages. They can generally be conducted with fewer patients than conventional trials, and they are considered to be more ethical for studies involving severe or potentially lethal diseases because conclusions regarding the drug's efficacy can be reached more rapidly. Moreover, they are less costly, and they allow organizers to identify a single well-defined time point for the end of the study. On the other hand, it can be difficult to find sufficiently well-matched pairs of subjects, individuals who, during the same period of time, are suffering from identical forms of the same disease, and this can lead to errors of the type associated with nonrandomized controlled trials.

Figure 8 Result of sequential trial: myocardial infarction or death in two treatment groups. Patients with angina pectoris or a previous myocardial infarction were maintained on the anticoagulant phenindione at two dosage levels. The higher dosage reduced the prothrombin levels to 20% of normal, on the average; at the lower dosage, prothrombin levels were 50% of normal. The infarction rate in the 20% group was significantly lower than in the 50% group ($P < 0.01$). If a patient developed a myocardial infarction or had a cardiovascular death, a preference was given to the group to which the other patient in the pair belonged. Here $2\alpha = 0.05$, $1 - \beta = 0.95$, $\theta = 0.90$.

2.06.3.2 Statistical Analysis

In clinical trials designed to establish the efficacy or identify the adverse effects of an NCE, selection of the statistical methods that will be used to evaluate the significance of differences must be based on the type of scale used for recording the results. An interval scale is a simple numerical scale. Blood pressure values, for example, might be expressed in millimeters of mercury, heart rate as beats per minute, body weight in grams or kilograms, or body temperature in Celsius or Fahrenheit degrees. When a nominal scale is used, items are assigned to qualitative groups or categories. Pain or anxiety, for example, may be classified as severe, moderate, minimal, or absent. No quantitative information is conveyed and no ordering of the items is implied. Nominal scales are particularly useful for trials involving neuropsychiatric disease. The third approach is ordinal. In this case, the responses to different drugs are originally recorded using an interval or nominal scale. The results are then compared and re-elaborated in an ordered manner, e.g., in producing a given therapeutic effect, drug A is superior to drug B, which in turn is superior to drug C.

Results measured on an interval scale can be compared after the means and standard errors have been defined for the values recorded in each group, and the significance of differences that emerge can be assessed with the Student t -test. When there are multiple variables that can influence the response to the drug, analysis of variance can be used. Confidence limits must also be calculated.

The statistical significance of results measured on a nominal scale can be evaluated with the chi square test (χ^2), while those measured on an ordinal scale should be assessed with a nonparametric test, e.g., the Wilcoxon or other ranking methods. Multivariate techniques of analysis of variance, covariance, and dispersion are particularly useful because they minimize differences related to other factors, e.g., interindividual variability, time-related differences, highlighting in this manner the differences actually related to the treatments. In most cases, however, these types of analysis require the assistance of a biostatistician.

In trials designed to compare the efficacies of two drugs, e.g., an NCE and the standard treatment or placebo, the analysis of statistical significance will indicate the frequency with which a given difference will occur purely by chance. In other words, if the null hypothesis (i.e., the absence of difference between the drugs) is indeed true, and if the experiment is repeated 100 times, how many times will a difference of this magnitude be observed? 1/100 (0.01), 5/100 (0.05), 10/100 (0.1). The level of statistical significance P (the lower the frequency, the greater the significance of the

difference) has been set at less than 0.05 ($P < 0.05$). For tests such as controlled clinical trials (including those that are randomized), the significance may be influenced by numerous variables. In general, a low level of significance, e.g., $P < 0.05$, is acceptable when the trial involves an NCE with a high safety index that is active against diseases associated with high mortality and morbidity rates. In contrast, higher levels, e.g., $P < 0.01$ – 0.001 , are required when the NCE has substantial adverse effects and is being used for treatment of diseases that are relatively benign. According to a glossary of terms used in therapeutics and diagnosis that is useful for statistical analyses⁵¹ the term relative risk reduction (RRR) refers to “the proportional reduction in rates of bad events between experimental (experimental event rate, EER) and control (control event rate, CER) patients in a trial, calculated as $(\text{EER} - \text{CER})/\text{CER}$ and accompanied by a 95% confidence interval (CI). In contrast, the RRI (relative risk increase) refers to an increased rate of bad events in the experimental drug group, compared with controls. It is calculated in the same manner used for the RRI. The RRI is also used for assessing the effect of risk factors for a disease.” The CI is an index of the uncertainty surrounding a measurement. It is usually reported as the 95% CI, i.e., the range of values within which we can be 95% sure that the true value for the whole population lies.

Intention-to-treat and interim analyses are important parts of drug trials.^{40,49} In the former, the groups are analyzed based on the manner in which the patients were randomized rather than on the treatment they received during the study. In an intention-to-treat analysis, the results are included for all eligible patients, regardless of their adherence to the protocol. Those who withdraw before treatment is begun are not considered. The rationale for this type of analysis is that, if a treatment is effective in 80% of the patients who tolerate it, but it has to be suspended in 70% of the cases treated due to the development of serious side effects, the treatment can be said to be effective in only 24% of those treated, i.e., $80\% \times 30\%$ of those for whom the treatment was prescribed.

Interim analyses are those that are conducted to determine whether or not a trial should be ended before its planned completion date. From a methodological point of view, this approach is incorrect: the data should only be analyzed at the end of the trial because the sample required to satisfy the aims of the study with the chosen study design has already been established in the protocol. Nevertheless, interim analyses may be justified by ethical, scientific, practical, or economic considerations. They might be indicated, for instance, in a long-term study based on mortality or other strong endpoints, e.g., a trial designed to test the effects of an angiotensin-converting enzyme inhibitor or beta-blocker on survival in patients with heart failure. If the interim analysis demonstrates that the test drug is clearly more or less effective than the control, it would be unethical to continue the trial, administering a treatment known to be inferior or ineffective to patients with disease of this severity.

2.06.3.3 Biomarkers, Real and Surrogate Endpoints

Evaluation of biomarkers, surrogate endpoints, and clinical endpoints is very important in clinical trials. A biomarker is, in simple terms, any observable physiological parameter. A valid biomarker is one that is measured in an analytical test system within a well-established scientific framework or body of evidence that elucidates the physiologic, toxicologic, pharmacological, or clinical significance of the results¹²; it is evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention.⁵² Use of a reliable and specific biomarker as an early predictor of long-term efficacy and toxicity can reduce the time, costs, and size requirements for clinical trials. Its specificity is an essential feature, and insufficient specificity can be due to several factors. The failure of a biomarker can be due to any of the following⁵³: (1) the marker is not in the pathophysiological pathway of the disease (i.e., several pathways are present); (2) the biomarker is also in other pathophysiological pathways (i.e., several such markers are present); (3) the biomarker is not in the pathway affected by the therapeutic intervention; (4) the intervention acts through different and unknown pathways; and (5) the biomarker does not correlate well with traditional clinical endpoints, being more sensitive than the latter. In a metaanalysis of patients with colorectal carcinomas in which tumor mass was used as a biomarker, correlation between the response of the tumor (reduction in mass) and the clinical endpoint, survival, was only 38%. In this case (number 2 in the list above), other factors influence the correlation between tumor response and survival.⁵³

Surrogate endpoints are biomarkers used as substitutes for clinical endpoints.^{52,54–56} Clinical investigators use epidemiologic, therapeutic, pathophysiological, and other scientific evidence to select a surrogate endpoint that can be expected to predict clinical benefit, harm, or lack of benefit.⁵² As defined by Temple,⁵⁶ a surrogate endpoint in a clinical trial is “a laboratory measurement or a physical sign used as substitute for a clinically meaningful endpoint that measures directly how a patient feels, functions, or survives. Changes induced by a therapy in a surrogate endpoint are expected to reflect changes in a clinically meaningful endpoint.” Surrogate markers must be well validated before they can be used to provide documented evidence of the activity of an NCE for submission to regulatory authorities.⁵³

In effect, a surrogate is a test or set of tests that indicates the progression or regression of a specific human pathology. Surrogate markers functioning as endpoints can be classified as follows:¹³

- type 0 – those associated with the natural history of the disease
- type I – those that indicate a known response to therapeutic intervention
- type II – those that reflect a clinical outcome

Surrogate endpoints are used to obtain acceptably reliable evidence that the NCE is actually influencing the target disease, and to do so more rapidly and more economically than would be possible with the real endpoint. Surrogates are obviously not necessary if the true clinical endpoint is rapidly attained and easy and economical to measure.

Toxic changes affecting soft tissues may be evaluated by means of correlating changes in gene expression in more readily accessible cells, e.g., peripheral blood mononuclear cells (PBMCs), buccal mucosal epithelial cells,³¹ or accessible tumor cells,⁵⁷ which can be used as surrogate biomarkers. Numerous groups have used bleomycin sensitivity of peripheral blood lymphocytes as a surrogate for identifying individuals with increased sensitivity to environmental mutagens. Those with increased sensitivity to bleomycin have an increased risk of developing lung cancer.⁵⁷

A recent review showed that surrogate endpoints, in particular tumor size as measured by MRI, were used in well over half of all oncology trials (53 of 71 trials).⁵³ Their use has recently been criticized as an unacceptable means for accelerating approval of cancer drugs.⁵⁸

Clinical (real, true) endpoints are characteristics or variables that reflect how a patient feels or functions or how long a patient survives.^{52,55}

2.06.3.4 Evaluating a Protocol for a Clinical Trial of a New Chemical Entity

In the protocol, or plan, for a clinical trial, the title of the study and its objectives must be stated in clear and simple terms. The scientific rationale for the study should be fully explained and documented with acceptable references. The problem being analyzed and its current importance should both be clearly defined. The project must be described clearly to give the reader an overall idea of what is being planned. Caution should be exercised in the statement of objectives, both primary and secondary: multiple objectives and/or those that are not unclear should be avoided. It is also important to specify any potential conflicts of interest, i.e., all material and nonmaterial benefits that might be derived from the study by the proponent or the institution conducting the research. The pathology being treated must also be clearly defined, and methods used for diagnosis and prognostication should be specific and reproducible.

In addition to the study objective(s), the protocol must define the primary and secondary endpoints that will be measured. To provide an overall view of the research project, the following points must be precisely described:

- experimental design and methods (randomization, placebo or active drug controls, double-blinding, etc.)
- the site at which the trial will be conducted, existing structures, relation to structures providing emergency treatment or intensive care
- the coordinating center for multicenter trials
- the duration of the trial
- the methods to be used for analysis of data (intention-to-treat, statistical elaboration)
- the statistical power of the protocol (to ensure that the study has sufficient statistical power, the number of subjects to be enrolled needs to be established with the aid of a statistician).

Attention should also be given to the facilities available in the structure where the study will be conducted. Rapid access to an intensive care unit is particularly important for adequate treatment of any serious adverse event that might occur during the study. The person or person in charge of the research, and in particular the team leaders, must be identified by name and function. In defining the criteria for recruiting trial participants, the researcher must consider all variables, known and unknown, that could influence the results. The number and type (patients or healthy volunteers) of subjects to be enrolled must be specified, along with their characteristics (age, sex, etc.), their possible relations to the researcher (as employees, students, etc.) and the method of enrollment. Each individual being considered for enrollment must receive information on the study itself, and those enrolled must provide written consent to all study procedures. (This aspect is explained in greater detail in the section on the phases of clinical testing, below.) If the study is going to involve multiple centers in more than one country, it is essential to specify the number of subjects to be enrolled in each center. The inclusion and exclusion criteria should also be spelled out clearly and in detail, along with the treatments and dosage regimens (doses and administration frequencies) that will be used,

the methods to be used for assigning participants to study arms and for evaluating the results, i.e., the types of testing to be performed, divided into invasive and noninvasive categories, and the frequency at which they will be carried out. Procedures might also be classified as 'minor' (collection of urine or stool samples, nasal or pharyngeal swabs, or moderate volumes of blood for nondiagnostic purposes) and 'major' (physically invasive involving biopsy, removal of body tissues, exposure to radiation). Use of procedures of the latter type should be carefully evaluated by the IRB or the ethics committee. The types and frequency of follow-up evaluations should also be specified.

It is also important to evaluate the information that will be given to potential trial participants in order to obtain their informed consent. (The information must be provided in a form that is clear and easy to understand. Alarmism should be avoided, but the candidate must be adequately informed on all operations or maneuvers planned in connection with the study and on all possible adverse effects of the NCE and of the control treatment.)

The description of methods used for recording and reporting results requires particular care. The protocol must specify the type(s) of measurements that will be made, when and how they will be carried out, and the procedures that will be adopted to safeguard the trial from biases on the part of participants and/or study personnel. It should provide for groups and assessment methods based on considerations of sex, age, renal and hepatic function, and the possibility of genetic polymorphisms. The possibility of a pregnancy and the risk of genetic damage to sperm (e.g., caused by cytotoxic chemotherapy) must always be considered, even if the subjects being enrolled are males.

The protocol should also specify other drugs that will be administered in response to particular situations that might arise during the trial. For example, in a study involving an asthma drug or one used to treat chronic obstructive pulmonary disease, an acute episode of severe bronchospasm might be treated with a short-acting bronchodilator, or in a trial focusing on a new drug for control of mild to moderate hypertension, nifedipine or some other rapid-acting antihypertensive might be identified as the treatment for critical blood pressure elevations.

It is also advisable to draft a letter for the participant's personal physician, particularly for phase II and III trials. The letter should provide a brief explanation of the objective and nature of the study and instructions for managing the patient during his/her participation in the study (signs and symptoms to look for, drugs – prescription and over-the-counter – and herbal preparations to be avoided).

Ethical evaluation of a trial protocol should focus on the appropriateness of the scientific method, the possible use of a placebo, and the information provided for patients during the enrollment procedure. It will also examine the potential benefits to the patient in relation to the risks, invasiveness, and secondary effects of the study treatment, and the inclusion of safeguards of the participant's right to withdraw voluntarily from the study without penalties or loss of benefits.

There have been trials in which the informed-consent procedure was criticized on ethical grounds. For example, in the study comparing foscarnet and placebo for the treatment of cytomegalovirus retinitis in AIDS patients, another active antiviral agent could have been used as a control, but the information was not given to enrolled patients. A similar situation occurred during testing of recombinant tissue plasminogen activator for treatment of myocardial infarction: streptokinase could have been used instead of placebo as the control treatment. Other examples include the use of sham therapy in controls enrolled in trials to evaluate the use of endoscopic sclerotherapy in the treatment of cirrhosis, as well as clinical trials of dubious validity that have been conducted in Third-World populations.⁶⁰

2.06.3.5 The Phases of Clinical Testing

Clinical testing of an NCE is carried out in four phases: I, II, III, and IV. With the exception of the first phase and an aspect of phase I known as phase 0, all have therapeutic significance. In effect, all research conducted on diseased humans to evaluate the effects of a drug that can potentially improve that disease must be considered therapeutic in scope, in contrast to the scientific research that offers no possible benefits to the individual patient despite its value to humanity as a whole. In any case, the necessity for scientific research can never justify the violation of an individual's rights.

Assessment of the effects of an NCE on humans, whether healthy or otherwise, raises a number of issues, the most important of which are:

- how to guarantee the safety of trial participants
- how to ensure that trial participants are aware of all the implications of treatment with the NCE (informed consent)
- the existence of factors that may be used to exert pressure on a candidate for enrollment, such as:
 - possible retribution
 - indemnity for damages other than the insurance protection provided by the sponsor
- subjects considered to be particularly vulnerable to indirect psychological influences (children, handicapped individuals, psychiatric patients, etc.).

2.06.3.5.1 Phase 0

The appropriateness of the term phase 0 has been discussed at length. It actually refers to an early phase of phase I testing that involves the administration of ^{14}C -labeled microdoses of the NCE, i.e., doses decidedly lower than the first dose used in healthy volunteers.^{11,61,62} Levels of the drug in the blood and other biological fluids are then determined by means of mass spectrometry (MS), a method that is both reliable and highly sensitive. With appropriate modifications, this approach could allow considerable reductions in the number of laboratory animals needed for pharmacokinetic studies.⁶² Criticism has been raised regarding the possible interference of P glycoprotein (P-gp) with microdoses of drugs like α_1 -antagonists, β -antagonists, or neurokinin-2 (NK_2) antagonists, which could destroy the linearity of the results. When the microdose method was used to investigate a new phosphodiesterase V inhibitor, a 14-fold difference in bioavailability was noted between doses of 10 and 800 mg.²⁸

2.06.3.5.2 Clinical phase I

These are open studies, in most cases nonrandomized, that are performed in a small number (25–50) of human participants (normal volunteers or patients). Their scope is to obtain information about the pharmacodynamic (dose–effect range for vital parameters) and pharmacokinetic (ADME in humans) properties of the NCE. They are useful in identifying minimal effective and maximal tolerated dosages and in establishing a safe dosage range.

The exact number of subjects needed for a phase I trial varies depending on the NCE, its similarity to existing drugs, and on the initial testing results. For evaluation of an NCE that appears to offer therapeutic benefits for a serious and potentially fatal illness, such as neoplastic disease or AIDS, phase I testing may be conducted on patients suffering from the targeted disease instead of healthy volunteers. In this manner, the risk of potentially significant toxic effects (which might be unacceptable for a healthy subject) is offset by the possibility that the enrolled patient might benefit from a therapeutic effect. Trials of this type naturally have to be evaluated with care by IRBs or ethical committees.

Initially, an NCE is administered orally (when possible) at the lowest possible dose (*see* [Section 2.06.2.2](#)) to small groups of subjects, generally 1–5. After an appropriate washout period (generally, a couple of weeks), the same subjects are treated with a higher dose, and the process continues until the maximum tolerated dose is reached. This approach is known as definite dose finding. If repeated administration of the NCE is being evaluated, a dose midway between the lowest effective and highest tolerated doses is given for a period of time that is proportionally equivalent to the duration of multiple-dose toxicity studies in animals. The results are compared with the subject's pretreatment condition, as far as subject aspects are concerned, and with baseline values of preselected biomarkers. It goes without saying that the measurement methods and evaluation criteria used must remain constant for the duration of the trial.

In order to provide informed written consent to enrollment in a phase I trial, a potential participant must be given the following information:

- a new and potentially useful drug has been discovered
- the nature, expected duration, and scope of administration of the study drug
- methods and means used for the administration
- methods and means used for collection of data (in particular, invasive methods)
- certain risks are possible (adverse effects associated with use of the NCE: describe them)
- other unexpected risks are also possible (list possibilities).

The information sheet for prospective participants, along with the protocol itself, must be reviewed and approved by IRB or the Ethics Committee (for further information on this subject, *see* [Section 2.06.3.4.](#)).

Subjects under 18 years of age, elderly persons (at least in the first phase), smokers, women in their reproductive years, and subjects who have taken part in other trials in the last few months are excluded from phase I trials, as are those individuals who might be subject to psychological pressure (students, employees of the company that manufactures the NCE, members of the armed forces, etc.). Phase I trials are generally conducted in research centers specialized in clinical pharmacology. Attempts to predict human pharmacokinetics and pharmacodynamics with a mechanistic approach have yielded variable results: some predictions compared well with clinical results, but others did not.⁶³

2.06.3.5.3 Clinical phase II

Clinical phase II trials are performed in a small number of patients with a disease or condition of interest and focus on the safety, efficacy, and appropriate dose range of an NCE in comparison with a standard treatment (positive control) or placebo preparation for treatment of the targeted indication. All types of study design may be used: open, randomized, blinded or double blind.

They normally include phase IIa, which is usually an open trial conducted on 25–50 subjects, and phase IIb, which includes 80–250 patients. The NCE is compared with an active drug or placebo to determine whether it is therapeutically active against the target pathology or pathologies. They will be conducted as dose–response studies using the doses considered safe for repeated administration based on the results of phase I studies. Surrogate endpoints are used.^{64,65} These trials should furnish a precise indication of the short-term safety and efficacy of the NCE, satisfying the proof-of-concept requirement for subsequent clinical testing of the product. They must be completed with additional studies on the metabolism and elimination of the NCE in healthy subjects as well as those with the disease of interest. Two-stage⁶⁶ designs were proposed that are optimal in the sense that the expected sample size is minimized if the regimen has low activity subject to constraint upon the size of the type 1 and 2 errors. Two-stage designs that minimize the maximum sample size are also determined.⁵⁹ Clinical trial simulation in late-stage drug development could predict the outcome of phase III trials using phase II data.⁶⁴

In order to provide informed written consent to enrollment in a clinical phase II, a potential participant must be given the following information:

- a trial is being planned to test a new and potentially useful drug
- for an accurate evaluation of the drug, some participants will be treated with the drug and others will not
- the beneficial health effects that are expected to be observed in subjects treated with the new drug
- the type of treatment that will be administered to the group of participants who do not receive the test drug (adequate standard treatment, which must be specified, or placebo)
- the nature and duration of NCE administration
- methods and means used for the administration
- methods and means used for collection of data (in particular, invasive methods)
- possible undesirable effects and risks
- other unexpected risks and undesirable effects (list possibilities)
- adverse effects that may be associated with use of the NCE (and the control treatment)
- the existence of alternative therapies that might be available for the patient.

2.06.3.5.4 Clinical phase III

These are large trials performed to confirm the safety, efficacy, and optimal dosage range of an NCE in comparison with placebo or with a standard treatment for the targeted indication (*see* [Section 2.06.3.1](#)⁸⁶). Clinical drug trials in the twenty-first century are primarily multicenter and multinational and are conducted at various sites.³⁴ The statistical power of the study must be adequate (>1000–2000 patients), and the trials must be conducted according to a randomized controlled double-blind design with endpoints that are exclusively clinical. The objective is to evaluate the short-term efficacy and safety of the NCE, ideally in different age groups, and to outline a final therapeutic profile for the NCE (indications, dosing, route(s) of administration, side effects, possible interactions with other drugs, and contraindications): in short, an initial risk–benefit assessment. NDA approval of an application for an NCE requires that the drug's efficacy be proven in at least two well-designed randomized double-blind placebo-controlled clinical trials.⁶

Depending on the number of subjects enrolled, a clinical trial should be able to detect adverse effects that occur with a frequency of 1:1000–1:1500.^{38,67,68} Rare adverse effects occurring with a frequency of 1:10 000 or less are generally the result of idiosyncratic reactions, and some are quite dangerous. Since the number of subjects enrolled in clinical trials rarely exceeds 3000, these effects are rarely detected unless by pure chance. This issue is discussed in greater detail in the section on phase IV postmarketing surveillance (PMS), below. In order to provide informed written consent to enrollment in a phase III RCT, a potential participant should be given the same information reported above for clinical phase II trials.

Clinical trials involving pediatric patients are associated with specific problems related to informed consent: this may be provided by the adults responsible for the children, or by children themselves after reviewing information sheets specially formulated for comprehension by children of different age groups. For these reasons, phase I clinical trials are generally conducted on adults, if possible, and those of phases II–III begin in adolescents (13–18 years of age) and proceed backward to younger age groups (infants up to 2 years of age and newborns a few weeks old).

2.06.3.5.5 Clinical phase IV

These large-scale long-term postmarketing studies³⁴ are conducted to identify the morbidity, mortality, and adverse events associated with an NCE. In some cases, they also reveal new indications for the drug. Phase IV testing can be

considered an indepth analysis in a normal clinical setting of the new drug's effects under approved usage conditions (indications and dosage). These trials can include all patient types for which the drug has been approved. It serves to confirm the results of phase II and III trials. All types of study design can be used. The new agent can be compared with other drugs or with formulations of the new agent that have not yet been approved. Its effects can be compared in different age groups, populations, or specific population subgroups, or at different approved doses. The number of patients that must be enrolled varies. Phase IV trials do not include testing aimed at identifying new indications for the drug, which can only be authorized after a new phase III trial.

PMS^{67,68} focuses on those potential adverse effects of the NCE that are likely to emerge only when the drug is used in large populations under the conditions of normal clinical practice. In effect, the latter conditions are substantially different from those that characterized phase II and III testing, in terms of dosage; and patient factors like the presence of associated disease, which may be complex; the use of other drugs, including over-the-counter products and herbal medicines; interactions with foods; and a large number of other variables.

For various reasons, premarketing studies of an NCE in diseased subjects (phases II and III) are an imperfect simulation of the conditions under which the drug will actually be used in clinical practice. First of all, the number of patients who receive the drug is limited.^{67,68} As noted above, these trials rarely include more than 3000 participants,⁶⁷ a population that is large enough to detect only those high-frequency adverse effects that must be excluded before marketing. In the second place, even when phase II and III testing is lengthy, the period of administration is usually shorter than it is in normal clinical practice (e.g., antihypertensives or drugs used for controlling diabetes have to be taken for life). And, finally, the subjects receiving the NCE are generally carefully selected, and their behavior during therapy is monitored to ensure compliance with the NCE treatment protocol and exclude the use of other drugs (e.g., those used on a *pro re nata* (prn) basis).

In contrast, PMS is designed to detect and characterize the adverse effects (but also unexpected therapeutic effects) that are liable to occur during widespread use of the drug under common clinical conditions. The objective is to identify special risks or benefits related to the presence of associated disease, sometimes highly complex, with use of other drugs, including over-the-counter products and alternative medicines (homeopathic or herbal preparations), and exposure to and interaction with a variety of foods, and a large number of other variables (e.g., ethnic origins).

PMS may also reveal novel properties of an NCE that were not recognized in the previous phases of clinical testing. What appear to be 'side effects' may some day be developed into therapeutic effects for the treatment of completely different types of illness. Some notable examples include:

- the hypoglycemic and diuretic effects of some sulfonamides
- the antidepressant effects of the tuberculosis drug, iproniazide, or the neuroleptic agent, imipramine
- the antiarrhythmic effects of the antiepileptic drug, phenytoin
- the hypotensive properties of propranolol given to control arrhythmias.

New controlled phase III trials must obviously be conducted for any new indication that might emerge during the PMS phase.

During the PMS, various means are used to ensure that the regulatory authorities are promptly informed of any adverse effect of a newly marketed drug that may have escaped detection during phase II and III trials. Reports can be filed by physicians, pharmacists, other types of healthcare workers, caregivers, and even patients themselves. For certain NCEs, authorization is granted with the temporary restriction that the drug be prescribed exclusively within a hospital setting, a measure that favors early detection of adverse events (possibly by the hospital's pharmacology or pharmacy services).

At this point, it will be helpful to review the characteristics of unwanted or unfavorable actions, known as adverse drug reactions (ADRs). ADRs include all involuntary harmful responses observed during administration of a drug at doses normally used for its intended purpose (prophylaxis, diagnosis, therapy). A fundamental requirement is the demonstration of a causal relation between use of the drug and the unexpected clinical event. This 'imputability' is often very difficult to establish, and one can never exercise too much caution. Two types of ADR are commonly distinguished: type A, which refers to those events characterized by dose dependence, predictability, high morbidity rates, and relatively low mortality rates, and type B, which are bizarre, unpredictable events that are unrelated to dose and characterized by limited morbidity but high mortality. These are the so-called idiosyncratic reactions mentioned earlier in [Sections 2.06.2.2 and 2.06.3.5.4](#). They are the ones that have the greatest impact on the general population because, while they are extremely rare (occurring at frequencies > 1:10 000 and in some cases > 1:100 000), their severe and often fatal nature can be extremely frightening and will create serious doubts in the general public regarding the drug's safety.⁶² Type B reactions are the ones most commonly detected during PMS. Because of their higher frequency,

dose dependence, and other characteristics, type A ADRs are more likely to be identified in premarketing surveillance or in large phase II or phase III trials involving 2000–3000 participants.

Establishing causality can be difficult for several reasons:

1. the effect may occur after a long period of latency, sometimes lasting years. An example is the hormone diethylstilbestrol which was given to pregnant women. Some 18–20 years later, the daughters born to the treated women presented an increased rate of genital cancer
2. the effect occurs infrequently
3. the effect resembles a form of spontaneous pathology that is fairly common
4. it is associated with ambiguous symptoms
5. difficulties in differentiating a drug-induced syndrome from one or more concomitant diseases
6. the possibility that the event is due to interaction with other drugs being used by the patient.

PMS utilizes methods used in epidemiologic studies: the descriptive approach (description of an effect related to the drug's toxicity or to its efficacy) and the analytical approach (to determine when the relation between the drug and adverse event is causal or not).

The historical prototype of the descriptive approach, still valid today, is the letter to the editor in a medical journal, but its importance is now outweighed by spontaneous notifications filed with the regulatory authorities by physicians, pharmacists, and the other groups listed above. Letters to the editor were responsible for establishing the relationships between thalidomide and congenital malformations, chloramphenicol and aplastic anemia, phenylbutazone and leukopenia, aminofumarate and primary pulmonary hypertension, practolol and the oculomucocutaneous syndrome, and α -methyldopa and hemolytic anemia. Spontaneous notifications led to the recognition of important ADRs, including the liver damage caused by amiodarone, halothane- and α -methyldopa-induced forms of hepatitis, the neurologic changes caused by nalidixic acid, the hepatic lesions associated with ibufenac, thromboembolic disease caused by oral contraceptives, the extrapyramidal effects of metoclopramide, the adverse cardiovascular effects of nonsteroidal antiinflammatory drugs (including the new cyclooxygenase-2 inhibitors), and the photosensitizing effects of protriptyline. Data are available from 1982 through 2002.⁶²

The spontaneous notification approach failed to identify the early cases of practolol-induced oculomucocutaneous syndrome. It also failed to identify estolate (and not other salts of the antibiotic) as the specific cause of erythromycin-induced cholestatic hepatitis.

In the analytical approach, random and nonrandom sampling is used:

1. experimental – This involves the promotion of controlled clinical trials similar to the RCTs of phases II and III without randomization. These studies are obviously ambiguous in many respects, and they also raise ethical questions that are extremely difficult to resolve, e.g., informed consent to take part in a study focusing on an adverse effect that is already known to occur
2. nonexperimental – These are cohort studies in which the incidence of a potential adverse reaction is compared in representative samples of the population, who are or are not exposed to the agent being investigated (in this case, the NCE to be tested), or case-control studies, in which the number of drug-treated subjects is determined in representative samples of individuals with a pathology that may be related to an ADR (e.g., aplastic anemia, pseudomembranous colitis, endometrial cancer).

These studies never involve the deliberate administration of the drug to patients by investigators: instead they are based on observations of patients who are being treated with the drug for therapeutic purposes by their own physicians.

In both cases, prospective and retrospective assessments are also possible. In the former, the possibility of adverse effects is evaluated in patients taking the drug for an approved indication on the orders of their physician. In retrospective analysis, the possible relation between the adverse event and drug use is evaluated after the event occurs. Excluding the effects of so-called confounding factors, a methodologically correct observational study can be a valid tool. Metaanalyses can also be used to detect rare adverse effects.

As previously noted, the statistical weight of the study plays a determining role in the interpretation of the results that emerge. In most cases, all of the unacceptable high-frequency (type A) adverse effects of an NCE will be identified before the drug is marketed, during the course of phase II and III trials,⁶⁸ or in any case years after the hit has become a lead and advanced into the phase of preclinical pharmacotoxicological testing.

Clinical testing of an NCE in a population of 1000–3000 subjects guarantees a confidence level of 95%. That is, the adverse reaction will occur at a frequency no higher than 1:500–1:1000.

Bizarre type B reactions generally occur in 1 out of every 10 000–60 000 persons (e.g., the aplastic anemia caused by chloramphenicol), but some are even rarer ($\geq 1:100\,000$). Thirty thousand patients have to be treated to detect an adverse reaction with a frequency of 1:10 000.⁶⁷ To attribute an event of rarer type to a drug with an acceptable level of certainty, the drug would have to be tested in about 2 million subjects. In addition, ADRs may be very difficult to differentiate from spontaneous forms of pathology.⁶⁹

Between 1982 and 2002, approximately 30 drugs were withdrawn from the world market due to unacceptable adverse reactions detected 4–290 months (and in one case, several years) after the drug had been marketed.⁶²

2.06.4 Modern Technologies of Interest for the Process of Drug Development

The modern technologies of interest for the process of drug development include:

- imaging technologies
- NMR spectroscopy, MS, and human tissue histology technologies
- the ‘omic technologies.’

2.06.4.1 Imaging Technology

CT, MRI, positron-emission tomography (PET), a dual photon nuclear imaging technique, single-photon emission computed tomography (SPECT), and other types of imaging technology exploit the interaction with tissues of various forms of energy to visualize the body in a noninvasive manner.⁷⁰ Among other things, they can be used to determine whether or not a putative drug is reaching its target, to evaluate the target’s expression and function (up- and downregulation, activation or inactivation), and ultimately whether an NCE has a disease-modifying effect.

2.06.4.1.1 Computed tomography

When x-rays pass through different types of tissue, they are differentially deflected or absorbed. In CT, an x-ray-emitting source is rotated around the subject or the structure of interest, and the x-rays transmitted are measured from different angles to produce a three-dimensional image.

2.06.4.1.2 Magnetic resonance imaging or nuclear magnetic resonance

MRI is a powerful diagnostic method that uses radiofrequency waves in the presence of a magnetic field to extract information from certain atomic nuclei (^1H in particular). It furnishes more parameters than CT: proton density, T1 (the longitudinal relaxation time), T2 (the transverse relaxation time), flow, tomographic differentiation, and susceptibility.^{53,70} It is used primarily for anatomical studies but also provides information on the physicochemical state of tissues, flow, diffusion, movement, and, more recently, molecular targets. MRI was used to measure tumor dimensions as a surrogate endpoint in 53 out of 71 studies of oncological drugs.⁵³ It has also been used successfully for the diagnosis, prognostic evaluation, and treatment of multiple sclerosis, and MRI findings are thus considered an important surrogate endpoint in the assessment of NCEs designed to treat this disease. Contrast-enhanced MRI has been identified as a promising technique for the evaluation of the glycosaminoglycan content of articular cartilage, which is abnormally high in areas where the cartilage surface is damaged.⁵² Whereas clinical scoring showed no significant differences between etanercept over methotrexate (the standard therapy at the time) in the treatment of erosive bone lesions of rheumatoid arthritis,⁵³ the imaging-based erosion score showed statistically significant differences⁵³ and that of interferon- β treatments over relapsing-remitting multiple sclerosis, the NCE PT787 in the treatment of colon cancer.⁵³ With the technique known as functional MRI (fMRI), physiological parameters can be measured in live subjects.⁷⁰ Molecular imaging may be used to visualize specific molecules and targets (distribution and binding of an NCE) or the target itself (for example, receptor expression and modulation of downstream targets).⁷⁰ Pien *et al.*⁵³ have tabulated several hundred imaging biomarkers on their website.⁹⁰

2.06.4.1.3 γ -Scintigraphy

γ -Scintigraphy is a noninvasive method that uses standardized radiolabeling techniques to investigate the presence of a test substance in the body. A computerized image of the emitted γ -rays reveals the presence of the substance in the body and distinguishes different concentration levels.²⁵

2.06.4.1.4 Positron-emission tomography

PET is a tomographic imaging method^{53,70} that identifies the positron emission associated with the breakdown of nuclides. It can be used to measure modifications in blood flow associated with cerebral activities based on the positrons emitted by selectively radioactive substances, such as ¹⁸F-deoxyglucose (¹⁸FdG),²⁵ a labeled form of glucose that emits fluoride protons and is used for metabolic studies that involve glucose uptake.⁵³ ¹⁸FdG PET has been used for early identification of responders and nonresponders in trials evaluating antitumoral NCEs like imatinib or bevacizumab. In patients with CT-documented responses, partial or lasting, ¹⁸FdG PET reveals reductions in glucose metabolism at the level of the tumor days or even weeks before decreases in the tumor mass can be appreciated on CT. It has also been used in studies of second-line therapy or surgical treatment for tumors of the lung or colon, again identifying nonresponders and allowing them to avoid useless treatment. Concordance has been observed between PET-documented reductions in glucose metabolism and both progression and survival times in patients receiving chemotherapy for nonsmall cell lung cancer (NSCLC), confirming the therapeutic value of the treatment. Research on patients with esophageal cancer has confirmed the value of this early metabolic study of tumor mass over the method based on CT study of tumor vascularization: the PET-based approach displayed 93% sensitivity and 95% specificity.⁵³

PET has also proved to be useful in pharmacokinetic studies. The concentrations of ¹⁸F fluconazole observed with this technique compare favorably with those required to inhibit the in vitro growth of fungal pathogens, and this observation is important for establishing dosages.⁵³ Concordance has also been observed between doses, blood levels, and receptor occupation. In some cases, PET studies have revealed no substantial differences in receptor binding after administration of high versus low doses of an NCE, justifying decisions to abandon further development of the molecule. [¹⁸F]-labeled substance P antagonist receptor quantifier, a radioactive tracer peptide that binds NK₁ receptors, was recently used to determine the active dose to be used in treatment with the new antiemetic drug, aprepitant, which is an NK₁-antagonist. The study demonstrated that maximal receptor occupation could be achieved with an intermediate dose of the drug, compared with the maximum dose that had been tested, eliminating the need for clinical assessment of the maximum dose that had been tested.⁵²

PET can also be useful for following microdoses of a drug during phase 0 studies of pharmacokinetics, metabolism, and excretion in particular (*see Section 2.06.3.5.1*).

The use of microdose studies for this purpose is not universally accepted: critics cite the activity of P-g, which facilitates extrusion of the drug, and the variability of the results obtained with different drugs. SPECT is a nuclear imaging technique in which radioactive tracers generating single photons of a specific energy are injected into subjects to produce imaging.

The imaging techniques discussed above can also be combined: MRI + CT + PET for evaluation of tumor angiogenesis, fMRI + CT for situations involving ischemic stroke, and MRI + PET or SPECT for neurodegenerative conditions like Alzheimer's disease.

Application of imaging technologies in drug discovery and development include⁵²:

- neuroreceptor mapping (with PET or SPECT tracers) to investigate receptor occupation by an NCE or, in clinical trials, specific transmitters involved in CNS system²⁵ pathology
- structural imaging to evaluate morphological modifications and their consequences (CT, MRI)
- metabolic mapping (with ¹⁸FdG NMR spectroscopy, molecular MRI) for neuroanatomic studies and assessment of the CNS effect of a drug
- functional mapping (e.g. by PET with ¹⁸FdG or fMRI) to evaluate drug–disease interactions.

Nuclear techniques, PET imaging in particular, can now be used on small rodents, and they are routinely used in canine and primate models. Small-animal micro-CT, microultrasound, and micro-PET detectors may allow identical protocol designs for in vivo assessment across the species, enabling truly comparative pharmacology, directing proof-of-concept studies, and reducing risk in decision making. For example, animals can be studied in small PET chambers to obtain data on receptor occupation relative to blood levels that can be achieved in vivo in patients or animal models.

Fluorescence and bioluminescence imaging (BLI) techniques are widely used in drug R&D because of their low cost, versatility, and HT capacity. A reconstruction method based on fluorescence-mediated tomography (FMT) that was developed for in vivo imaging of fluorescent probes produces images of deep structures mathematically that are reconstructed by solving diffusion equations, based on the assumption that photons have been scattered many times.⁷⁰ Fluorescence reflectance imaging (FRI) is a simple method of image acquisition that is similar to fluorescence microscopy except that different optics allow imaging acquisition of whole animals. It is best suited for imaging of surface tumors or those that have been surgically exposed.⁷⁰ The use of imaging endpoints instead of time-consuming dissection and histological and histochemical studies can significantly reduce the workload required for

tissue analysis, and this can greatly accelerate the evaluation of a candidate drug.⁷⁰ Image activators are caged near-infrared fluorochromes (NIRF), paramagnetic agents that change spin lattice relaxivity on activation or superparamagnetic sensors.

2.06.4.2 Nuclear Magnetic Resonance Spectroscopy, Mass Spectrometry, and Human Tissue Histology Technologies

NMR spectroscopy utilizes signals that are weaker than those produced by ^1H , e.g., ^{31}P , ^{13}C , or ^{15}N . It can provide information on specific compounds present in tissues. NMR spectra of biofluids serve two distinct but closely related purposes: they provide quantitative metabolic fingerprints as well as information on metabolite (biomarker) structure. NMR spectroscopy can be used to detect metabolites and biomarkers of toxicity or safety in biofluids or tissues^{62,71} and to identify the type of bonds formed between drugs/toxic agents and living material. Reliable analysis of plasma or cerebrospinal fluid (CSF) can be obtained with a sample of $\sim 5\ \mu\text{L}$, which means that even small animals, like mice, can be subjected to multiple assays.²⁷ NMR spectroscopy is being used with increasing frequency to investigate the biochemical changes induced in a tissue as a result of a toxic insult. High-resolution magic angle spinning (HRMAS) can be used directly on tissues, but it requires much more work and cannot be automated.²⁷ MS-NMR on intact tissues allows direct correlation of tissue indices and biological modifications. Future technologies include ^{13}C NMR spectroscopy, superconducting NMR probe technology (cryoprobes), and relaxivity on activation or supermagnetic sensors. More information on the direct applicational aspects of these methods can be found in [Section 2.06.4.3.5](#).

Technologies such as liquid chromatography coupled with tandem mass spectrometric detection (LC/MS/MS) or liquid chromatography coupled with NMR spectroscopy (LC/NMR), liquid chromatography coupled with NMR and MS (LC-NMR-MS), ultrahigh resolution and sensitivity of Fourier transform ion cyclotron resonance (FT-ICR-MS) have dramatically improved the sensitivity of pharmacokinetic and toxicokinetic assays: detection limits are now in the low picogram per milliliter ranges. Assays can now be easily performed on minute blood samples ($10\text{--}50\ \mu\text{L}$) from animals used in pharmacological and toxicological testing.^{25,62} More detailed characterization of metabolites can be obtained with hybrid quadrupole-time-of-flight (Q-TOF) LC/MS/MS systems.²⁵ Advances in NMR, MS, and high-performance liquid chromatography (HPLC) technology have resulted in hyphenated LC-NMR and now LC-NMR-MS.⁹ There are also several new technologies that are still in the developmental stages, such as surface-coated protein chips coupled with MS detection (SELDI).^{62,72} The need to analyze large numbers of well-characterized human tissues constitutes a major bottleneck in drug discovery and development. Up to 1000 assays (including immunohistochemistry, fluorescence in situ hybridization (FISH) or ribonucleic acid (RNA) hybridation) can be performed with tissue microarrays.⁷³

2.06.4.3 The 'Omic' Technologies in Drug Development

The human genome contains somewhere up to 32 000⁷⁴ and 35 000 genes^{2,29} and numerous RNA splice variants.²⁹ Around 15–20% of these genes have been identified and their functions established; of the remaining 80–85%, presumed functions based on sequence analysis have been assigned to fewer than half. These genes can synthesize over 100 000 different proteins, approximately 5000–10 000 of which have been identified as potential drug targets⁴ and 600–1500 as 'druggable' potential targets.³ Fewer than 1000 gene products have been identified to date as potential targets for therapeutics.⁷⁴ The genes responsible for almost all monogenically inherited human diseases have already been identified. Gene expression is a complex process involving coordination of dynamic events, which are subject to regulation at multiple levels: the transcriptional level (transcription initiation, elongation, and termination), the posttranscriptional level (RNA translocation, RNA splicing, RNA stability), the translational level (translation initiation, elongation, and termination), and the posttranslational level (protein splicing, translocation, stability, and covalent modifications). Whether or not messenger (m)RNA modulation results in an immediately measurable change in the steady-state level of the encoded protein will depend on the protein turnover rate and other factors.¹² Gene expression can be assessed by measuring the quantity of the endproduct, i.e., protein, or the mRNA template used to synthesize the protein.²⁰ In general, an array experiment includes the following processes: (1) fabrication of the array; (2) RNA isolation and labeling; (3) application of the labeled sample to the array and measurement of hybridization; and (4) data analysis and interpretation.²⁰

Gene expression microarray analysis can be used at all stages of the process of drug discovery, including target identification and validation, mechanism of action studies, and the identification of pharmacodynamic endpoints.²⁰ The advent of genetics and genomics has led to the discovery of a high level of conservation across the species in terms of deoxyribonucleic acid (DNA) sequences, proteins, gene functions, and signals.²⁷ Conservation of biochemical and

signaling pathways during the evolution of species makes it possible to use animal models as surrogates for human patients. The knowledge gained through the study of these animals can be applied to similar processes, pathways, and mechanisms that have been conserved in the human species.²⁹ Studies of the zebra fish, the fruit fly, *Drosophila melanogaster*, and the nematode, *Caenorhabditis elegans*, have played and continue to play key roles in resolving numerous human health problems.^{12,20,29}

Genetic polymorphism refers to the differences in DNA sequences among individuals, groups, or populations.³⁴ In some cases, the alteration involves only one nucleotide (A, T, C, or G) in the genome sequence. These single-nucleotide polymorphisms (SNP) are basepair changes observed with a frequency of at least 1% within a given population.^{74–76} They can occur in noncoding, coding, or regulatory regions of DNA.⁷⁴ They are abundant within the human genome, stable, and detectable with HT techniques like polymerase chain reaction and fluorescence. At present, testing is available to identify over 1.5 million different SNPs in the human genome.⁷⁴ The most common functional changes (e.g., traits referable to diseases) are manifested as SNPs. SNPs can have a considerable impact on responses to drugs. An example of a genetic factor that can determine interindividual and interpopulation variability in drug responses is the polymorphic expression of numerous P450 enzymes and glucuronyltransferase.¹⁸ Many drug-metabolizing enzymes are polymorphic as a result of SNPs, gene deletions, or gene duplications. The ones that have been most widely studied are CYP2D6⁷⁷ (Table 3) and CYP2C19.

SNPs are responsible for interindividual variations in a drug's efficacy: for example, losartan, an angiotensin type 1 (AT1) angiotensin II receptor antagonist, is less effective in individuals with reduced CYP2C19 activity. This difference is not seen with another AT1 antagonist, irbesartan, which is not metabolized by the CYP2C19 coenzyme. The anticoagulant effects of warfarin are also related to CYP2C19 polymorphism.²⁸ The presence of specific mutations in the promoter region of the gene for serotonin is predictive of the response to a selective serotonin reuptake inhibitor.⁷⁷ Other examples of response variability have emerged during clinical trials of several new drugs. For example, the anticancer monoclonal antibody, trastuzumab (Herceptin; Genentech/Roche), has proved to be active only in women who carry multiple copies of the ERBB2 gene (also known as HER2/*neu*),²⁵ and the FDA has approved the use of histochemical studies (Dako Herceptest) and FISH (Vysis Patuvision) for the selection of patients to be treated with this drug.⁷⁴ Potentially fatal idiosyncratic hypersensitivity reactions to abacavir have been related to two different genes on chromosome 6.^{62,74} During clinical trials with tranilast, hyperbilirubinemia was documented in roughly 10% of the patients treated with this drug. This evidence, which is suggestive of toxic liver damage, in all probability would have blocked further drug testing if an association had not been discovered between the cases of hyperbilirubinemia and the uridine diphosphoglucose (UDG)-glucuronyl transferase 1 (*UTG1*) gene. Instead, within the time course of a phase III trial, the manufacturer was able to attribute the 'adverse reaction' to a genetic risk factor associated with a clinically benign form of Gilbert syndrome.^{62,76} In IND and NDA applications presented to the FDA, pharmacogenetic/pharmacogenomic tests included in the early phase of development have shown that certain adverse effects are related to drug metabolism by 350P enzyme isoforms.⁷⁸ The outcome of drug therapy can be influenced by polymorphisms of genes within various functional categories, including those involved in drug transport (for example, glycoprotein P₁ (ABCB₁), which affects plasma levels of digoxin), drug metabolism (e.g. genes encoding thiopurine S-methyltransferases can influence the risk of thiopurine toxicity), and expression of target receptors (for example, the gene encoding the β_2 -adrenoceptor (β_2 AR), a G protein-coupled receptor that mediates the actions of catecholamines).⁷⁵ In asthmatics, a clear correlation has been demonstrated between the outcome of treatment with β_2 -agonist albuterol and specific haplotypes of the *ADRB₂* gene encoding β_2 AR.⁵²

In 50% of cases the pharmacogenetic polymorphism is not significantly associated with drug response therapy.³⁴

Despite our increased knowledge of the human genome and that of other species, the fundamental nature of many disease processes has remained obscure, and this has stimulated the development of methods for correlating gene expression with phenotypic results.

The so-called 'omic' technologies include:

- proteomics
- transcriptomics
- (pharmaco)genomics
- metabolomics
- metabonomics
- toxicogenomics.

These technologies should be able to reveal modifications produced in vitro or in vivo by drugs and toxic agents at the level of the gene itself (for example, toxicogenomics) and/or in the expression of proteins (proteomics). These pharmacological/toxicological fingerprints of an NCE's action on living material are useful in terms of predictive toxicology, identification of toxicological mechanisms (a major part of NCE risk assessment), and the preclinical and clinical development of NCEs. This approach could eliminate the need for costly histological, electron microscopy, and biochemical studies of living tissues, which are currently used to detect subtle forms of structural damage.⁶²

An entire volume in this book has been dedicated to the technologies. The present discussion will be limited to the aspects that are most important to the field of drug development. Genomics and structure–activity relationships (SARs) can lead to more rapid selection of new drug targets and new drugs and more rapid identification of mechanisms underlying toxicity.²³

2.06.4.3.1 Proteomics

The proteome is defined as the expressed protein complement of a cell, organ, or organism and it includes all isoform and posttranslational variants.⁷⁴ According to Kramer and Cohen,²⁹ proteomics is used to determine differential protein expression, posttranslational modifications, and alternative splicing and processed products. Two-dimensional gel electrophoresis is commonly used to fractionate proteins, which are separated first on a polyacrylamide gel according to isoelectric point (first dimension) and then at a 90° angle on the basis of molecular mass (second dimension). The technique is often used to separate the numerous proteins from a cell or tissue, which are subsequently analyzed by MS to identify those that are differentially expressed or modified proteins. Control of proteome can be affected at the translational, posttranslational, and functional level.⁷⁴ A recent example of this innovative strategy was used to study the anticancer drug bortezomid. In animal models, a single dose of this compound was associated with 80% inhibition of proteasome activity in PBMCs and no irreversible toxicity. The inhibitory effect was no longer detectable 72 h after drug administration.⁷⁹

2.06.4.3.2 Transcriptomics

Transcriptome analysis provides a measure of RNA abundance, and it is usually limited to isolated tissues or peripheral blood lymphocytes.

2.06.4.3.3 Pharmacogenomics

Pharmacogenomics uses biological indicators – DNA, RNA, proteins – to predict the efficacy of a drug⁸⁰ and the likelihood of an adverse event in individual patients.^{28,81} It is a relatively new field that includes the study of genetic variations (polymorphisms) between individuals and how these variations influence responses to therapeutic drugs.^{18,75,82–84} Although 'pharmacogenomics' and the older term 'pharmacogenetics' are often used interchangeably, the former term is broader in scope.³⁴ Pharmacogenomic research is proceeding along two main pathways: (1) the identification of new genetic targets associated with various diseases; and (2) the identification of specific genetic polymorphisms linked to the responsiveness to particular drugs.²⁸

In short, in pharmacogenomics the static aspect of pharmacogenetics becomes dynamic.⁷⁴ In effect, the genome is static whereas the proteome is in a state of continuous flux in response to internal and external stimuli. The proteome is the expressed protein complement of a cell, an organ, or an organism, and it includes all isoforms and posttranslational variants. A cell contains a single genome and multiple proteomes. The proteome can be modulated at the translational, posttranslational and functional levels.

2.06.4.3.4 Metabolomics

Metabolomics is used to study the metabolic regulation in single cell types.

2.06.4.3.5 Metabonomics

Metabonomics is the study of endogenous metabolites, systemic biochemical profiles, and data on regulation of organic function based on analysis of biofluids and tissues.⁷⁴ It can provide a 'snapshot' of the small molecules (amino acids, organic acids, sugars) present at a given time in a cell, fluid, or tissue. In MS analysis of samples, the peaks are compared with those contained in a standard library to identify and name known biochemicals and to catalogue unknown ones.^{12,27,74} NMR spectroscopy is an equally valuable tool in metabonomics due to its ability to furnish results rapidly and with reduced workloads.⁷⁴ Metabolic profiles of biological fluids (plasma, CSF, urine) reflect normal variations as well as the physiological impact on organs or organ systems of toxic insults and diseases. NMR spectroscopic analysis of biofluids has identified new metabolic indicators of organ-specific toxicity in rodents, and this explorative role is one in which the new technology excels.⁸⁵ For example, the combined alterations of a series of urinary parameters, trimethylamine-*N*-oxide, *N,N*-dimethylglycine, dimethylamine, and succinate, have been shown to reflect damage to the renal papilla, a condition for which no reliable marker was previously available^{27,85} (Figure 9).

MS-NMR on intact tissues allow direct correlation of tissue indicators and biological modifications. Metabonomic criteria can also be used to evaluate the efficacy of an NCE or other therapeutic agent. It may allow identification of the organ targeted by a toxic effect and the underlying biochemical mechanisms and define biochemical indicators of the onset, progression, and regression of the toxic lesions. HRMAS NMR spectroscopy can investigate biochemical changes in tissues directly. Unfortunately, this approach is rather labor-intensive and currently not amenable to automation.²⁷ It is possible to foresee future situations in which metabonomics, gene expression, and proteomic data are integrated using multivariate approaches to provide a unified vision of an organism under various types of stress, based on indicators furnished by all three platforms. Q-TOF, LC/MS/MS systems are also popular for the characterization of metabolite profiles. The configuration of a Q-TOF results in an instrument capable of high sensitivity, mass resolution, and mass accuracy in a variety of scan modes.²⁵

2.06.4.3.6 Toxicogenomics

Toxicogenomics is the application of microarray analysis toward toxicology. It aims to identify targets and mechanisms. An *in vitro* toxicogenomic assay will only find practical applications in drug discovery if gene expression patterns or markers can be identified that show close correlation with the potential drug toxicity.^{20,31} Because changes in gene expression precede changes at the histological or anatomopathological level, transcriptome analysis has the potential to identify compounds with toxic liability early in the drug discovery process.^{20,31} This task, however, has proven to be considerably more difficult than anticipated. In most cases, it is highly unlikely that a given toxic effect will be strongly correlated with an expression change involving any single gene. The results showed that, based on gene expression analysis, liver slices, followed by primary hepatocytes in culture, were the most similar to intact rat livers.³¹

Using gene expression profiling, trovafloxacin, a quinolone responsible for severe liver toxicity in a small number of patients not observed in preclinical studies, can clearly be distinguished from other quinolones; overall treatment with trovafloxacin resulted in far more gene expression changes than treatment with other quinolones.³¹

2.06.4.3.7 Usability and criticism

The significance of genotyping is different in the various phases of clinical testing³⁴:

- Phase I: identify polymorphisms correlated with phenotypic elements (e.g., pharmacokinetic and pharmacodynamic properties, excretion, and serum levels)
- Phase II: genotype–phenotype correlations. Associate specific polymorphisms with efficacy differences using the candidate gene approach. Data on molecular profiles associated with the response to an NCE
- Phase III: use the results obtained in phases I and II to design an optimal large-scale phase III study. Test candidate genes for efficacy and metabolism. Can be useful for carrying out large-scale genotyping studies to discover new pharmacogenomic indicators. Identify responders versus nonresponders to certain drugs or to the NCE itself
- Phase IV: the studies conducted in this phase might be useful: to identify rare adverse effects and the relations between these events and specific populations; for marketing considerations (that is, to determine whether a diagnostic test is capable of distinguishing the drug in question from its competitors and whether the market for a given drug would justify the development of diagnostic tests).

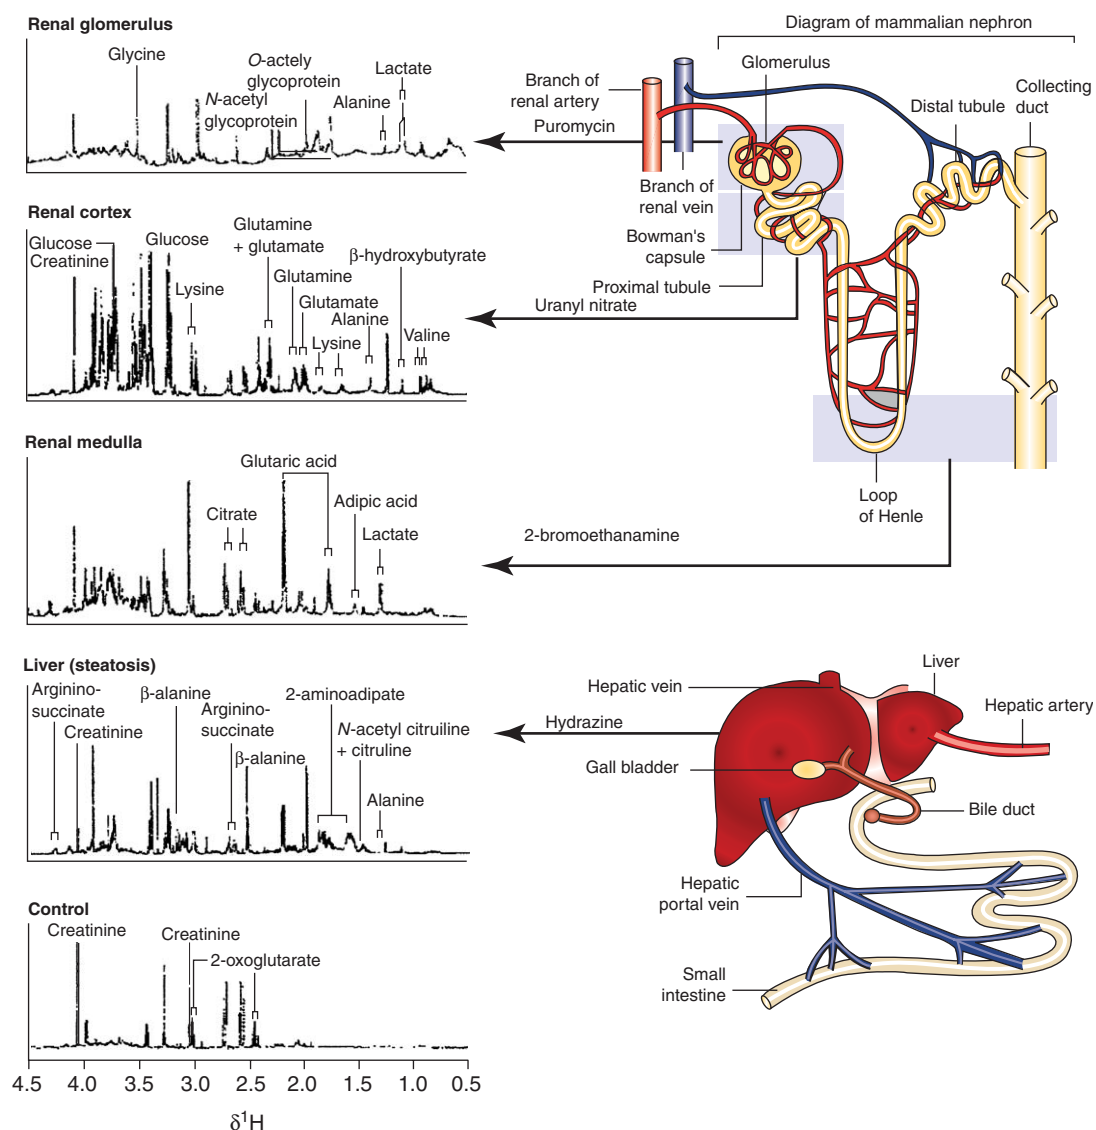

Figure 9 Metabonomic detection of liver and kidney toxicity. Stack plot of NMR spectra showing characteristic metabolic fingerprints of tissue-specific toxicity produced by different site-selective xenobiotics given in single doses to rats in relation to an untreated control. Each 600-MHz spectrum represents one time point after dosing for each toxic compound. The xenobiotics affect specific regions within the organs (depicted in the figure by shaded boxes); puromycin affects the renal glomeruli; uranyl nitrate affects the lower regions of the proximal tubules; 2-bromoethanamine affects the renal medulla, including the loop of Henle and the collecting ducts; and hydrazine affects the hepatic parenchymal cells. (Reproduced with permission from Nicholson, J. K.; Connelly, J.; Lindon, J. C.; Holmes, E. *Nat. Rev. Drug Disc.* **2002**, *1*, 153–161 © Nature Publishing Group.)

Pharmacogenomic studies could also reduce costs in preclinical and clinical phase III testing by allowing the early elimination of certain drugs and identifying a more selective target population for others. The selection of drug therapy based on individual genetic profiles can lead to a clinically important decrease in adverse outcomes.⁸⁰ On the other hand, however, individual subjects or groups excluded from trials based on genotype data may be deprived of the benefits associated with trial participation. Pharmacogenomics thus provides a new setting for reassessing the ethics of research on human subjects in terms of the tests performed for recruitment and the eligibility of various groups.

Ideally, a variety of drugs would be available, each designed for the genotype of a given individual, but it seems more likely that a patient will simply be classified as a responder or nonresponder with respect to a given treatment for a given disease or condition.

It is important to recall that environmental factors are also important. Many common diseases are polygenic and multifactorial and subject to the influence of gene–gene and gene–environment interactions. In addition, roughly 50% of all polymorphisms have no effect on the dose response to drugs.³⁴

As for the actual possibilities for using the omic technologies in drug development, it is important to recall that, at present, there is no universal consensus within the scientific community regarding the best design for genomic tests. It was hoped that HT genomic studies would clarify associations between ADRs and SNPs, but thus far no methods have been established for analyzing the data from clinical trials currently present in the literature.³⁴

Basal gene expression profiling of cancer cells can classify and predict long-term outcome, but these studies have yet to predict the initial response to therapy.²⁰ The immediate benefits promised by the genomic revolution remain to be seen⁷³ and the true value of toxicogenomics in the field of drug discovery and development has yet to be demonstrated.³¹

In most cases, drug responses depend on a complex series of factors, including multiple genes and environmental factors.^{75,82,83} Response variability can also be the result of other mechanisms, such as epigenetic factors that do not modify DNA sequences. Mechanisms of this type might explain the resistance to alkylating nitrosourea compounds that has been observed in certain cases of glioma.⁸⁴

In light of these considerations, cautious optimism can be justified, but there is still an enormous amount of work to be done in the validation and use of the omic technologies in drug development. The journey, in short, is just beginning.⁷⁴

2.06.5 Time and Cost Requirements for Development of a New Chemical Entity and Factors Contributing to Project Failure

Drug development is risky and time-consuming, and it requires substantial investments in terms of capital (~\$500 million), human resources, research skill, and technological expertise.⁶ Costs are high, even in the initial phases. Determining whether or not a small molecule can be developed currently requires about 6 months and \$500 000.²⁵ Long-term animal testing requires approximately \$3–7 million, and a detailed breakdown of these costs has been published.⁶² The development of new drugs requires nearly \$1 billion and 12 years to bring the average NCE to commercialization.⁵³ \$200 million might be attributed to compound failure.¹² Recently, an NCE targeting the peroxisome proliferator activated receptor γ family ragaglitazar (NN622), a dual acting insulin sensitizer, was found to be positive in the carcinogenic bioassay study (urinary bladder tumors were observed in mice and rats), and the drug had to be dropped during phase III trials, after many millions of dollars had been spent on its development.²⁵ The costs of fundamental clinical testing for an NCE are even higher (in millions of dollars): 15.2 for phase I, 15.7 for phase II, and 27.0 for phase III.⁶ Compounds that are abandoned during the testing process (some as late as phase III) represent an enormous loss, amounting on the average to roughly \$200 million.¹² Since the mid-1960s, the process of drug approval has been modified to significantly improve the safety and the efficacy of new drugs for use in general practice. However, one of the consequences of these changes has been an increase in the time and costs associated with placing a new drug on the market.⁶ It has been shown that small improvements in clinical trial outcomes and decision making translate into hundreds of millions of dollars of development cost-saving and a faster time to market.⁵³

The mean interval of time between synthesis of a compound and approval of the NDA was 7.9 years in 1960; by 1990, it had risen to 12.8 years. Estimates for 2004 dropped to between 3.2 and 8.5 years,⁶ but intervals of 10–20 years are not uncommon. The increasing time requirements are the result of the growing complexity of clinical tests, the demand for increasingly rigid testing protocols, administrative aspects of testing, and the indispensable inclusion in the study of particular population subgroups, such as the elderly.⁶ The duration of clinical testing ranges from 53 to 86 months for NCEs belonging to major drug categories: anti-infective agents: 74 months; antineoplastic drugs: 116 months; cardiovascular drugs: 103 months; endocrine agents: 115 months; and immunological drugs: 100 months.⁸⁶ A 25% reduction in the time needed for the clinical phases of drug development would decrease the capitalized cost of NCE development by 16%.⁵

Approximately one out of every 12 leads completes the process and becomes an NDA⁵⁹ (1:5000²⁵). Between 1983 and 2001, the overall final clinical success rate for all investigational drugs was 21.5%.⁶ The main causes of project failure in the advanced phases of NCE development are pharmacokinetic issues (39²⁷–40%⁸) and animal toxicity (11%⁸). Late evaluation of safety and efficacy, low therapeutic indexes (the ratio of the maximum tolerated dose to the therapeutic dose per kilogram based on repeated treatment in two animal species), and the time, size, and costs of clinical studies are other major reasons for compound attrition.¹² The latter variables can be reduced by the use of reliable and specific biomarkers that can be used as early predictors of efficacy and long-term toxicity.¹² Minor improvements in clinical trial outcomes and decision making have been shown to translate into major savings in terms of cost (hundreds of millions of dollars) and time to market.

The increasing number of potential hits generated each year has not resulted in a corresponding increase in the number of NCEs that reach the clinical trial stage, and this is due in part to inadequacies in the investigation of the candidate drug's pharmacokinetic properties.¹⁴ The advisability of requiring early pharmacokinetic studies in humans has recently been underlined by some authors.²²

In any case, due to the high cost and specificity of the drug development process, most manufacturers adopt a step-by-step approach, with well-defined points for evaluating the results obtained and deciding whether or not to proceed. A balance must be struck between investments and the length of intermediate periods between testing phases, and a continuous evaluation of the project time is needed to make decisions and ensure a reasonable possibility of success as early as the lead stage of the NCE.

2.06.6 Regulatory Problems

As noted at the beginning of this chapter in the US, the FDA reviews and acts on NDAs as well as applications for INDs. In Europe, the European Medicines Agency (EMA) authorizes the registration of innovative drugs, and it is currently the only body authorized to evaluate through the so-called centralized procedure biotechnical products and, more recently, cancer agents.^{87–89} An NCE that has been approved by the EMA can be marketed in all member states of the EU. There are also national regulatory authorities in each state, which can authorize phase I testing and marketing within their respective national territories of drugs belonging to categories other than those indicated above or drugs that are already being marketed in other European countries.

In the US, the time required for evaluation of a NDA and its approval by the FDA decreased in the late 1990s but rose again during the period 2000–2002, and this latest increase has been associated with a decrease in the time devoted to clinical development and an increase in the number of applications. Between 1980 and 2001, the FDA approved 504 small molecules, 40 recombinant proteins, and 10 monoclonal antibodies.⁸⁶

In 1993 with the passage of the Food and Drug Administration Modernization Act (FDAMA),^{6,86} the approval process was accelerated for drugs designed to treat serious or life-threatening diseases or conditions for which no treatment is currently available. These 'fast-track' products are eligible for priority review.

Fast-track approval can also be granted when efficacy data are based on surrogate endpoints, i.e., clinical endpoints other than survival or irreversible morbidity, but only when the NCE provides significantly greater benefits than those offered by existing treatments. In these cases, approval is sometimes issued with restrictions that ensure that the drug will be used safely. In addition, for all NDAs approved based on surrogate endpoint studies, the FDA requires well-controlled postmarketing studies to verify the drug's efficacy in the target population.

The FDA will review and act on 90% of standard original applications within 3 months of receipt and on 90% of priority original applications within 6 months.⁸⁶ The FDA has also pledged to assist industry in the preparation of high-quality applications in an attempt to reduce the need for multiple review cycles.

In efficacy assessment of an NCE, parameters measured with imaging techniques (CT, MRI, PET, etc.) can be used as surrogate endpoints or even as biomarkers if they are reasonably accurate predictors of clinical outcome. This principle was established in the FDA Modernization Act of 1997, which explicitly authorizes the FDA to approve drugs for the treatment of serious or life-threatening conditions on the basis of studies using endpoints of this type.

In a recently issued guidance, the FDA has attempted to clarify its policy on the use of pharmacogenomic data in the drug application review process.^{86,91} The Administration recognizes that, at present, most gene expression profiling data are of an explanatory or research nature and would therefore not be required for submission.³¹

Biography

Paolo Preziosi is Professor and Chairman of the Institute of Pharmacology, Catholic University, School of Medicine, Rome. He received his MD degree from Federico II Naples University and completed his training at the local Institute of Pharmacology, followed by a research fellowship at the Department of Pharmacology of Ghent University, Belgium, under the mentorship of Nobel Prize winner Corneille Heymans. He has authored or co-authored over 160 peer-reviewed papers in international journals in various pharmacological areas, mainly related to the pharmacology of the pituitary–adrenal axis, hypophyseal hormone release, mechanisms of endocrine and immune-related toxicity by anticancer drugs, and pharmacodynamics of various classes of drugs, and more than 300 abstracts. He holds many positions and offices in the pharmacological field: he was formerly President of the International Union of Toxicology and the Italian Societies of Pharmacology, Toxicology and Chemotherapy; Member of the Board of International Union of Pharmacology, of the European Society of Toxicology, of the Scientific Committee for Medical Products and Medical Devices, European Commission, Brussels, and the Scientific Committee for evaluation of medicinal drugs, Ministry of Health, Italy; and he is a fellow of the Royal College of Pathologists, the Czechoslovakian Academy of Medicine J Purkinje, the Academia Europaea, the French Académie Nationale de Pharmacie. He is also a member of the British Society of Pharmacology, the Society of Toxicology (US), the Société Française de Pharmacologie, and the Société belge de physiologie et de pharmacologie fondamentales et cliniques. He is honorary member of the International Society of Chemotherapy, of the European Society of Toxicology, and of Italian Societies of Pharmacology and of Toxicology. He is on the editorial boards of several journals.

2.07.1 Introduction

In his book on strategic out-sourcing, Maurice Greaver frames the issue of out sourcing in a clear and compelling context:

Out sourcing is not a secret formula for success, not a magic wand for vaporizing problems, and not a management fad. It is just a management tool – not ‘the tool’ but a newer tool, which is not well understood. In a capable executives toolbox, it coexists with tools such as benchmarking, reengineering, restructuring, and activity-based cost management.¹

To many chemistry managers and heads of discovery research, the discussion of chemistry out-sourcing takes on a much less dispassionate feel than the view expressed by Greaver. Many in the pharmaceutical industry view discovery chemistry as a ‘core competency.’ For this reason, out-sourcing this highly iterative, cycle-time critical activity with significant potential to generate intellectual property (IP) appears counter-intuitive at first blush. There are advocates on both sides of the equation. On one hand, the success and growth of the out sourcing market related to pharmaceutical R&D has caused some to ask whether all of pharmaceutical R&D can be out-sourced.² Others assert that certain activities (like the lead optimization phase of drug discovery) do not fit into the compartmentalized component model of out-sourcing.³ Others who take a broader perspective on the business of out-sourcing business process functions now suggest that out-sourcing will lose luster within large organizations.⁴

This chapter is directed to stakeholders of chemistry sourcing in order to help place this type of sourcing in perspective. It is directed to the managers of R&D organizations who are considering what activities are appropriate for sourcing and the risks to consider when out sourcing all or a portion of their chemistry activities. It is also directed at contract research organizations (CROs) participating in chemistry services. By offering a perspective on the perceived risks and benefits from a big pharma perspective, it may be possible to better consider what services, activities and performance criteria are considered important to your customers. Lastly, this chapter may also provide bench chemists in industry with a business perspective of the chemistry landscape that may help them better reflect on what they or their management may view as value-added activities within the chemistry discipline.

2.07.1.1 Context for Chemistry Out-Sourcing

Given the well-documented productivity gap of big pharma,^{5,6} R&D organizations face the business imperative to increase the output of clinical candidates relative to the amount of resources invested. The initial focus was on in licensing of advanced clinical candidates. However the competition in this area has produced a dearth of advanced clinical candidates, resulting in companies seeking to license compounds that are substantially less advanced in their clinical development. It remains to be seen if this early stage in licensing will indeed achieve its goal of reducing attrition and increasing productivity.

Sourcing of all varieties (out-sourcing and in-sourcing) has always been a component of the R&D process that has helped reduce the cost associated with drug development through efficient management of internal capacity and workflow.⁷ In discovery, companies have routinely established strategic alliances with biotechnology companies to gain access to a technology without buying the physical assets, the equipment, or the company in order to do so. Estimates

vary, but some suggest that by 2010, more than 40% of R&D is projected to be out-sourced to more specialized firms in order to efficiently maintain a strong and vital pipeline for new blockbuster drugs.⁸

In the chemistry business area, early deals and alliances tended to focus on access to natural products: an area that many companies lacked a scientific expertise in. However in the late 1990s, the desire to grow small-molecule, 'druglike,' compound collections led discovery organizations to sign deals with companies that produced compounds of a parallel chemistry origin. The smaller companies making these deals tended to offer a platform where parallel chemistry-enabled compounds could be produced in large numbers and at a lower cost than the traditional methods used inside many major R&D organizations. Over time, as the ability to prepare parallel chemistry enabled compounds grew, many small companies shifted their business model to licensing access to their small-molecule collections that were billed as more 'druggable' relative to previously offered compound collections.

As the 'out-sourcing' of parallel chemistry-enabled chemistry was increasing, the merger and acquisition within big pharma led to the growth of small CROs that focused on the type of chemistry activities critical to drug discovery that were not suitable to parallel chemistry-enabled technologies. Many of these companies were started in the countries where the large R&D organizations housed their discovery centers such as the US, EU, and UK. More recently, expatriates who had worked in large pharmaceutical organizations have started to found companies in China and India, a trend seen in a number of industries.⁹ Clark and Newton have provided an excellent review of this history and the partnerships that were formed during this period.¹⁰

2.07.1.2 The Stages of Drug Discovery

Before delving into the sourcing analysis, it is worthwhile to review the stages of drug discovery that relate to the quality and value of the lead compounds or lead matter. It is lead matter that is systematically modified in the drug discovery process that ultimately produces clinical candidates. This discovery process is often broken out into three distinct stages:

1. Hit follow up. This is the stage that follows the screening of the corporate compound file against an enzyme or target protein. The compounds that are identified at this stage are validated for their identity and potency and related analogs are prepared and tested to confirm a trend in activity.
2. Lead development. At this stage, the lead series are optimized for in vitro and in vivo activity. Initial screens for selectivity, safety, and drug metabolism are introduced to ensure the lead is not just potent but is becoming druglike.
3. Candidate seeking. At this stage, the compounds are optimized for their suitability as a clinical candidate. Leads that are evaluated at this stage are assessed more extensively for their pharmacological profile, safety, and drug metabolism properties. Pharmaceutical science plays a significant role at this stage and the drug attributes such as solubility, salt form, synthetic route and cost of goods come under increased scrutiny.

A lesser-known element of the discovery process is the high level of attrition associated with the progression of lead matter from hit follow-up to clinical development. An article by George Milne of Pfizer in 2003 indicated that of a hundred programs or targets that begin the discovery process, only one progresses to the market (see [Figure 1](#)).¹¹

2.07.1.3 Common Sourcing Terms

Sourcing can be characterized into four main categories depending on the relationship of the service provider to the client.

2.07.1.3.1 Domestic in-house

A model where the activity is conducted internally, within the current footprint of the R&D organization and performed within the same country or region from which the activity is sponsored.¹²

2.07.1.3.2 Domestic out-sourcing

A model where the activity is conducted externally using third-party resources within the same country/region as the client R&D organization.¹³

2.07.1.3.3 Offshore out-sourcing

A model where the activity is conducted externally using third-party resources in a different country or region from that of the sponsor location. Often referred to as offshoring, this type of relationship has often been associated with clients in the US or European Union (EU) and providers countries such as the UK,¹⁴ India,¹⁵ China,¹⁶ and Russia.¹⁷

Figure 1 Historical attrition of discovery programs as a function of stage. © Pfizer Inc. 2005.

2.07.1.3.4 Captive offshoring

In this model, the activity is conducted within the R&D organization located in a different country or region from that of the larger, more established US or European research centers. The facilities are typically located in a far-shore venues. Examples of this operating model include the Roche¹⁸ operations in Shanghai, China, and the GSK,¹⁹ Novartis²⁰ or AstraZeneca operations in India. Lilly,²¹ and more recently Wyeth⁷⁴ have established slightly different organizational models of a captive offshore facility. In these build-to-own (BTO) models, the companies have a dedicated set of chemists and support staff working in a facility that has the corporate logo on it, but is maintained and managed by an external service organization. Robert Ruffolo, R&D President at Wyeth recently described this arrangement at a presentation in 2005²²:

“As we speak we’re opening up medicinal chemistry centers. They’ll have the Wyeth name on it [but] it will be a building ... with no Wyeth employees in it, except one managing it. According to this report, the centers will be located in a number of different countries though no specific countries were named at the time.”

A related set of terms is emerging to describe the variety of service providers who operate in the discovery chemistry space.

2.07.1.3.5 Domestic providers

These CROs are colocated in the countries of their clients. Many tend to be founded or led by faculty of nearby universities or were founded by ex-pharmaceutical alumni who started their own companies.²³

2.07.1.3.6 Offshore providers

This refers to any service providers who are on a different continent than the client. For US companies, this often refers to companies in the EU, Russia, India, or the Asian rim. Scientists or managers formerly from large, US- or UK-based pharmaceutical companies have founded a surprising number of these companies. Within this group of providers, one can further break providers down into near-shore providers and far-shore providers. While the descriptors of ‘near’ and ‘far’ shore do refer to geographical distance from the client R&D organization, of greater relevance is that ‘far’ shore venues typically are in developing countries with lower cost bases than near-shore venues.

2.07.1.3.7 Hybrid vendors

This is an emerging type of business model where a CRO will have a presence in both low- and high-cost sourcing markets. More commonly it will be headquartered in a high-cost market but there are instances where it could be based in a low-cost market and have a presence in a high-cost market. This formation of a hybrid organization would usually be driven by the need to obtain greater breadth of service/capability than a single country model. For example, some US-based CROs have announced either a captive offshore facility in Asia,²⁴ while several Chinese-²⁵ or Russian-based²⁶ companies have established US facilities. For clients who are either unwilling or unable to tap into low-cost markets directly, these hybrid arrangements may represent a convenient way to access this labor pool.

2.07.1.3.8 University-based providers

This is a different kind of hybrid model where the CRO leases and uses laboratory space from a university. In some models, a professor at the university may be on the payroll of the CRO and postdoctoral scientists or graduate students

may be employees of the CRO. Many small start-up companies use this approach to build a client list and identify key talent prior to building their own facilities. While reports have emerged citing the success of this model,²⁷ the paucity of companies operating with this kind of model may reflect its niche or transitory role in the larger sourcing industry.

2.07.2 Why Out-Source Discovery Chemistry?

Although chemistry is central to the drug discovery process, there are several reasons to consider sourcing all or a portion of selected chemistry activities. Some of these points are listed below. Additional aspects related to the topic of out sourcing drug discovery have been previously described in the literature.²⁸

2.07.2.1 Expand or Improve Capabilities

A given service provider could offer unique synthetic expertise (e.g., experience with heterocyclic chemistry, chiral transformations, or resolutions²⁹), capabilities (to handle highly corrosive or explosive transformations involving fluorine, nitro-containing compounds, hydrazine, azide, diazomethane, or peroxide chemistries), high potency compounds such as beta-lactam or cytotoxic chemistries, etc.,³⁰ or technologies (massive parallel synthesis capabilities,³¹ high pressure chemistry,³² high temperature reactions) that are not available internally. The need for these competencies tends to be episodic in an R&D organization. However, when they are needed, time and access to knowledgeable staff are often critical factors in the decision to procure these services externally. While the cost avoidance associated with the purchase of assets is an independent driver to sourcing (see below), this aspect is especially important in the areas of chemistry described above where the need for this expertise is not anticipated to be routine.

2.07.2.2 Gain Access to a Larger or More Diversified Talent Pool

The sourcing of activities to regions outside of ones typical hiring market provides a firm with access to a larger talent pool. If the sourcing partner is located in a region outside of where the client operates, access to a diversified talent pool may expose the client's staff to different ways of thinking or approaches to problem solving. Countries with a strong reputation for developing talented scientists in chemistry include Russia,³³ China, and India.^{34,35} In addition, many Western-educated scientists from these regions are now returning to their home countries to start or join local chemistry service providers and pharmaceutical or biotech companies. The cultural or industrial experience that these expatriates provide can further enhance the efficacy of communication between the CRO and the pharmaceutical clients they work with. Of course, an external collaborator does not necessarily need to be from another country to provide a diversity of thought. Many domestic providers who have been trained or have worked in a different corporate culture can also provide a diverse perspective that enhances the decision-making within an organization.

2.07.2.3 Staffing Flexibility

There are times in an R&D organization where the demand for synthetic chemistry will exceed capacity. Faced with this prospect, the company can invest for the long term and grow the size of its permanent staff by starting or leveraging a recruiting, hiring, and training program.³⁶ However if the long-term demand for chemistry capacity is uncertain, or if the need for an immediate infusion of trained chemists is high, having access to quality out-sourcing capabilities will allow the organization to resource its immediate needs while it weighs the decision to grow its internal organization for the future.

Similar to the rise and fall of short- and long-term staffing needs, there are times when the financial resources of an organization can fluctuate. During times of financial surplus, out-sourcing chemistry projects that are important but not urgent can be achieved when they might otherwise not have been addressed. This is especially useful for the sourcing of monomers and templates (M&Ts: see below). Conversely, during times of financial shortfalls or distress (bankruptcy, attrition of clinical candidates or marketed drugs), the ability to leverage the contractual flexibility of CRO staff may reduce the need to cut back permanent staff within the R&D organization.

Lastly, there is an efficiency component of dynamic staffing that is sometimes overlooked in terms of flexibility. The orientation of CRO chemists is to simply provide whatever target compounds are requested, regardless from which programs they originate. In contrast, the decision to move internal chemists from one program to another can have implications related to a sense of program completion or anxiety about missing the key compound that could turn the program around. If internal program staffs are moved frequently from one program to another, there may be aspects of career development that need to be factored into the decision. Such aspects are not a factor for the typical CRO

chemists, particularly contract chemists who provide more synthetic capabilities rather than medicinal chemistry. This is not to devalue the tenacity or instincts that internal chemists routinely demonstrate. In fact, this tenacity and a knowledge of the program details has also rescued many a clinical candidate from program termination.³⁷ However with regard to advantages to the flexibility of sourcing, this particular human aspect is a point worth noting.

2.07.2.4 Reduce Labor Cost

Aside from technology-assisted areas of chemistry, synthetic chemistry continues to be a people-intensive activity. In labor-intensive efforts such as analog production, the ability for a CRO to produce compounds at a lower cost per chemist will lower the overall cost of compound production. The differences in labor rates are difficult to determine with great precision. Kathleen M. Schulz of BMGT said that PhD chemist salaries in India and China are 20–30% of US salaries.³⁸ An article by McGoy noted it costs roughly \$60 000 a year to hire a full-time equivalent (FTE) chemist in China or India while rates in the US range from \$200 000 to \$250 000.³⁹ For this reason, companies continue to leverage their global reach not only to gain access to intellectual capital from around the world, but also to leverage the arbitrage of labor costs that presents itself globally in selected areas of synthetic chemistry.

When looking at labor rates, it is important to assess the fully loaded costs of a CRO chemist relative to the internal cost. For example, it is worth determining if the lower labor costs are offset or enhanced by the cost of reagents, capital, and/or fees associated with customs or other import/export transactions. It is also important determine if the quality and productivity are similar to that provided by the client's internal chemists. This latter aspect is discussed in the metrics portion of the chapter.

2.07.2.5 Minimize Risks Associated with Acquiring Assets and Financial Flexibility

For large and small companies alike, the ability to sample a technology via an out-sourcing arrangement provides a significant advantage. An organization may de-risk the investment by acquiring access to assets that have been field tested by a service organization on the corporations' projects. This deferral may result in the organization buying the same technology or the next generation of that technology, thereby reducing the cost of upgrading the technology had it been purchased directly. The aforementioned example with parallel chemistry is such a case where this type of 'renting' prior to buying can help to inform the decision whether to purchase the technology internally.

In addition, the ability to out-source functions or tasks may free an organization to invest in areas that maximize cash flow or profits, or provide financial flexibility. For large pharmaceutical companies, stock value is predominately driven by growth versus assets creating incentives to utilize out-sourcing to minimize capital investments. This capital avoidance may also be pertinent to small companies that are just reaching the point where chemistry resources are needed. Small companies avoid financing assets that will not yield positive cash flow such as buildings, associated equipment (rotary evaporators, computers, etc.) and the supporting analytical instrumentation (nuclear magnetic resonance (NMR) instruments, mass spectrum devices, spectrophotometers, etc.), needed to enable a drug discovery organization.

2.07.2.6 Increase Value-Added Activities of Internal Staff

Discovery chemists take on a variety of tasks associated with drug discovery. While some are highly innovative activities which result in generating IP for the organization, others are repetitive, low-value tasks (compound resynthesis, preparation of custom monomers for a parallel chemistry library, etc.) that, while necessary, could be delegated to others or taken off-line from other, higher valued or time-critical activities where the organization should be focusing its attention. As Steven M. Hutchins, director of out-sourcing at Merck and Co., was quoted as saying, "We want our medicinal chemists concentrating on projects and not spending a lot of time producing intermediates and reagents."⁴⁰ From a strategic perspective, aligning high-salaried staff with highly valued activities and moving low-value work to lower-cost providers makes good business sense.

2.07.2.7 Improve Performance

An article by Chrai highlighted that a nonfinancial benefit to out-sourcing is that it tends to promote competition.⁴¹ In his analysis, he asserts that the competition among suppliers ensures the availability of higher-quality goods and services. An article by Tharp suggested that a careful assessment of performance versus cost metrics revealed a 30–80% cost savings by out-sourcing activities that were run both internally and externally.⁴² Easton asserts that CROs are expected to perform at higher levels of productivity than our own (internal) function in order to generate profits on what for the client may be an overhead function.⁴³ He also cites inferior travel policies and flatter management for

contributing to this enhanced performance of sourcing organizations. This presumably results in a higher percentage of the CRO staff working at the bench, which should translate to a higher output per employee than what may be observed in traditional Western-styled drug organizations. Others note that contract staff are positioned to make more efficient use of their time for the client since they do not have to be involved with personnel issues.⁴⁴

Prahalad notes that because remote development and delivery demands clear documentation, the process capabilities of both the customer and the vendor improve as a result of a sourcing relationship.⁴⁵ Most often, for sourcing relationships to work, the customers have to get their legacy processes cleaned up. Many firms have found that out-sourcing helps in better documentation of internal processes.

2.07.2.8 Commercial Considerations

Large pharmaceutical companies typically invest significantly in research. At the 2004, American Chemical Society/Pharma Leaders Meeting in Cambridge, MA, it was noted that the large potential market size and growing demand of customers in these parts of the world, coupled with the potential cost efficiencies they present, make movement of certain R&D functions an attractive option for companies.⁴⁶ James Shaw, president for China of Eli Lilly & Co., noted that the \$10 billion pharmaceutical market in China is growing at double-digit rates and is likely to be the world's third largest, after the USA and Japan, within a decade.⁴⁸ "China is important today," Shaw says. "But in the future it will be critical." In addition, countries such as India are considering 10-year tax holidays to pharmaceutical companies involved in R&D in India.⁴⁸

2.07.3 Developing a Discovery Chemistry Sourcing Strategy

For both the small biotech and the mature, fully integrated pharmaceutical organization, it is essential to establish a process to determine which activities lend themselves to being sourced. The first step in this process is to disaggregate the unit of work being assessed into discrete activities. Once the list of target activities is established, it is important to assess the activity against a set of criteria supporting the dimensions of activity ownership or control.⁴⁹ This step will help assess the suitability of the activity to be done by others outside of the R&D organization or whether it is better done inside the confines of the R&D organization.

If an activity is assessed as being sourceable, the next step is to determine the appropriateness of offshoring the activity. This methodology requires additional steps including assigning weights and scores to the criteria per activity, calculating the fully loaded cost differential for each activity, and assessing the external marketplace per activity. However for the purpose of this chapter, the application of this sourcing assessment will focus only on the initial three steps.

2.07.3.1 Defining the Primary Chemistry Activities

Many chemistry departments tend to be divided into the major subtheses of chemistry such as analytical chemistry, computational chemistry (which may include various components of information technology (IT) support), or synthetic chemistry (often used interchangeable with medicinal chemistry). Pharmaceutical sciences tends to be a development activity, but some companies have this as a preclinical function. For small companies that presently lack these large department functions, these departments units may be an appropriate sized bundle of activity to assess the suitability of procuring these services rather than building them.

For large pharmaceutical organizations that may have these functions already in place, it is difficult to do an analysis on such large departments that may have multiple subactivities with differing activity or control criteria. Moreover, not all companies have the same activities in the same organizational lines. For these reasons, it is important to look at the subactivities or skills that make up an activity when initiating a sourcing assessment. When one starts to get to this level of detail, it is possible to tabulate a series of subspecialization or subactivities within larger units or departments and generate hierarchies such as that shown in [Figure 2](#).

A review of a hypothetical mapping process will identify several types of activities. Some, like combustion analysis, are stand-alone activities that few companies today run internally. Others activities, like the design of an improved molecule for a lead optimization program, involve related activities such as data visualization, target or analog design, and perhaps even route design skills. For such activities, it may be beneficial to cluster all three activities into the broad category 'Lead design activity' though separate skills and competencies may be involved. Lastly there will be some activities that are similar in methodology but different in application when viewed across the organization. An example may be route design (in the synthetic chemistry unit) and process chemistry in the pharmaceutical science area. There may or may not be benefits to assessing this process as a unit rather than as two separate sourcing assessments.

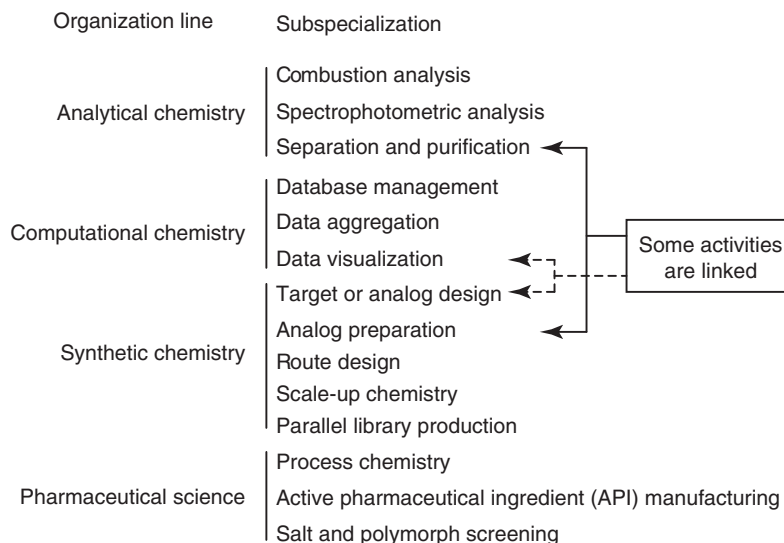

Figure 2 Deaggregating chemistry-related activities. © Pfizer Inc. 2005.

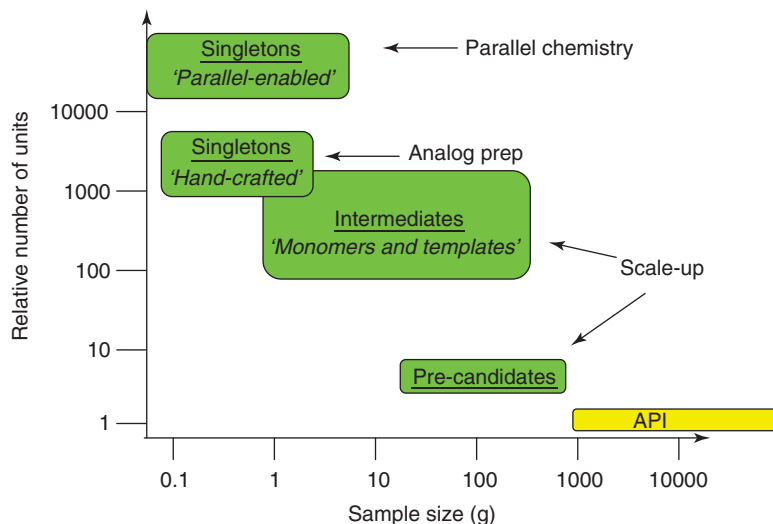

Figure 3 Subcategories of synthetic chemistry. © Pfizer Inc. 2005.

When a target activity is broad and complex, is composed of distinctly different work streams, and offers an attractive opportunity to evaluate available external market offering (e.g., structure–activity relationship (SAR) analysis), it may be helpful to break down the activity into smaller subcategories. Subcategories are activity-centric and can be determined by an understanding of where resources are focused (staff/budget) and as such are typically either labor-intensive activities (large staff count) or specific technology-dominated areas (low staff count but technology intensive). For example, synthetic chemistry can be thought of as the art and science of making molecules. However, depending on the amount of material prepared, the preparation may involve some unique skills or capabilities. Alternatively, if the number of compounds produced per unit time is anticipated to be large for one type of activity and sparse for another, this could become a distinguishing characteristic to create subcategories of activities. As Figure 3 indicates, one way to visualize certain subactivities of synthetic chemistry is to array them in a grid according to number of compounds produced versus the quantity of material typically desired. For the purposes of this analysis, the major activities in this space include parallel chemistry, analog preparation, and scale-up of compounds. While vendors exist for the preparation of metabolites,⁵⁰ or reference standards,⁵¹ this represents a small percentage of the discovery chemistry business and will not be expanded upon in this chapter.

The process of identifying subactivities can be either introspective as defined above or may be more opportunistic based on benchmarking the activities that peer organizations have out sourced or for which CROs have offered services. With an eye toward this latter approach, it is worth reviewing three activities in particular that tend to attract a lot of discussion when companies identify areas to review for their sourcing potential.

2.07.3.1.1 Scale-up or compound resynthesis

The out-sourcing of active pharmaceutical ingredients (API) is a well-established area of pharmaceutical out-sourcing.^{52,53} This activity is distinct from discovery chemistry sourcing in that it often centers on a well-characterized compound that has entered clinical development. It is sourced in larger quantities (kilogram to kiloton) than the scale-up typically encountered in discovery (typically kilogram or less).

In the discovery space, the step prior to clinical candidate identification often produces a small set of compounds that may themselves be named as clinical candidates. These pre-candidates are often identified late in a program, and tend to be needed in multigram quantities for more advanced, in vivo and safety profiling. The number of compounds identified as pre-candidates are usually small (fewer than five) and the amount required for profiling may vary depending on how extensive a set of studies will be required prior to nomination. Some key qualitative aspects to out sourcing pre-candidates include:

- An established protocol. Since these compounds have been prepared already, there will be a procedure for how to make these compounds. Depending on how robust the original synthetic procedure is, a reputable CRO should be able to reproduce the original procedure (base case) or improve upon the yield or process (best case).
- Time is a critical factor. While the protocol to make the compound may not be optimal, it may be important to have the compound made by the known, existing route than invest time and resources in optimizing the route or seeking to improve the yield. Often the resynthesis of compound in large quantities is on the critical path for in vivo profiling, and the scheduling of these studies with either internal or external collaborators requires adherence to strict timelines. Delays in delivering pre-candidates from a CRO could significantly jeopardize the nomination of a candidate and may irreparably harm the reputation of a CRO with regard to future business from within the client's organization.

An equally important, though more common, scale-up activity in the discovery sourcing area is the production of monomers and templates (M&Ts). M&Ts do not tend to have significant pharmacological activity as fragments; rather they tend to be the building blocks for more advanced leads or pre-candidates. While some M&Ts are available commercially, companies tend to source these fragments for reasons of cost or convenience. The time-criticality of these agents can vary depending on their use. In programs where analogs for an active discovery program are produced from a template, it may be very important to have a template produced in a timely fashion. In contrast, there are some M&Ts that are used as part of a proprietary corporate inventory for use in library production or as a repository for future use. These fragments may be less time-critical and their sourcing may be driven more by cost and quality rather than speed to delivery to the R&D organization. Some key qualitative aspects to out sourcing M&Ts include

- Their IP potential. Depending on the novelty, M&Ts may or may not be novel or have appeared previously in patents or publications. Hence there may be significant IP associated with their efficient synthesis, despite their lack of pharmacological activity and building block use in discovery. To this end, it is important to select CROs that have a rigorous IP protection policy in place to ensure that 'IP slippage' does not occur.⁵⁴
- Cost may be a significant driver. In the area where M&Ts are used to stock a corporate repository, the cycle time between requests for synthesis and compound arrival may be less of a factor than the cost per gram. While many of these fragments will have a protocol for their production, an opportunistic CRO with an experienced process chemistry team may seek to optimize the route in order to deliver the desired compound within specifications at a lower cost. This may position the CRO for favorable consideration when it comes to the re-supply of these fragments in the future.

2.07.3.1.2 Analog production (singletons)

Analog synthesis that is not technology-enabled relates to the preparation of compounds in the traditional 'hand-crafted' ways using bench chemistry. In contrast to library production, the production of individual compounds or 'singletons' is often reserved for compounds that are produced on scale or compounds that do not lend themselves

to parallel chemistry production. For the purposes of these discussions, the analog production stage represents the first time a compound is made for testing. As such, there are several key aspects to out sourcing analog production including:

- IP protection. As mentioned above, many of these compounds are made early in the discovery phase when the size and scope of the chemical space explored is small and the pharmacology and drug metabolism of these compounds are not yet optimal. For this reason, companies may choose to defer filing patent applications on the initial compounds until a clearer SAR has emerged. Given that the out-sourcing of this activity may have novel, unpatented compounds prepared at a CRO for the first time, the contract language and due diligence related to externally sourcing this activity is exceptionally important.
- Problem-solving is key. As noted previously, the external sourcing of novel analog will necessitate that the CRO prepare target compounds without an established route. For this reason, a key skill for CRO chemists to demonstrate is the ability to problem-solve in the area of route design. Having noted that, the ability and willingness of the chemists at the contracting R&D organization to research and provide as much information as possible to the CRO chemists remains the primary determinant of the success of out-sourcing analog production.

2.07.3.1.3 Parallel chemistry-enabled synthesis

As mentioned previously, parallel chemistry represents one of the most actively out-sourced areas of discovery chemistry. The heavy investment required for new technologies between 1995 and 1999 made pharmaceutical companies wary of buying or building platform technologies resulting in a preference for fee-for-service or leasing-type deals.⁵⁵ As the technology associated with parallel chemistry became more established, the capital costs were reduced and multiple companies able to offer this service started to appear. This resulted in two phenomena that had an impact on the sourcing of parallel chemistry:

- Commoditization of the market. The ready access to parallel chemistry-enabled technologies allowed both R&D organizations as well as second-generation CROs to start parallel chemistry teams in their organizations. Over time, as the chemistry on plates became more established and robust synthetic protocols were growing in number, the market for parallel chemistry started to fractionate into the high-volume, commodity-type library providers versus companies that could claim some element of added value to their process or products. This bifurcation of an activity is not unique to parallel chemistry and has been reported for other 'craft' processes that have become standardized.⁵⁶
- Migration up the value chain. While the commoditization of the market led to some consolidation,⁵⁷ several companies that started as library-based organizations have either migrated their science platforms,⁵⁸ or merged to jump-start their migration to an integrated drug company.⁵⁹ The risks of sourcing parallel chemistry to companies with their own internal drug discovery engine are discussed later in the chapter.

As a result of the standardization and reduced cost of parallel chemistry-enabling technologies, it is now common that most companies doing analog production sourcing have the capabilities to do parallel chemistry-enabled work as well.

These three activities (scale-up, analog preparation, parallel chemistry) are highlighted because of the maturity of the marketplace associated with sourcing of these activities. For CROs looking to provide synthetic chemistry services to a client, having a service platform that encompasses most if not all three of these activities positions them favorably for medicinal chemistry out-sourcing where a diversity of subactivities are often required.

For companies seeking to build a sourcing strategy, it is important to assemble a level of scholarship on the activities being assessed. Specifically, it is important to understand the sourceability and offshore ability of an activity.

2.07.3.2 Determining the Sourceability of a Chemistry Activity

Given the central role of discovery chemistry activities to drug discovery, the decision to source a particular chemistry activity will depend on a number of factors. Some of the most important factors to consider are found below. These factors may be weighted differently for each activity and the weightings may differ from one organization to another. To some extent, this begins the first step in an R&D organization process toward assessing what its core competencies are.

2.07.3.2.1 The maturity of the process

There are many activities in discovery chemistry that are so routine and well credentialed from a protocol standpoint that they lend themselves to being done externally. The analysis of carbon, hydrogen, and nitrogen content for a compound is a classic example of a mature process, and few pharmaceutical companies perform this analysis in-house. More recent examples include the resynthesis of compounds with established protocols (e.g., M&Ts), pre-candidates, and even parallel chemistry projects where established protocols for coupling and purification are well established. In these types of 'mature' processes, there is reduced uncertainty as to the ability to deliver the desired outcome without compromising quality. In general, the prototypical mature process is one with robust documentation that can be handed to a third party with sufficient detail that they can read and executed against by the CRO staff. Ideally, it should not require a lot of judgement/interpretation.

2.07.3.2.2 Control of the process outcome

An activity, no matter how discretely defined, may still have a several substages to it. Some may include upfront planning and design that influence the success of the outcome, others are simply tactical and executional in nature. To illustrate this point, one could break down the chemistry-related steps of lead optimization into three stages with varying degrees of influence on the process outcome:

1. Lead design. The first step in the process involves an upfront, design phase where trends in biology and drug metabolism data are identified. Based on these, a hypothesis is generated directing what the next target to be made should be. Computational tools that aid in the prioritization of one lead target over several may aid this design phase. Clearly the overall success of this activity (i.e., a more valuable lead) will be highly dependent on the outcome of this first step of the process.
2. Route design and target synthesis. The design of the lead has some element of synthetic do-ability factored in. Nevertheless, the route design phase may represent a mid-level activity with regard to the impact on the outcome of the process (i.e., a more valuable lead). For lead matter requiring new routes to access the target, there is still a significant potential to influence the process outcome. Therefore the quality of the staff and quality of the idea may still impact the ability to achieve the outcome. Both this and the lead design stages rely on a significant amount of experience and judgement to execute in processes that are less mature.
3. Target resynthesis. In a situation where the prototype has been made and found to be an improvement over the original lead, there may be a need to prepare more material. To the extent the original synthesis is substantially suitable for scale-up, the activity of preparing more material could be described as executional or tactical in nature.

This example serves to demonstrate how an activity (lead optimization) has several subactivities, between which there are various levels of control for the outcome. From a risk perspective, the target resynthesis activity has little suspense (hopefully) regarding the outcome, which is different from the target design stage that involves more planning and design.

2.07.3.2.3 Providing a competitive advantage

When assessing an activity, it is equally important to determine if internally executing the activity gives the R&D organization a competitive advantage. Can the R&D organization deliver the outcome of that activity faster, more cheaply, or in higher quality if the activity were to be introduced or retained in the organization compared to external resources? An illustrative example may be the ability of two different companies to convert the same lead for a kinase program to a clinical candidate. While both companies may have chemists who could design and synthesize compounds, perhaps one company has a competitive advantage in this arena by virtue of their staff (experienced in the lead matter of this gene family and/or a track record of converting kinase leads to candidates), their screening strategy (knowing what counter screens to run and how to weigh the relative importance of the data from these screens), their technology (access to data visualization tools, structure-based drug design (SBDD), computational chemistry tools), their understanding of safety science (knowing the prior art around safety related findings and the relative importance of some data over others to drug attrition) plus other key skills, assets, trade secrets, or experience within their organization. While no segment of the process may be uniquely advantageous to the organization relative to the industry, the ability to leverage these tools effectively and in concert may be the competitive advantage. Having said that, a competitive advantage can be realized even if the skills and technologies are physically separate from each other (i.e., acquired through strategic alliances with other service providers) if the integration provides a value greater than the individual parts.

2.07.3.2.4 Potential to generate intellectual property

While IP can be generated at each stage of drug discovery, some activities have more potential to generate IP than others and some IP has more commercial value than others. For example, the resynthesis of a compound that is in the public domain with no pharmacological activity and no commercial potential for the R&D organization offers little in the way of an IP risk. Hence it is unlikely to be an area the organization will look to patent and also an area where there is reduced concern about exposing information.

Consider the production of novel analogs, and the situation becomes less clear. The value of the IP surrounding the compounds increases if the analogs enter clinical development. However, given the attrition curves seen in [Figure 1](#), it is difficult to determine which programs, and therefore which lead matter, will advance to the clinic. However, the same graph would suggest that novel analog work done in the candidate-seeking stage is more likely to generate candidate-centric IP than the same work done in the hit follow-up stage where lead matter attrition is still relatively high.

Of the activities that are IP-generating, special attention and care should be made around activities that are associated with higher than average commercial value. For example, process chemistry innovations and research on salt or polymorph forms for a drug candidates undergoing clinical development may lead to IP or trade secrets that are more valuable from a commercial perspective than other applications in a candidates patent estate.⁶⁰

2.07.3.2.5 Activity interdependency

Drug discovery is a highly interactive process that involves a variety of chemists, biologists, safety, and drug metabolism scientists to optimize lead matter and identify clinical candidates. It is therefore quite likely that some of these activities are linked to other discovery functions and are therefore cycle time critical. In addition, the same activity might have different time criticalities depending on the stage in which the activity takes place. For example, in the lead development stage, it is likely that the ability to design new target compounds will depend on the speed at which biological data can be generated. If there is a significant delay in generating data for new analogs, there will either be a slowdown in analog production or the analogs produced may not be fully informed with the new data. In the hit follow-up stage, internal chemistry resources may be directed toward the more advanced programs while lead matter in an exploratory program languishes with a waiting assay but no new analog production activity. This is a huge frustration for both the biologists and the chemists in a discovery organization. Under these conditions, analog production is rate limiting, and the interdependency of data may be less cycle time critical.

In addition to cycle time considerations, it is important to consider the complexity of integrating data or samples into the internal work stream for activities that are highly interdependent. For data streams, it may be possible to have the CRO format data in a way that lends itself more readily to circulation to the team and/or archiving in corporate repositories. For this, automation of the data uploading becomes a key enabler. Sample logistics becomes a key consideration, and it is important to think through the steps needed to have the external samples get to the place they need to be (materials management, project team chemists, biologists who test the samples, etc.). Regardless of the activity, thinking through the supporting logistics and cycle time factors associated with integrating an external provider's data or material into the clients operating unit will be an important aspect of assessing an activities interdependency.

2.07.3.2.6 Existence of external capability

The ability to source an activity relies on the existence of a quality pool of suppliers. Ideally one wants both breadth (so that one has options and leverage) and depth (expertise) of the external market. In the three main areas of synthetic chemistry (scale-up, analog production, and parallel chemistry) there appears to be an ample supply of quality providers, too great to list in this chapter. Increasingly, a market is emerging for a number of highly specialized and eclectic activities associated with drug development such as protein crystallography⁶¹ and salt form screens.⁶²

2.07.3.2.7 Current company or industry practice

For a decision-maker who is considering out-sourcing, it may be helpful to know if companies in related situations have out-sourced the activity of interest. To the extent the prior experience in sourcing was successful in the company the barrier to additional or related sourcing will be lower. Where the prior art (internal or industry-wide) contains negative experiences, understanding the root causes of the failure will either confirm the decision not to source an activity, or provide knowledge to inform the present decision to source. This decision to source an activity in the face of a negative experience assumes there are lessons to be learned and steps to be taken that will lead to a more positive outcome. In cases where only industry experience is available, it is important to evaluate as broad a data set as possible

to determine which data, if any, are most informative for the situation under consideration. Having compelling examples (either internal or industry-wide) is useful for building confidence with internal stakeholders who will be needed to ensure the success of the relationship.

2.07.3.3 Determining the Offshore Ability of an Activity

After an activity has been determined to be sourceable, it is important to determine if the activity is best suited for domestic or offshore sourcing. As the sourcing industry continues to become more global, it is important to carefully consider the risk and cost benefit of domestic sourcing versus near-shore and far-shore sourcing relationships. On one extreme, domestic sourcing for US-centric companies offers the prospects of tapping into a mature and experienced CRO market that provides a shared time zone, language, business culture, and the convenience of domestic shipping and receiving of compounds. On the other extreme, sourcing from far-shore CROs in India, China, and other Asian countries offer a US-centered company the potential to tap into a highly educated workforce with a significantly reduced labor cost. If cost and experience were the only factors, the decision would be relatively straightforward.

Many of the same criteria used to assess the activity/ownership criteria for an activity (activity interdependency, external capability, etc.) can be reassessed with an eye toward the offshoreability of an activity. However when considering the offshore question, some additional criteria need to be considered (see below). As with the out-sourceability of an activity, the decision to offshore a particular activity may be weighted differently for each activity and the weightings may vary from one organization to another.

2.07.3.3.1 Communication requirements of the activity

Several articles have espoused the importance of communication to the success of pharmaceutical out sourcing.^{63–65} The advent of e-mail, telecommunications, and overnight delivery of packages has enabled a number of collaborations to take place at a distance. It is therefore important to assess if the target activity require frequent, person-to-person contact to achieve the desired quality or speed for a successful outcome.

While all out-sourcing relationships benefit from excellent communication loops, some activities require less oversight or interaction than other activities. For example the resynthesis of compounds with established, robust protocols requires little oversight. However the synthesis of novel analogs with uncharted synthetic routes may benefit from more intensive feedback loops where options can be discussed in a more timely fashion when problems occur. Additionally, in project teams where data is altering the priority list on a regular basis, having the ability to reprioritize rapidly is a plus.

E-mail and telecoms can be leveraged for many of the small and acute adjustments that need to be made on the fly. However the need or desire to meet face to face on a regular basis will influence the decision to move an activity offshore verses near-shore. This personal contact is important for new relationships with established vendors but is especially critical for relationships with start-up CROs who may not have worked with big pharma before and may therefore be unfamiliar with some of the drivers the client weighs heavily in a relationship. Thus, it is important to consider how frequently the client and CRO staff will be required to meet face to face to effect a productive collaboration and to factor any additional management and oversight costs into the calculation for offshoring an activity.

2.07.3.3.2 Import/export considerations

Unlike information technology, finance, or business process out-sourcing, the transactions associated with chemistry sourcing involve the movement of material from the CRO to the R&D client. To the extent the R&D projects are cycle time critical, the introduction of import/export issues to the equation may increase the risk of time delays to the discovery process. If these risks can be managed or are not critical to the particular activity being sourced, these factors can be weighted less than other factors.

Depending on the countries involved and the nature of the material being shipped, there may also be additional costs associated with the movement of compounds across borders. While these are likely to be a small portion of the overall cost of sourcing, they still need to be factored into the fully loaded cost of sourcing compounds.

2.07.3.3.3 Intellectual property risk

In addition to the previous IP assessment of the intrinsic activity, it is important to assess the IP environment of the region where an activity is being considered for out-sourcing. A key development of IP protection took place in 1998 when the World Trade Organization came to agreement on the Trade-Related Aspects of Intellectual Property (TRIPS). Countries had until January 2005 to comply with the terms of TRIPS, principally by allowing product patents

rather than just process patents under the current regime. Understanding where a country stands with regards to TRIPS and reviewing any country laws related to inventorship that may be different from the client country is an important step to de-risking the IP risk associated with offshoring.

2.07.3.3.4 Existence of external capability

The last 2 years has seen an explosion in the number and size of offshore providers for selected chemistry activities. There is a mature market for cost-driven activities such as the synthesis of M&T's or related scale-up activities. However there continues to be significant growth in the more technically challenging areas such as analog production and parallel chemistry. When the decision to assess the offshore potential is made, it is important to rapidly get past the general assessment of a country or the description of a company by its own documentation. An excellent way to assess a CRO's potential is by an on-site visit of qualified scientists to determine the effective external capacity for a specific activity.

2.07.3.4 Clustering of Activities for Further Analysis

With an assessment of the activities for the ownership/control potential as well as their offshore potential, it is possible to array specific activities into one of four quadrants (see [Figure 4](#)).

Quadrant 1 These activities are considered to have low out-sourcing potential and a low offshore potential. These activities may be at or near the core competencies of an R&D organization. If they were to be resourced by staff outside of the R&D organization, it would likely be via the in-sourcing model.

Quadrant 2 These activities are considered to have better out-sourcing potential but a low offshore potential. These activities meet the criteria that they lend themselves to being done outside of the R&D organization thought principally with domestic providers.

Quadrant 3 These activities have high out-sourcing potential and have the potential to be carried out on offshore locations. Given the cost saving potential associated with far-shore vendors, activities that fall into this quadrant should be looked at with more granularity if they are presently being sourced domestically or not being sourced in part or at all.

Quadrant 4 These activities are considered to have low out-sourcing potential but have the potential to be carried out on offshore locations. However, it may be the activity/ownership assessment suggest these activities are more suitable for work done in a captive offshoring setup.

When a series of activities are assessed against their out sourceability and offshore ability criteria, and scored on a scale of 1–5, it should be possible to generate a grid such as that shown in [Figure 5](#) where activities are distributed across the four quadrants. Depending on the activity, some activities may straddle the boundary between quadrants

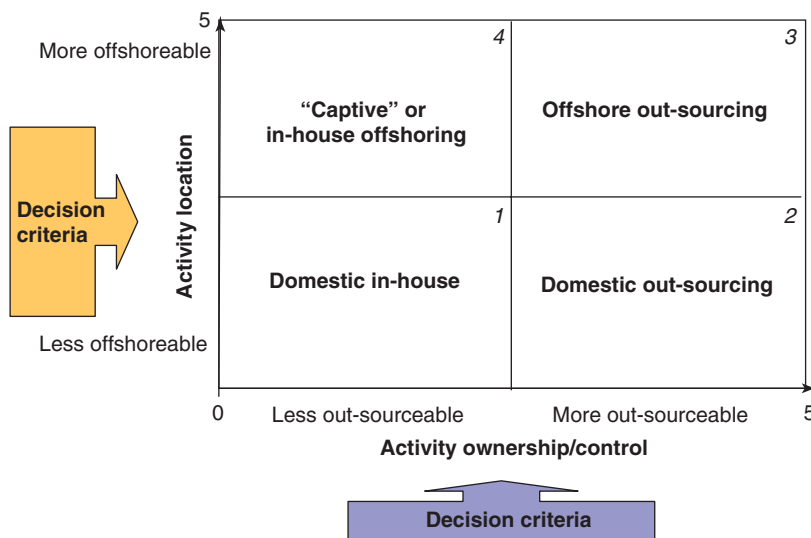

Figure 4 Clustering of activities by quadrants. © Pfizer Inc. 2005.

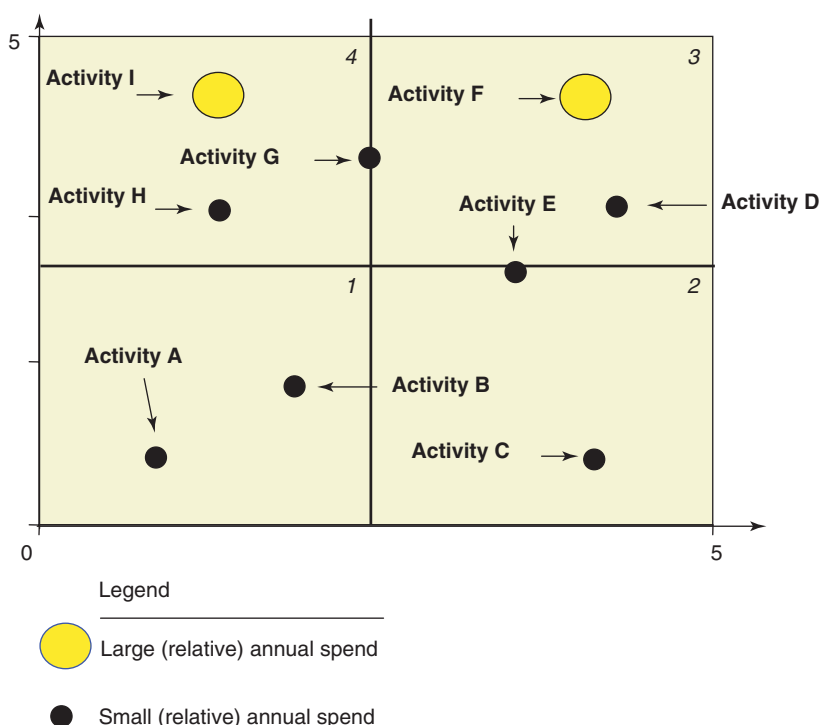

Figure 5 Simulated array of activities. © Pfizer Inc. 2005.

(i.e., activities E and G). In these situations, it may be worth assessing if the activity has a range of subscenarios associated with it. For example, if ‘scale-up’ were the initial activity, its composite score may be composed of the score for the scale-up of pre-candidates and the score for the resynthesis of M&Ts. Rerunning the analysis with the two smaller activities may provide outcomes that are more informative and actionable. As noted previously, it may be that the organization has activities being sourced domestically (quadrant 2) that this analysis suggests fall into quadrant 3 and its offshore potential. Alternatively, it may be that an activity is being sourced in the appropriate quadrant (i.e., quadrant 2 or quadrant 3), but only at a small percentage of the spend for that activity. It may be worth probing the activity in more detail to assess if there is a higher threshold percentage that could be realized and the effect a change in the percentage would have on the outcome of the activity.

To take this analysis further, it may be worth focusing on those activities that reflect the highest annual spend for the R&D organization. For example, while both activity F and activity D both fall in the quadrant 3, the higher spend on activity F suggest it may be worthwhile to start assessing this activity more closely with regard to its out-sourcing potential. Similarly, when considering the activities in quadrant 4, consider whether the spend is significant enough to warrant a captive offshore strategy, either alone or in combination of other smaller or interrelated activities.

Note that this is an oversimplification to serve as an example for the process. In reality, an organization may look at related activities in quadrants 1 and 4 together in assessing captive sourcing for any one line of business. However it is unlikely that any one activity in the discovery space would be of sufficient size or scope for an organization to buy or build a captive offshore facility. The decision to build a facility is most likely addressed as a part of a broader strategic discussion that includes commercial/market considerations as opposed to just R&D execution.

2.07.4 Assessing Performance

When analyzing sourcing relationships, many groups indicate that the lack of quantifiable metrics or performance standards is the main reason organizations become dissatisfied with out-sourcing. As with any service activity, it is important to determine measurements or ‘metrics’ of success. Depending on the activity, these metrics may center on cost, quality, and/or speed.

2.07.4.1 Analog Production

In an area where compounds are prepared by hand, the productivity of a chemist can be measured by assessing how many reactions are run per unit time (week, month, quarter, etc.). This metric has the advantage that it assesses the ability of the chemist to multitask or parallel-process reactions rather than focus on assignments in a slower, serial manner (i.e., not starting a second reaction until the first reaction is complete). The number obtained may be less meaningful if care is not taken to differentiate ‘successfully completed’ reactions rather than just reactions that were initiated but never completed.

An alternative method is to measure compounds prepared per unit time. This bottom-line metric is a good assessment to use when comparing the production of compounds with the same number of synthetic steps or the same degree of difficulty. This metric becomes less effective when the degree of precedence differs for one assignment versus another. For example, it may be easier to resynthesize a known compound or a related analog than to prepare the first prototype for a series.

Should either of these metrics be used to assess performance, it will be important to communicate this upfront prior to the relationship beginning. This may inspire the staff at the CRO to innovate the way they organize their work in order to drive the assessment as favorably as possible. However, as with most metrics, too heavy an emphasis on throughput as a singular or primary measure of performance may reduce the level of risk-taking in an analog program or discourage colleagues who make be positioned to identify improvements to the process chemistry along the way.

2.07.4.2 Scale-Up Activities

There are a number of metrics associated with the sourcing of multigram amounts of material. One important metrics to consider is timely delivery of material. This metric can be assessed as the percentage of deliveries that arrive prior to or on the agreed-upon delivery date. Another performance standard for scale-up activities in discovery chemistry relate to compliance to the requested amount. High marks are given to a provider that provides the agreed-upon amount of material (or more). Conversely, if a vendor establishes a track record of underdelivering the desired amount, it may be an indication of poor raw-material planning or synthetic execution. An interesting article by Tharp and colleagues describes a performance metric for scale-up activities in which the overall performance of a sourcing activity is defined as the multiple of the two metrics (delivery date and amount of material).⁴²

2.07.4.3 Parallel Chemistry

Like analog preparation metrics, the number of compounds produced per unit time is also an important metric for parallel chemistry. Since parallel chemistry is so heavily enabled by the particular technology platform used to prepare compounds, the number of chemistry transformations that can be provided by a CRO and their platform becomes an important metric. Alternatively, the CRO may be assessed on the number of new protocols they produce and use to enable chemistries. Lastly, the large technology capability that is associated with industrial-scale analog production may offer cost advantages to one CRO relative to another for the same type of compound libraries. Hence cost per compound produced may be a strong differentiator in this area, especially with chemistries that are deemed straightforward and are well preceded by protocols.

2.07.4.4 General Caution on Metrics

As with measuring the performance of internal staff, there is seldom one metric that will capture the essence of an outsourcing activity. For this reason, several metrics are often assessed in parallel. By gathering and assessing multiple metrics, it may be possible to identify trends that inform further questions about the process. Over time, one to two metrics may emerge as especially informative for an activity, or that certain metrics need to be refined to make them more informative. For all types of activities, it is important to factor in other qualitative aspects such as problem-solving, vendor–client interactions, or route optimization tasks that may not be obvious when assessments are based only quantitative metrics.

There is a cost associated with gathering metrics. Regardless of who captures the data (the R&D organization or the CRO) it takes time from somebody’s day to measure and analyze the data. If the R&D organization does this, this adds to the cost of oversight. If the CRO does this, this may increase the cost of the collaboration or decrease the productivity of the laboratory chemists if they are spending less time in the laboratory on metric-related tasks. For this reason, it is important to balance the justifiable desire to gather information against the cost associated with compiling and analyzing this information.

Lastly the maturity of the sourcing market and the need to track metrics for success will lead organizations to take a closer look at the comparison between internal and external performance. This is difficult to assess when sourcing new capabilities but more straightforward when an organization has exposure to CROs that provide additional capacity. To this end, it will be important to ensure that sensible data sets are used for these comparisons as the service providers may have a more focused mission than an internal scientists. The internal staff may have a broader set of commitments to the organization than the specific activity being measured (*see* [Section 2.07.5.2](#)).

2.07.5 Risks

While external sourcing provides the prospects of significant advantages to the R&D organization, there are also a number of risks associated with such relationships that need to be factored into the decision to source an activity.

2.07.5.1 Intellectual Property Loss

As noted previously, the most important risk associated with any collaboration, partnership, or sourcing relationship centers on the potential for IP loss. As Cavella noted in an excellent review article, the product from pharmaceutical development is essentially knowledge and as long as companies intend to keep corporate secrecy at or near their top priority, the incentive to out-source will not be strong enough.⁶⁶ While the contract language that governs the confidentiality of a relationship should provide sufficient legal and contractual protection, the inadvertent or unintended loss of IP from the client to the CRO and the CRO to other customers has to be prevented. The term ‘IP slippage’ has been coined to describe this type of IP loss, which differs from espionage, or the actions of a rogue employee.⁵⁴

The magnitude of the loss due to IP slippage will vary. One can lose IP if the patentable materials were disclosed through the CRO to the public domain before the client files a patent application (regardless of whether the disclosure was inadvertent or not). Alternatively, one can lose competitive advantage if trade secrets (not patentable or not intended to be patented) were taken advantage of by the CRO or appeared in the public domain. Lastly, one can lose competitive advantage or future IP if trade secret or patentable materials provided to the CRO were used as a source of information to advance competitors’ programs or the CRO’s internal programs. IP slippage is difficult to detect, and is easier to prevent with thorough site audits and a rigorous assessment of the IP protection policies of a potential CRO prior to engaging in a relationship. It is also worth monitoring during a relationship as business models,⁶⁸ collaboration partners, and senior leadership at the CRO can change over time.⁶⁹

2.07.5.2 Staff Morale

The sourcing of activities previously done by internal staff within an R&D organization can generate a lot of anxiety among the personnel. Unlike business process out-sourcing where an entire activity is out-sourced, many chemistry activities are only partially sourced and the line between what can be sourced and what is being sourced can appear vague to the internal staff. For this reason, it is important to discuss the drivers for sourcing within an organization and make it clear what activities are being sourced and the reasons behind those tasks’ selection for sourcing. If this is done in an organization that actively encourages and fosters staff and skill development, there will be less tension and conflict arising from the sourcing experience. However for this strategy to succeed, the staff needs to be willing and able to move to higher valued activities that are less commoditized or sourceable.

2.07.5.3 Competition for Quality Service Providers

When a company sources an activity for the first time, it is difficult to determine which service providers provide the best value for the dollar in the regions of interest. A CRO may be initially selected for a longer-term contract based on a presentation they made, a project they bid on, or word of mouth. If the CRO delivers value, and does the same with all their clients, there will invariably be other clients who will be looking to hire or expand their utilization of the CROs services. This competition for the quality service providers may translate to higher rates, less capacity to grow with the client organization, or a change in the CRO staff that manage the relationship.⁷⁰ For this reason, it may be worth considering what steps an organization is willing to take to retain or grow the relationship with quality vendors. For example, these steps could involve longer contract terms or identifying specific individuals from the CRO to remain on the team working for the client. It may also involve growing the collaboration in business areas related to the primary activity resulting in a more value-added product for both parties involved.

2.07.5.4 Introducing Organizational Complexity

The sourcing of an activity that is presently run within an organization provides unique challenges when compared to sourcing an activity that is new to an organization. For example, when a client procures an activity that introduces a new capability to their organization, the client may be much more forgiving about the disruptions that the CRO introduces to work streams, data flows, and team dynamics. However, when an organization procures additional capacity of an activity that is presently done internally, there may be a focus more on the disruption than the value (different data format, migrating data through firewalls, different sized vials, etc.). When this happens, it is usually because the teams do not see the service provider as bringing something special to the table, particularly since they have been procured simply for more capacity. The fact that the service provider is not internal requires that additional steps need to be taken to bring the same type of services, data, and material into the workflow of the project team. For this reason, it is important to anticipate the disruptions that a service provider may bring to an organization and manage the expectations around change that this relationship will impose on the organization.

2.07.5.5 Communication

In addition to managing expectations internally, there is a need to prepare for the unique challenges that working with remote service providers will bring. Discovery organizations tend to underestimate how much informal communication takes place in the matrixed environment between management and staff, members of a department or discipline, and members of project teams. For this reason, when a company procures additional capabilities with a service provider, there is often a period of adjustment where assumptions and unvoiced expectations lead to misunderstandings, unsatisfactory workflow, mistrust, or acrimony. It is therefore important to ‘sweat the details’ when forming or establishing a relationship and consider the value of launch meetings and face-to-face visits when starting a working relationship. Establishing a pattern post launch to discuss progress and encouraging informal or ad hoc discussions over the phone or e-mail will ensure mechanisms are in place as teams start working together. Lastly, it is important to recognize that all newly formed teams go through a forming–storming–norming–performing process of evolution.⁷¹ By having project teams and managers discuss these stages regularly with their service provider, it is possible to move the sourcing relationships more rapidly into a high-performance mode by creating a culture where both sides can lay issues open for discussion.

2.07.5.6 Publicity

There is an unusual tension regarding the publicity associated with working with service providers. The CRO may view their ability to issue a press release on a newly signed collaboration a key value driver for their organization. From their perspective, the announcement of a deal serves to validate their business model in the industry and may drive other clients to their door. From the client’s perspective, this may not be viewed as a positive development. Given the negative view that out-sourcing has in some circles, clients may prefer to avoid press releases on new sourcing collaborations, especially when they involve offshore vendors.⁷² As noted above, a client that has found a productive CRO may prefer to keep the CRO in relative anonymity in order to avoid increasing competition for the staff at the service provider. To avoid miscues and misunderstandings, it is advised that both parties discuss the level of disclosure they are comfortable with prior to deal signing. This will ensure there are no misunderstandings or surprises after the deal is signed.

2.07.5.7 Erosion of the Cost Differential

While differences in labor costs can be a significant driver in the decision to source an activity, some question how long this delta in pricing will continue. A recent report in the *New York Times* notes annual raises of 10% or more are now the norm in India’s \$17.2-billion-a-year out-sourcing industry.⁷³ As the competition for English-speaking scientific talent drives up salary costs, it may also increase staff turnover which may increase the aforementioned risk of IP loss or slippage.

2.07.6 Conclusion

Success in chemistry sourcing will ultimately depend on how the management prepares the organization for its introduction and how it is utilized within an R&D organization by the staff.

Chemistry sourcing is not a new phenomenon and there are fundamental, compelling reasons that companies have utilized sourcing to complement their internal activities (expand or improve capabilities, reduce cost associated with

acquiring capital or assets, etc.). What is relatively new is how companies are looking to apply out-sourcing to activities it has traditionally done in-house such as analog production and scale-up activities pre-API, activities long deemed core competencies within large pharmaceutical organizations.

Companies that will look to out-source discovery chemistry would benefit from doing an internal review of the activities it undertakes in-house and objectively assess the suitability of these activities for external sourcing. By establishing assessment criteria other than cost, such as IP risk, cycle times, and quality, a company may be able to identify tasks that lend themselves (all or in part) to be more efficiently sourced.

Once an activity is identified, it will be important to consider what process changes need to be undertaken to fully enable the sourced task to succeed. For example, do the IT systems need to be modified to enable data to be readily absorbed into the client's data network? Is there a strategy for sample logistics? Do the staff need to be retrained or educated on what changes in their roles and skill sets will be needed to enable sourcing to work for their project teams or departments? If an organization does not think through the process changes required to enable effective sourcing within their organization, they will be destined to be disappointed with the outcome.

Biography

Rick D Connell was born in Lowell, MA and received his BS in chemistry in 1984 from Merrimack College in North Andover, MA. He was accepted into the PhD program at the University of Notre Dame and worked under the direction of Prof Paul Helquist. During that period, he received a John G Bergquist Fellowship from the American Scandinavian

Foundation and spent 6 months at the Royal Institute of Technology in Stockholm, Sweden where he carried out research in the area of organo-palladium catalysis under the direction of Prof Björn Åkermark. He received his PhD in 1989 and worked as a National Institutes of Health postdoctoral fellow at Harvard under the direction of Prof E J Corey.

In 1990, he began his industrial career at Bayer pharmaceuticals in West Haven, CT. He worked as a medicinal chemist in the field of immunology until 1993 when he transferred to Wuppertal, Germany to do research in the cardiovascular (lipid lowering) division at Bayer's main pharmaceutical campus. He returned to West Haven in 1995 and subsequently was asked to lead the Medicinal Chemistry group focused on diabetes and obesity research. In 1999, Rick accepted a position at Pfizer's Groton, CT campus as the head of cancer Medicinal Chemistry. He spent a year on secondment at the Pfizer site in Sandwich, UK where he was asked to be head of the Medicinal Chemistry group for sexual health before returning to Groton in 2003. Shortly after his return to Groton, he was promoted to Executive Director of Discovery operations at Pfizer's Groton campus with responsibility for the antibacterial, immunology, and cancer (AIC) therapeutic area zones.

In July of 2005, Rick was asked to establish and lead a Chemistry sourcing group within the Discovery Chemistry Discipline. Centered in Groton, CT, this organization has responsibility for setting and implementing an integrated, worldwide chemistry sourcing strategy for the seven Pfizer R&D sites located in the USA, UK, and Japan. This organization is responsible for managing the network of sourcing-related collaborations around the globe as well as compound logistic activities within the Pfizer organization.

Rick is an inventor on over 35 patents and patent applications. He is a section editor for the journal *Expert Opinion on Therapeutic Patents* and serves on the Editorial Advisory Panel for the journal *Therapy*. Rick lives in East Lyme, CT with his wife Nancy, and their two children: Ricky (age 15) and Kelly (age 13).

2.08.1 Definitions

Implicit in the title for this chapter is an understanding of the meaning of the term ‘biotechnology.’ The word grew from the early focus of a first generation of new alternatives to traditional pharmaceutical companies, upon biologically produced therapeutics rather than chemically manufactured ones. But pharmaceutical R&D on biologicals is not confined to what most people understand to be the biotechnology sector (for example, drotrecogin alfa (Xigris) is a recombinant protein for sepsis from Lilly). Nor is this sector confined to R&D on biotechnological approaches to new drugs. Many companies in the so-called biotechnology sector have little or nothing to do with the discovery and development of biological medicines, preferring to follow traditional small-molecule approaches to new therapeutics.

Another metric that may be used to define a biotechnology company is the notion that it is a start-up, or a small-medium enterprise (SME), usually loss-making and backed by private investors (typically venture capital). This is also clearly unsatisfactory since the first ‘biotechs’ like Genentech or Amgen are now large organizations, making substantial profits. In common with a growing minority of biotechnology companies, and like their large pharmaceutical cousins, their shares are traded on the public stock markets. A crude attempt at drawing out the different strategies and characteristics of different ‘biotechnology’ companies is set out in [Table 1](#), from which it is clear that companies are often grouped into this sector without any clear common element. Like ‘Modern Art,’ it is a term that is difficult to define, but much easier to recognize.

Jurgen Drews, a well-known commentator on the strategy of pharmaceutical R&D, has suggested that the “first tier of biotechnology companies is likely to become the most effective segment of the drug industry.”¹ Many such companies, in themselves quite large entities, have a mixed portfolio of developments, some biological and some small molecules.

Overall, the biotechnology sector comprises a significant portion of the pharmaceutical R&D spend. As shown in [Figure 1](#), the biotechnology sector spends about half as much as large pharmaceutical sector on R&D.² The biotechnology sector spends about 60% of its revenue on R&D compared to about 15–20% for the pharmaceutical sector (as composed of members of the US PhRMA).

An alternative way to define sectors in pharmaceutical R&D is not by what they do, but by the way in which they do it. A discussion of the strategic organization of new medicines discovery, particularly in comparing the attributes of the large pharmaceutical versus the biotechnological approaches, cannot be complete without bringing another factor into the discussion. That is whether a company is involved in the provision of services or in the conduct of its own R&D programs.

Table 1 Categorization of biotechnology companies by various factors

<i>Company</i>	<i>Public or private</i>	<i>Discovery or development focus</i>	<i>Biological or small molecule focus</i>	<i>Product or technology based</i>
Microscience	Private	Development	Biological	Product
Speedel	Private	Development	Small molecule	Product
AERES Biomedical	Private	Discovery	Biological	Technology
Astex Molecules	Private	Discovery	Small molecule	Technology
Genentech	Public	Both	Biological	Product
Millennium	Public	Both	Both	Product
Cambridge Antibody Technology	Public	Both	Biological	Product
Sepracor	Public	Development	Small molecule	Product
Abgenix	Public	Discovery	Biological	Technology
Vertex	Public	Discovery	Small molecule	Both

**Figure 1** Biotech versus PhRMA: R&D spend in US\$ Billion. (Data from Kenley.²)

2.08.2 Service Companies

Some of the companies mentioned in [Table 1](#) are increasingly involved in technology service provision, whereas others are becoming more focused on developing their own projects, at least up until proof of concept clinical trials. Biotechnology sector companies that provide services have large comparators in the contract research organization (CRO) sector.

Historically, contracting out or outsourcing of pharmaceutical R&D began with chemical scale-up and bulk manufacturing activities, which had been part of the operation of the more mature industrial chemical industry for many years and became available for the younger pharmaceutical industry. The capital cost of building and maintaining chemical plant required that it should be fully utilized in order to maintain profitability; its use by a number of clients has obvious cost-saving elements. On the other hand, the requirement for biological studies changed in 1955, when the tragedy of thalidomide revealed the importance of adverse toxicology and transformed the public policy surrounding drug safety, and was furthered by the introduction in 1975 of Good Laboratory Practice (GLP). Since these two events, the pharmaceutical industry has accepted outsourcing preclinical safety studies as an integral part of its overall strategy. This can be similarly applied to the clinical work that is performed to supply proof of safety and efficacy of new medicines.

Figure 2 Pharmaceutical R&D expenditure in Europe, the United States, and Japan (Euro million), 1990–2003. (Data from Barnett International.⁴)

In the past two decades, the concept of the CRO has grown considerably, with some of the larger companies such as Quintiles or Covance having filed more New Drug Applications (NDAs) with the Food and Drug Administration (FDA) than many pharmaceutical companies. In a recent report, outsourcing in the pharmaceutical industry was estimated at about 30% of overall R&D spend, and rising.³ Given that pharmaceutical R&D was approximately US\$50 billion for the 2003,⁴ this amounts to some US\$15 billion of expenditure annually (Figure 2). Growth of external R&D is estimated to be 50% higher than internal R&D for the foreseeable future and overall outsourcing market is expected to grow to perhaps 40–50% of pharmaceutical R&D. In some areas such as outsourcing of chemistry-related functions the figure has recently been rising at a compound annual rate of 40–50%.

In the past few years globalization, through ‘offshoring’ has added to the growth of contractually outsourced R&D. The two countries representing the bulk of this activity are India and China; in 2004, the Indian outsourcing market was estimated at US\$120–470 million, growing at a compound annual rate of 75%. It is divided roughly equally into nonclinical and clinical research, and is able to offer substantially reduced costs, in particular much cheaper full-time employee (FTE) rates. In India, there is a large talent pool, with particular expertise in chemistry, and since January 2005, a new patent law has enabled the grant and validity of pharmaceutical product patents; there is also an increasingly widespread adherence to high quality standards (albeit from a low base), and of course the wide use of the English language makes India an easy place for scientists to communicate internationally. There are two other aspects that favor the conduct of clinical research in India, namely the existence of 16 000 hospitals and 171 medical colleges, and a large pool of naive patients, enabling fast clinical trial recruitment. Offshoring represents a significant commercial challenge to the service organizations based in the US, Europe, and Japan. Presently, the price advantage of outsourcing to India and China is offset by the better quality generally available in the higher-cost countries.

2.08.3 Advantages and Disadvantages of Outsourcing

Much has already been written on this subject,⁵ and it is not the intention of this review to repeat the detailed points here. The main advantages and disadvantages are shown in Table 2. Over the years many of the more commonplace problems have been ironed out, and the enhanced ability to communicate by telephone and e-mail has greatly facilitated distal outsourced relationships.

The advantages of outsourcing are particularly appealing for most product-focused biotechnology sector companies, which do not have the resources to put in place internal organizations for pharmaceutical development, and as a result the proportion of externally contracted work is generally higher in this sector. An example of the way in which multiple providers can be brought together by a small biotechnology company is provided by Ionix Pharmaceuticals (Cambridge, UK), a specialist pain therapeutics company. The company has extensive discovery relationships with a variety of chemical and formulation companies, including EvotecOAI AG (Oxford, UK) and Tripos, Inc. (Cornwall, UK) for medicinal chemistry, West Pharmaceuticals Services, Inc. (Lionville, PA) for intranasal formulation, and Xenome Ltd

Table 2 Advantages and disadvantages of outsourced relationships

<i>Advantages</i>	<i>Disadvantages</i>
Reduction in fixed costs (traded against increased variable costs)	Loss of control
Better allocation of resources in a project with variable demand	Difficulty of coordination and management
Access to specific technology, expertise, or skills either not present internally or cheaper than internal alternative or quicker than internal alternative	Increase in variable costs, traded against reduced fixed costs
Flexibility in disengagement from unsuccessful research; greater objectivity in making that decision	Differing cultures of external party
Better management of risk	Time taken to agree contracts
	Difficulties in agreeing ownership/split of intellectual property rights
	Instability in case external party becomes financially insolvent, merges or is acquired

(Brisbane, Australia) for peptide chemistry. Ionix is developing intranasal buprenorphine, either alone or in combination with other drugs, for the treatment of acute and chronic pain, and has used its contractual network in order rapidly to advance its product development plans.

Management of outsourcing is a much more complex process than that of internal R&D. Unlike the intramural alternative, it starts with the identification and selection of a suitable partner for the required work, followed by the negotiation of a contract: with more than 1000 companies in the business of offering contract pharmaceutical services, this can be a lengthy and complex process. Although certain of the larger CROs are offered a wide menu of services, the risk for the buyer is that the quality and value for money is not always equally high across all areas. Beyond the choice of partner, the success of outsourcing depends critically on the quality of the project management, because problems need to be anticipated before they occur, and can be difficult to rectify.

There is some evidence that, done correctly, the outsourced approach does offer improved efficiency across the industry as well as substantial improvements in time to achieve certain goals. Protodigm, as a subsidiary of Roche and through comparisons with its parent, documented a 38% advantage in the time taken to advance a cancer project through phase I/II relative to the internal alternative. In 2000 the company separated from its parent, Roche, and changed its name; Fulcrum Pharma Developments now operates as a contractual resource to provide customized development programmes that lead to early proof of concept studies, for client pharmaceutical companies. It does so using a customized network of contract research organisations assembled specifically for each project. Similar comparisons carried out by Barnett International Benchmarking Group⁶ have established reductions of 31–41% during phases II and III, and an overall time saving of at least 2 years on conventional intramural drug development times using the outsourced alternative (Figure 3).

Relative to other business sectors, pharmaceuticals has some features which particularly suits it to an outsourced approach. One is the multiplicity of scientific disciplines and skills necessary to advance a project through research and development: not all are likely to be present inside one organization. Another is the fact that specialized providers exist to offer expertise in all sections of pharmaceutical R&D, as well as sales and marketing. Third, the product from a pharmaceutical development is essentially knowledge, either in terms of intellectual property in the narrow sense of a patent, or in the broader sense of an information package for regulatory submission. In an era of electronic communication the mobility of such packages across international boundaries makes pharmaceutical outsourcing a global enterprise.

There are other features of the industry that mitigate against outsourcing, notably the very complexity of the development process, which make project management a difficult task in the absence of adequate competence in a wide range of disciplines (this argument is countered by the observation that in other business sectors complicated projects such as large-scale construction is conducted through a framework of outsourcing). Second, for historical reasons, the pharmaceutical industry has been late in adopting outsourced forms of operation. It is a relatively new industry, heavily regulated; and most ethical pharmaceuticals are protected from free market competition by patent coverage. Corporate secrecy is sometimes seen as a priority that conflicts with outsourcing in certain sensitive areas, where intellectual property is capable of being generated.

Figure 3 Reductions in pharmaceutical development cycle times using internal and outsourced resources. (Redrawn from Welcome to Kendler.⁶)

The counterpart to the rise of outsourcing is the increasing emphasis placed on management of project and of external relationships, to the point that some companies focus on this as a core competence.

2.08.4 Virtual Companies and Extended Enterprises

The virtual pharmaceutical company is one that concentrates on project management of extramural operations, and may operate within a part of the overall R&D process (for instance, from the end of preclinical development to the completion of proof of concept clinical trials). The management and direction of the project(s) are retained in house, and the operations are carried on externally by a network of suppliers, with whom the virtual company has strong contractual relationships.

The concept is not unique to pharmaceuticals: Nike, for instance, legally does only marketing and R&D. It manages its suppliers as part of a corporation, putting its own personnel in production sites, visiting plants regularly, running codevelopment teams, and sharing information extensively. Its strength relies substantially on the tight relationships it has with its suppliers.

The management of pharmaceutical discovery as opposed to development poses two additional challenges. One is that substantial detailed scientific expertise across multiple disciplines is necessary, and may be hard to find in a small virtual company. The other is that in research, changes in direction and iterative methods of working are essential, and this is difficult to manage via contractual relationships. A successful case of totally outsourced discovery from identification of a lead molecule and continuation successfully through to phase II has been reported from Napp Pharmaceuticals.⁷ This is not a widely replicated model and the difficulties should not be underestimated.

In pharmaceuticals, in addition to contractual relationships, knowledge and technology are vital parts of the process which are also amenable to transfer between organizations. The term “extended enterprise” (EE) has been introduced to cover this idea: its accepted definition is a “dynamic, networked organization.”⁸ The phrase has both a broader meaning and applies to a wider range of businesses than ‘virtual.’ Companies with their own internal focus may necessarily couple that with external elements to accomplish certain goals. The methods used to establish and manage these relationships are the same regardless of size and strategy.

The scope of relationships possible in pharmaceutical extended enterprises encompasses three forms: contracts, collaborations, and licenses. As will become clear, all these forms are used by both large pharmaceutical companies and biotechnology companies in their operations.

2.08.5 Comparison of Contracts, Collaborations, and Licensing

The three modes of link employed in pharmaceutical extended enterprises, namely collaboration, contracts, and licensing, are typically found at different stages of discovery, development, and marketing, and between different players

in the overall process. **Figure 4** represents some of the forms of interaction between the main components of the pharmaceutical R&D supply chain. In addition to the various genres of company mentioned above, this figure also includes the academic sector as a source of technology which is licensed or forms the basis of a collaboration with a product-based biotechnology or large pharmaceutical company. For simplicity the role of large pharma has been represented in development and marketing, whereas in reality such companies have large investments in pharmaceutical discovery too, and indeed the primary purpose of collaborations with platform biotechnology companies is to support these efforts.

A summary of the place of contracts, collaborations, and licensing in the pharmaceutical value chain is outlined in **Table 3**. Whereas contracts focus on the provision of services, collaborations allow for technology or expertise as well as services, and licenses rarely incorporate any element related to services, and concentrate on technology or knowledge transfer. While contractual relationships allow for better risk management and more efficient resource allocation at an operational level, collaborations and licenses permit trading in intellectual property in a global marketplace, and association of the companies and institutions most capable of inventing new products and technology with those most capable of commercializing and mass marketing.

Collaborations between large pharmaceutical companies and other parties are particularly appropriate for the discovery phase because management of external discovery is more difficult than development. Sufficient expertise and project direction needs to be left with the external collaborator to enable them to deal with upsets and failures, to solve

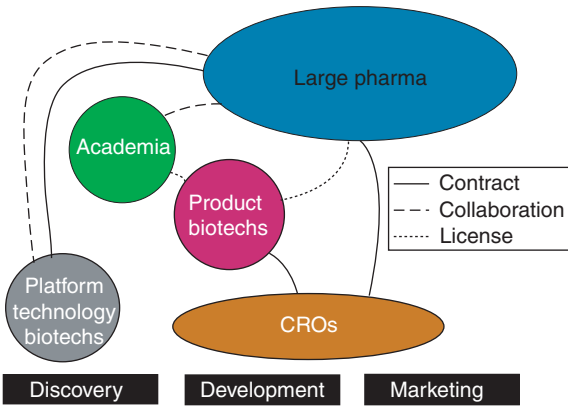

Figure 4 Examples of contractual, collaborative, and licensing arrangements between different components of the pharmaceutical R&D supply chain.

Table 3 Summary of differentiating characteristics of contracts, collaboration, and licensing

	<i>Contracts</i>	<i>Collaborations</i>	<i>Licenses</i>
Requirement	Access to resources not available or not sufficient internally	Access to technology for improved research productivity	Access to products (or occasionally technology) for enhancing development pipeline
Optimum stage of establishment	Development, and to a lesser but increasing extent, discovery	Discovery	Development
Reliance on external technology	Low	Medium	High
Aim	Completion of defined piece of (developmental) work	Integration of external technology into intramural discovery	Commercialization of external technology/product
Payments	Based on work done	Based on time allocated plus possible access fee, and success-related milestones and low royalties	Based on value of product development, plus success-related milestones and royalties

certain problems independently, and to apply their particular expertise in the most appropriate way. As they are earlier in the R&D process, collaborations are inherently more risky than later-stage development projects, and a component of the monetary exchange is often success-related. This may take the form of milestones and low rates of sales-based royalty as the project develops.

Licenses can take a wide variety of forms, but most often give the right for a company to develop, manufacture, and/or sell a product in a certain territory. They are thus oriented around a product rather than work or technology. Typically, licenses take the form of success-related payments (milestones) and royalties on sales. However, as discussed below, large pharmaceutical companies have sought more often to use in-licensing to bolster weak developmental pipelines, competition among licensees has increased and deals have grown in complexity. It is now not uncommon for biotechnology company licensees to demand (and get) an increasingly large share of the upside, including equity participation, codevelopment, and options to market in certain territories or well-defined indications.

2.08.6 Trends in Biotechnology Sector Companies: Products versus Technology Platforms

One of the key messages from [Figure 4](#) is the divergence between the product-based and the platform technology-based biotechnology sector company. During the early 1990s, the first generation of new technology in genomics, combinatorial chemistry, and high-throughput screening underpinned a dramatic change in the way in which pharmaceutical research was carried out. Mechanization would turn a cottage industry to mass production. The development of this new technology outside the main companies provoked a rush to collaborate with new, small, high-tech start-up companies, and substantially changed the attitudes towards outsourcing of pharmaceutical discovery.

With time, two things have happened to dampen the initial fervor. First, the rate of innovation in discovery technology has slowed, the technology has become more widespread, and much has been incorporated within large pharmaceutical companies, where large capital investments have been made. The bottleneck in R&D productivity has moved beyond discovery to early preclinical development.

Second, the promise of the triumvirate of new discovery technologies has largely not been realized despite the investment. That promise was to increase the productivity of pharmaceutical R&D and dramatically increase the number of new medicines reaching the market.⁹ That promise has not been realized: in order to be able to deliver 10% year-on-year increases in sales, and 15% growth in earnings per year, the largest companies such as Pfizer (which has annual sales of US\$50 billion) require a sales increment roughly the equivalent of that of the total sales of a company like Amgen, the biggest in the biotechnology sector.

As a result in the decreased value of discovery collaborations, there has been a concomitant trend towards them becoming contractual in nature. This trend was foreseen as early as 1997, and by the end of the decade there was a widespread belief that demand for drug discovery collaborations would decline and dramatic action was needed.¹⁰ The sentiment has been reflected in the investment community, which was largely caught out in the perimillennial technology rush. Today, investors in the sector are much more risk-averse and focused on products. Such investment criteria are ultimately important drivers for biotechnology sector strategy.

The changed climate quickly became manifest. In December 2001, Pfizer signed a deal for chemistry services with ArQule involving contractual payments of US\$117.5 million over 4–5 years and additionally an equity purchase arrangement. Unlike previous arrangements between large pharma and a combinatorial chemistry company, the deal did not involve milestone or royalty payments. ArQule would provide expanded lead generation capabilities using its automated solution phase chemistry and would transfer on a nonexclusive basis its proprietary library design and informatics platform. ArQule and Pfizer would work together to improve this platform to enhance the process of lead generation for early drug discovery. ArQule might also collaborate with Pfizer on lead optimization during the alliance.

Some technology platform biotechnology sector companies have acceded to the trend, and have become discovery contract organizations; others have invested the profits received in the era of large collaborative technology-based deals back into a new corporate strategy based on product development.

Two salient examples of these alternatives are Millennium and Lion Biosciences. Millennium Pharmaceuticals, Inc., historically a provider of genomic technology and the recipient of a huge 5-year collaborative deal with Bayer Healthcare AG, first announced a change of strategy in 2000 with the acquisition of Cambridge Combinatorial Chemistry. In 2002 this was followed by a further merger with Cor Therapeutics, whereby Millennium assumed rights to Integrilin (eptifibatide) for acute myocardial infarction. In 2003 the company announced a restructuring and loss of 600 jobs, in order to finance the launch of its first product Velcade (bortezomib) for advanced stage multiple myeloma. Millennium aims to reach profitability by late 2006.

In contrast, Lion Biosciences also started its internal discovery strategy (iD3) in 2000 and acquired Trega Biosciences, followed a year later by the construction of a chemistry R&D centre to support its internal research program. The cost of this transformation proved impossible to sustain, however, and in 2002 Lion abandoned iD3, announcing a corporate restructuring in 2003 with the loss of 86 jobs. Currently Lion's business model is that of a typical software company. Income is generated from the sale of software licenses, maintenance, and support, and from offering services in chemoinformatics and bioinformatics. It has been unable to achieve its goal to break even as a purely service company, and is currently not forecast to do so.

These examples demonstrate similar initial strategies based on a recognition of the transient appeal of discovery technology, both initiated in 2000. The difficulty of realizing the ambition and the substantial investment required for such a change led to one company abandoning the strategy and reverting to the service provider model, while the other achieved its aim, after the expenditure of hundreds of millions of dollars. The profitability of the service model is not assured, although many discovery contract organizations are performing much better than Lion.

Despite these trends, there remain certain technologies, normally in the developmental field, for which biotechnology companies can retain long-term value for the projects they work on.

One area where examples can be found is in bilateral agreements concerning controlled release formulation technology: for instance, SkyePharma offers such technology in the context of drug development support including formulation, clinical, regulatory, and manufacturing skills. The company worked with GlaxoSmithKline to develop a controlled release version of the antidepressant Paxil/Seroxat (paroxetine). The work was performed under a contract between the parties which also stipulated that SkyePharma receives low single-digit royalty payments on the sales of the product, clearly demonstrating the long-term value sharing element of the relationship.

Another example is in technology to enhance form and formulation. For instance, TransForm Pharmaceuticals was founded in 2001 around physical chemistry and novel high-throughput platform technologies, supported by a data informatics platform. It uses these capabilities to optimize drug form and/or formulations, and increase the clinical and commercial value of pharmaceutical products, across the entire spectrum of pharmaceutical development from early stage to life cycle management. In research and development, TransForm is working with partners such as Alza Corporation and Lilly to help them make better candidate selection decisions and reduce attrition and development time and cost. In the collaboration with Lilly, TransForm worked on several discovery and early developmental stage compounds. TransForm's work on the developmental stage compounds could generate various success-based payments including milestones and royalties. In some cases where TransForm's technology had, for instance, reinvigorated a compound whose development was otherwise stalled could give rise to a partial 'ownership' position on the drug. For later stage and marketed products, TransForm set up a collaboration with partners such as Johnson & Johnson to enhance the life cycle management of their products through improved bioavailability, broad intellectual property protection, and investigations into new indications. In 2005, this latter collaboration led to the wholesale acquisition of TransForm Pharmaceuticals for the headline figure of US\$230 million.

2.08.7 Types, Stage, and Value of Alliances with Large Pharmaceutical Companies

An analysis of pharmaceutical collaborations and alliances (which involve one of the top 20 pharmaceutical companies), and categorization by phase of alliance has been published for the period 1988–2002 ([Figure 5](#)).¹¹ The phase of alliance relates to the stage of development of the technology or compound at the point of entering into the alliance. This analysis demonstrates that in the period 1998–2002, there has been a roughly constant percentage (54–68%) of alliances related to projects in discovery or lead stages, 10–19% in preclinical development, phase I or phase II, and 20–29% in phase III, NDA filing, or approved. The preponderance of alliances in the discovery and lead phases of drug discovery has persisted for this entire period, although the focus of the alliance has perhaps changed.

More interestingly, an analysis of the type of deal, whether it relates to a diagnostic, drug delivery technology, or to a therapeutic focus, reveals an informative trend over the period 1988–2002 ([Figure 6](#)). The dominance of therapeutics as the foundation for alliances has grown from 75% of all deals done to 86% in the latest period 2000–02.

A second interesting point relates to the value of the deals done. As shown in [Figure 7](#), the greatest value is being devoted to deals that are done at late stages in development, particularly in the latest period 2000–02. The improved terms have an important beneficial effect on the commercial outlook for product-based biotechnology companies, and as described in more detail below, reflect a changing dynamic in licensing in particular. The current environment also tends to favor such licensees hanging on to products until later in development when the added value is better rewarded.

Figure 5 Alliances by stage involving a top 20 pharmaceutical company over the period 1988–2002. (Source: Recombinant Capital <http://www.recap.com>.)

Figure 6 Alliances by type involving a top 20 pharmaceutical company over the period 1988–2002.

Figure 7 Value of alliances by stage involving a top 20 pharmaceutical company over the period 1988–2002.

2.08.8 The Growth of Licensing

License opportunities, particularly from biotechnology sector companies for mid- to late-stage developmental compounds, are increasingly important to address deficits in large pharmaceutical companies' R&D pipelines. While, since 1995, the number of active compounds in early to mid-development has increased, there has not been a concomitant increase in numbers of compounds in late development (**Figure 8**).¹² Most large companies have now set up multidisciplinary teams composed of licensing executives and scientific expert assessors to scout for suitable opportunities. They evaluate thousands of opportunities each year, through a series of scientific and commercial filters; it is typical for approximately 1% of these opportunities to succeed to a completed license, thus emphasizing that a substantial effort is made to bring in as many as possible for consideration but only a very low proportion are ultimately accepted.

There is intense competition among the major companies for the most attractive in-licensing opportunities: the factors that lead to positive assessments (mainly scientific and commercial in nature) are likely to pick similar winners. In 2003, for instance, there were fewer than a dozen high-quality phase III products of commercial significance available for worldwide licensing, and demand for these opportunities significantly outstripped supply. In 2002, seven deals were worth headline figures of more than US\$250 million, and four exceeded US\$450 million in value. Large companies are promoting themselves to smaller companies as attractive licensing partners. For companies not in the largest tier, this is likely to include factors other than marketing capability. Roche, for instance, emphasizes its ability to do deals more quickly than others: 4.5 months as opposed to the industry average of 9–10 months. Such factors can have a substantial impact on development time, period of marketing exclusivity, and extent of competition when the product is introduced.

Another strategy for large pharmaceutical companies to enhance their ability to gain access to attractive licence deals with biotechnology companies is to enter into broad corporate alliances which offer options on such opportunities following a period of collaborative development. A good example of this is the arrangement between Theravance and GlaxoSmithKline.

In 2004, GlaxoSmithKline and Theravance entered into a broad-based collaboration to develop and commercialize novel therapeutic agents across a range of therapeutic areas, including bacterial infections, urinary incontinence, and respiratory and gastrointestinal disorders. Under the terms of the agreement, Theravance would receive US\$129 million, much of which significant amount related to an equity investment by GlaxoSmithKline in Theravance. In return, GlaxoSmithKline would also receive an exclusive option to license potential new compounds from all current and future programs on a worldwide basis, through to August 2007. Upon accepting a new program, GlaxoSmithKline would be responsible for all development, manufacturing, and commercialization activities. Depending on the success of these new programs, Theravance would receive clinical, regulatory, and commercial milestone payments and

Figure 8 Number of compounds at various stages of development 1995–2004. (Redrawn from Lloyd, I. *Scrip Mag.* 2005, February, 24–25.)

significant royalties on sales of medicines. Theravance retained its operational independence to continue discovering and developing new medicines outside of the agreement.

Later in 2005, GlaxoSmithKline exercised its option to license one of Theravance's programs in the respiratory field, led by an inhalable muscarinic antagonist/beta-2 adrenoceptor agonist developed to treat chronic obstructive pulmonary disease (COPD) and asthma. Using the principles of multivalent drug design, Theravance had discovered a series of long-acting inhaled bronchodilators that are bifunctional; one molecule functions as both a muscarinic receptor antagonist and a beta-2 receptor agonist, thereby producing a potential medicine with greater efficacy and equal or better tolerability than single-mechanism bronchodilators. The lead compound was under preclinical investigation for its potential in COPD and asthma at the time of the deal with GlaxoSmithKline. Following take-up of the option, GlaxoSmithKline would fund all future development, manufacturing, and commercialization activities for product candidates in this program.

The background to this deal was that the value of GlaxoSmithKline's respiratory franchise was expected to drop from US\$8 billion in 2005 to US\$5.7 billion by 2010. GlaxoSmithKline's leading respiratory product, Seretide/Advair, was expected to show a revenue decline over 5 years from US\$4.9 billion in 2005 to US\$4.2 billion in 2010, accounting for 74% of franchise sales at that point. As a result of these expectations, GlaxoSmithKline was looking to expand its pipeline in this area, and reduce its dependence on Seretide/Advair, which had been the victim of an adverse patent ruling in 2004 in the UK. Programs from the emerging biopharmaceutical world offer a potentially vital means of gaining new compounds, which would benefit from having GlaxoSmithKline's marketing and production muscle behind them.

The proportion of marketed products that derive from in-licensing has been the subject of some study.¹³ Based on the position in 2003, Bristol-Myers Squibb derives the highest proportion of revenues from in-licenses, at 64%, followed by Schering Plough, at 55% (Figure 9). But the greatest overall revenues are found in Pfizer's portfolio, for which US\$17.5 billion of revenue comes from in-licensed products, out of a total of nearly US\$50 billion. Products licensed in by the top 20 large pharmaceutical companies over the past 15 years have generated over 30% of the revenues in the cardiovascular, musculoskeletal/pain, and anti-infective areas. These figures underpin the importance of externally derived products to large pharmaceutical companies' revenues, and that the expectations of these companies in seeking to license developmental projects are based on the proven experience of the past, not just hope.

Figure 9 Proportion of in-licensed products for large pharmaceutical companies.

Two final points from this analysis: **Figure 9** includes one company that may not be typically regarded as in the large pharmaceutical sector, namely Amgen, the world's largest biotechnology sector company. Although devoid of significant revenue from significant in-licensing activities among its present marketed portfolio, this is unlikely to remain the case for much longer. Large biotechnology sector companies in general with an existing product range are seeking in-licenses just like their 'large pharmaceutical sector' cousins. Biogen-Idec, for instance, has set itself a target of deriving 50% of its pipeline from in-licensed products by 2010. In 2004, the company completed a deal with Vernalis giving it access to a phase I developmental product for Parkinson's disease; the product was an adenosine A2A antagonist.

Lastly, as a result of the increased in-license activity from large pharmaceutical companies, there has been a reassessment of some of the internal projects leading to them being assigned for out-licensing. These projects are seen as commanding too low a priority for their development within a reasonable time-frame. If the problems associated with the project are relatively easily solved, or if for instance they have insufficient market potential, they could be attractive opportunities for smaller firms to develop. GlaxoSmithKline has been particularly active in seeking licensees for such programs, often to small biotechnology companies in return for an equity stake in the company.

2.08.9 Changing Role of Contract Research Organizations

As well as biotechnology sector companies, potential licensees for projects at this stage from large pharmaceutical companies include some of the larger CROs. For instance, PPD has entered into a number of deals involving licensing opportunities at the late preclinical or phase I stage, which it then developed through clinical proof of principle to phase II or phase III, and sought a late stage development and/or marketing partner. Quintiles has set up a special division called PharmaBio specifically to pursue this strategy.

An example of a project which has been partially developed in this way includes dapoxetine for premature ejaculation. Dapoxetine is a selective serotonin reuptake inhibitor, structurally related to fluoxetine, which was initially being developed by Eli Lilly for the potential treatment of depression, for which it was in phase I trials; however, no development regarding this indication has been reported after 1995. PPD GenuPro, a subsidiary of PPD, which was established from a collaboration between Eli Lilly and PPD, gained the rights to develop dapoxetine in December 1999. Dapoxetine was evaluated in a phase II trial in the USA for the treatment of premature ejaculation. Results from the 155-patient trial indicated a significant increase in ejaculatory latency in dapoxetine recipients, relative to placebo. Dapoxetine moved into phase III development for the treatment of premature ejaculation in July 2003. In December 2000, ALZA Corporation, a wholly owned subsidiary of Johnson & Johnson, licensed exclusive rights to dapoxetine from GenuPro for genitourinary therapies, including premature ejaculation. Under the terms of the agreement, ALZA was to develop and commercialize dapoxetine and be responsible for manufacturing, clinical, regulatory, and sales and marketing costs resulting from the license. In exchange, GenuPro was to receive an undisclosed upfront payment. In addition to royalties on net sales, the terms of the agreement include milestone payments based on product approval and meeting certain sales levels. In December 2004, ALZA Corporation submitted a new drug application to the US Food and Drug Administration (FDA) for dapoxetine hydrochloride in the treatment of premature ejaculation. Very clearly, PPD used a series of license deals interspersed with financing of the development of a compound through some critical stages of pharmaceutical development, thereby adding value which it was to realise in the later of the license arrangements.

PharmaBio, Quintiles' development group, offers innovative partnering solutions to pharmaceutical and biotech companies. For instance, it has participated in various investments, either directly or indirectly, into biotechnology sector companies (e.g., Innapharma Inc., a New Jersey company engaged in the development of a series of 'small chain' peptide-based products to treat central nervous system disorders, such as major depression). It also is active in product partnering, in which PharmaBio acquires product rights or products from pharmaceutical companies to help them develop and manage product portfolios, utilizing the parent company Quintiles' development and commercialization capabilities. Finally, PharmaBio can also participate in various risk-sharing agreements for product development, in which a share in the end product value is returned for a financial contribution to product development.

These new ways in which CROs work emphasize the changing nature of the contract sector, and the desire of such companies to seek commercial advantage by offering a broader range of development alternatives which deflect the usual comparisons with competitors based solely on cost of service. These types of arrangements are currently only offered by the very largest CROs. With time, they may become more important as value drivers for the companies offering these services relative to the sector as a whole. These services may also be important differentiating factors for companies based in Europe, USA, and Japan when set against their competitors in India and China. As described above, offshoring is fast becoming a significant factor in contractual outsourcing and forcing the companies with higher cost bases to consider greater added value offerings.

2.08.10 Conclusion

Outsourced relationships are becoming increasingly common for pharmaceutical innovation. It is now very rare for a single company or organization to be solely responsible for the entire research and development and commercialization process. It is probable that some form of research collaboration (e.g., with an academic institution) will have played a part in the discovery of the product and/or parts of the development process will have been conducted under contract by a CRO. While contractual relationships operate on a fee-for-service basis, collaborations and licensing agreements normally include staged payments based on success. This reflects the fact that these types of relationship include the transfer of knowledge or intellectual property.

Presently many new medicines that originate in the biotechnology sector are licensed to large companies for later development and commercialization, and form a key source of growth, currently comprising roughly 30% of revenue and growing over 50% faster than internally developed products. A typical deal may involve a biotechnology sector licensor and a large pharmaceutical company licensee in relation to a project that has proven clinical potential in phase II trials. While the 'plain vanilla' license terms typically involve an upfront payment, milestones, and royalties on sales, increasing competition for the most attractive licensable products has permitted additional terms related to equity participation, codevelopment, and licensor options to market in certain territories or well-defined indications. The partners can often come from outside the biotechnology and large pharmaceutical sectors, and some CROs are becoming increasingly interested in leveraging their developmental and commercial services for a risk-based gain. Equally, it is certainly not unknown for middle and large biotechnology companies to comprise the licensee in licensing transactions.

Some commentators have proposed that the biotechnology sector will increasingly become the 'most effective segment of the drug industry.' The companies in the biotechnology sector are incredibly diverse in the kinds of discovery projects they work upon, the kinds of product they develop – whether large biomolecules or small conventional therapeutics, and the size of company – many being privately owned while a few have a public shareholder base. In addition, over the past 5 years an increasing gulf has opened between the high-risk, high-gain companies aiming to produce therapeutic products, and low-risk, low-gain companies operating in the service sector. As sentiment has cooled towards drug discovery technology, some have attempted to make the transition to product-focused entities, but not all have succeeded. The service providers in the biotechnology sector have to operate in an increasingly fierce competitive environment particularly given the growing importance of India and China as sources for similar services.

Biography

David Cavalla, following his studies at Cambridge University, UK and postdoctoral research in Washington, USA, joined Glaxo Group Research, where he was involved with the research projects that led to the marketed drugs Zofran and Imigran. Subsequently, as Head of Biosciences at Napp Research Centre, he initiated the PDE4 inhibitor project and directed the research strategy for asthma. This work, from discovery to clinic, was the first example of a successful research project carried out using an extended enterprise strategy, completed with the use of externally contracted resources coordinated by a small team of multidisciplinary project managers.

David is the author of *Modern Strategy for Preclinical R&D – Towards the Virtual Research Company*, published by John Wiley. He has been closely involved with the UK Society for Medicines Research, for which he is past-Chairman, and interested in the multidisciplinary aspects of drug discovery and development.

As a founder of Arachnova, he has been a pioneer in the strategy of drug repurposing as a means to substantially improve R&D times and costs, with minimized risks in the discovery of novel medicines.

2.09.1 Context

2.09.1.1 Why (and How) Leadership Matters

Does leadership matter? In a series focusing on the science and technology of medicinal chemistry, a chapter on leadership of R&D is at least an anomaly. Of course, most scientists would respond that leadership – to be defined shortly – does indeed matter. The crucial issues are: why might leadership matter; and, how?

Many books on creativity and innovation,^{1,2} as well as investigations of corporate innovations³ and biographies and autobiographies of innovators,^{4,5} concur that leadership matters for reasons described in a study of US National Aeronautics and Space Administration (NASA) scientists:

[It] is no longer enough to be excellent in [one's] scientific discipline ... A research leader needs to get work done with and through other people ... Time, money, morale, and quality of product are only a few of the elements that are at risk when ineffective leaders are at the helm.⁶

Leadership also matters because of its indirect effect on industries and nations. The US National Science Foundation's annual reviews of the status and role of science, engineering, and technology demonstrate that global economies both benefit from and depend on high-technology industries and services. The latter are defined by "their high R&D spending and performance ... [that produce] innovations that spill over into other economic sectors."⁷

When the output of research is high-quality innovation, institutions investing in R&D enjoy positive economic returns. More importantly, "[r]eturns to society overall are estimated to be even higher. Society often gains more from successful scientific advancements than does the organization conducting the research."⁷ It is not too much of an exaggeration, or simplification, to state that effectively led science contributes to social and economic welfare.

If social and economic welfare, as well as 'time, money, morale, and quality of product,' provides an answer as to why leadership matters, the more intriguing question remains. How does leadership affect the creativity and caliber of science?

The purpose of this chapter is to provide a brief overview of how leadership matters in terms of people and the organization of scientific work. Before continuing further, however, let me provide the definitions of leading, managing, and an effective leader that will be assumed throughout the chapter⁸:

- Leading: being an exemplar and inspiration, as well as directing people in their work, in decision making, and in problem solving
- Managing: administering the R&D organization (structure, systems, etc.)
- An effective leader: one who is capable of developing and maintaining an enthusiastic, energetic, and creative group of scientists and of managing R&D successfully.

2.09.1.2 Scientific Training and Leading Scientists

If the leader of R&D 'needs to get work done with and through other people,' it will be instructive to reflect on general scientific education and training as preparation for that role.

Individuals with a terminal degree in science (as well as medicine, engineering, and so on) can be described as narrowly trained professionals (i.e., specialists).⁹ Narrowly trained professionals typically undergo a lengthy and particularly designed education and socialization.¹⁰ During this time, their progress and rewards are based on individual intellectual accomplishments, such as solving technical problems, crafting hypotheses to explain new phenomena, devising bench experiments to test hypotheses, carrying out suitable experiments, and interpreting the results.¹¹ They may work in groups and sometimes conduct experiments with colleagues, but they are recognized for their own ideas and receive individual grades and individual degrees. Working cooperatively or collaboratively is typically neither required nor rewarded in graduate school or postdoctoral training.

When scientists graduate, they may work for a time as an individual contributor. However, whether or not they remain on a technical ladder, nearly all must take on the challenge of supervising people in their laboratory. When they do, they discover that the rules have changed. Although highly trained in the cognate sciences and competent in their specialty, they are likely to be ill prepared to deal with the behavioral aspects of their job such as working in and with teams and leading other people:

...While we are truly experts in the technical aspects of our job, we oftentimes have difficulty excelling at our non-technical responsibilities. This can lead to varied success managing people and projects, promoting our programs and initiatives, and ascending to high-level management or leadership positions within our organization.¹²

Moreover, by the very paradigms of their disciplines, scientists are predisposed to be skeptical of the sciences they perceive as "soft." Although even quantitative subjects like finance and accounting may be questioned as being hard sciences, behavioral and managerial theories are often of highly suspect credibility. "The idea of management as a professional skill with its own disciplines can be a tough sell. New training has much to overcome in the way of old prejudices."¹³

2.09.1.3 Scientists' Own Views on Good and Bad Leadership

Surprisingly, there is little information on how scientists themselves define effective and ineffective leadership (there are biographies and autobiographies of scientists and certainly anecdotal reports¹⁴). To address the gap, a colleague and I began to survey expert panels of scientists in 1996, because we were interested in scientists' experience of leadership – both leading and being led.¹⁵

Since then, seven panels consisting of 228 individuals have completed the survey. They include scientists from the USA, Europe, and Asia and are primarily PhDs (about 80%), with the remainder MDs (or MD/PhD) and MS (very few have only a master's degree). Most are working in the life sciences and have degrees in chemistry, biology, or medicine, although a number have doctorates in engineering, mathematics, or physics. They are about equally distributed between academia and government scientific enterprises and industry (large pharmaceutical and small biotechnology firms). Because this ongoing study is predominantly exploratory as well as descriptive, the sample is not meant to be representative of all scientists but rather to provide a window into what it may feel like to lead and to be led in R&D.

Scientists are asked three open-ended questions, either verbally or written on a short survey. The numbers of individuals and the responses that could be coded separately, per question, are as follows:

1. Describe the best example of scientific leadership you have encountered and explain why this person was effective (191 scientists generated 338 responses).
2. Describe the worst example of scientific leadership you have encountered and explain why this person was ineffective (164 scientists generated 219 responses).
3. Describe the most difficult of the typical problems you encounter in your scientific position, (200 scientists generated 301 responses).

2.09.1.3.1 The effective leader

If you were asked the same question, what would you describe as the most important attribute of an effective leader of R&D?

When I have posed this in a discussion, often a scientist will respond “intelligence, technical skills.” In fact, qualities of what I have termed being a nice person are most frequently listed. That attribute is followed by skills in management; then, intellectual accomplishment; and finally, being a good role model. To date, those four classes account for nearly 80% of answers to the question as to why the leader was effective. An effective leader is described as:

- Caring, compassionate, supportive, and enthusiastic (27% of all responses)
- Managerially skilled in communicating, listening, resolving conflict, and organizing (23% of responses)
- Technically accomplished to lead a scientific effort (15% of responses)
- Good role model, mentor, and coach (11% of responses).

Scientists also list diplomacy, fairness, patience, and having a sense of humor as important qualities in a leader.

2.09.1.3.2 The ineffective leader

Although the first question generated the largest number of responses per person, the second question generated the most intense feelings, as reflected in scientists' language. More than half of the responses to this question describe the worst example of scientific leadership as involving a boss who:

- Is abusive, publicly humiliates subordinates, provides only negative feedback (19% of responses)
- Is selfish, exploitive, dictatorial, disrespectful of others' contributions (19% of responses)
- Cannot deal with conflict (14% of responses).

Other attributes of the ineffective leader are being disorganized, having unrealistic expectations, taking prolonged absences from the laboratory, and being dishonest.

Does good science emerge from these conditions? As the next section illustrates, there is a sizable difference in the climate created by an effective leader and that created by an ineffective leader. Scientists' own responses attest to the impact of leadership on morale and, thence, on the caliber of results.

2.09.1.3.3 Climate in the laboratory

The best leaders are described as “scientifically very competent, and compassionate and caring deeply for collaborators and subordinates.” One respondent noted: “[the best leader is] caring but assertive. Good working rapport as well as friendship in the lab. Overall feeling of appreciation for the work done.” The effective leader “not only criticizes but also praises. A lot of people tell you when you’ve done something wrong. Very few people tell you when you’ve done something right.”

In a detailed example, one scientist described his former boss as:

... a great scientific leader and manager. He held regular group meetings, included everyone in the discussions, took risks scientifically and in management, and was not afraid to speak up. He kept everyone focused and was a real ‘cheerleader’ when it came to motivating us, keeping us a very focused and excited research team. He gave us a certain amount of independence and expected us to plan our work thoroughly. He also spent a lot of time in the lab, talking with us individually about the work. Our team was VERY productive! [respondent’s capitalization and punctuation].

Scientists describe a very positive climate in the laboratory produced by leaders who are “highly enthusiastic and support others’ unorthodox ways of thinking.” Such leaders create an atmosphere in which professional growth and scientific innovation seem just to happen without struggle. The effective leader “can get the best out of each person”; ensures that each individual “feels a part of what is happening and wants to do a good job”; and has “the ability to inspire and make everyone enthusiastic about the research.” These leaders generate a “fun and productive atmosphere in which each person can thrive in his/her own individual way”; they support a “stimulating environment,” they “encourage ingenuity,” and are able to “appreciate innovative/novel/different ideas.”

In contrast, the climate created by an ineffective leader is at best emotionally stressful and at worst pernicious. Respondents write that they are yelled at publicly, berated, nagged continuously, belittled. One scientist described “lab meetings [as] notorious for being forums for public denigration. [X] is abusive in meetings and often bluffs his way through things he knows little about.” Numerous scientists attest to the fact that ineffective leaders cannot deal with conflict. Instead, they “avoid conflicts and let problems fester”; they “look the other way” or they “hide from conflict.” One scientist wrote that the director “uses the technique of avoidance and, when problems are arising, simply never shows up in the lab.” Another gave an example of a situation in which the principal investigator “delayed dealing with interpersonal problems until they grew out of hand – then asked a post-doc to handle the issues.”

A powerfully negative climate – in other words, poor morale – can be created by an ineffective leader. Moreover, not one respondent has noted, in all the descriptions of ineffective leaders, that scientists are nevertheless productive. In fact, the opposite is described:

... I often find not only in my experiences but observing others that negative motivation doesn’t work. It makes me much less productive.

... There is much waste of human and financial resources in science from ineffective leadership.

... Having had both extremes – great and horrible – as leaders, I’m aware of the productivity associated with a good leader and the lack of productivity associated with a bad leader.

... The most ineffective leader I have had used intimidation to squeeze results from people. Fear is a great motivator, but resentment kills trust, certainty, and creativity.

2.09.2 Scientists’ Most Difficult Problems

Given the earlier description of scientific education and training, it should be clear that being trained as a scientist does not mean that one is therefore competent to lead scientists, as a survey respondent admitted:

I would like to become an effective manager and as far away as possible from being an ineffective one. There is a difference in management, and time, and self-motivation that leading others requires and that being a bench scientist did not.

To date, four classes of problems account for almost three-fourths of all answers to the third question (‘of the typical problems you encounter, describe the most difficult’):

- Becoming a leader (e.g., being authoritative, staying focused, balancing scientific efforts with management responsibilities, delegating) (26% of responses)
- Dealing with conflict (21% of responses)

- Motivating people, generating enthusiasm (15% of responses)
- Communicating effectively; especially, providing feedback (11% of responses).

Other difficulties include ‘not being taken seriously as a leader,’ ‘lack of respect and support from people in authority,’ and ‘being undermined by colleagues, mentors, even secretaries.’ Each of the four major problems is described below.

2.09.2.1 Becoming a Leader

Moving from a position as colleague and peer to being a leader with some authority over a group brings with it an array of problems. Scientists report that they are sometimes overwhelmed by administrative responsibilities (“NON-SCIENCE activities,” in the exact words and capitalization of one respondent), including “space conflicts and limited reagents.” Laboratory administration requires that they “solve equipment and material problems,” “deal with parking,” and “chase after borrowed equipment that was not returned.” These enlarged responsibilities result in the pressure of “too much work, too little time, and too few hands,” perhaps because (as one scientist stated) of the difficulty of “saying ‘No’.” Becoming a leader may also highlight a scientist’s lack of “confidence to delegate.”

The most challenging issues, as implied by the earlier citations from the survey, involve dealing with people, not only those in one’s laboratory. A principal investigator discovered that he also had to manage “difficult – arrogant and abrasive – people in other labs with which we must deal on a regular basis. I struggle with getting my point across, without causing a bigger dispute.”

2.09.2.2 Dealing with Conflict

Being skilled in resolving the inevitable conflicts that arise when people work together is an important attribute of the effective leader. With regard to their own most difficult problems, respondents write that they struggle with how to resolve disagreements that range from ‘which music is played in the lab to which experiments have higher priority.’ They struggle to ‘keep people from sniping at each other’; and they struggle with how to handle ‘jealousy,’ ‘moodiness,’ and ‘one bad apple who poisons the atmosphere.’

Conflict that is ignored and avoided invariably entangles more individuals than were first involved. They may not realize it, but scientists and technicians are drawn to take sides, which escalates the issues. People who are involved in a conflict even to a limited degree find that more and more of their energies go to the conflict situation rather than to the science, to the detriment of the science.

2.09.2.3 Motivating People

In their new role, scientists discover how hard it can be to generate ‘enthusiasm equal (or at least closer) to my own.’ The effective leader of science has been described, above, as a “‘cheerleader’ when it came to motivating...” Motivating people does require a great deal of time praising, supporting, cajoling, encouraging. The effective leader spends “a lot of time in the lab, talking with [people] individually about their work.” Thus, motivating people and communicating effectively are interdependent leadership challenges.

2.09.2.4 Communicating Effectively

Newly promoted supervisors in any organization face a common problem in giving feedback that will not be felt as ‘personal attacks.’ One scientist described her difficulty in “being able to convince people that they are going in a (likely) wrong direction in a way that will leave no resentment behind.”

Communicating effectively allows a leader to critique without “sounding confrontational” or “hurting [people’s] feelings.” Because R&D almost always requires multidisciplinary team efforts, because it involves complex processes and careful management of the flow of information, effective communication is critical both to motivation and to “keeping all team players focused on the critical path.” Communicating effectively is in fact a foundation skill for leading effectively.

2.09.3 The Twenty-First Century Scientific Workforce: Issues of Diversity and Inequity

Leading R&D is challenging for a number of reasons. First, leadership really does matter – it can have an impact on social and economic welfare, as well as on cost, quality, and novelty of the output from R&D. Second, scientific

education and training, to some degree, are counterproductive to the leadership skills of getting “work done with and through other people.” Third, and the topic of this section, the workforce that a leader of science faces will be diverse in terms of national origin, age, and education yet not diverse in terms of gender. Both issues present leadership challenges.

2.09.3.1 The Issue of Diversity

Let me start by describing a hypothetical average laboratory of about a dozen people in the USA: a number of different national cultures will be represented – several scientists will be foreign-born, predominantly from Asia. Nearly half will be between 35 and 49 years of age; one or two will be younger than 29 years and perhaps one will be 60 years or over. Several will be women. About half will have a doctorate and about half a bachelor’s degree, with several distinct disciplines represented.¹⁶

A major challenge raised by diversity is communication. Given the fact that our hypothetical group involves people trained in languages other than English, there are likely to be linguistic misunderstandings. In addition, though, national “[c]ultural differences in style, expectations, and work attitudes can create misunderstandings that impede the flow of information and the development of science.”¹⁷ Moreover, language barriers exist between the disciplines that are represented in the laboratory. Each discipline represents a group of people who share a common meaning for their language, which may be different from that shared by people trained in other disciplines.

Although laboratories in relatively homogeneous countries may have a smaller proportion of international scientists, their R&D workforce will also include people from a number of different countries and with different disciplines.¹⁸ The challenge of communication is inherent in the modern science organization and is directly related to the degree of diversity. Paradoxically, and often underappreciated by leaders of R&D, diversity is linked to the quality of thinking that can occur in the laboratory. In other words, diversity presents a sizable communication challenge to leaders of science, yet sufficient diversity is crucial to the caliber of output from R&D.

An early study of group problem solving showed that, among other qualities, there must be sufficient difference in (or diversity of) approaches, views, perspectives, and so on. With too little diversity, the scope of information search and the quality of the processing of the information by the group was degraded.¹⁹ In short, the caliber of thinking was compromised.²⁰ Put another way, “science is fundamentally a way of thinking, and people from other countries think differently,” as do people of different races and gender.¹⁷ Assuming requisite intellectual competencies of those involved, the caliber of science in a laboratory is dependent on the inclusion of people of different ages, from different countries, from different racial and ethnic groups, from different disciplines, and from both genders. The latter characteristic, gender, brings us to the issue of inequity.

2.09.3.2 The Issue of Inequity

In all industrialized nations, there is a marked under representation of women scientists. For example, according to two news reports:

The [US] National Academy of Sciences (NAS) announced 72 new members..., nearly 25 percent of them female, representing the largest proportion of women ever elected.... The new members boost the total number of women in the Academy to about 160, or approximately 8% of the 1,922 active members.²¹

A record nine women are among the 42 new fellows elected by the U.K.’s Royal Society this year. Women now make up 4.4% of the Royal Society’s total fellowship of 1290.²²

The president of Harvard University said recently that there is a lack of “women’s representation in tenured positions in science and engineering at top universities and research institutions” that is not restricted to the USA.²³ An earlier study of the academic career outcomes of men and women postdocs (Project Access) confirmed both the fact of under representation and the fact of pay and advancement inequities in academia. Of scientists who received their PhD before 1978, women were only half as likely as men to become full professor. Men published more articles, although articles published by women were cited more frequently. Career obstacles for women were “small in themselves in effect, but large in numbers ... [so that] a small set of misfortunes or disadvantages throughout the career accumulated in the same direction, so as to deflect the women in one direction.”^{24,25}

Apparently, female and male scientists can be judged differently, as illustrated by a 1997 study reported in *Nature* of the Swedish peer review system for postdoctoral fellowship applications. The authors found that “peer reviewers

cannot judge scientific merit independent of gender.” Regression analyses of factors influencing the judgment of competence showed that:

[Female] applicants started from a basic competence level of 2.09 competence points... and were given an extra 0.0033 competence point by the reviewers for every impact point they had accumulated. Independent of scientific productivity, however, male applicants received an extra 0.21 points for competence. So, for a female scientist to be awarded the same competence scores as a male colleague, she needed to exceed his scientific productivity by 64 impact points....²⁶

The same under representation and inequity hold true in industry. In Europe, “private industry is funding 56% of all European scientific research ... [yet] by now, only 15% of the industrial researchers are women.”²⁷ The gender pay gap also remains sizable in the European private sector, with women holding an advanced degree earning between 60% and 83% of what their male counterparts earn.²⁸

A study of women in industrial research found that, in most Organization of Economic Co-operation and Development (OECD) countries, “women scientists and engineers working in the industrial sector are under-represented and are also more likely to leave technical occupations, as well as the labor force, than women working in other sectors.”²⁸ That situation presents, for Europe, a “crisis” in terms of the shortfall of researchers more generally.²⁹

Even when women are present, they may not be heard. So-called “male stereotyping and preconceptions” can influence scientific communication:

The commonplace presence of women in the laboratory, and the occasional inclusion of women in management positions, masks one residual problem: scientific competence is still judged by male communication styles. Objective, unemotional, assertive. This stereotypic male style seems to be the very essence of research.³⁰

Responses from the expert panels reflect the reality many women scientists face:

- Being ignored (“My advisor ignores me when experiments don’t work; refuses to have productive discussions; takes experiments away from me if I don’t succeed; and is generally not supportive.”)
- Being excluded from important committees (One respondent wrote that her most difficult problem was “exclusion from the committees that contribute to the way the department is run.”)
- Not being taken seriously (“If I am too soft or quiet, then I am not taken seriously as a leader.”).

The question of why women may receive inequitable treatment is beyond the scope of this chapter (the European Women in Industry report cites barriers to recruitment, lack of career opportunities, and gender pay gap and gender stereotypes, among others⁸). What is within the scope of this chapter is the result. When women are underrepresented in the R&D organization, the level or degree of diversity among scientists may be suboptimal for creative thinking:

[Women] have different qualities than men, and therefore more women in research increases diversity, changes modes of communication and brings something new to the innovation process and thus improving the sector’s competitiveness.²⁸

In summary, good leadership matters. Good leaders understand that they may lack people skills, despite their scientific education and training. Good leaders appreciate the issues of diversity and inequity in the modern scientific workforce and the challenges they bring.

With this as background, in the following section I describe three positively stated people skills that are critical to leading R&D effectively: the skill of motivating, the skill of communicating and listening, and the skill of resolving conflict. The fourth people skill must be stated in the negative: not micromanaging.

2.09.4 Leading People

2.09.4.1 Motivating

It should be very clear that leadership affects motivation – how people feel about their scientific work, how eager they are (or are not) to come to the laboratory in the morning, how enthusiastically (or not) they approach difficult scientific and technical problems.

The word “motivation” comes from the Latin *movere*, meaning “to move” – not in the sense of picking up an object and carrying it to a different place but in the sense of a person’s being moved to action. This is also the root of the word, “motive.” Motives are defined as “relatively stable dispositions to strive for [in other words, be moved to action

towards] certain classes of goals.”³¹ A laboratory with motivated people is one in which there is high morale, or a positive climate. These terms are essentially synonymous. Studies in organizational behavior have demonstrated that being motivated depends among other things on a number of conditions being met. Each is quite straightforward and, one must admit, rather obvious. Yet, my experience suggests that they are not always achieved.

2.09.4.1.1 Reasonable working situation

Safety in the laboratory must be ensured; space must be at least adequate and decently appointed; the required equipment must be available to do the job, and so forth. Although these obviously influence morale, a reasonable working situation can be jeopardized by, for instance, commonly imposed budget constraints. Whether temporary or permanent, draconian approaches to containing or cutting the R&D budget can result in scientists’ using outdated equipment and/or sharing critical equipment so that project timelines are affected. They can also result in the outsourcing of tasks to less interested third parties. And, budget constraints always produce what one respondent called “increasing administrative time sinks: paperwork, forms, and hurdles.” The point of this example is not that limited space, or equipment problems, or even budget constraints are inherently bad or unavoidable. The point is that, if a problematic working situation is not addressed by the leader, it will be demotivating. (Of course, safety problems are inherently wrong as well as demotivating.)

2.09.4.1.2 Competent people trained appropriately for their job

We can assume that people hired into an R&D organization possess the scientific and technical skills required for a particular position, because human resource systems and personnel have matched technical competencies of recruits with technical demands of jobs. Jobs, however, “demand” human skills, and some require even more human or people skills than technical. Hence, we can also assume that some scientists in a leadership position are not competent for that role, as illustrated by respondents’ descriptions of leaders who are “capricious and insulting,” “intimidating and confrontational,” “given to public tirades,” and so on.

Even if competent for their role – at least insofar as they do not exhibit the above egregious behaviors – scientists in leadership positions are rarely trained appropriately for ‘getting work done with and through other people.’ Ineffective leaders, for example, are also described by respondents as individuals who “rarely praise,” who “do not take the responsibility for dealing with unpleasant issues,” or who “do not make the effort to listen to people in their lab.” Such scientists are clearly uneducated and untrained in what the role of leader requires. Ironically, poorly trained (or incompetent) leaders are also likely to be poorly motivated leaders, with poorly motivated scientists and technicians working for them.

2.09.4.1.3 Assurance of link between effort and outcomes

People must believe that their effort will lead to the desired work goal; they must believe that achieving this goal will lead to certain outcomes (e.g., personal recognition by their scientific peers); and they must value those outcomes. Some examples of leader behaviors (from the expert panels) that produced demotivating conditions, because one of the above links was absent or damaged, include:

- Asking people ‘for the impossible – way impossible’
- Expecting ‘too much from people and setting unrealistic deadlines’
- Pitting ‘individuals against each other’ in unachievable contests
- Doing a ‘flip-flop’ so often on project requirements that the goal literally disappeared.

There is also an important relationship between inequity, as discussed earlier in [Section 2.09.3.1](#), and this condition for motivation. Believing that goal achievement will lead to a desired outcome, such as recognition by one’s peers, may be difficult for women scientists. If “a female scientist to be awarded the same competence scores as a male colleague [needs] to exceed his scientific productivity by 64 impact points,”²⁶ then believing that she will be recognized by her peers may be hard to sustain by a woman scientist in the modern science organization.

2.09.4.1.4 Equity and fairness

This condition, which stipulates that people must be treated and paid fairly in the organization, as compared with similar organizations, is related as well to the above discussion of inequity. If women are not only underrepresented in the scientific workforce but also underpaid in comparison with men, then their morale will of necessity be affected.

2.09.4.1.5 Not micromanaging

This last condition must be stated as a required absence rather than a presence (e.g., ‘equity and fairness’). Micromanagement is demotivating and very clearly influences innovation. From studies of scientists at the Center for Creative Leadership, a number of factors were identified as antithetical to creativity³²:

- Constrained choice
- Overemphasis on tangible rewards
- Evaluation
- Competition
- Perceived apathy by leaders toward the scientists’ work
- Unclear goals
- Insufficient resources
- Overemphasis on the status quo
- Time pressures.

Several of these factors characterize the situation that can be provoked by micromanagement: constrained choice, evaluation, overemphasis on the status quo, and time pressures. Another manifestation of micromanaging behavior is the leader who attempts to stay on top of everything. A leader who tries to know every detail reduces morale by reducing scientists’ autonomy – and stifles creativity.¹¹

2.09.4.2 Communicating and Listening

An article in *The Scientist* a few years ago stated: “You can never do enough training around your overall communication skills.”³⁴ Communication, which comes from the Latin *communicare*, means to share or impart.³⁵ Note that what most of us take for granted as communicating is in fact the second aspect (to impart) – of primacy is sharing, which requires listening.

Communicating and listening figure prominently in the expert panel responses describing the most effective leader. Such individuals are articulate and direct. They seek feedback from their intended audience throughout the process of imparting information (in person or electronically), to prevent misunderstandings. They recognize the language barriers that may hinder communication in a group and act as translators and facilitators. People working for them ‘catch’ their enthusiasm, because such leaders communicate – share – their ideals and passion for the science.

Effective leaders also listen well, which means they:

- ‘put aside bad moods when interacting with others’
- ‘take time to listen’
- ‘look at me directly when speaking and listening’
- ‘are never too busy to discuss results.’

The most-repeated adjective associated with ‘listening well’ is open-minded. Effective leaders are described by the expert panel respondents as open to others, open to ideas, open to different views, open to alternatives. That characteristic of open-mindedness is the prerequisite for what is termed active listening, which describes both a mental stance (i.e., deliberate emotional state) and a set of skills.³⁶ The mental stance needed to listen well is being nonevaluative. If we judge either the person who is speaking or what we hear, then we are not listening well.

Being nonevaluative is necessary but not sufficient; additional skills required to listen well include:

- Paraphrasing manifest content
- Reflecting the implications
- Reflecting underlying feelings
- Inviting further contributions
- Using nonverbal listening responses (e.g., nodding, consistent eye contact, and so on).

Communicating and listening well are also crucial for the times when leaders must deal with the inevitable conflicts that arise in R&D, as described next.

2.09.4.3 Resolving Conflict

Conflict – resolving or not resolving – appears in each set of responses to the expert panel survey questions. Effective leaders can resolve conflict. Ineffective leaders cannot resolve conflict. Resolving conflict is the second most frequently mentioned difficult problem that scientists face in their role as leader. Because this is such an important topic, I first identify sources from whence conflict is likely to arise and then review approaches for resolving actual conflict.

2.09.4.3.1 Sources of potential conflict

Major sources of differences in R&D represent sources of potential conflict. These sources include individual differences, group differences, and power differences.

Differences among individuals are a likely source of conflict, because individuals may perceive the same issue differently and behave consistently with their perceptions. What we call personality affects our perception, as do age, education, race, gender, ethnicity, experience, religion, and so on.

Differences among groups are a likely source of conflict, because a group of people who have been working together for some time will share common experience and common understanding. Like personality differences, group differences result in a particular way of looking at the world and behaving in response to that perception. A pioneering study (in nonscience firms) revealed that:

[Group] differences include orientations toward the particular goals of the department, emphasis on interpersonal skills, and time perspectives. Departments, therefore, vary not only in the specific tasks they perform but also in the underlying behavior and outlooks of their members.³⁷

The final major source of differences is power; it is, perhaps, also the most obvious:

The power variable is a relational one; power is meaningless unless it is exercised ... Power relationships entail mutual dependency.³⁷

The greater the dependence of one person (or one part of the organization) on another, the greater the ability of the more powerful to influence the less powerful. Power derives from having resources that another wants and being in control of their allocation, especially when there are no alternatives. If there are alternatives (whether they are being used or not), the power of the agent holding the resources is diminished. Generally, what the powerful agent in an organization controls is access. For example, senior faculty in the university control access to key information, critical relationships, authorship order, as well as to space, equipment, and funds. The director controls access to general support as well as key information and critical relationships. These differences (or asymmetries) in control of access between the powerful and the dependent agents in science organizations are potential sources of conflict.

2.09.4.3.2 Resolving conflict

Management texts generally describe five approaches to dealing with conflict, of which the most common is avoidance.³⁸ In a very few situations, avoidance may be appropriate. For instance, if an individual is in serious emotional distress, then the leader needs to help him/her find assistance rather than to deal with the conflict at that moment. But, the problem with avoidance is simple: 'Avoiding a conflict neither effectively resolves it nor eliminates it. Eventually, the conflict has to be faced.'

A second approach is smoothing, which means that the leader minimizes the differences between individuals or groups and emphasizes the commonalities (smoothes the bumps, so to speak). Smoothing can be effective, if the parties generally get along well or if the issue is minor. 'But, if differences between groups [or individuals] are serious, smoothing – like avoidance – is at best a short-run solution.'

A third approach is to compromise, by asking each party to give up something or share a resource equally. Again, although such an approach may be effective, it remains problematic. 'With compromise, there is no distinct winner or loser, and the decision reached is probably not ideal for either group.'

A fourth approach is forcing, or using authority to command a particular decision. In some time-critical or crisis situations, forcing may be appropriate. When time permits, however, the real source of the conflict must be addressed:

[Forcing] usually works in the short run. As with avoidance, smoothing, and compromise, however, it doesn't focus on the cause of the conflict but rather on its results. If the causes remain, conflict will probably recur.

What is an effective approach to resolving conflict? Confrontation has been found to be an important technique, because it addresses two of the three sources of conflict, individual and group differences:

The confrontation method of problem solving seeks to reduce tensions through face-to-face meetings of the conflicting [parties]. The purpose of the meetings is to identify conflicts and resolve them ... For conflicts resulting from misunderstandings or language barriers, the confrontation method has proved effective.

The word, “confrontation,” is derived from the old French term for sharing a common frontier.³⁵ To be skilled in effective confrontation is to be skilled in finding the common frontier between people or groups. As should be clear, communication and listening skills are paramount in the process of confrontation.

Although effective in resolving conflicts caused by individual or group differences, confrontation is less effective for conflicts caused by power differences. Instead, leaders should consider the superordinate goals technique, which involves

developing a common set of goals and objectives that can't be attained without the cooperation of the [parties] involved. In fact, they are unattainable by one [party] singly and supersede all other goals of any of the individual[s] ... involved in the conflict.³⁸

The effectiveness of this technique is based on a willingness to discuss the issues by the more powerful person. The reality may be that a power asymmetry represents too high a gradient for meaningful communication between parties, no matter how skilled the leader in communicating and listening. Although not a conflict resolution technique, banding together in the face of power asymmetries and trying to make a general problem (e.g., verbal abuse by a boss) more visible can sometimes achieve the desired results.

2.09.5 Managing R&D

Let me repeat my definition of an effective leader, from [Section 2.09.1](#): an individual who is capable of developing and maintaining an enthusiastic, energetic, and creative group of scientists and of managing R&D successfully. Managing R&D comprises all the ‘NONSCIENCE activities’ required to produce results, such as designing the organization of work (structure), determining the right number of people in work groups (size), and setting up formal processes that support work (systems). Each of the latter activities, and its impact on the caliber of science, is briefly addressed in this section.

2.09.5.1 Structure

Structure, or how work is organized, refers to the pattern by which people relate to each other and communicate with each other. (Structure should not be assumed to be the same as the organization chart, which depicts formally established lines of authority.) My purpose in this discussion is not to describe all the concrete ways in which work can be organized but rather the two basic patterns by which work can be organized. One is vertical (superior to subordinate, hierarchical relationship and communication) based on the parent–child model. The other pattern is lateral (equal to equal, horizontal relationship and communication) based on the sibling (peer) model. Each pattern is more effective in certain situations.³⁹

Vertical structure is more effective in a stable environment and for work well defined by rules and established procedures. For this type of work (e.g., some late-stage development projects), a vertical structure (superior–subordinate, hierarchical relating and communicating) will be more effective. Lateral structure is more effective in an environment of rapid change and high uncertainty and for work ill defined by few rules and established procedures (e.g., some discovery projects). One reason for the effectiveness of lateral structure under such conditions is that people relating to each other as peers are more apt to collaborate informally and to communicate openly. Peer relationships and open communication foster the intellectual challenge that supports good and novel science.

Cognitive scientists describe two types of problems that correspond to the above definitions of types of work. The first is a well-defined problem, which has “an unambiguous problem state, a well articulated goal state, a limited number of potential operators, and clear criteria for when the solution has been found. Ill-defined problems lack one or several of these characteristics.”⁴⁰ Thus, we can also say that the vertical structure will be better for solving well-defined problems and the lateral for solving ill-defined problems.

2.09.5.2 Size

Size follows logically from structure. The number of people who can be organized in a vertical structure will be larger than the number who can be organized in a lateral structure. Lateral structure, by its nature, constrains the size of a work group. Scientists and technicians can only relate as peers with those whom they know (by definition, a limited number of people). They can only communicate directly with a limited number of people. Estimates of optimum size range from 8 to 12 for a work team up to 200 in the total work organization, such as a discovery unit:

Size [of an organization] is again the potential killer [of innovation]. The amount and level of communication required to sustain a consistently far-reaching, leading-edge, collectively identified community ... is very high and needs to have great fidelity.⁴¹

Even in late-stage technology development, problems may arise that can only be solved by work defined by few rules and established procedures (i.e., ill-defined problems). Under these conditions, the problem solving unit should be organized as a lateral structure. A small group of people on a task force, or a small team from vertical functions, should relate to and communicate with each other as peers, collaborating and challenging each other's ideas. These groups should be informal, responsibility should be broadly delegated, and the pattern of relating and communicating should be horizontal.

Let me emphasize that vertical structure is commonly found in R&D and is (frankly) the easier structure to design and manage. Work is divided by department, responsibility is clearly ordered, and there is a visible 'top' and 'bottom.' But, as was noted by one observer of R&D organizations: "Parents are not creative. They are defenders of the paradigm. They use words like 'ought' and 'must'."⁴¹ If the science will benefit from open challenge and debate, then vertical structures will be less effective. Unfortunately, when faced with qualities of the lateral structure, attributes of creative people, and the need to meet cost and/or time constraints, leaders' response may be to put in tighter controls and more explicit rules, and to expand the hierarchy. Such responses prevent a 'collectively identified community' from ever developing.

2.09.5.3 Systems

The caliber of science can also be influenced by formal systems, such as recruitment, performance appraisal and reward, decision making and approval, and information systems. For example, recruitment systems may be unwittingly designed to find people who 'fit'; thus, they may screen out those whose personal and intellectual styles are different from the majority. The consequences are likely to be lack of diversity, conformity and uniformity, people who are unlikely to challenge the status quo, and suboptimal creativity:

... the power of 'people who are like me' to be directly interpreted as 'people who are best for our organisation' is enormous. Its converse: 'If I do not like them as people, it cannot be good for me to have to work with them,' is a fundamental error of any manager in a creative field.⁴¹

Like recruitment systems, performance appraisal and reward systems may unintentionally promote mediocrity, by (for example) rewarding risk aversion. Leaders must be willing to reward people who use good judgement and take risks, even if they are not successful. Effective leaders understand the difference between disappointing results and poor judgement.

With regard to decision making and approval systems, I have observed that leaders of R&D have often designed, or accepted the design of, decision making and approval systems that are cumbersome, slow, and indicate lack of trust in the intelligence of those who use them. In fact, very few formal hurdles should be necessary.

Finally, information systems can provide numerous opportunities to enhance the caliber of science. Collaboration can be supported by electronically linking scientists both within and outside the institution. And, creativity can be enhanced by ensuring wide distribution of provocative material, such as work-in-progress within the organization, and by providing easy access to useful external data banks.

2.09.6 Conclusion

Even this brief overview of leadership issues in R&D would be remiss, if no mention were made of organizational culture. At the end of the day, a leader is also responsible for discerning what are the fundamental values held by people

in the organization and how those values either support or hinder good science:

The means by which creativity and innovation can be influenced [at the organizational level] are many and various but hard to measure. This is cultural.... The organization's culture must reward and encourage behaviour which challenges it, which burns with the desire for change.⁴¹

In some organizations, the qualities required for creative thinking and novel science are not valued, or they are given only lip service. There is little true collaboration across disciplines; little intellectual challenge from those who might bring a radically different way of thinking; little candid communication (under the guise of valuing civility); and little genuine risk taking (under the guise of valuing quality). Good science emerges when culture – values and norms – encourages and supports the right climate (i.e., morale) and right behaviors.

I do not know anything about the cultures of the institutions in which the expert panel respondents work, but it is a reasonable hypothesis that some norms support (or, at least, do not dissuade) the egregious behaviors of ineffective leaders. It is also a reasonable hypothesis that some values support the behaviors of effective leaders. Effective and ineffective leadership does not exist in a vacuum. If leaders' behaviors persist over time, they have to be supported by some larger context. That context is culture.

Biography

Alice M Sapienza, DBA received her bachelor degree in chemistry *magna cum laude* and was awarded US Public Health Service fellowships for doctoral studies in biochemistry to Johns Hopkins and the College of Physicians and Surgeons at Columbia University. After working for a number of years in industry, she received her MBA from Harvard Business School. Between then and entering the doctoral program at the School, she was a general manager in a Harvard teaching hospital. During her doctoral studies, she was awarded the Hawthorne Fellowship as outstanding doctoral student in Organizational Behavior, as well as the School's Division of Research Fellowship for her dissertation on organizational culture.

Now Professor of Healthcare Administration at Simmons College, Dr Sapienza's graduate teaching focuses on organizational strategy in the healthcare environment; her executive teaching focuses on leadership and organizational development. In her academic research, Dr Sapienza has studied the management of research and development and strategic planning in high-technology firms. In addition to articles, case studies, and book chapters, she has written *Managing Scientists: Leadership Strategies in Scientific Research* (Wiley, 2004, 2nd edn), *Forscher Managen* (VCH, 1997), and *Creating Technology Strategies* (Wiley, 1997) and is co-author of *Leading Biotechnology Alliances: Right from the Start* (Wiley, 2001) and *Successful Strategies in Pharmaceutical R&D* (VCH, 1996).

Dr Sapienza has an active consulting practice with high-technology organizations, particularly multinational pharmaceutical and biotechnology companies, working with scientists and executives on problems ranging from culture and organization development to competitive intelligence, strategy determination, and project management. Her public sector clients have included the US Veterans' Administration, Centre for Medicines Research (UK), Birmingham National Health Service (UK), and US National Aeronautics and Space Administration (NASA).

2.10.1 Swimming against the Current

Sir James Black is one of the founders of modern pharmacology.¹ While working at ICI (1958–64) and Smith, Kline & French (SK&F) (1964–72), he pioneered mechanism-driven research, in the process inventing two novel classes of drugs: adrenergic beta blockers, which are used to treat heart disease and hypertension; and histamine antagonists, which are used to treat stomach ulcers. His inventions of propranolol and cimetidine earned him a Nobel Prize (1988), so one might expect his research to be a case study in how industry correctly identified a bright individual with promising ideas and allowed him to pursue them successfully. In fact, Black's story is a case history of how an innovator fought against the current of scientific opinion, overcame pharmaceutical dogma, and battled corporate distrust to create two of the greatest successes of the century.

Like most innovators, Black was not trained in the field to which he contributed. He was a physician who turned to physiology because of his disgust with the nonscientific basis of most medical care. His research was directed not at drug development, but at solving basic scientific questions and his initial contacts with ICI were not for employment, but for basic research support. In a recent interview, he stated that:

I think you should understand that at no point have I ever professionally made claims about what I thought my work would achieve, for the simple reason I've never thought that it was going to achieve anything other than answer a question ... The challenge was to make a molecule which would have the properties of allowing you to answer a physiological question. Now, if the answer had come out a different way in each case, there would have been no drugs ...²

The fact that Black's beta blockers and histamine antagonists have medicinal value was thus serendipitous. Such basic research projects are not the sort that most pharmaceutical or biotech companies would even consider today and not ones that ICI and SK&F much liked at the time.

Black's second handicap was that he was neither a team player nor socially adept. One colleague described him as "a very vexing man ... He wants you to work in a particular way and he won't suffer fools."³ Another says that Black is very "disorderly."³ Black agrees, describing himself as congenitally and combatively skeptical, impatient, loud, and argumentative:

The only difference between me and some other colleagues would be temerity. I think I ask questions of chemists and physiologists which are really quite preposterous. And I don't seem to mind being thought stupid; I don't seem to care what people think about my questions. So I think in so far as what I've done has led to things, they have all involved turning something around the other way. I think my brain automatically does this. It always is challenging the accepted view of things. So if someone says to me, "The speed of light is constant", then I'll say, "Well, what would happen if it wasn't?"²

Needless to say, many colleagues at ICI and SK&F balked at his hectoring and a considerable number quit rather than continue working with him.³ Black notes laconically that his bosses “tolerated” him³ and, “fought many battles on my behalf to keep the initially controversial programme[s] going.”⁴

On the other hand, Black lived what he preaches. His invention of beta blockers began with the question of what causes angina. The standard dogma at the time maintained that angina resulted from the heart getting insufficient blood due to blocked coronary arteries. In consequence, the pharmaceutical industry was searching for ways to increase the amount of oxygen reaching the heart, which in practice meant increasing the heart rate using adrenalin (epinephrine) and its agonists. The problem with increasing the heart rate was that the heart itself then used more energy and needed even more oxygen, simply exacerbating the problem. Black, typically, turned the problem on its head. “Let us see if we can decrease how much blood the heart actually needs,”^{2,4} he proposed: block the adrenergic compounds that increase heart rate and blood pressure and see if that relieves the heart. The problem was, however, complicated by the fact that a chemical cousin of epinephrine (adrenalin in British terminology), norepinephrine (noradrenalin), was released by sympathetic nerves innervating the heart, and this raised blood pressure, increasing oxygen delivery to heart tissue, an outcome Black desired. Black therefore did not want to block norepinephrine’s actions, especially as previous studies had shown that blocking norepinephrine release exacerbated angina. Black, in short, needed to find a new class of compounds that would selectively block epinephrine activity (which was mediated by beta receptors) but not norepinephrine activity (which was mediated by alpha receptors).^{2,4}

Black, essentially ignorant of the art of chemical design and synthesis, but a quick learner and aided by the young medicinal chemist, John Stephensen,⁴ began the long process of finding a compound that would selectively block epinephrine’s beta receptors without interfering with norepinephrine’s alpha receptors. The eventual result was propranolol. But even with the compound in hand, the discovery process had only begun, because it was not until the clinical pharmacology was under way that Brian Pritchard of University College, London, discovered that beta blockers had antihypertensive effects in addition to relieving angina.⁴

With a major success in hand, one might have expected ICI to have rewarded Black with the freedom to investigate another fundamental physiological problem in hopes of an equally rewarding result. The opposite occurred. Black proposed to follow up his beta blocker success by addressing a similar problem regarding histamine production related to stomach ulcers.³ ICI administrators balked, believing that lightning never strikes twice in the same place. Black, holding in his head a novel approach to studying the entire field of monoamine receptor regulation, refused to be bridled, and moved to SK&F where former colleagues created a place for him. There the same science-centered, antidogmatic approach to exploring histamine regulation produced the same corporate doubts and difficulties with management and subordinates, but, within a few years, yielded cimetidine.²⁻⁴ Thus, in answering his second basic science question, Black created his second blockbuster drug and, in turn created his second unforeseen market. By that time, however, Black had found himself unable to work within the SK&F corporate structure, and had already left the company for academia. The man who had created two of the most profitable classes of drugs in pharmaceutical history could not work within the industry.²⁻⁴

2.10.2 Failing Innovation

If Black’s saga were unique, we could dismiss it as an aberration that could be ignored. Unfortunately, Black’s experiences in beginning with a basic research question, developing novel approaches to drug design, having to overcome scientific dogma, needing protection from managerial interference, and eventually leaving the industry, are all too typical, as I shall demonstrate below. These aspects of the pharmaceutical innovation process raise some hard questions for the industry. For example, how can research leading to blockbuster drugs and novel technologies be fostered if the process is often serendipitous and must employ difficult-to-manage, controversial individuals whose research may not even be focused on the development of drugs? Conversely, how can the independent, self-motivated scientists most likely to create real breakthroughs survive (or better, thrive) within cut-throat corporate environments in which acquiescence to corporate goals through teamwork and consensus are often required to obtain access to research resources? Make no mistake about it: the climate that grudgingly permitted Black the independence to perform his miracles is quickly disappearing to be replaced by top-down management practices too often driven by marketing executives who know nothing about research. Pharmaceutical innovation is the victim.

A dramatic decline in pharmaceutical innovation is undeniable. For the past two decades, the pharmaceutical and biotechnology industries have undergone a series of corporate mergers that have resulted in ever-larger multinational conglomerates.^{5,6} Two of the most commonly cited reasons for these mergers are to increase the efficiency of marketing and research divisions. Corporations with strong sales forces but weak product pipelines will often merge with those having strong sets of products but lacking the means to market them effectively. While such a strategy looks promising

at first blush, and may be so in the short term, it often results in centralizing and streamlining research, and enslaving it to market demands, with long-term adverse consequences.

It is an uncomfortable fact that, in the last 20 years, over half of the revenues accruing to the five largest pharmaceutical companies have come from drugs in-licensed from smaller companies, despite the fact that these five corporations invest as much in research as the rest of the industry combined.⁷ Even as the amount of money spent on R&D has increased exponentially within the industry as a whole, from around \$5 billion per year in 1980 to about \$35 billion in 2005, the numbers of new chemical entities, new drug applications, and FDA-approved drugs have declined continuously for more than a decade.^{5–8} The cost per new chemical entity launched has increased over the same time period from \$44 million per NCE to almost \$900 million.⁷ The vast majority of approved drugs begin their lives in the smaller, less affluent, but intellectually more vibrant, cauldrons of start-up companies and smaller firms.^{4–6} For many reasons, some of which will be discussed below, these small companies lose their innovativeness following mergers. Companies made ever larger by mergers require ever more blockbuster drugs to support their increased overhead, but fail to develop such drugs, requiring further rounds of mergers that become ever less effective at providing the necessary product pipeline. The innovators who support the industry find their intellectual freedom constrained by their new managers, undercutting their value to their new owners. As mergers continue, more and more innovators are leaving the large conglomerates, taking their ideas and techniques with them. Many of these entrepreneurs are successfully developing their drugs in new start-up companies that are able to salvage approaches the larger pharmaceutical firms have discarded or refused to support.⁹

In sum, the large pharmaceutical conglomerates are creating their own competitors through their failure to value innovation within their own corporations. The resulting situation is paradoxical: the largest companies with the greatest resources and the most flexibility take the fewest risks and reap the fewest discoveries, while the smallest companies, constrained by inadequate resources and lack of financial stability, take the greatest risks and harvest the most breakthroughs. As Theodore Shultz concluded in 1980 in a highly prescient analysis of industrial research innovation:

We have become enamoured of large research institutes and large programmes. [But] they are difficult to administer and they are subject to what is known in economics as diminishing returns to scale.¹⁰

The problem to be addressed in this chapter is how the pharmaceutical industry can best reverse this trend toward diminishing returns to scale by better fostering innovation.

2.10.3 Innovation: Problem Generation as the Route to Novel Solutions

On the pages that follow, I will be using a very specific definition of innovation. Innovation is the process by which novel, often unanticipated, modes of solving practical problems come into being. Innovation is not to be confused with discovering (which is the search for basic principles or understanding of nature), or inventing (the goal of which is a new technology), or engineering (which is the application of existing technologies to solve specific, well-defined problems). Innovation combines discovery, invention, and engineering and is arguably the most difficult of all to achieve. Thus, I consider Black's invention of beta blockers to be an innovation because it created a new paradigm for discovering and designing drugs that he, and other people, were able to apply fruitfully to other classes of problems. Propranolol itself is merely an invention – an exemplar of the innovation. This distinction is extremely important, because too much literature concerning pharmaceutical innovation pretends that every new drug, or every drug that treats a new class of diseases, is automatically an 'innovation' whether it involves novel methods of production, new theories of design or action, or is merely the application of well-understood and widely practiced techniques.

Intrinsic in the definition of innovation adopted here are two important points. One is that innovations, unlike inventions, cannot be planned. One of the major failings of pharmaceutical managers is to strive to produce a particular solution to a well-defined problem. The objective, all too often, is a product that will treat a specific indication and compete in a well-characterized market. Such top-down, end-driven research can only result in 'me-too' drugs and only rarely, usually as a result of failure or serendipity, in the kind of unexpected surprises that open up new fields. This leads to the second important point: the assumption behind most pharmaceutical research is that innovation consists of finding novel solutions to problems. In fact, the basis for all innovation is found in the choice and definition of the problem that is to be attacked.^{11,12} As Jack Kilby, one of the inventors of the integrated circuit, or 'chip,' has written:

The definition of the problem becomes a major part of the innovation. A lot of solutions fail because they're solving the wrong problem, and nobody realizes that until the patent is filed and they've built the thing.¹³

As a general rule, all innovations begin with the recognition of a novel problem or the recasting of a well-known problem into new terms. Innovators are therefore people who pose new sorts of problems, which in turn create possibilities that no one has previously imagined. There can be no innovation without such problem invention. The freedom to choose a solvable problem, and to define the problem in the way most likely to result in a solution, is therefore the most critical aspect of fostering innovation.

Examples of inventing new problems or recasting old ones are legion in the history of pharmaceutical innovation. While most cardiologists posed the problem of angina in terms of the heart needing more oxygen, Black recast it as how to let the heart get along with the oxygen that was available. By recasting the problem, he was led to develop a new class of drugs with actions that no one else was even considering.

Kary Mullis, the Nobel Prize winner who invented the polymerase chain reaction (PCR) concept, tackled the problem of artificially replicating a genetic sequence by first recasting an existing problem.¹⁴ The Cetus Corporation, for which Mullis worked at the time (about 1983–84), was trying to develop highly sensitive and accurate tests for the mutations in the beta-hemoglobin gene that are responsible for sickle-cell anemia. The standard approach was to create an artificial primer complementary to the open reading frame of the beta-globin gene and then to add DNA polymerase in the presence of adequate DNA bases to synthesize a complementary strand that could be analyzed for its sequence. Unfortunately, this approach was not sensitive enough. So Mullis's first step in recasting the problem was to wonder what would happen if he doubled the amount of information he acquired by making two primers. One primer would be against the mutated beta-globin gene and the other against its (untranslated) complementary strand. In the presence of the polymerase, short polynucleotides mimicking both the gene and its complementary strand would be synthesized and analyzed, each sequence providing confirmation of the information gained from the other: twice as much information, twice the sensitivity. Not long after this thought occurred to Mullis, he was

suddenly jolted by a realization: the strands of DNA in the target, and the extended oligonucleotides [synthesized from the primers], would have the same base sequences. In effect the mock reaction would have doubled the number of DNA targets in the sample!¹⁵

Primed by previous work he had performed as an avocation on recursive functions in computer programs (such as loops and fractals), Mullis immediately realized that what he could do once, he could do as many times as he liked to make a theoretically unlimited number of copies of any gene sequence:

Eureka! By then, I'd forgotten all about the problem of diagnosis. I realized that this is a process that I can use anywhere I want to amplify a little section of DNA ...¹⁵

After doing a literature search, aided by Cetus's librarian, Mullis discovered that no one had previously considered the possibility of gene amplification. It was a new problem posing new possibilities that created a new market.

The invention of an early form of combinatorial chemistry at Parke-Davis Pharmaceutical Research Division by Walter Moos's Bioorganic Group occurred in a similar way. The group was considering how best to invest several million dollars in peptide arrays to be synthesized by Chiron Corporation, a pioneer in peptide array synthesis. I had been hired as a consultant to the group and, not being a medicinal chemist, asked naively how the results of these arrays would be used. It was patiently explained to me that the peptide leads would be painstakingly converted into small molecules using a series of strategies well known to the industry. This process of finding a peptide lead and converting it seemed wasteful to me, so even more naively, I asked the group why they did not just make combinatorial arrays of non-peptide-organic compounds based on the same strategy by which peptide arrays are made, thereby saving themselves an expensive and time-consuming step. Once the question was posed, the group instantly realized that analogous combinatorial chemistry using small organic building-blocks could be done. It required only a few more weeks to produce a prototype set of compounds and a few months to produce a proof of concept. In retrospect, it is probable that every medicinal and organic chemist had the knowledge to have invented combinatorial chemistry, but none had asked the right question.¹⁶

Failures are another major source of fruitful problems. Leo Sternbach's invention of the benzodiazepine antianxiety drugs, such as Valium, resulted from his early experience as a dye chemist. While working as a young assistant in a chemistry laboratory at the University of Krakow, Sternbach spent several years trying to develop azo dyes, or their intermediates. During his researches, he came across the 4,5-benzo-[hept-1,2,6-oxadiazines], which he was able to produce in large, pure yields, but which turned out to be unsuitable as dyes. Sternbach did not publish his data and the class of compounds was almost entirely ignored by chemists for another generation. Then, some 20 years later,

Sternbach realized that these compounds had the right chemical properties to be biologically active, stable, and to permit novel chemical modifications that would provide a wide range of potential psychotherapeutic drug candidates.¹⁷

A combination of basic research and clinical failure also led to the identification of sildenafil citrate (Viagra), a phosphodiesterase-5 inhibitor that increases nitric oxide (NO) production, by Pfizer. The discovery of NO and its function as a smooth muscle relaxant came about, like Black's discoveries, from investigators asking basic science questions without regard for their potential applications. Robert Furchgott, Louis Ignarro and Ferid Murad, working independently, each became interested in the role that cyclic GMP plays in smooth muscle contraction and relaxation. Furchgott,¹⁸ originally trained as a physical chemist, provided the impetus to the research by discovering an endothelium dependent relaxation factor (EDRF) in aortic smooth muscle, which led to Murad and Ignarro's work. Murad,¹⁹ a physician with an additional degree in pharmacology, showed that compounds such as nitroglycerin released NO, which in turn activates cyclic GMP. Ignarro,²⁰ a pharmacologist, then demonstrated that NO itself relaxes vascular smooth muscle.

Notably, several major pharmaceutical companies had opportunities to support and capitalize on these men's work and did not. Ignarro's work was begun at Geigy Pharmaceuticals, where he reports having had unusual "freedom to pursue basic research on biochemical pharmacology" in addition to directed drug development research.²⁰ This freedom disappeared around 1972 after Geigy merged with Ciba and Ignarro left the company for academia shortly thereafter. Similarly, Murad's work on NO and its mechanisms of action, which began at Stanford University, was developed while he was a Vice President at Abbott Laboratories, where he became the company's senior scientist. Citing marketing pressures to develop drugs for which there was inadequate scientific basis, Murad left to become the founder, President and CEO of a new biotech company, Molecular Geriatrics Corporation and with him went his NO research.¹⁹ The discovery of Viagra thus had to occur by serendipity.

Around 1990, Pfizer scientists developing new classes of heart disease drugs discovered that chemical compounds of the pyrazolopyrimidinone class acted as phosphodiesterase-5 blockers, antagonizing cyclic GMP breakdown, and thereby maximizing NO effects. Sildenafil citrate was chosen from this class of compounds for clinical testing. Rather than exploring all the possible uses of the compound, a market-driven approach was adopted, resulting in its testing as an antihypertensive and angina medication in 1994. It failed. One unauthenticated story has it that patients refused to give back the pills they had been given when the clinical trial was terminated. The patients' odd response alerted the trial directors, Nicholas Terrett and Peter Ellis, that the drug must have some unexpected benefit and further inquiry revealed that men taking the drug had improved sexual performance. Another story has it that inquiries about side effects revealed enhanced erections. Pfizer researchers have steadfastly refused to comment on the actual discovery process.²¹ Whatever the case, the unexpected observation that sildenafil had aphrodisiac effects led Pfizer to reinvestigate the compound and apply for approval to test the drug to treat impotence, a novel indication for which it, and its competitors, have been very successful.

In short, one of the major obstacles to innovation is the belief that the role of the scientist is to solve existing problems posed by the marketing department, managers, or competitors using well-proven techniques. Quite the contrary, innovation can only occur when dogmas are questioned, questions are asked in new and different ways, and failures are used as clues to new problems that require new kinds of solutions.

2.10.4 Individual Strategies to Foster Innovation

While every innovation comes about in a unique way, the process is always similar and I have found that creative scientists share many research strategies that are foreign to the average scientist and unknown to most managers (Table 1). Black, for example, has said in his typically understated way that "I'm always just following something [puzzling], and always aiming for something which I ought to solve fairly quickly by asking simple questions."² This brief sentence contains three strategies shared by most innovators that are critical for developing breakthrough projects: (1) innovations are usually rooted in basic, rather than applied, research; (2) they involve problems that can be addressed quickly, easily, and cheaply; and (3) they concern simple, often antidogmatic, questions that can be clearly stated in testable ways.

More often than not, the questions that lead to major pharmaceutical innovations concern fundamental or basic science problems rather than applied or market-targeted problems. An analysis by Thompson shows that most blockbuster drugs developed in recent decades have originated in university laboratories funded by federally sponsored research programs such as the National Institutes of Health.²⁴ A more general review of biomedical innovations by Comroe and Dripps²⁵ has revealed similarly that over 60% of new therapies resulted from research that was not directed at creating a therapy or product. Examples of pharmaceutical innovations beginning with basic research questions are common, include Black's work on beta blockers and antihistamines as well as the discovery of NO, which eventually led

Table 1 Some strategies for innovating^{11,12,16,22,23}

-
1. Pay attention to anomalies, failures, and outliers.
 2. Turn every practice and theory on its head.
 3. Extrapolate, iterate, and recurse.
 4. Think simple.
 5. Court serendipity by running myriad controls.
 6. Court serendipity by trying to solve ‘impossible problems.’
 7. Analogize: what worked for one problem may work for another.
 8. Work on multiple problems simultaneously and look for intersections.
 9. Look back: recreate old discoveries with new techniques.
 10. Look back: apply old, simple techniques to new problems.
 11. Work on the problem that needs to be solved *after* your current problem.
 12. When nothing else works, try the unthinkable.
-

to the invention of Viagra, Cialis, and other impotence drugs. Francis Colpaert’s description of the path he and his colleagues took at Janssen Pharmaceutica to the creation of the antipsychotic risperidone also depended on the freedom to investigate basic science problems:

It occurred after a sinuous, unpredictable route to which previous drug discoveries (for example, those of haloperidol and fentanyl) gave impetus, through novel technologies (for example DD [the animal-based Drug Discrimination test invented at Janssen]) and through fundamental research (for example, in receptor theory and [the development of a novel theory of] opioid tolerance), which in some instances took decades for the scientific community to at least tolerate, if not endorse ... Other important factors in the development of risperidone were a resourceful medicinal chemistry group, and a climate of exceptional intellectual freedom and genuine concern with medical progress, in which boundaries between the theoretical and the applied, between the academic and the industrial, and between the hypothesis and the treatment were blurred ... It was fuelled by the desire to treat and understand, inspired by intense fundamental research.²⁶

Black’s second strategy is that the problem to be tackled be addressable quickly, cheaply, and simply. This criterion differentiates breakthrough research from developmental research. One of the best examples of such qualitative research comes from Albert Szent-Gyorgyi’s discovery of vitamin C. In order to screen many compounds for antioxidant activity very quickly, he developed a simple color reaction that took only minutes to perform. This test allowed him to narrow his research focus to a specific compound very rapidly.²⁷ As Nobel Laureate G. P. Thompson has argued,²⁸ the object of such breakthrough research is not to produce publication-quality quantitative data but to create quick-and-dirty qualitative techniques that can rapidly and extremely inexpensively test the potential of a wide range of possible research targets.

Black’s third strategy is that the problem should pose the possibility of turning a field upside down. Innovations (as opposed to inventions) rarely emerge from incremental modifications of existing technologies. New classes of drugs, whether they are the first antibiotics, the first beta blockers, the first impotence treatments, or novel technologies such as PCR, combinatorial chemistry, or genetically engineered proteins, result when people stop trying to improve current practice incrementally and look instead for a completely new way to address the problem. As C. Robin Ganellin, one of Black’s colleagues at SK&F (who also left for academia) has said, “The desire to play safe kills research.”²⁹

Thus, innovating often requires questioning daily practice. Students of medicinal chemistry are taught to use the latest techniques to address the most modern problems, yet many discoveries are made by adapting age-old techniques to new problems or by addressing old problems with new techniques. Szent-Gyorgyi wrote that one of his favorite techniques for making discoveries was to reproduce a 50- or 100-year-old discovery and to look at it with modern eyes.²⁷ It is therefore noteworthy that Edward Shorter has recently suggested that pharmacologists look back, rather than forward, in their search for new drugs:

The idea is not to recycle the golden oldies, but to determine the receptor profile of forgotten drugs of proven efficacy, and to determine what patentable compounds today might have a similar receptor profile. Since the introduction of modern psychopharmacology [for example] with the first chlorpromazine trials in 1952, thousands of compounds have been synthesized. Many of these have shown efficacy in open-label trials or anecdotally, only to be cast aside.³⁰

Similarly, old techniques can also be resurrected and combined with new problems. When I was consulting for Chiron Corporation around 1995, I realized that the drug discovery team had large libraries of compounds called ‘peptoids’ (*N*-alkylated glycine trimers) that they had combinatorially synthesized and tested for specific indications, but which now lay unused in storage. In my constant efforts to foster serendipitous discoveries, I approached various members of the team with the idea of screening these compound libraries for unintended and unexpected activities. In order to make such screening programs worthwhile, screens had to be (in accordance with Black’s criteria) extremely rapid, inexpensive, and simple, and they had to hold out the possibility of yielding very surprising, useful results. One outstanding problem fit the bill, and that was the inexorable emergence of antibiotic-resistant bacteria and the lack of new classes of antibiotics to treat them. Combining this major contemporary problem with one of the oldest drug discovery methods, I therefore suggested that all existing compound libraries be screened against antibiotic-resistant strains of bacteria using the same technique used by Alexander Fleming in the 1920s to discover penicillin: plate the bacteria on agar and then treat with mixtures from the compound libraries.²³ If the bacteria died, then one could assume that something in the mixture of chemicals was lethal to them. The mixtures could then be deconvoluted to single compounds that could be tested individually for their antimicrobial activity. The project was so simple that it was begun as an unfunded voluntary effort in the evenings and on weekends by virologist Jill Winter and several co-workers, including Mike Siani, a computer expert with minimal laboratory experience.³¹ Within a few months, a novel class of drugs with potent, broad-spectrum antibiotic properties, including rapid activity against antibiotic-resistant strains of *Staphylococcus aureus* and *Escherichia coli*, had been isolated. Within 6 months, the project had moved from an unfunded exploratory exercise to a formally recognized and funded focus of the preclinical research team. Chiron’s CHIR29498 became the first of what may prove to be a broad class of peptoid-based antibiotic compounds.^{32,33}

2.10.5 Innovators are Unusual, Inherently Difficult People

Innovators are, by their personal natures and in consequence of what they are attempting to achieve, difficult to manage.^{34,35} One cannot expect individuals who pose novel, often antidogmatic problems, and thereby attempt to change the daily practice and thinking of their colleagues and managers, to be comfortable team players. On the contrary, they are much more likely to be independent, demanding, overly confident, egotistical, self-motivated, difficult people. They are also likely to be trained outside of medicinal or organic chemistry, or even pharmacology, making them doubly suspect. Black, Furchgott, Mullis, Winter are all examples. Any company that wants to foster innovation has to be willing to work with such unusual people (Table 2).

Working with innovators is never easy. Sternbach, the inventor of Librium, Valium, and the other benzodiazapines, was so independent that he often caused conflicts at the Roche laboratories, Nutley, NJ:

In general, [he] was very critical of his superiors, especially those trained as chemists, and extremely demanding toward his subordinates. Critical, demanding, and implacable, occasionally unfair as well, Sternbach puts it in a nutshell: “Those who were above me were not my favorites.”¹⁷

Kary Mullis of PCR has been described in similar terms by colleagues at Cetus: “His irreverence, verging on belligerence, and his increasingly trenchant criticisms of current procedures produced clashes with [colleagues].”¹⁵ His boss later described Mullis as being “abrasive and combative and often times his comments would be counterproductive in meetings where people have to try and work together. Mullis had a grudge against his critics

Table 2 Some characteristics of innovators^{11,13,34–42}

-
1. Unusually and broadly trained.
 2. Outspoken, critical, and independent.
 3. Actively engaged in creative avocations.
 4. Physically active and energetic.
 5. Self-motivated.
 6. Able to work very intensively.
 7. Unwilling to work on ‘useless’ projects.
 8. High standards and expectations of selves and others.
 9. Competitive.
 10. Constantly exploring new fields and technologies.
-

and they had a grudge against him.”¹⁵ The grudges escalated to fist fights and at one point Mullis threatened a co-worker with a gun. Mullis even flouted the Human Relations regulations of the company by having serial affairs with co-workers at the laboratory. In retrospect, it is astounding that he was not fired.

The members of the Bioorganic Group who invented an early form of combinatorial chemistry at Parke-Davis were not as outrageous as Mullis, but several were generally considered to be difficult to work with when they were assigned to Walter Moos. Mike Pavia was known as a brash, outspoken chemist who would never have succeeded as a diplomat. Sheila Hobbs DeWitt was a fiercely independent chemist who, like Sternbach, expected the same superlative results from every colleague and subordinate that she expected from herself. John Kiely, the third senior chemist in the group, was skeptical almost to a fault and so critical that he frequently antagonized colleagues with his blunt assessments of their perceived failings. The extraordinary thing is that this group of ‘difficult’ individuals quickly formed a high-functioning team once they found a common problem to which they could all contribute their unique skills.¹⁶ Unfortunately, Parke-Davis was not ready for the innovation they produced, and every member of the Bioorganic Group left Parke-Davis within a couple of years of their innovation, as it became clear that the company had neither the intention nor the capability to implement combinatorial chemistry itself. In a classic case of a company creating its own competitors, each Bioorganic Group member became a successful senior executive at a different biotechnology corporation that valued their innovative spirit.

What it comes down to is that people who are capable of the best science know that they are capable of the best science. They have vision and they have the drive to make their visions reality. They are not, therefore, the type of people who take orders. They do not respect managers who lack the scientific credentials to make the decisions that need to be made daily in the laboratory. They disdain those who cannot see as they do how a small breakthrough signifies the potential of a much bigger one. They trust in their own ability to be pioneers, hacking their way into the uncharted waters of medicine with only their intuition, experience, and courage as guides. Black has summed up the problem for the pharmaceutical industry in these words:

People like me ... are ... bad news for industry because I was constantly rebelling. I was constantly challenging the assumptions they made. I challenged their practices. I was awful ... It wasn't that I set out to give them a hard time. It was simply that being there put me in an environment which wasn't conducive to what I wanted to do ... I was always sort of unhappy.²

Discontent is part of the innovator's life since the object of the innovator is to shake up existing modes of working and thinking. Innovators are themselves discontent because they see how things could be done better, faster, cheaper, more effectively. Innovators make everyone else discontent because innovation forces people out of their comfortable routines. Companies that truly want to foster innovation must be willing to put up with such problems. Any manager who thinks that it will be easy is fooling him- or herself.

2.10.6 Managerial Strategies to Foster Innovation

Despite the poor record that many pharmaceutical companies have in managing innovation, it is indisputable that some unusually enlightened corporate managers have played major roles in bringing every major pharmaceutical innovation from its inception in the mind of the pioneering inventor to its proof of concept and thence to its actual production. They tend to evaluate projects and people in unusual ways that ignore industry standards (Table 3).

One way to minimize problems is to isolate innovators as much as possible from the rest of the corporation. When ICI's managers refused to believe that James Black could follow up his invention of beta blockers with a similarly conceived approach to developing histamine blockers to treat stomach ulcers, Black began looking for other employment and quickly convinced a former colleague, Edward Paget, that what he had really developed was not a drug, but a novel approach to drug discovery. Paget, a manager at Smith, Kline & French Laboratories (based in Philadelphia) hired Black to be chief of pharmacology at the British Welwyn Research Institute and gave another open-minded colleague, William Duncan, oversight of Black's project. Black promised an antiulcer compound within 6 months and Paget let him loose to completely restructure Welwyn's research organization, carefully hiding from his bosses at SK&F in Philadelphia the revolutionary nature of Black's new approach to the problem. And then, despite Black's failure to provide such a compound within 6 months, or even six times that, Paget and Duncan continued to defend and protect Black's project, “isolat[ing] the scientists from the political and financial hardships of a company undergoing major reorganization and a new-product famine.”³ In the end, the problem was not the drug design program, which in retrospect had, in fact, yielded active drugs within the 6 months that Black had projected, but rather the pharmacological test that the company had adopted for testing the compounds. The standard test was incapable of

Table 3 Some criteria for evaluating innovative projects^{1,2,3,11,13,22,23,28}

-
1. Is the problem being addressed fundamental?
 2. Will a solution alter the way professionals think and act?
 3. Is the concept or experiment simple?
 4. Do clear-cut *qualitative* tests exist?
 5. Is it inexpensive to test?
 6. Can it be tested quickly and easily?
 7. Is it testable using existing equipment and personnel?
 8. Are there clear criteria for success or failure?
 9. Might it create a *new* market?
 10. Can it be used as a model for solving similar types of problems?
-

demonstrating antihistamine activity. When one of Black's employees secretly designed a new, more appropriate test, the efficacy of the compounds immediately became apparent, and SK&F, which was slowly going under, staked its hopes on the new class of drugs that resulted – and succeeded.³

Similarly, PCR would have been many years, if not decades, slower to be developed had not the management team at Cetus Corporation, especially Tom White, not coaxed, cajoled, guided, and perhaps even threatened Kerry Mullis into translating his idea into a proof of concept. Not only did White have to enlist reluctant colleagues to help Mullis test the concept despite severe questions as to its viability, but White also had to protect Mullis from administrators and colleagues who wanted him fired for his outrageous behavior. Everyone agrees it would have been much easier to ignore Mullis's hair-brained idea and simply fire him.¹⁵

What each of these managers did was what General Electric's most successful director of research (and Nobel Laureate) Irving Langmuir did: create the conditions under which innovations may flourish. And the most important condition is that of freedom for the investigator. As Langmuir wrote:

You can't plan discoveries. But you can plan work that will lead to discoveries. You can organize a laboratory so as to increase the probabilities that useful things will happen there. And, in so doing, keep the flexibility, keep the freedom ... We know from our own experience that in true freedom we can do things that could never be done through planning.⁴³

Langmuir's advice is echoed by fellow Nobel Laureate Baruch Blumberg, also a scientific director of several laboratories. Blumberg has written that

flexibility is essential and the scientists themselves have the responsibility of deciding the appropriate directions, within guidelines. The role of management is to supply funds and to not get in the way of the creativity of the scientists, while, when required, providing them with appropriate direction.⁴⁴

I would go further and argue that the manager's responsibility is to create conditions conducive to constant change by protecting innovators both from the complacency and routine practiced by the average scientist and from the all-too-often blinkered visions of upper management.⁴⁵ Innovations are like babies: they require time to mature before they are asked to compete in the adult world. Managers of innovation must be like parents, guiding innate tendencies in fruitful directions and finding the best opportunities for their offspring to succeed.

2.10.7 Corporate Strategies to Foster Innovations

Given the obstacles to innovation that inevitably exist within most large companies, it is worthwhile asking whether innovations must simply be licensed from biotech firms and universities where the freedom to explore is still possible. This is certainly one plausible model, and one that is being increasingly exploited. It is not, however, optimal. As Genallin has argued:

There is big pressure on universities now to go into areas that are determined politically by the funding councils and I think this is very bad for discovery. There is too much pressure to go into applied areas. One should allow people a lot more freedom to speculate and make their own discoveries. For that, you need to remove some of the pressure that is on people.²⁹

In addition, universities are increasingly spawning their own start-up companies that have every incentive to develop innovations as independently as possible in order to nurture their value.

Fortunately, other models exist. One was pioneered by Eli Lilly to produce the first genetically engineered drug (insulin). Lilly, one of the oldest manufacturers of insulin, realized early in the biotechnology revolution that insulin would eventually be produced by some company using recombinant DNA techniques. They wanted to be the first. Unfortunately, they quickly encountered a corporate culture that made it virtually impossible to hire the rare individuals who had appropriate recombinant DNA experience. (Sheila Hobbs DeWitt encountered similar problems in developing combinatorial chemistry at Diversomer Technologies, Inc., a failed Parke-Davis spin-off company, when the chemist-dominated Parke-Davis culture would not allow hiring of the robotics and computer experts necessary to the project.¹⁶) Lilly eventually partnered with Genentech, which supplied the needed biotechnology expertise.⁴⁶ Such partnering is much more likely to produce innovations than simple in-licensing, which can only occur after the innovation has been made, but still leaves the larger company without the in-house expertise needed to make additional innovations. In addition, the Lilly model can be applied only to products such as insulin that already have well-defined and lucrative markets. In this context, it is worth remembering that neither Lilly nor any other pharmaceutical company discovered insulin. That distinction went to a surgeon without academic credentials (Frederick Banting) working with a doctoral student in physiology (Charles Best) in a borrowed laboratory without funding or adequate equipment. Pioneers work in undeveloped wildernesses.

The trick, then, is to create an environment that mimics “outside the pale” inside the corporation (Table 4). A model for such an environment not only exists, but has been working with great efficiency and effectiveness in the aerospace (Lockheed), computer (IBM, Bell Labs) and manufacturing (3M) industries, and it goes by the now trademarked name ‘Skunk Works.’^{47–49} The purpose of a skunk works is to take proven innovators and give them a rich research environment completely protected from corporate planners with the simple expectation that they do whatever research they believe will most likely yield a fundamental, dogma-shifting innovation. Middle managers guide this process but do not determine the problems addressed, or how they are addressed. The key to making a skunk works work is to hire the right people, and this selection is not as difficult as it may at first appear. Studies have shown that there are three types of scientists who are identifiable by their very different patterns of research.^{11,39–41} There are those who have average or below average productivity (in terms of producing high-impact papers and patents) all of which remain in the field in which they were originally trained, and often focus on the topic of their dissertation research. These are competent, noncreative individuals. Among those who are very creative (again in terms of high-impact papers and patents), there are two groups. There are those who spend a few years exploring various possible areas of research and strike upon one that attracts their full and undivided attention for most of the rest of their careers. Such individuals will produce at most one major innovation during their lives because they know only one area of science. Examples are Jonas Salk and his polio vaccine or Kary Mullis and PCR. Such individuals are too focused and too narrow to make another important contribution in another area of science. The people who are most appropriate for a skunk works are those in the second group of highly innovative individuals. This group is characterized by performing research in multiple areas sometimes serially, but most often concomitantly, and by making at least one major breakthrough by the time they are in their early forties. Such individuals are very likely to continue to be innovative for the rest of their careers because they are constantly exploring new problems, acquiring new skills, and changing fields. People like Black and Sternbach are good models. Such people must be rewarded not by being promoted into managerial positions, but by being given increasing freedom and resources to do what they do best: innovate!

Table 4 Some guidelines for managing innovation

1. Provide freedom for investigators.
2. Keep innovation groups small.
3. Let the groups themselves define clear, fundamental, and compelling problems.
4. Let the groups direct their own research.
5. Don't hire people whose judgement you don't trust.
6. Choose independent, unusually trained, self-motivated individuals.
7. Generate multiple targets and approaches.
8. Use tight time and fiscal restraints to force groups to choose best targets.
9. Simultaneously provide long-term security for group.
10. Don't promote innovators! Reward them with more opportunities to innovate.

The key pitfall to avoid from a corporate level is the allure of efficiency. Efficiency is an oxymoron in the context of research. Consider a concrete example. More and more pharmaceutical houses are turning to massively robotized, high-throughput systems for creating and testing compounds. There is no evidence that this approach is working any better than having small numbers of chemists make individual compounds. The reason for this is quite simple. Machines can be designed to perform only those functions that have previously been codified in practice. Since innovations are, by their very nature, unanticipated and unpredictable surprises, and since the discovery process itself has not yet been codified, the use of machine codifiable procedures is a guarantee that nothing fundamentally new can be discovered. Robots are only good at optimizing approaches we already use, not for inventing new approaches, or new problems. If discovery technologies are a focus of a company's innovation strategy, then the focus must be on creating novel technologies, such as combinatorial chemistry, PCR, or recombinant DNA.⁵⁰

2.10.8 Conclusions

In sum, top-down, highly organized, efficient research organizations are the enemies of innovation. Innovative organizations focus on small, flexible, independent groups that generate and solve their own problems, bootstrapping their success stage by stage, beginning with simple, cheap, quick qualitative proofs-of-concept and building progressively toward demonstrations of effectiveness. The people who succeed in such groups cannot work in highly structured environments or for people less creative than themselves. They are intrinsically difficult to manage and impossible to direct. Exceptional managers can, however, create conditions that will bring out the best in such individualists by creating appropriate challenges and setting firm limits. In addition, innovators can employ many strategies to increase their chances of successfully navigating the innovation process. Among the most successful is identifying inexpensive, quickly addressable, simple problems that have the potential to overturn existing dogmas and practices. Turn problems on their head; redefine them; find rate-limiting steps; try lots of things in search of serendipitous, and surprising, results. Assume competitors will solve the problem first and ask what problems their solution will create that no one has even begun to think about. Create the conditions that foster innovation (freedom, independence, persistence). Plan for the unexpected. Be flexible. Innovation is not something that just happens. Innovation is a way of living and working.

Biography

Robert Root-Bernstein earned his AB in Biochemistry (1975) and PhD in the History of Science (1980) at Princeton University. As a Post-Doctoral Fellow in Theories in Biology at the Salk Institute for Biological Studies he was awarded one of the first MacArthur Fellowships (1981). This award enabled him to explore two areas that have remained central to his research: (1) the nature of scientific creativity; and (2) the roles of molecular complementarity in the evolution of physiological systems and as a guide to drug design. He has consulted for a number of pharmaceutical and biotechnology companies, including Parke-Davis, Chiron, and MitoKor. He is the author of several patents, over 100 peer-reviewed papers, 20 book chapters, and four books: *Discovering: Inventing and Solving Problems at the Frontiers of Science* (Harvard University Press, 1989), *Rethinking AIDS* (Free Press, 1993), and (with Michele Root-Bernstein) *Honey, Mud, Maggots and Other Medical Marvels* (Houghton Mifflin, 1997) and *Sparks of Genius* (Houghton Mifflin, 1999). He is currently a Professor of Physiology and member of the Lyman Briggs School at Michigan State University.

2.11.1 Introduction

Driven by the widespread availability of the personal computer and the subsequent internet revolution, the past two decades have seen spectacular advances in the sophistication of the technology platforms used to synthesize/identify and characterize new chemical entities (NCEs) as potential drugs.¹ As a result, more data has been generated regarding the physicochemical and biological properties of the many NCEs synthesized in the past 20 years than was ever known for the relatively smaller number of NCEs that had existed as discrete samples in the prior 80 years or so. The ability to interrogate this data² (assuming the existence of a database architecture at a facile, user-friendly level) to retrospectively understand NCE action(s) can provide critical information to prospectively design new NCEs against defined biological targets and thus represents a powerful tool in the drug discovery process. Such knowledge has not, however, apparently aided in the end game, namely that of the practical application of the advances in biomedical knowledge to the treatment of human diseases in the form of new drugs, the introduction of which has decreased over the past decade.³

Following publication of draft maps of the human genome in 2001,^{4,5} there were various predictions^{6–8} that new drugs, acting at hitherto unknown, disease-associated targets, having improved efficacy and fewer side effects, based on their origins in, and use of, genomic information (especially for clinical trial patient selection), were but a few years away from human use. Five years later, it appears unlikely that genome-based medicine will have a major impact on healthcare in the foreseeable future,^{9,10} a result of the dramatic oversimplification of the challenges involved in reducing one of the most complex data sets known to practice.¹¹ Similarly, proteomics, in itself an infinitely more complex science than that of genomics due to the multiple possibilities resident in the posttranslational protein modification process,¹² requires the dissection of primary tissue and cellular proteomes into numerous sub-proteomes.^{13–15} Nonetheless proteomics rapidly replaced genomics when it became apparent that the latter was a far greater challenge than had been anticipated and that it would be easier (for a time) to publish in a new area than productively work out issues with an existing one. The receptorome,¹⁶ the interactome¹⁷ and the epigenome¹⁸ are the more recent ‘omes’ predicted to change the practice of human healthcare. The interactome, derived from initial drafts of the human haplotype map (HapMap), is a collection of binary protein–protein interactions, even more complex than either the genome or the proteome. The epigenome involves environmental influences on gene expression and reflects the interface between nature and nurture.

Unfortunately with each new ‘ome,’ the initial anticipation for a wealth of new information has inevitably given way to skepticism, an unfortunate example of the Hype Cycle¹⁹ concept especially as initial genomic and proteomic data sets have repeatedly failed replication both within, and between, data sets and disease states.

In both genomics and proteomics, the critical challenge of target validation¹⁵ has been repeatedly trivialized to the level of an enthusiastic naivety,²⁰ lacking in apparent logic, appropriate insight, and necessary rigor. As an example, the 5HT₆ receptor has been known for well over a decade, being implicated as a potential target in CNS disorders that include schizophrenia and Alzheimer’s disease (AD). Several programs have been initiated in the industry to find 5HT₆-selective ligands and at least one antagonist, SG518, is being evaluated in the clinic for use in cognitive impairment. The 5HT₆ receptor is, however, a long way from being validated in terms of representing the site of action of a bona fide drug with discrete therapeutic opportunity. Activities directed toward target validation are thus more correctly characterized as *target confidence* building and are far more complex than had been – or even are – envisaged.^{15,21}

Several books^{22,23} and a variety of articles^{3,24–32} have highlighted the lack of productivity in drug discovery – the “unrelenting attrition statistics”³ – since 1996. While there are inevitably divergent viewpoints, all parties agree that productivity, as measured either in terms of Investigative New Drug Applications (INDs) or New Drug Applications (NDAs), is inconsistent with the investments being made in drug R&D and in the future viability of the pharmaceutical industry. Opinions differ as to the root causes of the productivity shortfall with additional opinions of what needs to be done to ‘save’ drug discovery, including the ever evolving role of the biotech industry in being the “main driver for new drugs” and “center[s] for drug innovation.”²⁶ Few of these ‘rescue’ recipes appear to have a current basis in reality.

The reasons cited for the productivity decrease include: (1) the intrusion of business mores into the science of drug discovery^{26,28}; (2) the excessive funding of marketing to the detriment of research; (3) more stringent regulatory hurdles for drug approval²⁹; (4) the intrinsic challenge of the disease states being currently addressed (stroke, AD, septic shock, cancers, etc.)^{24,25} that are focused on novel, often ‘unvalidated’ disease targets/hypotheses, these being consequently more difficult to test in the clinic with unproven/ill-defined clinical trial endpoints that confound efficacy outcomes; that all the low-hanging fruit in drug discovery have been picked²⁵; (5) that novel technologies/scientific concepts take considerable time to become productive²⁵; and (6) that the patenting of gene-related materials has had a negative impact on research progress.

New technologies and additional resources are thus failing to address the current shortfall in the drug discovery enterprise and Milne has predicted that in continuing on the ‘current’ path of drug discovery, the risk of continued failure is ‘arguably absolute’³ and has advocated “investment in quality thinking and experimentation...to improve the outcome” with “extra months spent at the front end [saving] time” reflecting a higher priority in strategizing the use of new technologies and new paradigms and how these will be used tactically in the context of a hypothesis-driven drug discovery effort.

2.11.2 The Drug Discovery Process

In his seminal monograph on drug discovery, Sneader³³ unsurprisingly equated effective drugs with the conquest of human disease, an activity that dates back to the traditions of Greek, Egyptian, Arabic, and ayurvedic medicine where: (1) products derived from natural sources evolved on a trial-and-error basis (those individuals using toxic drugs rarely

having the opportunity to complain) as safe and effective drugs for human use; and (2) the ‘astrologer-priest-physician’ prescribed the use of a medicine to be filled by a local apothecary with limited, if any, production standards. Issues with the latter led to the emergence of the pharmaceutical industry with its initial role being in a quality control capacity. The natural product pharmacopoeia still includes drugs like morphine and aspirin that remain widely used, albeit it in different formulations and delivery systems, highlighting one path to success in the drug discovery process that has largely fallen out of favor.^{34,35}

The two key disciplines that have driven successful drug discovery to date are medicinal chemistry³ and pharmacology.³⁰ Working closely together in an iterative manner with ancillary disciplines like physical and computational chemistry, high-throughput screening (HTS), and molecular biology to name but four of a potential 30 or more, medicinal chemistry and pharmacology have used the conceptual ‘lock and key’ hypothesis, now over a century old, as the framework in which to identify new drugs (Figure 1a). It has been noted that the chemistry contribution to successful outcomes in drug discovery is greater than 85%,³ if not absolute²¹ almost exclusively in the identification of drug-like molecules. However, experience and insight into the biological evaluation of these NCEs can be considered of equal value.

2.11.2.1 Phases of Drug Discovery

The human use of natural product-based drugs for therapeutic purposes dates back to two centuries BC. While the first pharmaceutical company, Takeda, was founded in Japan in the early seventeenth century, the foundations of modern day drug discovery in Germany were based on the systematic physiological studies of Betrand, Kekulé’s dream of the structure of benzene, and market-driven changes in the German dye industry in the mid-to-late nineteenth century.

Drug discovery can be loosely divided into four phases: the empirical/physiological phase, the biochemical phase, the biotechnology phase, and the genomic phase.

2.11.2.1.1 The empirical/physiological phase (1885–1948)

This involved the identification of NCEs from natural product sources with a long history of human use, or derived from the products of the aniline chemical industry, which were evaluated for their antimicrobial activity,³⁵ and in bioassays or in animals to assess phenotypic changes and other outcomes thought to be reflective of the targeted disease state.³⁶ During this period, the ‘lock and key’ theory of drug action, the ‘magic bullet,’ was conceptualized as the basis of pharmacology.³⁷ Following from this “the first task of the young science of pharmacology was to purge the pharmacopoeia by casting out useless drugs,” the latter being loosely defined (those without a mechanism of action³⁸).

2.11.2.1.2 The biochemical phase (1948–1987)

This originated in the seminal work of Alquist (1948) on adrenoceptor classification with the previous empirical, bioassay-based research approach being complimented by more precise in vitro biochemical approaches at the cellular and tissue levels to study both the mechanism of action of new chemical entities (NCEs) thought to have therapeutic potential and the molecular causes of disease. This approach, now reincarnated as ‘chemical genomics’ or ‘chemigenomics’³⁹ used NCEs to characterize/perturb drug targets (receptors, enzymes, etc.) and their subtypes and were used in turn to characterize NCEs in vitro for their target efficacy and selectivity to prioritize their advancement into more complex in vivo disease models. An important facet of the biochemical era was that it was used in conjunction with, and as an extension of, the empirical approach rather than replacing the former in a wholesale and exclusionary manner.

2.11.2.1.3 The biotechnology phase (1987–2001)

This emerged from the biotechnology revolution of the 1980s and encompassed four major themes: (1) the use of molecular biology to create a novel scientific approach termed *synthetic biology*⁴⁰ that focused on examining drug targets/disease processes using target cloning, recombinant protein expression, and target mutations to create cell lines and animals⁴¹; (2) the application of high-throughput, industrial-scale technology-driven approaches to NCE characterization (HTS)⁴²; (3) *computational-based/bioinformatics* approaches critical to the storage, access, and real-time interrogation of NCE-based data sets that numbered in the many millions²; and (4) a redefinition of the culture of biomedical research, which is discussed in detail below. In addition to its somewhat reductionistic approach^{32,43} the biotechnology era also became both exclusionary and revisionary in that the hype attendant on its introduction and revolutionary premise necessitated the dismissal of previous approaches to drug discovery as archaic and irrational. A direct result of this was a de-emphasis of the role of pharmacology and a movement away from classical animal disease models,^{30,36} the latter being replaced with elegant transgenic mouse models,⁴¹ flies and zebrafish, and sophisticated in vitro systems.⁴³

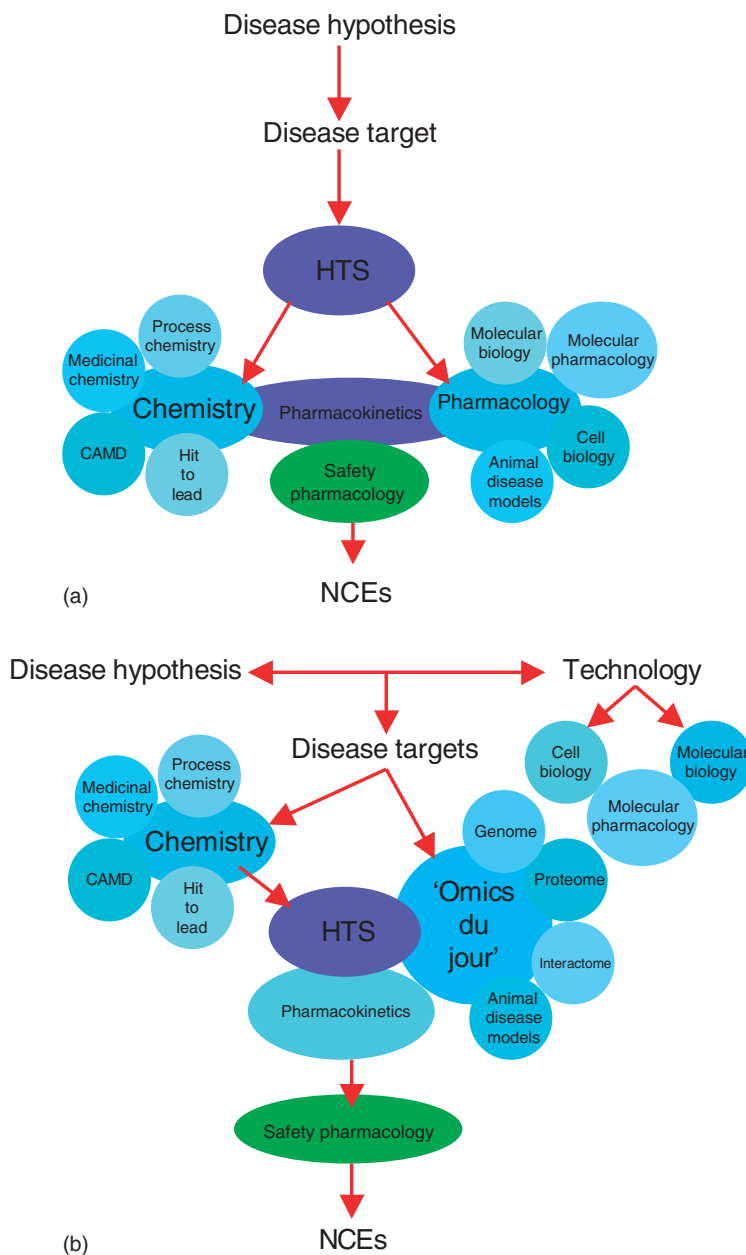

Figure 1 Cartoon representation of key elements of chemo-/pharmaco-centric approach as compared to the technology-driven approach. (a) Key elements of the hypothesis-driven approach. A hypothesis is formulated based on current knowledge from both preclinical and clinical studies and targets identified. An integrated chemo-/pharmaco-centric plan is put in place to find compounds and biological assay systems to gain proof of concept. Once this has been determined, an integrated, iterative, hierarchical flow chart is put in place to identify, test, and optimize NCEs for efficacy, side effect liability, and drug-like properties. (b) Key elements of the technology-driven approach to drug discovery. Disease hypotheses and targets can be linked with technology platforms around a rubric like that of systems biology to iteratively evaluate the three in order to identify NCEs that can then be optimized by a traditional chemistry driven campaign. The approach is heavily influenced by evolving trends on ‘omics’ technologies, represented here by the ‘Omics du jour’ kaleidoscope, an ever-changing technology resource. Astute readers will note that the more complex the ‘ome,’ the further away it is from NCE generation. The path to clinical NCEs is less integrated than that for the hypothesis-driven approach, and for those involved in technology evaluation it will come as no surprise that IND-enabling activities required by the FDA are sometimes planned to occur late in Phase II.

2.11.2.1.4 The genomic phase (2001–present)

This phase has been conceptually driven by the mapping of the human genome in 2001^{4,5} and an expectation, thus far generally unrealized, that disease-associated genomic targets, their proteomic progeny, and related interactomic ‘pathways’ would provide the means to more rapidly and accurately identify new generations of drugs that would be highly specific in their disease-related, beneficial effects and hence more efficacious and freer of side effects than existing drugs.

2.11.3 Facets of Drug Discovery

In two thought-provoking articles on biomedical research,^{24,25} the late David Horrobin questioned the rationale of the present approach to drug discovery, not only in terms of core technologies, but also the basic culture as well as some obvious disconnects that had entered the realm of cognitive dissidence. Initially, critiquing the failure of technologies like HTS and combinatorial chemistry to deliver compounds, and the faulty premise that pharmacogenomics would reduce the risk and cost in clinical trials,²⁴ Horrobin also questioned whether modern-day drug discovery had any basis in reality²⁵ noting that both the pharmaceutical industry and biomedical research in general were ‘failing’ in their attempts to find solutions to human disease states. In assessing the possibilities for this failure, he considered: (1) a lack of investment by the pharmaceutical industry; (2) that all the easy problems (e.g., the proverbial ‘low-hanging fruit’) had been solved with only the difficult ones remaining; and (3) that the new technologies needed additional time and investment to bear fruit. Horrobin concluded that none of these were causal, rather biomedical and pharmaceutical science had “taken a wrong turn in their relationship to human disease,” equating modern-day biomedical research with the world of Castila in Hesse’s *The Glass Bead Game*. In this novel, popular in the 1970s, the brightest and best scholars once highly educated were recruited to a “magical state within a state, the isolated world of Castila” where they played the “Glass Bead Game,” an intellectual game that Horrobin described as “beautifully refined and internally self-consistent,” but designed to “make...no real contribution to real world issues.” To Horrobin, current biomedical research, using “heavily funded and heavily hyped techniques,” e.g., cell culture and ‘unvalidated’ animal models, represented the biomedical equivalent of the “Glass Bead Game” and resulted from a reductionistic approach to biomedical research. Elements of Horrobin’s views have been echoed to varying degrees in a slew of recent papers,^{1,3,21,26,28,30,44} especially those focusing on the newly perceived value of systems biology in ‘salvaging’ drug discovery.^{32,43}

While it is a relatively facile process to address the challenges of productivity in drug discovery in terms of the metrics, e.g., numbers of compounds, screens and scientists, and address these by adding more of each, it is far more difficult to focus on issues related to organizational and individual culture, competence, and drug discovery experience. Such concerns have been raised by Black⁴⁵ who in focusing on the evolving culture of drug discovery, noted a lack of focused commitment in the present research environment, of a trend of giving up on difficult problems “when the breaks are not coming,” and transferring energies from unsolved problems to new ones – the peripatetic, and unproductive, path of least resistance. Interestingly, a recent survey of drug discovery scientists⁹ who while acknowledging that drug discovery was an experimental science, noted that “in many cases, people did not want to perform the experiments.” This was an interesting viewpoint, given that Wong *et al.*,⁴⁶ in their case history of the discovery and development of the SSRI fluoxetine, had noted that “it is essential that ideas are steadfastly championed by passionate believers to achieve the final goal.”

Not unexpectedly, nearly all aspects of the drug R&D process have changed markedly over the past decade and a half, driven to a very major extent by the biotech revolution, and the consequent mingling of science with business. Four key themes deserve special comment: (1) societal expectations for the pharmaceutical industry; (2) drug discovery strategies, culture, and organizational effectiveness; (3) scientific expertise, experience, and expectations; and (4) disease complexity and novel targets.

2.11.3.1 Societal Expectations for the Pharmaceutical Industry

The pharmaceutical industry and its biotechnology sister are ‘for profit,’ technology-based, innovation-driven enterprises whose products are life saving/enhancing drugs. Society looks to the pharmaceutical industry for these drugs to treat life-threatening conditions, e.g., infections, AIDS, cancer, depression, heart disease, etc., and to improve the quality of life, e.g., better analgesics, birth control pills, drugs to help prevent obesity and erectile and bladder dysfunction, etc. These expectations should also be consistent with those of the industry’s shareholders to provide an adequate return on investment in order to provide a sustainable path forward in terms of corporate productivity and viability given the 10–15 years it takes for a drug to reach the marketplace.

The pharmaceutical industry is thus celebrated in terms of its contribution to the gross national product (especially in the US) and for its historical ability to effectively apply the findings of basic biomedical research to discover useful drugs. At the same time the industry is vilified for the cost of its products and for its marketing strategies,^{22,23,28} which have been described as “undermining the cause of public health,”⁴⁷ a viewpoint not helped by the slew of lawsuits against Merck over the cardiovascular liabilities of the cyclooxygenase-2 (COX-2) inhibitor Vioxx⁴⁸ that have made the industry second only to the tobacco industry in the level of public distrust and legal opportunism. The repercussions of these lawsuits are profound and will have a long-lasting impact on how the industry conducts clinical trials, how the latter are reviewed by regulatory authorities, how these outcomes are published in key, peer reviewed medical journals (e.g., *JAMA*, *Lancet*), and how the industry then markets approved drugs.^{28,48}

2.11.3.1.1 Drug costs

The well-known cost of discovering a marketable drug (\$800 million), the NCE attrition rate in preclinical and clinical phases (80–90%), global regulatory hurdles, the time to approval and government as a third party payer⁴⁹ make the pharmaceutical industry unique as compared to other technology-based industries, e.g., telecommunications, computer software, and the oil industry (to which the pharmaceutical industry is frequently compared in terms of the analogy of drilling dry wells).

The global pharmaceutical industry has traditionally invested heavily in research and development for new generations of drugs and has depended on both innovation and serendipity for success. There is however considerable skepticism as to the true cost of drugs, a consumer commodity that unlike clothing, books, music, alcohol etc., the patient has little objective choice in using and often does not personally select, the latter being the purview of the prescribing physician. A public survey by Kaiser in the US equated rising health care costs with the high profits made by drug companies.¹¹² Drug costs in the US, and the perception that these are driven to a major degree by marketing budgets,^{22,23} have resulted in both states and individuals importing discount prescription drugs from Canada and Europe (some of dubious origin and quality), where prices are 40% lower.⁵⁰ This situation has been described as an economic ‘free-rider’⁵¹ where the major cost of drug development is underwritten by the US consumer¹¹² and where, if there were no US market, “no one would have to pay for drug development...[a situation involving]...economic illiterates.... who believe in magic”.⁵¹ This view has been disputed by a study where pharmaceutical R&D spending was compared to the Gross National Product (GNP) in countries where pharmaceutical research was conducted.⁵⁰ Switzerland spent 0.55% of its GNP on pharmaceutical R&D, the UK, 0.32%, and the US, 0.24%. The authors then argued that in Canada, where 0.08% of the GNP was spent on pharmaceutical R&D, income from domestic sales was 10 times greater than R&D costs. Given that pharmaceutical R&D effort in Canada is, at best, modest and is technically conducted by subsidized subsidiaries of foreign (US and UK) owned companies, this argument appears naïve if not untenable. If drug prices in the US were the same as those in Europe, Canada, and Japan where federal agencies rather than the marketplace set drug prices, it is highly questionable whether European, Canadian, and Japanese pharmaceutical companies could afford R&D without the US market to recoup costs. The analogy is similar to that of Boeing and Airbus who would certainly not build planes without customers outside their immediate domestic markets. Indeed the majority of customers for the Airbus 380, the world’s largest commercial aircraft are from the Middle and Far East. There is also a major trend by European pharmaceutical companies to move their research HQs to the US to more effectively compete such that the industry, while worldwide, is becoming increasingly ‘US-centric’.

It then becomes debatable whether the global pharmaceutical industry would exist in its present form and whether the public could have reason to expect new medications for diseases like cancer and AD where there is considerable unmet medical need. Furthermore, the proposition that reducing drug prices will either decrease healthcare costs⁴⁹ or aid in increasing the flow of innovative new drugs is in direct contrast to data showing that a dollar spent on newer drugs reduces nondrug expenditures, especially those involving hospital costs, sevenfold, e.g., \$7.⁵² Even though drugs represent less than 15% of the annual individual cost of healthcare, this 15% is typically a direct payment from the consumer and is thus the most apparent. Effectively taxing the pharmaceutical industry as a means to address the monumental economic challenges of providing healthcare to an ever-increasing number of patients that, due to the drugs produced by the industry, is living longer, is a solution that defies logic especially in the face of societal norms where paying \$25 for a book or compact disk, the cost of which to produce is in the 25¢ range, is deemed a fitting recognition of intellectual property rights, albeit for products that are used at the exclusive choice of the consumer.

2.11.3.1.2 Consumer advocacy groups

Consumer advocacy groups have also, to some extent, changed the way in which drug companies allocate their resources. The most visible of these was the AIDS group ACT-UP who were instrumental not only in advocating with

drug companies to accelerate the development of first-generation AIDS medications, but also in helping educate patients regarding their effective use. The wisdom of special interest groups in becoming involved in the science underpinning healthcare issues is, however, of questionable benefit.⁵³

There have been major political inroads into the funding of stem cell research, notably by the States of California and New Jersey, the UK and South Korea, as a means to find improved treatments for neurodegenerative and degenerative disorders, edging toward the search for longevity that was the topic of Huxley's *After Many a Summer Dies the Swan*. These initiatives, however, have ignored previously documented 'side effects' of fetal cell transplants where aberrant sprouting of transplanted dopaminergic neurons led to Parkinsonian patients developing uncontrollable and irreversible spontaneous movements that proved to be worse than the actual disease.⁵⁴ Considerable caution is therefore required in conveying perceptions of the immediacy of the application of cell replacement therapies given the woefully limited knowledge of the control of cell differentiation, regeneration, and functional recovery.⁵⁵ The expectation that stem cell therapies, like the genome, represent the wave of the future for medicine and that religious, rather than scientific, concerns have impeded the widespread acceptance of stem cell technology has led to a less than rigorous scientific assessment of progress, that has been equated with the Piltdown Man Hoax of 1912. This confusion of scientific logic with religious opinion and politics has led to the recent fraud in human embryonic stem cell cloning in South Korea perpetrated by Hwang Woo Suk.⁵⁶ The circumstances surrounding this case reflect how science can be subverted by politics. The chairperson of the US President's Council on Bioethics, Leon Kass, had noted⁵³ that "... American scientists and the American media have been complicit in the fraud, because of their zeal in politics of stem-cell and cloning research and their hostility to the Bush funding policy. Concerted efforts have been... to hype therapeutic cloning, including irresponsible promises of cures around the corner... The need to support these wild claims and the desire to embarrass cloning opponents led to the accelerated publication of Dr Hwang's findings... We even made him exhibit A for the false claim that our moral scruples are causing American science to fall behind".

In trying "to pursue profits too earnestly.[in]... pharmaceutical research... [that].... defeat[s] its own objectives"⁵⁷ the industry is perceived as losing focus on its strengths and the inherent value of innovative R&D, a view that falls in line with the various outside perceptions.^{22,23,48}

2.11.3.1.3 Governmental initiatives in drug discovery

In light of the shortfall of new drugs from the established industry, the US government has also begun to focus on initiatives in drug discovery. These are the US National Institutes of Health's (NIH) 'NIH Roadmap Initiatives'⁵⁸ that identified three major strategic themes in current biomedical research that required prioritization (which, by the way, will in many cases simply duplicate resources that first existed in big pharma, were later duplicated and advanced by biotech, and now will go through another generation of duplication and advancement in academia – is this an effective use of tax dollars?): (1) New Pathways to Discovery; (2) Research Teams of the Future; and (3) Re-engineering the Clinical Research Enterprise, in essence, moving the NIH into front stage of the drug discovery process.⁵⁹ Additional facets of the NIH Roadmap were efforts in diversity-oriented synthesis (DOS) supported by NIH-funded centers for Chemical Methodologies and Library Development (CMLDs)²¹ and efforts to seed translational medicine initiatives²⁸ via Clinical and Translational Science Awards (CTSAs) at academic medical centers.¹¹² This had been reinforced by the FDA's 'Critical Path Initiative' (CPI), a white paper⁶⁰ that identified the need to "strengthen... and rebuild... the disciplines of physiology, pharmacology and clinical pharmacology." An on-line update on the CPI in March 2006¹¹² identified new biomarkers, the streamlining of clinical trials, increasing bioinformatics and improving manufacturing processes as key to improve productivity in drug discovery. It has been further suggested²¹ that the NIH also establish an institute of clinical practice to conduct clinical trials where existing medicines are compared (both to one another and NCEs), to generate best-practice guidelines for physicians to prescribe drugs, and to look for new uses for old drugs, the latter being a strategy that is already gaining currency.¹⁶ The funding for this new institute was suggested as a puzzling 1% surtax on what the author already had concluded were drugs that were too expensive.²² Given concerns related to the NIH's ability to productively focus on the women's health care issues over a 15-year time period¹¹³ and the questionable returns on investment in the NCI's landmark search for new cancer drugs, it is questionable whether the NIH Roadmap Initiatives will have much impact on the drug discovery process. What is certain, however, is that funding for the basic research that has been the hallmark of NIH's success will be reduced and the number of acronyms will increase.

2.11.3.2 Drug Discovery Strategies, Culture, and Organizational Effectiveness

There are many approaches, real and perceived, to success in the drug discovery process: those that have succeeded based on historical perspective; those that have conceptual promise but are unproven and; those that result from

frequent reorganizations to address failure.²⁶ Key elements vary from the concept of the ‘drug hunter,’ individuals like Paul Janssen, James Black, Pat Humphrey, George Hitchings, Trudy Elion, etc., who effectively led research teams to success based on their passion, insights, and dedication, to organizations that with the help of management consultants continually re-engineer the ‘process’ to be more effective, the latter a corporate metrics-based approach that leads to a paralysis in decision making.

Historically, drug discovery has been populated with individuals with an overwhelming passion for their research, scientists who would change jobs rather than give up on an idea for a drug they thought was worthwhile, totally consistent with “ideas [being] steadfastly championed by passionate believers to achieve the final goal.”⁴⁶ In effectively executing a drug discovery paradigm it is important to recognize it as a distinct scientific discipline with goal-oriented challenges, day-to-day activities that can be extremely tedious and repetitive that require both matrix and hierarchical, time-based, goal-oriented and integrated management,^{61–63} together with individuals with the experience to make a difference in execution and outcome. This is a marked difference from how research is conducted in government and academia.

2.11.3.3 Scientific Expertise, Competence, and Career Expectations

In conducting R&D, it is assumed that a drug discovery organization has reached some level of strategic and tactical vision in its R&D operations that is hopefully underpinned by an objective, data-driven decision-making process, an integrated in-licensing function, and adequate resources. There is also an implicit assumption, recently evolved, that the full-time employees (FTEs), whether chemists or biologists, excluding the context of overt discipline specialization (chemist versus biologist), are reliably interchangeable elements with basic training, competencies, experience, and team-oriented motivation in common. In identifying a need for “rigorous data standards and quality” to improve productivity, Milne³ has obliquely raised the issue that perhaps this latter assumption is incorrect. In the biological realm, the recent trend toward an overtly reductionistic approach has resulted in a change in the way that experiments are planned, conducted (if at all),⁹ interpreted, and used as a basis for additional research initiatives. The overt focus on technology platforms leads to a perceived loss of individuality, scientific commitment, and changes cultural and ethical standards.²⁶ The current ephemeral approach to science and the lack of adherence to the Law of Mass Action have been extensively discussed.³⁰ These reflect a failure to replicate experiments, the arbitrary choice of NCE and drug concentrations used to perturb biological systems, the absence of dose/concentration response curves, the lack of characterization of NCE effects using the corresponding agonist or antagonist, and the lack of a null hypothesis approach (the use of negative controls), all of which were second nature to biologists trained in the 1970s. These are causes for concern, as is the increasing trend to ignore or even accept as ‘noise,’ failed experiments that in themselves can often have a tale to tell. In today’s research environment, Sir Alexander Fleming’s penicillin spores would probably have been consigned to the trash.

2.11.3.3.1 Data focus

In considering causes for this situation, biomedical science in the last 15 years has focused on reductionism (a powerful tool in an appropriate context), megaprojects (genomics, etc.), intense efforts to commercialize early stage science (often before its time), and data generation. In the pharmaceutical industry, scientists have been increasingly rewarded for producing data, and less for scholarship in terms of publications, peer reviewing activities, introspection, and investment in quality thinking,³ the focus being on quantity rather than quality. The incredible flow of biological data (with the *Journal of Biological Chemistry* publishing over 30 000 pages a year) and the focus on producing ever more data has decreased the time and ability to think. Firestein and Pisetsky, in developing guidelines for the publication of microarray experiments, noted that microarray-based experimentation has made “hypotheses... superfluous to the pursuit of research and that specific questions need no longer be asked” leading to “the illusion that all... information can be downloaded”⁶⁴ They recommended that microarray approaches be: replicated (!); subjected to statistical analysis(!); adequately controlled; and confirmed via nonarray techniques, all standards routinely used in classical pharmacology. This does not, however, devalue the premise of hypothesis-seeking as contrasted to hypothesis-testing experiments⁶⁵ provided the former are viewed as leading to the latter.

An additional facet of the current scientific training process is that scientists are trained less and less to think (or act) in an independent manner with a trend toward seeking external approval (condonment) of their activities, abnegating their personal responsibility for standards that should be second nature as the result of their training. If an ‘n’ value of 1 on a bioassay or making 1 mg of an NCE for biological testing is approved/accepted by an outside entity – supervisor, organization, grant review committee, etc. (the devil being in the details and the outcome, the path of least resistance) – then common sense and intrinsic values go by the wayside. With such externalization of scientific

approval, it is no surprise that the “brain turns off”¹ and researchers “behave like lemmings in the fog, running behind every new concept or method whether it is validated or not ... [relying] ... on artificial in vitro systems hoping that the information from bits and pieces holds true for the whole system”¹. The passion for research diminishes and innovation and common sense become scarce commodities. Extrinsic (salary, stock options, travel budgets) then replaces intrinsic (scientific inquisitiveness, passion) motivation leading to confusion in goals and rewards. Certainly, many biotechs have valued revenue above bona fide scientific progress.

Data using a single, millimolar concentration of a known drug interacting at a novel target has been used as evidence that the existing targets where these drugs were known to act at nanomolar concentrations were incorrect and that the newly cloned receptors were the ‘real’ targets for their efficacious actions. The “triumphant pervasiveness” of molecular biology⁶⁶ that emerged in 1992 has led to a qualitative, rather than quantitative, science, the latter based on the use of the Law of Mass Action to generate IC_{50} , EC_{50} , and pA_2 values.

More recently, and again in the context of external scientific approval, scientists in industry are willing to change their therapeutic areas of choice and their scientific disciplines in exchange for job security resulting in “a greater [scientific] uniformity.”²⁶ With complacency replacing the passion of discovery, it becomes just a job and it is then all too easy to give up on a topic when problems emerge.⁴⁵ Similarly, in academia, federal funding is dictated largely by what is perceived to be in scientific vogue. While the federal government via the US Food and Drug Administration (FDA) laments the limited availability of pharmacologists⁶⁰ and the NIH is now re-investing in their training,⁶⁷ the lack of seasoned pharmacologists, especially in the in vivo area, is a direct consequence of funding decisions made by the NIH in the 1980s and 1990s.^{30,68}

2.11.3.3.2 The PowerPoint generation and its consequences

There has also been a considerable focus on simplifying science for investors and management staff lacking a scientific background. Microsoft’s PowerPoint has now become the norm for scientific discussions even in the absence of a presentation, heavy on conclusions but light on data and controversy. This has further encouraged superficial thinking, for if the data is too complicated to be reduced to the context of a PowerPoint slide, then surely it lacks the import to warrant discussion.

The ability to simplify science was at one time viewed as a gift, with the communicator, in full knowledge of the limitations of the data, being able to communicate with an audience in a direct and engaging manner. This contrasted with the gifted scientific ‘nerd,’ popular in books and movies, who was so engrossed with minutiae that the audience could not comprehend what he or she was talking about. The value placed on facile communication soon progressed from the eloquence and insight of a George Poste to the scientific superficiality and self-serving obfuscation of a Sam Waksal.⁶⁹ While useful in communicating with investors, the currency of facile communication has de-emphasized the focus on bona fide scientific issues and created a new level of scientific management – that of the *scientific poseur* or spokesperson – good on memorable, if nonsensical, sound bites, short on science, and thus eminently qualified to communicate the complexities of science to nonscientists and to lead science in a technology-oriented environment where context and complexity remain unappreciated. Those that had continued to worry over scientific issues soon became naysayers with divergent opinions that were considered to be overtly conservative (nihilistic) with such individuals being avoided, and their input discounted. And scientific standards inevitably suffered. One apocryphal story is that of the biotech CEO or CSO, relentlessly pressured by investors to advance an NCE to Phase I trials despite limited scientific merit. Despite protests that the NCE is not ready, the CEO/CSO is told that if the NCE is not advanced, job security will be an issue and that the CEO/CSO is being too cautious. Acquiescing to the investors, the CEO/CSO advances the NCE to the clinic where it fails, being written up in *BioWorld*; the CEO/CSO is then accused by the same investors who have seen the value of their investment plummet, of not being firm enough in upholding his/her scientific standards. The CEO/CSO in this ‘damned if you do, damned if you don’t’ scenario is then fired.

Additional stereotypes have emerged or multiplied over the past decade and include the *technocrat*, certainly not a new phenomenon, but one that has become more pervasive and populated given the amount of funding available for technology acquisition. The technocrat has always been less interested in solving problems than in finding new ways to ask questions (often the same one), incrementally building on technology platforms that had yet to be proven either useful or productive. An example of this is the multiplication of formats for HTS with ever more NCEs being assayed in shorter time periods. The shift from the 48 assay tubes in racks used in the 1970s to the 96-well microtiter plates represented a major advance in resource utilization. Today 384-well microtiter plates are deemed as becoming inadequate with 1536 approaching the norm and with rare (and unreplicated) experiments focusing on ‘well’ -type formats in excess of 8000. As a result, the endpoint in screening, the ability to evaluate a total chemical library, can be done in far less time such that new bottlenecks have been created with an overwhelming amount of data to archive and sift through.

The continuing investments in technology and the need to provide evidence to investors and upper management that these were being used in an exciting and productive manner, the focus more on the former than the latter, led to multiple boards of directors and senior management teams being introduced to 3D molecular docking models on Silicon Graphics workstations that were simple, direct, and easy to grasp, albeit representing only a very small part of the drug discovery equation. While important in its own right and in an appropriate context, computer-assisted molecular design (CAMD) was perhaps not as uniquely self-contained a technology as nonscientists were repeatedly led to believe. It then became a difficult task to easily explain slow progress and failures when the audience had been convinced that the key to success was only an image on a Silicon Graphic terminal and a mouse click away.

From the *technocrat*, it became a short step to the *hype addict*,⁷⁰ usually an individual in management, driven by a need (or desperation) to acquire the latest technology, believing in all the things that the newly proposed technology may be able to do at face value, despite a long stream of previously acquired technologies that failed to live up to promises, in the hope and expectation that the next one might be the right one.

2.11.3.4 Disease Complexity and Novel Targets

2.11.3.4.1 Novel targets

The implicit opportunity in the human genome map was that of new, disease-associated targets. Of additional importance was the expectation that these newer targets would be discovered in an 'agnostic' manner, with no preconceived ideas to fit into an existing hypothesis. New targets would develop new hypotheses, correct older ones, and lead to new drugs. Instead, disease association has been tainted or subverted with existing hypotheses. The protein product of the novel schizophrenia-associated gene *g72* was used as a bait in yeast two-hybrid experiments. Among some 3000 prey, the enzyme D-amino acid oxidase (DAAO) was identified.⁷¹ The activity of DAAO is normally associated with bacterial detoxification in the kidney, making it, at first blush, an unlikely pathway candidate for a psychiatric disorder like schizophrenia. However, in earlier work it had been shown that the unnatural D-amino acid, D-serine, formed in mammalian brain by the enzyme serine racemase, was a potent allosteric modulator of the N-methyl-D-aspartate (NMDA) receptor and that D-serine, when given with traditional antipsychotic medications, had positive effects on symptomatology in schizophrenics⁷² (see 6.02 Schizophrenia).

While DAAO is still the subject of active research, its identification was not based on an 'agnostic' null hypothesis but rather on the heuristic relationship of the enzyme to the glutamate hypothesis of schizophrenia, interpreting 'new' science in the context of old. Whether a more novel, paradigm-shifting approach to schizophrenia may have existed in the other 2999 or so *g72* protein-associated pull downs or its partner gene, *g90*, remains to be seen.

2.11.3.4.2 Old target opportunities and metrics

In considering the apparently urgent need for new targets and their full exploitation, it is worthwhile considering existing targets of known structural homology and function. In addition to the diversity of 7TM receptors and their signaling pathways and ancillary proteins, there are more than 500 members of the human kinome (protein kinases), over 1300 distinct phosphatases, 18 members of the histone deacetylase (HDAC) family, and, at a minimum, 14 members of the phosphodiesterase family, all of which, based on: (1) the identification of important drugs/NCEs acting at these targets; and (2) their key roles in cell function, may represent viable drug targets.

Three other well-known receptor families have also been the focus of considerable research efforts in academia and the pharmaceutical industry. The first, the histamine 7TM receptor family, has been an active research area since the 1930s and has yielded many valuable drugs active at H₁ and H₂ receptor subtypes including the antagonists mepyramine, diphenhydramine, astemizole, cimetidine, and ranitidine.³³ Current research efforts are focused on the two newer, recently cloned members of the histamine receptor family, H₃ and H₄, for psychiatric and hematopoietic diseases, respectively.⁷³ Thus, this now 75-year-old research area, proven to be a fertile source for drugs, is still filled with untapped opportunity using a rich portfolio of existing NCEs in conjunction with molecular biology probes on which to base new chemistry efforts.

Acetylcholine (ACh) produces its pharmacological effects via the activation of two classes of cholinergic receptor, the ligand-gated nicotinic receptor family ($\alpha 7$, $\alpha 4\beta 2$, etc.)⁷⁴ and the 7TM muscarinic receptor family (m1 – m5),⁷⁵ both of which have been seminal in the history of receptorology. Prompted by studies on acetylcholinesterase inhibitors that began in the mid-nineteenth century³³ and long before molecular biology was a facile and widely used technique, the nicotinic receptor from *Torpedo electroplax* was the first to be obtained in any quantity. Coupled with the availability of natural products like nicotine, dihydro- β -erythroidine, and methyllycaconitine, this provided the biological and

chemical tools to study receptor perturbation in the 1950s, even with the relatively crude tools then available. However, it was not until the early 1990s that the culmination of research efforts at several academic laboratories (Changeux, Lindstrom, and Patrick) and at SIBIA, R.J. Reynolds/Targacept, and Abbott provided the context for bona fide drug discovery efforts in the nicotinic area, the ability to search for NCEs that had the positive attributes of nicotine on CNS function without many of its receptor subtype-selective side effects. From the late 1950s until the 1990s, the nicotinic ion channel remained essentially unexploited, especially in terms of medicinal chemistry, and it has taken another 15 years, from 1990 until 2005, for the first novel nicotinic drug, Pfizer's varenicline, to be approved for use in smoking cessation. And there is obviously still more to be done with unexploited uses of novel nicotinic receptor ligands in pain, cognition, attention deficit hyperactivity disorder, depression, anxiety, and schizophrenia.⁷⁴ The muscarinic receptor was the first 7TM/GPCR to be cloned in 1989 and was also the first to be freely available to all investigators from the NIH. While many ligands have been made to emulate classical ligands like atropine, pilocarpine, pirenzepine, etc., the majority, e.g., xanomeline, despite promising preclinical efficacy data, have been confounded by side effect liabilities. Darifenacin is a selective M₂ antagonist for the treatment of urinary retention.

Another class of receptors that are rich in complexity and function yet lack a diversity of drug-like NCEs and priority therapeutic targets are those for adenosine and ATP, the P1 and P2 receptor families, numbering 4 and approximately 15, respectively. Some 30 years of research in industry and academia, much of the latter focusing on NCEs as in vitro research tools rather than as leads for optimization, have resulted in only one NCE reaching late-stage clinical trials, the A_{2A} antagonist, istradefylline, which by acting as an indirect dopamine antagonist represents the next generation of treatment for Parkinson's disease.

From these examples, it may be argued that each drug target can take a minimum of 20 years of full-time, undiluted research effort to result in NCEs that have the potential to be drugs. The development of novel, receptor subtype NCEs and their subsequent use to perturb biological systems inevitably leads to new information that can then be used in an iterative manner to design newer NCEs to optimize their efficacy, therapeutic index, and drug-like characteristics. With this paradigm, one may then ask the question as to whether the obsessive search for new targets is truly a vision of the future or a reluctance to do the hard work required to properly exploit an existing drug target. A modern-day drug discovery scientist can spend his or her career always looking for something new without actually planning to achieve anything of substance.

An interesting exercise would be to take the industry metric of the FTEs required to support a discovery project at critical mass, currently considered in the range of 24–35, and multiply this by 15 as an average expectation of target life span for success. This results in a range of person years of between 360 and 525 and this number can then be used as: (1) a denominator for existing discovery scientists in the worldwide pharma/biotech industries; and (2) a multiplier for a conservatively useful 5000 new targets present in the human genome.

In the former instance, it can easily be imagined that the number of existing drug discovery scientists will be rapidly exhausted long before there were any need to delve into the genome for new targets. For the latter, the aggregate 1.8–2.6 million person years required to exploit the genome rapidly approaches the science fiction realm of the 3×10^{62} drug-like molecules that could possibly exist (W. Michne, personal communication). The translational medicine paradigm^{28,112} is key to improving this situation although it is probable that effectively extending the NCE research paradigm into Phase IIa will be more successful than the concept of CTSAs.

2.11.3.4.2.1 Target centric versus multiple targets

While the current approaches to drug discovery have an almost exclusive focus on finding NCEs that are selectively active at discrete molecular targets, a 'target-centric' approach, it is well known that many existing drugs have multiple targets that contribute to their efficacy and also their side effect liabilities.^{76,77} Imatinib (Gleevec), while originally characterized as a potent and selective *Bcr-Abl* kinase inhibitor, has since been found to be active at PDGF and KIT kinases.⁷⁸

The most cited of these multitarget drugs is the atypical antipsychotic clozapine.⁷⁶ This compound has superior efficacy in schizophrenics, an absence of extrapyramidal symptoms, albeit with several limiting side effects, the most important being that of potentially fatal agranulocytosis (see 6.02 Schizophrenia). The latter may be due to the interaction of clozapine with the histamine H₄ receptor while efficacy has been ascribed to: (1) a multitude of receptors in the CNS including dopamine D₂ and D₄, 5HT_{2A}, 5HT_{2C}, 5HT₆, etc.; and (2) the activity of its major metabolite, desmethylclozapine, as an allosteric modulator/agonist at muscarinic receptors.⁷⁹ The search for an improved version of clozapine lacking the liability for agranulocytosis has been ongoing for nearly 35 years on an empirical, chemically driven, 'trial and error' basis, since, despite a wealth of data on putative targets for clozapine and other antipsychotics, it is still unknown what mix of these activities, including partial receptor agonism, contributes to

the superiority of clozapine. Similarly, many kinase inhibitors have multiple effects, from the ATP-mimetic, staurosporine, which interacts promiscuously with multiple kinases,⁸⁰ to compounds that while still not totally selective, can inhibit drug-resistant mutants of ABL, KIT, and epidermal growth factor (EGF) kinases.⁷⁸ More recently, there have been deliberate efforts to design NCEs with multiple molecular actions.⁸¹

2.11.3.4.3 Systems biology and pharmacology

A logical extension of the multiplicity of putative molecular targets for existing drugs has been the evaluation of NCEs for their phenotypic effects in complex systems to derive a 'system response profile'.³² While being presented as a totally novel approach to drug discovery under the rubric of systems biology, a means for "rescuing drug discovery,"^{32,43} pharmacologists have used similar approaches to study NCEs in tissues and whole animal models for nearly a century,^{30,36} one notable example being the classical Irwin test,⁸² now some 40 years old, that is used to study the effects of NCEs on CNS function in terms of the behavioral phenotype they produce in rodents.

The systems biology approach is argued as a more cost effective and rapid way to do drug discovery and, as a consequence, increase productivity. Butcher⁴³ has naively proposed that since an NCE can enter human trials with established preclinical safety and, in some instances, efficacy in the absence of a known mechanism of action, the drug discovery paradigm should move from a 'target-centric' approach, based on the challenging and often futile task of target validation, to one of compound validation. Once shown to be efficacious in human trials, the mechanism(s) of action of compounds with a defined system response profile could then be determined, apparently for a fraction of the cost of a target-centric-based approach.

For industry researchers actually involved in such challenges, this is easier said than done. In the absence of a defined mechanism, it is exceedingly difficult, if not impossible, to establish a structure-activity relationship (SAR) and identify second-generation compounds that have improved efficacy and/or safety. While various mechanisms have been proposed to underlie the efficacy of the antiepileptic, valproic acid, as a mood stabilizer and as a treatment for AIDS, none have been entirely convincing such that second-generation NCEs have been designed on a structurally empirical basis leading to compounds like ABT-769⁸³ that have an improved safety profile as compared to valproic acid but still lack a mechanism of action (*see* 6.11 Epilepsy).

While systems biology is certainly a logical approach in helping to decrease NCE attrition rates, it, like molecular biology, is being currently used in an exclusionary manner rather than in conjunction with the proven tools of medicinal chemistry and pharmacology. The concept has been extended to that of 'systems pharmacology'?³² and has been further refined 'via multiplexing' using transgenic animals.¹⁶ Despite the varied nomenclature, it appears very much a recapitulation of what was being done in drug discovery in the 1970s, albeit with more sophisticated technologies and improved data analysis and storage systems.

2.11.3.4.4 Re-engineering/re-positioning known drugs

A key part of the NIH Pathway Initiative has been the Molecular Library Initiative that has facilitated the setting up of screening centers at the NIH, National Institutes of Mental Health (NIMH), Harvard, Rockefeller University, and Johns Hopkins University to evaluate NCEs against targets that are either of limited interest or not available to pharmaceutical companies.¹⁶ This initiative involved the setting up of large chemical libraries (currently including 500 000 compounds with projections to grow to 3 million by 2009) to provide academic laboratories with the opportunity to screen NCEs. This initiative also provides defined compound sets like that of 1040 FDA-approved drugs. From the latter, the β -lactam antibiotic, ceftriaxone, was found to upregulate levels of the glutamate transporter GLT1 *in vitro*,⁸⁴ functionally decreasing extracellular levels of this excitotoxic neurotransmitter and thus acting as a novel neuroprotectant. While these effects of ceftriaxone were confirmed in mouse models, they contrasted to the lack of efficacy of the antibiotic in human amyotrophic lateral sclerosis (ALS) trials, the latter of which have been criticized based on design and powering.¹⁶ This represents a newly emerging trend where the clinical trial outcomes for NCEs that have failed efficacy trials are discounted in light of 'interesting' and novel preclinical data. A similar situation exists for the propargylamine GAPDH ligand, TCH346, which, having failed in the clinic for the treatment of Parkinson's disease, has been reassessed in terms of its anti-apoptotic properties in cell and animal models and still apparently represents a viable molecular entity for clinical trials.⁸⁵

Systems biology has provided intriguing evidence of the potential for 5HT receptor antagonists to prevent viral entry into cells and for the potential use of nonsteroidal anti-inflammatory drugs (NSAIDs), statins, lipid-lowering agents, and PPAR γ inhibitors in AD, although, at least for the NSAIDs, the data has been inconclusive in terms of prospective evidence for their efficacy in retarding AD progression despite the high positive retrospective efficacy of indomethacin.⁸⁶

The repositioning (or ‘repurposing’) of existing drugs⁸⁷ has also been extended to the evaluation of drug combinations (e.g., NCEs active at multiple targets) to assess compound synergy *in vitro* using classical pharmacological approaches in conjunction with highly sophisticated, computerized data analysis techniques, e.g., Loewe and Bliss independence modeling.⁸⁸ While preclinical data on drug combinations have provided interesting uses for approved drugs, perhaps acting at unknown, off-target sites, the evolving FDA’s combination drug policy may be a hurdle in advancing these as NCEs.

2.11.3.4.5 Animal models

The animal models routinely used to characterize NCEs as part of the hierarchical process, while not infallible, are key in providing both evidence of putative efficacy to advance NCEs to the clinical testing stage and to assess NCE absorption, distribution, metabolism, and excretion (ADME) profiles to determine the drug-like characteristics of an NCE and to help in predicting doses for use in clinical trials. Few animal disease models recapitulate the human situation leading to considerable debate on their utility.^{25,89} Rodent models of chronic pain include: spinal nerve ligation, an acute and precise surgical insult; streptozotocin-induced models of diabetic neuropathy; and various cytotoxic treatments to model cancer therapy-induced nerve damage (*see* 6.14 Acute and Neuropathic Pain). The majority of these models are typically studied for periods of 1–4 months, a chronic time period in an animal but very different from the years or even decades that are thought to precede the development of chronic pain in humans — often with idiopathic causality. These longer term changes in humans may result in more subtle, more complex, and longer lasting synaptic/neuronal changes than those occurring in the shorter lived animal model — confounding the transition of NCEs from animals to humans. Animal models of psychiatric diseases like schizophrenia also have limited relationship to the human disease. A classical assay to assess NCEs for antipsychotic potential, rat catalepsy, is more a model of dopamine receptor blockade than a model of psychosis with the prepulse inhibition (PPI) model more accurately reflecting the occurrence of similar phenomena in humans⁹⁰ (*see* 6.02 Schizophrenia). For antidepressants, iterations of the classical behavioral despair model,⁹¹ now nearly 30 years old, remain state-of-the-art despite early inroads in assessing behavioral phenotypes in transgenic mice.⁹² Transgenically modified mice, fruit flies, and zebra fish have been used as surrogate models of human disease states with an apparent remarkable degree of success, albeit via a retrospective analysis.⁴¹

An issue with transgenic models is whether the gene alteration, especially in the embryo, results in compensatory developmental changes that eliminate the molecular lesion due to systems redundancy. For instance, while there are clearly defined pathways for pain transmission, these can be highly redundant as are the systems involved in responses to septic shock. Removal of a single molecular component of these systems may have no phenotype in surviving animals or they may be lethal. Given that many cellular systems active in the process of development are quiescent in adults, the embryonic ablation of a key protein in a pathway may indeed be lethal at the wrong stage of development. Conditional knockouts may provide very different phenotypes in adult animals that may help in determining the role of a target in a given disease state. Similarly, other systems may malfunction as the result of gene removal or insertion and in this context there is emerging evidence that ADME properties in transgenic animals may be different from their wild-type controls.

Animal models are also widely used to assess side effect potential⁹³ (from NCE effects on blood pressure and sedation to overt toxicity) and can be used to determine the therapeutic index — a ratio of the efficacious dose/plasma level of an NCE to the dose/plasma level producing robust side effects and to provide first approximations of compound dosing for clinical trials.

2.11.3.4.6 Intellectual property

Prior to the biotech revolution, much of the intellectual property (IP) from biomedical research conducted in academic and federal laboratories was freely available in the form of publications and presentations at scientific meetings. Such information could then be used by the pharmaceutical industry to drive their drug discovery efforts. With the advent of the biotech revolution, driven to a major degree by the Bayh–Dole Act,⁹⁴ intellectual property became a highly viable currency for academia, making technology transfer operations in universities akin to venture capital (VC) firms, in some instances resulting in a ‘gold digger mentality.’⁹⁵ This led to many inventions being excluded from industry use without a license, which was often exclusive in that only one party could use the invention. This latter situation was designed to avoid a ‘tragedy of the commons’-type situation⁹⁶ in that the previous system of patenting and disseminating new findings had left more than 95% of federally funded inventions ‘gathering dust’ as companies would not invest to commercialize without owning exclusive title. The Bayh–Dole Act, now 25 years old, transferred the title to the IP of discoveries made with federal research grants to the universities where such discoveries were made in order to facilitate

their commercialization, and has been credited⁹⁴ with helping create the biotechnology industry. In 1979, the year before Bayh–Dole, American universities received 264 patents. By 2004, universities were filing over 10 000 new patent applications and receiving approximately \$1.4 billion per year in revenues from license fees.⁹⁵ While many universities and their in-house inventors became wealthy from federally funded research, from 1992 through 2003 pharmaceutical companies engaged in approximately 500 patent suits, “more than the number filed in the computer hardware, aerospace, defense, and chemical industries combined” – “a giant, hidden ‘drug tax’ ... [that]...shows up in higher drug costs.”⁹⁴

The ease of filing and obtaining patents in the US, the number of patent applications having tripled since 1980 with the number of patents issued increasing fourfold,⁹⁷ has led to concerns, from the FTC’s “questionable patents are a significant competitive concern and can harm innovation,”⁹⁷ to Heller and Eisenber’s “anticommons” where “proliferation of [IP] rights upstream may be stifling life-saving innovation downstream”⁹⁷ to the *Economist*’s, “there is ample evidence that scientific research is being delayed, deterred or abandoned due to the presence of patents and proprietary technologies.”⁹⁵ In the anticommons argument, fragmented and overlapping patents are viewed as impeding product development, certainly the case some years ago when the total royalty rates on a diagnostic assay based on the use of several innovative technologies that had been negotiated at a 2–5% rate on individual technologies were found to total 47%, a level at which commercialization was not economically feasible. The impact of licensing on drug discovery research has thus been profound.

On the positive side, the ability to license patents exclusively has incentivized companies to work in an area. However, on the negative side, some biotech companies have taken good ideas from academia and created extensive and highly expensive-to-maintain patent portfolios ostensibly to commercialize the protected technology but, lacking in-house expertise and experience in drug discovery, have failed to add value to their assets, thus restricting access to promising technology – “coddled and kept out of the rain”⁹⁴ – in essence, squandering valuable scientific opportunities that a more experienced organization could have made into a value proposition. In the 1990s, a now long since acquired biotech company held a patent, colloquially known in the industry as ‘629,’ that apparently covered the signaling ability of every drug target system, both artificial and natural. Thus, in addition to covering luciferin–luciferase reporter systems, this patent claimed adenyl cyclase-linked systems in native cell lines, as well as the behavioral phenotypes of animals following NCE administration. In fact, just about any experiment run in biomedical research. This company aggressively attempted to enforce this patent forcing another promising biotech out of business and gaining collaborations with certain big pharma. When patent 629 was finally challenged in court, it was disallowed. Had this not occurred, nearly every experiment being run in biological systems throughout the world today would require paying this unnamed company royalties.

The ability to patent the gene-based elements of cell function, receptors, biochemical pathways, etc., has led to hotly disputed patents on the knowledge of life itself rather than true inventions involving composition of matter or trade secrets. The negative impact of this patenting strategies is now being actively debated^{98,99} with the NIH advocating the free⁹⁴ or nonexclusive⁹⁵ licensing of research tools, a position supported by the National Research Council.

Access to patented research tools has traditionally been more expensive in industry than academia (even though those same tools in academia were used to found companies or generated revenue for the inventors via licensing deals) or unavailable when the patent holder has licensed exclusive rights to a third party. The cost of these license fees and of accompanying collaboration milestones has increased the costs sunk in research. To the in-house costs of running a collaborative research program must then be added licensing (and legal) fees, milestones that can average from \$1–5 million before an NCE is tested in humans to \$30–120 million or even more when an NCE is approved via an NDA. These costs are all ‘at risk’ in that the sponsoring partner must pay them before a penny in revenue from the NCE occurs. To the projected \$800 million in cost for bringing a drug to market based on historical numbers must then be added another 15–25% in financial costs, which do not include the cost of money over the 8- to 12-year period.

2.11.3.5 Filling the Pipeline

The inverse relationship between the considerable investments in drug discovery, both financial and technological, to the current IND and NDA output^{3,44} has necessitated that drug companies and biotechs focus considerable efforts (often with less scientific expertise) on opportunistic compound in-licensing activities to sustain their product pipelines. As part of an integrated, global strategy that includes both consideration and inclusion of the company’s R&D efforts, in-licensing can be a highly productive endeavor. Several major pharma companies have deliberately licensed up to 50% of their current product portfolio from outside sources or via company acquisitions, e.g., Pfizer and Pharmacia, Amgen with Immunex and Abgenix, Abbott and Knoll, to both reduce risk and build depth in their pipeline

portfolio. Similarly, several of the biotechs that have survived from the boom of the 1990s have achieved sustainable success with in-licensed compounds, often in therapeutic areas distinct from that in which the company was initially founded, the initial scientific concept of the company having proven faulty.

The in-licensing paradigm has been clearly successful when “diamond[s] in the rough”²⁶ have been identified, e.g., the novel wake promoting agent, modafinil (see 8.12 Modafinil, A Unique Wake-Promoting Drug: A Serendipitous Discovery in Search of a Mechanism of Action).

The continuation of in-licensing activities at their current feverish rate creates a vicious cycle that needs to be placed in the context of the many and considerable in-licensing failures that are forgotten or ignored. Biotechs continue to search for compounds with overlooked and unexploited commercial potential in the archives of major pharmaceutical companies, an activity in which they often compete directly with the latter as the big pharmas similarly compete with one another to identify such opportunities in one another’s ‘shelved’ portfolios. However, the number of Phase II/Phase III failures reported on an increasingly regular basis in *BioWorld* reinforces the fact that many of these ‘opportunities’ were indeed the ‘coals’ that the originating company had already passed judgment on rather than the elusive ‘diamonds’ that the licensee had anticipated.

One unfortunate outcome from in-licensing activities is that drug discovery and development organizations, both big and small, begin to question the value of their internal research groups, arguing that the monies spent on the unpredictable and long-term ‘black hole’ of research would be better used in finding more near-term, external ‘diamonds,’ overlooking the fact that these ‘diamonds:’ (1) had to originate from a research-based organization; (2) are in increasingly short supply and/or of increasing questionable quality; and (3) because of industry consolidation and downsizing and the bursting of the biotech bubble, are not being replenished. As a result, an opportunistic in-licensing approach becomes ineffective unless it is part of a longer-term ‘strategy’ to sustain company growth and stability. Indeed, as many in-licensing activities are purely opportunistic, any corporate strategic plan can be subject to almost instant change in direction via the next acquisition, making the long-term vision required for the 10–12 year time frame of the R&D process a major challenge unless proactively and consistently managed.^{61,62,100} Also, the opportunities in in-licensing activities are often driven by the ‘grass being greener’ elsewhere in terms of compound quality and opportunity (and led at one point to the author’s suggestion that each drug company should put a select number of their second and third tier compounds into a ‘basket’ to provide the in-licensing functions, a portfolio of compounds that could be used as the self-perpetuating basis for deal making (you buy my compound, I’ll license yours) while R&D were left to create long-term value without the irritation of supporting ephemeral initiatives from the business development function) and effectively reduces the considerable investments being made in internal technology to enhance the drug discovery process to that of a prospecting expedition. This can result in a factious dynamic with the internal R&D staff who, in the process of due diligence, can transition an ill-conceived ‘billion dollar’ opportunity to the status of ill-conceived and poorly executed science, and are then perceived as territorial. An additional facet of the ‘grass being greener’ is that many companies intending to out-license compounds have second thoughts as other companies find value in their portfolio, and decide it is better to keep an asset than give it to a competitor who may show it had potential, an example of the “100% of nothing being better than 50% of something” school of drug R&D. As an anecdote, the author was at one time involved in due diligence on an in-licensing opportunity that had tremendous commercial potential but for which there were a number of serious and unresolved side effect issues. The result was that the opportunity went to another company and resulted in the head of marketing at the author’s company decrying the lack of vision in research, the proverbial NIH (‘Not-Invented-Here’) syndrome, for this compound that apparently had revenues of \$200 million in its first 2 months on the market. Within the following 6 months, the compound was withdrawn from the market following major safety issues and the acquiring company became immersed in litigation in the tens of billions of dollars. When confronted with the fact that the objective research evaluation had saved the author’s company from a similar fate, the head of marketing refused to comment.

2.11.4 Technological Impact and Integration

The imperative in building new biotech companies has been more often driven by financial opportunism than by any innate belief that the scientific concepts on which such companies were based would lead to new drugs and improved healthcare. Despite a technology revolution that promised safer, more efficacious drugs in a more rapid and consistent timeframe, it still takes from 8 to 14 years from the time an NCE is discovered to market introduction.

The revisionist approach inherent in the biotech revolution has resulted in drug discovery being considered a predictable commodity with drug targets, irrespective of their intrinsic complexity and dynamic nature, being totally interchangeable. Similarly, as already noted, the individuals conducting the research have become viewed as

interchangeable such that a chemist can function as a biologist (despite marked differences in training and culture) and a neuroscientist could easily work as a cell biologist in anti-infective drug discovery. This has reduced all aspects of drug research to a production line-like metric, discounting the fact that insight based on experience, innovation, and serendipity are unpredictable and highly necessary for success.

While the reductionistic approach of molecular biology has led to major advances in the understanding of cell function, the subtle nuances of the native target are frequently absent when human DNA is expressed in a cell line. 7TM receptors require key accessory proteins, e.g., β -arrestins and phosphatases, that are either missing in transfected cell systems or atypically linked due to receptor/target overexpression,¹⁰¹ such that reports of new signaling pathways for known receptors in transfected cell lines should be viewed with considerable caution. Receptors also undergo dimerization,¹⁰² trafficking, and internalization and may also have tissue- and disease-specific differences in their signaling pathways.¹⁰³ For protein kinases, the phosphorylation state of the substrate, which can be a function of the disease state, the endogenous ATP concentration, and the nature of the natural protein substrate (which is frequently unknown), all alter inhibitor activity as do disease-related constitutive forms of the enzyme.^{104,105} Finally, a molecular networks approach¹⁰⁶ to synaptic protein interactions (the synaptome?) can help delineate functional interactions for drug targets and their cognate signaling pathways in a highly complex, albeit physiologically rigorous manner.

Similarly, the interaction of NCEs with their target can be far more complex than the simple classification of either agonists or antagonists/activators or inhibitors. The demonstrated existence of partial agonists, allosteric modulators, neutral and inverse antagonists, and inverse agonists in multiple systems re-emphasizes the critical need for concentration/dose assessment of NCE activity rather than single-dose SAR.^{37,107} Extensions of such concepts include constitutive activity of 7TM receptors, the activity of receptor systems that occurs independently of the presence of the ligand, collateral efficacy, and permissive antagonism¹⁰³ and redefine both the ligand and the nature of its interaction with its target(s).

In operating almost exclusively at the cellular level, or integrating findings from a cell-based approach with a transgenic mouse that often recapitulates the test tube, the reductionistic approach has limited the ability to interpret data related to NCE efficacy, target selectivity, side effect liability, and ADME in increasingly more complex systems. The revisionist biotech agenda de-emphasized the integrative, hierarchical approach inherent in classical pharmacology, where NCE assessment progressed from a relatively simple tissue homogenate, sequentially to the whole cell, tissue and animal levels, with data being reviewed and integrated at each step to provide a more thorough understanding of NCE actions at the molecular, tissue, and whole animal levels (**Figure 1a**; **Table 1**) before advancing these to clinical trials. The challenge then became to take the newly synthesized NCE and get it into humans as rapidly as possible without bothering with all these 'old fashioned' constraints (and often ignoring not just the time-tested approaches but also the data already in the literature) (*see* **Section 2.11.3.4.4**).

The perceived importance and ease of cellular studies led to these being increasingly funded, not as additional tools to enhance the biomedical research endeavor, but to the exclusion of more traditional integrative research approaches. In 1994, 11% of NIH pharmacology fellowships involved whole animal research,⁶⁷ resulting in a de-emphasis in the teaching of classical pharmacology, and with the aging of the existing population of pharmacologists, a dearth of expertise and experience.³⁶

As the topic of drug discovery now extends beyond the pharmaceutical and biotechnology industries into the NIH and academia, it is clearly time that a more concerted effort be placed on integrating all the available disciplines relevant to drug discovery, both old and new, in an effort to improve productivity. Rather than continue the poseur/hype addict/technocrat approach with an exclusionary, revisionist focus on technologies to enable drug discovery, it is a critical necessity to take what worked in the past, e.g., pharmacology and medicinal chemistry, and revitalize it, while redirecting new technologies in strategies for drug discovery that have been proven to work (**Figure 1**). The author has addressed the need for a pharmacologically based integrative approach to address the shortfall in productivity in the context of an *iPharm* concept based on Apple's highly successful iPod.³⁰ In identifying a need in the marketplace, a design team at Apple took existing, off-the-shelf hardware and software to create a technologically sophisticated, well-designed, and functional portable digital storage device for music, photographs, movies, and books, the utility of which (and demand for) has far exceeded the sum of its parts. Thus, appropriate, cost-effective technology was successfully used to reach a previously defined endpoint rather than Apple searching for a project to justify the existence of their technology. The *iPharm* concept may provide a truly integrative framework to understanding compound action at all levels rather than a 'systems biology' approach that seeks to re-invent pharmacology while discounting the value implicit in knowing the mechanism of action of a drug, a 'modern-day back-to-the basics' approach.¹⁰⁸

Table 1 The pharmaceutical industry then and now: A comparison of organizational and individual cultures in drug discovery

	<i>Drug Discovery 1976</i>	<i>Drug Discovery 2006</i>
Organizational environment	Golden age of drug discovery	Empty pipelines, perception of poor prospects for new drugs, generic competition
	Merck 'most admired company'	Distrust of industry <ul style="list-style-type: none"> • Vioxx law suits • Conflicts of interest in clinical trials • Excessive emphasis on marketing
	First \$billion/year drug—cimetidine	Multiple \$billion/year drugs <ul style="list-style-type: none"> Statins—\$12 billion/year SSRIs—\$7 billion/year
	Major US, European, and Japanese pharmas	Multiple mergers to form mega pharmas
	Multiple local/family boutique pharmas	<i>Pfizer</i> = Warner Lambert + Pharmacia + Monsanto + Upjohn + Sugen + Goedecke + Agouron + Vicuron + Idun + AngioSyn + Esperion + Rinat
	Local markets	<i>Sanofi-Aventis</i> = Sanofi-Synthelabo + Aventis + Hoechst + Roussel Uclaf + Hoechst Marion Roussel + Marion + Richardson Merrill + Merrill Dow + Dow Pharmaceuticals + Rhone Poulenc Rorer + Rorer, etc.
	No biotech industry	Biotechnology industry firmly established – 4000 companies worldwide
	European/US pharmaceutical R&D	Emergence of Indian and Chinese pharmaceutical companies
	Research – science based	Consolidation of global pharma R&D in the US
	Research – science based	Research–market driven
Scientific approach	Hypothesis driven	Hypothesis seeking
	Using technologies to answer questions	Numbers and technology driven – using technology to find questions
	Integrated chemo-/pharmaco-centric molecular target-based approach	Reductionistic, exclusionary approach
	Evolving hierarchical complexity and integration in NCE evaluation in natural systems: <ul style="list-style-type: none"> • membrane • cell • tissue • animal 	Pharmacology by any other name
		Chemigenomics and emergence of systems biology
	DNA revolution evolving—no cloning, no expression	Multiple 'omics' sciences – genomics, proteomics, interactomics, epigenomics
	Traditional medicinal chemistry	
	Facile interface between industry, academia, and government	
	New scientific findings freely published and presented at meetings	
	HTS – 200 compounds a week	HTS – 1 million+ compounds a week
	Important new data initially published in peer-reviewed journals with information to ensure facile replication	New data 'published' in <i>Wall Street Journal</i> , <i>New York Times</i> or <i>BioWorld</i> – no peer review, often never published, and when published, key details for replication withheld for IP purposes
		Structures and patented 'know how' omitted from papers

Table 1 Continued

	<i>Drug Discovery 1976</i>	<i>Drug Discovery 2006</i>
Individual motivation and focus	Discipline/disease specialization	Technology orientation
	Passion for science	Passion for science tempered by concern for stock options
	Inquisitive	Directed
	Intrinsically (scientifically) motivated	Trend toward extrinsic (stock options, \$\$) motivations
	Motivated by drug discovery as an end	
	High level of career stability	
	George Merck ethos	Business influenced
	Card-carrying members of the scientific community	Scientific standards slipping ^{26,30}
	Publications	
	Peer reviewing	

2.11.5 Future Challenges

The concerns regarding the pharmaceutical industry related to lack of productivity, to drug costs, and to issues with the drug approval and marketing processes^{22,23,28} may be viewed either as the end of the golden era of drug discovery or a bona fide opportunity to remold the research enterprise based on the richness of information, technology, and experience that are now available. To do this requires a renewed focus on process management and best practices together with integration of all activities involved in drug discovery at the individual, organizational, cultural, and technological levels. The productivity gap can only be addressed if the drug discovery paradigm, as it now exists in big pharma, undergoes significant change.⁵ The consequences of not adopting a ‘new’ paradigm will continue to negatively impact the vitality and even the existence of big pharma in its present form and continue the productivity woes and inefficiencies.²¹ Thus, the risk of continued failure with existing approaches to drug discovery is ‘arguably absolute.’³

2.11.5.1 Cultural

As noted, biologists are being trained at a different level than they were 30 years ago. It may also be argued that current training in the chemical sciences tends to oversimplify the complexity and inherent variability of biological systems. The need to re-instill inquisitiveness and independence of thought is a key issue that extends to society as a whole but is particularly acute in the area of drug discovery where these qualities have proven to be critical to success. To do this will take time and requires leadership that can provide the challenge and mentorship to allow scientists to expand to their full potential by letting them invest time in quality thinking before the experiments begin.³ It is all too easy to find a library and set up HTS screens. Diminishing the visibility, impact, and presence of both the scientific poseur and hype addict within the research environment will be a major help in a return to reality.

A research organization cannot tolerate anything other than the best science; it must insist on timely decision making driven by data and encourage risk taking and the hiring of passionate people. It should have a high level of tolerance for individuality and should encourage its scientists to take risks on a daily basis without consequence.⁶³ As another anecdote, the author had considerable troubles with his management when celebrating with a project team the demise of the project just 2 weeks before the IND candidate was to go into humans. A class effect, presumably related to the target, had emerged, compromising the safety of the therapeutic approach. The risk of going forward to the clinic was deemed unacceptable. In light of the new data, the project team recommended that the project be terminated, a clear decision that was as worthy of acknowledgment as moving an IND forward. To be successful, a research organization must tolerate such failures.

The continued dependence of pharmaceutical management on input from outside thought leaders from academia and management consultants to help guide and organize drug R&D, respectively, in essence second guessing their own employees, is somewhat akin to BMW asking Michael Schumacher to design its production lines or the paints industry looking to Leonardo da Vinci to spend time away from his code, advising its chemists on how to develop the most durable paint composition for the Golden Gate Bridge. A major opportunity that has resulted from the widespread

mergers and downsizing in major pharma over the past decade is that individuals (drug hunters) with many years of practical experience, “precious knowledge gained in past projects,”¹ are now available as consultants, providing unprecedented insights and wisdom into the fundamentals of the process.

In a somewhat tongue-in-cheek anecdote, Lowe³¹ has noted that the “highest correlation with eventual success.. [in drug discovery is that] ... for your drug candidate to be a winner, someone has to have tried to kill it” – preferably at the VP or higher level and even more preferably numerous times. While amusing, this concept underlines two facets of modern day drug discovery. The first is that the process is highly dynamic, with many twists and turns in the process of advancing an NCE, with many opinions, new data sets, and decision points requires an imperative to operate in an objective, data driven mode. The second is that if management perceives an individual as being on the wrong track in a drug discovery project then that individual is inherently right from a scientific perspective. Unfortunately, for every Jim Black or Pat Humphrey, there are many well-intentioned, yet misguided scientists who fail to take an objective viewpoint as to what their data is telling them, a situation made worse by the ‘turn off the brain’ phenomenon.¹ The more they are told they are mistaken and the more their project is killed, the more zealous they become, perhaps providing another reason for the lack of productivity in the drug discovery process.

Drug discovery at its basic level reflects the interaction between medicinal chemists and pharmacologists to objectively test disease-related hypotheses in order to identify NCEs that may in time become drug candidates and eventually drugs. This is a highly risk-oriented enterprise inasmuch as the tools required to validate new hypotheses result from the activities being conducted, making the process extremely iterative and far from linear. Certain aspects, like HTS and NCE synthesis are less risky in that the activities are better defined and easier to execute. However, in the biology arena, predictability is a rare commodity and a biologist needs to remain highly attuned to discrepant, yet potentially informative, data to ensure that the path being followed is logical and that the right experiments are being planned and executed. With a reductionistic approach, unexpected data inevitably results in a dogmatic, often negative response, that concludes the data is wrong. However, the ability to objectively evaluate the data and place it in context can aid in designing future experiments and even result in breakthroughs. Some 25 years ago, in the days before ADME was a routine part of the early-stage drug discovery process, the author worked on a peptide receptor project. None of the NCEs worked in the selected *in vivo* model, which led to considerable consternation and questioning of the ‘druggability’ of the target. After a significant campaign to measure plasma levels of the peptidic NCEs, it was found that the NCEs had a maximal half-life of 2 min. The *in vivo* paradigm involved measuring the NCE effects 15 min after administration.

2.11.5.2 Operational

A research organization should maintain a high level of consistency. Thus, standards applied to the evaluation of external research opportunities should be similarly applied to internal activities¹⁰⁰ and the best opportunity to provide a drug candidate for the organization should take priority over any internally invested project that objectively cannot achieve its goals either due to scientific challenges or timing. All research projects should be objectively benchmarked against the pharmaceutical standard of care, if one exists, in a disease area to provide both the clinical and marketing organizations with information on the potential of an NCE. To this end, it is important that an optimal profile for the targeted NCE, a ‘quasi-package insert’, be developed early on and used to guide project activities.

The major theme of this chapter had been the reintroduction of the integrative discipline of pharmacology into the drug discovery process. This requires positing a hypothesis-related question and then using all available technologies, chemical, molecular, *in vivo* and clinical, to provide answers with a view to understanding the impact of NCEs on biological systems at increasing levels of hierarchical complexity. As argued, this should avoid exclusionary revisionist and political agendas, including those that dismiss any inherent value in animal models to those that argue against doing an experiment because the outcomes may provide contrary data. In this latter context, it is an absolute imperative that experiments be well planned with a clear idea of possible outcomes and plans to act on these using a decision tree-like approach. The existence of clear *go/no-go* decision points should aid in the design of these experiments. Project team activities should involve a critical path flowchart and avoid extraneous recapitulations of known activity via parallel experimentation. If the potential outcomes of a hypothesis-driven experiment in the context of the project flow chart will not provide data for making a decision, then the experiment should not be done. All research should be conducted at a peer-reviewed level so that the quality of internal and regulatory documents maintains the highest standards achievable. Quantitative rather than qualitative data with full replication based on a null hypothesis-based approach focused on “systematic and comprehensive approaches to understanding the mechanism of action of drugs,”¹⁰⁹ is *sine qua non*. An operational perspective is provided in [Figure 1](#), where the current fragmented and reductionistic technology-driven approach is compared to the more integrated ‘pharmacocentric’ approach.

A major hurdle to the rapid assessment of an NCE as a potential drug is its transition from animals to humans. Once safety has been established for an NCE, it should enter clinical trials as soon as possible to obtain a proof of concept. Examples of NCEs that showed half-lives of under an hour in animal models and were later found to have half-lives in excess of 10 h in humans are legendary with the inevitable question “which species predicts human?” In this context, much has been written on the topic of translational medicine, the ability to advance an NCE to human trials in an exploratory fashion.²⁸ For this approach to work effectively it requires clinical oversight with an appreciation of basic biological research. Too often, ‘pilot clinical studies,’ designed to get some idea of efficacy or proof of concept, end up being underfunded and underpowered and can rapidly transition to pivotal decision-making trials, making their execution a risk verging on the suicidal.

2.11.5.3 Scientific

There is a somewhat schizoid dynamic in the drug discovery process, that of the ability to maintain the scientific ethos in a ‘for-profit’ environment. In the 1970s, joining industry was judged to be passing to the ‘dark side’ of science, sacrificing one’s scientific standards in return for money. While Drews²⁶ has suggested that “good science” in industry has been replaced by “marketing dogma,” drug discovery research does require a well-managed process with clear goals, the resources to execute, and a forum for objective, data-driven decision making. To many drug discovery scientists, any form of management is anathema to their level of working comfort, raising concerns regarding the stifling of their creativity and innovation while to others, there is a comfort level in being directed with others making decisions and taking responsibility. As the lifeblood of research is success in delivering drugs, the ideal individual is the motivated person with an appreciation of order and a well-grounded sense of scientific self to help guide the organization in doing things in a consistent and scientifically credible manner. Within a well-organized, well-led research organization there is room for both a focused, time-mandated research effort and the opportunity to be innovative either concomitantly or sequentially. There should be little room in an effective research organization for individuals who have anointed themselves as the ‘thinkers,’ a quasi-elite, incapable of taking an idea to a tactical level without the help of more pragmatic individuals.

Today’s industry is overly focused on the new, from technology to targets. The outcome has been an increase in the cost of research with a corresponding decrease in the tangible output of new drug candidates. Nonetheless, drugs are an integral part of twenty-first century healthcare that immeasurably reduces the overall costs of healthcare. History may in time reflect that COX-2 inhibitors and sildenafil were business-driven aberrations in an otherwise illustrious record of providing vaccines, statins, and other drugs that have improved both longevity and quality of life. However, with the obsessive focus on new targets and the ever-changing kaleidoscope of ‘omes’ (Figure 1b), it is important to remember that many well-known targets (histamine receptors, cholinergic receptors, ATP receptors, kinases, PI3/AKT, etc.) have yet to be exploited to their full therapeutic potential. This will need a focused commitment and for each target will most likely take a 20-year time frame for success. The time spent in looking for and negotiating the rights to new targets and increasing comfort in their value is a high-risk endeavor that detracts from this effort, and must be considered in decisions regarding resource prioritization.

In a review of successful business enterprises in 1995, Jennings and Grossman¹¹⁰ identified the key to business longevity under the rubric of the “Tony Bennett Factor.” Mr Bennett, an established and successful entertainer (and accomplished painter) has a career that is now over half a century old and still viable (despite leaving his heart in San Francisco), which is based on Mr Bennett focusing on doing what he was doing in the 1950s, that is, entertaining; in essence, understanding his business and staying with it. In asking the question, “what business are we in?,” each of the companies surveyed by Jennings and Grossman “knew their strengths, developed strong market presences based on these strengths and never forgot their roots.” It may indeed be argued that today’s pharmaceutical industry has lost its way and has, as suggested by David Horrobin, “taken a wrong turn in [its] relationship to human disease.”²⁶ With research-based drug companies becoming involved in managed healthcare pharmacies and then divesting them and with Eastman Kodak and Procter and Gamble getting into (and exiting) ethical pharmaceuticals, this does beg the question of ‘what business?’

For productivity to reemerge requires that the pharmaceutical and biotech industries refocus on their core competency, that of innovation in applied biomedical research directed at ameliorating human disease. The industry must also recognize and commit to what business it is in and also recognize that the ‘old ways’ of carrying out drug discovery (Figure 1a; Table 1) have not been, and perhaps never will be, replaced by technology-driven *in vitro* and *in silico* approaches, nor will the passion of the drug hunter be replaced with either the golden-tongued sound bites of the scientific poseur or the ephemeral knowledge of the management consultant.

While the path forward in drug discovery has been viewed as “how we organize to implement new paradigms”³, it is important that the key elements that worked in the past are not overlooked. Abou-Gharbia has noted that “if you don’t have capable chemistry, you won’t have successful drug discovery”²¹ (and one might add, drug-like NCEs) while Reynolds has commented that “It’s the people who carry out drug R&D and their ability to exercise good judgment at many stages of the process that have perhaps always been and will continue to be the key in making drug discovery more efficient.”²¹ Finally, in the context of the Tony Bennett principle is George Merck’s seminal comment in an interview with Time magazine in 1952 that “We [Merck] try never to forget that medicine is for the people. It is not for profits. The profits follow, and if we have remembered that, they will never fail to appear. The better we remember that, the larger they have been.” A return to Mr. Merck’s sentiments with the pharma and biotech industries focusing on reinforcing their commitment to research driven by objective, innovative, and intellectually committed science and to supporting scientists rather than technologies will do much to reverse the current paucity in drug discovery.

Biography

Michael Williams received his PhD in 1974 from the Institute of Psychiatry and his Doctor of Science degree in Pharmacology (1987) both from the University of London. Dr Williams has worked for 30 years in the US-based pharmaceutical industry at Merck, Sharp, and Dohme Research Laboratories, Nova Pharmaceutical, CIBA-Geigy, and Abbott Laboratories. He retired from the latter in 2000 and served as a consultant with various biotechnology/pharmaceutical companies in the US and Europe. In 2003 he joined Cephalon, Inc. in West Chester, where he is Vice President of Worldwide Discovery Research. He has published some 300 articles, book chapters, and reviews and is Adjunct Professor in the Department of Molecular Pharmacology and Biological Chemistry at the Feinberg School of Medicine, Northwestern University, Chicago, IL from which vantage point he publishes his personal viewpoints on the drug discovery process.

2.12 How and Why to Apply the Latest Technology*

2.12.1 Introduction

If one were to start the process of drug discovery *de novo*, one would probably not begin; it is an incredibly daunting task. If you look at what one is up against in terms of discovering and developing a drug, the challenges are almost overwhelming. There is a veritable physiological labyrinth for determining drug efficacy and safety. What does a pharmacological agent, whether it is a large or small molecule, have to go through to be of some benefit to an individual with some pathologic state? It must survive gastric pH and gastrointestinal enzymes if it is an orally administered drug. Absorption is a key issue: it has to get to the systemic circulation. There is also the problem of enterohepatic recycling. There are barriers – lymphatic barriers, endothelial barriers, blood–brain barriers, and blood–retina barriers – blocking the movement of the molecule to the appropriate site of action or pathology. All of these are very important challenges for a potential new drug. Many of these barriers do not have good laboratory models at the present time. And this does not even take into account what the body likes to do with xenobiotics; namely, to metabolize, conjugate, excrete, and eliminate them. Eventually, some of the drug must get to the right organ, cell type, and molecular target (enzyme, receptor) to effect a beneficial response. In so doing, it must have sufficient selectivity relative to potentially deleterious effects on normal tissue to yield an acceptable benefit/risk ratio. This physiological labyrinth often takes more than a decade of research time for a single drug to traverse, while, in parallel, many more drugs fail. There are yet other prerequisites for a drug. It has to be stable, of course. It has to have a decent shelf life, but not only as the bulk material on a large scale under a variety of conditions; the formulation must also be stable and compatible with human life. There has to be an economical source, because, in the end, if one cannot produce the drug in a reasonably cost-effective manner, it is not going to be available to the marketplace. Lastly, one must have the necessary analytical tools for determining the various physical and chemical properties of the molecule and its presence in various biological fluids. All these tools need to be made available for one eventually to have something called a drug.

How did we discover drugs? **Table 1** divides drug discovery into five categories. The two that are highlighted in bold – modifying the structure of known drugs and screening inventories of natural products (primarily) – represent the history of drug discovery in the 1950s, 1960s, and 1970s. The others – proteins as therapeutics, modifying the structure of natural substrates, and structure-based, computer-aided drug design – emerged in the past two decades or so, and are really beginning to make an impact only today. We will review each of these categories of approaches to drug discovery.

Table 2 shows a few examples of drugs created by the modification of known drugs. There are certainly many more, but these are a few examples from the Parke-Davis research laboratories of building on past leads and establishing

improvements in a molecule based on a previously known drug: angiotensin-converting enzyme (ACE) inhibitors, quinolone antibiotics, cephalosporins, κ agonists, and 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. In some cases, these examples were very successfully marketed; other cases were not commercially successful but resulted in the creation of effective drugs. Nonetheless, the modification of known drugs is a successful paradigm for drug discovery, and represents the vast majority of the research investment in the 1960s and 1970s in drug discovery.

In many ways, this approach was predated by natural products. Many of our early drugs came from plant sources or, later on, from *Streptomyces* or other microorganisms. **Table 3** is a nonexhaustive but representative list of natural products that were sources of drugs, discovered using a screening paradigm. In some cases, the knowledge of ‘traditional medicines’ and folklore contributed significantly to the nonrandom sourcing for the eventual isolation and purification of the natural product. These secondary metabolites are still having a significant impact on medical therapy today. There are anti-infective products (antibiotics and antifungals), as well as products for the treatment of

atherosclerosis. Mevinolin (also known as lovastatin) is a paradigm for very important treatments of dyslipidemias and atherosclerosis (i.e., HMG-CoA reductase inhibitors). There are also treatments for hypertension and angina. There is an expanding group of anticancer drugs, many of them based on original plant- or microorganism-derived secondary metabolites that exhibited cytotoxic activity in a number of tumor cell assays.

Finally, there are neurologics and immunosuppressives. The category of drugs comprising natural products and derivatives is extensive.

This sourcing of drugs from natural products has changed over the past 10–15 years, with increasing numbers of drugs coming from chemical libraries rather than from natural products. The reason for this is that over the last four decades, pharmaceutical companies and chemical companies have established significant inventories of small molecules. These inventories were not being exploited as potential sources of drugs because of the absence of broad-based, automated screening methods and biologically relevant assays. This changed dramatically in the last decade of the twentieth century. Today, one can come up with an extensive list of potential drug candidates arising from the screening of chemical libraries (Table 4), and this has become the basis for significant new technologies in the area of high-throughput screening (HTS) and combinatorial chemistry. So, how did one discover drugs in the past? To recapitulate, in large part, one did it by modifying the structure of known drugs or screening inventories of natural products.

With the advent of molecular biology in the late 1970s, proteins as therapeutics came onto the scene. While the list of protein-based drugs is not yet long, it is growing, and it represents a very important drug category (Table 5). These drugs are important not only from the point of view of medical therapy but also because of their economic impact. This particular list of 16 proteins represents currently over US \$7 billion in sales annually. These proteins are having a dramatic impact on our industry, and they are having a dramatic impact on patient therapy. The fourth approach to drug discovery, the modification of natural substrates, has had less success in yielding new drugs. Table 6 lists examples taken from research efforts at Parke-Davis. These include adenosine deaminase inhibitors, renin inhibitors, angiotensin receptor antagonists (a very large area of investment for many pharmaceutical research laboratories over the past 15 years), and cholecystokinin B (CCK-B) receptor antagonists. While this is another valid approach for drug discovery, one subset of this approach – peptidomimetics as drugs – continues to be characterized by poor pharmacokinetics and delivery-related challenges.

There was an interesting statement in the May 1991 issue of *Business Week*: “The old way – screening thousands of chemicals in a hit-or-miss search – is inefficient and wastes time. That is why it can now cost more than \$200 million to bring one drug to market.” One can debate that statement, but it is still the case that “Boger and others like him are carrying the flag for a new wave of research and development, often called rational drug design.” While rational drug

Table 5 Biologicals (rDNA based)

<i>Drug</i>	<i>Indication</i>
Human growth hormone	Growth
tPA	Thrombolysis

- CCK-B receptor antagonists

design includes the approach of modifying natural substrates, it is most often thought of as structure-based and computer-aided drug design. This approach to drug discovery started in the early 1980s, and is now a significant skill set in many pharmaceutical companies.

The factor that drives this approach is specificity. The driving force for many in drug discovery is to find agents that are more specific for a particular molecular target because that should enhance efficacy, reduce side effects, and yield an agent that is unique to a particular pathology. However, the task is very daunting, as one can see by going down the list of molecular targets in [Table 7](#) and thinking about the implications. For instance, we are good at finding specific inhibitors of enzymes, but there are multiple classes, and even within classes there are isozymes. Similarly, with receptors, there are isoforms. Receptors are found not only in the plasma membrane but in the cytoplasm and nucleus as well. Ion channels have multiple subunits. The complications go on and on. There is, in each one of these vasopressin categories of potential molecular targets, a multiplicity of targets with, in many cases, a lot of similarity between those targets in terms of binding sites for the putative antagonist or modulator. There can be active sites and allosteric binding sites. Also, one must not forget other important carriers or modifiers to drugs in the biological milieu: serum proteins, cytochrome P-450 modification, glucuronidation, and sulfation, to name but a few. These all represent important factors in this aspect of specificity, and they must be taken into account in the area of rational drug design.

How, then, does one achieve specificity? Specificity is fundamentally molecular information. One builds in specificity by understanding the 'rules of recognition' between one molecule and another through the use of hydrogen bonds, ionic interactions, hydrophobic interactions, and, of course, the overall three-dimensional structure. If one analyzes our success in drug discovery so far, one can derive a 'specificity scale' ([Table 8](#)) relating the complexity of molecular targets to the amount of information one can incorporate into a potential inhibitor or binding agent. We have

Table 7 Specificity, The Holy Grail

-
- Enzymes: multiple classes, isozymes
 - Receptors: multiple classes, isoforms
 - Ion channels: multiple subunits and classes
 - Intracellular transducers: kinases, phosphatases, G proteins, lipases, prenylases, ion-binding proteins
 - Transcription factors
 - DNA: nucleus, mitochondria, coding/noncoding, binding proteins, repair enzymes
 - RNA: cytosolic (rRNA), nuclear (tRNA, mRNA)
 - Serum proteins, cytochrome P-450s, glucuronidation/sulfation

been most successful with enzymes in terms of specificity. On the other hand, transcription complexes, including transcription factors, activators, and repressors, often seven to nine components along with DNA in the milieu, represent a much more daunting challenge. They may very well epitomize the most complicated state so far for targets of drug discovery. In the middle tier are nucleic acids, antibodies, dimeric domain recognition kinds of targets, signaling proteins, and receptors. If one reviews the past decade of drug discovery progress, it parallels the specificity scale.

The challenge, then, is to build specificity into our drugs through the use of molecular information. Using proteins as drugs is one way of enhancing specificity (**Table 9**). By definition, you can build a lot of information into a large molecule, even if it has repeating units of amide bonds or, with an oligonucleotide, repeating units of phosphodiester bonds. There are related approaches to enhance specificity that have yielded to drug discovery in the last decade, such as antisense and ribozymes targeting RNA or DNA in the nucleus or the cytosol, having exquisite specificity for a particular sequence. Thus, structure-based drug design is increasing in importance as an approach to drug discovery by enhancing drug specificity.

However, one should not forget that nature has already shown us that small molecules can have sufficient information built into them to achieve specificity as drugs. Consider steroids, leukotrienes, nucleosides, mononucleotides, catecholamines, excitatory amino acids, or even something as simple as acetylcholine (**Table 10**). These are small-molecule messengers acting extra- or intracellularly, or both, and represent drugs with legitimate specificity in terms of their molecular targets. One does not necessarily need a molecular weight of 3000 in a drug to achieve appropriate selectivity or specificity. This provides continuing impetus that small molecules can, through various approaches, yield the degree of selectivity necessary to achieve the goal of being a drug for a particular disease. In spite of the efficacy of some of these newer approaches, however, one cannot forget screening because screening has

advanced in speed, quality, and in diversity of sources and targets. Over the past several years, the industry has moved from high throughput to ultrahigh throughput. Today, one can set up a screen and go through a library of 100 000 compounds in a day, even with a cell-based screen. Rapid, automated, high-volume techniques and instrumentation, as well as novel sources for diversity, biological as well as chemical, and the generation of molecular targets through biotechnology, have revolutionized screening as an important paradigm in drug discovery.

In a parallel fashion, another translational technology for enhancing screening as a drug discovery tool is the explosion in diversity of screening sources, namely through combinatorial libraries. Many libraries have been generated, including those for peptides, monoclonal antibodies, oligosaccharides, and oligonucleotides. Over the past several years, an additional focus on small-molecule combinatorial chemistry has generated multiple additions of low molecular weight 'organic' compound libraries for HTS. Rapid generation of libraries is becoming routine. Indeed, we are finding certain chemotypes recurring as frequent 'hits' (Table 11).

The power of this technology has been brought to bear, together with modification of natural substrate or structure-based drug design in this decade. If one looks back to 1990, one can find hardly any small molecules that bound to G protein-coupled receptors (GPCRs) and demonstrated appropriate agonist or antagonist activity. Within the past decade, this field has exploded, in large part because of these technologies. For example, some early work from the GlaxoSmithKline laboratories used ligand-based modification to generate cyclopeptides based on the natural ligand vasopressin, and GlaxoSmithKline scientists were able to generate nanomolar level antagonists targeting the V₁ receptor.¹¹⁰⁵ Concomitantly, scientists at Otsuka Pharmaceuticals in Japan were actually screening a chemical library for V₁ antagonists, and came up with a compound with lower molecular weight than the cyclopeptide on which the GlaxoSmithKline scientists had been working.¹¹⁰⁶ (Scientists at Yamanouchi had a parallel effort.) This represented an early example of a small molecule derived via screening that could act as an appropriate antagonist with reasonable selectivity, in comparison with the rather complicated natural ligand vasopressin or the cyclopeptides from GlaxoSmithKline.

In a similar fashion, discoveries were made regarding the related receptor oxytocin (OT). It had been shown that meperidine bound the OT receptor extremely weakly, but by modifying the structure, scientists generated a small molecule, where the natural ligand was a cyclopeptide for the OT receptor and, again, exhibited quite high selectivity.¹¹⁰⁷ A natural product that had high selectivity for the OT receptor was found by screening natural product libraries in parallel research efforts at Merck.¹¹⁰⁸

The relatively huge investment in angiotensin (AT) receptor antagonists really began from an initial disclosure of a Takeda Pharmaceutical patent on a small molecule that was based on a two-amino-acid component structure of angiotensin. From this came a plethora of AT₁ receptor antagonists from many laboratories. At Parke-Davis a different receptor was being screened, and it was found that a structurally unrelated low molecular weight compound was quite specific for the AT₂ receptor. This turned out to be an interesting lead in terms of understanding the pharmacology of the AT₂ receptor relative to AT₁. Again, the screening of small molecules in combination with structure-based design approaches generated interesting potential drug candidates.

Some laboratories (e.g., Parke-Davis) took a reductionist approach to looking for low molecular weight compounds that would act as agonists or antagonists at the CCK receptors. This approach led to the conclusion that Trp and Phe

were the two key recognition sites in a portion of the natural ligand for binding to the CCK-B receptor. Parke-Davis scientists were able to generate a 2 nM level antagonist at the CCK-B receptor; this agent eventually went into clinical trials (Figure 1).^{1109,1110} This agent has a molecular weight of about 600, which is, of course, much smaller than the natural ligand itself. This is an approach exemplifying structure-based ligand modification to generate a drug candidate. In a parallel fashion, drug discovery efforts generated low molecular weight (benzodiazepine-like) CCK-B antagonists at several other pharmaceutical companies. These molecules came out of a screening approach based on finding a natural product, asperlicin, that exhibited high binding to the CCK-B receptor. So, a combination of approaches yielded potential drugs that were evaluated in the clinic against several disease states.

Structure-based, computer-aided drug design, the last category of the five approaches, is an area of increasing investment for many groups in drug discovery. Table 12 lists four examples from the Parke-Davis laboratories. These approaches illustrate the increasing importance of structure-based drug design in the area of drug discovery. The HIV-1 aspartyl protease and its dimeric structure has really become the first major success story of this approach. We learned much in the early 1980s about inhibitors of a related aspartyl protease, renin, and applied this science to the first generation of inhibitors of HIV-1 protease. The industry now has a number of inhibitors that are approved, on the market, and being used, representing a significant advance in the treatment of HIV-positive individuals. Many share a key element, which is a hydroxyl group that is involved in the binding site to water and aspartic acid in the recognition site of the dimeric aspartyl protease. They are elongated peptide-like structures, and represent a challenge to achieving acceptable bioavailability and drug-drug interactions.

Second-generation agents (Figure 2) are under clinical evaluation, and represent smaller versions of the first-generation molecules, or even radically modified or divergent forms. The drug PNU 140690 was disclosed from Pharmacia and Upjohn, and has little structural relationship to the other inhibitors. It does have a close structural relationship to a series discovered through parallel research in the Parke-Davis laboratories. These compounds represent the combination of structure-based drug design with an iterative cycle of modeling, synthesis, testing, and crystallography, to come up with improvements in specificity, selectivity, and bioavailability.

In early 1992, through screening of the compound library at Parke-Davis, a particular pyrone, shown in Figure 3, was found to be a very modest, but nonetheless reproducible, inhibitor of HIV-1 protease. It was selective for HIV protease over other aspartyl proteases and related families. An iterative design cycle was begun, consisting of the structure

	CCK-B binding (K_i)
Asp-Tyr(SO ₃ H)-Met-Gly-Trp-Met-Asp-Phe (CCK 26-33)	3 nM
Trp-Met-Asp-Phe (CCK 30-33)	3 nM
Boc-Trp-Phe	70 μ M

determination (using x-ray crystallography, co-crystallization, and soaking experiments with additional inhibitors), modeling, additional chemistry to modify the structure based on what had been learned from modeling, and looking at the requisite biochemistry and enzymology of the agents. This cycle was repeated to determine the appropriate binding of these molecules in the three-dimensional structure using structure-based drug design. Parke-Davis scientists were able to alter this relatively simple pyrone with a series of modifications, principally in the P2 and P2-prime sites, which very rapidly led to nanomolar level inhibitors and represented legitimate advances in nonpeptide-based HIV protease inhibitors. This has now been extended to an interesting molecule whose IC_{50} is 5 nM. It has a different structure, but nonetheless binds in the active site, does not use water within the binding site, and is quite different from the first- and second-generation inhibitors.¹¹¹ This demonstrates the power of structure-based drug design, coming originally from a screening approach, to yield a drug candidate lead.

In the muscarinic area, quite a different approach was taken. Parke-Davis scientists had determined that there was a three-point pharmacophore based on a series of agonists that to bind to the M_1 receptor; however, the pharmacophore analysis had gotten bogged down at that point. As this had been modeled within the GPCR model, where it was binding was considered, and the other muscarinic receptors (M_2 or M_5) were looked at in terms of differences in the transmembrane region. It was hypothesized that, not unlike retinal binding to rhodopsin, if this very small agonist was binding in the transmembrane region, this simple pharmacophore could be elongated (much like retinal is extended) to generate something that would have greater specificity. In fact, the basic pharmacophore was able to be extended to produce a molecule that has much greater specificity for the central versus the peripheral muscarinic receptors. This compound is now under investigation in clinical studies targeting the treatment of patients with Alzheimer's disease (AD). Thus, this original idea of molecular modeling and pharmacophore analysis is in fact a validated approach to drug discovery.

How will we discover drugs in the future? While I believe that all five categories will be used (see Table 9), modification of known drugs (validated chemotypes) will probably be of decreasing interest over time. The integration

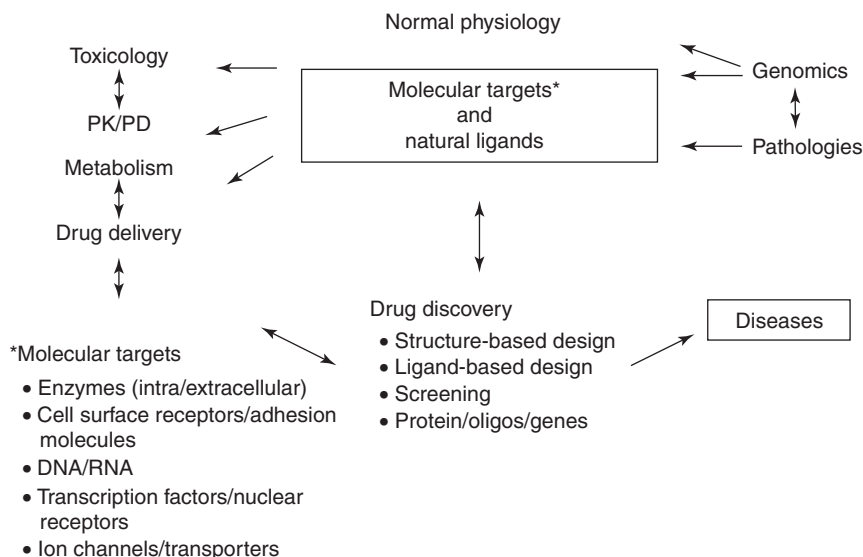

Figure 4 New drug discovery paradigm.

of the other four approaches will become more important in the future application of drug discovery. The targets are manifold. Table 4 is a highly simplistic representation of the source of molecular targets that we currently spend so much time identifying and finding antagonists or agonists for. They can be extracellular, membrane-based receptors, nuclear receptors, or cytosolic signaling receptors. There is a growing list of targets, such as serine/threonine kinases, tyrosine kinases, and phosphatases, as well as a significant interest in the cell cycle and understanding the regulatory enzymes involved in the cycle. Probably the newest frontier is transcription factors, where many are working on ways of finding agents that would regulate gene expression and affect some particular pathological state.

The technological foci for drug discovery, shown in Figure 4, are organized for a specific reason. The technologies of HTS, and biomolecular structure determination, molecular modeling, and combinatorial chemistry are having a dramatic impact on drug discovery today, and will continue to become even more important in the future. However, they are very dependent on finding the molecular targets. A veritable avalanche of new targets will be coming via genomics and proteomics. Concomitantly, there is the critical aspect of managing the plethora of data that emerge as a result of these data-rich approaches, and understanding from those data which are the truths that are important in the drug discovery process.

Genomics is a simple word, but it envelops many components that are more than simply the genetic map, or the physical map, or even the gene sequence. The advances made in these three areas during the last decade has been striking, and much more rapid than any of us would have imagined. In many ways, gene sequencing, as well as the maps, will probably be well in hand for a number of genomes in the next couple of years. However, gene function and gene regulation represent a formidable challenge for drug discovery and the molecular sciences. Genetic functional analysis has a number of tools already available, and there will undoubtedly be more to come. Transgenics, knockouts, and gene replacement are very powerful technologies in our understanding of gene function. Antisense is already available, and of course the two-hybrid technique is being exploited in many laboratories investigating gene function. Synteny, differential display, and single-nucleotide polymorphism (SNP) analyses are additional tools. Nonetheless, this is a bottleneck, and improvements are needed before we can move forward from sequence to function and understand regulation. The challenges in this field will include sequencing, informatics, multiple species, and the fact that it is not only the natural state that we are interested in but the pathological state as well. We need to understand function and mutations relevant to the pathological state. The output is the genetic footprint. Disease phenotype is what we are interested in. It has implications for diagnostics as well as for drug discovery, and it has implications down the road for preventive medicine and gene therapy.

Proteomics is also an important area. In fact, this is here and now, not in the future. Two-dimensional gel electrophoresis, together with matrix-assisted laser desorption/ionization mass spectrometry and image analysis, is used to determine the output of genomics. This is an area of intense investment in many laboratories that must be included in the bioinformatics database that is being generated. This database will be used to help determine which targets are the appropriate ones for drug discovery or for diagnostics.

Lastly, there are some important components for which tools are slowly evolving. We need to optimize a drug candidate not only for selectivity but for bioavailability, toxicity, target organ selectivity, stability, and scalability. These are all legitimate and important components. We have drug class issues in drug discovery and development that act as guides for us, but nonetheless there are going to be discoveries unique to particular drug candidates. Small molecules continue to present difficulties with toxicity and bioavailability. Proteins have associated cost and delivery issues. Peptides have stability and bioavailability issues. Oligonucleotides often have the same class issues as proteins and peptides. Gene therapy certainly has to face the safety, delivery, and duration-of-effect issues.

What, then, are the future issues for drug discovery and development, given all of these technological foci? Determining the importance of the molecular targets is one such issue. For the next few years, we will continue to operate with a pretty tenuous linkage of molecular target to disease. In many cases, our molecular targets are hypothesized to be linked to a particular disease; we do not really determine this until we find inhibitors and take them to the clinic to see if they work. Also, the diseases we are facing today and tomorrow are more challenging than those that confronted us yesterday and the day before. Many are chronic diseases with multiple etiologic factors, and will probably require combination therapy – another complication to drug development. Of course, we will have novel toxicities. Finally, as we move further into the area of gene regulation, nuclear targets will represent additional complexities. The opportunities and the challenges will yield new drugs, combination therapies, and patient-specific treatments during the next decade.

2.12.2 Target Identification and Validation: Coupling Genotype to Phenotype

2.12.2.1 Introduction

There are three basic components necessary for drug discovery and lead identification: (1) targets, (2) screens, and (3) compounds. Each of these plays a pivotal role in the drug discovery process and, ultimately, the success of clinical trials. During the past 50 years there has been a paradigm shift in drug discovery (Figure 5), closely bound to the development of technology.¹ Initially, companies focused on the effects of putative therapeutics on whole-animal models to study pharmacology and efficacy. Later, tissue and cell cultures led to a refinement in pharmacological studies and in the number of screenings performed. More recent progress has involved advanced purification and molecular biology technologies, which in the past 10 years has led to a wholesale move toward selecting molecular targets to screen. Most recently, there has been an explosion of genomics, proteomics, bioinformatics, and information technologies, which will significantly increase the potential to identify and validate novel disease genes and their corresponding pathways, representing enormous value to the pharmaceutical industry. Of the approximately 80 000–150 000 human genes, there may be as many as 10 000 potential ‘drugable’ targets, that is, amenable to low-molecular-weight molecules (enzymes, receptors, ion channels, hormone receptors, etc.) for treatment of the most common multifactorial diseases.²

In addition to these novel disease targets, there are a significant number of partially validated targets associated with major human diseases, such as nuclear receptors and GPCRs.^{3–6} These targets, combined with genomic technologies (including genetics, bioinformatics, data mining, and structural informatics) and compounds, offer potential for very selective drugs of the future. The best example of these are the so-called selective estrogen receptor modulators (SERMs), where a compound can be agonist in one cell type and an antagonist in another. In addition, one needs to consider that multifactorial diseases themselves have overlap (e.g., diabetes and obesity) and that single genes

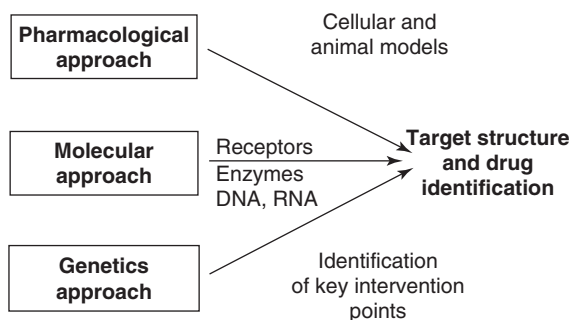

Figure 5 There has been a paradigm shift in the drug discovery process during the past 50 years. The pharmacological approach has used whole-animal and cellular models to discover drugs. Later, molecular targets were employed to screen for drugs. Most recently, genetics and genomics opened up a whole new approach to discover disease genes and pathways, creating enormous potential value to the pharmaceutical industry.

(e.g., chloride transporter) can be involved in the etiology of multiple diseases (e.g., cystic fibrosis, asthma, pancreatitis, and male infertility).

The process of ‘gene to drug’ will accelerate with the ever-increasing volumes of new genetic information, with increased biological understanding of how the pathways are connected, and with the technologies that make it possible for each step of the process to be completed more quickly and efficiently. The purpose of this chapter is to demonstrate to the reader which technologies can be used to identify gene targets and validate them to speed up the quality of drug discovery by providing an increased number of better validated targets.

2.12.2.2 Target Identification/Validation

2.12.2.2.1 Genomics

Thomas Roderick⁷ coined the term ‘genomics’ in 1986. Genomics describes the study of a genome by molecular means distinct from traditional genetic approaches. The term is derived from ‘genome,’ a fusion of the words ‘gene’ and ‘chromosome,’ and is used to describe the complete collection of genes possessed by an organism.⁸

Genomics as currently practiced can be categorized as follows:

- (1) structural genomics;
- (2) functional genomics; and
- (3) pharmacogenomics.

Genomics technologies, which are already more or less impacting drug discovery identification and validation, are as follows:

- positional cloning and association genetics;
- genome sequencing (humans, animals, and pathogens);
- expressed sequence tag (EST) sequencing;
- derivation of full-length cDNAs and their sequences (gene families);
- microarrays of oligonucleotides and cDNAs (chips);
- subtractive hybridization;
- differential display;
- antisense;
- in situ hybridization;
- serial amplification of gene expression (SAGE);
- Taq-Man/quantitative polymerase chain reaction (PCR);
- protein–protein interactions using yeast 2 hybrid techniques;
- reporter genes (e.g., green fluorescent proteins, GFPs);
- transgenic/knockout animals (especially mice);
- model organisms (e.g., yeast, *Caenorhabditis elegans*, *Drosophila*, zebrafish, mouse, and rat);
- two-dimensional gel electrophoresis; and
- databases (bioinformatics, structural informatics).

Presently, this collection of genomics technologies for drug discovery is used in variations or combinations of two approaches:

- (1) the ‘top-down’ approach, which uses positional cloning and association genetics to identify disease-related genes; and
- (2) the ‘bottom-up’ approach, which predominately focuses on the random sequencing of cDNA and an inference of the function of the protein product based on sequence similarity to well-characterized genes and proteins.

In the future, emerging technologies will further impact drug discovery target identification and validation. These are:

- integrated databases (structure to function);
- single-nucleotide polymorphism (SNP) identification/scoring in high-throughput mode;
- second-generation solid phase DNA arrays;
- single-cell PCR;

- laser capture;
- protein–protein and protein–compound interactions;
- in-solution RNA profiling technologies (liquid arrays);
- phage display libraries (antibodies);
- genetic suppressor elements (GSEs);
- zinc finger proteins;
- conditional knockout mice (Cre/lox);
- inducible promoters in vitro and in vivo (e.g., tetracycline on/off systems);
- gene trapping;
- biochips;
- microfluidics;
- in vitro and in vivo imaging;
- fiber optics;
- structures of membrane-bound proteins (e.g., GPCRs); and
- RNA as targets for infectious diseases

The approach of this chapter is to first describe the existing technologies and their impact on target identification and validation and then to turn to many of the emerging technologies to predict their potential impact on drug discovery.

2.12.2.2.1.1 Genetic mapping and positional cloning

One of the objectives of the Human Genome Project was to advance genetic mapping from the restriction fragment length polymorphisms used initially to microsatellite markers.⁹ The accent now is on biallelic marker systems using SNPs, which are very prevalent within the genome.^{10–12} This has allowed the cloning of many single genes causing human diseases inherited in a simple Mendelian fashion. Some of the most important genes controlling hypertension have been found by studying the molecular genetics of blood pressure variation in this way.^{13,14} Recently, the ATP-binding cassette transporter 1 (ABC-1) was positionally cloned using Tangiers patients.¹⁵ The ABC-1 transporter is involved in cholesterol efflux, and is linked to low levels of high-density lipoprotein and coronary heart disease. Furthermore, the implication of potassium channels in long-QT syndrome and epilepsy by their positional cloning¹⁶ simply reinforces the power of genetics for biochemical understanding and for providing a genetic validation of a biological hypothesis.^{17,18} It also illustrates that the comprehensive study of a gene family (e.g., potassium or sodium channels) by using data mining and genomics approaches in concert with genetic mapping is a paradigm for the study of more complex traits. It may also be a rapid way to find new ‘genetically validated targets’ for drug intervention.¹⁹ Unfortunately, until now the unraveling of the biochemical pathology of common diseases in humans based on an understanding of complex, polygenic disease traits by the cloning of relevant genes has been somewhat disappointing. A number of linkages have been made for several diseases such as diabetes, obesity, asthma, and cognition, but very few of the genes have been uncovered.^{20–22}

Positional cloning has also been used to isolate mouse genes, which cause Mendelian diseases in this species. Several of these genes have been instructive regarding similar human syndromes.²³ One of the best studied is leptin and the leptin receptor for obesity derived from analysis of ob/db mice.²⁴ The mouse has certainly become one of the most useful models of polygenic models of human disorders. Often, the phenotypic characteristics are strikingly similar to those for the analogous human disorder.²⁵ Generally, the predicted amino acid sequence homology ranges from approximately 80% to near-identity. Therefore, in some cases it is likely that drugs that interact with these gene targets using the mouse as the model will have similar physiological effects in humans, although the downstream signaling (e.g., the interleukin-4 receptor) may not be identical in the mouse and human. However, the mouse can be ‘humanized’ (i.e., the mouse gene exchanged for the human in a knockout/knock-in approach).²⁵

In addition, there has been conserved organization of the gene order and relative position in the genomes of human and mouse for large chromosomal regions. This is known as synteny, and the ability to jump between human and mouse genetic information based on synteny is of great advantage in gene identification and localization.²⁶ The fundamental approach is to use conserved synteny to determine if the same genomic region is functionally involved in a disease phenotype in both human populations and the mouse.²⁷ If the same chromosomal region is involved, then it is generally easier to identify the gene in the mouse than in humans, and one can use mutation detection/analysis to determine if the same gene is involved in human polygenic disease. “Although several textbooks and other reference works give a correct definition, the term synteny nowadays is often used to refer to gene loci in different organisms located on a chromosomal region of common evolutionary ancestry,”²⁸ as just described. Originally, the term ‘synteny’ (or ‘syntenic’) referred to

gene loci on the same chromosome regardless of whether or not they are genetically linked by classical linkage analysis. However, molecular biologists inappropriately use the original definition of synteny and its etymological derivation, especially as this term is still needed to refer to genes located on the same chromosome. “Correct terms exist: ‘paralogous’ for genes that arose from a common ancestor gene within one species and ‘orthologous’ for the same gene in different species.”²⁸ To make a long story short, the process described above as synteny should be described as orthologous. Nonetheless, the approach is very powerful. Gene mapping of complex disorders has resulted in the identification of a number of cases that are clearly orthologous between humans and the mouse.^{28,29} Furthermore, the similarity in gene structure between the mouse and humans is very high. This homology extends from the exon–intron organization of many genes to the predicted amino acid sequence of the gene products.²⁰

One of the best examples of the power of genetics has been provided by studies on Alzheimer’s disease (AD). All of the genes known to be involved unequivocally were found by positional cloning or by association genetics (i.e., the amyloid precursor protein (APP), presenilin (PS1 and PS2), and ApoE4 genes).³⁰ There is unlikely to be a pharmaceutical or biotechnology company investigating AD, which does not have a drug discovery program, based on one or other of these genes. It is also worth mentioning that access to transgenic animals is still an important component of the drug discovery process (see Section 2.12.8.2). In AD, for example, various transgenic mice strains have been used to examine amyloid deposition. Genetic crosses have shown that ApoE4 and transforming growth factor β 1 influence amyloid deposition, and that the presenilins act synergistically with APP in the development of the pathology. Some of these animals may become models for the disease, with utility for finding compounds that modify the pathology of plaque formation.³¹ None of this would have been possible without having the genes in hand. The lesson is simple: genetics is the key to mechanism; mechanism is the key to therapeutic discovery; and therefore genetics is the key to therapeutic discovery.

2.12.2.2.1.2 Genome sequencing

At present, the greatest impact of genomic research has come from DNA sequencing projects.³² One of the first applications of genomics to drug discovery was through the development of EST sequencing and the creation of large gene sequence databases.²⁰ This approach to generating large-scale DNA sequence information was carried out by Craig Venter at TIGR and by Human Genome Sciences. These initiatives and the development of commercial EST sequence databases and data-mining tools by companies such as Human Genome Sciences and Incyte have had a rapid effect on drug discovery, by giving pharmaceutical companies access to potentially new targets related to previously known ones. The best (and most obvious) examples are targets such as GPCRs, steroid hormone receptors, ion channels, proteases, and enzymes. The value from this approach is considerable, although it is not always clear what disease a relative of a known target might be useful for without further validation. Any antagonist or agonist of such a target can, however, be used in animals to rationalize or validate the protein as a target for intervention in a particular disease. A reasonable example would be the development of a novel serotonin receptor of active small molecules working via a new receptor.³³ Evidence of the anticipated impact on drug discovery of such sequence databases is clear from the rapid take-up of subscriptions to the Incyte (ESTs) and Celera (genomic) databases by many of the major pharmaceutical companies.

Nowhere has comprehensive genome sequencing had more effect than in bacterial genetics. The sequences of well over 20 different bacterial genomes are now available.^{34–36} The information derived from the comparisons of these sequences within and between microorganisms and with eukaryotic sequences is truly changing microbiology. The greatest benefit from these approaches comes from being able to examine homologies and gene organization across whole genomes at once. For target identification this has obvious benefits, because if the potential target is conserved among target organisms but not in the host, then it may be a reasonable target. This is not new thinking; the development of dihydrofolate reductase inhibitors and some antifungal drugs followed exactly the same rationale. In the bacterial studies, procedures such as ‘signature-tagged mutagenesis’ and in vivo expression methods are tying together genomic and biological data to reveal genes permissive for virulence and pathogenicity.^{37,38} Recently, the smallest of all genomes, that of *Mycoplasma genitalium*, which has only 517 genes, was sequenced at Celera. The big surprise was that only 300 of the 517 genes are essential for the life of the organism, and 103 of these 300 essential genes are of unknown function.³⁹ This tells us what is in store for the future when we consider that the human genome is estimated to have some 80 000–150 000 genes. Still, this approach will be valid for higher eukaryotes too, once the genomes of the mouse and humans have been fully sequenced and assembled.⁴⁰

Genomics is made possible through the large-scale DNA sequencing efforts of many public and private organizations, including the Human Genome Project, which has provided major impetus to the discovery of the genome and information technologies.⁹ This international program to determine the complete DNA sequence (3000 million bases) was first completed in draft form in 2001 through the combined efforts of a very large number of researchers.^{180,1112}

It is fair to say that early estimates were, in many respects, roughly on target, though conservative. (It was originally projected that by 2002 a comprehensive working draft (90% of the genome) should be expected, and that by 2003 the entire sequence would be completed.⁴¹) Recently, chromosome 22 has been completely sequenced as part of the Human Genome Project. Chromosome 22 is especially rich in genes. While sequencing the 33 million base pair chromosome, Dunham *et al.*⁴² identified 679 genes, 55% of which were previously unknown. Approximately, 35 diseases have been linked to mutations in chromosome 22. These include immune system diseases, congenital heart disease, and schizophrenia, among others.

The purpose of structural genomics is to discover, map, and sequence genetic elements. Annotation of the sequence with the gene structures is achieved by a combination of computational analysis (predictive and homology-based¹⁰⁹⁰) and experimental confirmation by cDNA sequencing. Recently, a website entitled the 'Genome Channel'¹⁰⁹¹ has offered a road atlas for finding genes by zooming in from chromosomes to annotated DNA sequences. Furthermore, the site links the user to sequencing centers for 24 organisms, including humans, mice, and *Escherichia coli*, to name a few. Detecting homologies between newly defined gene products and proteins of known function helps to postulate biochemical functions for them, which can then be tested. Establishing the association of specific genes with disease phenotypes by mutation screening, particularly for monogenic/single disorders, and provides further assistance in defining the functions of some gene products, as well as helping to establish the cause of the disease. As our knowledge of gene sequences and sequence variation (*see* Section 2.12.2.3) in populations increases, we will pinpoint more and more of the genes and proteins that are important in common, complex diseases.⁴¹ In addition, by comparing corresponding genomic sequences (comparative genomics) in different species (man, mouse, chicken, zebrafish, *Drosophila*, *C. elegans*, yeast, *E. coli*) regions that have been highly conserved during evolution can be identified, many of which reflect conserved functions, such as gene regulation. These approaches promise to greatly accelerate our interpretation of the human genome sequence.⁴³ In the future, it will be possible to understand how specific sequences regulate the expression of genes in the genome.

2.12.2.2.1.3 Functional genomics

Complete sequencing of the human genome is really only the beginning. As the geneticist Eric Lander has characterized, "Molecular and cell biologists are still only approaching a phase of development of their discipline reached by chemists 100 years ago, when the periodic table was first described."⁴⁴ We still need to link the genetic makeup of an organism (its genotype) to its form and function (its phenotype) and how the environment effects them. To that end, whereas structural genomics seeks to discover, map, and sequence these genetic elements, functional genomics is the discipline that seeks to assign function to genetic elements. A more detailed understanding of the function of the human genome will be achieved as we identify sequences that control gene expression. In recent years, our knowledge of gene sequence has increased massively, principally due to large-scale cDNA and genome sequencing programs.⁴¹ The availability of this information resource has fueled efforts to develop ways of analyzing gene expression systematically, and as a result there are a range of approaches available that allow parallel analysis of a large number of genes. These tools can provide a comprehensive view of the genes expressed in samples of tissue and even individual cells, and in so doing will advance our understanding of biochemical pathways and the functional roles of novel genes. Most importantly, genome sequences will provide the foundation for a new era of experimental and computational biology, providing the essential resources for future study.

Genes are sections of genomic DNA that encode proteins. They are copied into messenger RNA (transcribed), and it is this mRNA that carries the genetic code from the nucleus to the cytoplasm to direct protein synthesis. It is thought that there are 80 000–150 000 genes in the genome of humans and other mammals. In each cell, only a portion of these genes is active at any one time, thought to be in the region of 10 000–15 000. The expression of these genes instructs the protein synthetic machinery to produce a specific set of proteins that are required for the cell to perform its normal functional role. Certain genes are expressed in all cells all of the time, and encode so-called housekeeping proteins, whereas others are expressed only in certain cell types and/or at certain times. It is these latter proteins that give a cell its unique structural and functional characteristics and, ultimately, make one cell different from another. However, the complement of genes expressed by a cell is not a fixed entity, and there are many genes whose expression can be induced or reduced as required. This provides the flexibility in biological systems to respond and adapt to different stimuli, whether they are part of the normal development and homeostatic processes, or a response to injury, disease, or drug treatment. As the transcription status of a biological system reflects its physiological status, the ability to study the complement of genes expressing its 'signature' and the abundance of their mRNAs in a tissue or cell will ultimately provide a powerful insight into their biochemistry and function.⁴⁵

However, there are certain inherent difficulties in the study of gene expression. Unlike DNA, which is essentially the same in all cells of an individual, there can be enormous variation in the abundance and distribution of a particular

mRNA species between cells. Some genes are highly expressed, that is, their mRNA is abundant (>1000 copies per cell), whereas other genes are weakly expressed, with their transcripts present at only a few copies per cell. In addition, because most tissues are composed of distinct cell populations, an mRNA, which is only present in one of those cell types, perhaps already at low levels, becomes even rarer when the RNA is extracted from that tissue as it is diluted in the RNA derived from nonexpressing cells. It is also becoming increasingly apparent that for many genes the transcripts can exist in different forms, so-called alternative splice variants. These splice variants allow an even greater diversity in the complement of proteins that can be generated from the genetic code, but adds another level of complexity to the analysis of gene expression. Furthermore, these mutations of splice sites can lead to reduction of a biological function (e.g., sodium channels¹⁹).

Knowledge of the sequence of a novel gene alone usually provides few clues as to the functional role of the protein that it encodes. However, sequence information can be used for further characterization of the gene, and is a good starting point in defining its expression. If the expression of a gene is limited to certain tissues or cell types or is changed during disease, then we can begin to postulate and focus in on those sites. Likewise, if the expression of other genes maps to the same cells, we can begin to understand which protein complex or biochemical pathway the gene product might interact with.⁴⁵

The other major goal of RNA expression profiling has always been the identification of genes that are expressed at different levels between one system or experimental paradigm and another. Knowledge of these genes not only sheds light on the biochemical events underlying the change but in some cases also provides a list of potentially interesting genes, such as which genes are expressed in malignant but not in normal cells. For these reasons, expression profiling will help in our understanding gene function and the biology of complex systems, as well as in many aspects of the drug discovery process.⁴⁵

The past several years have witnessed the development of a plethora of new methodologies to study gene expression:

- subtractive hybridization⁴⁶;
- subtractive PCR^{47,1092};
- differential display⁴⁸;
- in situ PCR^{49,50};
- single-cell PCR^{51,52};
- SAGE^{53,1093};
- DNA chips^{54,1094}; and
- microarrays.^{55,1095}

These all can provide insights into the complement of genes expressed in a particular system. However, what really makes the difference and ultimately determines how widely they are used in the future is the detail of how they work and quality of data they yield. We also need to distinguish what is important in (1) the discovery of novel genes (e.g., subtractive hybridization, subtractive PCR, and SAGE), (2) large-volume RNA profiling of known genes (e.g., PCR, DNA chips, and microarrays), and (3) the expression of genes occurring in a subcellular region of a tissue (in situ hybridization and in situ PCR).

The main issues in expression profiling are therefore as follows:

- Novel versus known genes – is the objective to discover novel genes or to evaluate known genes in a high-throughput mode?
- Localization within a tissue – can the technology distinguish expression at the cellular level within a tissue?
- Sensitivity – can the method detect low-abundance sequences and how much starting material (mRNA) is required?
- Specificity – is the assay highly specific for the transcript of interest?
- Quantification – how accurately can the technique measure mRNA abundance?
- Reproducibility – how robust is the methodology?
- Coverage – how many transcripts can be analyzed at once and does the approach have the ability to detect previously uncharacterized genes?
- Redundancy – how often is each transcript sampled? (Some systems have the potential to analyze the same mRNA a number of times, therefore increasing the complexity of the data.)
- False positives – how often do things appear to be differentially expressed but turn out not to be?
- Scale of analysis – is the approach amenable to HTS data output and does the assay give results that are easy to interpret?
- Cost – how much does it cost for the initial investment and cost/gene/assay?

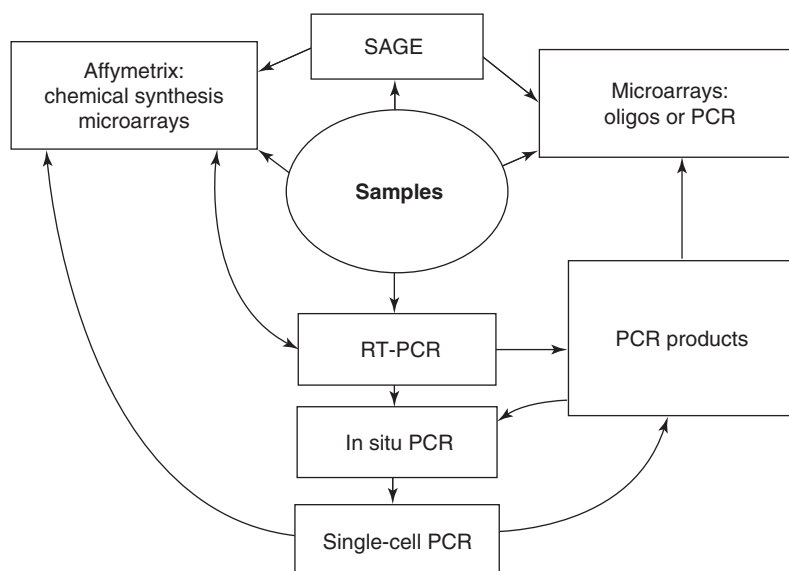

Figure 6 Numerous RNA-profiling technologies are available, which are interdependent. Depending on the question posed, the experimenter may choose to use a specific combination of technologies. SAGE provides the best approach to discover and quantify novel and known genes. However, the throughput is lower than that of Affymetrix DNA chips or microarrays. Affymetrix chips are convenient to use, but cost more than microarrays and are less flexible for following up on genes of interest in a high-throughput mode. PCR microarrays are more sensitive than oligomicroarrays; however, PCR microarrays cannot detect splice variants such as oligomicroarrays.

Depending on the question the experimenter is asking, one or a combination of these technologies will be needed. This is outlined in [Figure 6](#), which illustrates that any one RNA sample may require use of one of these technologies (e.g., SAGE) to detect novel and known genes at low throughput and thereafter require the use of DNA chips or arrays for high-volume throughput and reproducibility testing. In situ hybridization, in situ PCR, and/or single-cell PCR would test the most important genes identified and validated by chips and arrays.

As mentioned above, though the methodologies have been widely used in the research environment, not all are applicable for high-throughput, routine analysis of gene expression. However, one approach above all others shows most promise in this respect, and is now driving the field of expression profiling: the use of DNA chips and microarrays. Although there are some important differences between DNA chips and microarrays, both work by a similar mechanism (i.e., the hybridization of complex mixtures of DNA or RNA to complementary DNA probes immobilized on a solid surface). DNA chips are presently available through one company, Affymetrix who pioneered this approach.⁵⁴ Affymetrix makes microchips of overlapping oligonucleotides ('oligos') available, representing sequences from thousands of genes. These chips can also be used to measure sequence variation and for the detection of SNPs. One of the perceived disadvantages of the Affymetrix format is its lack of flexibility.

Other chips are available from Synteni and elsewhere that comprise cDNAs or oligos⁵⁶ covalently attached to a solid phase. Oligos have an advantage over cDNAs in that oligos can detect splice variants, which can make very interesting drug targets. These chips can be interrogated by using fluorescently labeled hybridization probes, and the results displayed by color integration. By far the most impressive use of such chips has been carried out in Pat Brown's laboratory at Stanford University. Two elegant experiments have been done. The first compared the pattern of yeast gene expression during sporulation,⁵⁵ and the second looked at the expression of a subset of the genes expressed in fibroblasts after serum starvation and activation. The take-home messages from these beautiful experiments are as follows: the reproducibility of the biology of the system is crucial for consistent results; (2) the need for sophisticated pattern matching is absolutely essential for data interpretation.^{57,58} The function of an unknown gene based on its pattern of expression under different conditions is compared with a known data set. From the experiments reported above, the functions of many 'unknown' yeast and human genes were suggested, based on their expression characteristics relative to known sets such as cell cycle genes or genes involved in DNA replication. Now that the *C. elegans* and *Drosophila* genomes are completely sequenced,⁵⁹ it will not be long before worm and fly gene chips are available for the same kind of experiments. In fact, the first signs are here; White *et al.*⁶⁰ published an elegant paper on

the microarray analysis of *Drosophila* development during metamorphosis, where both known and novel pathways were assigned to metamorphosis.

So what role will RNA profiling have in the future of drug discovery? High-throughput RNA expression profiling is still in its infancy, and clearly much remains to be done to apply it for maximum impact on drug discovery. We have yet to identify all human genes and, to an even greater extent, those of model organisms (the mouse and rat). There is also considerable room for improvement on the basic technologies and methodology. Judging by the number of recent small start-up companies and new emerging industries (e.g., Motorola, HP, Corning, and IBM), one of the most active areas of genomics is the use of microarrays for the large-scale measurement of gene expression.⁶¹ In addition, second-generation technologies (e.g., Corning, Third Wave Technologies, Luminex, Curagen, and QuantumDot) are underway. These second-generation technologies are expected to (1) design better surfaces, (2) produce more sensitive dyes, and (3) develop totally new approaches such as the in-solution assays (liquid arrays), e.g., ‘Invader’ technology,¹⁰⁹⁶ or by exploiting electronics by designing digital micromirrors.⁶²

The ability to examine the expression of all or a large number of genes at once will provide new insights into the biology of disease, such as in the identification of the differences between normal and cancerous cells,⁶³ as well as gene expression during aging⁶⁴ or during HIV infection.⁶⁵ Undoubtedly, there must be gene products that play a crucial role in metastasis that could be targeted by drug treatment. However, working out which those are, which cancers they are active in, and their specificity to tumor cells should now be possible. Golub *et al.*⁶³ have demonstrated that molecular classification of cancer types could be predicted by gene expression profiling. Furthermore, this information can be integrated into the genetics of cancer and histopathology building a three-dimensional model.⁶⁶ Companies such as LifeSpan provide disease and normal tissue banks of more than 1 million samples or a ‘customized approach’ to genomics. In addition, Velculescu *et al.*⁶⁷ released approximately 3.5 million SAGE transcript tags from normal and diseased tissues.

Indeed, expression profiling is a powerful research tool for analyzing the differences between tumor types and for distinguishing between tumors, which up to now have been classified based on their morphological characteristics and presence of a few markers. The recently developed technology ‘laser capture’ should also help to better define tumor types in vivo in combination with chips⁶⁸ and how they relate to mouse xenografts, not to forget just defining differences or reliable markers in tumor cell lines for in vivo studies. Another example is the case of genetic disorders that have a complex multigenic basis but that can be mapped back to so-called quantitative trait loci. It has been recently demonstrated how microarrays can be used alongside classical genetic approaches to identify the genes underlying the defect.⁶⁹

Genome-wide arrays also have more direct application in drug discovery. It is possible to use them to profile the effect of various drugs or compounds on gene expression so as to assess their potential efficacy or side effects.⁷⁰ It is also possible to compare the profile of genes expressed in a deletion mutant compared to wild type. If the deletion mutant has a ‘desirable’ phenotype it may be possible to phenocopy the deletion by finding a chemical inhibitor of the protein product or the deleted gene using whole-scale gene expression screening. In addition, the expression of the gene can be induced or repressed in vitro or in vivo, and then its responsiveness characterized by RNA profiling. Such examples are (1) tetracycline on/off,⁷¹ (2) GSEs,^{72,73} (3) zinc finger proteins,⁷⁴ (4) gene trapping,⁸ and (5) correcting the mutation using chimeric RNA–DNA oligonucleotides.^{75–83}

Still, one of the major problems with the simultaneous analysis of the expression of thousands of genes is the sheer weight of data generated (see Section 2.12.3.4). Not only is it essential to link the result from each DNA probe back to the parent sequence; it is also necessary to decide which result is significant, and then generate a list of ‘interesting genes.’ If, say, 300 genes change in a given experimental paradigm, due to experimental error, which ones are interesting and worthy of follow-up and what do they tell us about what is really happening in the system under investigation? How also can one store and integrate this enormous amount of data over years of experimentation and even compare data generated by different laboratories? These problems will undoubtedly remain for sometime; however, too much data is better than not enough. While clearly there is much to do on many fronts, it is almost certainly true to say that expression profiling will help revolutionize the way in which we perform biological investigations in the future. RNA profiling, together with the many other genomic technologies, promises to have a big impact on the process of drug discovery.⁴⁵

Recently, three new approaches to validate target genes have been developed:

- GSEs;
- zinc finger proteins; and
- gene trapping.

GSE (retroviral based) is a unique technology to rapidly discover and validate novel pharmaceutical targets, as well as design therapeutic agents that regulate the function of these targets in specific disease processes.^{72,73} Presently, there are four start-up biotechnology companies dominating the field: Arcaris (formerly Ventana), Rigel Pharmaceuticals, Genetica, and PPD. GSE technology is based on the rapid creation of high-titer helper-free recombinant retroviruses capable of infecting nearly any higher eukaryotic cell type.⁸⁴ Novel in its conception and application, this technology facilitates both target and drug discovery in diseases previously resistant to standard approaches. Unlike traditional small-molecule screening approaches, which can underrepresent a given library, the GSE technology delivers highly complex ‘expression libraries’ into target cells where each cell contains unique information. This information is decoded to synthesize a single peptide or antisense RNA, which interacts with potential targets within the cell. By examining the specific physiological effect of the introduced molecule, the peptide or antisense RNA capable of changing cellular physiology in a desired manner is obtained, and the essential link to identifying a target is made.^{85–87} To date these studies have been primarily in oncology and virology.^{88,89} Other fields of immediate potential use include antimicrobials, neurosciences, immunology and transplantation, and cardiovascular and metabolic diseases.

Zinc finger proteins are DNA-binding proteins that mediate the expression, replication, modification, and repair of genes. Pabo and Pavletich⁷⁴ solved and published the first crystal structure of a zinc finger protein bound to its cognate DNA sequence – perhaps the seminal publication in the field of zinc finger protein rational design. The discovery of zinc finger DNA-binding proteins and the rules by which they recognize their cognate genetic sequences (up to 18 base pairs) has made possible the rational design of novel transcription factors that can recognize any gene or DNA sequence. The start-up biotechnology company Sangamo¹⁰⁹⁷ has combined these protein–DNA recognition rules with powerful selection methods to allow the rapid generation of proteins that recognize and bind to target DNA sequences. Sangamo can rationally design zinc finger proteins that selectively up- or down-regulate the expression of target genes and that in vitro or in vivo.

Traditional gene-trapping approaches, in which genes are randomly disrupted with DNA elements inserted throughout the genome, have been used to generate large numbers of mutant organisms for genetic analysis. Recent modifications of gene-trapping methods and their increased use in mammalian systems are likely to result in a wealth of new information on gene function. Various trapping strategies allow genes to be segregated based on criteria such as the specific subcellular location of an encoded protein, the tissue expression profile, or responsiveness to specific stimuli. Genome-wide gene-trapping strategies, which integrate gene discovery and expression profiling, can be applied in a massively parallel format to produce living assays for drug discovery.⁸ Gene trapping was originally described in bacteria.^{90,91} Since then it has been used in many other organisms, including plants,⁹² *C. elegans*,⁹³ *Drosophila*,⁹⁴ mouse embryonic stem cells,⁹⁵ zebrafish,⁹⁶ and yeast.⁹⁷

Gene trapping provides another approach to help validate targets for modern drug discovery efforts, including bioassays to sort through the large number of potentially active compounds. The need for an integrated technology platform to discover genes, pathways, and corresponding drug candidates drives the development of novel approaches, termed ‘gene-to-screen genomics.’ Gene trapping/tagging strategies may provide such a link to drug discovery.⁹⁸

2.12.2.2.1.4 Model organisms

“Connecting genotype to phenotype is not always straightforward.”⁹⁹ Thus, the power of less complex organisms for understanding the function of unknown human genes derives from the essential homology of many genes from different organisms.²⁰ Examples are transcription factors, neurotransmitters and their receptors, growth factors, signaling molecules, apoptosis factors, GPCRs, and membrane trafficking and secretion factors.^{100,101} During the past several years, a great deal of work, much of it in yeast, has identified a network of proteins, constituting ‘checkpoints’ of cell cycle regulation. One has been linked to the hereditary disease Li–Fraumeni syndrome, which leaves patients prone to developing multiple forms of cancer.¹⁰² Yeast genetic screening has also been used to identify mammalian nonreceptor modulators of G-protein signaling.¹⁰³ Yeast screening has resulted in the identification of novel biochemical pathways based on a biochemical genomics approach to identify genes by the activity of their products.¹⁰⁴ Bikker *et al.*⁴ took the global approach by developing an array of 6144 individual yeast strains, each containing a different yeast open reading frame (ORF) fused to a reporter gene/purification tool, glutathione *S*-transferase (GST), as originally described by Simonsen and Lodish.¹⁰⁵ The strains were grown in defined pools, GST–ORFs purified, and activities of each strain identified after deconvoluting. This approach yielded three novel enzyme activities.

The nematode *C. elegans* is a principal organism for the analysis of the development and function of the nervous system. This is because it is especially amenable to molecular genetic analysis.¹⁰⁶ Its complete cell lineage and nervous system connectivity have been mapped.¹⁰⁷ *C. elegans* is the first animal for which the complete genome has been sequenced.⁵⁹ Since the *C. elegans* genome was sequenced, an enormous amount of novel functions have been discovered

and linked to more complex organisms, including humans.^{106,107–111} For example, presenilins and APP of *C. elegans* are particularly attractive given the ease of making animals lacking the function of a single gene either genetically or by using RNA interference.¹⁰⁸ Subsequently, suppressor mutations are selected in genes in the same pathway and their DNA sequence is determined. One of the most impressive examples of this approach is in studies of apoptosis, where the major components of apoptosis pathway are conserved in *C. elegans* and mammalian cells.¹¹² Another example is the identification that p66^{shc} expands life by enhancing resistance to environmental stresses such as ultraviolet light and reactive oxygen species.¹¹³ p66^{shc} knockout mice show the same phenotype as the worms.¹¹⁴ Taking a global two-hybrid approach, Walhout *et al.*¹¹⁵ have functionally annotated 100 uncharacterized gene products starting with 27 proteins of known function. The most striking set of interactions involves the Rb tumor suppressor protein complex, which regulates gene expression during the cell cycle. The screens yielded 10 interacting proteins, comprising three known interactors and seven known to interact with other proteins of the complex. This publication showed that by having the total sequence of *C. elegans*, it is now possible on a genome-wide scale to map the interacting proteins and enhance our understanding of molecular mechanisms both in this organism and in humans. The model organism *Drosophila* has also provided insights into mammalian signaling pathways and their importance in development,¹¹⁶ and will continue to, especially since its genome has been sequenced.¹¹⁷ Both yeast and *C. elegans* are used for drug screening, both at the expression level using chips and at the organism level, and by creating strains designed (by phenotype and genotype) for screening compounds against a particular biochemical step or pathway.^{20,118} Andreatic *et al.*¹¹⁹ demonstrated that cocaine sensitization could be demonstrated in '*Drosophila*'. Cocaine sensitization was absent in all but the mutant fly strains missing the *timeless* gene. This implication of a subset of the circadian clock genes in drug responsiveness echoes recent suggestions that at least some of these genes may act in more places and in more functions than just the brain's clock.¹²⁰

Over the past 40 years, the mouse has certainly become one of the most useful models of human genetic disease. Multiple single-gene and polygenic models of human disorders have been characterized in the mouse. Often the phenotypic characteristics are strikingly similar to that for the analogous human disorder.^{121–126} The mouse has many advantages over other model organisms for these kinds of studies:

- The relatively short generation time facilitates breeding approaches for genetic linkage studies and accelerates the development of genetic models.²⁵
- The genetic understanding and characterization of the genome in the mouse is second only to humans in depth and breadth among mammalian species. The ability to genetically map in the mouse¹⁰⁹⁸ and then clone single-gene disorders rapidly with emerging technologies will allow the economical identification of the polygenes controlling quantitative traits.^{27,127,128} There are numerous examples of single-gene mutations in the mouse having virtually identical phenotypes in humans, and cloning of the mouse gene has led to cloning of the human homolog.¹²⁹
- The sequence/structural homology between humans and the mouse is quite good. The mouse can be used in parallel with human studies for gene discovery and target identification. This parallel approach can be used for the identification of disease genes (and putative targets or pathways involved in pathogenesis) as well for as phenotypic characterization. As described above (*see* Section 2.12.2.2.1.3), the fundamental approach is to use conserved 'synteny' (or orthology) to determine if the same genomic region is functionally involved in a disease phenotype in both human populations and the mouse. If the same chromosomal region is involved, then it is generally easier to identify the gene in the mouse than in humans, and one can use mutation detection/analysis to determine if the same gene is involved in human polygenic disease.
- The ability to make transgenic and gene-targeted deletions or substitutions both classical and conditional is now a mature technology for the mouse.^{121,122,130,131}
- The ability to phenotype the mouse is becoming more precise and achievable despite the small size of the animal (e.g., magnetic resonance imaging^{132–134}). The ability to phenotype is of utmost importance. This is why obesity was one of the first therapeutic indications tackled. Many obesity genes have been identified in the mouse during recent years.^{135–138} Therefore, the mouse is emerging as one of the premier models for disease gene discovery and utility in the drug discovery process.

The premise of genomics in drug discovery and validation is that genes found to be associated with disease are prevalidated. If mutations in these genes affect the disease risk or phenotype, then we know that these genes are likely to be important in the disease process.²⁵ However, the identification of an association between a gene mutation or sequence variant and a disease trait does not necessarily imply that the gene, or its protein product, is a 'druggable' target. In addition, one must not forget the role of the environment even in well-controlled genetic backgrounds. Crabbe *et al.*¹³⁹ have demonstrated that subtle environmental differences between laboratories could have a significant effect on behavioral measures in inbred and mutant mouse strains, not to mention nongenomic transmission across

generations of maternal behavior and stress responses found recently in rats.¹⁴⁰ Thus, these genes may simply be important players in the disease process, and an understanding of their role may serve to provide access to the pathways involved in disease and, ultimately, the appropriate targets for therapeutic intervention. Still, the utility of the mouse extends beyond being just a gene discovery tool to provide prevalidated targets. It can also be used for the development of animal models, and the testing of compounds in specifically constructed transgenic and knockout strains to further define the target and pathway of a therapeutic compound.²⁵

2.12.2.2.2 Proteomics

The proteome of an organism is the complete set of proteins that it can produce. Proteomics is the study of the proteome of cells, tissues, or organisms, including the interaction of the proteome with the environment, where the proteomic signature is the subset of proteins whose alteration in expression is characteristic of a response to a defined condition or genetic change.¹⁴¹ Besides genomics there is also a great interest in working at the genome level with polypeptides or proteomics. In fact, proteomics is one of the most important 'postgenomic' approaches to understanding gene function. Given that the mRNA concentration in any cell and the amount of cognate protein are not always correlated (owing to the differential kinetics of both types of molecule), there may be a good deal of new information to be found by studying proteins in this way. It is especially interesting because post-transcriptional regulation of gene expression is a common phenomenon in higher organisms.¹⁴²

Presently, proteomics primarily uses two-dimensional gel electrophoresis to profile gene expression and cell responses at the protein level. Protein spots are identified by matrix-assisted laser desorption/ionization (MALDI) and tandem mass spectrometry techniques, using proteomics for target identification, mechanism of action studies, and for comparing compounds based on the similarity of proteomic signatures they elicit. Probably the most advanced organization taking the global approach to proteomics, especially in higher eukaryotes, is UCB, which, along with Incyte, has launched an integrated proteomics database that includes information about how mRNA expression levels correlated to protein expression levels. Large Scale Biology has focused on establishing databases of hundreds of compounds, effects on rat liver, and Proteome has established excellent yeast (*Candida albicans*) and *C. elegans* protein databases. To date, the bottleneck with the two-dimensional gel approach has not been running the gels but rather sensitivity, the quantitative detection of spots, as well as the time needed to 'gel gaze,' (i.e., to image the gel so as to identify differences from gel to gel). To that end, Genomic Solutions¹⁰⁹⁹ has assembled and developed a complete suite of technologies and systems for protein characterization-based electrophoretic separation, which includes a fairly sophisticated and proven imaging technology that permits the identification, quantification, and comparison of two-dimensional separations. Other companies, such as Amersham/NycoMed, are developing second-generation dyes and stains to increase the sensitivity of the detection of the spots in the two-dimensional gels. Ruedi Abersold at the University of Washington is developing an approach whereby he is miniaturizing classical electrophoresis technologies in a way that is compatible with automation.¹⁴³

As described in a recent *Nature* survey¹⁴³ on the prospects of proteomics, the now well-established two-dimensional gel approach has many limitations. Still, the development of the more advanced technologies (e.g., protein chip, antibody, and protein array) that may deliver fast and parallel quantitative analyses of protein distributions has a way to go (e.g., see below – Phyllos, CIPHERgen, CAT, Morphosys, etc.).

One such technology that is further advanced comes from CIPHERgen Biosystems. The ProteinChip system that CIPHERgen uses is the patented SELDI (surface-enhanced laser desorption/ionization) ProteinChip technology, to rapidly perform the separation, detection, and analysis of proteins at the femtomole level directly from biological samples. The ProteinChip system can replace and complement a wide range of traditional analytical methods, which not only are more time-consuming but require specialized scientific expertise. ProteinChip arrays allow the researcher to affinity capture minute quantities of proteins via specific surface chemistries. Each aluminum chip contains eight individual chemically treated spots for sample application; this setup facilitates simultaneous analysis of multiple samples. A colored hydrophobic coating retains samples on the spots and simultaneously allows for quick identification of chip type. Typically, a few microliters of sample applied on the ProteinChip array yields sufficient protein for analysis with the ProteinChip Reader. Designed with proprietary technology, the Reader takes advantage of modern time-of-flight (TOF) mass spectrometry to determine the precise molecular weight of multiple proteins from a native biological sample. To enhance the appearance and facilitate interpretation of the protein mass data collected, ProteinChip software offers various presentation formats or 'data views.' Recently, Garvin *et al.*¹⁴⁴ has employed MALDI-TOF to detect mutations in gene products by tagging a PCR fragment after *in vitro* transcription and translation. The process can be multiplexed, and is amenable to automation, providing an efficient high-throughput means for mutation discovery and genetic profiling.

To bring functional genomics to the protein arena, Phyllos has pioneered PROfusion technology, whereby proteins are covalently tagged to the mRNA.¹⁴⁵ Using this technology, both synthetic and natural libraries (representing the repertoire of proteins naturally expressed in a given cell type or tissue source) have been constructed. Due to the in vitro nature of library construction, Phyllos libraries are the largest described to date, up to 1014 in size. From a library of such molecules, one can select for a protein function of choice, with the benefit that the genetic material is linked to the protein for subsequent PCR amplification, enrichment, and, ultimately, identification.¹⁴⁶ The key to the Phyllos technology is in the development of a puromycin-containing DNA linker that is ligated to RNA prior to translation. Puromycin is an antibiotic that mimics the aminoacyl end of tRNA, and acts as a translation inhibitor by entering the ribosomal A site and accepting the nascent peptide, a process catalyzed by the peptidyltransferase activity of the ribosome. To accomplish this, puromycin is chemically protected and attached to controlled-pore glass for automated synthesis of a DNA linker consisting of 5'-dA27-dC-dC-P (P is puromycin). The PROfusion molecule represents a very unique entity with characteristics that can be utilized for the production of protein chips. The presence of the RNA tail offers a convenient appendage for anchoring the antibody mimic onto a microarray similar to a DNA chip. Since the technical aspects of chemical attachment of nucleic acids to a chip surface have been well worked out, one can take advantage of this reagent and convert an existing DNA chip to a protein chip through the hybridization of a pool of PROfusion molecules. Because the PROfusion molecule has a unique genetic tag associated with it, specific capture probes can be designed and a specific DNA chip produced for the pool of molecules. Upon hybridization of the PROfusion molecule to the DNA chip, the surface now displays the covalently attached peptide or protein portion of the PROfusion molecule.¹⁴⁵ Furthermore, by using a drug or protein physically anchored either to a solid support or to a chemical ligand (e.g., biotin), the PROfusion cellular library is passed over the target and the interacting proteins eluted and amplified for the next round. Such a methodology brings with it a number of significant advantages. Direct selection of interacting proteins from a cellular PROfusion library through rounds of selection and amplification allows for the identification of both low-abundance and low-affinity targets.¹⁴⁵

Other approaches to identifying interactions of chemical entities with target peptide libraries are described by Kay *et al.*¹⁴⁷ These libraries can be generated on pins, beads, or in solution, expressed in bacteria attached to phage or synthesized in vitro off of polysomes. However, the complexities only range from 108 to 1010. A method of quantitative analysis of complex protein mixtures using isotope-coded affinity tags has been reported by Gygi *et al.*¹⁴⁸ The method is based on a class of new chemical reagents, termed isotope-coded affinity tags, and tandem mass spectrometry. The first successful attempt using this technology was comparing yeast using various sources of carbon to grow on. The future will show if this technology can be used to quantitatively compare global protein expression in other cell types and tissues.

Another protein chip approach has been demonstrated by Bieri *et al.*¹⁴⁹ by which they were able to develop a novel assay of GPCR activity that employs immobilized receptors on a solid surface and in a functional form. To achieve this, the authors used a specific labeling procedure to biotinylate the carbohydrate located in the glycosylated extracellular domain region of the rhodopsin receptor, a G protein-coupled receptor responsible for dim light detection in animals. This in turn reacts with the surface on the chip using lithography. Rhodopsin interacts with a specific Gα subunit, transducin, to activate cyclic GMP phosphodiesterase, and thus can activate the immobilized rhodopsin on the sensor chip with the flash of light, which is monitored by receptor activation through the release of transducin from the chip surface.

Monoclonal antibodies raised against purified native protein have typically been used as the optimal reagent for many research purposes. However, creation of this type of reagent is both costly and time-consuming. A more rapid and cost-effective alternative, but one that is less attractive, is the use of polyclonal antibodies to the target protein or peptides derived from the target. These reagents are generally inferior to monoclonal antibodies with respect to affinity of binding, specificity of reactivity, and utility. An attractive alternative to these approaches is phage display antibody technology (e.g., marketed by Cambridge Antibody Technologies, Morphosys, Dyax, and UbiSys). Phage display antibodies are at least equal, and in most cases superior, to monoclonal and polyclonal antibody approaches with regard to affinity of interaction, selectivity of reactivity, utility in a variety of applications, speed of antibody generation, and numbers of antibodies that can be generated. Moreover, single-chain variable regions with affinities and selectivity equal to monoclonal antibodies can be generated in a period of weeks (as opposed to months). As a result, it is possible to generate much larger numbers of antibodies in the same period of time. It has become clear that there is a critical need for potent and selective antibodies for target identification and validation.

2.12.2.2.3 Pharmacogenetics and pharmacogenomics

The intimate connection between drug discovery and genetic information has only become widely recognized in recent years, primarily due to the fact that the two disciplines were perceived to have nothing in common. The discovery of

SNPs has united the two fields.^{150,151} SNPs are the predominant basis of genetic variability in the human population. SNPs will provide the genetic markers for the next era in human genetics.⁴¹ Particular advantages of using SNPs over other types of genetic marker include the relative ease of automating SNP typing assays for cheap, robust, large-scale genotyping, and the abundance of SNPs throughout the genome. Comparisons of the DNA sequence between two individuals reveals, on average, one nucleotide difference for every 1000 base pairs.¹⁵² This frequency increases as more samples are included in the comparison.^{153,154} The majority of changes are single-base substitutions (i.e., SNPs), although deletions and insertions of one or more bases are also observed. Heritable sequence variations arise as a result of a copying error, or damage and misrepair of DNA that results in alteration of the genomic sequence in germ cells. As a result, the changes are passed on in subsequent generations, and the two or more alternatives at a particular position, or locus, become established in the population. Further diversity arises as a result of recombination between homologous segments of chromosomes during meiosis.^{41,155}

In the early days of the genomics revolution, when a comprehensive working draft of the human genome was yet to be completed, and when 'The Human Pharmacogenetics Consortium' was still in the beginning stages of identifying hundreds of thousands of common sequence variants (SNPs), no one could accurately predict the outcome. In addition, private companies were assembling SNP databases (e.g., Celera, Curagen, Genset, Orchid, Phenogenex, etc.) in partnership with larger pharmaceutical companies. In the interim, pharmaceutical companies limited their analysis of SNPs to selected candidate genes (pharmacogenetics) to identify associations between polymorphism and drug.⁴¹ Today, though many of the original companies who pioneered the area have faded away, these data are used regularly by academia and the entire healthcare industry in support of various R&D tasks.

The goals for pharmacogenetics/pharmacogenomics are to associate human sequence polymorphisms with drug metabolism, adverse events, and therapeutic efficacy. Defining such associations will help decrease drug development costs, optimize selection of clinical trial participants, and increase patient benefit. Retrospective analysis and rescue of nonconclusive studies as well as determination of the genetic causality of disease are also possible. In addition, the ascertainment of DNA samples from clinical trial patients will facilitate the discovery and validation of targets using linkage disequilibrium and association methods. Candidate genes identified by positional cloning in the mouse can be followed up by using the appropriate patient's DNA to confirm the importance of the gene(s) in disease.¹⁵⁶

Pharmacogenetics covers a new aspect of drug development, which will apply to discovery, development, and marketed programs. To date, benchmarking-type information is not available. However, it is expected to play an important role in the near future for many pharmaceutical companies. To associate polymorphism with drug effects, DNA samples are obtained from both drug- and placebo-treated patients. To associate polymorphism with disease risk (i.e., target discovery/validation), DNA from patients affected by a specific disease should be compared with DNA from patients unaffected by that disease. The latter group may be affected with other disease states; hence, patient DNA samples from one trial may serve as controls in another, provided that they have been obtained from a population of comparable ethnic composition. In effect, supplementary DNA collection will not be necessary to effect properly controlled pharmacogenetic and target validation studies. Moreover, power simulations suggest that sample sizes obtained during standard clinical trials are sufficient to detect genetic association, given that the genetic effect is of sufficient magnitude and the allele is not rare.¹⁵⁷ Drugs can be more accurately profiled for drug-drug interactions by looking at the metabolism of the compound by the known enzymes and variants thereof. If a drug is found to have limited efficacy but virtually no (or very mild) side effects, then it may also be possible to subtype the patients by genotype so as to distinguish responders from nonresponders. Similarly, if a compound has a potentially severe but very rare side effect (but good efficacy), then genotyping may be used to identify patients in whom a side effect is more likely.

Polymorphisms in coding, regulatory, intronic, untranslated, and other regions can all cause variation in gene activity. Cytochrome P-450 2D6 gene is an example of a coding polymorphism that modulates the activity of the gene and thereby influences a drug's metabolism rate. Finally, there is growing activity in profiling compounds for toxicity by using SNP and expression chip 'signatures.'¹⁵⁸ Good examples of genotyping currently being done in clinical trials include measuring ApoE4 genotypes for AD and measuring polymorphism in various cytochrome P-450 genes. As the general population to be treated is genetically diverse, the statistical considerations of these approaches are complex. However, recent examples show that in outbred populations, linkage disequilibrium can be regularly observed at distances of 25 kb from a causative polymorphism. Hence, a useful genome-wide SNP map will be composed of 300 000 evenly distributed SNPs localized to specific points in the genome.¹⁵⁹ Given the sample sizes available in clinical trials, the rare allele in a biallelic SNP must be present in a population at a frequency greater than 15%. The 'Holy Grail' is undoubtedly a genome-wide 'SNP' map by which correlation of SNP haplotypes with drug-person phenotypes will be made. From a commercial perspective, there will be a trade-off between marketing a drug in a subset of the population and prescribing it for everyone with the disease. Diagnostics

will go hand in hand with pharmacogenetic/pharmacogenomic testing.²⁰ Presently, there are numerous start-up companies developing technologies to score SNPs in a very high-throughput mode to meet the needs of pharmacogenetics and, in the future, pharmacogenomics. These technologies include mass spectrometry and DNA arrays to fiber-optic arrays.¹⁵⁹ For more information, see the websites of the following companies: Third Wave Technologies, Kiva Genetics, Hexagen, CuraGen, GeneTrace, Sequenom, Orchid, PE, RapidGene/Chiroscience, Affymetrix, Nanogen, Illumina, Renaissance Pharmaceuticals, Varigenics, Celera, PPGx, and Sangamo, among others. It is safe to say that profiling humans by genotyping will become part of drug development in the future; it is simply a question of when.²⁰

2.12.2.2.4 Bioinformatics/structural informatics/chemi-informatics

Bioinformatics encompasses the acquisition, storage, and analysis of information obtained from biological systems. The information is derived primarily from genomics (genomic and EST DNA sequences, RNA profiling, and proteomics) and HTS.¹⁶⁰ Structural informatics refers to the acquisition, storage, and analysis of structural genomics data, especially that from whole genomes (i.e., genomes that have been totally sequenced, such as those of microbes, yeast, and *C. elegans*).^{161,162} “High level protein expression systems, robotic crystallization, cryogenic crystal handling, x-ray area detectors, high field NMR [nuclear magnetic resonance] spectrometers, tunable synchrotron radiation sources and high performance computing have together catapulted structural biology from an esoteric niche to biological mainstream.”¹⁶² The next step is to integrate the bioinformatics and structural informatics data. There are both private (Inpharmatica) and public (Structural Research Consortium¹¹⁰⁰) initiatives underway. As described above in the introduction, defining SERMs by using the three-dimensional structure of the estrogen receptor, combining expression profiling (chips) to specific cell types (both in vitro and in vivo), and linking the data to chemi-informatics will be most fruitful for drug discovery in the future.

Many pharmaceutical and biotechnology organizations have expressed the desire to create a means for tying together structural genomics and chemical information. A GenChem Database would map the gene sequence (actually, the protein sequence) to the chemical structure in a multidimensional matrix. Two dimensions would be the sequence and the chemical compounds, where each dimension could be examined for similar or dissimilar sequences or chemistry (technology for both exists). The additional dimensions are the different ways to fill in the two-dimensional chemistry versus sequence matrix. A simple method that has some predictability is to score sequences against chemicals for binding ability. You would then find, for example, that proteases cluster by sequence similarity and by inhibitor similarity. Another way to map the sequence-to-chemical matrix in terms of whether the chemical compound upregulates or downregulates the gene expression.

Researchers are now populating the multidimensional matrix with different types of data (ligand-binding affinities, expression changes, etc.). In addition, so-called digital organisms are already on the horizon. These are computer programs that self-replicate, mutate, and adapt by natural selection.¹⁶³ The availability of these comprehensive data sets will fundamentally change biomedical research and healthcare practices. Bioinformatics, structural informatics, and chemi-informatics seek to lead the industry into this new era by bringing genomic information to bear on drug discovery, development, and therapy (Figure 7).¹¹¹⁴ However, in the ‘postgenomics’ world, everyone has realized that bottlenecks exist in the measurement and analysis of data. Participants at the Genome V session held on October 6–10, 1999¹⁶⁴ discussed strategies for systematic information gathering on genes and proteins, how to improve pattern recognition algorithms, and ways of analyzing large data sets efficiently without the need for supercomputers. Many meetings such as this one were held to push genomics to the next stage of development.

Genomic studies have shown that many genes in mammals are present in four copies relative to metazoan genomes.¹⁶⁵ Individual members of these gene families have, in many cases, evolved to take on new functions. Nonetheless, there are numerous cases of functional redundancy in mammalian genomes. Therefore, drugs that target single proteins may induce the activity compensatory proteins that cancel the effect of the drug. Using sequence similarity algorithms, bioinformatics may identify targets likely to have functionally redundant gene relatives. Reports of multifunctional proteins have become increasingly common; for example, signal transduction pathways have proteins that act on multiple substrates. Drugs that inhibit multifunctional proteins may induce unwanted effects. Gene expression (RNA profiling) and protein expression (proteomics) tools reveal patterns that characterize the response of a cell or tissue to compounds.¹⁶⁰ When correlated to efficacy, toxicity, and biological mechanism, these patterns become powerful tools for generating testable hypotheses. In the future, when the databases are large and robust enough, such patterns will be diagnostic and will not require further experimental validation.

A common problem in large, multidimensional data sets is variable data quality. It is seldom possible to apply weighting factors in genomic data sets, and therefore early genomic data sets will be noisy. Key in identifying important

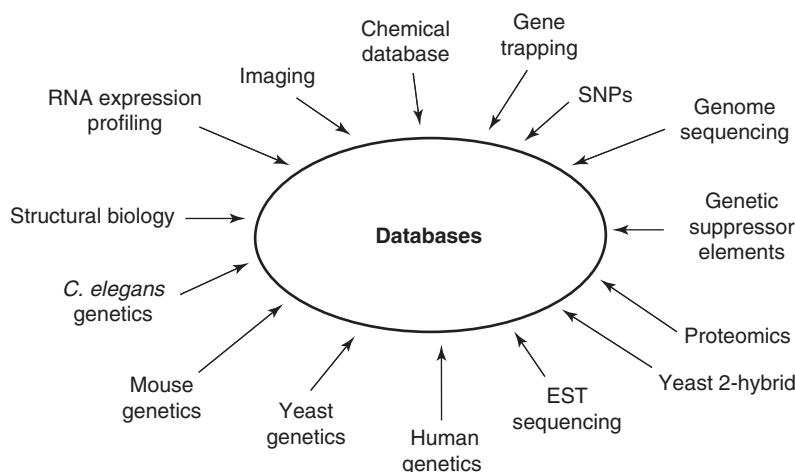

Figure 7 To capitalize on genomics, the most important task is the integration of databases. The plea is for better visualization and data-mining tools as well as better interfaces for databases.

signals in this background are larger experiments (increased sampling frequencies) and the creation of novel algorithms tuned to identify biologically significant patterns. A typical array experiment generates thousands of data points and creates serious challenges for storing and processing data. Informatics can include both 'tools' and 'analyzers.' Tools include software that operates arraying devices and performs image analysis of data from the readers, databases to hold and link information, and software to link data from individual clones to web databases. The DeRisi Lab has made available software for operating custom-built arrayers.¹¹⁰¹

The quality of image analysis programs is crucial for the accurate interpretation of signals for slides (chips) and filters. Yidong Chen (NHGRI) has developed a software image analysis package for slides and filters called 'deArray' that is available but not supported. Mark Boguski and colleagues have developed software to analyze and link databases such as Entrez and UniGene.⁵⁸ Software packages for commercial arrayers and chips are also available:

- Synteni (Gem Tools);
- Genomic Solutions (Visage Suite); and
- Silicon Genetics/Affymetrix (GeneSpring).

Additional development of algorithms for pattern recognition and cluster analysis of complex genomic data sets is key to the successful completion and integration of the complex data sets.¹⁶⁴

Most EST databases and all gene expression technologies are tuned to detect genes expressed at moderate-to-high levels (100 transcripts per cell or better). Genomic sequence, subtracted normalized cDNA libraries, and gene-finding sequence analysis algorithms will all help to identify genes expressed at low levels. Tools for highly parallel measurement of mRNA levels will require significant improvements before gene expression changes for rare transcripts can be reliably measured. Similar gains in technology will be required to approach comprehensive sampling of the proteome and molecular identification of its constituents. Presuming adequate quality control, genomic databases (sequence, polymorphism, gene expression, and proteomic) all increase in value as more data are deposited. To maximize the investment in genomics and bioinformatics, data must be stored in a series of central databases. These databases must be made available for browsing/mining to scientists and those interested in multiple therapeutic areas. Moreover, links between databases will facilitate the integration of information from multiple types of experiments and data. A current common theme in the pharmaceutical industry is the importance of information technology as a key support factor in drug discovery and development.

2.12.2.3 Conclusion

As the reader can see, there are two major approaches using numerous technologies to identify and validate targets: 'top-down' and 'bottom-up.' The choice of approach depends on the knowledge of the disease indication at hand, and in some cases both approaches may apply. Irrelevant of the approach or approaches, key is information technologies. The biggest concern of pharmaceutical companies in terms of drug discovery in the postgenomic era is data integration,

particularly as it relates to target validation. Their plea is for better visualization and data-mining tools as well as better interfaces for databases.¹⁶⁶ At present, there is no quick way to validate a target. Indeed, there is no universal definition of what a validated target is. All of the data being generated on a genome-wide scale must be captured and integrated with other data and with information derived by classical, hypothesis-driven biological experimentation to provide the picture from which completely new targets will emerge. This is a daunting bioinformatics challenge.¹⁶⁷ However, one thing is clear: target validation has become a term that is often used but not rigorously applied. The evolution of truly validated targets is a much slower process than target identification. At present, even large drug discovery organizations in the biggest pharmaceutical companies are not capable of producing more than a handful of well-validated targets each year.² Thus, the technologies described in this section must be applied such that the number of disease gene targets identified is rigorously validated to improve the quality of drug discovery while providing an increased number of better validated targets because even the best validated target does not guarantee lead compounds for development. Targets are only truly validated when a successful drug (not compound), working through that mechanism, has been found.

2.12.3 Functional Genomics

2.12.3.1 Introduction

A well-known paradigm in biology is that the function of a biological entity is closely linked to its physical structure. Based on this principle, predictions of biological function have been made by analyzing the structure of the organic molecules on which cells are constructed, such as DNA, RNA, and proteins. Since proteins provide the raw materials by which the superstructures of cells are constructed, it is reasonable to conclude that the amount, kind, and state of proteins found within a cell can be used to predict how a cell or organism will respond to chemicals, drugs, and the environment. Due to the hierarchical nature of genetic information (i.e., DNA to RNA to protein), it has been possible to approximate the structure and function of proteins by studying the information contained within the primary sequence and abundance of DNA and RNA, respectively. The massively parallel research methods used to determine the sequence and abundance of DNA and RNA are collectively called genomics. Functional genomics is the study of the DNA and RNA component of gene expression, coupled with biological and biochemical experimental data, to approximate the structure and function of proteins.¹⁶⁸

Since it is with proteins that drugs primarily interact, investigating the properties of proteins may lead to innovations in the treatment of human disease.¹⁶⁹ Nevertheless, due to the public resources now available through the efforts of the Human Genome Project, it is the study of the DNA and RNA component of gene expression that is most immediately available. For this reason, genomic methodologies allowing for the parallel characterization of DNA and RNA are now available and routinely practiced. Functional genomics now serves as a tool by which predictions of cellular function and potential drug–cell interaction can be made. Moreover, given the complexity of cellular signaling and regulatory pathways, numerous simultaneous measurements of the interdependent changes occurring during biological processes can be used to predict how drugs will affect these pathways.¹⁷⁰ This section will highlight the primary considerations given to the use of functional genomics as an approach to drug discovery. These are (1) the functional characterization of proteins, (2) the molecular pathways by which proteins provide complex cellular function, and (3) the use of genomic technologies to determine function and find drug targets.

2.12.3.2 Proteins: Structure and Function

All proteins rely on a linear arrangement of 20 amino acids to create the complicated structures that serve a cell or organism with such properties as locomotion, exchange of raw materials, and procreation. Although there are as many as 10.24 trillion combinations of these 20 amino acids for every 10 residues, based on the proteins sequenced to date many of the same sequences are observed. This observation suggests that very few protein sequences translate into proteins that can perform some function. In the hope of better understanding how certain protein sequences are selected over others we must explore the way in which proteins originate and improve the reproductive strength of the cell or organism – its evolutionary history.

The term ‘molecular evolution’ suggests that, just as species are selected based on their reproductive advantage, proteins are selected based on their ability to improve the health and well-being of a cell at the molecular level. The origin of all proteins starts with the production of an open reading frame through genetic alterations introduced by such events as point mutations, chromosomal rearrangements, and transposable elements. Therefore, it is the environment that provides the physical and functional constraint by which proteins are selected through the evolving genomes of the world. By relying on the form and fit of proteins to the molecules of the cellular microenvironment, such as nucleic

acids, ions, and other proteins, a subset of all possible protein sequences have been selected and modified to produce the diversified adaptations observed in nature.^{171–173} Moreover, it is this connectivity between sequence and function that provides biologists with the primer for unraveling the cellular role of proteins with unknown function ('orphans'). By observing the conservation of sequence elements, the profile of protein expression, and the effects of mutations, a crude approximation of the function of an orphan protein can be ascertained.^{174–179}

2.12.3.2.1 Molecular evolution

Since it is the function of the protein that keeps it from being lost during evolutionary selection, it is reasonable to conclude that any segment of a protein that has not been altered in sequence over great evolutionary distances must be performing some role in the health of the organism. The most abundant and extensively characterized class of proteins, first observed in prokaryotes, appears to be selected to perform a series of functions related to the maintenance of the cellular microenvironment (i.e., housekeeping genes). These consist mostly of proteins involved in energy metabolism, the biosynthesis of required amino and nucleic acids, transcription/translation, and the replication of the genome of the cell (Figure 8).¹⁸⁰

These fundamental requirements of all cells provide the backbone on which subsequent protein adaptations are made during evolution. As a consequence of speciation, many proteins are composites of functional units acquired during the fusion or rearrangement of ancestral genes. These small segments of protein sequence are called domains or modules.^{176,181,182} These modules are made up of independent segments (motifs), which provide the module with important contact and energetic attributes, allowing the module to perform a task. It has been suggested that during molecular evolution the exons containing these functional units are partially responsible for the shuffling of modules to create alternative composite proteins.^{175,176,182,183} Many environmental changes occur over small periods of evolutionary time, and therefore require adaptations on behalf of the organism to survive. Due to this immediate need in the production of proteins required to compensate for the environmental change, it is easy to see how the coordinated rearrangement of functional domains within a genome would arise. By using bioinformatic sequence alignment tools it has been possible to group these modules into classes, and demonstrate the conservation and expansion of shared modules during the course of evolution (Table 13).

Figure 8 Functional categories in eukaryotic proteomes. The classification categories were derived from functional classification systems, including the top-level biological function category of the Gene Ontology Project. Initial sequencing and analysis of the human genome.¹⁸⁰

^aNumber of unique domain arrangements/number of human proteins in which these arrangements are found. The second number is larger than the first because many proteins may share the same arrangement. For example, in the case 4/10, there are four unique arrangements of three-domain proteins with two domain types. In other words, the arrangement A-B-A has three domains but only two domain types, A and B, which have been conserved among humans, flies, worms, and yeasts. In humans there are 10 such proteins, hence the 4/10 designation.

Ancestral proteins of prokaryotic origin have given rise to eukaryotic proteins with new functions, such as the suspected transition of the bacterial FtsZ to the eukaryotic tubulin protein,¹⁷¹ as well as immunological proteins restricted to multicellular organisms. It is the molecular evolution of these ancestral genes that have given rise to a multitude of proteins that have diverse function yet can be categorized into families on the basis of their relatedness.

In addition, through genetic and biochemical experimentation of proteins with similar motifs and domains, the functions of these sequences are being identified and will provide us with even more information about proteins with undefined function. By the association of sequence and biochemical/biological data, the suggestion of biological function for proteins is possible.

2.12.3.2.2 Sequence and protein families

As stated previously, the proteins selected by molecular evolution are a subset of all possible proteins, and can be categorized into families (Table 14). It is the sequence similarity of DNA, as well as the protein, that serves as the measure of evolutionary distance, and perhaps suggests altered or new protein function.

Through the use of bioinformatic tools, as well as the extensive amount of sequence data available in public databases, it is now becoming a common practice to investigate the relationships between the protein sequence of a gene and to classify it in a specific protein family. Comparing the protein and DNA sequence of novel proteins with other proteins of known function and similar structure, we are able to predict biochemical or biological properties based on previously collected data on these family members.^{174–176,181–184} An important caveat and difficulty with this process is that many proteins in higher organisms have evolved through the fusion of the functional domains of existing proteins, and are a composite of more than one protein ancestral family (Figure 9).

The homeodomain family of transcription factors serves as the best example of this modular design. Since many transcription factors rely on a DNA-binding domain as well as an additional domain that allows for the activation of the transcription factor, multiple protein sequences will align and cluster under these separate domains. Therefore, insight into the biological function of these new proteins from its family association can be misleading. Nevertheless, these bioinformatic techniques are expected to provide a wealth of detailed information to the biologist searching for clues as

Table 14 The largest protein families^a

<i>Family</i>	<i>Source</i>	<i>Modules in Swiss Prot</i>	<i>Found where?</i>
C2H2 zinc fingers	PF00096	1826	Eukaryotes, archaea
Immunoglobulin module	F000471	351	Animals

Chymotrypsins	PR00722	464	Eukaryotes, bacteria
Homeodomain	PF00046	453	Eukaryotes
ABC cassette	PF00005	373	All kingdoms
Sushi domain	PF00084	343	Animals
RNA-binding domain	PF00076	331	Eukaryotes
Ankyrin repeat	PF00023	330	Eukaryotes
RuBisCo large subunit	PF00016	319	Plants, bacteria
Low-density lipoprotein receptor A	PF00057	309	Animals

^aThe sources for these numbers of modules are Pfam (PE) or Prints (PR).

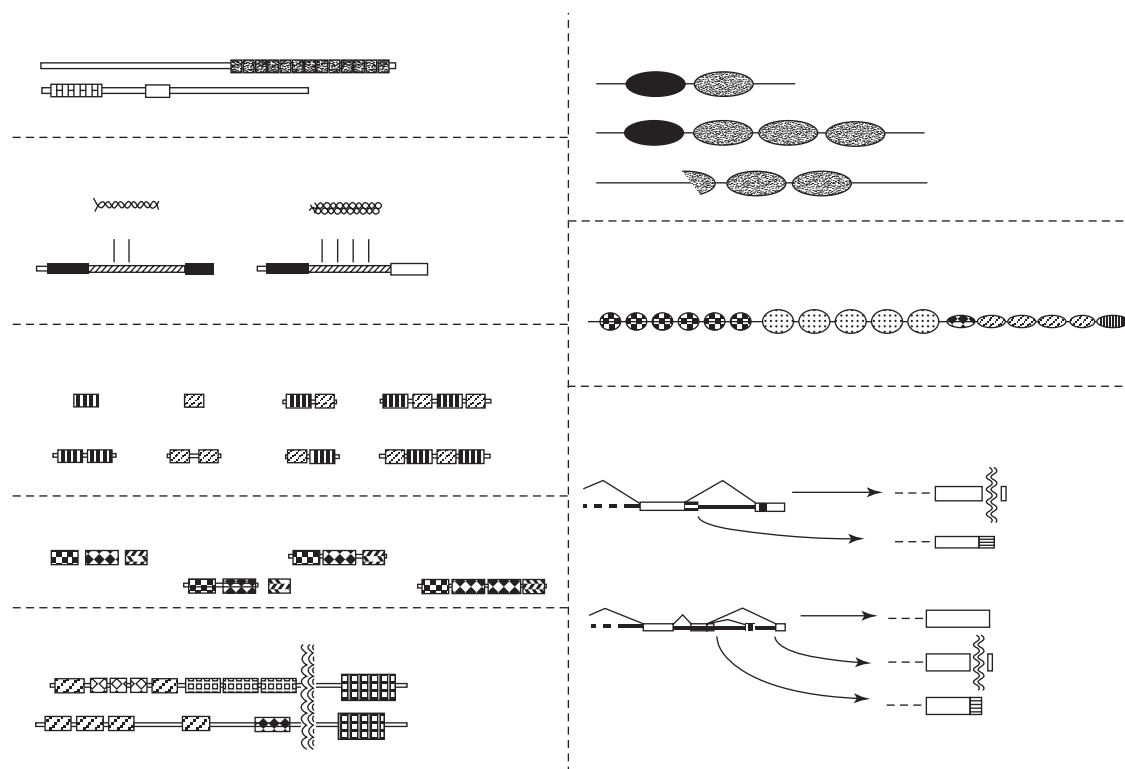

Figure 9 A comparison of protein families in which the sequence conservation during molecular evolution has given rise to proteins of similar yet distinct function.

to how the orphan protein of interest is involved with the model under investigation.¹⁸⁵ **Table 14** is a short list of the largest protein families and where they can be found.¹⁸¹

As a consequence, the DNA sequence similarity of most proteins is highly conserved between protein families as well as species in regions of functional importance. The most common observation is that the portion of the protein that is responsible for the interaction of that protein with other molecules has at least a weak similarity in protein sequence and is the focus of family categorization.

2.12.3.3 Molecular Pathways

Through large-scale analysis of human genes and the proteins that they produce, a detailed map of the human body will provide a blueprint of molecular pathways, which will describe how the complicated interactions of proteins support our existence. A blueprint of this interdependent network is vital to the development of drugs that will be used to influence the quality of life through pharmaceutical intervention. The final response to the environmental signal is largely dependent on the abundance and state of the proteins in the pathway. The lack of expression or the inactivation of the downstream proteins can lead to a breakdown in the communication of the signal or the diversion of the signal toward an alternative pathway.

Drug discovery is based on determining which compounds are best suited for the systemic, or tissue-specific, manipulation of biological function for the long-term chemical compensation of patients with a weak genetic background or the temporary modulation of life-sustaining systems threatened as a result of injury.^{168–170,186} Functional genomics promises to provide researchers with detailed feedback on the effectiveness, as well as negative consequences, of this intervention at the molecular level. In order to produce drugs that manipulate biological function but do not produce side effects that prohibit its use, it will become commonplace to incorporate large-scale genomic methods that reveal the shortcomings of the drug being tested.

2.12.3.3.1 Signal transduction

The foundation of most drug discovery projects relies on the ability of cells within a tissue to be influenced by the local environment. This response is due to the presence of proteins on the surface of the cell, like the platelet-derived

growth factor (PDGF) receptor, that sense the environmental changes and transduce this signal into the cell and alter its biochemical state. By altering the behavior of even a subset of cells within a tissue, the function of whole organs can be altered, leading to the adjustment of life-sustaining parameters necessary to maintain higher order functions. Signal transduction is made possible by networks of interacting proteins working in concert to achieve changes in cellular function. The state of the cell is defined by parameters such as the complement of proteins being synthesized and processed, their enzymatic activity, and their location within the cell, as well as changes in the equilibrium of ions across intracellular and extracellular membranes. The state of the cell determines how it will respond to the environment.¹⁸⁷ For instance, will it secrete specific humoral factors, such as insulin, or contract upon neuronal stimulus like muscle cells? The presence of receptors that are inserted into the cell membrane allow for the interaction of signaling molecules, called ligands, on the outside of the cell to influence the function of cells by altering the state of protein networks within the cell.

2.12.3.3.2 Protein–protein interaction

The cellular signaling mechanism responds to perceived signals from receptors through networks of proteins that come in direct contact with one another. This protein–protein interaction serves as one criteria for protein domain conservation during molecular evolution,^{172,173} and can be recognized by the massively parallel collection of sequence and expression data offered by genomic technologies. Sequence alignment of protein family members across many species, in conjunction with biologically relevant experimentation, provides important insight into the function of these conserved sequence elements, and therefore must be carefully considered during the assignment of function of any one protein.

2.12.3.3.3 Tertiary structure and convergence

In some cases the functions of two proteins separated by great evolutionary distances converge. In these cases, it is common to have very little similarity in protein sequence yet similar function (Figure 10).¹⁷³ By viewing the tertiary structure of two proteins that share a similar function, general similarities can be seen. The tools for comparing the three-dimensional conformation of proteins in order to understand function are still in their infancy. Therefore, it is necessary to rely on the information contained within the primary sequence of the two proteins to investigate the rules that control the ability of that protein to perform its function. Determining what structural characteristics allow proteins to interact with the rest of its molecular pathway will make it possible to more accurately predict the consequences of their individual contribution to that pathway. For example, it is well known that defined mutations within the homeodomain of certain transcription factors will specifically alter the sequence specificity on which the transcription factor binds, required for the induction or repression of gene transcription. Moreover, a better understanding of their structural characteristics would allow for the logical design of small molecules to modulate specific components of that pathway, potentially translating into drugs with higher fidelity and fewer side effects, and increasing the number of targets on which drugs are designed.

2.12.3.3.4 Gene expression and protein kinetics

Proteins function at the molecular level, and are governed by the laws of probability and molecular kinetics. If the concentration of a protein is increased beyond some critical value, the probability that that protein will come into contact with its correct partner is increased. Yet, as a consequence of its increased rate of interaction with all molecules in the cell, interactions with inappropriate branches of the intracellular regulatory network become common. This altered protein function is similar to the altered specificity of drugs that have been given at high doses to achieve an effect but cause unwanted side effects. By monitoring the normal concentration of regulatory proteins in the cell, it may be possible to recognize patterns of expression that are associated with disease, as well as define the correct abundance ranges of proteins to achieve stability and avoidance from a pathological state. [Figure 11](#) represents data collected through the use of microarray technology in which mRNA from patients with the premature aging disorder progeria is compared with that of 'normals' of differing age groups. These data provide an example of similarities in the abundance of proteins expressed within these two groups, and suggests that these proteins are somehow involved in progeria.

Techniques that provide information on the abundance of proteins in cells will be crucial to understanding how the many molecular pathways coordinate the maintenance of the intracellular environment. It is also well known that cells of multicellular organisms do not express all available proteins in every cell. By expressing specific proteins at a particular abundance, alternative cell types are available to the organism. To understand biological function, it is necessary to determine which protein complements are required for any one specific cellular contribution to the organism.

Another possibility for the use of this kind of information is that it may make it possible to treat one cell type so that it may carry out the function of another. By modifying the abundance of a subset of proteins required to compensate for the loss of that cell type, pharmaceutical intervention may allow for the compensation of diseases in which cells of a particular type have been destroyed. Potential targets for such treatment are found in diabetic patients where the loss of insulin-producing pancreatic islet cells has been effected through an autoimmune response, as well as dopamine-producing cells of the central nervous system involved in Parkinson's disease. The ability to control cell identity is dependent on being able to determine which signaling molecules are necessary to achieve changes in protein expression, thereby mimicking the cell that has been destroyed. For this, the expression profile of that cell must serve as the defining characteristic to be achieved by pharmaceutical intervention.

2.12.3.3.5 Autoregulation of gene expression

The state of a cell is regulated by the activity as well as the complement and abundance of proteins. Therefore, it is common to have immediate changes in cellular function without any change in the expression of proteins. It is this immediate early response that allows for quick adaptation and compensation to environmental conditions. The presence of phosphate on proteins that alter their specificity or enzymatic rates is a prime example of changes of state that lead to rapid cellular responses, as is subcellular localization. To use genomic techniques for the characterization of novel drugs that are designed to influence these sorts of immediate early responses, it is necessary to identify changes in protein activity. This is classically performed through the addition of radioactive phosphate that identifies proteins that have incorporated or lost these molecular markers. The purpose of this experimental approach is to ascertain if a regulatory pathway has been altered. Since genomic approaches rely on the measurement of mRNA and only approximate protein abundance, immediate early responses are not easily recognized. Nevertheless, the induction of early response mechanisms can lead to secondary effects on the abundance of proteins through transcriptional modulation. Transcription factors that regulate their own expression have been observed, and it is this autoregulation that allows the inference of changes in regulatory pathways by levels of protein expression.¹⁸⁸ It is the change in gene expression observed at times later than the initial treatment of cells that can be used to better understand the way in which a drug has influenced the state of the cells. Functional genomics is a tool, and all of the limitations must be recognized when inferring functions onto proteins, cells, and drugs based on changes in gene expression. Nevertheless, the power of large-scale experimentation may provide the information necessary for the informed selection of efficacious drugs.

2.12.3.4 Genomics Techniques

Genomic methodologies, like microarrays, have been recently implemented to supplant techniques like Northern and Southern blot analyses because, in general, they provide the same type of information with regard to the kinds and abundance of proteins in cells.^{189–192} Northern blot analysis serves as a measure of the steady state abundance of mRNA for a transcript of interest, and this is used to approximate the abundance of a protein, since for most genes the

Figure 11 Data collected through the use of microarray technology in which mRNA from patients with the premature aging disorder progeria are compared with 'normals' of differing age groups.

mRNA abundance in the cell is at least proportional to the amount of the protein. The primary difference between genomic and blotting techniques is that many simultaneous approximations of the protein complement of a cell or tissue can be obtained in a fraction of the time. Furthermore, simultaneous measurement of experimental conditions reduces the many false assumptions made from experimental data accumulated over great periods of time. This section will survey and explain a few genomic techniques so that the relevance of the techniques may become obvious.

2.12.3.4.1 High-throughput screening

HTS relates to the parallel or serial processing of many individual samples in an attempt to obtain a large data set by which subsets will be identified through selection criteria of many forms. Like looking for the proverbial needle in a hay stack, the elementary question raised by HTS is whether or not a particular 'straw' matches your selection criteria. Unlike the more traditional one-straw-at-a-time approach of a sequential search, HTS is characterized by performing massively parallel searches. That is, it tries to look at large numbers of 'straws' simultaneously, with each one assessed for the same criteria. As simplistic as it may seem, it is the most direct method by which one evaluates a sample and decide whether it is involved with one's model or not, and the rate at which one proceeds depends greatly on how quickly and accurately the screening takes place. Microarrays are glass slides on which DNA of many different types is placed in an array format. This substrate serves as a methodological platform to identify and measure the level of expressed genes. By placing either of these substrates in direct contact with labeled cDNA, a fluorescent copy of the expressed genes of the cell, a measure of gene expression can be made. The question of whether gene A is on or gene B is off can be answered in parallel. If the question is when gene A gets turned on, a million samples may have to run in series before the answer is 'yes,' therefore making HTS a necessity.

2.12.3.4.2 Microarrays

Microarrays and other solid substrates can augment the progression of genetic analysis. The early to mid-1960s saw the beginning of a genetic revolution, which led to discoveries that until then had not previously been thought possible. Regularly, such journals as *Cell*, *Science*, and *Nature* were publishing articles pertaining to the cloning and characterization of novel genes. As technology progressed, it became clear that the regulation of the newly found genes was complicated and interlaced with environmental influences, as well as intercellular communication pathways. To make any headway into the analysis of such a complicated network of gene regulation, a fast and effective protocol for looking at the expression of these genes was critical. Microarray technologies were developed to help researchers investigate the complex nature of gene expression, and continue to be utilized on an enormous scale. To better understand the full scope of microarray and other technologies, it is helpful to be introduced to the applications in which the genomic tools are used.

2.12.3.4.3 Single-nucleotide polymorphism detection

Polymorphism is the property of taking on many forms, and it is used to describe the natural changes in the DNA sequence of a gene relative to other alleles. Microarrays and new techniques can quickly and reliably screen for single-base-pair changes in the DNA code for an entire gene (polymorphism) by using the sequence by hybridization method.¹⁹² Sequencing through the hybridization of a target molecule to a known array of oligonucleotides has been performed successfully, and will be used extensively for the monitoring of changes related to disease.¹⁹² With the help of genomic technologies, or by knowing the sequence of a gene associated with a disease, the diagnoses of patients with a higher degree of confidence is predicted to mature.^{169,170,186,189} Since the sequence of a gene can identify phenotypic characteristics that are associated with many metabolic processes, the technique may also make it possible to use this information in deciding the proper course of treatment for patients when the ailment is known; this is called pharmacogenomics. It is well known that patients with varying genetic backgrounds respond to treatments of disease to varying degrees. Through the sequencing of particular genes related to drug-metabolizing enzymes and genes as yet unknown, we may obtain a rationale for drug therapy and design.¹⁸⁹

SNP detection will be very similar to the sequencing of a whole gene, but there will only be representatives of known polymorphisms. An example of this kind of approach to diagnostics was presented by Smith and his co-workers in 1994. They used PCR to produce a defined probe, hybridized this probe to a matrix of known oligonucleotides representing exon 4 (the coding component of messenger RNA) of the human tyrosinase gene, and then scored and assessed the presence of polymorphisms. Another example of this kind of approach was performed by Klinger and her co-workers, whereby a complex, defined PCR probe was used to assess the presence of polymorphisms in the genes involved in cystic fibrosis, beta-thalassemia, sickle cell anemia, Tay-Sachs disease, Gaucher's disease, Canavan's disease, Fanconi's anemia, and breast cancer.

2.12.3.4.4 Deletion detection

Microarray and other analyses may also be performed to characterize a deletion, insertion, or mutation in genes that have been correlated to disease, such as the p53 gene to cancer. If it is suspected that a gene is mutated, clinicians will isolate DNA from the patient, use this DNA to create a probe, and then hybridize this probe to an array that can identify mutations in that gene.

2.12.3.4.5 Differential display by hybridization

Use of microarrays and other substrates for hybridization with cDNA produced from cells or tissue will make possible the identification of regulatory genes involved in the control of human disease.¹⁸⁹ There are models for cellular differentiation and diseases in which cDNA probes can be obtained for the purpose of hybridization to microarrays and others. The genes identified by differential hybridization to these substrates can be used as candidates in the characterization of human disease and, once identified, confirm the involvement of these candidate genes in disease. If this approach is successful, these disease genes can be used as a target for the production of drugs that influence the expression of the genes. An example of this approach is the treatment of prostate cancer cells with a chemopreventive agent to determine its involvement in prostate cancer. The observation that makes this example important is that the cells were cultured under two different conditions but, of the 5000 genes that were screened, all but a few were differentially expressed. This suggests that the change induced by the treatment may be minor and understandable. These sorts of experiments, in conjunction with additional supporting data, will provide candidates that can be screened for their usefulness as drug targets.

One of the most important questions asked by today's research scientists is, what is different between two cell types (e.g., disease versus normal, or treated versus untreated)? The only methods available for this kind of query are differential display, representational difference analysis, subtractive hybridization, serial analysis of gene expression, and differential hybridization to cDNA libraries. An exceptional example of this approach was performed by Jordan, who implemented microarrays in his hunt for genes that define the existence of three cell types in the murine thymus. By creating a 3' complex probe and hybridizing this to a microarray, he found novel genes that were differentially expressed between the three cell types. This methodology can be implemented for other models of disease as well, and may lead researchers to rational therapies for the devastating medical disorders that plague our society.

2.12.3.4.6 Expression monitoring

Expression monitoring is another approach that takes advantage of the large databases of sequenced cDNAs. By designing arrays that contain representatives of the most important genes that control the cell cycle and involve cellular regulation, an evaluation of cellular and tissue state is possible. The power of new bioinformatics software will improve the usefulness of this method, and such software is frequently used. Another possible application that has been discussed is the diagnosis of disease by association of a pattern of hybridization with that disease, as compared with positive and negative controls. In other words, does a tissue resemble a specific expression pattern as a consequence of disease?

With the recent advances in bioinformatics technology and the development of microarrays and tools that contain the number of probes necessary for the analysis of gene expression, it is now possible to confront the daunting task of human genetic analysis. Moreover, some pathological conditions caused by environmental insults instigate a cascade of changes in gene expression that can have drastic outcomes, as experienced by patients with the autoimmune disorder rheumatoid arthritis. Given the complexity of cellular signaling and regulatory pathways in a cell, it has been impossible to address these numerous interdependent changes occurring during biological process, be it pathological or normal. This allows physicians and scientists to address the needs of the cell, clearly a substantial contribution to the reduction of human morbidity.

2.12.3.4.7 Finding targets for drug development

As mentioned previously, most drugs are small organic molecules that are ingested and introduced into the circulatory system, whereupon they bind to receptors on the surface of cells whose function is to be influenced. There are approximately 30 000–35 000 genes in the human genome, producing an even greater number of proteins through alternative splicing and differences in post-translational modification. Unfortunately, only a handful of these proteins serve as targets for pharmaceutical intervention.¹⁶⁹ To increase the range of influence available to clinicians through drug treatment, it will be necessary to broaden the scope of protein targets used during drug development. Yet, before drugs can be specified for the treatment of clinical symptoms, a clear picture of the physiological and molecular pathways involved with the disease or pathological process must be assessed. To understand the function of any system,

all the components of that system as well as their interactions must be known. It is not enough merely to catalog all of the proteins expressed in a cell type. The interrelationships of expressed proteins must be determined through careful planning of experimental models that have defined measurable physiological or molecular changes. The extent to which the model has been characterized can synergistically increase the amount and value of the conclusions drawn from the individual experiment. Like a jigsaw puzzle, the next piece of data must be based on the existing framework. In order to increase the rate of discovery, experimental data must be gathered in parallel. This has been made possible through the advent of molecular techniques such as that associated with microarray technology. The probability of success in any experimental fishing expedition is the size and quality of the net used. With microarrays, the expression of approximately 10 000 genes can be monitored from as little as 5 µg of total mRNA. Since there are many experimental models that have distinct physiological or molecular changes associated with a defined cell type, a wealth of data can be acquired in parallel. Nevertheless, the quality of the data rests in the hands of the individuals who are responsible for the sample handling and tracking. As there is so much data to be analyzed, a small error in sample tracking can lead to devastating errors in the conclusions drawn from experiments. Sample tracking is a crucial component of the data collection and review process. In this case, the adage 'garbage in, garbage out' rings true. If the acquisition and storage of highly parallel data can be performed with some degree of confidence, then the sky is the limit. Similarities and differences, or the correlation of expressed genes with changes in responses of cells to their environment, will expand our understanding of the human machine at rates not thought of 10 years ago.

2.12.3.5 Overview

Functional genomics is a term used to describe the assembly of data to better understand the form and function of the cell. Much is already known about the mechanisms that govern the interaction of a cell with its environment, and it is this base of knowledge that will act as the primer for solving the puzzles of biology. DNA, RNA, and proteins act together to maintain the integrity of the cellular environment, and how they interact with each other is the information accessible through many newly developed high-throughput technologies. By applying high-throughput technologies to the information already known about how cells respond to their environment (functional genomics), the development of efficacious drugs with few side effects through intelligent design will be possible.

2.12.4 Integrated Proteomics Technologies

2.12.4.1 Introduction

Proteomics is a powerful approach for integration into drug discovery because it allows the examination of the cellular target of drugs, namely proteins. Understanding how drugs affect protein expression is a key goal of proteomics in a drug discovery program. Mapping of proteomes, the protein complements to genomes, from tissues and organisms has been used for the development of high-throughput screens, for the validation and forwarding of new protein targets, for the development of structure–activity relationships and for exploring mechanisms of action or toxicology of compounds, and for the identification of protein biomarkers in disease. For example, Arnot and co-workers describe an integrated proteomics approach to identify proteins differing in expression levels in phenylephrine-induced hypertrophy of cardiac muscle cells (myocytes).¹⁹³ Once a proteome is established, and expressed proteins are linked to their respective genes, then the proteome becomes a powerful means to examine global changes in protein levels and expression under changing environmental conditions. The proteome becomes a reference for future comparison across cell types and species. It is expected that proteomics will lead to important new insights into disease mechanisms and improved drug discovery strategies to produce novel therapeutics.

The application of proteomics to the study of biochemical pathways and the identification of potentially important gene products as targets for drug discovery is well established in the literature.^{194–196} Celis *et al.* have explored the possibility of using proteome expression profiles of fresh bladder tumors to search for protein markers that may form the basis for diagnosis, prognosis, and treatment.¹⁹⁷ Ultimately, the goal in these studies is to identify signaling pathways and components that are affected at various stages of bladder cancer progression and that may provide novel leads in drug discovery. The explosive growth of the proteomics arena is illustrated by the rapid increase in the number of publications in the past few years (Figure 12). Studying individual proteins in the context of other cellular proteins is complementary to the information gathered from a genomics-based approach.

In order to increase the capacity and throughput of the information flow derived from a proteomics-based research program, several recent technologies must be highly integrated to yield a complete and efficient proteomics-based methodology.^{198,199} The traditional approach involves the separation of the highly complex protein mixture, with

Figure 12 'Proteomics' literature publications as a function of publication year. The literature search was accomplished through the SciFinder program (American Chemical Society).

two-dimensional electrophoresis (2DE) – the most popular method because of its high sample capacity and separation efficiency. Associated with 2DE are the necessary means to analyze and store the gel images for protein correlation and data tracking. A major component of the proteomics assembly is bioinformatics, including methods that correlate changes observed in the gel patterns (attributed to changes in the environment) and software that identifies proteins from genomic and protein sequences.

A proteomics-based approach has been practiced for many years, to monitor differential protein expression. However, at the time the term 'proteomics' was coined,²⁰⁰ the technology presented by new mass spectrometry (MS) methods was developed to make the identification of proteins separated by polyacrylamide gel electrophoresis (PAGE) more amenable, and it has greatly expanded the range of applications to which proteomics can contribute. MS provides a robust method for protein identification (provided the genome or protein sequences are known and available) and is being applied in many laboratories worldwide. The method can be automated, thereby greatly increasing the throughput of the analysis if many proteins need to be identified. The virtues of MS have played an important role in honing the burgeoning field of proteomics, and MS will continue to support these escalating efforts. This section serves to outline the major technologies associated with a proteomics-based approach to drug discovery.

2.12.4.2 Gel Electrophoresis

2.12.4.2.1 Two-dimensional gel electrophoresis

Since its inception, 2DE has provided researchers with a powerful tool that is capable of resolving a complex protein mixture into its individual components.²⁰¹ As implied by its descriptive nomenclature, 2DE systems separate proteins on the basis of distinct properties in each of two dimensions. In each dimension, the chosen property of the individual proteins within the mixture defines the mobility of individual proteins within an electrical field. As defined in this section, the term 2DE describes a technique that separates proteins in the first electrophoretic dimension on the basis of their charge and in the second electrophoretic dimension on the basis of their molecular mass. While 2DE separations of protein mixtures can theoretically be carried out in free aqueous solvent systems, the resultant separations are of little practical value, due principally to thermal convection and diffusion effects. Thermal effects caused by joule heating during the separation, and the effects of diffusion following the separation will serve to severely limit protein separation and, ultimately, protein resolution. To minimize these effects, 2DE is carried out in a polyacrylamide support medium. The utility of polymerizing acrylamide monomers into an electrophoretic support matrix capable of reproducibly separating complex protein mixtures was recognized long before the advent of 2DE systems.^{202,203} While either electrophoretic dimension alone can independently resolve 100–200 individual proteins, the combined separation properties resident in 2DE systems offer investigators the ability to resolve up to 10 000 individual proteins.²⁰⁴ The route to this level of understanding of how 2DE systems can facilitate our understanding of the proteome has been a scientifically arduous evolution.

Protein separation in the first dimension is based on the isoelectric point (pI) of individual proteins. Isoelectric focusing (IEF) depends on the formation of a continuous pH gradient through which a protein migrates under the influence of an electrical field. The net charge on the protein varies with the pH but approaches zero at its pI. At a pH equivalent to its pI, movement of the protein in the electrical field ceases, and the protein is 'isoelectrically focused.' In practical terms, IEF is achieved using either carrier ampholyte gels or immobilized pH gradient (IPG) gels. Carrier ampholytes are oligoamino and oligocarboxylic acid derivatives with molecular weights ranging from 600 Da to 900 Da.

By blending many carrier ampholyte species together, highly reproducible continuous pH gradients between pH 3 and 10 can be formed in a polyacrylamide support matrix. Typically, the first-dimension pH gradient and polyacrylamide support matrix are cast in a tube gel format that conforms to the physical measurements of the second-dimension gel system. Carrier ampholyte IEF tube gels possess several advantages over IPG strip gels. First, they are easily prepared and do not require specialized gradient-forming instrumentation. Second, carrier ampholyte IEF gels can be experimentally tailored to generate linear or nonlinear pH gradients in broad or very narrow ranges.²⁰⁵ Disadvantages of carrier ampholyte use include (1) lot-to-lot variation in the ampholytes themselves, attributable to complicated organic synthetic methods, and (2) the physical chemical effect termed 'cathodic drift' that prevents a truly stable pH equilibrium state from being obtained in the first-dimension gel system. The tangible effect of cathodic drift is a progressive deterioration of the basic side of the pH gradient that can be compensated for by addressing factors such as the time and power requirements.²⁰⁶

IPG gel chemistry is based on Pharmacia Immobiline acrylamido buffers.²⁰⁷ These chemical entities are bifunctional. The general chemical structure $\text{CH}_2=\text{CHCONH R}$ defines one end of the molecule, designated R, as the titrant moiety where a weak carboxyl or amino group provides an ionizable buffer capacity that defines the range of the continuous pH gradient. At the other end of the molecule, the $\text{CH}_2=\text{CH}-$ moiety provides an acrylic double bond that copolymerizes into the polyacrylamide support matrix. It is the polymerization of the Immobiline buffers into the polyacrylamide support matrix that provides an IPG. Because the Immobiline molecules themselves are rather simple chemical entities, the discrete molecules can be produced in a very reproducible manner with minimal lot-to-lot variation. This eliminates a principal concern associated with carrier ampholytes. IPG gradient gels also offer the prospect of increased sample loading over the carrier ampholytes. Carrier ampholyte tube gels can routinely accommodate up to 100 μg of protein, and in certain instances several hundred micrograms of protein. In comparison, IPG gels offer higher protein-loading potentials that can accommodate up to and in certain instances more than 1000 μg of protein.²⁰⁸ Another benefit associated with IPG gels is the virtual elimination of cathodic drift, which permits basic proteins to be resolved.²⁰⁹ While both carrier ampholyte and IPG gels offer similar pI resolution, IPG gels have been viewed as providing less reliable positional focusing for discrete protein species than carrier ampholyte gels.²⁰⁵ Although casting procedures for IPG gels require specialized gradient-forming instrumentation, the increased commercial availability of IPG gels from several manufacturers minimizes this potential disadvantage.

Sample preparation presents a problem that must be considered in the context of the first-dimension IEF chemistry.²¹⁰ The first-dimension IEF chemistries that produce the desired continuous pH gradient depend on protein charge to effect zonal concentration of discrete protein species. Consequently, the introduction of charged species, especially detergents, with the sample must be minimized. This constraint makes sample preparation for 2DE analysis a daunting task. To maximize protein representation with the sample and simultaneously retain a fixed linear relationship with respect to the original material being sampled necessitates that (1) the starting material be handled appropriately to minimize modification to the protein due to degradation and spurious post-translational covalent modification, (2) the disruption and solubilization of proteins that participate in intermolecular interactions be ensured, (3) highly charged species such as nucleic acids are removed, (4) intra- and intermolecular disulfide bonds are disrupted, and (5) transmembrane proteins are solubilized and removed. To accomplish this task, basic 2DE sample preparation buffers employ high concentrations of a chaotropic agent such as urea, employ nonionic or zwitterionic detergents, use nucleases, and depend on reductants such as dithiothreitol in the presence of alkylating agents to disrupt disulfide bonds. Consideration must also be given to post-first-dimension buffer exchanges that facilitate the egress of proteins from the first-dimension gel and permit efficient penetration of the second-dimension gel matrix. An excellent compendium of recent procedures that address protein solubilization concerns associated with specific organisms and specific protein classes has been provided in a text edited by Link.²¹¹

Protein separation in the second dimension is based on the molecular size of individual proteins. Many variations exist as to the composition of the second dimension. Specific applications have been designed that optimize protein separation under denaturing or nondenaturing conditions, reducing or nonreducing conditions, linear or nonlinear polyacrylamide support matrixes, and numerous buffer compositions. The most frequently used second-dimension buffer systems are based on the pioneering work of Laemmli.²¹² In the Laemmli system, the polyacrylamide support matrix is used to sieve proteins that have been subject to denaturation in the presence of sodium dodecyl sulfate (SDS). This crucial step is based on the premise that SDS binds uniformly to denatured macromolecules with a fixed stoichiometry, and in so doing forces them to assume a prolate ellipsoid shape. Theoretically, all protein species assume the same shape and migrate through the polyacrylamide support matrix with rates that are dependent on only their hydrodynamic radius. Consequently, the position to which a protein species migrates during a fixed time is correlated to its molecular size. This fact offers investigators the opportunity to move to dimensionally larger gel formats to increase protein loading and subsequently resolution. A larger 2DE gel system can accommodate more protein. This increases

the likelihood that low-abundance proteins will be detected and that these can be separated from other proteins in the gel. An alternative approach to this problem is present in so-called zoom gels. Zoom gel systems run the same sample on narrow first-dimension pH gradients and separate on as large a second-dimension gel as possible. The broadest pH range and most extensive molecular weight range can then be reassembled into a single composite image by visual means or attempted using specialized software applications. In practice, this is very difficult to accomplish.

2.12.4.2.2 Staining methods in two-dimensional electrophoresis

As is the case for most technologies in which there are numerous acceptable methods, there is no single method that is universally used to detect proteins separated by 2DE. Various stains are widely available to visualize proteins.²¹³ A number of parameters need to be evaluated before a stain or dye can be chosen for a particular application. The weight of each parameter in the decision-making process is a function of the goals of the study. The sensitivity, dynamic range, and compatibility with analytical techniques associated with protein identification, as well as the cost, are all important considerations that must be addressed in order to select the most appropriate visualization agent.

The needs of a study are critical determinants when choosing a staining approach. Many factors require consideration prior to initiating 2DE, including the need to quantify protein abundance or changes in protein expression levels, the amount of protein sample available, the number of samples involved, and the need for protein identification. Most proteomic-based studies are relatively large undertakings, requiring substantial time and effort. The use of methods to visualize and detect proteins of interest consistently and to a required degree of sensitivity will ensure the success of those projects.

2.12.4.2.2.1 Coomassie stains

The Coomassie blue stains have been the most widely used for proteins separated by 2DE. Two forms of the Coomassie blue stain are available, namely Coomassie blue G-250 and Coomassie blue R-250. First used by Meyer and Lambert to stain salivary proteins, Coomassie blue stains can be used to detect as little as 200 ng of protein mm^{-2} on a 2D gel.²¹⁴ The mechanism of binding between the stain and the protein occurs through several different interactions, including the binding between basic amino acids and the acid dyes, as well as by hydrogen bonding, van der Waals attraction, and hydrophobic interactions between protein and dye.²¹⁴ A common Coomassie blue staining protocol utilizes 0.1% Coomassie blue R-250 dissolved in water-methanol-glacial acetic acid (5:4:1). The duration of gel staining increases with the thickness of the gel and decreases as a function of temperature. Gels that are 1.5 mm thick are generally stained overnight at room temperature. The quickest way to remove excess stain from the gel is by destaining in a solution containing 30% methanol-10% acetic acid. An alternative method dissolves the stain in trichloroacetic acid (TCA). The relative insolubility of Coomassie stain in TCA results in the preferential formation of protein-dye complexes. The result is the rapid staining of a 2D gel with little destaining required.²¹⁴

The major disadvantages with the use of Coomassie stains are the inability to accurately quantify proteins and the relative insensitivity of the stain. Despite these drawbacks, Coomassie blue stains have a number of advantages that will ensure their continued utility for visualizing proteins separated by 2DE. There are many instances in which a high degree of sensitivity is not required. The proteins of interest may be in high abundance, either naturally or through manipulation of the sample preparation using affinity chromatography. In addition, the inherent pH stability of the IPG strips allows the application of milligram quantities of protein to the first dimension,²¹⁵ dramatically increasing the abundance of protein spots present in the SDS-PAGE gel. Most importantly, unlike silver stain, proteins stained with Coomassie blue can easily be processed with analytical procedures used in protein identification. Finally, Coomassie stains are inexpensive and reusable, making them attractive to laboratories with low budgets.

2.12.4.2.2.2 Silver staining

The use of silver stain to visualize electrophoretically separated proteins was proposed in 1979 by Switzer and co-workers.²¹⁶ With a sensitivity approximately 100 times that of Coomassie blue, silver stain offers the ability to detect as little as 1 ng of protein. Numerous studies have focused on optimizing the various steps in the silver staining protocol.²¹⁷ The majority of methods conducted have utilized either silver diammine (alkaline methods) or silver nitrate (acidic methods) as the silvering agent. The acidic methods can be further categorized into lengthy procedures, which require greater than 5 h, and the less sensitive rapid methods, whereby staining can be completed in less time. A comparative study conducted by Rabilloud determined protocols utilizing silver diammine as well as glutaraldehyde as an enhancing agent (discussed below) to be the most sensitive staining methods.²¹⁸ Although somewhat laborious, the silver staining of 2DE gels is a relatively straightforward procedure. The initial step of the silver stain procedure involves the immersion of the gels in a fixative solution. This solution (generally containing acetic acid and either

methanol or ethanol) functions to precipitate the proteins within the gel matrix as well as remove interfering substances such as detergents, reducing agents, and buffer constituents (e.g., Tris).²¹⁷ The second step is aimed at enhancing the subsequent image formation. Enhancement can be achieved through increasing the silver binding (referred to as amplification) to the proteins through the use of aromatic sulfonates or dyes such as Coomassie blue. The process of minimizing the formation of a background image through the use of oxidizing agents (permanganate or dichromate) is known as contrastization, and is usually used only in the acidic methods. A third major enhancement technique (sensitization) involves increasing the rate at which silver reduction occurs on the proteins. Sensitization can be accomplished using sulfiding agents (thiourea) and/or reducing agents (e.g., dithiothreitol or DTT). Many of the existing staining protocols contain a combination of enhancement techniques to improve the subsequent image formation. Following silver impregnation, image development is accomplished through the reduction of Ag^+ to metallic Ag. Development solutions used with silver nitrate generally contain formaldehyde, carbonate, and thiosulfate, while those methods utilizing silver diammine are composed of formaldehyde and citric acid.²¹⁹

Despite the high sensitivity of silver stain, there are a number of major drawbacks and limitations associated with this technique. The routine use of silver stain is relatively expensive due to the high price of reagents as well as the cost of disposal of hazardous waste. In addition, poor images may result from high background noise, often resulting from the use of poor-quality water. A study investigating the contributing factors of background silver staining also suggested the involvement of a redox initiator system such as ammonium persulfate and an amine (e.g., N,N,N',N' -tetramethylethylenediamine).²¹⁹ There is also a significant protein-to-protein variability relative to the extent of silver deposited on the protein. Some proteins do not stain at all, or are detected as negatively stained in contrast to a dark background.²²⁰ The polypeptide sequence and the degree of glycosylation function to influence the intensity and color of the resulting stained proteins. Silver stain is not exclusive for proteins, since DNA as well as lipopolysaccharides may also be stained. Other limitations of silver staining include poor linearity to protein concentration²²¹ and relative incompatibility with subsequent analytical techniques. A study by Gharahdaghi and co-workers demonstrated an improvement in sensitivity when MS was used to identify proteins from silver-stained gels destained with Farmer's reducer prior to enzymatic digestion and analysis.²²² The ability to routinely identify silver-stained proteins using MS analysis would be a significant advancement in the field of proteomics.

2.12.4.2.2.3 Fluorescent stains

One of the most promising new developments in the area of visualizing proteins on 2DE gels has been the recent commercial availability of reliable fluorescent stains. A widely used fluorescent stain is the Sypro line, available from Molecular Probes. Stains such as Sypro ruby have a number of distinct advantages over both Coomassie and silver stains. Several of these advantages are a function of the binding that occurs between the proteins and the stain. Rather than binding to specific functional groups or portions of the polypeptide backbone, the Sypro stains actually bind to the SDS molecules coating the protein.²²³ This type of interaction minimizes the protein-to-protein signal variation and allows quantitative comparison between proteins. In addition, the noncovalent binding of the stain to protein-SDS complexes does not mask antigenic sites, permitting Western blot analysis when the gels are processed using a nonfixative staining procedure.²²³ The dynamic range of the fluorescent stains is 5–10 times higher than either Coomassie or silver stains, which allows for accurate determination of protein expression levels. Equally impressive is the fact that many of the new fluorescent stains have sensitivities equal to or greater than silver stain. In addition, the protocol for fluorescent staining is very simple, requiring only a brief incubation (30 min) in a fixative solution followed by incubation in the dye from 90 min to overnight. The fluorescently labeled proteins can be visualized using an ultraviolet transilluminator, a blue-light transilluminator, or a laser scanning instrument with documentation being achieved through the use of black-and-white print film, charge-coupled device (CCD) camera, or laser scanning instrument. Several of the newer stains, such as Sypro ruby, are completely compatible with MS and micro-sequencing.²²³ Despite all of the positive attributes of fluorescent stains, the major drawback is the cost of the stain, which can be prohibitive to most laboratories running large-format 2D gels.

Fluorescent dyes such as the cyanine dyes have also been used to detect proteins separated by 2DE.²²⁴ The major advantage of fluorescent dyes is the ability to detect protein differences between samples using a single gel. The technique employed is referred to as difference gel electrophoresis (DIGE). DIGE involves labeling the samples of interest with different dyes, and combining the samples into a single sample that is then subjected to 2DE. The fluorescence images obtained from the different dyes are then superimposed to detect protein differences between samples. The use of a single gel eliminates the gel-to-gel variability associated with 2DE as well as the difficulties associated with matching spots between gels.²²⁴ The success of DIGE is based on identical proteins labeled with different dyes having the same electrophoretic mobility. Similar to the case of fluorescent stains, the high cost associated with fluorescent dyes is the major drawback, along with the fact that many are not readily available as consumables.

2.12.4.2.3 Imaging and image analysis

Rigorous attention to detail from sample preparation to image analysis is necessary if the 2DE project is designed to generate valid comparative and numerical data. While precisely determining how much protein is loaded on the first-dimension gel determines the validity of subsequent image analysis, the type of 2DE image is in large part determined by the nature of the sample itself. Autoradiographic images derived from isotopically labeled samples can be collected on film or phosphor imaging systems. Difficulties associated with film response to weak beta-emitting isotopes and a modest linear dynamic range of 300:1 have led most investigators to employ phosphor imaging devices. Phosphor imaging systems have linear dynamic ranges that span up to five orders of magnitude and are as much as 250 times more intrinsically sensitive to radiolabeled proteins than film.²²⁵ Other advantages of phosphor imaging systems include fast imaging times, acquisition of digitized data ready for computational analysis, and the chemical development of films is not required. A significant drawback to phosphor imaging systems is their cost and the requirement that different screens be used to measure specific radioisotopes. A particularly attractive use of phosphor imaging technology is the application of double-label analysis. Experimental samples can be prepared with two different radiolabels. Phosphor images can be acquired that track two different biochemical processes within the same sample and from the same gel by imposing selective shielding between the source and the target following the initial image. This approach circumvents problems associated with intergel reproducibility. Nonradiolabeled samples can be imaged using chromogenic or chemiluminescent immunological methods^{226,227} or conventional stains or dyes. Current methods for 2DE image acquisition depend primarily on CCD camera systems and document scanning devices.^{228,229} CCD camera systems employ CCD devices in lieu of conventional film to acquire the image. A characteristic emission spectrum and stability of the light source as well as a uniform diffusion of the light across the 2DE gel surface are necessary to ensure that optimized, consistent images are obtained over time. The CCD chip image map can be readily converted to digital form and downloaded to a computer for subsequent analysis. Document scanners acquire 2DE image information through an array of photodetectors that are moved across a 2DE gel illuminated by a white or filtered light source. For 2DE gel applications it is important that the scanner obtain and record a uniform image map across the length and width of the gel. Document-scanning features that change the gain settings to optimize text contrast during image acquisition should be disabled to ensure that a uniform image is obtained for subsequent analysis. During image acquisition, any changes in the relationship between the image CCD device or scanner must be noted. A gray scale step tablet should be used initially, to calibrate and to recalibrate the system following any changes.

All steps of the 2DE process culminate in the generation of an image and establish its analytical value. The central tenet of 2DE image analysis (i.e., to provide a comparative means to detect and measure changes) has changed little since the QUEST system was designed and developed by Garrels *et al.* about three decades ago.²³⁰ The specific intent for the QUEST system was to develop a system for quantitative 2DE that was exemplary in gel electrophoresis, image processing, and data management. Although advances in computer computational speed and power have made more complex analyses possible by more sophisticated algorithms in less time, these principal goals remain. Currently, several 2DE image analysis software systems are available commercially; among them are Melanie II and PDQUEST (BioRad Laboratories), BioImage (Genomic SolutionsI), and Phoretix 2D Advanced (Phoretix International). While each software system possesses unique features, the basic approach to 2DE gel analysis is quite similar. The process of image analysis begins with spot picking and image editing. Spot-picking algorithms are effective but they frequently miss spots, fail to resolve multiple spots, or identify artifacts as spots. These occurrences must be visually identified and corrected by the investigator. Once edited, reference spots are identified that appear consistently and are well resolved on each gel in a project. These are used to register the individual gels across a project. Matching individual spots across all gels in a project follows the gel registration process. This process is arduous and time-consuming. For each hour spent producing a 2DE gel, 4–6 h may be spent in image editing and analysis. Once the imaged spots have been matched, statistical processes can be applied that detect and define significant differences between spots across respective groups within a project. At this point, data management and data visualization tools are required.

Data management and data visualization are critical concerns in the evolution of a 2DE project. Although all investigators confront these issues when a 2DE project is completed, an integrated approach that considers data management and visualization during the planning stages of a 2DE project offers the best opportunity to optimize the process and achieve intended project goals. A clear understanding of the specific aim of the project at its onset can define several important strategic concerns. How will the 2DE data be analyzed and what level of validation is needed? Is visual examination of the 2DE gel data sufficient or are statistical methods required? Is the experimental design appropriate and are sample numbers adequate to ensure that the experimental outcomes can be determined without ambiguity? What form of raw data must be harvested from the 2DE images and by what analytical method? Does this project stand alone or will data be integrated into a larger ongoing project? Will data be added to a database? If so, what annotation will be necessary to ensure continuity with existing data? Will important spots be excised from the gel for

subsequent identification? In simple terms, the outcome of a 2DE project is determined by careful planning. If visual inspection of the 2DE gel data is sufficient to achieve project-specific aims, then 2DE images must be evaluated in a consistent manner and the results cross-checked and agreed on by several observers. If statistical methods are to be used, then the type of raw data that will be used in the analysis determines the output of the image analysis system. The statistical analysis can be performed at a single level with an analysis that employs *t* tests or can be multilevel, with each successive level dependent on the previous analysis. The type of assay that is used is an important determinant of whether the final 2DE data represent a completed project or become a covariant in a larger model that includes data from other sources. Preliminary statistical analysis of the spot data can be accomplished using a straightforward *t* test procedure based on individual spot intensity values or integrated spot intensity values. Mapping statistically changed spot matches onto the 2DE gel images can provide a visual signature that is characteristic of a treatment, organism, or pathologic process. Signature patterns can be visualized on gels or by more complex statistical methods that cluster data and create strong visual links between related and disparate statistical data. There are many alternative approaches to the visualization of complex computational data sets.²³¹ In the absence of established standards, investigators should be guided by a desire to present data graphically with simplicity, clarity, precision, and efficiency.²³²

2.12.4.2.4 Protein spot excision

The excision of protein spots from a 2DE gel can fulfill a tactical objective or be a component of a more strategic objective. Fundamentally, spots are excised from 2DE gels to provide a source of material that can be used to identify the protein(s) resident in the spot. From a tactical perspective, a 2DE project can represent a completed experimental objective. In this context, the identification of important spots derived from analytical means applied completes the project. In contrast, a 2DE project can be a component of a much larger ongoing project. In this circumstance, exhaustive protein spot excision that accounts for all spots in a 2DE gel may be used to establish a repository of information that can be stored and drawn on at a later date. Regardless of the intent, protein spot excision requires that spots be precisely removed, and that protein(s) present in the spot be abundant with respect to the detection limit of the identification technology and be stained in a manner that does not interfere with identification technology. Several approaches to protein spot removal should be considered. With respect to protein spots, the 2DE gel is quite variable with respect to spot density. Consequently, picking methods that remove defined sections of the 2DE gel in a grid pattern are inefficient in some regions of the gel and prone to cross-contamination from multiple spots in others. Conversely, a picking method that punches specific spots performs equally across the gel but requires considerable investigator skill and time. An alternative is the application of a spot excision robot to the process. This is feasible only if large numbers of protein spots are to be excised from many gels over time due to the fact that robotic systems are costly and have only recently become commercially available (e.g., Genomic Solutions), suggesting that performance and reliability remain largely unknown. Many wide-bore needles can be beveled flat and used as spot excision devices for the price of an automated robotic system. In regions of high density, great accuracy must be used to remove only the spot intended without contaminating the target spot or affecting the ability to excise proximal spots. To accomplish this manually or through automation requires that the excision device be precisely centered on the spot and have a diameter that does not exceed the diameter of the spot. The flip side of this is that in instances where a large spot needs to be excised in its entirety, a larger punching device or multiple punches must be taken. Given the present state of robotic systems, this is much easier to accomplish manually. Another factor should be considered in the sampling of low-abundance protein spots. First, staining is not necessarily linearly correlated to spot intensity. If multiple spots are to be pooled to increase the apparent abundance of a protein, a point of diminishing returns may be reached where excision from multiple 2DE gels fails to increase the protein extracted from the gel above the detection limit of the detection device. In this instance, preparative sample loading on a fresh 2DE gel is often the better solution. Keratin contamination is a major concern during spot excision. Keratin proteins from many sources must be assumed to be present in the laboratory environment unless specific and heroic measures are taken to ensure and guarantee its absence. Precautions against keratin contamination must be taken at all steps of the 2DE gel process to avoid contamination of the sample, gel chemistry components, and the surface of the gel. During spot excision, the investigator should wear protective clothing, gloves, a hair net, and a mask. If a robotic system is used, careful maintenance, cleaning, and use of an enclosure system will greatly reduce potential keratin contamination.

2.12.4.3 Protein Identification

2.12.4.3.1 General concepts

Proteins are separated first by high-resolution 2D-PAGE and then stained. At this point, to identify an individual or set of protein spots, several options can be considered by the researcher, depending on the availability of techniques. For

protein spots that appear to be relatively abundant (e.g., >1 pmol), traditional protein characterization methods may be employed. Specifically, methods such as amino acid analysis and Edman sequencing can be used to provide necessary protein identification information. With 2DE, approximate molecular weight and isoelectric point characteristics are provided. Augmented with information on amino acid composition and/or amino-terminal sequence, accurate identification can be achieved.^{198,233,234}

However, most of the emphasis the last few years has focused on employing MS-based methods. The sensitivity gains of using MS allows for the identification of proteins below the 1 pmol level and in many cases in the femtomole range. More confident protein identifications can be made with the mass accuracy of the MS molecular mass measurement. For peptide fragments less than 3000 Da, a mass accuracy of better than 100 ppm can be obtained. For example, for a peptide of molecular mass 1500 Da, the accuracy of the MS measurement can be ± 0.075 Da (50 ppm). Moreover, MS is highly amenable to automation, as steps from sample preparation, to sample injection, to data acquisition, and to data interpretation can be performed unattended. Automation is an important concept as capacities increase. It can reduce sources of sample contamination as well as sample-handling errors. A general approach employing MS for protein identification is shown in [Figure 13](#). Great strides have been made toward the automation of these procedures, and many more improvements will become evident in the near future. The rapid increase in proteomic sample throughput arising from constant improvements in the automation of sample preparation and data acquisition have resulted in ongoing generation of an overwhelming amount of data that must be mined for significant results. This has necessitated the parallel development of increasingly efficient computer-based data-searching strategies, which can rapidly provide protein identifications from experimentally derived polypeptide molecular masses and sequences. With these clear advantages of using an MS-based approach, proteomics research has embraced MS with enthusiastic support.

2.12.4.3.2 Automated proteolytic digestion

For the application of MS for protein identification, the protein bands/spots from a 2D gel are excised and are exposed to a highly specific enzymatic cleavage reagent (e.g., trypsin cleaves on the C-terminal side of arginine and lysine residues). The resulting tryptic fragments are extracted from the gel slice, and are then subjected to MS methods. One of the major barriers to high throughput in the proteomic approach to protein identification is the ‘in-gel’ proteolytic digestion and subsequent extraction of the proteolytic peptides from the gel. Common protocols for this process are often long and labor-intensive. An example of an in-gel digest and extraction protocol²³⁵ is as follows:

- (1) Washing and dehydration of the gel:
 - (a) Add 100 μ L of a 1:1 mixture of 100 mM NH_4HCO_3 / CH_3CN to each tube containing a gel piece and let stand for 15 min.
 - (b) Remove the supernatant and dehydrate with 25 μ L of CH_3CN for 10 min.
 - (c) Remove the supernatant and dry by vacuum centrifugation for 5 min.
- (2) Reduction and alkylation of the protein:
 - (a) Add 10 μ L of 10 mM dithiothreitol in 100 mM NH_4HCO_3 and let stand for 60 min at 56 °C.
 - (b) Allow to cool, then add 10 μ L of 100 mM fresh iodoacetic acid in 100 mM NH_4HCO_3 and let stand for 45 min at 45 °C in the dark.
- (3) Washing and dehydration of the gel:
 - (a) Add 50 μ L of 100 mM NH_4HCO_3 and let stand for 10 min, then remove the supernatant.
 - (b) Add 25 μ L of CH_3CN and let stand for 10 min, then remove the supernatant.
 - (c) Repeat steps a and b.
 - (d) Dry by vacuum centrifugation for 5 min.
- (4) Trypsin digestion:
 - (a) Swell the gel disk in 15 μ L of 50 mM NH_4HCO_3 containing 10 ng μL^{-1} of TPCK-modified trypsin in an ice bath for 45 min.
 - (b) Add 15 μ L 50 mM NH_4HCO_3 and digest overnight at 37 °C in the dark.

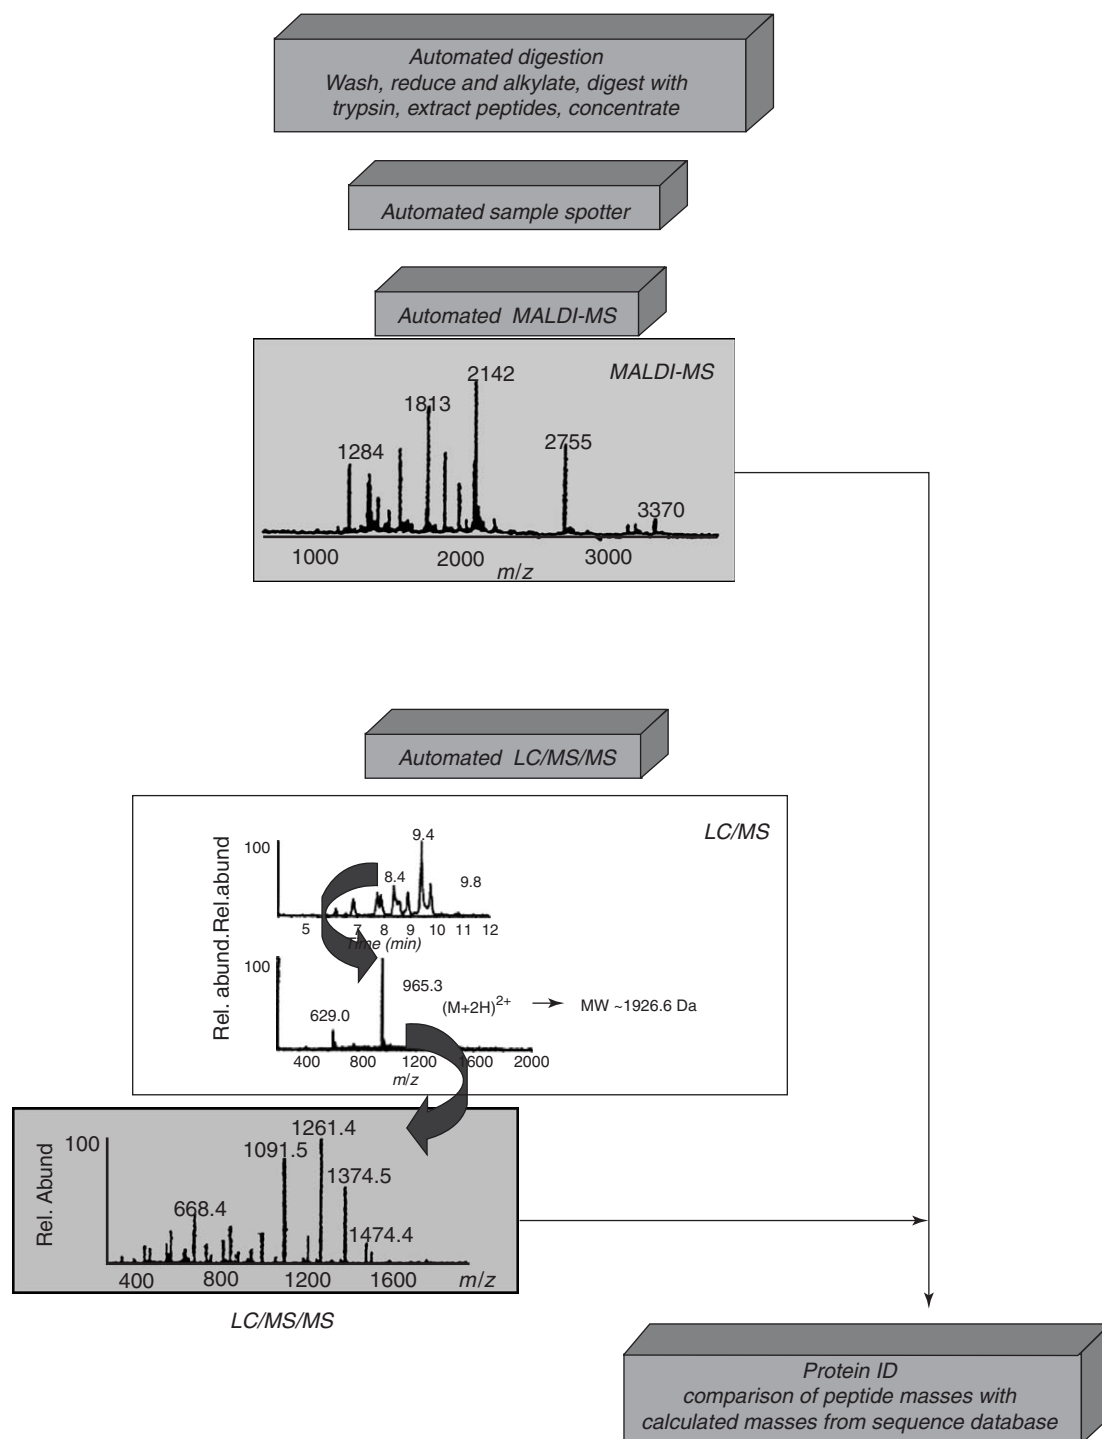

Figure 13 A general scheme for protein identification utilizing an MS-based approach.

(5) Extraction of tryptic peptides from the gel:

- Extract with 30 μL of 50% CH_3CN containing 1% trifluoroacetic acid (TFA) three times for 10 min each.
- Combine the supernatant for each of the three extractions and dry by vacuum centrifugation.
- Resuspend peptides in 5 μL of 30% CH_3CN containing 1% TFA and store at -80°C .

Using the above protocol, a scientist can comfortably digest and extract 25 samples in less than 36 h, which limits the throughput to approximately 100 in-gel digests and extractions per week. (In our experience, significant human error can be introduced over time while manually processing more than 25 samples per day.) Reducing the digest time from overnight to 2–3 h can improve the throughput, but not significantly. However, a 2D gel of a cell lysate can contain literally thousands of unique proteins, seen as stained spots. Even if the spots are excised from the gel manually, hundreds of samples requiring digestion and extraction can be generated per day. Setting aside the fact that in a proteomics project it is rare that each experiment would require every single spot from the gel to be identified, it is obvious that many more samples can be generated per week per scientist than digested and extracted manually.

A welcome alternative to the lengthy and laborious manual digest and extraction process are several commercially available automated digest and extraction robots.^{236–238} The most useful of these robotic systems have the following features in common: some form of computer control, temperature control, options for allowing digestion with multiple enzymes, and the ability to digest gel pieces and extract the subsequent proteolytic peptides in a 96-well plate format, allowing parallel sample processing of 96 samples at a time. This will increase the throughput to approximately 400 samples per week per robot using the above protocol, and potentially far more using a shorter digestion period.

Commercial units from Genomic Solutions (ProGest) and AbiMed (Digest-Pro) incorporate a particularly ingenious mechanism for overcoming possible sample contamination issues arising from the liquid-handling syringe system. The syringe never touches the solutions in the wells. Instead, it pressurizes the wells such that the liquid flows from two small holes laser drilled into the bottom sides of each of the wells in the 96-well PCR plate. The robot slides the reaction PCR 96-well plate over either a waste position for adding and discarding reaction reagents or a sample collection position for the extraction of proteolytic peptides. This methodology also decreases the opportunities for sample loss to adsorptive surfaces, although this remains a significant issue for low-level samples.

2.12.4.3.3 Peptide mapping by matrix-assisted laser desorption/ionization mass spectrometry

A mass spectrum of the resulting digest products produces a ‘peptide map’ or a ‘peptide fingerprint’; the measured masses can be compared with theoretical peptide maps derived from database sequences for identification. There are a few choices of mass analysis that can be selected from this point, depending on the available instrumentation and other factors. The resulting peptide fragments can be subjected to MALDI²³⁹ and/or electrospray ionization (ESI)-MS²⁴⁰ analysis.

MALDI-MS is a tool that has rapidly grown in popularity in the area of bioanalytical MS. This is due to recent improvements in time-of-flight (TOF) technology through enhancements in resolution and, subsequently, mass accuracy, which have increased the usefulness of MALDI-MS data. Currently, the TOF analyzer is the most common system for MALDI. Improvements such as the reflectron analyzer and time-lag focusing (delayed extraction) have greatly improved the quality of MALDI-MS data.²⁴¹ Automation has also played an important role in the increased use of MALDI-MS as a tool for proteome analysis by allowing automated acquisition of data, followed by fully automated database searching of protein sequence databases such as SWISS-PROT and NCBI.^{194,242,243}

To better understand the reasons for the popularity of MALDI-MS, one must first understand the simplicity and speed of the approach. The peptide analyte of interest is co-crystallized on the MALDI target plate with an appropriate matrix (i.e., 4-hydroxy- α -cyanocinnamic acid or 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid)), which are small, highly conjugated organic molecules that strongly absorb energy at 337 nm. In most MALDI devices, 337 nm irradiation is provided by a nitrogen laser. Although other lasers operating at different wavelengths can be used, size, cost, and ease of operation have made the nitrogen laser the most popular choice. The target plate is then inserted into the high-vacuum region of the source, and the sample is irradiated with a laser pulse. The matrix absorbs the laser energy, and transfers energy to the analyte molecule. The molecules are desorbed and ionized during this stage of the process. The ions are then accelerated under constant kinetic energy (V) down the flight tube of the TOF instrument by using acceleration potentials up to 30 kV. This acceleration potential imparts the ions with nearly the same kinetic energy, and they each obtain a characteristic flight time (t) based on their mass-to-charge (m/z) ratio and total flight distance (L):

$$t = \sqrt{[(m/z)(1/2v)]}$$

As a result, ions of different masses are separated as they travel down the field-free region of the flight tube of the mass spectrometer (lighter ions travel faster than larger ions), then strike the detector and are registered by the data system, which converts the flight times to masses.

A MALDI-TOF mass spectrometer consists of six major sections:

- (1) Laser system: a device capable of supplying an appropriate wavelength of energy sufficient to desorb and ionize matrix and analyte from the target surface.

- (2) Source: a section of the instrument that contains the target plate that holds the matrix and analyte of interest. Ions generated in the source region are accelerated down the flight tube.
- (3) Flight tube: a field-free region of the mass spectrometer where separation of the ions based on their characteristic mass-to-charge ratio occurs.
- (4) Detector: a device that detects and measures ions.
- (5) Data system: a computer that converts the detector output into an easily interpreted form (mass spectrum) and allows storage of the spectral data.
- (6) Vacuum system: components necessary to evacuate the source and free-flight region, creating pressures in the 10^{-6} – 10^{-7} torr range.

To obtain the best mass accuracy possible, MALDI-MS instrumentation equipped with a reflectron and time-lag focusing is commonly employed.²⁴¹ A reflectron is used to compensate for the initial energy spread that the ions may have following desorption off the sample target plate. Ions of the same mass-to-charge ratio, which have slightly different energy, have different final velocities, and therefore arrive at the detector at slightly different times, resulting in loss of resolution. To compensate for this effect, an ion mirror or reflection is used to focus the ions by creating a flight distance gradient: ions with higher kinetic energy penetrate more deeply and thus travel a longer total distance than ions of lower energy. In addition, time-lag focusing (commonly referred to as delayed extraction) allows the initial energy spread to be partially focused prior to accelerating the ions. The combination of time-lag focusing with an ion mirror provides for higher order energy focusing, resulting in significantly enhanced mass-resolving power and improved mass accuracy. In many cases, this combination can increase MALDI-TOF mass accuracy to better than 20 ppm for peptides of molecular mass 500–3000 Da.

The large number of samples generated by a proteomics approach requires a capability for very high throughput that can be achieved through automation of the entire process. Most commercial MALDI-MS instruments have capabilities for automated data acquisition. However, the amount of interactive control feedback can vary greatly, and this feature should be considered carefully when evaluating this type of analysis. The quality of the data and the speed at which it is obtained can be greatly affected by laser energy and the homogeneity of the analyte spot. To minimize the effects caused by inhomogeneous analyte crystals and searching for ‘the sweet spot’ across a sample spot, an automated MALDI sample preparation robot can be used. Currently, there are several automated sample preparation robots available commercially, including ones from Micromass, Bruker, and PerSeptive Biosystems.

The MALDI sample spotter supplied by Genomic Solutions is capable of spotting the target configurations of various instrument manufacturers’ systems. In addition, the system can be programmed with sample preparation protocols to remove gel contaminants (i.e., salts, ammonium bicarbonate, SDS, etc.) that could interfere with or degrade spectral quality. For example, the use of pipette tips packed with reversed-phase media (e.g., C18 ZipTips from Millipore) effectively desalts and concentrates peptides for MALDI-MS analysis.

A small aliquot of the digest solution can be directly analyzed by MALDI-MS to obtain a peptide map. The resulting sequence coverage (relative to the entire protein sequence) displayed from the total number of tryptic peptides observed in the MALDI mass spectrum can be quite high (i.e., greater than 80% of the sequence), although it can vary considerably depending on the protein, sample amount, and so forth. The measured molecular weights of the peptide fragments along with the specificity of the enzyme employed can be searched and compared against protein sequence databases using a number of computer searching routines available on the internet. An example of such an exercise is depicted in [Figure 14](#) and is discussed further in [Section 2.12.4.3.5](#).

2.12.4.3.4 High-performance liquid chromatography-mass spectrometry and tandem mass spectrometry

An approach for peptide mapping similar to MALDI-MS involves the use of ESI-MS. ESI is a solution-based ionization method. Analyte solutions flowing in the presence of a high electric field produce submicrometer-sized droplets. As the droplets travel toward the mass spectrometer orifice at atmospheric pressure, they evaporate and eject charged analyte ions. These ions are sampled by the mass spectrometer for subsequent mass measurement. A peptide map can be obtained by the direct analysis of the peptide mixture by ESI-MS. A major advantage of ESI over other analytical approaches is its ease of coupling to separation methodologies such as high-performance liquid chromatography (HPLC). Thus, alternatively, to reduce the complexity of the mixture, the peptides can be separated by reversed-phase HPLC with subsequent mass measurement by on-line ESI-MS (see [Figure 13](#)). The measured masses can be similarly compared with sequence databases. An example of an LC/MS application is shown in [Figure 15](#).

Figure 14 MALDI-MS peptide map of *Escherichia coli* protein, Cell Division Inhibitor MinD (MIND_ECOLI, accession #P18197), separated by 2DE. The molecular masses labeled on the spectrum were compared with the sequence of the protein for identification (** denotes trypsin autolysis peaks). The portions of the protein sequence for the observed tryptic peptides are highlighted on the sequence.

To provide further confirmation of the identification, if a tandem mass spectrometer is available, peptide ions can be dissociated in the mass spectrometer to provide direct-sequence information. Peptide fragmentation typically occurs along the polypeptide backbone to produce products termed ‘y-type’ and ‘b-type’ fragment ions (in which the y ions contain the C-terminal portion of the peptide and the b ions contain the N-terminal portion). These product ions from an MS/MS spectrum can be compared with available sequences using powerful software tools as well. In many examples, laboratories may use nanoelectrospray with MS/MS to examine the unseparated digest mixtures with a high degree of success.¹⁹⁴

One of the most common tandem mass spectrometers used for proteomics applications is the quadrupole ion trap mass spectrometer.^{193,243–245} An ion trap is a ion storage device that utilizes radiofrequency voltage across a ring electrode to contain ions.²⁴⁶ As the radiofrequency amplitude increases, ions of increasing mass become unstable in the trap, and are ejected toward a detector. The ion trap mass spectrometer has become a workhorse instrument for proteomics because of its ease of use and because of its high efficiency for generating sequence information. Examples of MS/MS spectra derived from tryptic peptides are shown in Figure 16. For the examples shown, the MS/MS spectra were readily interpreted via computer programs.

For a single sample, LC/MS/MS analysis included two discrete steps: (1) LC/MS peptide mapping to identify peptide ions from the digestion mixture and to deduce their molecular weights, and (2) LC/MS/MS of the previously detected peptides to obtain sequence information for protein identification. An improvement in efficiency and throughput of the overall method can be obtained by performing LC/MS/MS in the data-dependent mode. As full-scan mass spectra are acquired continuously in the LC/MS mode, any ion detected with a signal intensity above a predefined threshold will trigger the mass spectrometer to switch to the MS/MS mode. Thus, the ion trap mass spectrometer switches back and forth between the MS mode (molecular mass information) and the MS/MS mode (sequence information) in a single LC run. This feature was implemented to generate the spectra shown in Figure 16. The data-dependent scanning capability, combined with an autosampler device, can dramatically increase the capacity and throughput for protein identification.

2.12.4.3.5 Computer-based sequence searching strategies

The concept of database searching with mass spectral data is not a new one. It has been a routine practice for the interpretation of electron ionization mass spectra for many years. However, there is a fundamental difference between database searching of electron ionization spectra and proteomic spectra. In the former, an experimentally acquired

Figure 15 (Left): HPLC mass chromatogram for the tryptic digest of ovalbumin. (Right): the resulting mass spectra at the indicated retention times. Approximately, 0.25 μg of protein was loaded onto an SDS-PAGE gel, and the protein was stained with zinc imidazole. An ESI ion trap mass spectrometer (LCQ, Finnigan MAT, San Jose, CA) coupled on-line with capillary HPLC (MicroPro Syringe Pumping System, Eldex Laboratories, Napa, CA) in conjunction with a capillary peptide trapping precolumn was used for peptide analysis.

spectrum is compared with a large collection of spectra acquired from known, authentic standards. Fundamental features, such as the ions present and their relative intensities, are compared, to establish a match and a 'quality of fit.' This type of computer-based searching is typically referred to as 'library searching.' This is in contrast to the strategy employed with proteomic data, where a list of experimentally determined masses is compared with lists of computer-generated theoretical masses prepared from a database of protein primary sequences. With the current exponential growth in the generation of genomic data, these databases are expanding every day.

There are typically three types of search strategies employed: searching with peptide fingerprint data, searching with sequence data, and searching with raw MS/MS data. These strategies will be discussed below. While the strategy employed often depends on the type of data available, there is also a logical progression, based on the cost of each strategy in terms of time and effort. While many of the computer-based search engines allow for the purchase of an on-site license for use with proprietary data, most are available on the internet for on-line access and use with public domain databases (Table 15). One limiting factor that must be considered for all of the following approaches is that they can only identify proteins that have been identified and reside in an available database or are highly homologous to one that resides in the database.

2.12.4.3.5.1 Searching with peptide fingerprints

MALDI peptide fingerprinting is probably the most rapid technique with which to identify an unknown protein. Computer software is used to theoretically 'digest' the individual protein components of a protein database using the same protease, generating a list of theoretical peptide masses that would be derived for each entry. The experimentally

Figure 16 HPLC-MS/MS data-dependent scan results for a tryptic digest of yeast enolase. The ion trap mass spectrometer automatically acquires MS/MS data for peptide peaks above a defined abundance threshold. The HPLC mass chromatogram is shown on the left, and representative MS/MS spectra are shown on the right. From top to bottom, the observed tryptic peptides of enolase are TAGIQIVADDLTVTNPK (residues 312–328), AAQDS-FAAGWGVMSHR (residues 358–374), and SGATEDT-FIADLV-VGLR (residues 375–391).

determined peptide masses are then compared with the theoretical ones in order to determine the identity of the unknown (as discussed in [Section 2.12.4.3.6](#) and depicted in [Figure 17](#)).

The majority of the available search engines allow one to define certain experimental parameters to optimize a particular search. Among the more typical are: the minimum number of peptides to be matched, allowable mass error, monoisotopic versus average mass data, the mass range of the starting protein, and the type of protease used for digestion. In addition, most permit the inclusion of information about potential protein modification, such as N- and C-terminal modification, carboxymethylation, and oxidized methionines. However, most protein databases contain primary sequence information only, and any shift in mass incorporated into the primary sequence as a result of post-translational modification will result in an experimental mass that is in disagreement with the theoretical mass. In fact,

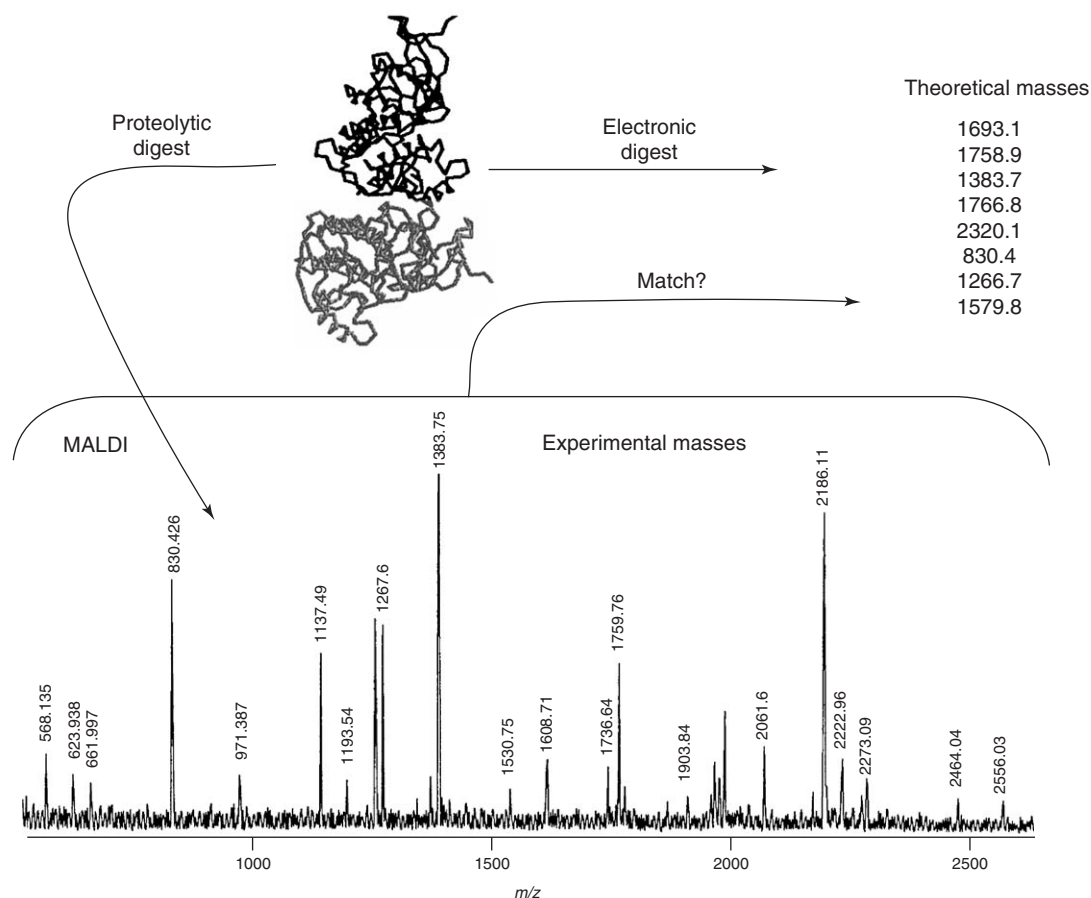

Figure 17 Principles of protein identification by MALDI-MS peptide fingerprinting.

this is one of the greatest shortcomings of this particular method. Modifications such as glycation and phosphorylation can result in missed identifications. Furthermore, a single amino acid substitution can shift the mass of a peptide to such a degree that even a protein with a great deal of homology with another in the database cannot be identified. Interestingly, one software package, ProteinProspector, has a feature within its MS-Fit subprogram that allows one to search peptide fingerprint data in the 'homology mode.' In this mode, the software considers possible mutations of individual amino acid residues in an effort to transform a theoretical peptide mass to match an experimental one. This can be an extremely powerful tool for the identification of a protein that is not in the database yet is significantly homologous to one that is in the database.

A number of factors affect the utility of peptide fingerprinting. The greater the experimental mass accuracy, the narrower you can set your search tolerances, thereby increasing your confidence in the match and decreasing the number of false-positive responses.²⁴⁷ A common practice used to increase mass accuracy in peptide fingerprinting is to employ an autolysis fragment from the proteolytic enzyme as an internal standard to calibrate a MALDI mass spectrum. Nevertheless, in terms of sample consumption, throughput, and the need for intensive data interpretation, peptide fingerprinting is always a logical first approach for protein identification.

Peptide fingerprinting is also amenable to the identification of proteins in complex mixtures. Peptides generated from the digest of a protein mixture will simply return two or more results that are a good fit. As long as the peptides assigned for multiple proteins do not overlap identification is reasonably straightforward. Conversely, peptides that are 'left over' in a peptide fingerprint after the identification of one component can be resubmitted for the possible identification of another component.

2.12.4.3.5.2 Searching with sequence information

Computer-based searching of databases with sequence information is the oldest and probably the most straightforward of the three strategies. Typically, an experimentally determined partial amino acid sequence is compared with the

sequences of all of the proteins listed in a database, and a list of those proteins containing the same partial sequence is generated. Virtually all of the web-based search applications are able to search with sequence information. One advantage of this approach is that typical search engines, such as BLAST, allow for increasing levels of ambiguity in the submitted experimental sequence, facilitating the identification of homologous known sequences.

Protein identification via searching with sequence information employs similar strategies irrespective of how the sequence information is obtained. Automated Edman degradation is one of the traditional methods for obtaining sequence information. However, several drawbacks make this approach somewhat less attractive. The collection of data is time-consuming, typically requiring 12–24 h. The subsequent interpretation of the data to extract an amino acid sequence is still largely done by hand, making it a difficult process to automate. And information is limited to the N terminus of the protein; if interior information is desired, the protein must be proteolytically digested, and the individual peptides separated and collected for off-line analysis.

The ability to rapidly generate amino acid sequence information via MS/MS experiments, whether it is with a triple-quadrupole instrument, an ion trap, or via postsource decay with MALDI-TOF, has revolutionized the practice of generating sequence information. Many software packages can use a combination of sequence information and mass spectral information, such as the molecular weight of the individual peptide under investigation. With an accurate value of the parent ion mass of a peptide, and even partial sequence information, it is possible to get a strong match for an unknown. A disadvantage of this approach is that it requires manual interpretation by the operator, making it more difficult to automate, and can require two separate experiments to get both pieces of information.

Some software packages employ a combination of predictive MS/MS data and sequence information. An example is the so-called error-tolerant software that is part of the PeptideSearch package (available from the EMBL website). This strategy is employed when a certain amount of sequence information is available from an MS/MS spectrum, but not the complete sequence. The starting mass of the partial sequence, followed by the sequence itself and then the ending mass, are submitted for database searching. The partial sequence must be manually derived from the experimental MS/MS data, which requires operator input and is not amenable to automation. However, a weak spectrum in which only 4–5 amino acid residues can be deduced typically does not yield enough information to unequivocally identify a protein, or may return a deluge of poor matches. By incorporating the ion mass at which the partial sequence starts and stops, as well as the mass of the peptide itself, PeptideSearch is often able to generate a strong match from marginal data. Potential candidate proteins in the database must contain the partial sequence, must generate a theoretical proteolytic peptide of the correct mass, and must contain the partial sequence positioned appropriately within that theoretical peptide, based on the starting and ending masses of the partial sequence. If a candidate protein meets all of these requirements, then a strong match can be argued for even a very short experimentally derived sequence.

2.12.4.3.5.3 Searching with raw tandem mass spectrometry data

Current mass spectral technology permits the generation of MS/MS data at an unprecedented rate. Prior to the generation of powerful computer-based database-searching strategies, the largest bottleneck in protein identification was the manual interpretation of this MS/MS data to extract the sequence information. Today, many computer-based search strategies that employ MS/MS data require no operator interpretation at all. Analogous to the approach described for peptide fingerprinting, these programs take the individual protein entries in a database and electronically ‘digest’ them, to generate a list of theoretical peptides for each protein. However, in the use of MS/MS data, these theoretical peptides are further manipulated to generate a second level of lists that contain theoretical fragment ion masses that would be generated in the MS/MS experiment for each theoretical peptide (Figure 18). Therefore, these programs simply compare the list of experimentally determined fragment ion masses from the MS/MS experiment of the peptide of interest with the theoretical fragment ion masses generated by the computer program. Again, as with the peptide fingerprint strategy, the operator inputs a list of masses, and typically has a choice of a number of experimental parameters that can be used to tailor the search as appropriate. This is a very processor-intensive function, and, due to the size of current databases, is only possible on a routine basis due to the explosive increase in desktop computing power.

The recent advent of data-dependent scanning functions on an increasing number of mass spectrometers has permitted the unattended acquisition of MS/MS data. Another example of a raw MS/MS data-searching program that takes particular advantage of this ability is SEQUEST. The SEQUEST software processes the input from a data-dependent LC/MS chromatogram, automatically strips out all of the MS/MS information for each individual peak, and submits it for database searching using the strategy discussed above. The appeal of this approach is that each peak is treated as a separate data file, making it especially useful for the on-line separation and identification of individual components in a protein mixture. No user interpretation of MS/MS spectra is involved.

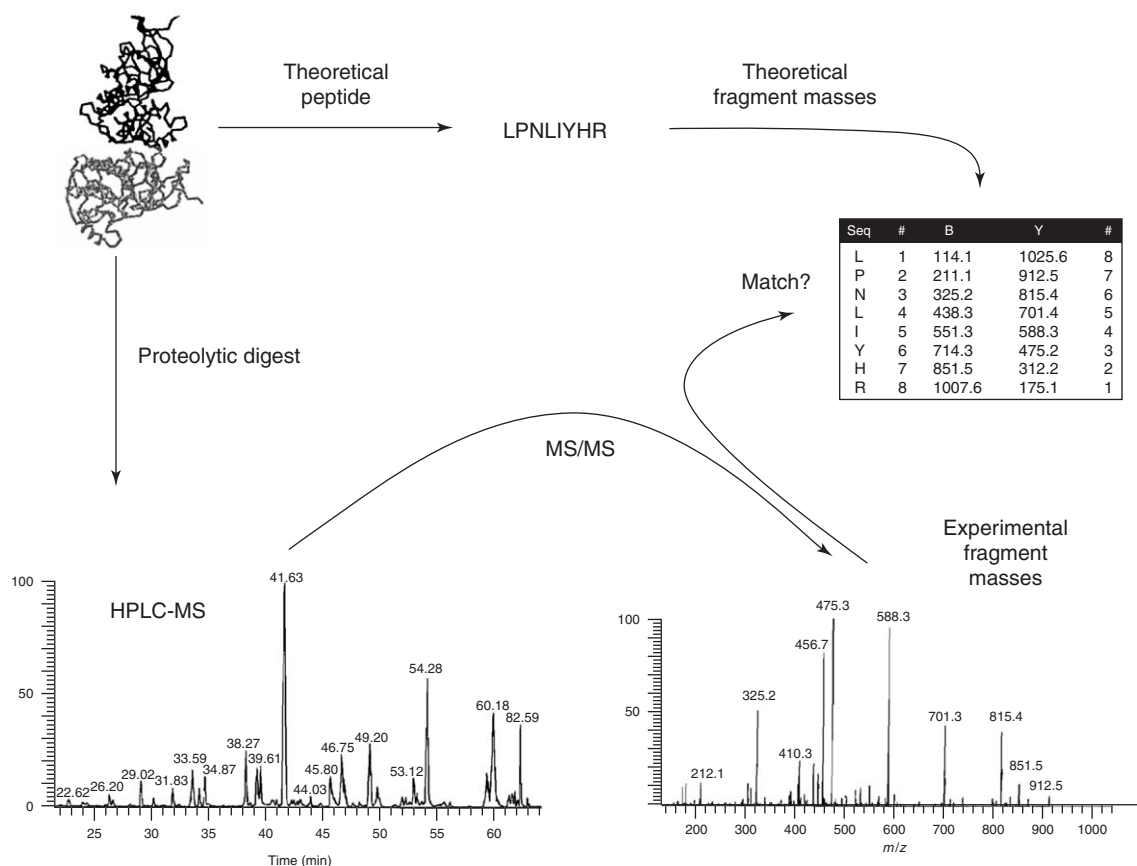

Figure 18 Principles of protein identification by HPLC-MS/MS peptide sequencing.

Several different strategies are applicable in the computer-based searching of sequence databases for the identification of unknown proteins. The choice of strategy employed is often dictated by the format of the data available. However, one must always use caution and examine the results with a critical eye. It is the responsibility of the investigator to examine the list of resultant matches with respect to quality of fit. Often this is aided by examining the individual MS/MS spectra and ensuring that most of the abundant ions are being used for identification, not simply those that are in the 'grass.'

The capacity to perform these searches using web-based programs provides direct access to the rapidly expanding collection of public domain protein databases that are also on the internet. Furthermore, most of the programs take great advantage of the ability of HTML to weave various sources of information together through hyperlinks, so that when a strong candidate for a protein identification is found, a wealth of additional information is only a mouse click away.

2.12.4.3.6 Other methods used for proteomics research

Seeking to avoid the difficulties associated with extracting proteins embedded in gel matrices, other approaches to proteome analysis dispense with polyacrylamide gel separations and rely on multidimensional chromatography. One such approach has paired size exclusion chromatography with HPLC for intact protein analysis, offering convenient preparative capabilities by directing column effluent to a fraction collector.²⁴⁸ For identification purposes, ESI-MS mass analysis offers an intact molecular weight accurate to about $\pm 0.1\%$, and fractions can also be analyzed at significantly lower throughput by Edman degradation for N-terminal sequence determination, enzymatic digestion followed by successive stages of MS and MS/MS for higher confidence identification and/or characterization, or by other assays. While promising, the comprehensive chromatographic method is currently limited by dynamic range (ability to see low-level proteins present at only a few copies per cell in the presence of abundant proteins present at tens of thousands or more copies per cell). Moreover, identification on the basis of molecular weight alone is risky, particularly in complex systems presenting many post-translational modifications; the availability of chromatographic retention times does not enhance the confidence of proposed identifications significantly. Finally, membrane proteins and other

Figure 19 Schematic of a capillary electrophoresis system.

hard-to-solubilize proteins may not be recovered by this methodology, and tend to be harder to handle as intact proteins versus tryptic peptides.

Capillary electrophoresis (CE) is a very high-resolution technique similar to gel electrophoresis, except that the separations take place in a capillary filled with an electrolyte. The term 'CE' encompasses all of the electrophoretic separation modes that can take place in a capillary. A schematic of a CE system is shown in [Figure 19](#). In the simplest terms, separations are achieved in CE based on differences in the electrophoretic mobilities of charged species placed in an electric field. However, one other phenomenon present in CE also contributes to the movement of analytes in an applied potential field, that being the electro-osmotic flow. Electro-osmotic flow describes the movement of fluid in a capillary under the influence of an applied electric field, and is brought about by the ionization of silanol groups on the inner surface of the capillary when in contact with the electrolyte. An electrical double layer is formed when hydrated cations from the electrolyte associate with the negatively charged ionized silanol groups. When a potential is applied, the hydrated cations migrate to the cathode, creating a net flow in the same direction. The velocity of the electro-osmotic flow can be directly affected by changes in the field strength, electrolyte pH, and viscosity of the electrolyte solvent system used. The contribution of electro-osmotic flow to the movement of charged species in a capillary can most easily be determined experimentally by observing the migration time to the detector of a neutral marker species. The flow characteristics of electro-osmotic flow are plug-like, in comparison with the laminar flow achieved in LC. As a result, far more theoretical plates can be generated in CE as compared with comparable column lengths in LC. There are any number of excellent texts available that cover in-depth the theories associated with CE.^{249,250}

As described for HPLC, by far the most widely applied ionization method used in interfacing CE to MS for the analysis of biomolecules is ESI. An uninterrupted electrical contact is essential for both the continued operation of CE and for the generation of the electrospray when interfacing CE with ESI-MS. Several interfaces have been developed to achieve this electrical contact. The three most widely applicable interfaces are liquid junction, sheath liquid, and sheathless interfaces.

Although detection limits down to attomole ranges have been reported, CE is generally recognized as having a very low concentration limit of detection (CLOD). To achieve the best resolution and peak shape, it is necessary to inject only very small volumes (low nanoliters) of sample, which forces the use of highly concentrated samples initially. Several groups have developed various preconcentration techniques to attempt to overcome this CLOD.²⁵¹ All of these techniques involve trapping or preconcentrating the samples on some type of C18 stationary phase or hydrophobic membrane in the case of tryptic digest mixtures.

Capillary IEF (CIEF) has been combined with on-line ESI Fourier transform ion cyclotron resonance (ESI-FTICR) MS to examine desalted, intact *E. coli* proteins.²⁵² The methodology's promises of simultaneous ppm mass measurement accuracy, high sensitivity, and ultrahigh MS resolution would be particularly attractive for intact protein analyses from proteomics samples. Protein pI in combination with molecular weight can provide a useful means for proposing protein identifications. However, the CIEF conditions employed for on-line MS have so far employed native or near-native separation conditions, yielding pI values that are not predictable from sequence alone and that do not necessarily correlate with the denatured pI values. MS/MS dissociation techniques compatible with FTICR MS, such as infrared multiphoton dissociation or sustained off-resonance irradiation, may provide structural information to yield higher confidence protein identifications.

The most developed, automated nongel methodology for proteome analyses was demonstrated by the analysis of *E. coli* periplasmic proteins, partially fractionated by using strong anion exchange chromatography.²⁵³ Each fraction was digested with trypsin and then analyzed by using microcolumn LC/ESI/MS. The MS/MS spectra were used to search the *E. coli* sequence database, from which a total of 80 proteins were identified. The procedure limits the amount of sample handling, and by manipulating the proteins as mixtures, the higher abundance proteins act as carriers for lower abundance proteins, further reducing losses. However, the presence of a single highly abundant protein can potentially suppress the acquisition of MS/MS spectra for lower abundance peptides present in the mixture (a dynamic range limitation). Also, because the procedure is a superficial sampling of the peptides present, there is the possibility that a protein may be present but no MS/MS data for peptides from that protein are acquired. For relatively simple mixtures this approach greatly increases the speed and efficiency of analysis.

Relative quantification can be difficult to achieve with all of the above methods. One trend, designed to deliver quantitative information, has been to isotopically label samples reflecting different conditions.²⁵⁴ Based on the isotope ratios of tryptic peptides (or appropriately sized intact proteins when Fourier transform MS is employed²⁵⁵), one can attempt to determine whether a protein is upregulated or downregulated. Clearly this methodology can only be employed when it is possible to isotopically label cells (e.g., bacterial cell cultures).

A newer approach to the delivery of quantitative information on all types of samples relies on alkylating cysteine residues with unique tags (e.g., isotopically encoded) that incorporate biotin functionalities.²⁵⁶ Cysteine-containing tryptic peptides can be withdrawn selectively from mixtures for subsequent LC/MS/MS analysis, yielding both identification and quantification. The approach should also reduce limitations on dynamic range because only cysteine-containing proteins would be loaded onto the LC column, albeit at the cost of losing all information about noncysteine-containing proteins.

2.12.4.4 Conclusions

Much of the technological advances to support proteomics research were developed during the past decade. However, it is obvious to those active in the field that many more developments will be unveiled in the near future. With improvements in sensitivity, throughput, and ease of use, proteomics will continue to flourish as a promising biomedical research endeavor. The tools used to generate the data will be better crafted, and the way in which the data generated from a proteomics approach are used to further the goals of drug discovery will become more sophisticated.

2.12.5 Where Science Meets Silicon: Microfabrication Techniques and Their Scientific Applications

2.12.5.1 Introduction

The historical trend in chemical and biological instrumentation and the development of analysis protocols over several decades has been to work with increasingly smaller sample volumes and quantities of analytes and reagents. This trend has been greatly facilitated by the development of very sensitive measurement technologies, such as mass spectrometry and laser-induced fluorescence. Additional benefits have included reduced reagent costs as well as lower environmental impact.

Microtechnologies merely continue this historical trend, but with a new twist – the jump to an entirely new technology platform. Moreover, new scientific problems can now be studied that take advantage of phenomena unique to micrometer scale domains, such as greatly increased surface to volume ratios. As an example, chemical reactions that are too energetic at a macro-scale and that require synthetic detours through less reactive intermediates can often be conducted directly on a micro-scale, where heat and mass transfer can be controlled much more efficiently. New intermediate products, never seen before, may also result.

The construction of microdevices is based on many of the fabrication technologies employed in the semiconductor industry. However, only recently has its use in microfluidic applications become a reality. A seminal paper that anticipated the use of silicon as a structural material for micromechanical systems is the one written by Petersen.²⁵⁷ He suggested and illustrated that microstructures with mechanical functionality were indeed possible with silicon as the construction material. This led gradually to the construction of active microfluidic components, such as valves, pumps, motors, and separators on chips.

Much early research focused on the use of different micromechanical systems and devices, such as pumps and chemical functionalities, for reaction, separation, and detection. As these became more robust and more routine,

increased complexity resulted in packaging of entire chemical protocols on a microdevice. On-board detection or interfaces to detection systems are also appearing in research laboratories and the marketplace.²⁵⁸

Microdevices are highly suited to field or portable use. We will see increased usage of these devices in medical care and environmental monitoring. Coupled to network systems, these devices can serve as a distributed laboratory. The economies of scale realized in the production of these systems will result in single-use or disposable systems.

This section will cover some of the traditional fabrication methods and discuss trends in new materials and techniques. Some discussion will focus on systems packaging and integration techniques and issues. This will be followed by descriptions of a selection of commercial systems that are emerging. It is difficult to predict where these technologies will lead. However, it is safe to assume that they will have a widespread and fundamental impact on many areas of scientific endeavor. These areas include materials research, environmental monitoring, healthcare, drug discovery, and national security.

The microtechnology field literature is rich.^{259–261} It is not the purpose of this section to restate this material but rather to provide a quick overview from the perspective of the use of these technologies in the chemical and biological laboratory.

Microtechnologies in the semiconductor industry cover a size regime of roughly 0.1–100 μm . For example, microprocessors are currently being fabricated with 0.18 μm feature sizes that make possible not only faster performance but also the packaging of greatly increased functionality on the same size chip. This is the same scale that we will use to describe microtechnologies for chemical and biological applications.

Another new emerging field – nanotechnology – covers the atomic and molecular domains from a few nanometers to about 100 nm. Nanotechnology is defined as the creation of useful materials, devices, and systems through the control of matter on the nanometer length scale and the exploitation of novel properties and phenomena developed at that scale. As such, nano- and microregimes overlap and, indeed, there will be synergies between the two. For example, we will see nanoscale sensors as detection components in microscale laboratory devices. A brief discussion of nanotechnology and its applications will also be given.

2.12.5.2 Traditional Methods of Microfabrication

The term ‘microfabrication’ broadly refers to all techniques for fabricating devices and systems on the micrometer scale. As such, it borrows heavily from the processes and techniques pioneered in the semiconductor industry. To fabricate such small devices, processes that add, subtract, modify, and pattern materials are heavily used. The term ‘micromachining’ can also be used to describe technologies to make devices other than electronic and semiconductor circuits. Similarly, these technologies can be characterized as additive (i.e., deposition of materials, metals, etc.) or subtractive (i.e., removal of materials through mechanical means, etching, laser processes, etc.). Micromachining processes can further be described as either surface or bulk. Surface techniques act on layers of materials above a base or substrate whereas bulk techniques also involve removal or modification of the substrate.

2.12.5.2.1 Lithography and photolithography

Lithography is the most basic method for the construction of microscale devices, and is an old technique first developed in the early nineteenth century. Used originally and still widely in use today in the printing industry, lithography is also the mainstay of modern semiconductor manufacturing.

Lithography is basically a technique or suite of techniques for transferring copies of a master pattern onto the surface of a solid material. The most widely used form of lithography in the construction of microdevices is photolithography, where the master pattern (i.e., a mask) is transferred onto a photosensitive solid material using an illuminated mask. Transfer of the mask pattern can be accomplished through either shadow printing, whereby the mask is held close to (10–20 μm) or in contact with the surface of the photosensitive resist layer, or by projection printing, whereby the pattern is projected through an optical lens system onto the target layer. The latter can take advantage of magnifying or reducing optics to make very small features such as those seen in very large scale integrated devices.

2.12.5.2.1.1 Bulk micromachining

The exposed resist material is then removed or developed through various etching processes. The exposed portions of the resist layer are removed if positive resist materials are used and, conversely, unexposed portions of the resist are removed if negative resist materials are used. The basic positive resist process is illustrated in [Figure 20](#).

In bulk micromachining, the substrate is removed wherever it is not protected by the resist material during the etching process. Etching can be either isotropic or anisotropic. In isotropic etching, removal of material occurs in all directions at the same or approximately the same rate. Isotropic etching tends to produce structures with rounded

Figure 20 (a) The basic photolithographic process is illustrated wherein a photosensitive resist material on a substrate is exposed through a patterned mask. (b) After exposure the resist material is removed through a developing step. Positive photoresist material is shown in this example.

features. Anisotropic etching, on the other hand, tends to proceed along a preferred direction, and results in more sharply defined features. While these terms describe the extremes of potential etching behavior, it is rare that either process operates to the exclusion of the other, and the resulting structures are generally along a continuum somewhere between the two extremes.

2.12.5.2.1.1.1 Isotropic etching Isotropic etching removes material in all directions at the same or nearly the same rates. Deviations from true isotropic behavior are generally attributed to differences in chemical mass transport of etchants to target surfaces. Agitation of the material during etching greatly improves true isotropic performance. **Figure 21** shows the individual steps involved in chemical etching, namely diffusion from the bulk etchant solution and adsorption to the surface of the substrate where chemical reaction occurs. This is followed by desorption of the reaction products and, finally, diffusion of the reaction products back into the bulk solution.

Material removal is often accomplished through etching in acidic media. A mixture of hydrofluoric acid (HF)/nitric acid (HNO₃)/water and acetic acid is commonly used.

The overall reaction²⁶² is given by

Mechanistically, this reaction can be broken down into several sequential half-reactions. Local oxidation of silicon takes place in nitric acid. The anodic reactions are also described as the injection of ‘holes’ into the silicon, and are given by

The corresponding cathodic reaction is the attachment of OH[−] to Si²⁺ to form Si(OH)₂, and is given by

followed by

Figure 21 Chemical etching involves five steps: diffusion of reactants to the surface where they are adsorbed, reaction with the surface, and desorption and diffusion of reaction products into the bulk solution.

Table 16 Isotropic HNA-based silicon etching solutions

<i>Nitric acid</i>	<i>HF</i>	<i>Acetic acid</i>	<i>Comment</i>
100	1	99	Removes shallow implants
91	9		Polishing etch at 5 μm min ⁻¹ with stirring
75	25		Polishing etch at 20 μm min ⁻¹ with stirring
66	34		Polishing etch at 50 μm min ⁻¹ with stirring
15	2	5	Planar etch
6	1	1	Slow polishing etch
5	3	3	Nonselective polishing
3	1	1	Selective etch of n ⁺ or p ⁺ with added NaNO ₂ or H ₂ O ₂

and, finally:

This is followed by the dissolution of the SiO₂ by HF:

At high HF and low HNO₃ concentrations, the etch rate is controlled by the HNO₃ concentration and the rate of oxidation of silicon. Conversely, at low HF and high HNO₃ concentrations, the etch rate is controlled by the ability of HF to remove SiO₂. The addition of acetic acid extends the oxidizing power of nitric acid over a wider range of dilution. The dielectric constant of acetic acid of approximately 6, compared with a value of 81 for water, results in less dissociation of the nitric acid. The etching reaction is diffusion controlled, and the concentration determines the etch rate, so that mixing is important for uniform etching behavior. [Table 16](#) summarizes some typical isotropic etching solution concentrations and their effects.

Table 17 Typical etch rates and conditions for anisotropic etchants

<i>Formulation</i>	<i>Temp (°C)</i>	<i>Etch rate ($\mu\text{m min}^{-1}$)</i>	<i>$\langle 100 \rangle / \langle 111 \rangle$ etch ratio</i>	<i>Mask film</i>
KOH, water, isopropanol	85	1.4	400:1	SiO ₂ (1.4 nm min^{-1}) Si ₃ N ₄ (negligible)
KOH, water	65	0.25–1.0		SiO ₂ (0.7 nm min^{-1}) Si ₃ N ₄ (negligible)
TMAH, water	90	3.0	10	SiO ₂ (0.2 nm min^{-1})

Although isotropic etching agents are simple to use, there are several drawbacks. It is difficult to mask with high precision with a masking agent such as SiO₂ because the masking agent is also etched to a measurable degree. Moreover, the etch rate is sensitive to temperature and stirring conditions. For this reason, anisotropic etching agents were developed.

2.12.5.2.1.1.2 Anisotropic etching The discovery of anisotropic etchants in the 1960s addressed the lack of geometrical control presented by isotropic bulk etching agents. These agents preferentially etch along a particular crystalline direction with a discrimination or anisotropy ratio (AR) that can exceed 500:1. The anisotropy ratio is defined as

$$\text{AR} = (\text{hkl})_1 \text{ etch rate} / (\text{hkl})_2 \text{ etch rate}$$

AR is defined as approximately 1 for isotropic etchants, and can be as high as 400/1 for the $\langle 110 \rangle / \langle 111 \rangle$ crystal orientations using potassium hydroxide.

A wide variety of etching solutions are available for anisotropic etching. Two popular ones are KOH and tetramethylammonium hydroxide (TMAH). [Table 17](#) gives some of the properties of these popular anisotropic etchants. Others include the hydroxides of other alkali metals (e.g., NaOH, CsOH, and RbOH), ammonium hydroxide, ethylenediamine pyrocatechol (EDP), hydrazine, and amine gallates. For each, a key feature is the fact that the $\langle 111 \rangle$ crystal directions are attacked at rates at least 10 times, and typically 20–100 times, lower than other crystalline directions. Anisotropic etching can also be further controlled by the introduction of dopants or by electrochemical modulation.

2.12.5.2.1.1.3 Etch stopping It is often desirable to stop the etching process at precisely defined places. Highly doped p^+ regions, generally obtained with gaseous or solid boron diffusion into the silicon substrate, greatly attenuate the etching rate. It is believed that doping leads to a more readily oxidizable surface. These oxides are not readily soluble in KOH or EDP etchants.

Other attenuation methods include electrochemical modulation. This involves holding the silicon positive to a platinum counter-electrode. A very smooth silicon surface can result (referred to as electropolishing). Photon-pumped electrochemical etching is also a popular modulation technique, especially for high-aspect-ratio features.

2.12.5.2.1.2 Surface micromachining

Surface micromachining refers to those processes that act on layers above a substrate. [Figure 22](#) illustrates the principle. As in bulk micromachining, both additive and subtractive processes can occur with surface micromachining. A problem unique to surface techniques is sticking, whereby supposedly freestanding surface micromachined structures adhere to the substrate after the last rinse.

The primary cause of sticking is the capillary force of water that pulls the structure against the wafer. Ethanol can be added to the rinse water to reduce surface tension. Ethanol and *t*-butyl alcohol followed by freeze drying can also be used as can the addition of antisticking surfaces such as fluorocarbon film.

Many structures have been made with surface techniques. These include digital micromirror devices (DMDs) or arrays (DMMA), which are used in digital light projectors and have now also seen application in the construction of oligonucleotide hybridization arrays. Other common surface micromachined devices include valves²⁶³ and nozzles.²⁶⁴

Figure 22 Surface micromachining operates on layers deposited on the surface of a substrate.

2.12.5.2.1.3 Metal electrodeposition

Electroplating is a very useful process for producing additive metal structures above a substrate. A large number of metals can be electroplated, including copper, gold, silver, nickel, and platinum. These are generally reduced from a salt solution, typically a sulfate or cyanide. Either DC or AC current can be used, with the latter generally resulting in much finer grain growth.

As an alternate to electricity, some metals can be deposited using chemical reducing agents. These are the so-called electroless processes, and can be used for gold and nickel. Chemical reducing agents include potassium borohydride and dimethylamine borane for gold and NaH_2PO_2 for nickel. Aspect ratios for structures generated by electroless plating can reach 10:1.

2.12.5.2.2 Newer techniques and materials

Many techniques have evolved and been developed in the last three decades. A few of these are profiled below. This list is far from complete, and there are also many variations on the ones described below. However, these techniques are commonly used, and therefore some familiarity will be useful.

2.12.5.2.2.1 Plasma and deep reactive ion etching

There are several dry-etching processes that include the use of reactive gas plasmas and ions. External energy in the form of radiofrequency power drives the chemical reactions. In a plasma etcher, the wafer is one of two electrodes, and is grounded. The powered electrode is the same size as the wafer. Plasmas are generally low temperature, and operate in the 150–250 °C range; however, some operate down to room temperature. In DRIE, the powered electrode is the wafer with the other electrode being much larger. Very-high-AR devices (40:1) can be obtained with these techniques. Reactant gases generating ions in the radiofrequency field generally have unusually high incident energies normal to the substrate. Some common etch gases and mixtures are CClF_3 plus Cl_2 , CHCl_3 plus Cl_2 , SF_6 , NF_3 , CCl_4 , CF_4 plus H_2 , and C_2ClF_5 .

2.12.5.2.2.2 X-ray LIGA

LIGA is an acronym for the German ‘Lithographic, Galvanoformung, Abformung,’ a succession of lithographic, electroplating, and molding processes. LIGA can generate high-aspect-ratio devices in excess of 100:1. Developed by Ehrfeld,²⁶⁵ LIGA is a template-guided microfabrication process that uses an extremely well-collimated synchrotron x-ray radiation source to transfer a pattern onto a substrate.

Figure 23 shows the basic steps of the LIGA process. A primary substrate is coated with a conductive top layer. Polymethyl methacrylate (PMMA) is then applied typically through a series of multiple spin casts or as a commercially prepared thin sheet solvent bonded to the substrate. The PMMA is then exposed through a mask opaque to x-rays and then developed, resulting in high-aspect structures. Metal is then electroplated onto the PMMA mold, and the resulting assembly is diamond lapped and polished to the desired height. The remaining PMMA is then developed away, and a chemical etch removes the conducting top layer, thus freeing the part.

One drawback of LIGA is the need for a synchrotron radiation source, which restricts access to the technique dramatically, even though there are many such light sources available worldwide. Many devices have been constructed using the LIGA process. These include microvalves,²⁶⁶ micropumps,²⁶⁷ fluidic amplifiers,²⁶⁸ and membrane filters.²⁶⁹ Some of these devices, while manufactured by the LIGA technique, have subsequently proven inferior to or more expensive than those made by other technologies.

Figure 23 The LIGA process. Steps 1–5 are conventional lithography. Nickel is electroplated in step 6, after which the wafer is lapped to the desired thickness. Step 6 shows the remaining PMMA removed. The structures can then be freed from the seed metal base layer.

2.12.5.2.2.3 Ultraviolet LIGA

To overcome the limitation of synchrotron light source requirement, thick ultraviolet-sensitive resists, such as polyimides, Hoechst AZ-4000, and Epon SU-8, have been developed as alternatives to the x-ray-sensitive PMMA. SU-8 is an epoxy-based, transparent negative photoresist material that can be built up into 200 μm -thick layers. AZ-4000 is a positive resist material that can be built up into layers 15–80 μm thick with multiple spin coats. These materials and the technique certainly are more accessible than LIGA. Aspect ratios of 5:1 to 15:1 can be achieved with these materials.

2.12.5.2.2.4 Polymer replication

The fabrication of microdevices with conventional plastic molding technologies, such as reaction injection and thermoplastic molding and hot embossing, should not be overlooked. These continue to be by far the cheapest alternatives to making microstructures in materials. The entire CD industry is dependent on these technologies, so that micrometer-sized features in plastic are readily achievable. Many of the microfluidic devices currently appearing on the market are made by this technique, and are designed to be inexpensive and disposable.

2.12.5.2.2.5 Laser ablation

Powerful laser beams have sufficient energy to ablate silicon through thermal evaporation. The 1.06 μm Nd:YAG and carbon dioxide laser systems are used routinely for drilling silicon. Lasers can be used for subtractive as well as additive processes, and have been used for annealing, deposition, and welding. In laser beam cutting, coherent light replaces electrons as the cutting tool. Removal rates tend to be slow. Lasers have also been used to assist in chemical etching to photodissociate the reactive etchant.

2.12.5.2.2.6 Ion beam milling

Ion beam milling is a thermomechanical drilling technique wherein the drill bit is a stream of ions. Typically, a liquid metal, such as gallium, is focused to a submicrometer diameter. Like laser ablation, ion beam milling is a slow serial technique. Atomic force microscope tools are made by ion beam milling, but the technique is generally too expensive to use in a mass production mode.

2.12.5.2.2.7 Ultraprecision machining

Single-crystal diamond tools have made ultrahigh-precision mechanical machining possible. A machining accuracy in the low-submicrometer range is possible. Throughput is extremely slow, and there are stringent environmental requirements on the machine. This technique will thus find limited use in the mass fabrication of microscale laboratory devices.

2.12.5.2.2.8 Porous silicon as a sensor material

Porous silicon was first discovered²⁷⁰ during the electropolishing of silicon in 1956. At low current densities, partial dissolution of silicon results during etching with hydrofluoric acid, with the formation of hydrogen gas:

A very porous silicon structure results that can have aspect ratios up to 250. Silicon can be made either microporous or macroporous. The pores follow the crystallographic orientation, and vary in size from 2 nm to 10 μm . Porous silicon oxidizes readily, and etches at a very high rate. A prepattern is generally defined by a photolithographic transfer. The etch pits formed on the exposed area of the mask serve as nucleation centers for macropores.

Porous silicon has been used in a number of applications, including electrochemical reference electrodes, high-surface-area gas sensors, humidity sensors, and sacrificial layers in micromachining. Recent research has focused on using porous silicon as a substrate for chemical sensors.²⁷¹ The silicon pillars can be derivatized using well-known chemistries, and linked to chemical recognition molecules (i.e., antibodies or oligonucleotides). When immersed in a solution of target molecules and exposed to light, an interference pattern results that is extremely sensitive to concentration. These porous silicon sensors can serve either as standalone instruments or as the sensing element in an integrated fluidic chip.

2.12.5.3 System Integration Issues

Integration covers a whole spectrum of issues from the semiconductor and fluidic levels to the control, information display and treatment, and user interface levels. Integration must address electronic interfaces, mechanical and optical interfaces, and materials and packaging issues, as well as the chemical compatibility and functionality.

Many single components, such as valves, pumps, separation columns, and optical and electrochemical detectors, have been made in the last three decades, and have been proven to work individually. The focus of much current work is to show how these components can be assembled into a multiple-function device. Activities such as sample preparation, detection, and data presentation are increasingly being collocated.

The choice of materials is wide. Materials must be chosen not only for ease and expense of fabrication but also for chemical and biochemical compatibility. [Table 18](#) lists some common choices, along with their advantages and disadvantages.

2.12.5.3.1 Interfaces

Fluid interconnects do not exist for microfluidic devices, and those that have been used vary widely from pipette tips and glue to gas chromatographic fittings and microfabricated fittings.^{272,273} In general, the ‘macro-to-micro’ interface issues have not been well resolved. Various technologies, including electrokinetic samples made by Caliper, allow for the sampling of multiwell microtiter plates.

2.12.5.3.2 Fluidics and electronic integration

Monolithic integration places all components on the same device. Typically, actuators and sensing elements are made in the same process. Little or no assembly is required, and monolithic systems are highly reliable and low in cost. The

Table 18 Microchip systems material selection guide

<i>Material</i>	<i>Advantages</i>	<i>Disadvantages</i>
Silicon	IC compatible, large technology base, bulk etching, surface micromachining, and dry or wet processing; can include electronics	Chemically reactive surface
Glass	Insulating, transparent, good chemical compatibility, bulk etching (like silicon), long laboratory experience	Little commercial technology base
Plastics	Low cost, used widely in commercial diagnostics systems, replication, using hot embossing on a nanometer scale	Untried commercially for line resolution, hydrophobic chemicals absorbed

Source: S Verpoorte and J Harrison (short course on microfluidics taught at LabAutomation2000, Palm, Springs, CA, January 22–23, 2000).

limitations include incompatibilities with process steps, low overall yield due to many points of failure, and high costs for small quantities. Several layers, all with their own processing requirements, can be sandwiched together to make a final assembly in a collective system. The benefits of collective integration include being able to segregate chemical and processing step incompatibilities. Higher individual step yields are countered by the final assembly requirements, and are often highly variable. As in collective integration, hybrid integration results in a sandwich construction. The layers of silicon, glass, or plastic can be either fluidic, controlled, or electronic, and are assembled and bonded together.

2.12.5.3.3 Integral detection systems

Sample measurement in chips presents new challenges to detection systems. The most popular modalities are fluorescence, absorbance, luminescence, and chemiluminescence. Other methods include the use of mass sensors, such as mass spectrometry and acoustic wave devices; electrochemical sensors, such as potentiometric, amperometric, and conductivity; and, finally, thermal sensors, such as bolometers and thermopiles. All are handicapped to an extent by the small sample sizes encountered on chips, and therefore must be very sensitive or coupled to chemistries that exhibit amplification.

2.12.5.4 Applications of Microtechnologies

2.12.5.4.1 Bead-based fiber-optic arrays

The ability to etch silicon materials predictably has given rise to an interesting technology based on fiber optics.^{274–276} Optical fibers are made from two kinds of glass or plastic: a core and a cladding. The core has a slightly higher refractive index than the cladding, permitting the fiber to transmit light over long distances through total internal reflection. Today's high-bandwidth telecommunications technology is based on optical fibers.

The fibers can be made with 3–7 μm outside diameters. One thousand of these fibers can be bundled together into a 1 mm-diameter bundle. The ends are then etched with hydrofluoric acid, to produce micrometer- or femtoliter-sized pits. [Figure 24](#) shows an image of these wells taken with an atomic force microscope.

It is possible to insert individual microspheres into these wells. The beads are sized so that they self-assemble, one to a well, when the fiber bundles are dipped into a 20% solids slurry. One milliliter of such a slurry can contain 100 million beads. Each individual bead can be optically encoded with fluorescent dyes²⁷⁷ so that it reports a unique optical 'bar code' when interrogated with a laser. Moreover, it is possible to construct an array of 384 of these fiber bundles on a 4.5 mm pitch to fit into a standard 384-well microtiter plate. This increases the amount of information gathered in a single experiment to more than 2 million data points. This technology has been commercialized by Illumina, Inc.²⁷⁸

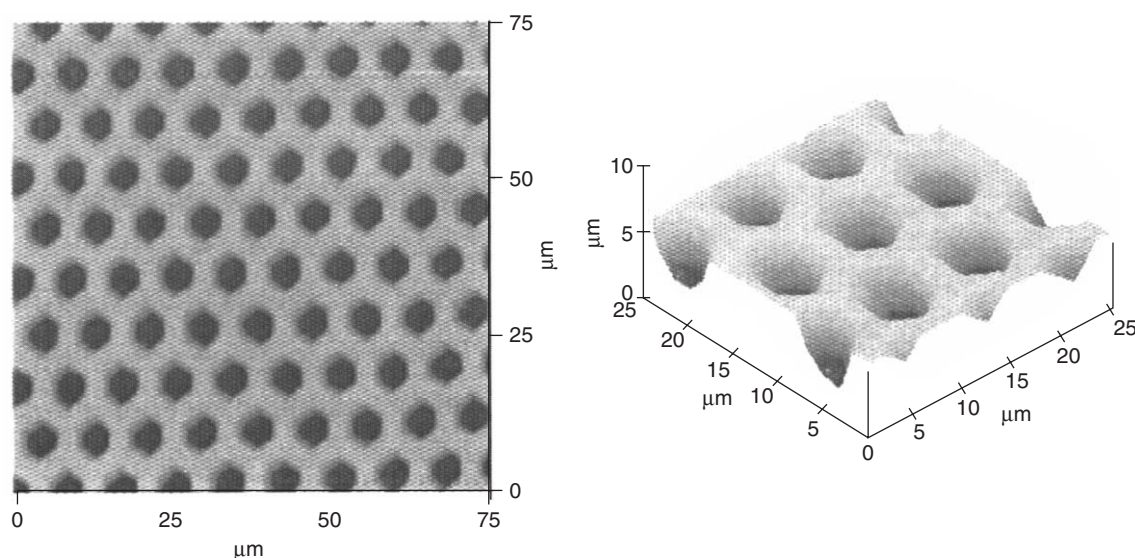

Figure 24 An atomic force microscope image of the wells generated by etching the inner core of each optical fiber in an optical fiber bundle. The capacity of each well is of the order of a few femtoliters. (Reproduced by courtesy of the D R Walt group, Tufts University).

Illumina's proprietary Oligator technology complements its BeadArray technology. The Oligator synthesizes in parallel many different short segments of DNA to meet the requirements of large-scale genomics applications. With unique segments of DNA attached to each bead, the BeadArray technology can be used for single-nucleotide polymorphism (SNP) genotyping.

2.12.5.4.2 Deoxyribonucleic acid arrays

Much has been written about oligonucleotide, DNA or cDNA, and RNA microarrays. This technology was first commercialized by Affymetrix, Incyte, and Hyseq. It relies on surface micromachining techniques wherein the 'layers' are successively photolithographically masked in light-directed oligonucleotide synthesis steps. For example, the Affymetrix technique works by shining light through a photolithographic mask onto a light-sensitive surface. The surface reactions are controlled so as to carry out the standard phosphoramidite oligonucleotide chemistry. Various cycles of protection and deprotection are required to build up a typical 20-mer oligo at specific sites.²⁷⁹

Some of the limitations of this approach to making arrays are that masks are not cheap or quick to make and are specific to the pattern of oligonucleotides that make up the array. A new approach, based on surface micromachining semiconductor technology from Texas Instruments,²⁸⁰ uses a DMD. A DMD consists of individually addressable mirrors on a dense 600×800 array in a $10 \text{ mm} \times 14 \text{ mm}$ area. There are nearly half a million addressable locations available for light-directed synthesis of oligonucleotides. DMD technology is in common use today in digital light projectors. A research group at Wisconsin²⁸¹ has demonstrated the use of DMD in the construction of oligoarrays. Light from an arc lamp directed by digitally controlled micromirrors cleaves photolabile protecting groups off the ends of DNA molecules. The illuminated areas then couple to the next base to be added while the dark areas remain unreactive.

The ability to spatially control selective chemistries is the basis of much array-based technology. Even higher densities can be obtained with arrays of femtoliter microwells made with standard polymer-embossing techniques. Whitesides *et al.*²⁸² have described soft lithographic techniques to construct planar arrays of approximately 3 fL wells with $107 \text{ wells cm}^{-2}$. Basically, an array of posts formed in a photoresist on a silicon wafer is used as a 'master' to form the arrays of microwells. The master is generated by rapid prototyping or standard photolithography with a chrome mask. The arrays of wells are fabricated by molding an elastomeric polymer against the master. The wells have aspect ratios ranging from 1:1 to 1.5:1. The authors describe a technique for filling the wells that takes advantage of the difference in the interfacial free energies of the substrate and the liquid of interest and controlling the topology of the surface. Liquid is allowed to drain off an array of microwells either by gravity or by pulling the array from a bulk solution.

One application of DNA array technology is that of Hyseq. The HyChip system uses arrays of a complete set of DNA probes in conjunction with a target-specific cocktail of labeled probes to identify differences between a reference and test samples. Since the chip contains all possible probes, the HyChip system has the distinct advantage of being able to sequence DNA from any source. Other available DNA chip technologies require prior knowledge of the gene sequence and mutations prior to chip design, and require no less than one chip for each gene being tested. The HyChip system is therefore universal, and requires only a single chip for a wide variety of targets.

The arrays produced by the companies above tend to be very high density, with thousands if not millions of uniquely addressable locations. There is also a very large market for lower density arrays produced on coated surfaces by mechanical systems such as robots and Cartesian spotting devices. Table 19 lists some of the leading manufacturers of microarray spotting systems, slide suppliers, scanners, image-processing software, and data analysis software.

2.12.5.4.3 Electronically enhanced hybridization

DNA sequencing by hybridization^{283,284} and other oligonucleotide hybridization protocols rely on a rather time-consuming hybridization step. Although there are many variables to control for a successful hybridization, migration of the DNA to the fixed complementary probe tends to be slow. Often, this step requires hours to overnight reaction times. Nanogen has commercialized a chip that electronically drives the target DNA to the probes, greatly speeding up this process.²⁸⁵ After hybridization, the chip is washed, and detection occurs, reducing a typical several hour experiment to less than 30 min.

Nanogen's technology allows small sequences of DNA capture probes to be electronically placed at, or 'addressed' to, specific sites on the microchip. A test sample can then be analyzed for the presence of target DNA molecules by determining which of the DNA capture probes on the array bind, or hybridize, with complementary DNA in the test sample. In contrast to nonelectronic or passive hybridization with conventional arrays on paper or glass 'chips,' the use of electronically mediated active hybridization to move and concentrate target DNA molecules accelerates

hybridization so that hybridization may occur in minutes rather than the hours required for passive hybridization techniques. In addition to DNA applications, this technology can be applied to a number of other analyses, including antigen–antibody, enzyme–substrate, cell–receptor, isolation of cancer cells from peripheral blood cells,²⁸⁶ and cell separation techniques.

2.12.5.4.3.1 Electronic addressing

Electronic addressing is the placement of charged molecules at specific test sites. Since DNA has a strong negative charge, it can be electronically moved to an area of positive charge. A test site or a row of test sites on the microchip is electronically activated with a positive charge. A solution of DNA probes is introduced onto the microchip. The negatively charged probes rapidly move to the positively charged sites, where they concentrate and are chemically bound to that site. The microchip is then washed, and another solution of distinct DNA probes can be added. Site by site, row by row, an array of specifically bound DNA probes can be assembled or addressed on the microchip. With the ability to electronically address capture probes to specific sites, the system allows end-users to build custom arrays

through the placement of specific capture probes on a microchip. In contrast to current technologies, these microchip arrays can be addressed in a matter of minutes at a minimal cost, providing research professionals with a powerful and versatile tool to process and analyze molecular information.

2.12.5.4.3.2 Electronic concentration and hybridization

Following electronic addressing, electronics are used to move and concentrate target molecules to one or more test sites on the microchip. The electronic concentration of sample DNA at each test site promotes rapid hybridization of sample DNA with complementary capture probes. In contrast to the passive hybridization process, the electronic concentration process has the distinct advantage of significantly accelerating the rate of hybridization. To remove any unbound or nonspecifically bound DNA from each site, the polarity or charge of the site is reversed to negative, thereby forcing any unbound or nonspecifically bound DNA back into solution, away from the capture probes. In addition, since the test molecules are electronically concentrated over the test site, a lower concentration of target DNA molecules is required, thus reducing the time and labor otherwise required for pretest sample preparation.

2.12.5.4.3.3 Electronic stringency control

Electronic stringency control is the reversal of electrical potential to quickly and easily remove unbound and nonspecifically bound DNA as part of the hybridization process. Electronic stringency provides quality control for the hybridization process and ensures that any bound pairs of DNA are truly complementary. The precision, control, and accuracy through the use of the controlled delivery of current in the electronic stringency process permits the detection of single-point mutations, single-base-pair mismatches, or other genetic mutations, which may have significant implications in a number of diagnostic and research areas. Electronic stringency is achieved without the cumbersome processing and handling otherwise required to achieve the same results through conventional methods. In contrast to passive arrays, Nanogen's technology can accommodate both short and long single-stranded fragments of DNA. The use of longer probes increases the certainty that the DNA that hybridizes with the capture probe is the correct target. Nanogen's electronic stringency control reduces the required number of probes and, therefore, test sites on the microchip, relative to conventional DNA arrays. In contrast, traditional passive hybridization processes are difficult to control and require more replicants of every possible base pair match so that correct matches can be positively identified.

2.12.5.4.4 Microfluidic devices

There are many university research laboratories and institutes across the world working in the area of microfluidic devices of all kinds. Much early work was done by such groups as Ramsey's at Oak Ridge National Laboratory,^{287–289} which, in addition to the groups of de Rooij,²⁹⁰ Manz,²⁹¹ and Harrison,^{292,293} for example, continue to be very active.

Microfluidic technologies have over the past decade and a half matured sufficiently to become the basis of many companies. Many of these companies also perform fundamental research while providing their technologies to customers either as products or in early technology access partnerships. Still other companies use microfluidics technology in a specialized application, and market the value added in a specialized field of endeavor, such as environmental monitoring, patient diagnostics, genetic testing, or drug discovery. For example, complete instrument systems based on microfluidic separations are emerging, many integrated with detection.

As will be seen from the selected examples discussed below, many products and services are being developed based on microarray and microfluidic components. [Table 20](#) lists some of the companies, to which the readers are referred for additional information.

2.12.5.4.4.1 Microfluidic separations

Caliper Technologies was founded on the technologies originating in many of these research laboratories. In the late 1990s, Caliper introduced its first two LabChip systems – a personal laboratory system for the life sciences market and a HTS system to aid pharmaceutical companies in discovering new drugs. Co-developed with Agilent, the first laboratory system consists of the Agilent 2100 bioanalyzer, a desktop instrument designed to perform a wide range of scientific experiments using a menu of different LabChip kits. Each kit contains chips and reagents designed for specific applications. The LabChip system brings the benefits of miniaturized, integrated, and automated experimentation to the researcher's desktop. Agilent launched this product in 1999 for applications including DNA and RNA analysis. The analyzer works with a series of chips optimized for DNA and RNA analysis (e.g., the DNA 7500 LabChip assay kit provides size and concentration information for DNA fragments ranging in size from 100 to 7500 base pairs).

^aACLARA Biosciences merged with Monogram Biosciences.

^bThis company now trades under the name Nuvelo, and its direction has changed.

Caliper's LabChip HTS system utilizes chips that draw nanoliter volumes of reagents from microplates for analysis. The system performs a wide range of experiments using a menu of different chips. Caliper currently offers chips to perform drug screening for several classes of targets and anticipates offering more chips, currently in development, to increase both capability and throughput.

Using a similar approach, Monogram Biosciences has demonstrated rapid, high-resolution electrophoretic separations in plastic chips.^{294–296} DNA fragment sizing is required in numerous applications and represents an attractive target market wherein Monogram Biosciences provides ready-to-use disposable plastic chips, prefilled with a proprietary gel. Monogram Biosciences produces plastic chips in polymers, thereby enabling the mass production of low-cost disposable chips. They use two main steps in the production of plastic chips: (1) the formation of microstructures in a base layer and (2) sealing of the base layer with a cover layer. To form the base layer, microstructure patterns are replicated from a micromachined master (or submaster) onto a polymeric substrate. Monogram Biosciences has developed several different replication technologies that span a range of capabilities and economies of scale, enabling the company to select the most appropriate technology for any application under development.

2.12.5.4.4.2 Microfluidic synthesis

Traditional means of transferring fluids with pipettes are severely challenged much above 384 wells in a microtiter plate. The microfluidic technology developed by Orchid Biocomputer²⁹⁷ provides a viable route to achieve much higher levels of densification, unachievable by traditional systems. Orchid is developing modular chip-based systems with 96, 384, 1536, and 12, 288 (8×1536) reactor arrays that accommodate 100–80 nL sample volumes.

The unique features of the Orchid Biocomputer chips include the ability to process hundreds of reactions in parallel through the use of precise fluidic delivery methods. These chips use hydrostatic pressure pulses with nonmechanical microvalves fabricated in the multilayer collective device to transfer fluids vertically and horizontally into 700 nL microreaction wells. The highly complex three-dimensional architecture of these chips enables the broadest range of capabilities of any chip in the industry. With this enclosed system there is no risk of evaporation or reagent degradation. One important application of Orchid Biocomputer's microfluidic technology is in parallel chemical processing, as embodied in the Chemtel chip.

2.12.5.4.4.3 Chip-based flow cytometry for medical diagnostics

A multidisciplinary team was formed at the University of Washington School of Medicine's departments of bioengineering, mechanical engineering, electrical engineering, and laboratory medicine. The developments resulting from this multidisciplinary research have been licensed from the University of Washington to Micronics.²⁹⁸

Micronics is further developing microfluidics-based systems for application to clinical laboratory diagnostics and analytical and process control chemical determinations. In both instances, the small size and autocalibrating characteristics of the microfluidics technology lends itself to application at the point of the sample. This avoids the

transportation of sample to centralized laboratories – a step that results in both delays and degradation of the sample – and it provides answers at the point where decisions can be made immediately.

A major area of Micronics's technology is in microfluidic-based cell cytometry. In operation, biological cells from a sample, such as blood, pass in single file through a channel on which is focused a laser beam. Light-scattering measurements are taken at multiple angles, and these multiparameter scatter measurements provide a 'fingerprint' for the various types of cells. This technology, known as flow cytometry, is not new. However, Micronics is implementing the technology on a microfluidic scale using new miniaturized optical technology developed for CD readers. Micronics microcytometer technology has demonstrated the capacity to count and classify platelets, red blood cells, and various white cell populations by means of laminate-based microfluidic flow channels and light-scattering optics. Additional light-scattering and data analysis channels will be used to extend the capabilities of the microcytometer toward a complete blood cell assay, including a five-part white cell differential.

2.12.5.4.4 Microfluidics in a rotating CD

Gyros Microlabs has integrated a microfluidics system based on a simple modular design, consisting of a spinner unit, a flow-through noncontact liquid microdispenser, a CD with proprietary applications and chemistries, detector(s), and software.

Many complex steps, such as sample preparation, fluid handling, sample processing, and analysis, can be carried out seamlessly within the confines of a single CD. The CD is made up of intricate molded microchannels in plastic, creating interconnected networks of fluid reservoirs and pathways. No pumps are required because spinning the CD moves the liquids around. What makes the technology versatile is the ability to rapidly and easily create application-specific CDs, where the applications are embedded in the intricate microstructures on the CD.

One application explored is high-throughput SNP scoring on a CD in combination with solid phase pyrosequencing.²⁹⁹ The centripetal force in the CD device allows for parallel processing without complex tubing connections. One of their current designs integrates the whole process for SNP analysis, including sample preparation, achieving more than 100 000 SNPs per day.³⁰⁰

Gyros has also developed a flow-through, noncontact, piezoelectric dispenser allowing the deposition of a precise amount of liquid into each microstructure while the CD is spinning at 3000 rpm, thus managing many operations simultaneously without any evaporation problems. The flow-through principle facilitates the use of thousands of different samples or reagents. Gyros is developing a full range of dispenser variants including arrays, which will revolutionize the way small volumes of liquids can be handled.

2.12.5.5 Nanotechnology

Nanotechnology³⁰¹ is a very broad emerging discipline; it describes the utilization and construction of structures with at least one characteristic dimension measured in nanometers. Such materials and systems can be deterministically designed to exhibit novel and significantly improved physical, chemical, and biological properties, phenomena, and processes because of their size. Since they are intermediate between individual atoms and bulk materials, their physical attributes are often also markedly different. These physical properties are not necessarily predictable extrapolations from larger scales. Currently known nanostructures include carbon nanotubes, proteins, and DNA.

In biology, recent insights indicate that DNA sequencing can be made many orders of magnitude more efficient with nanotechnology. It can also provide new formulations and routes for drug discovery, enormously broadening the therapeutic potential of drugs. For example, drugs or genes bound to nanoparticles can be administered into the bloodstream and delivered directly to cells. Furthermore, given the inherent nanoscale of receptors, ion channels, and other functional components of living cells, nanoparticles may offer a new way to study these components.

Nanosensors with selectivities approaching those of antigen–antibody or hybridization reactions will greatly influence chemistry and instrumentation development. These sensors would be naturally complementary to microfluidic systems, and we should expect to see these systems integrated in the future.

Scientists are just now beginning to understand how to create nanostructures by design. A more complete understanding will lead to advances in many industries, including material science, manufacturing, computer technology, medicine and health, aeronautics, the environment, and energy, to name but a few. The total societal impact of nanotechnology is expected to be greater than the combined influences that the silicon integrated circuit, medical imaging, computer-aided engineering, and manufactured polymers have had. Significant improvements in performance and changes of manufacturing paradigms will lead to several industrial revolutions in this century. Nanotechnology will change the nature of almost every man-made object. The major question now is, how soon will this revolution arrive?

2.12.5.6 Overview

The above examples are merely illustrative and not intended to be a comprehensive coverage of all the available systems of current research. This field is changing very rapidly; new products, services based on microfluidic systems, and even new companies are constantly emerging. Most of the above products were made by combinations of the fabrications technologies described in [Section 2.12.5.1](#). They also illustrate how fundamental developments made in various research groups are migrating to the private sector and, eventually, to the marketplace.

These devices are the tip of the iceberg. They are indicative of the state of the technology and also serve as a prelude to products to come.

2.12.6 Single-Nucleotide Polymorphism Scoring for Drug Discovery Applications

2.12.6.1 Introduction

An important byproduct of the Human Genome Project is an appreciation of the nature and degree of individual genetic variation.³⁰² While small insertion and deletions and variation in the length of repetitive DNA elements are common, by far the most frequently occurring type of genetic variation is the SNP. An SNP is a nucleotide position in genomic DNA where the nucleotide base varies within a population.³⁰³ In humans, it is estimated that between any two genomes, 1 in 1000 bases will be an SNP. When a large population consisting of many genomes is considered, as many as 1 in 100 bases will be polymorphic. Thus, in the human genome, which contains some 3 billion base pairs, there are expected to be more than 3 million SNPs. Many of these SNPs will have biomedical uses ranging from the identification of potential drug targets to the diagnosis of disease susceptibilities and targeting of therapies. The analysis of millions of SNPs in millions of patients presents a daunting challenge, with new types of considerations and requiring the development of new approaches. In this section, we will briefly cover some of the uses of SNPs and describe some of the assay chemistries and analysis platforms that will allow SNPs to be used on a large scale for these emerging pharmaceutical applications.

2.12.6.1.1 Single-nucleotide polymorphism applications

SNPs have several potential applications relevant to drug discovery and development. First, SNPs located in the protein coding or regulatory regions of genes can affect protein function or expression. In some cases, such alterations can be identified as the cause of a disease, thereby pointing to a potential drug target as well as having diagnostic uses. While in some diseases a single mutation can be identified as the cause of a disease, more often disease is expected to be the result of an interacting combination of differences in a number of genes.³⁰⁴ Case-control association studies that focus on protein-altering SNPs within a set of candidate genes can reveal the involvement of specific genes in such complex diseases.³⁰³ In a set of related applications, SNPs can be used as mapping markers to identify genes that may be associated with a particular disease. In these scenarios, hundreds of thousands of SNPs are scored in affected and control populations consisting of hundreds to thousands of individuals. While the experimental design and statistical considerations for large-scale association or linkage disequilibrium studies are still the subject of debate (discussed and reviewed by Terwilliger and Weiss³⁰⁵), it is hoped that this approach may help address the difficult problem of diseases with complex genetic susceptibilities.

Similarly, amino acid-altering SNPs can affect a patient's response to a drug. Variation among individuals with respect to drug targets as well as drug metabolism can result in important differences in drug efficacy and toxicity.^{306,307} As for complex diseases, drug responses will most often have a polygenic character, and patient responses will be determined by an individual variation in the relevant genes. The understanding of pharmacogenetic variation will not only be important for diagnostic uses but for the design of clinical trials for new drugs as well. Ensuring that known drug target and metabolism genotypes are represented in a clinical trial population should make it possible to more precisely predict drug efficacy and safety in the general population. In the broad vision of pharmacogenomics, disease and susceptibilities as well as highly individualized therapies would be ascribed on the basis of a patient's genotype, thereby ensuring safe and optimal treatment for every patient.

2.12.6.1.2 Single-nucleotide polymorphism discovery and scoring

A prerequisite for the applications described above is the identification and mapping of SNPs throughout the genome. Most of this task will be accomplished in the course of various large- and small-scale sequencing efforts.³⁰⁸⁻³¹¹ There are currently active efforts in both the public and private sectors to discover and map SNPs on a genome-wide scale.^{312,313} There have been several reviews on the methods and considerations that are relevant for SNP

discovery.^{302,314} While large-scale sequencing is the source of the majority of newly discovered SNPs, there are also efforts to develop methods of ‘scanning’ genomic DNA for variation, with sequencing being used to confirm and identify SNPs. Although most SNP discovery methods can be configured for subsequent scoring of a SNP in unknown samples, scanning methods do not, in general, scale well for high-throughput genotyping applications. Scoring of large numbers of known SNPs is more efficient using one or more methods designed to interrogate an SNP directly.³¹⁵ In this section, we will consider the methods and analysis platforms available for large-scale SNP scoring in a drug discovery environment.

2.12.6.2 General Considerations

Before discussing in detail the chemistries and platforms used to score SNPs, it is useful to consider the important characteristics of large-scale SNP analysis for drug discovery applications, because the requirements in this setting are very different from those of a smaller scale research setting. As discussed above, though estimates vary for applications related to gene discovery, on the order of 100 000 SNP markers will have to be screened in thousands to tens of thousands of individuals. Thus, any single application will likely require the scoring of millions of SNPs. This scale of analysis involves particular consideration of issues of throughput and cost that will influence the choice of assay chemistry and analysis platform. Two issues that are especially important in this regard are the amenability of methods to automation and the multiplexed analysis of many SNPs in each sample.

2.12.6.2.1 Sample preparation

In most cases, the starting material for an SNP-scoring project will be purified genomic DNA, which is then subjected to polymerase chain reaction (PCR) to amplify the regions containing the SNPs. PCR amplification is a major cost for most SNP-scoring methods, and although there is much interest in developing ‘PCR-less’ assays, as yet the combination of sensitivity and specificity of PCR has not been surpassed. Fortunately, PCR reactions are readily set up and performed in microwell plates with commercially available laboratory automation equipment. Additional cost and time savings can be obtained by multiplexing the PCR step, although the technical challenges to performing many PCR reactions in one tube are still significant enough to keep this approach from being routine on a large scale.

Once the DNA template is prepared, some assay chemistry is performed, generally consisting of a hybridization or binding procedure, often coupled to an enzymatic reaction, that allows identification of the nucleotide base located at the SNP position. Such chemistries usually require incubations ranging from minutes to hours, but these need not be rate-limiting if they can be performed in parallel in microplates. Specialized enzymes, fluorescent nucleotides, or other reagents are often required, and represent another major cost for SNP-scoring assays. Again, multiplexed sample processing of many SNPs in a single tube can dramatically decrease the cost per SNP scored, as well as increase the throughput.

2.12.6.2.2 Sample analysis

If upstream sample-processing steps can be conducted in parallel, sample analysis is often the rate-limiting step in SNP-scoring applications. The ideal method would permit analysis of the products of SNP-scoring reactions directly, without the need for further purification, including highly multiplexed analysis of many SNPs per sample, as well as the analysis of many samples simultaneously and/or a high serial sample analysis rate. The method should also be integrated with commercial laboratory automation instrumentation commonly used in a drug discovery environment. While no single analysis platform meets all of these criteria, a few meet several of them, and continued instrument development will likely improve performance in these respects.

2.12.6.2.3 Automation and multiplexing

Especially important features for large-scale applications are multiplex and automation capabilities. Microplate-based assays are particularly well suited to automation, and many commercial robotic systems can perform large-scale sample preparation and analysis using microplates. Automation permits the processing of large numbers of samples, and microplate assays can be configured to use small volumes (a few microliters), providing a reduction in assay reagent costs. An even bigger reduction in assay costs can be obtained by performing the multiplexed scoring of many SNPs in a single sample. For some SNP-scoring chemistries the expensive reagents (enzymes and/or labeled nucleotides) are in excess, so that additional sites can be scored using the same pool of these reagents. This results in a decrease in the cost per SNP scored that is directly proportional to the level of multiplexing.

While microplates are well suited to the parallel processing of many samples, it is difficult to multiplex solution-based SNP-scoring assays beyond a few sites. Electrophoresis-based methods can provide a modest degree of multiplexing combined with parallel sample analysis, and automation capabilities are improving. Microarray-based analysis methods are especially well suited for highly multiplexed assays, enabling the analysis of many more SNPs in a single sample than microplate-based assays. Flat microarrays (DNA chips) facilitate the multiplexed scoring of 1000 or more SNPs from a single sample, while soluble microarrays (DNA microspheres) can support the analysis of dozens to a hundred SNPs simultaneously, and potentially many more. Sample preparation and analysis for DNA chips can be automated using vendor-supplied equipment, while multiplexed microsphere-based assays are compatible with parallel sample preparation in microplates and conventional laboratory automation equipment.

2.12.6.3 Single-Nucleotide Polymorphism-Scoring Chemistries

The objective of an SNP-scoring assay is to determine the nucleotide base at specific sites in the genome. A variety of approaches have been developed to score SNPs, some of which exploit differences in the physical properties of the DNA and oligonucleotide probes, while others rely on highly specialized enzymes to analyze DNA sequences. These methods vary in their ease of use, flexibility, scalability, and instrumentation requirements, and these factors will affect the choice of approaches employed in a HTS environment.

2.12.6.3.1 Sequencing

Conceptually, the simplest approach to scoring SNPs is probably direct sequencing, since sequencing is used to discover and confirm SNPs initially. However, in practice, direct sequencing is a fairly inefficient way to score SNPs. While the speed and throughput of sequencing instruments continues to improve, with capillary-based sequencers capable of generating 96 sequencing reads of 400–500 bases each in 2–3 h, such read lengths will, in general, contain only one to a few SNPs on average. Considering this throughput rate (96 SNPs every 2–3 h per instrument) and sample preparation costs (PCR amplification or cloning followed by one or more sequencing reactions for each target), direct sequencing is not suitable for most large-scale SNP-scoring applications. In some highly variable regions of the genome – certain human leukocyte antigen (HLA) genes, for example – a sequencing read may contain dozens of potential SNP sites. In such cases, sequencing can be quite efficient, providing multiplexed SNP scoring in one reaction. However, such cases are rare exceptions, and for most applications, sequencing is not a viable high-throughput SNP-scoring method.

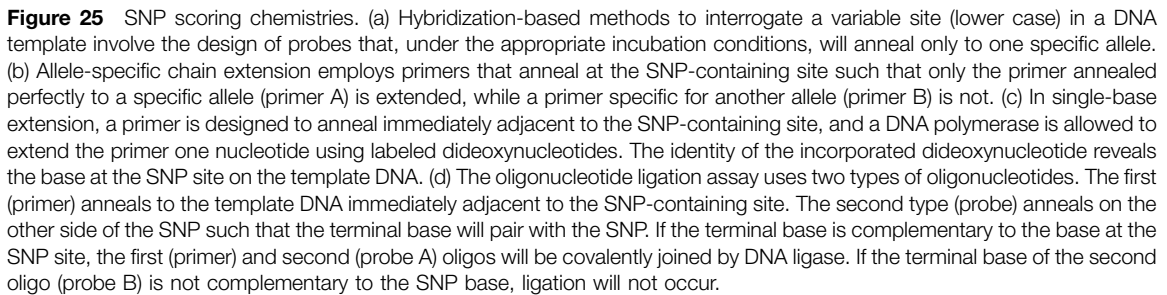

2.12.6.3.2 Hybridization

SNPs can often be detected by measuring the hybridization properties of an oligonucleotide probe to a template of interest. The melting temperature for hybridization of an oligonucleotide of modest length (15–20-mer) can differ by several degrees between a fully complementary template and a template that has a one-base difference (i.e., an SNP). By carefully designing oligonucleotide probes and choosing hybridization conditions that allow the probe to bind to the fully complementary template, but not to a template containing an SNP, it is possible to use hybridization to distinguish a single-base variant (**Figure 25a**).

In practice, this approach generally requires careful optimization of hybridization conditions because probe melting temperatures are very sensitive to sequence context as well as to the nature and position of the mismatched base. This difficulty in choosing optimum hybridization conditions (buffer and temperature) can be eliminated by continuous monitoring of probe hybridization as the temperature is increased, allowing the melting temperature for matched and mismatched probes to be determined directly in a process known as dynamic allele-specific hybridization. Alternatively, the use of highly parallel microarrays enables an SNP-containing template to be interrogated by many different hybridization probes for each SNP,³¹⁶ providing a redundancy of analysis that effectively increases the signal-to-noise ratio. PNA, which are oligonucleotide analogs with a structure that make hybridization very dependent on correct base pairing (and thus very sensitive to mismatches),^{317,318} can improve hybridization-based assays. Locked nucleic acids, another oligonucleotide analog, are likely to be similarly useful.

2.12.6.3.3 Allele-specific chain extension

The combination of a hybridization probe with a sequence-sensitive enzymatic step can offer very robust and accurate SNP-scoring chemistry. Allele-specific chain extension (ASCE) involves the design of a primer whose 3' terminal base will anneal to the site of the SNP.^{319,320} If the base at the SNP site on the template DNA is complementary to the

Originally implemented as a PCR-based assay, allele-specific PCR (AS-PCR) used gel electrophoresis to detect the PCR product as a positive indicator of the presence of the SNP of interest.^{319,320} AS-PCR is widely used in diagnostic assays for several disease-associated mutations³²¹ as well as for HLA typing.³²² In addition, by using two allele-specific primers, AS-PCR can be used to distinguish whether two SNPs are present on the same chromosome.³²³ AS-PCR assays can also be multiplexed to some extent, enabling several SNPs to be assayed in a single sample.³²⁴ More recently, ASCE has been adapted to detection platforms more compatible with large-scale analysis, including microarrays.^{325,326}

The ability of DNA polymerase to discriminate correctly paired bases is the principle underlying conventional DNA sequencing as well as ASCE. Another approach employing the sensitive sequence discrimination of DNA polymerases is SBE of a primer, also known as minisequencing or genetic bit analysis. In SBE (**Figure 25c**), an oligonucleotide probe

is designed to anneal immediately adjacent to the site of interest on the template DNA. In the presence of dideoxynucleoside triphosphates, DNA polymerase extends the annealed primer by one base.^{327,328} This is essentially the same dye terminator chemistry widely used in conventional sequencing, and, as long as the SBE primer is specific, can be very accurate with an excellent signal-to-noise ratio. Most often, the dideoxynucleotide is labeled. Usually the label is a fluorescent dye, but in some configurations biotinylated dideoxynucleotides can be used and detected with a labeled avidin in a secondary labeling step. If fluorescent dideoxynucleotides are used, all four bases can be scored in a single reaction if each of the four dideoxynucleotides is tagged with a different fluorophore. Thermal cycling of the SBE reaction using a temperature-stable polymerase can provide signal amplification, although, at present, amplification of the genomic template by PCR is still required.

2.12.6.3.5 Oligonucleotide ligation

Another method that takes advantage of enzyme discrimination of correctly paired bases is the oligonucleotide ligation assay (OLA). Two types of oligonucleotide probes are designed: one that anneals immediately adjacent to the SNP site on the template DNA and one that anneals immediately adjacent to the other side of the SNP (Figure 25d) such that the terminal base will pair with the SNP. If the terminal base of the second primer is complementary to the SNP base, then a DNA ligase enzyme will covalently join the two primers. If the terminal base is not complementary, ligation will be very inefficient. As for SBE, OLA exploits highly specialized enzymes to discriminate correctly matched bases, and can be very accurate. In addition, because it uses two primers to interrogate the SNP, OLA can also be configured to detect small insertions or deletion mutations.

Often, one primer is immobilized on a solid substrate³²⁹ and the second primer is labeled, either directly with a fluorophore or with a biotin for subsequent detection with labeled avidin. OLA is generally performed on PCR-amplified template DNA, but a variant, the ligase chain reaction, uses genomic DNA as the template for the ligation reaction, the products of which are then amplified.³³⁰ Another variant suitable for use with genomic DNA template is 'padlock probe' ligation, which generates a circular oligonucleotide product, which can then be amplified many hundred-fold using rolling-circle amplification.^{331,332}

2.12.6.3.6 Nuclease-based assays

Several SNP-scoring methods based on the nuclease cleavage of oligonucleotide probes have been demonstrated. A relatively straightforward assay targets SNPs that alter the recognition site for a restriction endonuclease, resulting in a change in the electrophoretic migration of the template molecule. More general approaches that can be configured as homogeneous assays are Taq-Man³³³ and Invader,³³⁴ both based on hybridization combined with an enzymatic 5'-nuclease activity.

In Taq-Man, the 5'-nuclease activity of Taq DNA polymerase cleaves a hybridization probe that specifically anneals to the template DNA during PCR. The Taq-Man hybridization probe is labeled with fluorescent donor and acceptor molecules that exhibit fluorescence resonance energy transfer (FRET) that is released upon cleavage. The Taq-Man probes must be carefully designed to hybridize only to a perfectly matched template and not to a template with a mismatched base. The Invader assay uses the 5'-nuclease activity of a thermostable flap endonuclease enzyme, to cleave a 5' 'flap' displaced by an invading probe. Probe cleavage produces a short oligonucleotide bearing a label that can be detected. Alternatively, the short cleavage product can serve as an Invader probe for a second stage of probe cleavage. This results in an amplification of the signal under isothermal conditions, and detection of signals from genomic DNA without PCR has been reported.³³⁴ Both the Taq-Man and Invader assays are gaining popularity for the analysis of single-point mutations. Highly multiplexed analysis of many SNPs simultaneously, such as is desired for large-scale applications, has not yet been demonstrated for these assays.

2.12.6.3.7 Overview

For large-scale SNP scoring, the SBE chemistry is probably the most robust, flexible, and easily multiplexed chemistry. For SBE, one primer is designed for each SNP, which are then labeled by extension with dideoxynucleotides. The extension of primers with labeled dideoxynucleotides by DNA polymerase is essentially the same chemistry used in conventional sequencing, and is generally very accurate. Allele-specific chain extension requires a different primer for each allele, but also benefits from the specificity of DNA polymerase. Ligation assays can be very accurate as well, but they require a primer and a different probe to score each SNP. On the other hand, ligation assays are more readily configured to score small insertions or deletions than SBE. Ligation, ASCE, and SBE assays are not well suited to score SNPs in highly variable regions of the genome, as variability in primer binding sites makes primer design more difficult. In these rare instances, conventional sequencing may be the most effective method of assessing the genotype.

2.12.6.4 Platforms

Just as there are a variety of assay chemistries for scoring SNPs, there are several platforms on which samples can be analyzed. Although all chemistries are not compatible with every platform, most can be analyzed by a variety of instruments. Key considerations for large-scale SNP scoring in a drug discovery environment are compatibility with highly parallel and automated sample preparation and the ability to perform multiplexed scoring of many SNPs in each sample.

2.12.6.4.1 Electrophoresis

Being a standard technique in molecular genetics laboratories, gel electrophoresis is widely used for SNP scoring. Most often, mobility through the gel or sieving matrix is used to identify a particular DNA fragment by its size. In addition, fluorescence detection of one or more probes can be used to identify primers or incorporated nucleotides. These two features form the basis of automated DNA sequencing, but also have applications in SNP scoring. In allele-specific PCR, agarose gel electrophoresis is often used to identify amplified products based on size.³²⁴ For SBE assays, different-sized primers, each interrogating a different SNP, can be resolved by electrophoresis, enabling multiplexed analysis of several sites simultaneously.^{335,336}

The limitations of electrophoresis as an SNP-scoring platform stem from fairly low throughput. The current state of the art in electrophoresis for sequencing applications, capillary electrophoresis instruments with 96-sample capacity, can perform an analysis every 2–3 h. Assuming a size-based primer multiplex to analyze 10 SNPs simultaneously, one could score roughly 4000 SNPs per workday. New-generation instruments with 384-capillary capacity could quadruple that throughput.

2.12.6.4.2 Microplate-based assays

Many SNP-scoring assays have been adapted to a microwell plate format, enabling highly parallel and automated sample processing and analysis. This platform is compatible with commercial high-throughput sample handling and measurement instruments that are widely used in the pharmaceutical industry. SNP-scoring assays in microplates can be configured as heterogeneous (requiring wash steps to remove excess reagents) or homogeneous (no wash steps required), with fluorescence or absorbance detection.

For the heterogeneous approaches, the microwell is often used as a solid support for oligonucleotide probes. For example, OLA and SBE assays have been configured with the SNP primer immobilized on the microplate bottom.^{329,337} PCR-amplified template, reporter oligos or nucleotides, and enzyme (ligase or polymerase) are added, and the enzymatic reaction causes the immobilized primer to be labeled. Excess reagents are then washed away, and the signal remaining in the well is measured.

For homogeneous assays, the microwell serves as a cuvette in which fluorescence is monitored. The key to the most homogeneous assays is the use of FRET, which results in a change in the fluorescence spectra of a sample when two fluorescent dyes are brought into proximity. In addition to the example of the Taq-Man assay described earlier, FRET-based approaches have been configured for hybridization using molecular beacons,³³⁸ OLA,³³⁹ and SBE.³⁴⁰

Fluorescence detection provides sensitive detection for the microwell format, and the use of FRET provides essentially real-time scoring of the SNP. An entire microwell plate can be measured in less than a minute, enabling high sample throughput, and, in the case of 384 or higher densities, the reaction volumes can be quite small (on the order of 10 μ L). A disadvantage of microplate-based detection is the limited capacity for the multiplexed detection of many SNPs per sample. The use of differently colored probes can enable simultaneous detection of multiple signals, but because currently available fluorophores have relatively broad emission spectra, it will be very difficult to configure homogeneous solution assays with a multiplex capacity of more than three or four SNPs per sample.

2.12.6.4.3 Mass spectrometry

There is a significant effort aimed at adapting mass spectrometry to genomic applications, including SNP scoring. The advantages of mass spectrometry as an analytical tool stem from its capacity to produce very rapid and precise mass measurements. This allows many assays to be configured without the use of exogenous labels. For instance, SBE reactions can be analyzed by measuring the mass of a dideoxynucleotide added to a primer. Because each of the four dideoxynucleotides has a distinct mass, it is possible to identify which nucleotide(s) was added to the primer.³⁴¹ In addition, by using several primers of different masses (lengths) to interrogate several SNPs, it is possible to perform a multiplexed analysis on each sample.³⁴²

Current limitations of the mass spectrometry-based SNP scoring include a marked dependence on the size of DNA molecule being analyzed. Single-base resolution decreases for larger oligonucleotides, especially between nucleotides of similar mass such as A and T. The use of mass-tagged nucleotides (i.e., isotopically labeled nucleotides) can increase

this resolution,^{342–344} but at added expense. Another limitation is the requirement for highly processed and purified samples. Current mass spectrometry-based genotyping protocols call for the purification of samples before analysis. This requirement increases the cost and time of the procedure, although these steps can be automated and performed in parallel. It is very likely that some of these limitations will be overcome, given the current high level of interest in adapting mass spectrometry to genomic applications.

2.12.6.4.4 Flat microarrays

Perhaps one of the best publicized biological technologies of the last decade is the use of microarrays to perform large-scale genomic analysis.^{345,346} These microarrays, typically constructed on glass using photolithographic or robotic printing or spotting processes, can contain hundreds to hundreds of thousands of different DNA molecules on a surface of just a few square centimeters or less. Assays are generally configured using fluorescent reporter molecules, and arrays are read using scanning methods such as confocal microscopy.

For SNP-scoring applications, DNA microarrays have generally been used in conjunction with hybridization assays.³¹⁶ In these assays, the sensitivity of hybridization to the local sequence context of an SNP is overcome by interrogating each SNP with multiple hybridization probes, providing a redundancy to the analysis that reduces ambiguous SNP scoring. Chips designed to interrogate hundreds of SNPs simultaneously have been developed,³¹⁶ and it should be possible to make chips with even higher SNP-scoring capacity. In addition to hybridization-based SNP scoring, the SBE chemistry has been adapted to flat microarrays.³²⁸ Currently, flat DNA microarray technology is expensive and not very flexible. Acquisition of proprietary or specialized array manufacturing technology and dedicated array analysis instrumentation requires a large initial investment. However, for large-scale SNP-scoring applications, the investment may be justified.

2.12.6.4.5 Soluble arrays

An approach that has not yet generated the publicity of the DNA chip but will probably have a major impact in a variety of areas is the use of soluble arrays and flow cytometry. Soluble arrays are composed of microspheres that are dyed with different amounts of one or more fluorophores such that many distinct subpopulations of microspheres can be identified on the basis of their fluorescence intensity using flow cytometry. Conceptually, the soluble array approach is similar to that of flat microarrays, with different levels of fluorescence intensity replacing x - y positions on a surface. Currently, soluble microsphere arrays of 100 elements are commercially available (Luminex),³⁴⁷ but this number could in principle be expanded to thousands with the use of additional dyes to create multidimensional arrays.

The analysis of soluble arrays by flow cytometry has a number of advantages over flat surface microarrays. First, oligonucleotides are readily immobilized on microspheres using well-known benchtop chemistry. Second, because each array element is a distinct population of microspheres, array preparation consists of the combining of individual microspheres into a mixture using a pipette. Reconfiguration of the array requires only the modification of individual microsphere populations, followed by the preparation of a new mixture. The use of universal oligonucleotide address tags^{348,349} to capture tagged primers after a solution-phase SNP-scoring reaction further increases the flexibility of the array by allowing assays to be redesigned. Third, because the array is in a liquid phase, conventional liquid-handling hardware can be used for highly parallel sample preparation in microplates. In addition, improved sample handling capabilities for flow cytometry³⁵⁰ should boost throughput by more than a factor of 10 from the current 1–2 samples per minute. Fourth, because flow cytometry can discriminate between free and particle-bound probe, under most conditions no wash or purification step is required. Finally, because flow cytometry is capable of measuring tens of thousands of particles per second, soluble arrays can be analyzed in just a few seconds.

A variety of SNP-scoring chemistries are compatible with the use of microspheres as solid supports and fluorescence detection by flow cytometry. Hybridization-based assays have been used to detect PCR products³⁵¹ as well as to interrogate SNPs by multiplexed competitive hybridization.³⁵² In addition, the OLA and SBE chemistries have been adapted to microspheres.^{349,353,354} While soluble array technology does not yet have the parallel analysis capacity of the flat microarrays, advantages in serial sample throughput, ease of automation, and flexibility will make it attractive for many applications.

2.12.6.4.6 Overview

The key feature of a large-scale SNP-scoring platform is the ability to analyze highly multiplexed assays with high serial sample throughput in an automated manner (Table 21). Microplates are an excellent platform for automated parallel sample processing, but cannot offer a high level of multiplexed analysis. Flat DNA microarrays offer very highly

Table 21 Characteristics of SNP scoring platforms

<i>Platform</i>	<i>Hardware costs (US\$)</i>	<i>Throughput</i>	<i>Automation compatibility</i>	<i>Multiplex capacity</i>
Gels	Low–high	Low–moderate	Low–moderate	Moderate
Microplates	Moderate–high	High	High	Low
Mass spectrometry	High	Moderate–high	Moderate–high	Moderate
Flat arrays/scanner	High	Low	Moderate	High
Microspheres/flow cytometry	Moderate–high	Moderate–high	Moderate–high	Moderate–high
Low	< 20 000	< 1 sample min ^{−1}	Custom high-throughput screening	< 5 SNPs per sample
Moderate	20 000–100 000	1–10 samples min ^{−1}	Custom commercial hybrid	5–50 SNPs per sample
High	> 100 000	> 10 samples min ^{−1}	Commercial high-throughput screening	> 50 SNPs per sample

multiplexed analysis (thousands of SNPs), but a low sample analysis throughput. Soluble arrays have a high multiplex capacity (dozens to a hundred SNPs), with a fairly high serial sample throughput. Microplate-based sample processing combined with a highly multiplexed array-based measurement probably represents the most efficient combination of current technologies.

2.12.6.5 Conclusions and Prospects

Many strategies are being employed to score SNPs. Large-scale SNP scoring such as is required for drug discovery applications requires special consideration of the issues of throughput and cost. Especially important for optimizing throughput and cost are the ability to automate sample preparation and analysis and the ability to perform multiplexed scoring of many SNPs in a single sample. In this section, we have focused on those methods currently available that could be configured for large-scale applications. However, with the intense interest this area of research is generating, improvements in all aspects of sample preparation and analysis are to be expected. In closing, we would like to point to a few areas of likely progress.

Most SNP-scoring assays involve PCR amplification of the DNA template. PCR not only improves assay sensitivity but provides added specificity for the resolution of specific SNP sites against similar sites in gene homologs or pseudogenes. For the efficient highly parallel analysis of multiple SNPs, such as is possible with microarrays, the PCR amplification step must be highly multiplexed. Multiplexed PCR is a challenging problem, requiring the design and pooling of PCR primers that will specifically amplify many sequences under the same conditions yet will not interact with each other to produce primer artifacts. Because this is a universally important problem, with applications beyond SNP scoring, it is hoped that automated informatics and computational tools will be developed to supplement the largely empirical approach to multiplex PCR currently employed.

Applications of DNA microarray technologies will continue to be developed, providing highly parallel multiplexed analysis. Flat surface microarrays should prove to be much more useful for SNP scoring when combined with SBE and universal capture tags. The parallel analysis capabilities of soluble microsphere arrays are expected to increase as improved dye chemistry enables the production of multidimensional arrays, providing the parallel analysis throughput of flat microarrays with conventional liquid handling automation. Newer formats, such as microarrays configured on the ends of optical fibers (see [Section 2.12.7](#)), may also prove to have unique advantages as detection platforms for SNP-scoring applications. Finally, the push of micro- and nanofabrication toward integrated lab-on-a-chip approaches will likely have an impact on reducing costs, especially if these can provide a highly multiplexed analysis. An understanding of human genetic variation, especially in the form of SNPs, offers enormous potential for enhancing and improving the process of drug discovery and development. The realization of this potential depends on the ability to score rapidly and efficiently large numbers of SNPs in large numbers of samples. Technologies that combine automated sample preparation with highly multiplexed analysis will play a central role in meeting these needs.

2.12.7 Protein Display Chips

2.12.7.1 Introduction to Protein Chip Technologies

The genome-sequencing revolution has presented protein biochemists with blessings and challenges. At the DNA level, high-throughput technologies enabled the rapid discovery progress that the gene discovery community has enjoyed. Innovative, chip-based technologies have provided molecular biologists with a completely new set of tools. At the same time, the incredible amount of information from the various genomic analysis efforts has added additional layers of complexity to the way a lot of biological and medical questions are addressed. The simultaneous genetic analysis of many species and tissue types has broadened our view and quickened our understanding of key physiological processes on a genetic level. As will be discussed in this section, technology platforms originally introduced for nucleic acid analysis would eventually also have a significant impact on protein biochemistry in the hands of drug discovery researchers.

The rapid developments in the DNA and RNA analysis field have led the way to smaller sample volumes and rapidly increasing sample throughput. Arraying technologies, as well as microfluidic and robotic systems, have revolutionized industrial molecular biology. However, the fast and furious pace in that area has widened the gap in the understanding of proteins and protein-protein interactions, which has not progressed at the same speed. The reasons for this are both of a philosophical and a practical nature. In the minds of the molecular biology community, proteins have been, for a long time, gene expression products. The umbrella of this term very conveniently shields the molecular complexity and diversity with which proteins present us. This molecular diversity is the main practical reason why the study of proteins is much harder to press into a multiplexed high-throughput format. The beauty of nucleic acid biochemistry lies in the simple variation of a known theme, the repetitiveness of a very limited number of building blocks, with the triplet-based sequence as the brilliant key to the language of life. This key encodes the bountiful variety of the protein world, where things become much less predictable. Already, the 20 amino acids as components with very different chemical characteristics present a considerable analytical challenge when one considers the combinatorial possibilities. In addition to that, proteins can undergo post-translational modifications with other classes of molecules, such as lipids or carbohydrates, which can alter the behavior and characteristics of the entire molecule. Yet from the earliest studies in protein biochemistry, especially in the area of enzymology, the need for efficient as well as meaningful protein analysis has been clear, especially in two aspects: proteins as antagonist targets and, lately, also as therapeutics themselves in the fight against disease. The increasing pace of discovery in cell biology and molecular biology discovery research has made that need all the more pressing. Protein development efforts drive large programs in the pharmaceutical industry. The focus of these programs has undergone many changes over the years. Enzymology clearly made its mark on drug discovery research early on. The advent of recombinant bacterial and eukaryotic protein expression systems now allows the production of large amounts of functional proteins for small-molecule antagonist screening, structural characterization, and functional studies.

Tagging recombinant proteins further facilitated upstream optimization as well as downstream processing and analytical work. Tagging systems represented the first step toward an integrated assay platform for proteins that went beyond polyacrylamide gels. At the same time, advances in the fields of immunology and signal transduction presented new challenges. The functionality of a protein in these areas could not be measured through a catalytic reaction that was monitored as a color change or fluorescence enhancement. Instead, the function of a protein was based on its proper interaction with another protein or other class of effector molecule. This called for the development of new types of assays that allowed real-time monitoring of binding kinetics and the determination of binding specificity in a physiological setting. Also, the genome sequencing efforts led to the discovery of whole families of novel genes with unknown functions. This presented an additional need for interaction studies that would allow the identification of binding or reaction partners. HTS groups started to expand into the areas of rapid biological assays for proteins with unknown activities. Aside from these exploratory and discovery applications, functional assays have become increasingly important at downstream junctures of the drug development process. To catch up with the speed of gene discovery, protein development was in need of sensitive, multiplexed assays that still would have the flexibility to accommodate the diverse needs of the protein world. As it turned out, the technology toolbox that revolutionized the nucleic acid world also changed the way we look at proteins. This section will attempt to cover the advances in the area of chip-based protein analysis technologies over the past decade and a half, and highlight the most important implications of these technologies for the drug discovery process.

2.12.7.2 Surface Plasmon Resonance-Based Technology: How Optical Biosensors Revolutionized Protein–Protein Interaction Studies

2.12.7.2.1 Optical biosensor technology: technical background and development

Development in the field of optical biosensors received significant impetus from the need of improvement in the area of laboratory-based immunodiagnosics. Optical techniques seemed an obvious choice for this area, since refractive index is one of the few physical parameters that vary upon the formation of an immune complex.³⁵⁵ While interest in diffraction phenomena and the curious absorption anomalies of metallized optical diffraction gratings in particular dates back to the turn of the last century, more systematic theoretical work in the field did not start until the 1950s, with the major advances published again much later.^{356–359}

Optical biosensor technology relies on a quantum mechanical detection phenomenon called the evanescent field. It is used to measure changes in the refractive index that occur within a few hundred nanometers of a sensor surface. These refractive index changes are caused either by the binding of a molecule to a second molecule that has been immobilized on the surface or by the subsequent dissociation of this complex.³⁶⁰ There are several ways to create an evanescent field.^{361–363} SPR, which is the technology platform of the Biacore instrument, has established itself as the most commonly used over the past 15 years. In SPR, polarized light is shone onto a glass prism that is in contact with a thin gold–glass surface. Light is reflected at all angles off the gold–glass interface, but only at the critical angle does the light excite the metal surface electrons (plasmons) at the metal–solution interface. This creates the evanescent field, and causes a dip in the intensity of the reflected light. The position of this response is sensitive to changes in the refractive index as well as the thickness of the layer in the vicinity of the metal surface.³⁶⁴ Resonance is described by an arbitrary scale of resonance units (RU). A response is defined as the RU difference compared with a baseline that is normally established at the beginning of an experimental cycle with the immobilization of the capture protein or molecule. **Figure 26** shows the setup of a typical SPR detection system, consisting of a detector, the sensor chip, and an integrated microfluidics system, which allows for the continuous flow of buffer, sample, and reagents.

In a typical experiment, a capture molecule is first immobilized covalently on the sensor surface. Subsequently, the residual binding sites are blocked. After a wash with a buffer of low ionic strength, the interaction sample is passed over the sensor, followed again by buffer. **Figure 27** depicts a typical SPR sensogram. Response is measured with time, and is proportional to the mass of the adsorbed molecule.^{360,365} As ligand adsorption on the immobilized capture molecule occurs, the adsorption profile allows the determination of the association rate constant, k_{on} . After passing of the sample

Figure 26 Schematic representation of an SPR detection system.

Figure 27 Typical SPR sensogram.

plug, dissociation of the complex follows, as buffer passes over the sensor. The logarithmic decay of the dissociation reaction then allows the calculation of the dissociation rate constant, k_{off} . Earlier studies exploring the potential of SPR in the field of biomolecular interactions employed simple adsorption to the metal surface for the immobilization of the capture component. This strategy comes with certain limitations. Some proteins may denature when absorbed directly to the metal; and hapten-type ligands are very difficult to immobilize on metal. Furthermore, the performance of the sensor depends on the even and reproducible distribution as well as correct orientation of the adsorbed molecules. With a directly immobilized ligand there can be undesired interaction of solutes with the metal as well as exchange processes between the ligand and solute. To overcome these limitations, a carboxylated dextran surface coupled to the gold film was developed, which evolved into the standard surface medium for the covalent immobilization of capture molecules in the Biacore system, the CM5 sensor chip. The concept of this surface technology was first described by Johnsson *et al.*³⁶⁴ Their hydrogel-modified surface was designed to minimize nonspecific adsorption of ligands at physiological ionic strength and at the same time facilitate accessibility of the ligand in the subsequent interaction study. Since the Biacore system has grown into a generally accepted and commercially available analysis platform, the associated surface chemistry has been refined and diversified to accommodate the constantly growing number of applications. Today's gold-dextran surfaces basically have five different layers: the glass basis layer, the gold film, a linker layer, the dextran layer, and a specific layer. In the original surface design, the covalent coupling of the biological capture molecules occurred directly by nucleophilic displacement of *N*-hydroxysuccinimide (NHS) esters on the carboxymethyldextran chains.³⁶⁶ Modern CM5 surfaces come preactivated for four different covalent coupling strategies: amine, ligand thiol, surface thiol, or aldehyde. In addition to the covalent binding, hydrophobic surfaces are now available for the capture of membrane complexes, and nickel-chelate surfaces allow the selective binding of His-tagged proteins.

The popularity of biotinylation as an efficient tag for the capture of both proteins and nucleic acids via streptavidin has prompted the development of streptavidin precoated surfaces.

On the instrumentation front, development has yielded a higher degree of sophistication and sensitivity, addressing some of the earlier problems associated with reproducibility and difficulty in detecting low-affinity interactions. At the same time, a greater level of automation has standardized and facilitated the use of the technology, opening it to the nonspecialized user. High-end systems allow the most elaborate kinetic analyses of biological interactions, whereas more simply designed yet fully automated systems allow rapid and reliable screening of a large number of samples.

2.12.7.2.2 Types of surface plasmon resonance applications and experimental considerations

Since its original development in the area of immunodiagnosics, optical sensor technology has expanded into a wide variety of biological and medical areas of interest. An obvious choice for signal transduction research, SPR has become a standard tool for the analysis of receptor-ligand interactions.^{367,368} The field of chaperonins also discovered the technology early on.^{369–371} Beyond mere protein-protein interactions, SPR has found applications in small-molecule screening³⁷² as well as protein-carbohydrate³⁷³ and protein-nucleic acid interactions.^{374–376} Even viral particle binding to cell surface receptors has been analyzed by SPR.³⁷⁷ At downstream junctures of the drug development process, specialized optical biosensors are used for bioprocess monitoring and product analysis.³⁷⁸ In spite of the great diversity

of molecules analyzed, SPR studies mainly fall into two categories as far as experimental goals and design are concerned. Screening applications look for the relatively simple answer of an approximate kinetic ranking, basically to see if an analyte is specifically binding to a given ligand or not. Functional studies look at the mechanism of a certain biological interaction by determining quantitative rate constants. Clearly, a functional study with the aim of retrieving key mechanistic data requires a different level of insight and experimental premeditation than a simple 'quick and dirty' screen. Yet it is crucial to realize that the mimicking of a biological interaction event on a two-dimensional platform is not a trivial endeavor per se. Failure to understand the key biochemical parameters, caveats, and limitations of the system will inevitably lead to the failure of even the simplest of studies.

The continuously advancing simplification and automation of commercially available SPR systems has made life easier for the inexperienced user, and it has become more and more tempting to forget about the cumbersome underlying theory. Increasing simplicity and user friendliness have allowed an explosion in SPR-related references in the scientific literature. Reviewed over time, the literature reveals a typical trend for an evolving technology platform. Most of the earlier papers in the field were devoted predominantly to experimental designs, technological details, and, most of all, the analysis of kinetic data.^{379–381} More recent papers are overwhelmingly application driven, and for the most part have moved the more theoretical aspects into the background.^{382,383} This development clearly comes at a price, for it appears that less and less effort is spent on both careful experimental design and the critical evaluation of the answers provided, leading to a situation where more data actually provide less value but increased confusion instead.³⁸⁴ Therefore, it seems worthwhile to revisit the key factors that control both the experimental as well as the data analysis parts of SPR experiments.

Clearly, when a reaction that usually occurs in solution is forced into a two-dimensional setup, the limitations of mass transfer will have to be considered. At the same time, the immobilization of one binding partner on the surface can actually help mimic a biological situation where the capture molecule is immobilized in a molecular superstructure such as a membrane. While no systematic efforts have gone into the comparative analysis of SPR and solution binding, several researchers have revisited their SPR-derived affinities using other techniques, such as isothermal titration calorimetry, for confirmation. They have generally found good agreement, provided that the experimental design was chosen wisely.^{385–387}

Obviously, background understanding of the biological system to be analyzed will help in the design of the study. If the ligand or the analyte is a novel protein of unknown function, the data obtained in the experiment will have to be qualified with the possibility in mind that the binding partners may not have been presented in the correct orientation or configuration for an interaction to take place. When coupling the ligand to the surface in a covalent fashion (e.g., via the primary amines), this basically constitutes a random binding event that may hamper the formation of the correct capture configuration to receive the analyte. Tumor necrosis factor and similar ligands, for example, bind their receptors in a trimeric fashion: three receptor molecules have to form a homologous trimer to receive an analyte trimer. The addition of tags can help to overcome this problem: the use of Fc fusions, for example, allows capture on the surface via a protein A bridge that orients all capture molecules in the same way. Also, Fc tags even without the help of protein A, force their fusion partner into homologous dimers with other molecules. While this can help to increase the percentage of correctly oriented capture ligands on the sensor surface, it also has to be considered as an additional source of artifacts. Some tags, such as Fc tags, are quite bulky, and can lead to considerable structural changes in the proteins they are attached to. They may destabilize them to the point of breakdown or simply lead them into an inactive configuration. If the fusion breaks down, the empty Fc will still bind to other molecules and produce inactive multimers. Molecule size does matter for another reason in this context: it should be considered in the decision which partner of the binding experiment to immobilize covalently: the bulkier antibody, receptor, fusion protein for example, or the small peptide analyte. In many situations, this decision is made out of necessity rather than choice, as, for example, when one binding partner is available in a purified form but the other needs to be fished out of conditioned cell culture supernatant.

The purity and homogeneity of the ligand and analyte play a key role in the kinetics of the experiment. If contaminants are present that interfere with binding or act as competitors, this will undoubtedly at least complicate the situation, and at most render kinetic data useless. Contaminants can also obstruct the formation of specific multimers necessary for capture. Especially if the stoichiometry of the reaction is unknown, it is important to analyze a wide concentration range of both the ligand and analyte. Problems of mass transfer have been extensively studied from a theoretical point of view, and the reader is referred to the literature for a comprehensive treatise on the phenomenon.^{388–390} In a high-density binding situation the crowding of molecules in the association state will push the balance from the desired multimerization to unwanted aggregation. It has been observed that, in general, valid kinetic measurements are best obtained with low levels of ligand immobilization.³⁹¹ If the analyte concentration chosen is too high, the mass transfer limitations hamper its access to and from the surface. The valency of the interaction also needs

consideration, since multivalency leads to avidity effects, even in a low-density association. This has been extensively studied using the example of whole antibodies that are at least bivalent.³⁹²

Since SPR analysis represents the *in situ* monitoring of an interaction with one binding partner in flow, the time component of the setup naturally plays an important role, and the optimization of flow rates deserves some consideration. As a general rule, a higher flow rate helps to minimize mass transfer limitations.³⁹³ In a typical Biacore experiment, the flow rate is kept constant, and the sample is delivered to the surface in a small sample plug (typically in a volume between 50 and 200 μL) at a low analyte concentration, preceded and followed by low ionic strength buffer. In this way, a discreet amount of analyte is delivered to the chip while the continuous flow necessary for kinetic analysis is maintained. This configuration is useful for first-order or pseudo-first-order kinetics and the determination of affinity constants. However, because of the finite volume of the sample plug and the limited data collection time associated with it, some binding reactions cannot be measured to equilibrium. To do this, the sample has to be recirculated over the surface or delivered in the buffer at a constant concentration.^{394,395}

The scope of this section precludes in-depth discussion of kinetics and data analysis methods that apply to SPR applications, and the reader is referred to the more specialized literature for that area. However, it seems appropriate to at least touch on the most important parameters involved in deriving reliable kinetics and a sound statistical analysis of experimental data. In a very insightful 1994 review, O'Shanessey critiqued SPR studies described in the literature thus far.³⁹⁶ His article shows that inappropriate interpretation of raw experimental data and incorrect mechanistic assumptions for the kinetics of a reaction are as much a source of error and failure as are faulty experimental design and execution. The single biggest error observed in documented SPR studies to this day is the application of simplistic kinetics and statistical models to reactions that in reality are very complex. This has in part been driven by the goal to create user-friendly software analysis platforms for commercial automated SPR systems. In a lot of cases, to keep things simple, attempts are made to fit data to the simplest 1:1 interaction model. This works out if the data actually fit this situation, but, as described earlier, the reality is often a lot more complex. Then the derived numbers become apparent rate constants that bear no resemblance to the reality of the molecular interaction. At the same time, use of the wrong statistical fits can be equally detrimental, and the user should invest some effort in the evaluation of linear, nonlinear, and global fitting methods.

2.12.7.2.3 Surface plasmon resonance in the drug development process: conclusion and outlook

The usefulness of SPR as a label-free monitoring technique for biological interactions at the many junctures of drug discovery and development is obvious, and the annual number of publications in the field bears substantial testimony to this. With commercially successful and widely used platforms such as that from Biacore, the innovative technology has now crossed into the field of established methodology, attracting more and more nonspecialized users. Both an increase in sample throughput and advanced automation permit the efficient handling of large numbers of samples. Currently, the more automated systems at the same time apply simpler analysis methods and are designed for 'quick and dirty' answers. For these answers to be of any value downstream, SPR systems need to be integrated with complementary analysis tools for the independent confirmation of positives. Eventually, hits from screens also have to be revisited with a more sophisticated SPR tool for more meaningful mechanistic studies. As the body of experience with the technology continues to grow, and systems at the same time become more and more sophisticated electronically, eventually even high-throughput systems will allow more elaborate answers – that is, provided the right questions are asked.

2.12.7.3 Time-of-Flight Mass Spectrometry-Based Technologies

2.12.7.3.1 Matrix-assisted desorption techniques: technical background and development history

Before we attempt to discuss the two currently available true protein chip technologies for mass spectrometry, surface-enhanced laser desorption/ionization (SELDI) and biomolecular interaction analysis/mass spectrometry (BIA/MS), we need to take a step back. The development of mass spectrometry from an analytical chemistry technique into a more user-friendly biochemistry and biology tool deserves some attention. The technology was established mainly for purity analysis and molecular weight confirmation of organic chemicals and peptides with molecular weights under 1000 Da. Fragmentation-related mass limitations initially prevented the analysis of larger molecules. Several desorption techniques, such as field desorption, secondary ion mass spectrometry, fast atom bombardment, plasma desorption, and, finally, laser desorption/ionization, extended the molecular weight range of analytes above 100 000 Da.³⁹⁷ This obviously made a big difference for the usefulness of mass spectrometry in the area of protein biochemistry. The technique of MALDI was simultaneously and independently discovered in two laboratories in 1987 and reported at international conferences that same year. Results from both groups were first published in 1988.^{398,399} The technology has since evolved into a standard technique in the area of protein characterization by mass spectrometry. With MALDI

it became possible to very accurately and sensitively analyze large, intact biomolecules, and even derive information about their quaternary and tertiary structure. Commercially available MALDI platforms have become user friendly as well as much more powerful over the years. Mass accuracy in the 50–100 ppm peptide range is the expected norm. Eventually, the field of mass spectrometry started to open to nonexpert users, though real biology applications remained limited.

To put this technique into perspective, it is important to understand the key factors that make a MALDI-TOF experiment work. Very simply speaking, in a TOF mass spectrometry experiment the protein of interest is turned into a molecular ion. Subsequently, the travel time or TOF of this molecular ion through a vacuum tube toward a charged detector is measured. For singly charged ions, the TOF is proportional to the square root of the molecular weight of the analyte. There are different strategies to turn an uncharged molecule into a molecular ion. In the case of MALDI, an organic compound, the so-called matrix, in combination with an energy source, usually an ultraviolet laser, is used. A better term for ‘matrix’ would actually be ‘energy-absorbing molecules’ (EAMs), since that is exactly the purpose of these compounds. After the protein of interest has been mixed with an EAM solution and applied to the instrument probe in a tiny drop, EAMs and protein co-crystallize in a dry film. When the laser hits this film, the EAMs absorb the energy, expand into the gas phase, and carry the analyte molecules with them. At the same time, a charge transfer between the EAMs and the analyte leads to the creation of intact molecular ions. Usually the EAMs are present in vast excess over the analyte. The high matrix/sample ratio reduces the association of sample molecules and at the same time provides protonated and free radical products for the ionization of the molecules of interest. As the sample molecules acquire one or multiple charges, they are propelled down the vacuum tube toward a charged detector.

The matrices used in MALDI are mostly organic acids. They are prepared as saturated solutions in a solvent system typically consisting of an organic and a strongly acidic inorganic component. The choice of the matrix and solvent system very much depends on the nature of the molecule analyzed and is a crucial determinant for the success or failure of a MALDI experiment. Sinapinic acid and α -cyano-4-hydroxycinnamic acid are among the most popular matrix compounds for general protein and peptide analysis. The preparation in 0.5% trifluoroacetic acid and 50% acetonitrile is a good starting point for a first experiment. The purity of the matrix component as well as of the solvent chemicals can critically influence the outcome of the experiment. Accordingly, the choice of the highest grade material is well advised.

Figure 28 shows a spectrum derived in a typical MALDI experiment. The x axis represents mass/charge (m/z), and the y axis the percentage of signal intensity. The two peaks visible represent the singly and doubly charged entities of the same molecule. The singly charged entity is detected at the molecular mass plus 1 (H^+), the so-called monoisotopic mass, the doubly charged entity shows at apparently half the molecular mass. In addition to the analyte, matrix molecules are ionized as well, and show up at the very low end of the mass spectrum. This has to be kept in mind when attempting to detect very small molecules with molecular masses between 0 and 300 Da. When analyzing larger molecules that have hydrophobic qualities, matrix molecules can adhere to the analyte and create artifactual shoulders in the detected peaks. Fortunately, the generally high accuracy of mass detection allows distinction between the different molecular species and subtraction of matrix-related peaks.

Outside of finding the best matrix and solvent composition for a successful experiment with a particular protein, the purity of the protein and the buffer system used have a crucial influence on the outcome of the MALDI analysis.

Figure 28 Typical MALDI spectrum of a purified protein.

Certain ions, such as Na^+ , cause a phenomenon called ion suppression that usually results in tremendous chemical noise and inhibited ionization of the protein of interest. Due to this, Tris-based buffers as well as other buffers with a high content of sodium ions are unsuitable. Detergents can be very problematic, too. Very few can be considered compatible with the technique. Even under ideal conditions, the protein forms a three-dimensional crystal with the large excess of matrix on the instrument probe. To obtain the optimal signal, it is often necessary to search wider areas of the probe surface. This limits the quantitative value of the data.

The overall biggest limitations of the MALDI technique are the restrictions on the quality and nature of the sample that can be analyzed. Unless the protein sample is relatively pure and soluble in ionization-compatible buffers, analysis is difficult and requires great skill and understanding in the area of sample preparation. This clearly limits the usefulness of the technique in the area of biological screening, and has driven the development of matrix-assisted technologies that address these limitations.

The development has mainly gone in three directions: use of micropipette tip clean-up methods for standard MALDI applications, the direct modification of mass spectrometry probes for specific analyte capture and clean-up (SELDI), and the use of Biacore chips as the MALDI platform (BIA/MS).⁴⁰⁰

2.12.7.3.2 Surface-enhanced laser desorption/ionization: protein display chips for mass spectrometry

The SELDI technique was developed by Hutchens and Yip at Baylor College of Medicine, and the first experiments were published in 1993.⁴⁰¹ With a background of protein purification and characterization from very dilute biological samples like tear fluid and urine, Hutchens and Yip had found the available MALDI techniques unsatisfactory and limited for the sensitive characterization of biological samples. They began experimenting with surface modifications of MALDI probes that would selectively tether biomolecules, allow for in situ clean-up and concentration, and then release the molecules again in the laser desorption analysis.^{402,403} Soon they moved on to chemistries that would allow covalent molecule linkage, similar to the Biacore chips: that is, immobilize one binding partner covalently, capture a ligand from biological samples, wash away contaminants, and desorb the ligand.⁴⁰⁴ As Hutchens' group changed from an academic setting into industry, their new partner, Ciphergen Biosystems, obtained comprehensive patent coverage for the chemical modification of mass spectrometry surfaces. SELDI and ProteinChip Arrays have become registered trademarks. Since then, the technique has been refined and, again similar to Biacore, turned into an integrated analysis platform that consists of a chip reader (a linear delayed-extraction TOF device), the arrays, and an analysis software package.

Being a lot younger than SPR technology, SELDI today is where the Biacore was probably in 1994. The technology is a few years past its commercial introduction, the first publications are starting to appear outside of the development community,^{405,406} and users are starting to explore the potential and limitations of this new analysis strategy. Similar to the SPR situation, SELDI has brought a new analysis strategy into the hands of medical and biological researchers, for the most part users with no background knowledge in mass spectrometry. This has somewhat slowed the general acceptance of the technology, since initially a lot of inexperienced users had to discover the laws and limitations of MALDI by trial and error. Core laboratories and established mass spectrometry facilities initially avoided the technology widely, mostly due to the low accuracy of the first-generation mass reader. Ciphergen Biosystems has so far refused to license the surface technology to other instrument manufacturers, with the vision in mind to keep the hardware, chemware, and software under one roof. This has most certainly slowed the spread and development of the technology. Ciphergen Biosystems targeted the biotechnology and pharmaceutical industries as initial customers, and project collaborators rather than academia. This has led to a large body of unpublished proprietary research, very different from SPR, which stimulated significant interest in the academic community right away that proliferated into a greater number of publications from the start.

2.12.7.3.3 Surface-enhanced laser desorption/ionization applications: general principles and experimental considerations

Unlike SPR, SELDI quickly came along with a variety of different surfaces, mainly of two categories: preactivated surfaces for the covalent binding of biomolecules via primary amines, and chromatographic surfaces for the selective capture of proteins via charge, hydrophobicity, or metal-chelate interaction.

Preactivated surfaces support applications quite familiar to SPR users: the study of biomolecular interactions. While SPR looks at the affinity as expressed in on and off rates, SELDI takes a snapshot of everything that the capture molecule has pulled from a biological sample. Retention can be influenced by the chosen conditions for binding and washing. Molecules bound via the covalently attached capture protein are desorbed in the ionization process.

Figure 29 SELDI affinity study of a ligand captured via a receptor from human serum. Effect of different stringency modulators on nonspecific background binding.

Figure 29 shows a SELDI experiment where a ligand of interest is captured via a receptor from a background of 100% serum. As expected for this medium, a significant amount of nonspecific binding by serum proteins is detected. The experiment shows how the addition of stringency in binding reduces this background but does not completely eliminate it. However, complete background elimination in SELDI is not necessary. If the molecular weight of the ligand is known, competition binders are easily distinguished, as the mass spectrometer has a resolution superior to other molecular weight detection methods, generally much better than 0.1%. In an important difference from SPR, SELDI identifies the interacting molecules by molecular weight. This is important in a situation where the ligand of interest is captured from a complex biological background. In this situation, competition binding can lead to confusing results in SPR analysis. SPR and SELDI are very much complementary techniques in this application area: SPR allows the determination of affinities, and SELDI contributes protein identification capabilities. SELDI is limited by similar constraints as SPR; in both approaches a biological interaction is forced onto a two-dimensional platform. Different from SPR, though, the binding does not occur in a flow situation but rather in a tiny, stationary drop on the chip. With the limitations of sensitivity in a very small surface area, the high density of capture molecules is key. Since kinetic considerations do not apply to the same extent in this analysis strategy, the main concern with high molecule density has to be steric hindrance.

From a preparation point of view, SELDI experiments with preactivated chips share some similarity with enzyme-linked immunosorbent assay (ELISA) techniques. **Figure 30** shows a schematic outline of the process. The capture molecule is usually applied to each spot in a volume of less than $2\ \mu\text{L}$. For a protein, the concentration of the applied solution should be between 0.5 and $1\ \text{mg mL}^{-1}$. Because of the primary amine coupling, Tris and azide-containing buffers are incompatible. After binding of the capture molecule, residual sites are blocked with ethanolamine. To remove noncovalently attached capture molecules remaining on the surface, pH-cycle washes in phosphate and sodium acetate buffers with high salt are recommended. Right before ligand application the chip is washed with phosphate-buffered saline. The ligand is applied in a volume between 1 and $10\ \mu\text{L}$, depending on the concentration. After the ligand binding, the spots on the chip are washed with physiological buffers of appropriate stringency. The latter can be adjusted with salt or detergent. Due to the incompatibility of detergents and sodium salts with the desorption technique, a final wash in carbonate buffer or HEPES is necessary for good detection results. A conventional MALDI matrix mix is finally applied to the semi-dry sample for co-crystallization. Once dry, the chip is read in the instrument.

The even spread of molecules on the surface, forced by the specific capturing, and the layering of matrix on top of the biomolecules, dramatically enhance the quality of analysis compared with a conventional MALDI probe. More importantly, the opportunity to wash the surface without removing the protein of interest allows the use of previously

Figure 30 Flow chart of a typical SELDI experiment using preactivated arrays.

MALDI-incompatible buffers and detergents in all steps of the process prior to ionization. This is a significant breakthrough that opened the door to the successful analysis of complex biological samples. On-chip sample clean-up is probably the biggest benefit that the world of mass spectrometry sample preparation has seen in a long time, especially when considering that at the same time a biological affinity interaction is kept intact on a mass spectrometry probe. A carefully designed SELDI binding experiment explores a wide range of ligand concentrations and applies the same data collection parameters across the different spots of the same chip. In this case, quantitative correlation between the signal intensity and the actual concentration of the ligand can be quite impressive. The study of a wide range of ligand concentrations as well as the challenge of specificity in a competition binding experiment are as important as in the SPR technique to assure quality data.

The application type just described finds use at many junctions of the drug development process. In the discovery area, the method is a tool to obtain information about unknown ligands to known capture molecules. With known molecules such as purified antibodies, it is useful to confirm binding activity. In the area of pharmacokinetics, it allows the monitoring of molecules in patient serum: if the molecule of interest is a peptide with a molecular weight under 10 000, the mass accuracy will even allow reading of the degradation sequence from the molecule, providing it desorbs with decent resolution. In the current absence of post- or in-source decay capabilities for the mass reader, the degradation sequence has to be generated by on-probe carboxypeptidase digestions.

In direct comparison with ELISA methods, SELDI cannot quite compete with the levels of sensitivity, but the protein identification capability eliminates false positives by revealing cross-reactivity, if present. This can be as important as mere sensitivity, especially when dealing with molecule families that have a high level of conservation in structure and sequence, leading to immunological cross-reactivity. In one aspect SELDI is more limited than SPR: not all biomolecules are easily ionized and detected. In SPR the mode of detection is more or less independent of the molecular characteristics of the analyte; hence, the broad applicability to proteins, nucleic acids, even carbohydrates. The last two classes of molecules present special problems for matrix-assisted desorption techniques. They trap a lot of

salt in their molecular backbone that causes ion suppression. This also affects the detection of proteins with carbohydrate modifications. Glycoproteins ionize very poorly, which affects the mass accuracy of detection, as well as the sensitivity of the assay. SELDI has greatly enhanced the number of ionizable proteins by the simple fact that on-chip washes are very powerful in removing incompatible chemicals and ions, even from very difficult molecules. However, some molecules just will not fly, as mass spectrometrists say. Still, the use of DNA or carbohydrates as capture molecules is possible in SELDI, as long as the ligand is easily detected. In SELDI, as in SPR, the choice of the binding partner to immobilize is very important but is often driven by necessity, as discussed earlier. If the capture molecule is small, a higher density can be achieved on the chip, and hindrance does not become a problem as quickly as with larger molecules. If the captured target ligand is very large, it is more difficult to ionize, and the assay loses sensitivity in the detection step. The random binding to the chip also presents the familiar problem of not having all the capture molecules correctly oriented to receive the ligand. In the case of antibodies and Fc-fusion proteins, protein A coupling is helpful despite the fact that it increases the level of chemical and biological noise in detection. In a protein A sandwich assay, both the capture protein and the ligand will be ionized; only the protein A stays attached to the chip. The quality of the protein A used for capture can critically influence sensitivity and noise levels in this type of experiment. In a protein-protein binding experiment, the goal generally is detection of a single binding entity, sometimes multimers of it, or at the most a heteromeric complex.

A completely different set of data is obtained when protein chips are used for profiling applications. These applications look at the protein inventory of a biological sample in a given molecular weight range. Protein-profiling applications are very interesting in the area of disease research. A comparison of lysates from normal versus diseased cells can reveal the expression of important marker proteins. For cancer research this approach has found a faithful following. Crude cell lysates are spotted on protein chips with different chromatographic surfaces, allowing a multidimensional binding picture based on different types of interaction. Control lysates are read against lysates of interest under the same data collection conditions, and subsequent peak subtraction allows the identification of differences. Once a peak of interest has been detected, this protein can be singled out for further analysis. This is made possible by the application of more stringent conditions to the surface. Depending on the type of interaction, this can be achieved in gradient washes of pH, salt, or organic solvent, followed by an ionization-compatible wash. Once a peak is singled out sufficiently, the possibility of on-chip digestion with proteolytic enzymes and subsequent analysis of the peptide patterns can yield important identification information. At the current stage of the technology, protein identification applications are still somewhat limited by the mass accuracy of the protein chip reader, and it is very important to use careful calibration techniques with known peptides of comparable molecular weight to obtain reliable peptide maps. Even with a mass accuracy in the millidalton range, the proteomic researcher is cautioned that the protein chest of nature contains enough redundancy and sequence conservation to make wrong identification calls based on peptide masses. It is therefore necessary to have powerful fragmentation and sequencing capabilities combined with a front end of protein chips to obtain high-resolution data and novel protein information directly from biological samples. Developments in this area are ongoing and already provide exciting glimpses into a very bright future for proteomics by SELDI mass spectrometry.

Aside from the described discovery profiling, chromatographic protein chips are very useful tools in the day-to-day routines of the industrial protein chemistry laboratory. They can be used for expression monitoring and purification screening, as well as a simple identification tool at the end of a high-throughput purification process based on the same type of affinity chromatography.

2.12.7.3.4 Surface-enhanced laser desorption/ionization in the drug development process: a bright future

In general, protein chips for mass spectrometry have a very bright future in the drug discovery laboratory. The versatility of SELDI and the speed of the analysis will eventually lead to very elaborate multiplexed systems that provide an incredible amount of information in a very short time. In discovery as well as process development, production, and quality control, the mass accuracy of mass spectrometry joined with a platform for chemical or biological affinity for very small sample volumes will prove to be a very powerful combination. The technology still needs time to mature. As learned from the Biacore example, a crucial step will be taken when the technology acquires a user base large enough to speed up the elimination of problems with experimental as well as instrument and platform design. It is safe to say that the future of protein biochemistry will be revolutionized by label-free chip technologies, and a few years from now protein gels may have become a thing of the past.

2.12.7.3.5 Biomolecular interaction analysis/mass spectrometry: connecting a popular surface plasmon resonance platform to matrix-assisted laser desorption/ionization-time-of-flight

We have already discussed some of the striking similarities that SPR and SELDI share in terms of surface activation and specific capturing of biological molecules on analysis chips. Hence, it is not surprising that researchers have looked at the possibilities of directly connecting a Biacore platform with a MALDI-TOF system. Two facts have driven the development in this area: the wide acceptance of the Biacore platform in industrial and academic laboratories, and the comprehensive patent coverage in the hands of Ciphergen Biosystems for the chemical modification of mass spectrometry probes. BIA/MS circumvents the issue of surface modification specifically for mass spectrometry, and allows users to retrieve additional information from an SPR experiment. Two experimental strategies are mainly used in BIA/MS. In the first technique, the captured molecule of interest is eluted from the Biacore chip with a MALDI-friendly solution (typically a small volume of formic or trifluoroacetic acid) and subsequently applied to the MALDI probe. This has been successful for elution from metal-chelate chips.⁴⁰⁷ In an alternative strategy, the Biacore chip is directly used as a MALDI probe by the application of matrix after conclusion of the SPR cycle.⁴⁰⁸

Compared with SELDI, the BIA/MS strategy has several disadvantages. As has been discussed earlier, to obtain good results in SPR, it is important to maintain a low molecule density on the chip as well as a low analyte concentration. This challenges the detection capabilities of the best MALDI systems, especially when molecules with poor ionization qualities are analyzed. Furthermore, the Biacore chip was not designed as a mass spectrometry probe in the first place, and thus has several intrinsic problems when used as a probe.

Overall, BIA/MS is not a straightforward and easily adapted experimental system. So far, the literature in this area has mainly come from two groups.^{409,410} BIA/MS advocates stress MALDI sensitivity as well as the tolerance of the technique for difficult buffer systems, but the examples demonstrated in the literature so far mainly focus on examples from *E. coli* lysate, where protein abundance and available sample preparation options are generally not limiting factors.⁴⁰⁸ It remains to be seen how well the technique will fare with difficult biological backgrounds such as membrane systems. In those areas the opportunity for higher molecule density and sample clean-up on the SELDI chip will most likely prove more advantageous.

2.12.7.4 Conclusion: Protein Display Chips in Drug Discovery – the Future is Here

This section shows that protein display chips are still very much a developing field, and there are far fewer players than for the respective technology for nucleic acids. Nevertheless, as the genomics field has come of age, development in the protein area has picked up, profiting from the great leaps that have been made in nanoscale analysis for DNA and RNA. Still, for proteins the most exciting discoveries are probably yet to come. Accommodating the incredible diversity of proteins in discovery, development, analysis, and validation is an enormous task, requiring not one or two but at least a handful of technology platforms. These in turn must be integrated to render a multidimensional analysis picture. The overlap between techniques such as SPR and SELDI as well as the limitations of both already point us in this direction. The techniques and platforms discussed give us a glimpse of the future that has finally arrived in protein biochemistry.

2.12.8 Integrated Proteomics Technologies and In Vivo Validation of Molecular Targets

2.12.8.1 Proteomics in Molecular Medicine

The identification and selection of a therapeutic target can determine the success or failure of a drug discovery program. This decision is influenced by the underlying biases of the drug discovery research strategy, which can be a reflection of the applied technologies. Since the vast majority of drug targets are proteins, the identification and characterization of a novel molecular target will be greatly facilitated by carrying out the analysis at the protein level, thus focusing “on the actual biological effector molecules”⁴¹¹ of the gene. This section will examine the role of proteomics in drug discovery with a particular focus on preclinical target evaluation. Until we can truly rely on experimental medicine for drug development, disease models will play a pivotal role in molecular medicine for the safety and efficacy evaluation of a new therapeutic. To succeed with this strategy, the relevance of these models must be considered. Proteomics may facilitate this assessment through a comparison of the human disease phenotype to the one obtained in an animal model through a comprehensive analysis of protein expression maps (PEMs) of the relevant body compartments such as bodily fluids and the affected organ tissues.

2.12.8.1.1 Proteome terminology

The term ‘proteomics’ is twinned with another new term, the ‘proteome,’ which originated in 1995,⁴¹² to describe the complete protein expression profile in a given tissue, cell, or biological system at a given time. Proteomics represents an extension of the earlier established concepts of the genome and genomics. The human genome delineates the entire human genetic information contained in two copies within the nucleus of each cell of the human body, with the exception of mature platelets. “Functional genomics is the attachment of information about function to knowledge of DNA sequence,”⁴¹³ giving an indication of whether a gene is transcribed but not necessarily translated in a disease- or tissue-specific manner. More specifically, functional proteomics describes the biochemical and biological characterization of proteins. These efforts are aimed at identifying structurally and functionally significant sequence motifs in the primary protein sequence with respect to the subcellular location of their activities and to relate these to disease- or tissue-specific changes. Pharmacogenomics is aimed at identifying genetic polymorphic variations in the human population that are relevant to the disease state or the ability to metabolize a drug. Recently, a lot of emphasis in the area of pharmacogenomics has been directed at the identification of the majority of single-nucleotide polymorphisms (SNPs) involved in human disease and drug response. SNPs are single-nucleotide variations between the DNA sequence of individuals that can be substitutions, insertions, or deletions. Information on these variations may allow the clinician of the future to stratify a patient population in clinical trials based on individuals’ predicted drug sensitivity–response profile.⁴¹⁴ First applications are emerging, such as chip-based mutational analysis of blood, urine, stool, and breast effusions.⁴¹⁵ However, it remains to be determined what impact the presence of genetic polymorphisms will have on the application of animal models in preclinical development.

Although pharmacoproteomics aims at patient stratification, it is based on protein expression polymorphisms in body fluids and tissues, which could be indicative of susceptibility to disease and responsiveness to drugs in pharmacoproteomic pharmacology or toxicology studies. Longitudinal serum samples from drug-treated animals should identify individual protein markers or clusters thereof that are dose related and correlate with the emergence and severity of toxicity. Structural genomics could be considered an extension of functional genomics using structural information obtained by x-ray crystallography to infer the folding and three-dimensional structure of related protein family members. It can be envisioned that the discipline of structural proteomics could apply the information available on the tertiary structure of a protein or motif to establish its biological significance by systematically mapping out all its interacting protein partners. This information could suggest their role in the pathogenesis of a particular disease and assess its dependence on post-translational modifications (PTMs). We will illustrate some applications for structural proteomics in [Section 2.12.8.1.8](#) on the proteomic analysis of protein complexes. Definitions of these terms are given in [Table 22](#).

2.12.8.1.2 Genome versus proteome

Until recently, biological and biochemical analyses were carried out on single molecules. The dramatic advances in genomic sequencing and mRNA-based analyses of gene expression have generated important descriptive information. The field is now quickly evolving from its primary objectives of information collection, organization, and mining to functional and structural genomics, whereby one uses DNA-based technologies to make inferences about the structure and behavior of an organism mainly through large-scale analysis of gene expression. The Human Genome Project, together with the availability of an increasing number of methods for gene expression, has led pharmaceutical companies to review their strategies to discover new drugs. However, it is becoming apparent that purely gene-based expression analysis is not sufficient for the target discovery and validation process. There may not necessarily be a tight temporal correlation between gene and actual protein expression.⁴¹⁶ Differences can arise from the different stabilities and turnover of mRNA and proteins, post-transcriptional mRNA splicing yielding various protein products, and PTMs. Proteomics can take these variables into consideration, and contribute additional information through expression analysis of subcellular fraction and protein complexes ([Figure 31](#)).⁴¹⁷

2.12.8.1.3 Changes in post-translational modifications associated with pathogenesis

An understanding of the control of cellular processes and of the molecular basis of inter- and intracellular signaling can only emerge when the protein and the protein complexes involved in these processes can be elucidated together with the dynamics of their PTMs and associated activities. It is largely through an understanding of such protein-based mechanisms that real insight into the molecular bases of complex phenotypic diseases will emerge, leading to more relevant molecular targets for drug discovery. Ample evidence has distinctly validated numerous novel enzymes modulating protein PTMs as targets in many diseases, including cancers, diabetes, and sepsis, as well as certain cardiovascular and neuronal abnormalities.^{419–425} The rational design of modulators of these new molecular targets has

Table 22 Definition of terms used in genomic and proteomic research

Term	Definition
Genome	Total genetic information possessed by an individual
Genomics	Characterization and sequencing of the genome
Functional genomics	Systematic analysis of gene activity in healthy and diseased tissues
Structural genomics	Systematic analysis of the three-dimensional structure of a protein based on homology to a protein with a known structure
Pharmacogenomics	Stratification of patients by their genetic susceptibility to disease and responsiveness to drugs
Phenotype	Observable properties of an organism produced by the genotype (in conjunction with the environment) ^a Genetically inherited appearance or behavior of organism ^b
Proteome	Total protein profile of a cell or tissue at a given time
Proteomics	Systematic analysis of a protein expression map in a particular tissue or body fluid
Functional proteomics	Systematic analysis of protein expression and post-translational modification of proteins in various cellular compartments of healthy and diseased tissues
Structural proteomics	A proteomics approach for structure determination using native protein array technology
Pharmacoproteomics	Patient stratification based on protein expression polymorphisms in body fluids indicative of susceptibility to disease and responsiveness to drugs

^aFrom Devlin.⁵¹¹
^bFrom Forum on Data Management Technologies in Biological Screening.⁵¹²

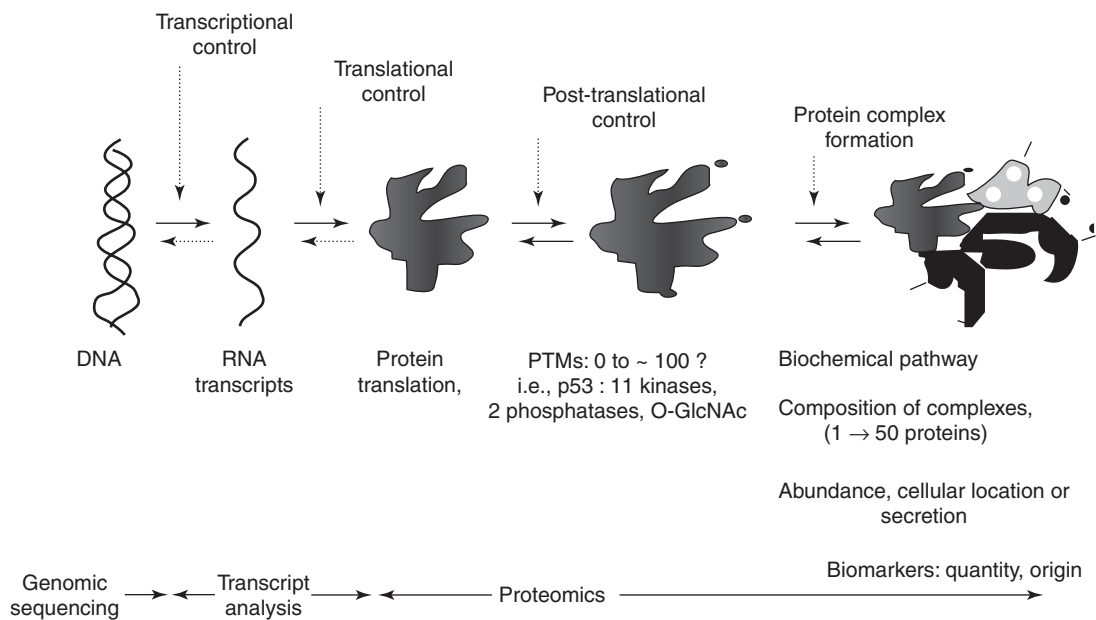

Figure 31 Genome to proteome. Gene expression can be regulated by the rate of transcription, translation, and further post-translational regulation of protein expression and activity are known.⁴¹⁸ Each protein may undergo various levels of PTM. In some instances, more than 10 serine-, threonine-, and tyrosine-phosphorylated and serine- or threonine O-linked-glycosylated amino acids can be detected on a single protein. Additional PTMs include asparagine-linked glycosylation, farnesylation, and palmitoylation, all of which can affect the activity, stability, and location of a particular protein (see [Section 2.12.8.1.3](#)). There are an increasing number of examples where enzymes carrying out these PTMs become targets for therapeutic intervention (see [Section 2.12.8.1.4](#))⁴¹⁷.

yielded multiple drug candidates, promising more selective therapies. In cancer research, for example, several pharmacological approaches have focused on the enzymatic activity of enzyme-linked cell surface receptor signaling cascades such as the epidermal growth factor (EGF) receptor family signaling pathway.

2.12.8.1.4 New drug candidates directed against molecular targets modulating protein post-translational modification

As illustrated by the EGF receptor family signaling pathway, tumorigenesis via the erbB receptor signaling cascade has a proven biological significance in experimental tumor metastasis systems.⁴²⁶ This provides ample opportunities for novel therapeutic modalities at multiple sites within the pathway such as the EGF receptor kinase antagonists⁴²⁷ and trastuzumab (herceptin), an anti-HER2 monoclonal antibody blocking the activity of HER2 (ErbB-2), the second member of the EGF receptor family.⁴²⁸ The importance of membrane anchoring via acetylation of certain signal proteins, such as Ras, is exemplified by the farnesyltransferase inhibitors, a putative cancer therapy with a better therapeutic index than standard chemotherapy. Originally designed to target tumors with mutant *ras* genes, farnesyltransferase inhibitors also affect growth of tumors with no known *ras* mutations.⁴²⁹ Several protein kinases, including the immediate downstream effector of Ras, Raf kinase, and protein kinase C, are targeted clinically via the antisense approach.^{430,431} Inhibition of the tumor growth-promoting protein kinase MEK1 (MAPK kinase) leads to arrest at the G₁ phase of the cell cycle. In addition to blocking cancer cell growth, MEK1 inhibitors reverse some of the transformation phenotype, such as resumed flattened morphology and loss of the ability to grow in the absence of a substrate.⁴³² A detailed understanding of such a pathway in the context of the disease may enable us to select the right drug directed to a particular step the pathway or a combination thereof for each subcategory of the disease.

Initial emphasis in the development of small-molecule protein kinase inhibitors focused on modulating catalytic activity directly. However, homology among the catalytic ATP-binding site of hundreds of protein kinases active in a mammalian cell at any given time severely limits the degree of selectivity attainable. A strategy to overcome this has been illustrated by MEK1 kinase inhibitors that appear to act through an allosteric mechanism of inhibition. This novel class of MEK1 inhibitors displays very good toxicity profiles, suggestive of a high degree of selectivity.⁴³² However, the MAPK signal pathway plays an important role in normal cell signaling for the immune response and neuronal functions, mandating thorough validation in vitro and in vivo.⁴³³ Such validation studies increase the knowledge about the behavior of the small-molecule inhibitor in a complex biological system, and may lead to label extension for completely different indications. For example, the MEK1 kinase inhibitors are being evaluated for their ability to reduce postischemic brain injury.⁴³⁴

A similar approach of allosteric inhibition of intraprotein binding led to the development of small-molecule inhibitors that block the interactions between the tumor suppressor protein p53 and its inhibitor MDM2. Initial studies on the regulation of p53 focused largely on phosphorylation, the complexity of which is emphasized by at least nine kinases, two phosphatases,⁴³⁵ and cytosolic O-linked glycosylation, modulating p53 location, stability, and activity.⁴³⁶ p53 activity is further regulated by the proto-oncoprotein MDM2, which impedes its transcriptional function and targets p53 oligomers only for ubiquitin-dependent degradation.⁴³⁷ Small-molecule inhibitors blocking this protein–protein interaction led to the release of active p53 to activate programmed cell death (Figure 32). These two examples emphasize the importance of studying protein complexes, as will be discussed in Section 2.12.8.1.8, since they may yield an immediate new target for therapeutic intervention.

The small-molecule MDM2 inhibitor mimics the activity of the endogenous cell cycle regulatory protein p19^{ARF}, which also binds MDM2 and stabilizes p53. The diverse expression of the p19^{ARF}/p16^{INK4a} gene exemplifies the complexity of gene expression at another level of regulation. The second p19^{ARF}/p16^{INK4a} gene product originates from an alternative splicing product, which is translated into p16^{INK4a}. p16^{INK4a} has a peptide sequence different from p19^{ARF} because the use of an alternative start exon causes a frameshift, and the mRNA is translated in a different reading frame. The alternative splicing occurs in a tissue-specific manner (Figure 32). A third splice form, p12^{INK4a}, was discovered to be of functional significance in pancreatic cancer.⁴⁴⁰ Originally studied as a tumor suppressor in cancer, p16^{INK4a} is now being evaluated as a novel therapeutic agent for the management of rheumatoid arthritis.⁴⁴¹ The physiological and therapeutic importance of distinct splice variant isoforms of a protein has already been recognized for seven transmembrane G protein-coupled receptors.⁴⁴² These splice variants arising from exon skipping, intron retention, alternative start exons, or splicing will also affect ligand-binding profiles, G-protein coupling, and receptor desensitization in a tissue-specific manner.⁴⁴²

In conclusion, the discovery and characterization of molecular targets resulting from abnormal cellular function through abnormalities in protein expression and their PTMs cannot be achieved through descriptive genetic analysis. Exploring how the protein products of individual genes interact dynamically to control cellular processes, as well as how

Figure 32 Gene sequence does not predict protein functions; tissue-specific transcription and translation of the p16^{INK4a}/p19^{ARF} gene. The tumor suppressor p16^{INK4a/ARF} gene locus on human chromosome 9p21 is a site of frequent deletion in many cancers, including leukemias, gliomas, and non-small cell lung cancers.^{513,514,515,515a,515b} Three splicing forms of the p16^{INK4a/ARF} gene yield three distinct proteins: p16^{INK4a}, p19^{ARF}, and p12. p16^{INK4a} blocks the cyclin D/cyclin-dependent kinase 4 complex, preventing phosphorylation and inactivation of Rb. Active Rb will inhibit the transcription factor E2F and prevent gene expression of cell cycle machinery protein for S phase progression, causing arrest in the G₁ phase of the cell cycle. The second splice form p19^{ARF} uses a different start exon, and yields a different peptide sequence due to a resulting frameshift. p19^{ARF} prevents MDM2 from binding p53. The third protein product of the p16^{INK4a/ARF} gene, p12, composed of the INK4a exon 1a and a novel intron-derived C terminus, also inhibits the cell cycle without interacting with the Rb pathway.⁴³⁸ MDM2 blocks p53 tumor suppressor function by blocking its transcriptional activity and targeting it for ubiquitin-dependent degradation.⁴³⁹ MDM2 also binds a close homolog of p53, p73α, inhibiting its transcriptional activity without inducing its degradation.

these protein interactions and activities are controlled by PTMs, will lead to greater insight into the control of the complex and dynamic processes of protein PTM that are central to cellular behavior and cellular responses. Understanding the control of subcellular protein expression and PTMs will lead to our understanding with greater precision the molecular basis of abnormalities in cellular control processes and protein networks, leading ultimately to more specific and more relevant molecular targets for disease control.⁴⁴³ This implies a central role for the proteomic analysis of molecular targets in the evaluation process in vitro and in vivo. Although proteins reflect the physiology of normal and diseased tissue more closely than transcript analysis, the technology requirements for the reproducibility, sensitivity, and throughput of two-dimensional gel electrophoresis hampered the fast and direct access to this information. Significant advances in the technology combined with new approaches to disease models and access to clinically relevant tissues may provide us with a molecular fingerprint of diseases at the protein level, and identify further targets for therapeutic intervention.

2.12.8.1.5 Protein expression mapping

Protein expression mapping aims to define global protein expression profiles in tissues, cells, or body fluids. A protein expression profile may be representative of a given time point in an experiment or a disease state and become the basis for a comparative analysis. The most common implementation of proteomics is based on 2DE of proteins in a complex mixture and their subsequent individual isolation, identification, and analysis from within the gel by mass spectrometry (MS). If multiple isoforms of a protein exist within the sample due to PTMs and splice variants as described above, they may be identified because PTMs affect the charge and molecular weight of protein isoforms altering their mobility in the two-dimensional (2D) gel.

In the proteomic process, proteins are initially extracted from tissues, whole cells, or cell organelles using extraction procedures well documented in the literature.⁴⁴⁴ The proteins are solubilized in 2D sample buffers and run on 2D polyacrylamide gels by separating them according to their charge (pI) in the first dimension using isoelectric focusing. They are then separated by size, using sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), in the second dimension. Most commonly, proteins within the gel are visualized by Coomassie blue or silver staining. The proteins referred to as features in the raw primary image represent the proteome. At UCB, the image is scanned through fluorescent detection and digital imaging to yield a PEM. An electronic database containing all PEMs (now in

digitized form) can be constructed. Each protein feature in each PEM is assigned a molecular cluster index (MCI). Each MCI has attributes of pI, relative molecular mass, quantity in each sample, frequency in each sample set, and a linkage to the feature ID in each gel for subsequent analysis of any proteins in any archived gel. By this process, all protein features in a sample are linked to MCIs, and are then available for quantitative analysis. A comparison of the proteomes generated from normal and disease samples is summarized in the proteograph. The PC-Rosetta software is capable of rapidly identifying those proteins that are unique in PEMs of control and diseased samples, or those that show increased or decreased expression. It provides information on its pI and molecular weight, and in large sample sets, statistical data on differentially expressed proteins are computed. Several other commercial companies also provide basic image analysis tools, such as Melanie (BioRad Laboratories¹¹⁰²) and Phoretix 2D (Nonlinear Dynamics¹¹⁰³).

Many modifications have been made at UCB to improve the handling, throughput, sensitivity, and reproducibility of 2DE. For example, proprietary attachment chemistry causes covalent attachment of the gel to the back plate. This greatly enhances reproducibility by avoiding warping and other distortions of the gel. Fluorescent dyes that bind noncovalently to SDS-coated proteins facilitates the detection of protein spots in the gel over a greater linear range than densitometric methods while not interfering during the MS analysis.⁴⁴⁵

Zoom gels can be used to further expand the resolution of a gel or to analyze a particular area of the gel containing a protein of interest with greater accuracy. For this purpose, proteins are separated in the first dimension in three isoelectric focusing (IEF) steps (pH 4–6, 5–7, and 6–8) rather than standard IEF (pH 3–10). Through this process the number of features resolved can be increased considerably. For example, the number of features resolved from a cell extract of Huh7 human hepatoma cells can be increased from approximately 2000 features to more than 5000 features.

Selected features are isolated from the gels and chemically or enzymatically fragmented in the gel slice^{446,447} or after electrotransfer onto a suitable membrane for MS analysis.^{448–451} The resulting peptides can be separated by on-line capillary high-performance liquid chromatography for subsequent MS analysis through matrix-assisted laser desorption ionization MS,^{452,453} tandem MS (MS/MS), or electrospray ionization MS/MS, or as described by others.^{454,455} Protein identification is based on searching the resulting peptide fragmentation spectra against genomic and EST databases using either the automated SEQUEST program or proprietary algorithms. Thus, protein identification has moved from the traditional laboratory N-terminal sequencing method to a highly dynamic fast MS-based method that correlates the MS data of peptides with information contained in sequence databases.⁴⁵⁶

As pointed out by Haynes *et al.*,⁴⁵⁶ there are a number of alternative approaches to proteome analysis currently under development. There is a considerable interest in developing a proteome analysis strategy, which bypasses 2DE altogether, because it is a relatively slow and tedious process, and because of perceived difficulties in extracting proteins from the gel matrix for analysis. However, 2DE as a starting point for proteome analysis has many advantages compared to other techniques available today. The most significant strengths of the 2DE-MS approach include the relatively uniform behavior of proteins in gels, the ability to quantify spots, and the high resolution and simultaneous display of hundreds to thousands of proteins within a reasonable time frame.

In addition, a comparative analysis carried out with digitized PEMs, described above, enables us to compare hundreds of samples/PEMs obtained from 'normal' and 'disease' samples, each containing thousands of proteins. In concurrence with a statistical analysis of the fold changes for each protein, a disease-specific protein marker can be selected out of several hundred thousand proteins queried.

An alternative 2DE independent approach for a comparative global proteome analysis⁴⁵⁷ is based on an isotope-coded affinity tag (ICAT) method combined with direct MS/MS analysis. The approach relies on an isotopically coded linker coupled to an affinity tag specific for sulfhydryl groups in the side chains of cysteinyl residues in the reduced protein sample. Two versions of ICAT, an isotopically light and a heavy form, are used to label protein mixtures from state A and state B of the sample. The samples are mixed and digested for direct MS analysis, as described above. The relative signal intensities for identical peptide sequences can be quantified by being traced back to the original sample based on the respective ICAT. This allows for simultaneous identification and quantification of components of protein mixtures in a single automated operation from a fairly limited amount of sample such as laser capture microdissection (LCM) (see below).

2.12.8.1.6 Cellular proteomics

To understand the molecular basis of a disease as the difference between normal and diseased tissues and organs, it is necessary to interpret the complex interactions between many different cell types at the protein level. In addition, it may be necessary to isolate and characterize abnormal cells within or adjacent to unaffected areas of the diseased tissue or organ. LCM technology⁴⁵⁸ has made this difficult task achievable with a minimal effect on the gene and protein

expression profile present *in vivo*. LCM allows for a precise identification and isolation of specific cells and their application to reverse transcriptase PCR,⁴⁵⁸ cDNA microarrays,⁴⁵⁹ enzyme activity,⁴⁵⁸ and proteomic analysis.⁴⁶⁰ Cells in frozen tissue slices are first identified through a conventional staining method of choice, before they are selected through a microscope. A solid-state near-infrared laser beam is then focused on the target cells, causing their selective adhesion to a transfer film. The film is lifted away from the surrounding tissue, and placed directly into DNA, RNA, enzyme assay, or protein lysis buffer. Since Emmert-Buck *et al.* published their original findings in 1996, LCM has become routine for the identification of tumor-specific mRNA/gene expression analysis in a variety of cancers. The technology has progressed in the meantime from applications in conjunction with cDNA microarrays to profile gene expression of adjacent neuronal subtypes.⁴⁵⁹ At the same time, Banks *et al.*⁴⁶⁰ described the first proteomic analysis of LCM-purified normal and malignant human cervix and renal cortical tissues. These technological advances provide us with an opportunity to map out complex interaction of many cell types throughout human anatomy in both the normal and diseased states at an unprecedented level of complexity and detail. In oncology research, such valuable information can give an understanding of the alterations taking place in the cells surrounding the diseased tissue, such as stromal and endothelial cells, as well as the cancer cell itself. These additional insights provide us with an opportunity to broaden our therapeutic approaches, as illustrated by novel cancer therapeutics targeted against tumors and/or surrounding activated vascular endothelial cells.^{461,462} But more importantly for the purpose of this review, we can now assess how closely our chosen animal models mimic the *in vivo* situation in the patient. For example, in tumor angiogenesis and metastases, researchers are faced with the dilemma that xenograft tumors (human tumors implanted underneath the skin of mice with faulty immune systems) do not behave like naturally occurring tumors in humans,^{461,463} as will be discussed further in [Section 2.12.8.2.3](#). In such a case, a proteomic comparison of LCM-purified stromal and endothelial cells from a human biopsy and the mouse model may be revealing, and identify critical differences in the two protein expression profiles that may be linked to the deficiencies of the animal model.

2.12.8.1.7 Proteomic analysis of body fluids

Body fluids represent a central link between various body compartments to exchange metabolic ‘fuels’ and dispose of metabolic waste products and toxins. The complex mixtures of proteins present in systemic fluids such as serum or plasma are secreted from many organs, such as the liver, pancreas, lungs, and kidneys, and are central to energetic drug metabolism and catabolism and homeostasis. For example, many steroids and peptide growth factor-binding proteins constantly present in the serum are responsible for a tight regulation of these potent circulating cell regulatory molecules. Many alterations in the physiological or disease states of an animal or human change the levels of the proteins in body fluids. Information about the magnitude of the change of identified proteins and clusters thereof may be of diagnostic, prognostic, or therapeutic significance. Proteomics body fluid analyses have been carried out for plasma, serum, cerebrospinal fluid (CSF), urine,⁴⁶⁴ joint fluid,⁴⁶⁵ tears,⁴⁶⁶ pancreatic fluid,^{467,468} amniotic fluid,⁴⁶⁹ ascitic fluid,⁴⁷⁰ pleural fluid,⁴⁷¹ cyst fluid,⁴⁷² sweat,⁴⁷³ milk,⁴⁷⁴ and seminal fluid.⁴⁷⁵

The objectives of these studies were to discover and characterize disease-specific proteins in body fluids by building databases of high-resolution PEMs from the relevant body fluids obtained from individuals. Interrogation of these databases may reveal proteins whose expression is significantly increased in a disease-related manner for subsequent molecular characterization. Routine application of this approach for a rapid and reliable identification of disease-specific protein markers had been severely limited by the interference by high-abundance proteins such as albumin, haptoglobin, IgG, and transferrin. For example, without removal of these high-abundance proteins, no more than 300–500 individual features can be separated in CSF. UCB has refined the use of proteomics for these type of analyses through immunoaffinity-based depletion methods, in which these four highly abundant proteins are removed from the sample to be analyzed. After such an enrichment, many additional features previously masked by the high-abundance proteins become visible. Now, up to approximately 1500 features of a CSF sample can be separated through 2DE. As with the analysis of cell extracts, zoom gels may be used to further enhance the resolution and sensitivity of the separation. This approach can be extended to all known body fluids and the removal of any known interfering high-abundance proteins prior to a proteomic analysis. PEMs obtained from human biofluids may serve as a reference point for the selection of the appropriate animal model. A comparison of body fluid PEMs between randomly mutagenized mice and human disease samples may establish a link between the disease and a single genetic abnormality.

2.12.8.1.8 Analyses of protein complexes

Once a putative therapeutic target protein has been identified, the need to assign a biological function and establish the relevant pathway for such a protein drives our attempts for cataloging binding partners. As discussed in [Section 2.12.8.1.3](#), changes in cellular location and protein binding partners in response to stimuli-driven PTMs may suggest

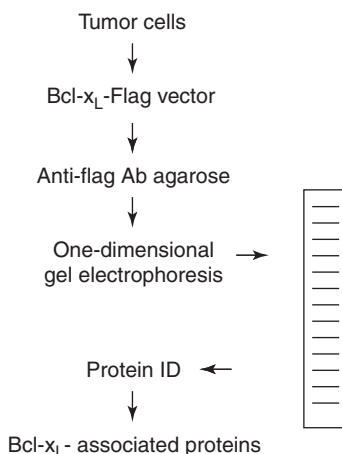

Figure 33 Example of a proteomic analysis of protein complexes as described previously. ⁴¹¹

protein function. For example, proteomic mapping of purified protein complexes has led to the discovery of novel signal proteins such as FLICE,⁴⁷⁶ IKK,⁴⁷⁷ and components of the spliceosome complex.⁴⁷⁸ For this purpose, the cell lysate is enriched for protein partners of the protein complex either with a tagged version of the protein such as FLAG⁴⁷⁹ or GST⁴⁸⁰ or through well-established immunoaffinity-based technologies. Again, it is 2DE that will assist in a reliable and quick identification of those proteins or isoforms thereof that are changed within the complex in the disease only, guiding the investigator toward the disturbances in a given pathway pertinent to the disease. In the case of the Ras pathway, multiple alterations cause uncontrolled proliferation and the loss of the ability to carry out programmed cell death (apoptosis), thereby promoting carcinogenesis. The proto-oncogene Raf kinase prevents apoptosis by phosphorylation-dependent activation of the Bcl-2 protein, a mechanism downregulated by the anticancer agent taxol in ovarian cancer.⁴⁸¹ The exact mechanism by which Bcl-2 and BclXL (a related protein) prevent cell death is not known. However, it has been suggested that alterations in the mitochondrial membrane permeability through a Bcl-2/BclXL Bnip3L (Bcl-2-interacting protein-3-like) protein heterocomplex may be a prerequisite for apoptotic cell death.⁴⁸² In a classic proteomic mapping exercise summarized in **Figure 33**, Gygi *et al.*⁴¹¹ were able to identify 23 BclXL-associated proteins, many of which have already a proven association with apoptosis.

One can imagine how this process can be continued iteratively until an endpoint for a particular pathway has been reached or sufficient novel putative targets have been selected. The throughput of this technique may be further accelerated in some instances by applying technologies such as ICAT-MS/MS analysis (described above), and further improvements in MS now facilitate characterization of even complex mixtures of proteins.⁴⁵⁷

2.12.8.1.9 Combined mRNA/protein expression analysis for pathway mapping and candidate target selection

Although mRNA expression analysis may have no direct utility in the analysis of protein complexes, combined with proteomics it may yield useful information for additional target validation experiments. Effective integration of nucleic acid- and protein-based technologies may accelerate the selection of the best candidate target. Whereas the target discovery process described above is largely protein-driven, knockout technologies and overexpression strategies rely on molecular biology. In a case where a protein is downregulated in the disease, one can envision the use of inducible gene expression vectors as a quick means to restore protein expression and normal cell function (i.e., the reintroduction of a tumor suppressor such as p53). More commonly, an overexpressed disease-specific protein becomes the target for a therapeutic inhibitor strategy. If access to pre-existing small-molecule inhibitors are not available or cannot be generated easily, the gene can be readily ablated through antisense strategy. An antisense oligonucleotide can be synthesized or an antisense cDNA can be expressed in the cell in an inducible gene expression vector. In some cases, ribozyme constructs (small DNA fragments with intrinsic endonuclease activity that binds the target mRNA through a small DNA sequence complementary to a coding region in the target mRNA) are more useful. However, the effectiveness of these strategies is again monitored most accurately at the protein level. In particular, for the antisense strategy it is important to determine that the antisense DNA selectively blocks the expression of the target protein only, and does not result in nonspecific effects on protein expression. In the case of cell surface protein targets, quickly

advancing phage display technologies now promise functional inhibitory antibodies within months. With these tools, one can now establish if interfering at different levels in the pathway will affect the protein expression profile differently, and which protein expression profile resembles that of the normal state most closely. This approach is facilitated by the fact that, in most cases, whole clusters of proteins rather than a single protein will be changed. By using new bioinformatics tools, clusters of proteins can be used in a specific PEM to describe a phenotype, thus increasing the predictive value of the analysis.

2.12.8.2 In Vivo Validation of Molecular Targets

In this new millennium, rapid advances in molecular medicine may provide us with a molecular fingerprint of the patient and disease phenotype that could represent the molecular and genetic bases for a preclinical animal model to evaluate novel candidate therapeutic targets. The preclinical evaluation of candidate targets requires complex animal models that will represent as many of the aspects of the drug discovery process as possible in order to identify the successful therapy. At the stage where small-molecule inhibitor leads have been identified, the relevance of the disease model becomes even more important, to investigate the mode of action, efficacy, and safety of these leads. To illustrate this, we will continue to use examples of oncology and central nervous system (CNS) research, with particular emphasis on AD.

2.12.8.2.1 Disease model relevance

The assessment of lead compounds in the most suitable animal model is of great importance because many agents that look highly promising in vitro or in animal models fail because of insurmountable toxicity problems or lack of efficacy in humans. Knockout and transgenic technologies have made the creation of mouse models of genetic disorders almost routine. As we will discuss below, specific gene mutations and conditional knockouts are now achievable in a tissue and/or time-dependent manner. An analysis of the complexity of most human disease necessitates a global comparison of the protein phenotype, well suited to a gene-related proteomic analysis (*see* [Section 2.12.8.2.5](#)).

2.12.8.2.2 Animal models of Alzheimer's disease

AD is a progressive neurodegenerative disorder that first presents clinically with memory impairment followed by continuous deterioration of cognitive function. The pathology is characterized by the presence of neurofibrillary tangles (NFTs) within critical neurons and neuritic plaques, causing synaptic and neuronal death. NFTs are largely composed of hyperphosphorylated tau, a structural microtubule-associated protein. The plaques contain deposits of the amyloid- β protein ($A\beta$), a cleavage product of the β -amyloid precursor protein (APP). Of the two isoforms of $A\beta$ present in brain tissue and CSF, $A\beta_{42}$ aggregates more readily into plaques than $A\beta_{40}$.^{483,484} In fact, the APP gene was the first gene identified causing familial AD. Mutations in APP affect its cleavage and the generation of $A\beta$ (for a review, see Selkoe⁴⁸⁵). In addition, mutations in the presenilin genes *PS1* and *PS2* are also observed in familial AD, and patients with *PS1* mutations display increased $A\beta_{42}$ deposition as well.^{486,487} The formation of amyloid plaques has been recognized as an early, necessary step in the pathogenesis of AD.⁴⁸⁵ Many transgenic mice have been used to model the biochemical and neuropathological effects of the known genes implicated in familial AD. Animals overproducing human familial AD APP in neurons produce AD-like amyloid deposition,^{488,489} with a morphology and regional distribution similar to that of humans.⁴⁹⁰ While some of these transgenic mice strains show increased $A\beta$ levels, amyloid, and correlative memory deficits,⁴⁹¹ NFTs or severe neuronal death were not observed in any of these models.⁴⁹⁰ In addition, in some models, cognitive impairments appear prior to plaque formation.⁴⁹² Synaptic alterations in these mice have not yet been identified. It appears likely that sporadic forms of AD as well as familial AD, as modeled by familial AD mutants, originate from multiple causes. As a result, the complex phenotypic changes in many interacting cell types in critical areas of the brain must be evaluated comprehensively. This analysis should be carried out through a global analysis of the biological effector molecules (i.e., the protein expression of normal and diseased CSF and CNS tissue). This may be achieved through a systematic correlation of each gene mutation to complex changes in protein expression pattern through applications such as gene-related functional proteomics (*see* [Section 2.12.8.2.5](#)) supported by pharmacoproteomics (*see* [Section 2.12.8.2.6](#)) in transgenic animal models and human tissue with clinical aspects of the phenotype.

2.12.8.2.3 Animal models of cancer

An increasing number of studies in the analysis of signal transduction pathway of human cancers reveal that many regulatory proteins generate stimulatory and inhibitory signals at the same time. For example, in early stages of cancer, transforming growth factor β (TGF- β) can inhibit cancer growth via induction p21 (*see* [Figure 32](#)). However, in cancer cells where the Ras signal cascade is activated, TGF- β promotes invasiveness and tumor metastases.⁴⁶² Attempts to

study cancer in an in vivo model such as the human xenograft are further complicated by the fact that human tumor-derived factors may interact differently with mouse host than human host machinery. For example, cancer-associated fibroblasts now have a recognized role in the tumorigenesis of transformed epithelial cells.^{462,493} While this opens exciting new avenues for therapeutic intervention, it also points to further difficulties for the reliable use of human xenograft models in rodents. This might explain why some metastatic human tumors do not spread to other tissues in mice.⁴⁶¹ In fact, the US National Cancer Institute (NCI) has encountered serious challenges in its efforts to establish a meaningful screening system for candidate anticancer drugs. For example, the human xenograft models employed for the NCI in vivo screen show very limited predictive information for the clinical setting. When the NCI tested 12 anticancer agents used in patients against xenograft models, more than 60% of the tumors did not show a response.⁴⁶³ In other cases, tumors showed opposite behaviors in vitro and in vivo. Tumors with a deletion in the p21 gene (see [Figure 32](#)) respond to radiation therapy in vivo, whereas the same tumor is equally resistant to radiation in an in vitro clonogenic assay.⁴⁹⁴ In addition to similar findings in other models, this suggests that the efficacy of currently available chemotherapy may be linked to genetic mutations such as those associated with checkpoint or cell cycle-related genes.⁴⁹⁵ This has led many investigators to a molecular characterization of new targets and away from classical drug-screening efforts in models with poor predictability. A comprehensive summary of animal models of cancer is provided by DePinho and Jacks.⁴⁹⁶

2.12.8.2.4 Knockout and mutagenesis models, and tissue-specific inducible gene in vivo models

The examples discussed in [Sections 2.12.8.2.1 and 2.12.8.2.2](#) signify the importance of gene-targeting technologies in mouse models of human disease (see the literature for reviews^{497–500}). Recent advances in creating conditional and tissue-specific knockouts enable us to study the disease in a more relevant temporal and organ-specific context. For example, until recently it was not possible to study the *BRCA1* gene responsible for about 50% of hereditary breast cancer in animal models, since homozygous *Brca1* null mice would die early in embryogenesis. Conditional knockouts were generated with the Cre-loxP approach (for reviews, see Plück⁵⁰¹ and Stricklett *et al.*⁵⁰²) in mice expressing Cre recombinase with a mammary epithelial cell-specific promoter allowed for an analysis of a selective inactivation of the *BRCA1* gene in mammary glands.⁵⁰³ These mice develop mammary tumors, and have abnormally developed mammary glands that would form the basis of a better understanding of *BRCA1* in tumorigenesis. Similar advances have been made for CNS models using the tetracycline-regulated system. Vectors have been reengineered for CNS-specific gene expression, and led to the development of an inducible gene expression system specific to several brain regions, including the CA1 region of the hippocampus, cerebellum, and striatum.⁵⁰⁴ It is now conceivable that in the near future tedious gene knockout technology may be replaced by new tissue-specific gene-targeting systems that use rapid retroviral vectors in genetically engineered mice expressing the receptor for the retrovirus in a particular organ or tissue.⁵⁰⁵ These approaches or a combination thereof may be particularly useful in conjunction with proteomics. For example, the viral receptor responsible for organ-selective infection by the retrovirus could also provide the molecular basis for immunobased cell purification procedure or a fluorescent tag to be recognized during LCM/proteomics. Such systems allow for a rapid and reproducible expression of many single genes or a combination thereof as well as selective purification of those cells only for a detailed molecular characterization of the disease at the protein level.

2.12.8.2.5 Gene-related functional proteomics

The definition of the phenotype of an organism was recently given as ‘the integral of fulfilled gene functions and environmental effects’ wherein ‘the protein of a gene offers all the molecular structures and properties needed to fulfill the functions of a gene.’⁵⁰⁶ Considering that any phenotype may be the result of more than one gene, it is important to determine the extent by which each gene contributes to the phenotype in order to determine the function of a particular gene. New approaches in gene-related functional proteomics (reviewed by Klose⁵⁰⁶) may allow us to gain new insights into the relationship between the genotype of an organism and the phenotype of its proteins. A disease such as AD defined by its clinical symptoms may be described by the phenotype at the morphological, physiological, biochemical, and molecular levels, and enable us to subdivide a disease into mechanistic subclasses of individual steps in the pathogenesis according to the proteins affected. This could facilitate the evaluation of many putative therapeutic targets specific to different aspects/pathways/stages of the disease.

In order to evaluate the role of a single gene product/protein in a disease, we need to consider existing protein polymorphisms, such as PTM-specific isoforms. Some of the origins of these protein polymorphisms may be revealed by mouse genetics. Tracing the origin of PTM variant protein through genetic techniques in animal models can lead to the definition of the origins of a protein at the genetic level, as discussed above for body fluid analysis. Furthermore, a 2DE comparison of 10 000 protein features obtained from the brains of various genetically distant mouse strains revealed

variations in more than 1000 protein features. Identification of the subset of protein isoforms unique to a particular mouse strain correlated with genetic linkage studies, and gene mapping may reveal some of the responsible relevant genes.⁵⁰⁶ For example, the tau polymorphism results in more than 100 protein spots in a 2DE gel of human brain proteins caused by various levels of phosphorylation and multiple splice variants.⁵⁰⁷

In addition, 2DE may identify PTM variants originating from gene mutations causing amino acid substitutions in flavin adenine dinucleotide from various mutations in APP, PS1, or PS2, all causing increased cerebral production and deposition of A β peptide in amyloid plaques (reviewed by Selkoe⁵⁰⁸). A protein polymorphism characterized at the molecular and genetic level will reveal more detailed information about its origins and significance in the diseased tissue. Studies of its relevance in normal tissues and other organs not affected by the disease or its occurrence at a particular age of the animal can be compared between the animal model and that observed in the patient. Contrary to the above example, where multiple proteins result in the same phenotype (e.g., increased amyloid deposition), a single protein affects the phenotype of several other proteins simultaneously, and a similar analysis can be applied.

In conclusion, it is important to define the origins of a detected protein polymorphism at the molecular and genetic level, in particular, for any multifactorial disease. A phenotypic analysis originating at the protein level rather than the gene level seems more likely to identify the primary defective protein linked to the disease as well as other proteins affected by the defective proteins. At this stage it is appropriate to identify the gene linked directly to the defective proteins.

2.12.8.2.6 Pharmacoproteomics

The application of preclinical drug development may be summarized as one aspect of pharmacoproteomics. Within preclinical development, proteomics can be used beyond the evaluation of a model, and confirm the modes of action of candidate drugs, once the appropriate model has been selected. For the majority of cancers, diagnostic, prognostic, or therapeutic proteins identified in serum may have great potential, since blood samples are readily available for proteomic analysis. In the CNS, the CSF bathes the brain almost completely. Therefore, it seems likely to contain many important secreted proteins and neuropeptides mediating the interaction of different cell populations, and reveal insights into disease-related changes when CSF from patients with neurodegenerative disease is compared with that of normal patients. Protein expression changes within these body fluids underlying specific disease states can be compared with the animal model counterparts. The degree of similarity may guide the investigator to the most relevant model available for the *in vivo* evaluation of candidate drugs.

At this stage in development, proteomics can be applied to identify serum protein markers associated with overt toxicity and efficacy or lack thereof. Such markers may be predictive of toxicity in a particular organ or indicative of efficacious therapy. This approach offers greater sensitivity than conventional toxicology, and enables candidate drugs to be screened for toxicity at the earliest possible stage of development. Thus, pharmacoproteomics may allow us to refine a multifactorial disease into subcategories more suitable for a particular therapy or less likely to bring about undesirable side effects. These findings may be applied during clinical development to enhance the successful selection of lead candidates for clinical trials (Figure 34).

2.12.8.3 Proteomic Technology in the Molecular Characterization of Novel Therapeutic Targets: Future Perspectives

Most human disease, as defined in clinical pathology, should be regarded as multifactorial, and its complexity must be understood at the molecular level. It has been recognized that all complex diseases, such as cancer, must be

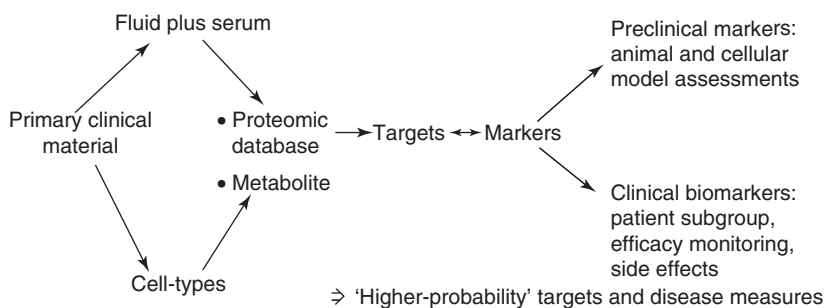

Figure 34 Emerging strategy for proteomic applications in drug discovery.

characterized in terms of the host organism.⁵⁰⁹ Disease models will continue to play a significant role in modern drug discovery. Rapid genomic and proteomic discovery technologies reveal great insight into the disease phenotype at the gene and protein level. This increasing knowledge can be applied to a more mechanistically based and target-driven discovery process. In preclinical development, more emphasis will be based on a refined molecular characterization of the target rather than classical efficacy assessments in animal models. Proteins represent the main biological effector molecules of any given cell, and appear most suitable for the target evaluation process. Classical proteomic approaches offer the unique opportunity to identify disease-specific changes in the protein expression profile in a complex system comprising up to 10 000 proteins. This strategy will generate an increasing number of disease-specific protein markers that can be utilized for the evaluation of preclinical models.

The following important questions can now be addressed:

- Does cluster analysis of multiple protein changes reveal similar changes between normal and disease in humans and in the selected model?
- Are these changes reversed in the validation studies with candidate target protein inhibitors?
- Are these changes unique to a particular step in the pathway in a cell type-specific manner indicative of selectivity/specificity?
- Do small-molecule inhibitors modulate protein expression profiles of human disease and correlate with those observed in the validation studies?
- Do clinical lead compounds affect the same cluster of proteins in the animal model as in samples obtained in clinical studies from humans?

Interfaces with other technologies, such as protein chip arrays,⁵¹⁰ will quickly expand to a more versatile platform with the ability to evaluate biological systems of great complexity at great speed. An integrated proteomics tool can assign up to several hundred disease-specific proteins in body fluids and purified authentic tissues with statistical confidence. This information becomes valuable in a comparative analysis between the preclinical model and the clinical situation, which can feed back into a refined experimental design (Figure 34). Rapid advances in genetically engineered animal models should enable researchers to tailor design models in such a way that complex gene–protein interactions can be studied in a temporal and spatial context reflective of the clinical situation and with easy access to proteomic analysis.

2.12.9 High-Throughput Screening as a Discovery Resource

2.12.9.1 Background

Over the past two decades, we have witnessed the most dramatic change in drug discovery since the launch of antibiotic research in the 1940s. HTS evolved from a part-time, low-priority activity in the late 1980s to become the core of discovery operations in most pharmaceutical companies before the turn of the century. That development not only created unprecedented opportunities in the identification of new bioactive molecules; it also established a unique working relationship and dependence among different scientific and support disciplines that had never been achieved. Discovery became an integrated multidisciplinary activity.

Prior to 1990, new drug discovery was largely a departmental effort based on the contributions of innovative chemists and biologists. Biotechnology had made its entry, but the impact on ‘small-molecule’ discovery was, at best, vague. In most major companies, considerable emphasis was still based on analog synthesis, with breakthroughs dependent on the serendipitous finding of novel activities in new structural classes devised by chemists or on the skilled observations of biologists in the recognition of unusual activities in conventional bioassays. The standard therapeutic targets, which encompassed the commercial gamut of therapeutic significance, were believed to be well represented in clearly defined pharmacological models, and presumably supported by comprehensive structure–activity relationship (SAR) bases in medicinal chemistry. The situation was stagnant and breakthroughs became less common. The number of new-development compounds in a company’s pipelines were dwindling, and costs increasing. ‘Me-too’ chemistry was also losing its appeal as markets became saturated and shares in those markets shrank to single digits. Management became concerned, and reached out for new opportunities.

Concurrent with the above were the dramatic developments in genetic engineering and molecular biology, along with the emergence of economical access to biological reagents not previously imagined. The ability to explore specific macromolecular interaction in rapid biochemical and cellular screens became an economic reality. Targets and protein ligands were soon identified (e.g., the interleukins) that promised new forms of therapy and the hope of useful

intervention with small molecules. Whole-animal or tissue models, which had been the mainstay of primary screening for decades, slowly disappeared from the discovery armamentarium, and were replaced by biochemical and cellular assays that reflected mechanistic responses rather than whole-organism behavior. Screening became specific and economical.

With new biomolecular assays available and the ability to screen larger numbers of test compounds than the conventional pharmacological models, management turned to the chemist, with the anticipation of satisfying the need for the compounds required as screening candidates. Here lay the first problem. Designing a synthesis program that would ultimately yield a new molecule that interferes at a biological target is an impossible task when there is no chemical precedence to guide the initial probes. 'Rational' drug design had been touted as the answer, but despite two notable successes (cimetidine and captopril), it was clearly limited in application by strict demands of support data at the molecular and biological levels. The real answer was to resort to the almost 'unscientific' task of screening all possible structural types in the new assay with the hope that some chemical lead (a 'hit') would surface. It was the only solution, but the corporate infrastructure was not prepared.

This 'random screening' approach was not well received by industrial scientists, who were accustomed to more aesthetic research activities. Nevertheless, it was reluctantly accepted as a part-time activity of a few biochemistry and pharmacology laboratories. With the absence of a central focus, budgets were small and progress was slow. The available instrumentation was based on a variety of liquid handlers redesigned from diagnostic applications. HTS robotics was in its infancy. Information systems were primarily developed in-house, with the exception of established core software for data (e.g., Oracle) and chemical structure management (e.g., MDLs ChEMbase); again, the market was not fully developed, and incentives were few.

In 1990, assay throughput was at best 100 compounds per week, but that level was sufficient to handle the limited compound collections available. Compound archives in most companies were large, but highly focused and low in diversity. The organic chemist reluctantly took on a new responsibility in the discovery process: manual selection of a few thousand representatives from the corporate compound archives that would reflect the structural scope available. The many gaps in diversity in these small collections were filled by the purchase of compounds from conventional chemical suppliers, occasionally by direct purchase from academic chemists worldwide, and from the new breed of 'compound brokers' that had emerged.

A reluctance to share experiences in early HTS development was also a problem. In 1992, the first conference dedicated to HTS technologies was held at SRI International (Menlo Park, CA).⁵¹¹ The purpose of that meeting was to bring together scientists involved or interested in HTS, with the intention of stimulating dialog in the implementation of this new technology, and discussing common problems in organization, technical integration, data management, and personnel issues. Finding the audience for this event was difficult at that time because screening had no internal management focus and the individuals involved were distributed throughout the departmental structure of most companies. Nevertheless, 140 participants gathered to discuss screening challenges and solutions. Open discussion periods provided enough catalysis to stimulate dialog and to make the conference a grand success. A by-product of the conference was the launch of the first publication on screening technologies, *Screening Forum*, which provided information and technology reports on HTS topics.⁵¹²

So it began. HTS, now synonymous with 'grunt work,' was a part of the weekly schedule of R&D and accepted as such. Enthusiasm was initially low but, fortunately, a new breed of scientist emerged who recognized the challenge and the potential rewards of screening and was able to convince management of the immense potential if the technology were provided sufficient opportunity and resources. Such scientists were quick to take up the challenge of penetrating interdepartmental barriers and blending complex technologies, current instrumentation, and the available data management tools into functional and productive discovery machines. While instrumentation designed for HTS had yet to be developed, innovative adaptation of available instrumentation (e.g., from Beckman, Tecan, Packard, and Wallace) initially proved satisfactory. Notable was Tomtec's 96-well plate duplicator (Quadra) as an important asset at this early stage. The drive and foresight of these pioneers was the catalyst necessary to demonstrate the productivity of HTS and its importance as a discovery process.

As with any new technology, the standardization of tools became a critical matter. Fortunately, the 96-well microplate had already been proven in diagnostic applications, and quickly became the standard screening vessel. Its origin can be traced to 1960⁵¹²; however, it was not until the mid-1970s, when Ken Walls at the US Centers for Disease Control and Prevention started using it for enzyme-linked immunosorbent assay testing, that its benefit in automated assays became apparent. Robotic systems were developed to accommodate the microplate, and integrated test systems established. It was a natural transition to apply these systems to the demands of the new and now lucrative market of screening.

Targets and assays were primarily developed in-house, since they represented the company's proprietary interests and technologies; however, novel and more sensitive detection systems evolved externally that provided useful tools in

optimal protocol development. New microplate designs^{513,514,515,515a,515b} were similarly created in the support industries that saved time and reagents in assay development and operation. Packaged data management systems evolved from companies such as Molecular Design (now MDL Information Systems) and Tripos, which formed the core of chemical structure management. The SD file became the standard file format for structure display and storage. Compound libraries could be created by the purchase of small samples from a growing list of brokers who gleaned their collections from academic laboratories and 'chemical factories' throughout the world. However, the cost of establishing the all-important structurally diverse compound library was formidable and a serious bottleneck for start-up companies.

In 1993, MicroSource Discovery Systems⁵¹² pioneered the provision of test compounds in microplate format. This approach provided efficiency, economy, and diversity in a single product with full data support. It was based on the realization that even with a modest level of assay miniaturization, a few milligrams of a test compound were sufficient to support years of screening. Purchases of the standard 50 mg sample were unnecessary, and the cost of acquisition of large libraries was cut by as much as 90%. Diversity was drawn from world leaders in chemical synthesis, and samples were provided in a format that avoided handling, documentation, and storage. Today, MicroSource Discovery Systems has evolved into a leading provider of natural products and drug standards in microplate formats.

By 1994, HTS had become an integral part of the drug discovery process. Large companies reorganized their internal structure to accommodate the multidisciplinary character of this new technology. The hierarchical distinction between HTS and conventional 'research' was resolved by the recognition of the distinct differences in the tools and goals of these activities and their equivalent and complementary contributions to the development of new drugs. Screening operations became centralized and new positions created. Topics such as assay miniaturization, integrated automation, compound acquisition, and data management became key activities in discovery operations. New companies sprang up that were based solely on new assay targets and the ability to screen efficiently. A myriad of support industries were also created to provide tools and resources that facilitated screening and improved return. Test compounds, automation systems, and even cloned target receptors became available from outsource groups.

In 1994, the second forum on HTS technologies was held in Princeton, NJ. It was a sellout in attendance, with almost 400 participants squeezed into a small conference space. The meeting was a tremendous success, and launched HTS as a formidable tool in discovery. That conference also provided the seed for the beginning of the Society for Biomolecular Screening, which today is the foremost source of information on HTS technologies.⁵¹⁷

2.12.9.2 Where We Are

HTS, as applied in the pharmaceutical industry today, refers to the integrated technologies that permit the rapid evaluation of millions of compounds annually in scores of bioassays in search for new therapeutic agents. There are three objectives: *de novo* discovery, hit development, and the preliminary assessment of the metabolism and toxicity of lead candidates. The first two are widely applied and complementary; the last is new to HTS, but is rapidly becoming an important facet of drug development.

De novo discovery addresses the search for compounds that interact with a new biochemical or cellular target for which there is no precedence in chemical structure. The identification of both ligands and antagonists for most orphan receptors is an excellent example of such applications. The discovery of drugs against diseases that cannot be satisfactorily treated with existing therapies or for which no treatment is available is another. *De novo* HTS requires the use of large compound collections with as broad a structural diversity as possible and bioassays that accentuate the specific character of each target. The goal is to find one or more 'hits' that can provide a chemical focus for further screening. Such hits need not be at the activity level anticipated for a development candidate; structural information about a weak inhibitor is much better than no information at all. *De novo* HTS generally addresses a broad spectrum of targets.

Unlike *de novo* HTS, hit development begins with some level of chemical intuition. Such information may have been gleaned from *de novo* programs (see above), from historical data on the character of ligands or antagonists, or from computational analysis of the structure of the target receptor. This is the area where the use of high-throughput organic synthesis (HTOS) has provided the greatest benefit and has resulted in important advances in optimization of a lead and dramatic reduction in the time required for lead development. These benefits are discussed in greater detail below. Bioassays employed in developmental HTS focus on the overall activity profile anticipated for the test substance.

Preliminary assessment of the metabolism and toxicity of new drug candidates is a critical part of drug development. The requirements for such assessments are heavily regulated and, with the companion characteristics of absorption and distribution, constitute key elements in the success of any new drug application and its subsequent introduction. These processes are critically dependent on *in vivo* studies that are costly and time-consuming. Failure of a compound in any of these aspects usually results in its removal from development; the investment made to that point is essentially

lost. Recent developments in the miniaturization of metabolic and toxicological assessment procedures permit high-throughput assessment of lead candidates at a preselection stage. Such *in vitro* information has yet to be accepted by regulatory bodies; however, it does provide an important preview of the performance of a lead. The use of such data in the selection of candidates for development can significantly improve compound survival rates and shorten development time.

The primary components of any HTS program can be roughly divided into three areas: test substance supply, bioassay development and implementation, and informatics (data management). How these are organized is another dimension that segregates throughput – low from high, high from ultrahigh, and so on. The result is the same: discovery. Instrumentation and systems integration have become integral parts of all aspects of HTS, and need not be addressed separately.

2.12.9.3 Test Substance Supply

A structurally diverse test substance supply is the key to discovery. It is the critical resource (i.e., the sole factor that determines the success level for every assay). Careful attention to the quality of the test substance resource is an essential aspect of HTS management. Essentially, a well-managed, structurally diverse test substance supply holds a company's equity in new drug discovery. This is true for any screening program, low and high capacity, in both small and large corporations.

A large variety of sources for test substances are available for HTS programs. Accessing any of these in a naïve 'numbers-only' approach can be disastrous. Heavy dependence on commercially available combinatorial libraries is not advisable. Structural diversity alone dictates the number of test substances required. A small but carefully selected collection of 10 000 compounds may be a much better resource for discovery than a mass-produced library with millions of components. The design and maintenance of an appropriate test substance resource is an important facet of corporate survival.

2.12.9.3.1 Compound library development

The demand for large and complex chemical libraries as test resources in HTS programs continues to grow to meet the dramatic increase in the throughput potential of today's HTS systems. However, it is noteworthy that a small, low-capacity screen can still yield important advances. This principle is manifested by the early screening successes in the potent PAF inhibitor WEB-2086 and the HIV reverse transcriptase inhibitor nevirapine. Both of these were discovered in libraries of less than 10 000 compounds without any indication of structural guides, certainly not 'pharmacophores.'

Despite the above comments, numbers are important if the compounds selected for inclusion in the corporate HTS pool have reasonable structural diversity; essentially, the higher the number of diverse test compounds, the better the chances of success. Today's million-compound libraries have simply improved the odds.

Compound collections that are truly diverse in skeletal and functional array are especially important in achieving a meaningful probe into the unknown three-dimensional space of a new receptor or enzyme. The classical approach in *de novo* discovery has been to draw on the structural riches of a well-designed and stocked compound collection that represents not only the scope of in-house synthesis but also the diversity available from external suppliers: direct chemical sources, brokers, and microplated compound libraries. The structural richness of the numerous pure natural products and their derivatives that are commercially available^{512,521} must also be included since these displays cannot be mimicked by current HTOS.

Claims that high-throughput solid phase and solution phase chemical synthesis is a reliable source for the generation of limitless diversity are unfounded. This position is softened when such libraries are multitemplate based and constitute millions of representatives. Companies such as ArQule and Pharmacopeia offer such access, but cost again becomes significant. The unquestioned strengths of these sources are in the rapid development of series with some chemical insight. This aspect is addressed below.

Compound management and acquisition has become an important facet of HTS structure and function. It requires a continuous awareness of what is in hand, what has been depleted, and what is necessary to enhance the chemical and topological character of the corporate collection. The responsibility lies not only in filling gaps in the functional parameters and their display within the collection, but also in avoiding those substances that are inherently reactive with biological systems. Certain groups that are chemically reactive can give meaningless false positives that waste time and money and interrupt the discovery process. Acid chlorides, anhydrides, active esters, and the like are among these. Many halogenated compounds also fit into the category of nonspecific alkylating agents – α -haloketones, halomethyl aromatics, 2-halopyridines, and other reactive heterocycles are common constituents in commercial collections. There are other groups that are cytotoxic and unwelcome components; most organometallics and nitroso, alkyl nitro, and

nitroso groups, are among these. Hydrazines, hydrazides, and similar structures should not be removed entirely, since these structural features have found their way into several important drugs; however, their ease of preparation makes them a more than necessary component in available collections. The same applies to aryl nitro representatives. Instability is another concern: *t*-butyl esters, acetals, aminals, and enol ethers are some examples. Other groups that have been the subject of extensive analog development (e.g., adamantane and per-haloalkanes) should also be carefully filtered. Redundancy is another problem. Analog representation is necessary to efficiently represent a new compound class; however, excessive representation can become an unnecessary expense and distraction.

It is nevertheless important to be sensitive to the rigors of implementing some of these rules. Some published guidelines recommend the removal of compounds that are potential substrates for Michael addition (e.g., α,β -unsaturated ketones). Such restriction is important if the group is especially activated, but that is frequently not the case – progesterone and a myriad of similar molecules are potential Michael addition candidates. Other restrictions, such as molecular size, the number of rotatable bonds, and chemical functional density, are fine on paper but destructive if applied generically in library design. The end product can lead to a library that is pretty in presentation but sterile in discovery! These matters become serious concerns when the tailoring of the corporate compound collection is assigned to individuals insensitive to the potential of discovery in complex systems that violate one or more of the above guidelines. There is no substitute (yet) for the practiced eye of a medicinal chemist.

Software packages are available^{518,518a-c} that claim to provide assessments of diversity and recommendations for its enhancement. Very large libraries must depend on these or other computational techniques in such assessments, but caution must be exercised as to the extent that such packages are used. The utility of many of these programs is strained when the assessment attempts to include complex molecular arrangements. Diversity assessment is especially important in small collections (about 10 000 compounds); however, it is best in these instances to resort to manual review.

2.12.9.3.2 High-throughput organic synthesis applications

HTOS (also termed combinatorial chemistry) has had a dramatic impact on both the organization and productivity of industrial medicinal chemistry. It was first applied in new drug discovery in the late 1980s in the form of combinatorial peptide coupling. Solid phase synthesis of peptides, which had been developed by Merrifield (Rockefeller University) 20 years earlier, was used to create large polypeptides by affixing one end to a solid support (e.g., a resin bead) and adding the individual units sequentially by standard peptide-coupling techniques. Subsequent chemical cleavage from the resin yielded the target polypeptide. Application of these techniques to the simultaneous synthesis of families of related peptides was pioneered by Geysen (Glaxo) in the mid-1980s. The concept was further applied to new drug discovery in the synthesis of large libraries (20 000 to more than 1 million) of peptides fixed to beads or silicon chips and the assessment of the binding of these fixed libraries to labeled soluble targets (Selectide, Affymax, and others). Research managers were attracted to these systems by the remarkable numbers of test substances and the simplicity of the detection systems. Unfortunately, the impact of fixed supports in the binding of biomolecules and the limitations of peptides as structural leads in development were underrated. Soluble peptide libraries (e.g., from Houghton Pharmaceuticals) were similarly offered as discovery tools, but again applications were limited, and interest and corporate support waned.

Despite the shortcomings of large peptide libraries discussed above in *de novo* drug discovery, the use of peptide HTOS technologies in the identification of their direct roles in receptor responses *per se* or as surrogates for ligand definition in orphan receptor research brings forth a new and important role for these HTS approaches (see below).

The slump in the popularity of peptide-based HTOS in the early 1990s quickly turned around as the concept was applied to the synthesis of nonpeptide libraries using diverse synthetic techniques. Pavia (then at Sphinx) was an important pioneer in the development of these technologies and their implementation in microplate format. His innovation and that of his associates facilitated the introduction and adaptation of HTOS into HTS applications and encouraged the automation/robotics industries to develop instrumentation that would meet the needs of industrial chemistry. It revived HTOS as a discovery technology with little apparent interruption, but once more the enthusiasm was unchecked, and promises of satisfying the needs of discovery programs in structural diversity became unrealistic (see Figure 54).

Early HTOS also launched support industries that could take a chemical lead or hunch and expand it into large libraries that encompass relevant structural diversity. Companies such as ArQule and Pharmacopeia offered efficient application of HTOS in the exploitation of solution and solid phase syntheses in the development of libraries that addressed specific client targets. These two successful corporations have, in their years of operation, amassed libraries including millions of components. Notwithstanding the above-mentioned limitations of HTOS in the generation of structural diversity, these massive libraries can offer a first-pass opportunity in discovery simply on the basis of the huge library populations and the diversity of the templates.

Reactions performed on solid supports have a number of process advantages over classical solution methods. The ability to drive reactions to completion with large excesses of reagents is one such advantage; the ease with which the product is cleaned at each step is another. The reaction kinetics is often found to be different between solid phase and solution syntheses, and is often favorable to the solid phase approach. But there are shortcomings. Many reactions are impossible or at least exceedingly difficult to perform on solid phase due to the sensitivity of the linker or the resin itself. The inherent need to base such syntheses on common platforms also produces redundancy in the library generated. The common linkage site on each molecule further dampens structural diversity. Multiple platforms and nonfunctional linkage residues offer partial solutions to these problems. Nevertheless, today's HTOS compound libraries sorely need to be supplemented by selected products of classical synthesis and pure natural products to attain a meaningful three-dimensional, functional display for a *de novo* discovery program. This aspect is best illustrated by assessing how a hypothetical HTOS program would be designed if the goal were to rediscover (from scratch) representative nonplanar drugs, such as glucocorticoids, lipid-lowering agents (e.g., mevalonin), and taxol. Would today's solid phase or even solution phase synthesis collections achieve such a goal?

There are new directives in process that will provide some solutions to these problems. For example, the introduction of naturally derived, three-dimensional platforms can dramatically broaden the scope of HTOS. Variables will increase dramatically, and thereby create another dimension in numbers as libraries of millions of compounds become commonplace. MicroBotanica⁵¹⁵ has identified proprietary natural templates as the core of unique libraries and cheminformatics tools. These templates offer three-dimensional access not available to conventional laboratory-based syntheses. ArQule, a leader in the progressive development of diverse and directed HTOS libraries, has made significant advances in improving the efficiency of HTOS in both solid and solution phase modes.^{519,519a}

Simultaneously, HTOS was applied to bringing a HTS hit or otherwise-identified bioactive entity to lead status and its rapid development into a clinical candidate. In most cases, HTOS has replaced the drudgery of 'one-at-a-time' analog synthesis in the generation of SAR data and dramatically reduced development time. Essentially, all possible analogs are prepared rather than a small population selected by medicinal chemistry on the basis of immediate relevance and economics. HTOS libraries provide the full SAR analysis, with little reference to what would formerly be perceived as redundant. Such a 'bulk' approach leads to a more definitive analysis of SAR and a better selection of candidates. This application is clearly the most important contribution that high-throughput technologies have made to medicinal chemistry and perhaps to drug discovery in general. Its impact is best appreciated in consideration of development time and on-market patent life (Figure 35). Today, an annual market return of US \$1 billion is not unusual for a new therapeutic entity. That translates into US \$83 million for every month that the new drug is on the market and under patent protection. The development time for a new drug can easily consume half of its patent life. HTOS can reduce the development time and dramatically increase market returns.

Figure 35 illustrates the time-line of drug development from discovery to introduction. It does not reflect the additional savings that HTOS provides in hit-to-lead generation. That aspect can provide an additional year of benefit in earlier recognition of the lead. While that generally does not impact patent life (a subsequent event), it does give the advantage of 'first on the market' in a highly competitive field. The illustration (Figure 35) also does not take into consideration the emerging benefits of high-throughput absorption, distribution, metabolism, and excretion (ADME) and toxicity profiling, discussed below.

Conventional development

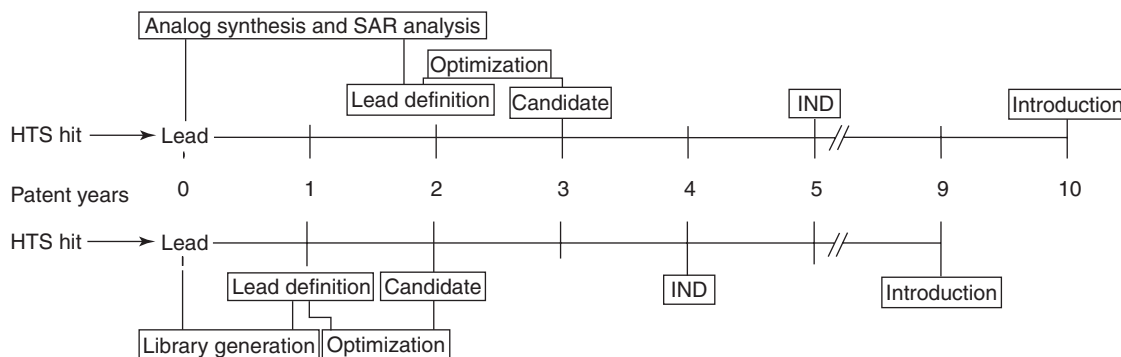

Figure 35 Impact of HTOS on new drug development (IND, investigational new drug).

2.12.9.3.3 Natural products as a discovery resource

The unique structural diversity inherent in natural products continues to be an important HTS resource. As with HTOS and other technologies, trends have had a disturbing influence on the adoption of natural products as a primary discovery resource (Figure 36). Notable is the stability of microbials as a discovery resource, but plants have had a sine wave history, and continue to be susceptible to technological pressures and prejudices.

Microbials are by far the most widely used natural resource in industrial screening programs. They have been the mainstay in HTS applications in several major companies, with little fluctuation in their use over time. The reason is threefold: economics, reproducibility, and a continued history of new biomolecular discovery. Once a company has established and staffed a microbiological facility on-site, costs are manageable and predictable.

The use of microorganisms over the past six decades in antimicrobial research and development has established a sound technological basis for the culture, preservation, and manipulation of bacteria and fungi. Clear projections of scope and cost can be made for their use at the semi-microscale in discovery and the macroscale in commercial processes. Microbials are accountable for most of the antibiotics in therapeutic use today, and, in addition, have served as biochemical factories for chemical modifications that cannot be reasonably achieved otherwise. In the past two decades, we have seen the successful use of microbials in broader pharmacological screening with remarkable success – ivermectin, FK-506, rapamycin, and mevalonin, to name only a few. They can also provide unique chemical substrates for further manipulation in the chemist's laboratory, and in this application constitute the basis for important semisynthetic variations in antibiotics and other products. The shortcomings of microbials are (1) the limited biochemical scope compared with plant resources, and (2) the critical need for dereplication at an early stage in screening. Novelty in new structural types is less common in microbial screening.

Marine organisms offer a remarkable variety of chemical variation. Many such natural products are not available from other natural sources, and certainly not through laboratory synthesis. Unfortunately, access to this resource is very expensive, limited to initial structural leads, and rarely amenable to commercial development. Even recollection for research purposes is limited by cost and environmental concerns.

Plants, although entrenched in the early history of drug development, have not been used as a discovery resource to the extent that microbials have in recent times. In the 1950s and early 1960s there was a flurry of tissue- and animal-based screening based on plant extracts (Figure 36). Important discoveries in the alkaloid classes (e.g., reserpine) created an inordinate level of optimism, and many companies established extensive plant-based screening programs in *in vivo* systems. Unfortunately, the narrow focus on alkaloids in both collection (selected plant families) and chemistry (nitrogen-containing constituents) led to a great deal of redundancy, so that by the mid-1960s many of these expensive industrial research programs were closed as discovery attended to the more lucrative area of analog synthesis.

The revival in natural plant products' research in the 1970s, on the heels of the then-fashionable, marine-based research, was cut short by the introduction of rational drug design through computational modeling. The high level of hype associated with this area was short-lived (Figure 36), but soon replaced by a similar optimism with peptide-based combinatorial chemistry (see above). Plant natural products as a classical (and expensive) program again lost favor.

This persistent quick-change attitude in research management reflected its frustration with conventional discovery resources, its determination to be at the cutting edge of new technologies and among the first to harvest the benefits. Happily, stability is returning, as HTOS finds its place in drug development, and the significance of assuring structural diversity in test substance supply is addressed in practical terms. Plant-derived natural products are beginning to resurface and take their rational place as a source of immense structural diversity.

The lack of adoption of plant sources as a test resource is somewhat paradoxical. The plant genome is much larger than other natural sources (bacteria, 1000 genes; fungi, 10 000 genes; plants, more than 100 000 genes), and therein

Figure 36 The rise and fall of technological hype in the use of plant natural products and sequential influence of early attempts in rational drug design (RDD), peptide combinatorial chemistry (PCC), and HTOS in HTS programs.

offers a broader biochemical network for the generation of unique chemical structures. Unfortunately, until recently, the technologies and protocols of collection, processing, recollection, and scale-up had changed little in 50 years. Each sample collected individually demanded shipping, storage, and handling expenses; the attention of a chemist and considerable laboratory-based preparation time prior to assay were also required. Few attempts had been made to adapt these classical collection and preparative techniques to modern screening programs and budgets. As a result, plant-based research commanded a much higher cost per test sample than microbials, and it is this cost, and the requirement for a dedicated research team, that turned program directors away from the use of plants as a significant HTS resource.

Companies that have continued to use plants over the past two decades have done so at low throughput, with the evaluation of only a few hundred species per year. In 1993, MicroBotanica addressed the economics and efficiency of plant collection, with the goal of making this unique source available to screening programs at a throughput level that permits broad evaluation in modern HTS systems and a cost that is compatible with HTS budgets. It established a joint program with three groups in Peru: Perubotanica srl, Universidad Nacional de la Amazonia Peruana, and Conservacion de la Naturaleza Amazonica del Peru. The goal was biodiversity, and the collection, classification, documentation, and development of the plant resources in the Amazon Basin with strict compliance with the terms of the Convention on Biological Diversity.^{520,521}

The technical approach is based on the position that the initial collection of test materials for HTS should be only what is required for the first pass and the initial confirmation of a hit (i.e., about 1 mg of a crude extract). Larger scale collection and extraction must be implemented only on the identification of hits. Such a 'microcollection' program dramatically reduced costs and increased the number of plants sampled. It also permitted extraction in the field, and thereby eliminated on-site specimen processing as well as laboratory handling time and expenses. This consortium can also respond immediately to a hit with sufficient material for confirmation and secondary profiling, and simultaneously assure recollection and the receipt of larger scale extract preparation in a timely manner – usually 2–3 weeks.

Another issue of special concern in the implementation of a plant-based natural product program is the sensitivity of many HTS assays to interference by polyphenols and tannins through nonspecific binding. Such substances are common constituents in plants, and their removal prior to bioassay is frequently required. This issue has also been addressed by MicroBotanica through the development and application of proprietary liquid–liquid partitioning amenable to automation or the more conventional use of polyamide binding. Today, MicroBotanica boasts ready access to samples of more than 30 000 extracts from approximately 13 000 plant specimens and the ability to follow through from recollection to isolation on any hit. MicroBotanica's participation in the Amazon consortium also makes it a unique source for the collection of and research on any plant endogenous to the Amazon Basin.⁵¹²

2.12.9.3.4 Structure-based design

The use of the structure of the target as a basis for computational design is not a new concept. Two decades ago it ran rampant through the pharmaceutical industry (Figure 36). Research management, heady with the developments in molecular modeling software and x-ray crystallography that were current, was impressed with the purported ability to design new drugs on the basis of target structure alone. Misinformation, misinterpretation, and bad timing took its toll. Structural analyses were weak and presumptive; computational power was overestimated, and projections totally unrealistic. Fortunately, only a few companies made major commitments in this area, but those that did lost a great deal in program deletions, time, and credibility. Today, the *de novo* design of an active molecule for a new biomolecular target is still fanciful. Finding structural precedence in small-molecule interaction is the key. Enter HTS and the revival of structure-based drug design.

Today, structure-based drug design (SBDD) encompasses the integrated use of computational design software, HTOS, and HTS. In principle, SBDD is based on the sequence illustrated in Figure 37.

Figure 37 (a) Structure-based drug design. (b) Definition of target dimensions. (c, d) Computational analysis of structural features for small-molecule interaction. (c, d) HTOS generation of relevant compound libraries and identification of first hit through HTS. (e) Optimization of the hit to one or more leads.

Information based on x-ray crystallographic data, nuclear magnetic resonance, and other analytical techniques facilitates the definition of the molecular dimensions and functionality of the target and its active site (Figure 37a). Computational techniques are applied to the identification of the optimal small-molecule characteristics for interaction at the target site. This information is then used to screen real or virtual libraries for compounds suitable as first probes. A test library is then generated, acquired, or synthesized through HTOS, and screened in the relevant assay(s). If hits are not realized, the process is repeated by retooling the target definition or anticipated small-molecule characteristics. Once significant data are obtained (Figure 37c), larger libraries are prepared, and the molecule is optimized to lead status. Conventional medicinal chemistry usually takes over at this point, to provide the optimum candidate(s) for development. The system works. Of course, it still has both the requirement of a considerable knowledge base for the target and the risk associated with projections of biomolecular interaction to therapeutic significance. Nevertheless, it is reassuring to know that such a simple but elegant approach can be successfully implemented, provided all the tools are present and realistically evaluated.

SBDD is also applied to assess the significance of the myriad of therapeutic targets anticipated from comparative analyses in functional genomics (*see* Section 2.12.9.4.2). While estimates of new and therapeutically relevant receptors are in the hundreds, finding those in the sea of information is a Herculean task. The relevance of these targets, the identification of natural and artificial ligands, and the discovery of small molecules that can modulate their effects are goals in the practical application of this immense information base. Information gleaned from these studies will find application in drug discovery, diagnostics, toxicology, and other areas yet to be fathomed.

A recent and dramatic example of the efficient application of SBDD was in the identification of inhibitors of the nuclear factor of activated T cells (NFAT) in the search for new modulators of the immune response that do not have the limitations of cyclosporine or FK-506. Hogan and collaborators⁵²² applied HTOS in the form of peptide libraries of more than a billion units to identify optimal amino acid composition at seven sites of a hexadecapeptide sequence associated with calcineurin binding. This is an area that is by definition peptide in content and well suited to peptide HTOS. Transfer of the information gleaned into a useful immune-suppressive drug is yet to be achieved, but the ground is laid and open to innovation.

2.12.9.4 Bioassay Development and Implementation

The identification of a cellular or molecular target for drug discovery and the development and validation of a relevant bioassay are critical early milestones in a HTS program. There must be a persuasive reason to believe that the cellular or molecular (enzyme, receptor, protein–protein, or protein–DNA interaction) target is involved in a pivotal step in the targeted disease process. That link – the molecular target to the disease process – requires exhaustive analysis. Today, with the cost of screening at US \$5–10 per well (compound and reagents) at the 96-well plate level, the assessment of a 50 000-member library will cost as much as US \$500 000 before personnel costs and overhead are considered. Many of us can recount pre-HTS times when certain animal or biochemical assays formed the core of a discovery program only to prove of little or no value in the identification of a clinically active agent. Relevance must be carefully balanced against cost (Figure 38).

Once a target has been selected, the next step is to develop a bioassay that is appropriate and compliant with the parameters applied in the corporate HTS system. Typically, such assays have to be robust and avoid the use of temperamental or unstable reagents. Each assay must be amenable to miniaturization to at least the 96-well microplate level, but preferably beyond. Miniaturization to 384 wells is commonplace, but further reduction is encouraged, with

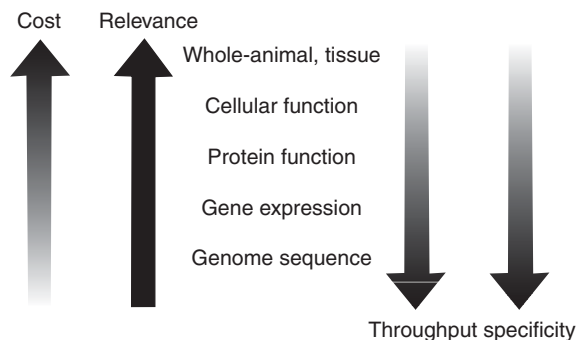

Figure 38 Relationship of bioassay targets to relevance and HTS compatibility.

the potential of lower cost and simultaneous higher throughput and data analysis. Cost savings are in attention time, and the amount of compound and reagents used. By the simple shift from 96 to 384 wells the practical reaction volume and, correspondingly, the required reagents and compound are reduced by 75%. The latter is of special significance since many compounds, especially pure natural products, are in limited supply, and the conservation of a supply is often critical. Shifts to 1536 plates or high-density formats have corresponding benefits, although sample handling becomes a problem. Moreover, some detection systems are unreliable beyond 384.

Assays and even therapeutic targets have a defined lifetime. Frequently, even the most comprehensive and structurally diverse compound collection will not yield a hit in some assays. Such events generally are attributed to the inability of a small molecule to interfere in a complex biological process. Protein–protein interactions are often difficult to disrupt or block. At some point, usually the exhaustion of the current compound library, the decision is made to remove the assay for re-evaluation. Occasionally this may result in a minor variation in the reagents or protocol, or may lead to the elimination of the assay or even the base target. The number of compounds screened through any bioassay may range from 10 000 to millions, depending on the culture of the organization, the extent and diversity of the chemical resources, and a judgment as to the importance of the target.

Assays are generally established to permit a return of 0.05% or less hits. High-density systems with large numbers and low diversity in the test substances used may be a log or two lower. The frequency with which assays are removed from a HTS program on the basis of ‘no yield’ can be reduced by critical analysis of the assay and the dose level prior to introduction into the HTS program. This is especially true in *de novo* applications where there is no drug reference to guide appropriate test concentrations and time. Nevertheless, the effects of a broad group of bioactive compounds on the assay response can be a useful directive. Fortunately, compound collections such as GenPlus (960 bioactive compounds) and NatProd (720 natural products) are available from MicroSource Discovery Systems⁵¹² in microplate format. Such collections can be valuable tools in defining the sensitivity and specificity of any new assay. These are preplated at standard concentrations (mg mL^{-1} or 10 mM dimethyl sulfoxide), and can be easily blended into an assay validation protocol.

The living cell is the preferred format in discovery programs, offering a test response at the ‘organism’ level while still allowing automation and high throughput. Cells can be engineered to house complex receptor systems tailored to represent a myriad of therapeutic targets. Detection modes are colorimetric, fluorescent, chemiluminescent, and radioisotopic systems. While regulatory and disposal problems continue to encourage the displacement of radioisotopes by other detection modes, innovations in simple and sensitive homogeneous systems, such as the SPA developments by Amersham,⁵²³ maintain a stable market.

The validation of a lead prior to further development involves the testing of the lead for efficacy in an animal model. The biological connection of a target to a disease, and the utility of such a target in drug discovery and development, is speculative without whole-animal data. Once a lead has been identified, it is essential to establish a ‘proof of concept’ through *in vivo* evaluation. The selection of such a model is a process that should be concurrent with the development of the HTS assay. Such models may already be established, but it is likely that, with the emergence of novel genomics-based targets, they will require creative pharmacology and critical validation before confidence is established.

Activity in a whole animal is still not definitive for activity in humans, but the absence of activity draws attention to the need to reconsider the utility of the target. It is best to have such revelations early in a discovery program. The time-line and milestones applied in the collaboration of Axys and Merck in the identification and development of a small-molecule inhibitor of cathepsin K as a therapeutic modality in osteoporosis is a good illustration of this approach.^{524,524a}

All of these technologies are not only complementary but feed back on one another with dramatic amplification of discovery potential. This can be of significant benefit as new activities in new indications are uncovered; however, there is a serious danger of misdirection. Incorrect information derived from a missed false-positive, incorrect analysis of an assay output or poor assay design can expand into unproductive and expensive voids. Any new development in HTS in design, discovery, or data analysis must be carefully assessed before it becomes an integral part of the process.

2.12.9.4.1 Fluorescence detection systems

Fluorescence technologies are dominant in HTS. Numerous well-characterized fluorescence tags suitable for differentially labeling specific cell components and protein probes are now commercially available.⁵²⁵ Many quantitative techniques have been developed to harness the unique properties of fluorescence; several of these are represented in the following chapters in this book.

An excellent example of such technology is provided in [Section 2.12.10](#), discussing the development and advantages of functional screening based on high-resolution fluorescence imaging of multiple targets in intact cells. [Section 2.12.15](#)

discusses the application of multiple fluorescence read-out methods in the development of single-molecule detection technologies that enable a variety of parameters to be evaluated in a single sample.

Fluorescence resonance energy transfer (FRET) is an ultrahigh-throughput technology developed by Aurora, one of the most progressive biotechnology companies in the HTS arena. FRET uses a coumarin-linked phospholipid asymmetrically bound to the plasma membrane as the donor and negatively charged oxonol acceptors that partition across the plasma membrane as a function of the transmembrane electric field. In [Section 2.12.16](#), the use of FRET in cell-based and reporter–receptor binding, protein–protein interactions, and other applications is discussed. Aurora's platform also includes ultrahigh-throughput screening technologies and discovery modules, which allows for computer-directed delivery and bioassay of more than 100 000 selected compounds per day in 96- or 384-well plates.

Homogeneous time-resolved fluorescence, as well as its chemical basis and application in a broad scope of cellular and biomolecular assays, is described in [Section 2.12.17](#).

2.12.9.4.2 Comparative functional genomics

The identification of genome-based targets and representative bioassays is a more recent facet that already has spawned opportunities that were unimagined a decade ago. The use of human functional genomic data as a basis for new drug discovery is taking a commanding lead in industrial HTS programs. The technologies used in this area are not new, but the huge amount of data that has become available is, and their comparative analysis in normal and disease states constitutes one of the most rapidly growing and promising areas in the identification of new therapeutic targets.

Comparative functional genomics focuses on the identification of human genes associated with disease response in the whole organism and their role in the proliferation or suppression of the disease state. Such analysis has yielded hundreds of new targets that have no precedence in therapy or medicinal chemistry; many more are anticipated. The definition of the significance of these 'orphan' receptors relies on classical strategies of genetic engineering and disease gene modeling. These orphan receptors require validation before becoming an integral part of a discovery program; the identification of associated ligands is a first step.

Needless to say, these technologies have produced considerable hype in the projection of their impact on health management. Such hype is seen both in the marketplace and in industrial research planning. Fortunately, we are probably at the peak of the hype curve, and look forward to tangible contributions in new target modeling and ultimately in therapeutic benefit.

Proteomics, an essential supportive technology in functional genomic applications, addresses the characterization of the physicochemical properties of a protein expressed by a newly discovered disease-relevant gene and its production in large amounts through transfected cell cultures. Such probes have also been conducted in the HTS mode. These proteins, if beneficial, may lead to therapeutic agents in their own right, but for our purpose they can serve as tools for de novo assay development. Antibodies to such proteins provide insight into their function and location, and may also serve in therapy or assay development as specific antagonists.

2.12.9.4.3 Absorption, distribution, metabolism, and excretion, and toxicological profiling

ADME and toxicological studies are critical parts of any drug development program, and essential for compliance with regulatory guidelines. Historically they were conducted only on drug candidates that had survived the rigors of chemical optimization, process development, and pharmacological profiling. The reason for this segregation was simply that such studies invariably involved whole-animal models and therefore were time-consuming and expensive. It was not economically sound to expend such resources on candidates that were not firmly committed to development by other selection criteria. Unfortunately, when an ADME problem was finally detected, it was at late investigational new drug preparation or even in the clinic. Such events created serious disruption of the development process, and often resulted in closure of the project and a lost opportunity.

The parallel development of several candidates from the same compound class has been a standard procedure to avoid project termination in the event of the emergence of an untoward effect. The considerable cost imparted by this approach was justified as being necessary for project survival.

Today, the situation is changing rapidly and dramatically. ADME and toxicology technologies have evolved to permit the use of rapid and less expensive methods that have made the early assessment of drug candidates very attractive to the pharmaceutical industry. Major companies are shifting ADME assessment to become an integral part of the candidate selection process. Costs are still substantial but justified.

The goal is to move the assessment of drug metabolism and toxicity up in the discovery/development process ([Figure 39](#)). Metabolic profiles of a large group of compounds that are considered for development can provide important information at the preselection level, save considerable time, and significantly reduce the cost of new drug

Figure 39 Current shift in the emphasis of ADME assessment in the drug development process.

development. Structural characteristics of test compounds that impart resistance to rapid metabolism are often independent of the biotarget pharmacophore and yield a different SAR analysis. Early ADME assessment can uncover such compounds before they are discarded on the basis of activity alone.

The principal source of drug metabolism is the cytochrome P-450 enzymes, which constitute a superfamily of monooxygenases (requiring NADPH). They are found primarily in the endoplasmic reticulum of the liver, although a prominent member is also found in the gut. In vitro ADME assays can be based on human liver microsomes or hepatocytes, which incorporate the full complement of cytochrome P-450 and other microsomal and cytosolic enzymes, or individual enzymes. Most cytochrome P-450 enzymes have been identified, and many are available through recombinant techniques; their monoclonal antibodies are also commercially available.⁵²⁵ Information can be obtained through in vitro systems about the patterns of metabolism, which cytochrome P-450 enzymes are involved, metabolite hepatotoxicity, and drug–drug interactions. Such analyses are amenable to HTS. Metabolite isolation and identification is a HTS challenge that can build on the technology already in place in HTOS and combinatorial technologies.

HTS applications in ADME and toxicology are discussed in [Section 2.12.19](#). The ease of isolation of human hepatocytes and their importance in metabolic and toxicological studies are underscored. These hepatocytes are stable and can be cryopreserved, thereby providing a regular supply of hepatocytes for screening without dependence on frequent access to fresh human liver.

Gentest⁵²⁸ has described a microplate-based fluorimetric approach to rapid screening of test compounds for their susceptibility to and effects on cytochrome P-450 enzymes. The technology is efficient (100 compounds in 4 h) but limited in scope.

If a drug has an inhibitory effect on one enzyme and enhances the effect of another, its blood level in diverse ethnic populations can be dramatically different and create risks of ineffective dose or toxicity. It is likely that more stringent assessment requirements will be forthcoming for drugs that demonstrate inhibitory or enhancing activities on metabolic enzymes. HTS again can provide the tools.

2.12.9.5 Informatics

The analysis and efficient use of the massive amount of data generated in HTS and related areas has created the new discipline of bioinformatics, which has opened doors to new modes of discovery. Bioinformatics combines software, hardware, and database architecture to facilitate the storage, retrieval, and analysis of HTS data and to cross-reference such data with archival information on the basis of structure, physiochemical characteristics, biological profile, and therapeutic application. Such analyses enhance the efficiency of lead detection but also can provide unanticipated ‘finds’ in areas not previously considered; serendipity continues to play an important role.

The complex network of biological and physicochemical interactions of test compounds with receptors, endogenous proteins, metabolites, and other cellular constituents provides a ‘pedigree’ of behavior that constitutes the equity of the corporate screening resource. This pedigree also includes its chemical character, which incorporates chemical functionality and topological display. It is also important to add any data that are associated with compound-handling characteristics (solubility, instability, etc.), chemical character (reactivity, chelation potential, etc.), as well as the potential for interference in bioassay detection systems (color, fluorescence, etc.).

It is not enough to record that a compound is active or inactive in one or more assays. Any unusual observation with a test compound must be stored within its pedigree and not lost in the archives of a project. It is important to tabulate these findings with assay conditions and activity levels, although the simple ‘yes/no’ record for many of today’s high-density assays limits such input. Much of this information is not readily available for large collections, but can be accumulated in time as aspects of these and other features surface. ADME information is also an important aspect of such an information base, but, today, that is especially limited. Storage and handling of these data and their integration into analytical and decision-making protocols yields a valuable information pool. This is the basis of HTS informatics.

Variation in the nature of assay protocols and performance must be addressed in the design of the information-handling system. Protocol compliance and experimental error – mechanical, biological, or chemical interference – are important factors in defining the integrity of the data retrieved. False positives and negatives and the relationship of their incidence to assay or compound character are other aspects that can improve data quality and future performance.

Today, the term ‘data mining’ brings forth the realization that the data retrieved in a HTS run have a value that goes beyond the initial assay intention. Such information can lead to pattern analysis that will impact future inquiries. Negative and positive data hold equal value and constitute valuable equity in a company’s HTS operations. This aspect is of special importance as we enter into the realm of unknown receptors and ligands.

2.12.9.6 Management and Personnel Issues

Centralization of HTS activities was an early organizational change in R&D. It was essential on the basis of coordination of robotics, assay development and integration, data retrieval and management, and, most importantly, personnel development. This section began by acknowledging the arrival in the early 1990s of a new breed of scientist who recognized the challenge and the potential rewards of screening and the important catalyst that such individuals provided in the rapid growth and success of HTS. That breed has evolved into a new professional elite that forms the core of discovery operations in many companies.

The specific goals of HTS have made it a separate and important corporate entity. This has been a natural process as technologies and information output have become exclusive to the discipline. Personnel have also become highly specialized, with attention and skill directed to aspects not previously part of conventional discovery operations.

Even the equipment employed for HTS in major companies has introduced new dimensions, requiring huge space allocations and large staff commitments. Witness the means employed for the storage, retrieval, and dispensing of dry compounds and solution samples. Such systems significantly improve HTS efficiency and accuracy, but can require thousands of square meters for operation. Notable is the Haystack system from Automation Partnership, which has become the standard system for most large HTS operations. Haystack can automatically handle millions of samples as well as providing scheduling and tracking support. A more recent addition is the HomeBase system, which extends that capacity to include microplate management up to densities of 1536 wells with dispensing potential from 0.5 μ L to 250 μ L. Such equipment and associated robotics support constitute a ‘production level’ operation. This physical feature and the corresponding emphasis on massive data management and analysis separate the operation from the mainflow of research activity. While such separation is inevitable, there remains the need to ensure that feedback is given to the HTS team on the development of any hits and leads uncovered.

In small and large corporations, the integration of multidisciplinary technologies and personnel into a productive and innovative HTS team is as important as the anticipated advances in throughput and discovery. The latter follows automatically from a well-integrated, self-supportive team. Excellent reviews and commentaries by others on these all-important ‘people’ aspects have been published elsewhere.^{530,531}

2.12.9.7 Projections

Throughput has been increased with higher density microplates, free-form systems, chips, and other innovative devices that take advantage of advances in microfluidics and the associated micronization of sample transfer, assays, and read-outs. These advances also significantly reduce operational costs.

Microfabrication and microfluidic technologies are in a growth phase and creating a significant impact on innovation in screening design. They are a lucrative outsource activity, and likely to remain so as the scope of these technologies continues to be explored. Application in miniaturization in drug discovery and genomics are two areas that impact our interests. Monogram BioSciences⁵³² employs plastic and glass microfluidic array chips in sample processing and analysis at picoliter volumes. Caliper Technologies⁵³³ applies similar microchip technologies in facilitating liquid handling and biochemical processes. Their ‘lab-on-a-chip’ technology uses nanoliter volumes of reagents in enzyme, receptor binding, and functional cell-based assays as well as systems that address toxicological and pharmacokinetic parameters.

Aurora developed the NanoWell assay plate, which boasts 3456 miniaturized wells suitable for fluorescent assay applications. The assay volume used in these plates is 100 times smaller than the conventional 96-well format. This reduces the cost per test and the amount of compound needed. The required microfluidic technologies have also been developed by Aurora for compound transfer (<1 nL) at rates of up to 10 000 wells per hour; fluorescence detectors capable of handling more than 500 000 assays per day are also in place.

How small can we go? Biosensors based on molecular recognition force measurements between individual molecules using atomic force microscopy (AFM) have been described.⁵³⁴ These include interactions between individual

ligand–receptor, antibody–antigen, and DNA–DNA molecules. Using similar single-molecule measurements, discrimination between two chiral molecules has also been achieved at the single-molecule level by chemical derivatization of the scanning probe tip in AFM.⁵³⁴ These assay technologies are far from high-throughput, but offer considerable promise for such at the monomolecular level.

We have overcome the demands of sample throughput up to the point where meeting the demands of compound supply and diversity is a strain. Robotics, detection systems, sample density, and data management have increased to a level that was not conceivable a few years earlier. Unfortunately, assay systems that provide relevance as well as throughput are few and far between. All too often, relevance is set aside as a matter for secondary evaluation rather than the primary screen. Such an approach is fine, provided there is an appropriate second screening stage to bring both numbers and relevance to acceptable levels. The challenge now is in the development of systems that allow significant flexibility for assay enhancement in therapeutic relevance and the increase of information gleaned from each. Increase in the latter is important, but not at the expense of the former.

2.12.10 Fluorescence Correlation Spectroscopy and FCS-Related Confocal Fluorimetric Methods (FCS⁺ plus): Multiple Read-Out Options for Miniaturized Screening

2.12.10.1 Introduction: A Rationale for New Read-Out Methods in Drug Discovery

The process of drug discovery has been in a state of rapid change over the past decade and a half. The advent of genomics and combinatorial chemistry has lead to an increased reliance on efficient and effective techniques for screening large numbers of chemical compounds against an increasing number of potential pharmaceutical targets. The discipline of high-throughput screening (HTS) has been at the center of a revolution in drug discovery. Not only has HTS emerged as an important tool in the early stage of drug discovery, it is also the stage for the interaction of profound biological and chemical diversity with new technologies in the area of automation, robotics, and bioinformatics.^{536,537} The way in which assays are performed for screening is changing significantly. Whereas once assay volumes of 100–150 μL were common for such screening techniques as enzyme-linked immunosorbent assay (ELISA) and radioligand binding assays, modern miniaturized HTS favors homogeneous ‘add-and-read’ assay formats with volumes as low as 1 μL per well. Miniaturization will become the rule throughout the drug discovery process as compounds will be needed for more assays while being synthesized in smaller quantities. The process of HTS is also seeing increased application of industrial standard automation and robotics technology to improve efficiency. In parallel developments, novel detection technologies and assay strategies are being implemented to improve the effectiveness of the process. Therefore, novel detection technologies will be tested in an environment that requires the maximum determination of biological information in the shortest amount of time with a minimum of reagent and compound, and with maximal precision.

The technology described in this section has emerged from physics laboratories and the analysis of rapid chemical reactions to find application in drug discovery. Use of the confocal optical systems described herein facilitates the analysis of biological interactions at the molecular level. Changes in the molecular environment of a fluorescently labeled biological molecule result in the change in signal used by FCS and related technologies. The changes in molecular environment typically occur as a result of binding or biological processing, and therefore provide an ideal basis for screening assays.⁵³⁸

The challenges with regard to modern assay techniques and the related technologies are large. These include the need to maintain sensitivity as volumes, and therefore quantities of reagents and compounds, decrease as much as 100-fold; to obtain as much information as possible from a single measurement; to help eliminate the disturbances often encountered in compound screening, such as compound autofluorescence and turbidity; and to be compatible with homogeneous assay formats. The following describe how FCS⁺ plus meets most of these challenges.

2.12.10.2 Single-Molecule Confocal Fluorescence Detection Technology

Fluorescence-based confocal detection technologies allow molecular interactions to be studied at the single-molecule level. Combining laser spectroscopy with confocal microscopic optical systems, the laser beam can be highly focused in such a way that only molecules in a volume of 1 fL are hit by the light – a volume equal to roughly the size of a bacterial cell.⁵³⁹ With the laser illuminating such minute parts of the sample, even volumes of 1 μL or less are sufficient for sample testing. On the basis of this technology, new methods have been developed in recent years that allow the molecular properties of fluorescent biomolecules to be studied in 1 μL sample volumes, enabling a wide range of solution-based and cellular assays to be established for HTS.

The ability to make full use of the fluorescent molecule and all of its properties should be the benchmark of any fluorescence-based assay technology. While most assay strategies make use of only a single fluorescent property, the broad applicability of a screening system requires that flexibility of assay design be extended to the read-out technology by including a variety of detection modes. While most scientists may associate the use of fluorescence in biological assay systems solely with the measurement of fluorescence intensity, the measurement of additional fluorescent properties, such as lifetime, polarization, fluorescence energy transfer, and quenching, can yield a wealth of information from a single measurement. This ability to collect multiple data points per measurement not only provides an internal control but also contributes to screening efficiency by enabling rapid multiparameter evaluation of compound–target interactions.

2.12.10.2.1 FCS⁺ plus: multiparameter fluorescence read-out technology

FCS is used to determine the translational diffusion of fluorescent molecules.⁵⁴⁰ Each fluorescent molecule that diffuses through the illuminated confocal focus of the laser gives rise to bursts of fluorescent light quanta. The length of each photon burst corresponds to the time the molecule spends in the confocal focus. The photons emitted in each burst are recorded in a time-resolved manner by a highly sensitive single-photon detection device. The detection of diffusion events makes possible the determination of a diffusion coefficient. Upon binding of a fluorescently labeled ligand to its receptor, the molecular weight, and therefore the diffusion coefficient, changes. Thus, the diffusion coefficient serves as a parameter to distinguish between free and bound ligand. The confocal optics eliminate interference from background signals, and allow homogeneous assays to be carried out.

Since translational diffusion relies on significant changes in molecular weight upon molecular interaction, new methods were developed at Evotec that use a variety of fluorescence parameters as the read-out. These new methods, collectively called FCS⁺ plus, evaluate fluorescence signals from single molecules on the basis of changes in fluorescence brightness, fluorescence polarization, fluorescence lifetime, or fluorescence spectral shift, by fluorescence energy transfer, or by confocal imaging (Table 23). Brightness analysis is a unique read-out method that allows one to determine concentrations and specific brightness values of individual fluorescent species within a sample.⁵⁴¹ As a measure of fluorescence brightness, the number of photon counts per defined time interval in the confocal volume is detected. Changes of molecular brightness during a binding event can be due to two mechanisms: (1) if one of the two partners is labeled with a fluorescent dye, quenching of fluorescence may occur upon binding; and (2) amplification of

Table 23 Read-out modes offered by FCS⁺ plus

<i>Method</i>	<i>Principle</i>
Translational diffusion (fluorescence correlation spectroscopy, FCS)	Translational diffusion properties of molecules are dependent on the molecular weight. Diffusion coefficients of fluorescently labeled molecules therefore change upon interaction, and enable distinction between free and bound states of the molecule
Fluorescence brightness	The number of photon counts per defined time interval in the confocal volume serves as a measure of the molecular fluorescence brightness. Changes in fluorescence brightness of a fluorescent molecule upon binding are monitored
Fluorescence polarization	The fluorescence polarization of a molecule is directly proportional to its molecular volume. Changes in the molecular volume due to binding or dissociation of two molecules, conformational changes, or degradation can be detected as changes in polarization values of the fluorescently labeled molecule
Fluorescence lifetime	Fluorescence lifetime describes the average time that a fluorescent molecule remains in the excited state. The lifetime of the fluorescent signal is dependent on the molecular environment of the fluorescent tag, allowing monitoring of molecular interactions
Fluorescence energy transfer	The emitted light of a fluorophore serves as the energy source to excite a second fluorophore. The energy transfer between a donor fluorophore on molecule A to an acceptor fluorophore on molecule B depends on proximity, and can therefore serve as a measure of the interaction of A with B
Spectral shift	The excitation and/or emission wavelength of a fluorescent tag is dependent on the molecular environment. Changes of the spectral properties of a fluorescent molecule induced by molecular binding serve as a read-out for binding
Confocal imaging	Fluorescence changes on the cell surface or within cells caused by biological reactions are visualized by confocal imaging techniques combined with two-dimensional scanning

Table 24 Comparison of Evotec's technology and other fluorescence methodologies

Feature	Conventional fluorescence methods				Technologies at Evotec	
	FI	FP	FRET	HTRF	FCS	FCS ⁺ plus ^a
Homogeneous	0	+	+	+	+	+
Mass independent	+	–	+	+	–	+
Signal independent of assay volume	–	–	–	+	+	+
Single-molecule sensitivity	–	–	–	–	+	+
Insensitive to autofluorescence	–	–	0	+	0	+
No significant inner filter effects	–	–	–	0	+	+

Components to be labeled	1 or 2	1	2	2	1	1 or 2

FI, fluorescence intensity (total); FP, fluorescence polarization; FRET, fluorescence resonance energy transfer; HTRF, homogeneous time-resolved fluorescence.

+, advantage always featured; 0, not always featured; –, disadvantage/not a feature.

^aFCS⁺ plus comprises the detection of fluorescence brightness, polarization (FP), molecular diffusion, and lifetime. In addition, assay systems based on FI and FRET can be applied with FCS⁺ plus.

the molecular brightness takes place when both partners are labeled or a particle offers multiple binding sites for the fluorescent ligand (e.g., receptor-bearing vesicles or beads/bacteria with one binding partner immobilized on the surface). This technique has wide applications, since it can be used to study the interactions of proteins with similar molecular weight and binding of ligands to membrane receptors (see below).

Changes in any of the molecular parameters described in [Table 23](#) can be used as a read-out to characterize molecular interactions. In most cases, the same optical and electronic configurations are utilized, merely employing a different algorithm for analysis. This means that all fluorescent parameters noted above can be monitored using the same detection unit. Some of the fluorescence parameters described in [Table 23](#) can even be monitored simultaneously in a single measurement (multiplexing), resulting in exceptional data quality regarding reproducibility and statistics. A comparison of Evotec's detection technology with other commonly used fluorescence methodologies is shown in [Table 24](#).

2.12.10.2.2 Advantages of using FCS⁺ plus for miniaturized high-throughput screening

The major advantages of FCS⁺ plus technologies over other detection technologies are summarized in the following sections.

2.12.10.2.2.1 Inherent miniaturization

All macroscopic fluorescence methods, whether based on intensity, polarization, or lifetime detection, measure by averaging all signals across an optical collection volume, which is usually a significant portion of the sample well. For such ensemble measurements, lowering the assay volume results in a lower number of fluorescence signals contributing to the ensemble measurement. In most cases, this results in reduced assay performance, with the signal decreasing relative to the background as the assay volume decreases toward the 1 μ L range. With FCS⁺ plus, fluorescence parameters are measured from individual molecules in a detection volume of 1 fL regardless of sample volume. The signal-to-background ratio is effectively independent of the sample volume. Using FCS⁺ plus as a detection technology, miniaturized screening is possible in assay volumes of 1 μ L and lower without loss of signal. Miniaturization applied to large-scale screening has a considerable effect on the costs: to run a screen with 100 000 compounds, the reagent savings of 100 μ L versus 1 μ L assay volumes can make a difference of US \$1 million versus US \$10 000, assuming average costs for reagents include standard purified proteins. The cost savings will increase all the more if precious reagents are needed.

2.12.10.2.2.2 Homogeneous assay format

Since the bound and unbound state of a fluorescent biomolecule can be distinguished by different fluorescent parameters (see [Table 23](#)), no physical separation of bound and unbound ligand is required. The elimination of washing and separation steps make such 'add-and-read' assay formats easily amenable to automation, and rapid to perform.

2.12.10.2.2.3 Increased safety of reagents

Fluorescence detection technologies avoid the use of hazardous radiochemicals and the production of large-scale radioactive waste.

2.12.10.2.2.4 Elimination of background effects

Due to the short pathlength of the confocal optical configuration, background effects and signal reduction caused by turbidity and ink-like solutions can be substantially reduced in comparison with other methods. In addition, other disturbing background effects, such as those from light-scattering or autofluorescent compounds, can be eliminated by registering only the signal of the fluorophore used for labeling.

2.12.10.2.2.5 Single-component labeling

In most cases, fluorescent labeling of one binding partner with standard dyes is sufficient using FCS⁺ plus. FCS⁺ plus is therefore more widely applicable than FRET or homogeneous time-resolved fluorescence (HTRF), where both partners have to be labeled.

2.12.10.2.2.6 Multiple read-out modes

Since FCS⁺ plus encompasses a variety of read-out modes (see [Table 23](#)), it offers unique flexibility: the most suitable read-out mode can be selected for each assay system. FCS⁺ plus is applicable to the study of protein–nucleic acid, protein–peptide, and protein–protein interactions, enzymatic reactions, the interactions of ligands with membrane fractions or live cells, the detection of secretory products, and intracellular events such as reporter gene activity or translocation events. Some of the read-out modes described in [Table 23](#) can even be applied in parallel (multiplexing).

2.12.10.2.2.7 Multiple read-out parameters

FCS⁺ plus provides an intrinsically information-rich output for each measurement: each read-out mode allows the detection of several read-out parameters, such as the total concentration of fluorescent species as well as absolute concentrations of bound and free ligand. These additional parameters provide valuable intrawell controls and help to eliminate false-positives results.

2.12.10.2.2.8 Throughput

FCS⁺ plus measurements are fast (typical read-out times are 1–2 s per well), allowing for high throughput. However, high-performance and HTS in a miniaturized format can only be carried out by combining the FCS⁺ plus technology in an automated HTS system with microfluidics and robotics technology working with the same level of precision. Using the EVOscreen system, a fully automated ultrahigh-performance screening platform, a throughput of up to 100 000 compounds per day can be achieved for most FCS⁺ plus assays.

2.12.10.2.3 Case studies 1: using FCS⁺ plus multiparameter read-outs

We have chosen a number of different biological systems as case studies that demonstrate the unique potential of the FCS⁺ plus technology in meeting the demands of modern drug discovery described in the introduction.

2.12.10.2.3.1 Effect of assay miniaturization

Since FCS⁺ plus uses highly focused confocal optics, the volume illuminated by the laser beam is as small as a bacterial cell. The signal-to-background ratio is therefore effectively independent of the sample volume. This is demonstrated in [Figure 40](#), where the DNA-binding properties of topoisomerase were studied. Since the molecular weight of fluorescently labeled oligonucleotides increases by approximately a factor of 17 upon binding to topoisomerase, this event can be monitored using FCS. As shown in [Figure 40](#), the performance of the assay in a miniaturized 1 μ L format is identical to that in a ‘large’-scale format of 20 μ L with respect to both statistics and the observed protein–DNA affinity.

This demonstrates that in comparison with other methods currently used in industrial HTS, such as ELISA, fluorescence polarization, scintillation proximity assay (SPA), and HTRF, assay miniaturization down to a 1 μ L volume is achieved without compromising assay performance.

Besides the need for a sensitive detection technology, screening in a miniaturized format requires significant expertise with liquid handling of nanoliter volumes. In addition, evaporation and adsorption effects must be overcome. Typically, target characterization and assay development are initially carried out in volumes of 20 μ L. Subsequently, the assay volume is reduced to 1 μ L for HTS adaptation and screening.

Figure 40 FCS⁺plus allows assay miniaturization to 1 µL formats. The interaction of topoisomerase with a fluorescently labeled oligonucleotide was monitored using FCS in 1 µL and 20 µL assay volumes. Maximal binding was normalized to 100%.

2.12.10.2.3.2 Multiparameter read-out

The success of HTS strategies in drug discovery depends on the reliable determination of the compound activity, thus distinguishing between promising potential drug candidates and useless false positives (where inactive compounds score active in the assay). Elimination of false positives is a drain on time and resources because it requires retesting. While the use of fluorescence is usually associated solely with the measurement of fluorescence intensity, FCS⁺plus allows the determination of several fluorescence parameters in a single measurement. Therefore, FCS⁺plus delivers more information on a compound, allowing for efficient elimination of false positives in the primary screen.

To demonstrate FCS⁺plus multiparameter read-outs, a model system based on biotin–streptavidin was used. Binding of fluorescently labeled biotin (molecular weight 1 kDa) to streptavidin (molecular weight 60 kDa) can easily be monitored by FCS. This allows one to determine the diffusion rates of free and bound biotin, and the distribution of fluorescent biotin between these two species. A test run was carried out in a miniaturized format in a HTS mode (1 µL sample volume, 2 s read time per well) using unlabeled biotin as a competitor. A sample of 40 wells from a single row of a high-density plate is shown in [Figure 41](#). Three fluorescence parameters are obtained from a single measurement within each well: (1) the fluorescence count rate (average fluorescence intensity in the sample), (2) the particle number (a measure of the total number of fluorescent biotin molecules present in the confocal volume), and (3) the ratio of bound to total biotin (ratio of streptavidin-bound biotin relative to total biotin).

Other detection systems based on radioactivity or fluorescence typically deliver a single read-out parameter per well, usually the amount of complex formed. In this case, well 6 would score as a hit. The additional read-out parameters obtained by FCS⁺plus show that both the count rate and the concentration of biotin (particle number) in this well are increased. This can be attributed to the failure of a dispenser to deliver the appropriate amount of streptavidin to this well. The resulting lower volume yields an increase in the count rate and the particle number (the final concentration of biotin is higher due to the lower volume), whereas the lower amount of streptavidin results in a decrease in the amount of complex formed. Thus, with the additional information obtained from the FCS⁺plus read-out parameters, well 6 is discarded as a false positive.

This example shows how the simultaneous analysis of multiple fluorescence parameters helps to significantly improve the precision of primary screening by the efficient elimination of false-positive results. Using the EVOscreen platform, the screening database automatically eliminates false positives on-line during the primary screen if control parameters within a well, such as the total count rate or the particle number, deviate from a previously defined range.

2.12.10.2.4 Case studies 2: flexibility of multiple read-out modes

Ideally, a detection technology must allow maximal flexibility in assay design since assay types developed and screened in pharmaceutical companies vary enormously. Since FCS⁺plus encompasses a variety of different read-out modes, for

Figure 41 FCS⁺plus offers multiparameter read-outs. Binding of fluorescently labeled biotin to streptavidin was studied with FCS on EVOscreen. Shown is a segment from a nanocarrier (total assay volume of 1 μ L). The data was fitted using a two-component fitting procedure, assuming the presence of a fast-diffusing component (free fluorescent biotin) and a slowly diffusing component (fluorescent biotin–streptavidin complex). The fit procedure yields the percentage of fluorescent biotin present in the two fluorescent components ('% biotin bound' and '% biotin free'), the total fluorescence intensity (count rate), and the total concentration of fluorescent biotin (particle number).

Figure 42 Enzyme kinetics in 1 μ L assay volumes. Src kinase activity was determined on a nanocarrier (1 μ L assay volume) using FCS. The production of phosphorylated peptide was monitored for 30 min using increasing enzyme concentrations.

each specific assay system the most suitable read-out mode can be selected. In the following sections, we have chosen several important target classes/assay systems in order to demonstrate the degree of flexibility and performance offered by FCS⁺plus.

2.12.10.2.4.1 Enzyme assays

Kinases are important therapeutic targets in drug discovery programs. We have selected p60^{c-src} as an example of tyrosine kinases that are involved in controlling important cellular functions such as mitogenesis. Kinase activity is usually monitored by quantifying the amount of phosphorylated peptide formed using an anti-phosphotyrosine antibody. Since the molecular weight of a phosphopeptide increases significantly upon antibody binding, enzymatic activity can easily be determined with FCS using a fluorescently labeled peptide as the substrate.

Other detection methods, such as fluorescence polarization and HTRF, are also applicable. In comparison with these methods, FCS offers significant advantages. Using FCS, assays can be designed not only to determine the endpoint activity of a given kinase but also in a kinetic mode where enzyme activity is monitored over time.

Thus, during the assay development phase, new kinases are characterized by determining kinetic constants such as k_{on} and k_{off} . During assay adaptation to a miniaturized HTS format, suitable assay conditions are investigated, as shown in Figure 42. In this experiment, different amounts of enzyme were used, and the amount of product formed was monitored over time in a 1 μ L format. After successful completion of this stage, the assay was run in a HTS mode on the EVOscreen platform (1 μ L per assay, endpoint mode) in order to identify compounds that inhibit kinase activity. Thus, FCS⁺plus can be used for target characterization, for assay development, for miniaturized, fully

automated HTS, and for hit profiling, yielding maximum information using a minimum of assay components and compounds. Using the EVOscreen system, a throughput of up to 100 000 compounds is achieved within 24 h for this type of assay.

2.12.10.2.4.2 G protein-coupled receptor assays

GPCRs belong to another important target class because they are involved in a variety of diseases such as asthma, AIDS, and neurodegenerative and cardiovascular diseases.⁵⁴² However, technologies currently used have significant disadvantages as they typically involve the use of radioactively labeled ligands. This means exposure to hazardous radioactivity, limited shelf lives of labeled components, and the production of radioactive waste on a large scale. Also, radioactive assays are still carried out in the standard 96-well format using volumes of 100–150 μL , and are not easily amenable to miniaturization beyond the 384-well format (30–50 μL per well).

These assays involve the use of membrane fractions prepared from receptor-expressing cells; therefore, standard FCS cannot be applied because of the very slow diffusion rate of membrane vesicles. To overcome this restriction, a new read-out method was developed, based on brightness analysis. This method complements FCS since it measures the brightness of fluorescent species and not diffusion times; as a result, it is entirely mass-independent. It allows one to study the interaction of proteins with similar molecular weight but is also applicable to monitor interactions of soluble ligands with receptor-bearing vesicles. The principle of brightness analysis in this case is multiple fluorescently labeled ligands binding to a receptor-bearing membrane vesicle. Bound ligand can be distinguished from unbound because a membrane vesicle with many fluorescent ligand molecules bound is significantly brighter than a single fluorescent ligand molecule.

Figure 43 shows an example of such an assay using the chemokine receptor CXCR2 and its ligand, fluorescently labeled interleukin 8 (IL-8). The results from 500 wells during a screening run using the EVOscreen platform are displayed. The competitor added was easily identified since the assay yields a nice screening window with a signal-to-background ratio of approximately eightfold.

Using radioactive methods, only the amount of bound ligand can be determined. In contrast, with brightness analysis, the concentration of both bound and free ligand is obtained from a single measurement, thus providing a valuable internal control.

2.12.10.2.4.3 Cellular assays

A further challenge to modern HTS is the use of living cells. Cellular assays provide a more physiological approach, and put functional data into a biological context. However, the requirements for miniaturized HTS on cellular assays are high: assays must be single step and homogeneous, which presents a technical challenge.

FCS⁺ plus is applicable to a wide variety of cellular assay systems. One example is shown in **Figure 44**, where binding of a fluorescent ligand to cell surface receptors was monitored with live cells. In this experiment, the activity of

Figure 43 Test screen of the chemokine receptor CXCR2 in a miniaturized format. A sample of 500 wells from a nanocarrier is shown from a fully automated test screen using EVOscreen. 100 nL of 10% dimethyl sulfoxide with (\square) or without (\blacksquare) competitor were added from 96-well plates to nanocarriers. Ligand (100 nL) and membranes (800 nL) were added by dispensers, and the assay was analyzed by brightness analysis. The solid line represents the mean of each sample, and the dotted line represents the mean \pm three standard deviations.

Figure 44 Studying ligand–receptor interactions using live cells. Live cells expressing the chemokine receptor CXCR2 were incubated with fluorescently labeled IL-8 in the presence of increasing concentrations of a low molecular weight compound analyzed by brightness analysis. The membrane brightness was determined by FCS⁺plus.

a chemical compound was analyzed for competing with IL-8 binding to CXCR2 receptors expressed on the cell surface. In this case, a variation of the brightness analysis read-out described above was used to study the binding event. Here, the cells were placed at the bottom of a well, and fluorescently labeled ligand added. Cell-bound fluorescence was quantified by scanning with the confocal volume through the cells.

In addition to cell surface binding, secretory products from cells in the surrounding medium as well as gene induction using reporter systems can be measured by FCS⁺plus. Due to the small confocal detection volume, subcellular resolution is obtained with FCS⁺plus by using confocal imaging techniques. This makes assay systems accessible to HTS where the distribution of fluorescence across a cell changes while the total fluorescence remains unaltered (e.g., during translocation events).

The combination of sensitivity and miniaturization capabilities of FCS⁺plus offers a further major advantage: primary cells can be used in HTS because restrictions resulting from the availability of primary tissue are overcome by the very small numbers of cells needed for each assay (1000–2000 cells per well).

2.12.10.3 Overview

FCS and related confocal fluorescence-based detection technologies provide a valuable platform for assay development, HTS, and subsequent optimization of assays. The technology is applicable to a wide variety of target classes and assay techniques, allowing great flexibility in assay design. Screening applications as varied as the kinetic study of compounds acting on tyrosine kinases, the binding characteristics of compounds acting on GPCR systems, and the study of binding to and secretion from living cells have been accomplished with this technology.

FCS⁺plus technologies overcome the use of hazardous radioactive probes, are amenable to miniaturization, can be used in a kinetic or endpoint mode, and deliver internal control values for each sample measured. Because of the inherently small detection volume, the techniques are independent of sample size, suffering no loss of sensitivity in low volume assays, and therefore are ideally suited for assay miniaturization. The multiple parameters read in a single measurement improve the precision of each measurement taken. The potential to impact all areas of drug discovery is yet to be fully exploited, but FCS⁺plus is a technology platform that we feel will contribute significantly to improvement of the drug discovery process.

2.12.11 Homogeneous Time-Resolved Fluorescence

2.12.11.1 Introduction

The evolution of high-throughput screening (HTS) has created the need for more sensitive, rapid, and easily automated assays. Combinatorial chemistry, expanding compound libraries, increasing numbers of drug targets, and

increasing pressure for the discovery of new chemical entities in the pharmaceutical industry have fueled the expansion of HTS methods.⁵⁴³ The advent of homogeneous, 'mix-and-measure' assays led to a significant leap in the throughput of typical HTS. Homogeneous assays eliminate the need to separate bound from free label, which also reduces waste and error. Furthermore, homogeneous assays are easier to automate since they require only addition steps. Scintillation proximity assay (SPA) (Amersham International) was the first mix-and-measure assay developed. With the TopCount scintillation and luminescence microplate counter (Packard Instrument Company) and the MicroBeta microplate scintillation counter (EG&G Wallac), SPAs made HTS a reality.⁵⁴⁴ However, SPAs still require a radiolabeled binding partner, long counting times for accurate measurements, and correction for the quench and color interference effects of biological compounds. In addition, SPAs involve a scintillating solid phase bead, which settles out of solution.⁵⁴⁵ The need for a nonradioisotopic, truly homogeneous alternative led to the development of HTRF, an in-solution, homogeneous, nonradioisotopic method. This section describes the theory and application of HTRF – a sensitive, robust, homogeneous, fluorescence method for HTS.

2.12.11.2 Unique Properties of Homogeneous Time-Resolved Fluorescence Chemistry

2.12.11.2.1 Specific requirements of homogeneous assays

Based on the specific requirements of homogeneous assays, a new class of long-lived fluorescent tracers was utilized to create this novel assay method. The following sections describe the unique challenges of creating a fluorescence-based, homogeneous method in general, and the unique solution provided by HTRF chemistry.

2.12.11.2.1.1 Unique tracers

Assaying a specific effect on biological targets without the luxury of a separation step requires unique tracers. The natural fluorescence of proteins and other compounds in biological samples and media creates limitations for the use of conventional fluorescent labels. Upon laser excitation, conventional fluorophores shift to a longer wavelength and are measured immediately, based on the change in wavelength.⁵⁴⁶ Most background signals are prompt in nature, and also dissipate within 50 μ s after excitation, making them difficult to separate from specific signals. HTRF utilizes the rare-earth lanthanide ion Eu^{3+} , which exhibits a signal as long lived as several hundred microseconds, permitting time-resolved measurement and elimination of prompt background fluorescence.⁵⁴⁷

2.12.11.2.1.2 Signal modulation

Another requirement of homogeneous assays is a method of modulating the signal between the affected and unaffected assay targets. Making the distinction between the bound and unbound target molecules by a method other than separation is necessary. HTRF technology utilizes a carefully selected pair of fluorescent molecules to generate signals specific to the bound and unbound states. The 'donor' molecule is europium cryptate, referred to as (Eu)K. When excited, (Eu)K transfers energy to an 'acceptor' molecule, a modified (stabilized) allophycocyanin called XL665. A long-lived signal at a specific wavelength is generated only when a binding event between donor and acceptor molecules occurs. For example, when the target molecules are unbound as a result of the presence of an inhibitor, the specific signal is not generated.⁵⁴⁸ Such signal modulation is required for a truly homogeneous assay.

2.12.11.2.1.3 Resistance to biological media

Since no separation step is involved in a homogeneous assay, biological assay components and media remain in the presence of the target molecules of interest during measurement. The signal of a homogeneous assay should be resistant to unrelated, nonspecific effects of biological assay components, such as media and natural products, if involved. HTRF technology is measured by a patented 'ratiometric' method, described later in detail, which eliminates or corrects for nonspecific interference from biological assay components.⁵⁴⁹

2.12.11.2.2 Lanthanide cryptates: a new type of fluorescent label

2.12.11.2.2.1 Chelates as fluorescent labels

The rare-earth lanthanides europium, terbium, dysprosium, and samarium are naturally occurring fluorophores, and their chelates have a number of applications in immunological and biological assays.⁵⁵⁰ In lanthanide chelates, the lanthanide is the fluorescent label. It is held by chelation that permits conjugation with biological components. Since lanthanide chelates are not fluorescent when conjugated to biological components, a dissociative enhancement step is required to free the lanthanide ion from the conjugated chelate, to make a new and different ion complex that can generate measurable fluorescence, as in the DELFIA chemistry (EG&G Wallac). The exception is the LANCE

(EG&G Wallac) chemistry, which has demonstrated a measurable signal in homogeneous form, but with a substantially diminished signal-to-noise ratio, relative to the DELFIA heterogeneous method.⁵⁵⁰ Lanthanide chelates are subject to potential dissociation of the ion, which can undermine the integrity of the label, increasing the background and nonspecific binding contributions. In addition, lanthanide chelates are subject to inactivation by EDTA, and require separation and washing steps for best results.⁵⁵¹ These limitations of chelates are overcome by the use of the novel family of lanthanide cryptates as fluorescent labels, for which Professor Jean Marie Lehn was awarded the 1987 Nobel Prize in Chemistry (shared with J. Pederson and D. Cram).

2.12.11.2.2.2 Cryptates as fluorescent labels

Lanthanide cryptates are formed by the inclusion of a lanthanide ion in the cavity of a macropolycyclic ligand containing 2,2'-bipyridine groups as light absorbers (Figure 45). The cryptate can undergo intramolecular energy transfer when the cavitated species is Eu^{3+} . The cage-like structure of the cryptate protects the central ion, making it stable in biological media. Well-known heterobifunctional reagents can be used to conjugate the diamine derivative of the europium trisbipyridine cryptate, (Eu)K, to biological assay components, such as proteins, peptides, receptors, nucleic acids, and antibodies, without loss of reactivity. Even upon conjugation to such components, the photophysical properties of (Eu)K are conserved, making it particularly useful for homogeneous assays as a fluorescent label. No dissociation enhancement step is required, and cryptates are stable and kinetically very inert, as the activation energy required to reach the transition state of dissociation is significantly higher for cryptates than for chelates.⁵⁵² Excitation of (Eu)K at 337 nm yields an emission spectrum with a strong peak at 620 nm, as shown in Figure 45.⁵⁵³

2.12.11.2.2.3 Use of XL665 as an acceptor

The best choice for an acceptor molecule for the (Eu)K donor will complement the cryptate fluorescence energy spectrum, accept the transfer of energy efficiently, be stable in common assay media, and lend itself to appropriate chemistry for conjugation with biological components. For HTRF assays, the best choice for the acceptor molecule is one of the main constituents of the phycobilisomes of red algae. These protein-pigment complexes absorb light and channel it to the photosystem of the cell. In the phycobilisome, the last component that transfers light is allophycocyanin (APC), a phycobiliprotein of 105 kDa with an absorption band ranging from 600 to 660 nm and an emission maximum at 660 nm. APC, when modified by cross-linking, emits at 665 nm, and is called XL665 (Figure 46).

XL665 has a high molar absorptivity at the cryptate emission wavelength, which enables very efficient energy transfer of about 75% for a donor-acceptor distance of 7.5 nm. Spectral emission is high where the cryptate signal is insignificant, making it particularly complementary (Figure 47). The quantum yield of energy is high, at about 70%. XL665 is stable and not quenched by the presence of biological media.⁵⁵³

2.12.11.2.2.4 Signal amplification of the cryptate fluorescence

Forster theory (1948) defines the nonradiative energy transfer that occurs between fluorescence resonance energy transfer (FRET) pairs, such as the (Eu)K donor molecules and the XL665 acceptor molecules of HTRF. The efficiency of transfer is a function of the distance ($1/d^6$) between the donor and acceptor pairs.⁵⁵⁴ Figure 48 illustrates the energy

Figure 45 Europium trisbipyridine cryptate has an excitation peak at 337 nm and an emission peak at 620 nm.

Figure 46 XL665, cross-linked allophycocyanin has a strong emission peak at 665 nm.

Figure 47 The complementary spectra of (Eu)K and XL665.

transfer between (Eu)K and XL665 in HTRF. (Eu)K excited separately has a spectrum that allows only about 60% of the signal to be measured. Paired with XL665, the signal is amplified by the transfer of energy to the XL665 spectrum, which provides a spectrum that allows one to measure essentially all emitted energy, at the shifted wavelength. Therefore, by being paired with XL665, the (Eu)K signal is effectively amplified.⁵⁵⁵

2.12.11.2.3 Homogeneous time-resolved fluorescence signal and measurement

The specific FRET pair of (Eu)K and XL665 exhibits both temporal and spectral emission characteristics that provide opportunities for measurement in unique ways. The Discovery HTRF microplate analyzer (Packard Instrument

Figure 48 Energy transfer and amplification between (Eu)K and XL665. When the fluorescence is measured at the emission wavelength of the XL665, an amplification is obtained when $(\phi_A)(\phi_T) > \phi_{Eu}$, where ϕ_A , and ϕ_{Eu} are the quantum yields of XL665 and the europium ion, respectively, and ϕ_T is the transfer efficiency.

Figure 49 Principle of time-resolved detection of HTRF. The time delay of 50 μ s allows short-lived background fluorescence and the signal from free XL665 to dissipate.

Company) was developed and optimized specifically for the detection of HTRF assays for HTS. Since no separation occurs between bound and free assay components, the signals from each individual fluorophore may be distinguished from the signal of the bound pair based on both time and wavelength. The Discovery analyzer takes into consideration the following characteristics of HTRF chemistry to make the most efficient and useful measurement.

2.12.11.2.3.1 Time-resolved measurement

Background and nonspecific fluorescence from microplates, media, and biological components has a short lifetime of emission. Unbound or isolated XL665 also emits a short-lived signal when excited at 337 nm. Unbound or isolated (Eu)K emits a long-lived signal at 620 nm, easily separated by optical discrimination. Together, the (Eu)K–XL665 pair emits a long-lived signal at 665 nm (**Figure 49**).

The Discovery analyzer excites each sample with a nitrogen laser excitation pulse at 337 nm. Measurements are taken after a 50 μ s delay, allowing any short-lived fluorescence to dissipate before the emission light is collected. Time-resolved fluorescence measurement has been incorporated into a number of fluorimeters, such as the Victor (EG&G Wallac) and the Analyst (LJL Biosystems), although the excitation sources vary.

2.12.11.2.3.2 Dual-wavelength measurement

Although time-resolved measurement is a feature now copied in and common to various vendors' instruments, simultaneous dual-wavelength detection is unique to the sophisticated Discovery instrument. **Figure 50** illustrates the optical design of the Discovery analyzer used to make measurements of HTRF assays at 620 nm and 665 nm, simultaneously. Together, time-resolved measurement and simultaneous dual-wavelength detection distinguish the bound from free fluorophores. In addition, the extent to which binding has occurred can be measured independently of interference effects from media, biological components, and physical assay complications such as turbidity. **Figure 51** shows the detection of an HTRF assay by the Discovery analyzer. During the course of 1 s per well, excitation by the

Figure 50 Optical configuration of the Discovery HTRF Microplate Analyzer. A nitrogen laser provides the excitation energy of 337 nm. Simultaneous dual-wavelength detection provides measurements at 620 nm and 665 nm after a time delay.

nitrogen laser at 337 nm elicits a long-lived signal at 620 nm from free (Eu)K and a long-lived signal at 665 nm from the (Eu)K bound to XL665 by biomolecular interaction.⁵⁴⁸ The ratio of the two simultaneous measurements is a specific measure of the extent to which the labels are bound in the assay. Inhibitors of binding or enzyme effects on the binding partners can be measured directly without separation of individual assay components or biological media.

2.12.11.2.3.3 Data reduction

Assay data can be presented in terms of the ratio of the 665/620 nm measurements, R , to correct for any interference from media or absorption of excitation or emission wavelengths by the media. ΔR is the change in ratio that occurs with respect to the blank or negative sample. It is used to express the specific signal in the assay. ΔF is an instrument-independent measurement that shows the signal-to-noise ratio of the assay.⁵⁵⁶ Both measurements utilize the patented ratio method of detection, which eliminates interference from test compounds, or turbidity of test samples.

$$\Delta R = (\text{ratio of the sample} - \text{ratio of the negative sample}) \times 10000$$

$$\Delta F = (\Delta R / \text{ratio of the negative sample}) \times 100$$

The Discovery analyzer can provide raw 665 nm counts, raw 620 nm counts, or ratios. This patented technique is unique to HTRF measurement, and is proprietary to this detection technology.

The following sections describe applications of HTRF chemistry for HTS.

2.12.11.3 Applications of Homogeneous Time-Resolved Fluorescence for High-Throughput Screening

HTRF assays can be constructed using several formats. The direct-assay format requires that the binding partners of interest be directly conjugated to the (Eu)K and XL665 fluorophores. The advantages of this format are that the assay

Figure 51 Ratio measurement of 620 nm and 665 nm wavelengths. The long-lived signals, 620 nm emission from free (Eu)K and the 665 nm emission from the bound (Eu)K and XL665 pair, provide a method for correcting for color or turbidity in the reaction.

optimization depends only on the particular interaction of the binding partners, with no consideration of antibody affinities. A disadvantage is that a substantial quantity of the binding partners is required because some material is lost in purification of direct conjugates. In addition, the integrity of the binding interaction may be affected by direct conjugation. The more commonly used indirect method utilizes a high-affinity pair, such as streptavidin/biotin, or antibodies specific to the binding partners to construct the assay. The semidirect method involves one directly labeled binding partner and another indirectly labeled partner.⁵⁵⁷

HTRF assays are typically run in a 200 μ L volume in a 96-well plate or 70 μ L volume in a 384-well plate. The Discovery analyzer measures plates in either format. HTRF assay technology is not appropriate for intracellular assays, but is particularly suitable for kinetic studies due to the fast read times and the ability to measure each sample repeatedly over time. Most widely performed assays include immunoassays, enzyme assays, receptor-binding assays with purified receptors or membrane fragments, protein–protein interactions, and nucleic acid hybridizations. The following are examples of HTRF assays and results as measured on the Discovery instrument.

2.12.11.3.1 Immunoassays

Immunoassays can be created using HTRF, as it was first developed for clinical applications and sold under the name of TRACE chemistry by CIS Bio International. These are conducted as sandwich assays in which monoclonal antibodies raised against the target are conjugated directly with (Eu)K and XL665. The following example compares the HTRF assay with a commonly used enzyme-linked immunosorbent assay (ELISA) method.

The ELISA version of this cytokine assay requires the first antibody to be bound to the well of a microplate. The second antibody to the same cytokine is linked to the reporter enzyme.⁵⁵⁷ This assay requires three separate wash steps, four reagent additions, and four incubations, and can be used to screen a maximum of 10 000 assay points per day. The HTRF assay, as shown in [Figure 52](#), requires no separation steps, one reagent addition, and one incubation at room temperature, and can be used to screen up to 10 000 assay points in 2 h. Samples contained red blood cells up to 5% by volume. [Figure 53](#) shows the comparison of the optical density of the ELISA assay at 405 nm with the ratio

Figure 52 HTRF immunoassay configuration. Polyclonal antibodies are conjugated directly with (Eu)K and XL665. The presence of cytokine is measured by the binding of both antibodies.

Figure 53 Comparison of ELISA and HTRF methods for the detection of cytokines. Both are capable of picogram levels of detection, but the HTRF assay has fewer steps.⁵⁵⁸

measurement of the HTRF assay. Both methods are capable of detecting picogram quantities of cytokine in complex samples; however, HTRF is considerably easier to perform for HTS purposes. An HTRF prolactin immunoassay has also been described previously.⁵⁵³

2.12.11.3.2 Enzyme assays

Enzyme-mediated reactions that cleave, synthesize, or modify compounds represent a significant group of targets for HTS. The HTRF assays can be constructed such that enzyme activity can be measured by the absence or presence of high signal. Protein tyrosine kinases play a critical role in the cellular signal transduction pathways, with significant implications for mechanisms of allograft rejection, allergic response, and autoimmune diseases. Hundreds of tyrosine kinases have been identified, and many are still to be discovered through genomic research.^{559,560} The following is an example of an HTRF tyrosine kinase assay.

Biotinylated polypeptide substrates are incubated with kinase enzymes to catalyze the phosphorylation reaction. Eu(K) conjugated with PY20 antibody recognizes those peptides that are successfully phosphorylated. Streptavidin conjugated to XL665 binds to the biotinylated substrate, whether or not it is successfully phosphorylated. Those peptides that are phosphorylated effectively bring together the HTRF pair such that a high signal is achieved upon excitation at 337 nm with the nitrogen laser of the Discovery analyzer (Figure 54).

Figure 54 Tyrosine kinase assay using HTRF reagents. Biotinylated substrate binds streptavidin–XL665, and antiphosphotyrosine–(Eu)K recognizes those peptides that are phosphorylated.

Figure 55 Titration of kinase inhibitor for the Src-1 family of enzymes.

A number of known inhibitors were titrated against five Src-family tyrosine kinases tested using this HTRF format. The IC_{50} values obtained from the HTRF assay were very similar to those achieved using a comparable radiometric SPA (Amersham International).⁵⁶¹ Figure 55 shows the inhibition curves as measured by HTRF.

Sensitivity is a critical issue in HTS when the cost of reagents must be considered and the availability of enzyme and sample materials is limited. In order to determine the sensitivity of the HTRF chemistry for kinase activity, varying concentrations of Lck enzyme were added to reaction mixtures containing peptide and ATP. As time points up to 80 min, reactions were stopped and measured in the Discovery instrument. As little as 20 pM Lck enzyme gave significant results with a signal-to-noise background of 10:1 after 40 min (Figure 56). This result demonstrates that the HTRF assay method provided about two orders of magnitude more sensitivity than the SPA method, making it the first nonradioisotopic alternative capable of yielding results that could be achieved previously only with the use of radioisotopes. The high sensitivity of this HTRF method saves both enzyme and library samples, and enables screening of weaker inhibitors not easily measured by less sensitive methods such as SPA.

Additional examples of the application of HTRF specifically to kinase assays have been published.^{562,563} Other HTRF enzyme assays that have been published include a viral protease assay⁵⁶⁴ and a ubiquitination assay.⁵⁶⁵

2.12.11.3.3 Receptor-binding assays

Biomolecular interactions between nuclear receptors and their coactivators are associated with transcriptional regulation, and are therefore seen also as an important target for HTS in drug discovery. Ligand-binding promotes the

Figure 56 Time course of the Lck kinase assay. The concentration of the enzyme varies from 0.002 nM to 0.1 nM.

Figure 57 HTRF strategy for the detection and quantification of the interaction between a receptor and a coactivator.

association of nuclear receptors with nuclear proteins, such as CREB-binding protein (CBP) and steroid receptor coactivator 1 (SRC-1), which are believed to function as coactivators of transcriptional activity.⁵⁶⁶ A description of how HTRF methods were used to characterize and screen for potential agonists to these ligand-dependent interactions follows.

Nuclear receptors contain a well-conserved, 200–300-mer amino acid ligand-binding domain (LBD) in which a number of functionalities are encoded, including ligand and coactivator binding and transactivation. The LBDs of peroxisome proliferator-activated receptor γ (PPAR γ) were used as a model in this study. PPAR γ -LBD was expressed and purified as a glutathione *S*-transferase (GST) fusion protein from *E. coli* strain DH5. Both coactivators CBP_{1–453} (amino acids 1–453) and SRC-1_{568–780} (amino acids 568–780) were biotinylated.⁵⁶⁶

In this assay, (Eu)K is covalently bound to anti-GST antibody to create (Eu)K- ∞ -GST for labeling the nuclear receptor. The secondary fluorophore, XL665, is covalently bound to streptavidin (streptavidin-XL665) to label the biotinylated coactivators. Both streptavidin-XL665 and (Eu)K- ∞ -GST are available as ‘generic’ or ‘off-the-shelf’ reagents from Packard Instrument Company. Figure 57 illustrates the indirect-assay format used to create the HTRF assay of nuclear receptors and coactivators. Agonist-induced interaction between the nuclear receptors and their coactivators brings the two fluorophores in proximity, and results in a high signal.

Known agonists have been shown previously to activate ligands for PPAR γ in mammalian cell-based assays.⁵⁶⁶ Using the HTRF assay approach described above, increasing concentrations of thiazolidinediones (TZDs) were added to reaction mixtures. Figure 58 shows that TZDs induced a dose-dependent specific interaction between PPAR γ -LBD

Figure 58 Effects of TZDs on PPAR γ -CBP interactions using the HTRF approach.

Figure 59 HTRF assay configuration for the detection of small-molecule inhibitors of the CD28/CD86 interaction.

and the nuclear receptor-binding domain of CBP with similar EC_{50} values to those obtained in transactivation studies. This assay indicates that HTRF assay methods can provide a powerful alternative to cell-based assays for screening large compound libraries for potential agonist drug candidates.⁵⁶⁷

2.12.11.3.4 Protein-protein interactions

A number of HTRF protein-protein interactions have been described previously. The JUN:FOS assay was done by directly labeling the FOS protein with (Eu)K and using biotinylated JUN to bind with the streptavidin-XL665.⁵⁶⁸ Now, antispecies or antiepitope tag antibodies conjugated with (Eu)K are available and used more often than direct labeling and streptavidin-XL665.⁵⁵⁶ The following example is an HTRF protein-protein assay using the indirect method.

Ligation of CD28 and CD86 leads to signals that are required for the production of interleukin-2, a process that is implicated in the regulation of T cell anergy and programmed cell death.^{569–572} An HTRF assay was constructed to screen for small-molecule antagonists of this interaction, which could be considered possible drug targets (Figure 59). The acceptor, XL665, was covalently bound to antihuman antibody that recognizes the Fc region. CD28 was expressed as a fusion protein to the human immunoglobulin (Ig) domain. The other binding partner, CD86, was expressed as a fusion protein with a rat Ig domain, recognized by biotinylated sheep anti-rat antibody. Streptavidin-(Eu)K then binds to complete the HTRF reaction.⁵⁷³

Dose-response curves were created with blocking antibodies that prove that the binding of CD28/CD86 proteins causes the signal generation (Figure 60). Since the affinity of interaction between CD28 and CD80 was shown to be relatively low (200 nM to 4 μ M) by different methods,^{550,551} ELISA methods would result in dissociation of the bound complex during washing, and SPA methods would require high levels of radioactivity. The HTRF method uses readily available generic reagents, was shown to be resistant to color quench effects, and requires few steps, thereby minimizing the errors associated with pipetting. In addition, this modular approach makes development of other related assays for specificity testing easier than direct-labeling approach.⁵⁷³

Figure 60 Dose-response curves illustrating the inhibition of binding by blocking antibodies.

Figure 61 HTRF assay for the detection of nuclease activity.

Another published HTRF assay for measuring protein–protein interactions is given by Farrar *et al.* in their paper entitled “Stoichiometry of a ligand-gated ion channel determined by fluorescence energy transfer.”⁵⁷⁴ HTRF was used to elucidate the stoichiometry of subunits within an oligomeric cell surface receptor in a way that could be applied generally to other multisubunit cell surface proteins.

2.12.11.3.5 Nucleic acid hybridizations

DNA hybridization and related enzyme assays using nucleic acid-binding partners can be conducted in solution using HTRF. A simple measure of hybridization was conducted using one oligonucleotide directly labeled with (Eu)K, while the complementary strand was biotinylated and labeled with streptavidin–XL665. The extent to which the complementary strands are bound can be measured by the HTRF signal that results from the proximity of the two fluorophores.⁵⁵³ The following assays were more recently developed to measure nucleic acid-related enzyme activity.

2.12.11.3.5.1 DNA nuclease assay

A 21 bp oligonucleotide was directly labeled with (Eu)K on the 3' end, and biotinylated on the 5' end. Streptavidin–XL665 was added to complete the FRET reaction (Figure 61). Increasing amounts of DNase enzyme were added, to show the specific signal decrease as activity increases. This assay may be used to screen for DNase inhibitors⁵⁷⁵ (Figure 62).

2.12.11.3.5.2 Reverse transcriptase assay

Inhibitors of reverse transcriptase activity remain a major target for viral research in drug discovery. The following HTRF assay configuration enables one to screen for increases of inhibition of enzyme activity in high throughput. Oligonucleotide primers labeled directly with (Eu)K are added to RNA templates (Figure 63). Addition of reverse

Figure 62 Increasing amounts of DNase enzyme decreases the HTRF signal.

Figure 63 HTRF reverse transcriptase assay configuration.

transcriptase and biotinylated dUTP to nucleotide building blocks creates a biotinylated double-stranded molecule labeled with (Eu)K, to which streptavidin–XL665 is added to complete the reaction. Complete reverse transcriptase activity results in a high HTRF signal. Inhibition would decrease the signal to the extent that the enzyme is blocked. Increasing amounts of reverse transcriptase enzyme results in higher activity, as the HTRF fluorophores are brought into proximity while the double-stranded molecules form^{572,576} (Figure 64).

2.12.11.4 Homogeneous Time-Resolved Fluorescence Assay Optimization

The following sections are included to provide an insight into how one might best develop and optimize an HTRF assay. HTRF assays are normally performed with only a few steps, mainly additions, so there are a smaller number of considerations when designing an HTRF assay than there may be with a more complicated method. The main considerations for optimizing an HTRF assay are buffer selection, whether label (Eu)K or XL665 should be used for each assay component, and what controls should be run.

2.12.11.4.1 Buffer selection and stability

Homogeneous assays by nature involve no washing step, so that all buffer and assay components are present during the ultimate measurement of activity or binding. As a result, the following work has been done to help determine how

Figure 64 Increasing amounts of reverse transcriptase enzyme increase the HTRF signal.

Figure 65 Effects of various buffers and KF on the stability of (Eu)K.

HTRF assays, specifically the (Eu)K component, are likely to perform in various buffers. (Eu)K was added to 200 μL samples of the most commonly used buffers, with and without 50 mM KF. KF provides a fluoride ion, which has been shown to form ion pairs with Eu^{3+} . The fluorescence lifetime was measured to determine if KF had an effect on the stability of the signal of the (Eu)K component as measured at its emission peak of 620 nm. Figure 65 shows that, in all cases, the lifetime of the signal from the (Eu)K label was stabilized and, in effect, equalized by the presence of fluoride ions, illustrating the protective effect of the F^- ion.

2.12.11.4.2 Choice of label for each assay component

(Eu)K and XL665 are both available conjugated with streptavidin, biotin, antispecies, and antiepitope antibodies, as well as a number of other biological components. However, the following recommendations apply. Due to the difference in sizes of the fluorophores, it is better to use the (Eu)K label on the smaller assay component and XL665 on

the larger assay component. In terms of the smaller component, if it can be biotinylated, it is likely acceptable to label it with (Eu)K. XL665 should be used on the component that is in excess in the assay, and (Eu)K should be used on that component that is most sensitive to change.

2.12.11.4.3 Suggested assay controls

For the purposes of assay development and analysis of screening results, the following controls should be run for each assay. A buffer blank should be created that includes buffer only at the volume of the assay. An (Eu)K blank should be included that contains buffer and (Eu)K at the concentration used in the assay. This control enables one to do an (Eu)K background subtract (or 'K blank') to subtract out the small peak that exists at the 665 nm wavelength. Finally, as always, a negative control should be created that includes total assay conditions with something to make it negative (e.g., completely inhibited or inactivated). Using ratio and ΔF calculations and the above controls helps to attain the most reproducible and precise data from the HTRF assay.

2.12.11.5 Overview

HTRF chemistry was developed to help overcome some of the obstacles to HTS in general. It is homogeneous, so that separation steps are eliminated. It is fluorescent in nature but has the time-resolved, simultaneous, dual-wavelength detection that enables one to achieve a high fluorescent signal with extremely low backgrounds. HTRF is best measured on the Discovery HTRF microplate analyzer, because it was designed specifically and optimized for the particular wavelengths of HTRF. However, a number of detection systems are now available for measuring TRF and HTRF applications. The HTRF reagent list is growing; thus, fewer assays require customized conjugation with (Eu)K and XL665. Many of the applications described utilize off-the-shelf reagents that are readily available and require no license fee. As a result, this tool is widely accepted in the literature as one of the few truly homogeneous methods available to meet the HTS demands of drug discovery today.

2.12.12 Screening Lead Compounds in the Postgenomic Era: An Integrated Approach to Knowledge Building from Living Cells

2.12.12.1 Introduction

The new face of drug discovery is focused on the living cell, with its myriad ionic, metabolic, macromolecular, and organellar networks as the ultimate target of drug activity. Wilson essentially set the stage for a cell-centric approach to drug discovery in his introduction to a textbook that was one of the earliest attempts to combine cytology, physiology, embryology, genetics, biochemistry, and biophysics into the newly coined discipline of cellular biology.⁵⁷⁷ Among other insights, he stressed the importance of measurements made on living cells in the presence of "changed conditions in the physical or chemical environment." Since then, there have been countless reports on the characterization of isolated components of living cells. There have also been reports where components from single cells have been characterized. One early approach to single-cell biochemistry, which appeared around the same time that Watson and Crick described the structure of cellular DNA, involved the extraction of nucleic acids from single neurons, their hydrolysis, electrophoresis on copper fibers, and analysis with ultraviolet light.⁵⁷⁸ Although knowledge of the components of the chemistry of life soared during the latter part of the twentieth century, resulting in the modern disciplines of genomics and proteomics, there remains the great challenge of discovering the functional integration and regulation of these living components in time and space within the cell. We envision that the integration of genomics and proteomics with a new knowledge base built from temporal and spatial data on the chemical and molecular interrelationships of cellular components will provide an extremely rich platform for drug discovery.

2.12.12.2 Genomics and Proteomics as the Foundation for Cell-Based Knowledge

Whereas other sections in this chapter specifically expand on the role of genomics and proteomics in modern drug discovery, we view the genome and proteome as important building blocks for the construction of new cell-based knowledge. The genomics era, begun two decades ago, has realized a one-dimensional description of human and other organismal genes, each a potential new drug target. Even those genes coding for molecules other than functional proteins are theoretically new drug targets.

The level of DNA organization in the genome is surprisingly simple. There are an estimated 100 000 genes in the human genome and they are encoded within about 3 billion base pairs of nucleotides. The precise sequence of genes

within the context of these billions of units, which are themselves organized into larger structures such as chromosomes, has been the primary goal of the human genome project. The enormous impact of genomics on drug discovery can be attributed first to advances in automated sequencing instrumentation and reagents. A successive and arguably more important phase of genomics is the association of gene expression to normal and disease physiology. This phase has been empowered by technologies and platforms to measure message level changes in response to drug treatment and new informatics strategies to organize DNA sequence information into logical, searchable, and meaningful databases. Proteomic analysis has become the logical extension of genomics and its associated databases. The daunting task of defining the protein complement expressed by a genome within cells, tissues, and organisms can be rationalized with several arguments.⁵⁷⁹ These include the much less than perfect correlation between mRNA and protein expression levels; post-translational modifications of proteins that affect intracellular localization, activity, or both; and proteome dynamics that reflect the physiological state of the cell, tissue, or organism. Nevertheless, the proteome of a single native organism has yet to be completely described, let alone a mapping of drug activity overlaid onto one. Although proteomic databases are continually growing, both the methodology to measure proteomic changes and the approaches to extract, analyze, and characterize proteomic data have yet to be attacked as systematically as the genomic platform development has been. It remains unclear if current sample preparation methods and two-dimensional protein electrophoresis, the highest-resolution approach available for proteome mapping, will be perfected to the point where an entire proteome can be mapped,⁵⁸⁰ especially as sample sizes diminish toward the single-cell level. Several factors make proteome analysis inherently more complicated than genomic analysis. For example, many genes in the human genome code for multiple proteins depending on mRNA processing; proteins can be post-translationally modified; and proteins may have several distinct functions. Overlaid on the complexity of individual protein molecules are the temporal and spatial interactions between proteins and other molecules. At any one time, there is of the order of tens of thousands of different proteins arranged within a cell. Each protein may have up to hundreds of thousands of copies. Thus, out of the relative simplicity of the genome comes an astronomical number of molecular and biochemical reactions, nearly all of which are mediated by proteins, occurring in time and space within a living cell. As we move into the postgenomic era, the complementarity between genomics and proteomics will become apparent, and the connections between them will undoubtedly be exploited. However, neither genomics nor proteomics, nor their simple combination, will provide the data necessary to interconnect molecular events in living cells in time and space, especially the network of events that targeted drugs inevitably interrupt or modulate.

2.12.12.3 Creation of New Biological Knowledge

A new perspective on drug discovery is cell-centric rather than focused on isolated genes or proteins. Because the cell is the smallest unit of life that can live independently, it must be highly organized to perform life functions. This organization begins at the one-dimensional level encoded by its DNA. The intrinsic information of cellular structure and function is encoded by the simple language of the genome. The translation of genomic language into the proteins and other macromolecules that participate in every chemical reaction occurring within a living cell represents an even higher level of organization than the blueprint held within the DNA. However, cells are not composed of a random collection of these macromolecules, which includes the entire proteome. Additional orchestration of the highly organized interactions of ions, metabolites, and organelles makes cells living entities. The knowledge base of the living cell is built by connecting layers of these interactions into the pathways and networks that govern all aspects of cellular life. Cellomics has extended cell-based knowledge to include cellular responses to drugs, including pharmacokinetic effects as well as pharmacodynamic effects on multiple cellular targets, pathways, and networks under the heading of 'PharmacoCellomics.' All deep biological information will be captured, defined, organized, and searchable in the Cellomics Knowledgebase of cellular knowledge. Just as automated genome analysis and bioinformatics tools are pushing the genomics era to a conclusion, automated cell analysis systems and cellular knowledge will be key to the era of the cell. Coupling of cellular knowledge to the drug discovery process will be essential for faster and more effective drug discovery. Such a process, composed of automated whole-cell-based detection systems, fluorescent reagents, and informatics and bioinformatics, is referred to as high-content screening (HCS).

2.12.12.4 High-Content Screening of Target Activity in Living Cells

The wealth of information obtainable from genomic and proteomic databases has led to at least one bottleneck in the early drug discovery process – target validation. Here, potential targets are evaluated for suitability within new or established drug screens.⁵⁸¹ Once validated, targets are incorporated into primary drug screens that are typically high capacity and high throughput. Large compound libraries can be screened in a relatively short time, thus producing a

plethora of ‘hits,’ that is, combinations of compounds and target activity that meet certain minimum, usually crude, criteria. Due to recent emergent technologies for primary screening, increasingly larger numbers of hits have created another bottleneck at candidate optimization, where hits are qualified to leads through structure–activity relationship investigations, cytotoxicity, and secondary screening assays.⁵⁸¹ Thus, both bottlenecks have arisen as a consequence of advances in technology, especially miniaturization and automation, at their respective preceding steps in the drug discovery process. To break these bottlenecks, Cellomics has developed HCS to automate steps downstream of bottlenecks and to obtain deeper biological information from cells. Cellomics’s goal is to reduce the high failure rate of lead compounds by providing high biological content information at earlier stages in the drug discovery process. Such HCS information elaborates both temporal and spatial measurements of single or multiple target activities within cell populations at the level of single cells. Although the details about HCS reagents, automated imaging analysis systems, and the bioinformatics support have been described elsewhere,⁵⁸¹ some of the advantages of HCS are listed here (Table 25). It is important to stress that HCS is a platform for knowledge building; its advantages are derived from the unique combination of its component technologies.

HCS starts with live cells. Following compound treatment of live cells, two different HCS approaches can be taken. In one approach, cells are fixed and, in many cases, fluorescently labeled, prior to imaging analysis. The advantages of fixed-endpoint HCS include the flexibility to analyze samples without time constraints and the ability to optimize and augment analysis because fixed samples can be repeatedly processed and reanalyzed. Several single- and multiparameter assays have been designed using fixed-endpoint assays. These assays, designed and validated by Cellomics and several pharmaceutical companies, include transcription factor activation and translocation,^{581,582} microtubule reorganization,⁵⁸³ G protein-coupled receptor internalization,⁵⁸⁴ and apoptosis.⁵⁸¹ A second approach to HCS is the live cell kinetic assay. In this mode, temporal as well as high-content spatial data on target activities are collected and analyzed simultaneously.

Designed specifically for HCS, the ArrayScan VTI system, developed by Cellomics, detects multiple fluorescence channels over the visible spectrum within living or fixed cells prepared with corresponding fluorophore-labeled targets. Importantly, the ArrayScan VTI system is distinguished from standard fluorescence microscopy systems by its fully automated acquisition, processing, and analysis of cell images with the capability of arraying cells in stacks of

Table 25 Advantages of HCS in the early drug discovery process

Cell-centric physiological context

- Target activities are measured within multiple living cell types
- Entry of drugs into specific cellular compartments is measurable
- Screening can be accomplished within mixed cell types
- No need to isolate and purify targets
- Effects of compounds on cell structure, communication, and development can be measured
- Cellular functions (e.g., division, endocytosis, and motility) become quantifiable drug targets
- Signal detection is done within volumes of the order of a picoliter
- The entire screening process can be miniaturized (e.g., the CellChip platform)

Multiparametric approach to screening

- Drug specificity is assessed by simultaneously measuring competing targets in the same cell
- Measures of toxicity are accompanied by target activity values
- Measurement of activities downstream of target activity is possible
- Unanticipated side effects of compounds can be measured

Automation of complex tasks

- Sample preparation uses optimized fluorescent reagent kits (e.g., HitKit existing automation technology)
- Imaging algorithms extract target activity values concurrent with data collection
- Automated kinetic assays that include automated liquid handling are possible

Generation of new biological knowledge

- New data management technology transforms enormous amounts of raw data into meaningful information
 - Couple genomics, proteomics, and compound library databases with HCS data using the linking tools provided by the Cellomics Knowledgebase
 - Discover complex cellular pathway interrelationships and the effect lead compounds have on them using the data-mining tools in the Cellomics Knowledgebase
-

high-density microplates. The ArrayScan VTI system has a total magnification range from approximately $10\times$ to $400\times$. This gives optical resolution ranges from less than $1\mu\text{m}$ for subcellular spatial measurements to hundreds or thousands of micrometers for field-based measurements. During acquisition, fields of cells are automatically identified, focused upon, exposed, and imaged using a cooled charge-coupled device camera. A high-capacity plate stacker enables 'walk-away' operation of the system, and a live-cell environmental chamber maintains optimal temperature and atmospheric conditions for kinetic screening. Details of the unique multiparameter HCS capabilities of the ArrayScan VTI system are presented elsewhere.^{581,1104}

The Cellomics KineticScan HCS Reader was designed to automate large-scale HCS of live cells, specifically facilitating drug-induced kinetic studies, by virtue of a 30-plate incubated plate stacker, on-board fluidics, and plate handling. Additional distinguishing features include eight excitation and eight emission channels, a continuous-focusing system, a fluorescence polarization capability, and a higher HCS throughput capacity. Currently, no alternative automated HCS platform exists for live cells. The KineticScan HCS Reader can be used as a stand-alone screening workstation or as a module within an integrated drug discovery platform comprising both high-throughput and high-content screening. Both fixed-endpoint and live-cell kinetic HCS assays provide a cellular context that *in vitro* assays of target activity do not match.

2.12.12.5 High-Content Screening of Drug-Induced Microtubule Cytoskeleton Reorganization

As detailed above, HCS assays fall into two general classes: fixed endpoint and kinetic. Here, we demonstrate both assay types in the quantification of microtubule targeted compounds. In the first assay, cells are treated with drugs, incubated for various times, fixed, and labeled to visualize microtubules. The labeling procedure involves immunofluorescence to visualize cytoplasmic microtubules. Figure 66 shows the results of an assay where mouse fibroblasts have been treated with several known microtubule-disrupting drugs. The effects of these standard drugs are being used in the development of imaging algorithms to automatically classify and quantify the effects of potential lead compounds on the microtubule cytoskeleton.

Apart from immunofluorescence-based reagents, live-cell kinetic HCS assays necessitate the use of molecular-based fluorophores, most notable among them is the green fluorescent protein (GFP) from jellyfish⁵⁸³ and other sources.⁵⁸⁵ Protein chimeras consisting of mutant GFP molecules and a protein that interacts specifically with intracellular microtubules have been constructed, and at least one has been reported.⁵⁸³ We present here a chimera that has been transfected into cells and acts to provide live measurements of microtubule dynamics in living cells. Figure 67 shows cells transfected with this fluorescent chimera, which converts the cells into HCS reagents, and the effects of drugs on the microtubule cytoskeleton in these engineered sensor cells. In these cells, with this reagent, the microtubule-disrupting drugs had just as profound an effect on microtubules as they did in the fixed-endpoint assay described above. Although not shown here, the kinetics of microtubule disruption were measured over periods ranging from seconds to hours using these chimeric HCS reagents. Nevertheless, the data shown here represent well the cytoskeletal reorganization and microtubule dissolution that these drugs induce in living cells. Imaging algorithms similar to those developed for the fixed-endpoint assay of microtubule reorganization are being developed for the live-cell assay, but they contain a kinetics component as an added dimension. Therefore, the reagents described above for the fixed-endpoint and kinetic assays can be used either alone or in conjunction with other reagents to form the basis of multiparameter assays, a powerful application of HCS.⁵⁸¹

2.12.12.6 Specialized Fluorescent Reagents that Find Dual Use in High-Content Screening and High-Throughput Screening

In many cases, high-content screens involve intracellular spatial measurements (e.g., translocation of molecules between cellular compartments), yet there is a class of screens where the fluorescent reagents can be engineered to yield high-content data from a high-throughput read-out. That is, using the example of intracellular translocation as an illustration, a fluorescent reagent can be designed not only to translocate between cellular compartments in response to some molecular activity but to alter its fluorescence spectral properties upon translocation. Thus, a measurement of the spectral change of the reagent, rather than a high-resolution measurement of spatial distribution, is used as a reporter of an intracellular translocation. Such dual-use reagents that report both their dynamic distribution and activity within living cells are often designed from macromolecules and are termed fluorescent protein biosensors.^{586,587} Careful design of HCS reagents therefore makes it possible to build powerful platforms where high-throughput and high-content screens can be coupled.

Figure 66 A fixed-endpoint, high-content assay of microtubule disruption. Mouse fibroblasts were treated with drugs followed by the visualization of the microtubule cytoskeleton using immunofluorescence techniques. The cells were treated as follows: (a) no treatment, (b) paclitaxel, (c) curacin A, (d) nocodazole, (e) staurosporine, and (f) colchicine. Each drug had a distinct effect on cell morphology and microtubule organization. Scale bar = 20 μm .

An example of a relatively simple fluorescent reagent that finds dual use in high-content as well as high-throughput assays is JC-1, a fluorescent dye that partitions preferentially into live mitochondria and acts as a reporter of membrane potential within the organelle.^{588,589} JC-1 monomers (green fluorescence) are present in regions of mitochondria that exhibit relatively low membrane potential, whereas JC-1 aggregates (orange fluorescence) partition preferentially into regions of relatively high membrane potential. **Figure 68** shows an orange fluorescent image of JC-1 (Molecular Probes) in porcine epithelial cells. At the magnification shown, it was possible to resolve numerous mitochondria in a population of living cells. Furthermore, a heterogeneous distribution of JC-1 aggregates was measured in a single mitochondrion. Thus, a high-content measurement of JC-1 monomers and aggregates in living cell mitochondria can be used not only to assess the effects of lead compounds on mitochondrial physiology but also to identify the mitochondrial compartment as a fiduciary marker for the co-localization of other fluorescent reagents in the same cell.

JC-1 also finds use as a fluorescent reagent for high-throughput live-cell screening. The fluorescence signals emanating from all the cells can be measured simultaneously for both the monomeric and aggregated forms of JC-1 using, for example, a fluorescence microplate reader. Unlike the ArrayScan VTI system, a microplate reader provides no cellular spatial information, but rapidly assesses average cellular mitochondrial potential by measuring the ratio of green

Figure 67 A live-cell reagent for kinetic high-content screening of microtubule disruption. Porcine epithelial cells were transfected with a plasmid encoding a chimera composed of a protein that readily incorporates into cellular microtubules and a mutant GFP. (a) Cells showing the distribution of microtubules in untreated cells, with the inset depicting a brightly labeled spindle in a mitotic cell. The other panels show the effects of microtubule disrupting drugs that include (b) vinblastine, (c) curacin A, and (d) colchicine.

Figure 68 Porcine epithelial cells labeled with JC-1. LLC PK cells were labeled in culture with JC-1, and this micrograph depicts the intracellular distribution of the fluorescent probe. Once added to the extracellular medium, JC-1 rapidly crosses the plasma membrane and partitions specifically into mitochondrial membranes, where it reports the electrical potential.

Figure 69 A prototype high-throughput assay for drugs that alter the mitochondrial potential. LLC PK cells, labeled with JC-1, were either left untreated (circles) or treated with 10 nM valinomycin (triangles) at time = 0. Kinetic measurement of the JC-1 fluorescence ratio is used to quantify the loss of mitochondrial membrane potential induced by the ionophore valinomycin. A high-throughput assay using this approach would simultaneously measure mitochondrial potential changes in multiple wells of a microplate.

and orange fluorescence from an entire monolayer of labeled cells. **Figure 69** shows an example of living cell mitochondrial potential measurements made with a fluorescence microplate reader. The kinetic data are presented as a fluorescence ratio (JC-1 aggregate/JC-1 monomer) that is independent of dye concentration but proportional to the mitochondrial potential averaged across an entire well. The kinetic trace for untreated cells exhibits a small decrease over the first minutes, which is likely due to the cooling of the cells within the microplate reader as well as the change in cell medium pH that occurs with the transfer of the microplate from an incubator (5% CO₂) to atmospheric conditions. Nevertheless, a significant decrease in mitochondrial potential was measured upon the addition of an inhibitor of oxidative energy production, valinomycin, to the living cells. Thus, a high-throughput assay of mitochondrial potential can be used to qualify promising lead compounds for more sophisticated high-content assays that may include spatially resolved mitochondrial potential measurements as well as macromolecular translocations^{581,582} and organellar functional morphology changes within a population of the same cells.⁵⁸⁴ Dual-use fluorescent reagents therefore will find utility in many distinct aspects of the drug discovery process, and become reagents that are even more powerful when used to couple high-throughput and high-content assays on the same drug discovery platform.

2.12.12.7 Coupling High-Throughput Screening and High-Content Screening with Microarrays of Living Cells: The Cellchip System

Miniaturization of assays is one of the major forces driving improved productivity in early drug discovery.^{590,591} New drug development technologies and the explosion in genetic data as a result of the Human Genome Project have driven the development of miniaturized test beds or 'biochips' for genetic analysis based on microarrays of nucleic acid sequences. These biochips encompass a very diverse array of technologies and applications. Imprinted with several hundred different nucleic acid sequences, biochips use electro-optical means of addressing applications ranging from expression analysis to genotyping and mutation screening.^{592,593} Biochips integrated into sample processing, metering, measuring, mixing, and sorting systems have laid the foundation for miniaturized 'sample-to-answer' systems. The first generation of biochips is focused on surface-anchored oligonucleotides and oligopeptides whose information content is dictated by the four-character nucleotide language of the DNA or the 20-character language of amino acids. Furthermore, the single-stranded DNA oligonucleotides are limited in their information content and applications, as they do not provide information on DNA-protein and other interactions.⁵⁹⁴

Figure 70 Colonies of cells microarrayed on polymer- and glass-solid phase supports. Each domain is fluidically and optically isolated. This enables massive parallelization of assays on a single chip. The production of a library of chips, where the library encompasses multiple cell types and multiple biochemical pathways, enables high sample throughput coupled with high information output of the pharmacological profile of compound libraries.

We believe that miniaturized cell arrays constitute the next logical frontier in early drug discovery. The multidimensional language of cellular physiology is only partly described by the combinatorial integration of nucleotide and amino acid languages. When high-content screens of living cells arrayed on miniaturized solid supports are used to dissect this complex language, they provide deep biological information on target distribution and activity in space and time. The Celloomics CellChip system is a combinatorial of surface chemistries, cell and tissue types, and HCS fluorescent reagents. On the chip, single or multiple engineered cell types are microarrayed in predetermined spatial addresses (**Figure 70**) on an optically clear polymer- or glass-solid phase support substrate.⁵⁹⁰ The ‘footprint’ of each cellular domain can be adjusted to accommodate either a single cell or a colony of cells. The cell adhesive domains can be populated either with a single cell type or with multiple cell types by adhesive cell sorting from a mixed-cell population, according to selective adhesive interactions with particular cell-specific ligands coupled to the individual domains.⁵⁸¹

HCS assays designed for microplates have been successfully transferred to the CellChip system. One of these assays – the cytoplasm-to-nucleus translocation of intracellular molecules – is a class of cell-based screens that tests the ability of candidate drug compounds to induce or inhibit transport of transcription factors from the cytoplasm to the nucleus. Sensor cells arrayed on CellChips are treated with a combination of chemical entities. The assays can be run as fixed-endpoint or live-cell kinetic assays. For example, in a fixed-endpoint assay, an array of sensor cells is treated with a chemical fixative and labeled with a fluorescent nucleic acid probe and an antibody against the transcription factor or stress-associated protein labeled with another fluorescent conjugate. The test consists of measuring the fluorescence from the antibody in the nucleus (the nucleus being defined by the nucleic acid probe), versus the cytoplasm defined by the cell domain outside of the nucleus. Proprietary algorithms facilitate quantification of the kinetics and the amount of transcription factor or stress protein translocation into the nucleus over time.⁵⁸² Using a polymer-based CellChip system, the activation-induced translocation of NF- κ B, a transcription factor involved in cell stress molecular pathways, in response to tumor necrosis factor- α (TNF- α) has been quantified. Appropriate cellular domains on the CellChip platform were dosed with TNF- α ; the cells were fixed, permeabilized, and labeled for the NF- κ B p65 and nuclear domains (NF- κ B Activation HitKit – Celloomics). As seen in **Figure 71**, there was a redistribution of the transcription factor to the nucleus because of stimulation. There was up to a fourfold increase in both the normalized nuclear intensity and the normalized ratio between nuclear and cytoplasmic intensities post-translocation. This increase is equivalent to the results obtained using the microplate platform.⁵⁸²

The advantages offered by miniaturization of a drug discovery platform include (1) a combined HTS and HCS platform with a single-pass read of the HTS data from all ‘wells’ prior to HCS ‘drill-down’, (2) higher throughput, (3) reduced processing time, (4) an increased number of tests run in a massively parallel format on one substrate, (5) smaller reagent volumes, (6) conservation of new chemical entities, and (7) reduced waste. The integration of such advantages translates into a dramatic reduction of cost and the acceleration of productivity in candidate compound testing. For example, migration of assays from 96-well microplates to 1536-well microplates reduces the reagent cost by 100-fold. Migration from the 96-well microplate format to microarrayed cells on chips will further reduce the volume of reagents and the cost of plate handling. For example, a chip with microarrayed cells in a density format of 100 wells cm^{-2} will reduce the reagent cost by 500-fold from the 96-well format. Furthermore, developing chips microarrayed with

Figure 71 Mammalian cells contained within the CellChip system employed in a high-content screen for transcription factor activation. As a result of stimulation with a proinflammatory factor such as $\text{TNF-}\alpha$, there is a spatial redistribution of NF- κB . There is a fourfold increase in normalized nuclear intensity post-stimulation. (a) Unstimulated cells on the polymer-based CellChip platform. (b) $\text{TNF-}\alpha$ stimulated cells on the polymer-based CellChip platform.

tissue-specific cells will have a tremendous impact on screening the potency, specificity, toxicity, and efficacy of test compounds against a ‘tissue-like’ ensemble, leading to higher predictive relevance of the live-cell data. Developing multiple cell-based test beds microarrayed in addressable biochips will facilitate the use of these ‘microscale tissues’ as powerful indicators and predictors of the *in vivo* performance of the lead compound or toxin using HCS.

The evolution of a miniaturized cell-based drug discovery and identification platform, the CellChip system,^{581,590} a variant of the generic biochip, will march in tandem with other miniaturization technologies aimed at shrinking benchtop instruments into their hand-held miniaturized versions.⁵⁹⁵ The integration of HTS and HCS onto a single platform (Figure 72) will meet the high-sample-throughput and high-information-output needs of the pharmaceutical industry. This combined platform will reduce the data capture, processing, and analysis times, and provide a complete cell-based screening platform. Developing technologies to enable arrays of multiple cells on glass or plastic chips, with each cell carrying its own reagents in the form of single or multiple fluorescence reagents, including fluorescent protein biosensors,⁵⁸⁷ adds multidimensional power to a complete drug-screening platform. Furthermore, reagent and assay technology developments made on platforms based on the present HCS technology or standard microplates will migrate directly to the CellChip system.

The future of biochips in early drug discovery is bright because enabling HTS technologies, such as biochip platforms for screening, have captured the attention of the biopharmaceutical market. The early biochips were designed for applications driven by genomics. ‘Gene chips,’ such as those manufactured by Affymetrix, have captured a significant portion of a billion dollar HTS market since the completion of the Human Genome Project. Close on the heels of the ‘gene chips’ are ‘protein chips’ that exploit the proteome as a tool for drug discovery. The CellChip system will build on present and future genomic and proteomic databases to provide multidimensional measures of cellular physiology. Furthermore, the integration of high sample throughput with high information output on the CellChip system will yield faster and more efficient winnowing of ‘leads’ from ‘hits,’ thereby optimizing the selection of the compounds early in the process of drug discovery.

2.12.12.8 The Cellomics Knowledgebase – A New Paradigm for Bioinformatics: Creation of Knowledge from High-Content Screening

Genomics, proteomics, and the knowledge base built from cellular information are critically important to the drug discovery process. The Cellomics Knowledgebase is the logical extension of genomics and proteomics because it defines the organization and analysis of cellular information based on new knowledge. The Cellomics Knowledgebase will contain all the knowledge related to cell structure and function. Pharmaceutical researchers will interact with this knowledge base in a biologically intuitive way to explore cellular mechanisms to be able to select optimal targets for drug discovery and to screen potential lead compounds more effectively.

Figure 72 Combining HTS and HCS on the same platform. The massive parallelization achievable with miniaturization is shown in a simple simulation on this surface-modified plastic platform. The HTS is simulated here to detect 'hits' on the miniaturized chip platform. Lack of fluorescence signals in wells E3, F3, A3, and B4, for example, indicates 'non-hits.' HCS measurements are then made only on the 'hit' wells, to gain more in-depth information to produce more 'highly qualified hits.' Further depth and breadth of information can be obtained by arraying multiple organ-specific cells on a single chip and fluidically addressing each domain with a reagent of choice.

The Cellomics Knowledgebase captures the complex temporal and spatial interplay of all the components that compose the living cell. For example, the process of signal transduction relies on a highly coordinated network of intracellular ions, metabolites, macromolecules, and organelles. Most signal transduction processes are therefore a series of specific physical-chemical interactions. In this aspect, the functioning of a cell is conceptually similar to that of a computer neuronetwork. Computer neuronetworks are composed of simple subunits that perform rudimentary mathematical operations. However, there are many such units and, most importantly, these units are highly connected, using the output from one unit as the input for another. Cellular signal transduction offers a parallel strategy to the neuronetwork approach; the basic units of signal transduction are proteins and other cellular components. Each component can participate in one or more cellular functions while involved in a complicated interaction with one or more other cellular components in time and space. Therefore, the design of the Cellomics Knowledgebase reflects the functional significance of the interactions among the cellular constituents. [Figure 73](#) illustrates cellular interactions by showing a simplified fragment of the model for the Cellomics Knowledgebase. This fragment captures the core information of cellular pathways. This core is composed of a record of interactions of cellular constituents and the logical connections among these interactions. The cellular constituents are abstracted into the 'functional unit' class in the model. A functional unit can be either a 'component' or an 'assembly.' A component represents a single protein, metabolite, or other cellular constituent together with external stimuli. An assembly is composed of functional units, meaning that it can be made up of individual components or other assemblies. Functional units, assemblies, and components record the interactions of cellular constituents. The logical connections of these interactions are recorded in the 'transformation' class. A transformation can have many functional units acting as inputs, outputs, and effectors. For example, in the simple transformation depicted in [Figure 74](#), the chemical conversion of a substrate into a product is catalyzed by an enzyme, a motif that is repeated for many of the hundreds of millions of chemical reactions that are occurring simultaneously in a living cell. In this model, for the transformation from the substrate to the product, the substrate acts as the input, and the output is a chemically altered product. In this case, an enzyme acts as an effector. If we drill down on any of the components shown in the scheme, we find that each may be a complex assembly made up of more components that maintain their own temporal, spatial, and chemical properties within the living cell. For

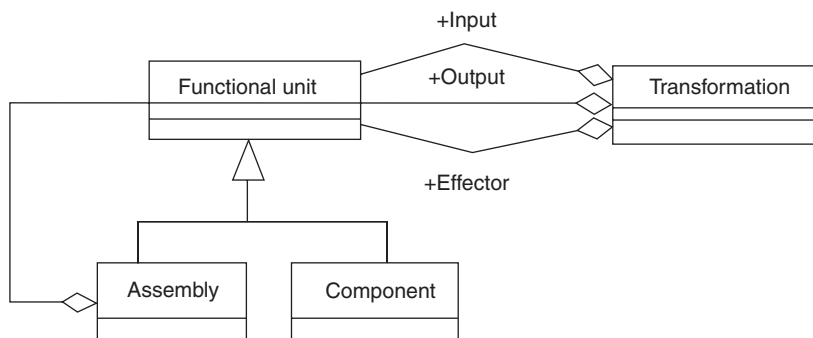

Figure 73 Fragment of the UML (unified modeling language) model for the Cellomics Knowledgebase.

Figure 74 A transformation.

example, if the enzyme chosen in the model as an effector is pyruvate dehydrogenase, the enzyme that couples two major oxidative metabolic pathways, we find that it is itself a complex macromolecular assembly. The pyruvate dehydrogenase complex comprises multiple copies of three distinct enzymes that require five coenzymes for activity.⁵⁹⁶ The pyruvate dehydrogenase complex is precisely assembled to optimize the oxidation of pyruvate to acetyl coenzyme A and CO₂. In eukaryotes, the enzyme complex is further localized into a higher-order structure, the mitochondrion, which in turn exhibits a temporal and spatial distribution of activities or transformations within the cell. Therefore, constituents of the transformation class exist as collections of cellular components in time and space from the continuum of ions, metabolites, macromolecules, and organelles.

Having captured cellular interactions, the design of the Cellomics Knowledgebase must also take into account the unique features of cell biological information, such as:

- The flow of information from genomics to proteomics to the living cell. Any insight into the function of cell biology will require seamless integration of information across this continuum.
- Cell biological information is often incomplete or in an unconfirmed state. For example, we need to be able to record the fact that a protein X interacts with an experimentally isolated assembly Y, although Y is not characterized well and the components of Y may be unknown. The database must be flexible enough to be rapidly and accurately updated as unknown components become characterized entities.

How might cellular knowledge be best visualized and probed by the user? One common way to represent cellular knowledge is through pathway diagrams. There are many well-defined metabolic and signaling pathways, but, in isolation, they have lost their physiological context. In reality, pathways often intersect with other pathways to form networks of molecular interactions. Within the Cellomics Knowledgebase, a pathway is a collection of transformations. This collection contains the same functional units and transformations as defined in a well-known pathway, and it can be generated de novo from a database query. Hence, the term ‘molecular wiring diagrams’, instead of ‘pathway diagrams’, is used by Cellomics to describe these connections.

The Cellomics Knowledgebase will also provide a new generation of data-mining capabilities. For example, the Cellomics Knowledgebase will provide functions for the analysis of complex cellular response patterns to drug candidates. Data-mining tools will make possible automated comparison of these patterns with the patterns of successful and unsuccessful leads, to guide the user further down the drug discovery process.

In summary, the Cellomics Knowledgebase is a knowledge management tool for cell biology and cell-based drug discovery. In the drug discovery process, knowledge is generated from 'data' and 'information.' Data are the measured values from cellular events that have been acquired, such as from HCS. Information is the result of putting data into a relevant context. For example, an HCS value becomes information when related to a particular assay with specific parameters such as cell type, reagent or reagents used, and the structure and concentration of the drug used in the assay. Knowledge therefore is the understanding of the biological meaning of information. With this understanding, the acquisition of data can be modified, and new information extracted to further improve the knowledge base. Knowledge is synthesized by forming connections between disparate pieces of information. Thus, the Cellomics Knowledgebase strives to provide tools for the analysis and visualization of these connections, such as the connection between screening results, compound structure, and biological context. This connection, and the knowledge built from it, will enable researchers from diverse backgrounds to interpret and utilize new and established information, thus unifying multiple screening projects from multiple laboratories.

The construction of complete cellular knowledge will be achieved with deliberate steps of discovery. Being able to incorporate these incremental discoveries into the context of the existing knowledge through the Cellomics Knowledgebase will become critical to a systematic understanding of cell biological functions. We believe that the pharmaceutical industry will be a primary beneficiary of this new level of understanding.

2.12.12.9 Prospectus

An epoch is rapidly approaching in which the sequence of many organismal genomes, including that of humans, will be deciphered and in which a genomics knowledge base will be built on the foundation of the voluminous data. Nevertheless, we envision this period in the near future as a prologue to the era of the cell where life science discovery, especially in the pharmaceutical industry, will be cell-centric rather than focused on isolated genes and proteins. New thinking will be required to interpret the exceedingly complex web of molecular processes that compose life at the cellular level. How, then, will we begin to unravel the integration of living components in time and space within cells? We predict that an amalgamation of molecular biological, biochemical, and cell biological disciplines will be tapped to supplant cells into being reporters of their own molecular activities. Furthermore, a novel approach to informatic and bioinformatic knowledge building integrated with a miniaturized platform for cellular data acquisition will become a major force in defining and shaping the molecular circuitry of the cell.

Several issues will be resolved during the evolution of the integrated technologies that will be required to define and structure cellular knowledge. First, new generations of luminescent reagents, including fluorescent protein biosensors, will be necessary to simultaneously measure multiple molecular processes in time and space within living cells. Innovative engineering of cells and the surfaces with which they interact will ensure that a wide range of cell types (adherent and nonadherent, mixtures of cell types, etc.) will be amenable to HCS. A fully automated system for extracting cellular data from images will speed the analysis of multiple cellular pathways and provide for computation concurrent with data acquisition. Finally, a fresh approach to informatics and bioinformatics will combine published data of cellular chemistry with HCS data into an unrivaled knowledge base of the multidimensional processes involved in the molecular basis of life. Therefore, the key to unlocking the door to this new era will be the intuitive integration of technologies required to decipher the language of the cell.

2.12.13 Miniaturization Technologies for High-Throughput Biology

2.12.13.1 Introduction

A strategy is summarized for the integration of cellular biology with instrument systems to miniaturize fluid delivery, assay containment, and detection for HTS and biological research. Specific components of the process include the handling of microliter scale volumes of liquids (microfluidics), fluorescence detection, sample handling, and bioassay technology amenable to high-density formats. The components enable ultrahigh-throughput (e.g., 100 000 samples per day) biological assays. These systems provide the increased productivity required for determining gene functions in a whole-cell context. Miniaturization of these technologies is essential to achieve the goal of 100 000 samples per day.

2.12.13.1.1 Key integrated miniaturization technologies

The key miniaturization technologies for high-throughput biological assays are:

- Small-volume assay plates (e.g., Aurora NanoWell plates).
- Sample handling and liquid dispensing:
 - piezo-based aspiration and dispensation;
 - solenoid valve-based aspiration and dispensation; and
 - reagent dispensation – cells, dyes, media, etc.
- Fluorescence detection.

This section discusses these technologies, using the procedures and instrumentation of Aurora as examples.

2.12.13.1.2 Why is miniaturization critical to ultrahigh-throughput screening development?

Miniaturization of the assay reactions enables conservation of compounds, reagents, and biologicals, and makes facile the scale-up for parallel (simultaneous) screening of a large number of compounds. Ultimately, miniaturization of the assay reaction is a critical and essential aspect of achieving high-throughput sample processing. Materials handling, robotic speed, material cost, and other logistical aspects would ultimately prevent optimal deployment of a high-throughput (>100 000 samples per day) system without assay miniaturization and increased reaction well density in the assay plate. Successful miniaturization requires optimization of the assay, the cell density, the expression level of the active read-out protein, and the fluorogenic substrate concentration inside the cells to provide sufficient signal intensity to facilitate rapid measurement of the activity of the cellular process under study. Typical assays are staged with positive and negative controls run in separate assay wells such that endpoint readings of fluorescence provide meaningful data, and the determination of kinetics is unnecessary. Kinetic or rate measurements are possible with the instrumentation, but typically require additional time-based liquid additions or optical measurements in order to establish analyte concentration.

2.12.13.2 The Screening Process

2.12.13.2.1 Assay development

Aurora is developing assays for cellular physiological processes based on fluorescence resonance energy transfer (FRET). In FRET, excitation energy is transferred from one fluorophore (the donor) to another fluorophore (the acceptor) when the two molecules are in close proximity (<10 nm) and in the optimal relative orientation, and the emission spectrum of the donor overlaps the absorption spectrum of the acceptor. Aurora has developed a variety of energy transfer fluorophore pairs that undergo efficient energy transfer when the donor is excited. Some of these FRET pairs are covalently bonded together, and this bond is broken to detect molecular change. Other FRET pairs are spatially associated but not covalently linked. The FRET rate constant is quantifiably diminished after the critical association between the donor and acceptor fluorophores is disrupted. FRET can also be effected by the bringing together of a donor and an acceptor. Either method provides a clear read-out of the molecular event. Aurora has commercially developed three different types of FRET-based fluorophores: Green fluorescent protein (GFP) and its variants, a gene expression reporter that is intrinsically fluorescent; β -lactamase, an enzyme-based reporter that cleaves a FRET-based substrate; and the voltage potential dyes, which make possible the detection of voltage potential across a cell membrane. The gene expression reporters can be introduced into the cell by transfection of the cell, with a plasmid encoding its sequence. Regulatory elements incorporated upstream from the enzyme-coding sequence can be specified to enable linking expression of the reporter with cellular physiological processes and signal transduction cascades. Some of the fluorophore pairs under development by Aurora are as follows:

- Pairs of mutated GFPs with overlapping fluorescence spectra. The proteins are covalently linked by an amino acid sequence tailored to be the substrate for specific proteases, phosphatases, and associative binding mechanisms.
- Coumarin and fluorescein dyes linked by a cephalosporin moiety that is a substrate for bacterial β -lactamase. The combined dual-fluorophore compound is synthesized in a cell membrane-permeant acetoxy ester form that can be passively loaded into cells and activated into the fluorescent form by endogenous esterases. With this compound, cells are transfected with an expression plasmid encoding β -lactamase under control by transcription factor elements that are gene regulatory elements for the physiological signal transduction cascade that is of interest to the investigator.

Figure 75 The Aurora UHTSS. The compounds are stored in industry-standard 96- and 384-well storage plates in the store. Compounds are screened for effects on physiological processes (probed in the assay cell lines) by automated selection from the store and conveyance of the compound plate to replication stations, where compounds are prepared for assay. Assays are staged by combining the compounds with assay reagents and cells in miniaturized reaction vessels at the microfluidic stations, incubating the reagents, and measuring fluorescence of donor and acceptor fluorophores at the detector.

- Coumarin dye linked to the headgroup of phosphatidylethanolamine and bisoxonol cyanine dye is a lipophilic fluorophore pair that partitions to lipid bilayer membranes of cells from the aqueous phase. Since the distribution of the charged oxonol is determined by the membrane potential of the cell, this probe pair is suited to assay membrane ion channels.

Assays are developed by transfection of cells with the desired expression plasmid. Once a cell type is successfully transfected and the transfected cells are selected and propagated as a clonal cell line, the miniaturized assay is ready for staging. Assays are constructed by the addition of the cells and the fluorogenic substrates in combination with either activators or inhibitors of the physiological process under study, together with the chemical compound under test in a reaction well. Fluorescence intensities of the donor and acceptor are measured under donor excitation. Aurora has constructed the Ultra-High-Throughput Screening System (UHTSS) as an industrial platform that automates the performance of miniaturized assays in a replicated format that can screen a large number of chemical compounds in a single pass through the platform (Figure 75). The UHTSS has been developed to enable reliable miniaturization of the construction and measurement of FRET-based cellular assays.

2.12.13.2.2 Compound distribution

Chemical compound libraries are screened by introducing the compound in cellular physiological assays, to determine whether the compound exerts a pharmacological effect and is of physiological interest. Library screening demands considerable precision of automation to handle the vast number of compounds in libraries, and accurate liquid handling to preserve a stock of potentially valuable material for a large number of assays. A database is used to maintain the information on each compound, such as its location in the storage facility, its well location in a bar-coded storage microplate, its stock concentration, and assay information such as the details of cellular assay experiments. Key automated steps are the retrieval of storage plates and redistribution into assay plates. High-throughput compound distribution is achieved with automated liquid handling, to enable a large number of parallel assays to be run on a large number of compounds at the same time. This requires that liquids be distributed rationally by the automation system into arrays of reaction wells that provide for a scientifically significant screen to ensure that each chemical compound is tested in a physiological assay and to decrease the possibilities of false-positive or false-negative responses that necessitate retesting. Miniaturization demands that the very small quantities of material be delivered accurately and precisely to individual small reaction volumes.

2.12.13.2.3 Loading the assay

To facilitate the construction of parallel assays for large numbers of test compounds at a time, special high-density reaction well formats have been created that enable scaling of biological assays to the reduced volume required. To

construct assays in small volumes requires the confluence of accurate and precise fluid handling, the automated positioning of fluid dispensers, and assay well design, to avoid a series of potential pitfalls inherent in miniaturization. Thus, assays are constructed by bringing reaction wells that are formatted to evolving industry-standard designs under arrays of multiplexed fluid dispensers from which are ejected the constituents of the reaction. These include the engineered cells developed to serve as chemical and physiological platforms for the reaction, the cell culture medium, the buffers and any particular reagent requirements, the cell-permeant dual fluorophore, the traditional agonist (or antagonist) used to stimulate the transduction pathway, and the chemical compound under test. Each reaction requires a particular concentration of reagent or compound, and the delivery of each chemical may be constrained by particular physical properties such as solubility. Thus, loading an assay to a total final volume of 1–2 μL requires combining assay constituents that are dispensed in volumes that may range from 0.1 to 1 μL (i.e., a range of 10 000-fold). This range of volumetric liquid delivery requires dispenser modalities that are adapted and suitable for specific ranges of volumes such as 0.1–10 μL or 0.1–10 nL. Each range of dispensing is performed by a single modular platform that can be replicated for the different reagents or to improve speed of delivery. Typically, at these volume ranges, noncontact dispensation methods have inherent advantages over contact-based methodologies. Contact-based dispensation can be particularly effective in a ‘touch-off’ mode with larger volumes or in dry plates, but becomes cumbersome for small volumes.

2.12.13.2.4 Incubation

With cellular physiological assays, biochemical action occurs predominantly inside the cells, even with cascades that are triggered at the cell surface, such as agonist binding to a receptor. Thus, once the assay is loaded into the reaction well, the cells are incubated to enable:

- (1) The generation of a steady state level of the expressed read-out enzyme. This is determined by the activation (or inhibition) of the signal transduction cascade under study by the added agonist (antagonist) and the concomitant effect of the test compound (if any) on the steady state level of activation of the pathway. The steady state level of the read-out enzyme is a direct indicator of the level of pathway activation.
- (2) The membrane-permeable dual-fluorophore compound (chemical name CCF2/CCF4) permeating the cells and becoming fluorescent by the action of endogenous esterases on the acetoxymethyl esters that facilitate membrane permeation.

This requires that the cells be incubated to achieve physiological steady state after assay loading. Assays are typically constructed in several steps:

- (1) the cells and medium or buffer are loaded, and the cells are allowed to attach to the reaction well bottom in one step;
- (2) the physiological activators and test compound are loaded in other steps; and
- (3) the reagents necessary for the fluorescent read-out are loaded.

Each step may be performed at a different temperature. The challenge for miniaturization in large formats is that both the high-density format array of (miniaturized) reaction wells and the incubator must be optimized for the maintenance of physiological conditions. This includes the maintenance of the atmospheric conditions of relative humidity and temperature, as well as buffer capacity (percentage of CO_2), at levels propitious for cell survival and for the avoidance of evaporation over the periods needed (up to 24 h) to stage the assay. In addition, this places demands on the plate material to be favorable for the growth of cells, i.e., no toxic constituents that interfere with cell survival, no materials that contribute to the fluorescence background, and high thermal conductivity to enable uniform warmth.

2.12.13.2.5 Detection

Miniaturized assays impose stringent requirements on the sensitivity and gain of the detection system. All Aurora-based assays are FRET based, and so it is necessary to measure both the donor and acceptor emission intensities in well-separated wavebands with high sensitivity. With miniaturized high-density format assays, the detector measures the fluorescence of each color and in each reaction well of the high-density format plate. Miniaturization forces the detector to provide the capacity to accurately measure the fluorescence signals arising from small numbers of cells (1000–10 000) within each small well. Thus, each cell must contain a sufficient number of fluorophores to contribute a detectable signal. Additional demands on sensitivity arise from heterogeneous responses in the population of cells within each well. Thus, the fluorescence detectors need to be relatively noise free and stable in order to accurately

measure the fluorescence using a smaller number of spatial and temporal samples of each well. For high throughput, the detectors need high sensitivity and fast response to enable accurate measurement with a minimum of dwell or transit time over each well.

2.12.13.2.6 Results database

To discover new therapeutic lead candidates in the compound library, the effect of each test compound on the physiological processes under study in the cell-based assays needs tabulation in the compound database. The initial step is the rapid conversion of the raw output of the detectors into a format suitable for storage in a database and statistical analysis. Database records for each compound are linked to other databases that include spectroscopy and other data to provide the compendium of data for each compound. High-throughput, miniaturized, high-density format screening generates potentially a large number of individual data records that include (1) the test compound concentration, (2) the physiological processes tested, (3) the agonist identity and concentration for each assay, (4) the presence of modulators in addition to the test compound, and (5) the different physical and chemical conditions that may be used during an assay. Furthermore, in addition to these sets of data, the outcomes of various analytical procedures, such as EC_{50} , IC_{50} , inhibitor concentrations, competitive and noncompetitive K_m and V_{max} , and other types of analysis (Schild, Dixon, nonparametric indices of significance, etc.) are recorded. The limitation imposed by miniaturization is that an extremely large data set is produced for each compound. To fully understand the efficacy and potential effects of each compound, and to rapidly identify leads, large data reduction and visualization tools are used to enable the effect of a compound to be compared against other test compounds and standard agonists or modulators and across physiological assays.

2.12.13.3 Plate Design and Performance

Two criteria are important for the design of a miniaturized assay plate. The plate must provide a high-density array of identical reaction vessels to which reagents and cells can be readily added during assay construction. In addition, it must not contribute distortion to the fluorescence intensity signals being read. The high-density well array plate is constructed to be as nonreactive as possible and to provide an inert physical platform that physically stages the assay and the detection of the assay read-out. Aurora has designed and manufactured specialty NanoWell assay plates that consist of a 48×72 well array that is scaled from the industry standard 96-well (8×12) format. The plate has the same footprint as 96- and 384-well plates, and is fitted with a custom-designed lid that prevents evaporation and contamination. Each reaction well in the NanoWell plate is capable of holding 2.5 μ L of liquid. The scaled format of wells makes possible automated positioning to be effected by subdividing the ranges used in 96-well format motor placement systems.

The bottom of the NanoWell plate (Figure 76) consists of a single <0.2 mm thin sheet of clear cyclo-olefin copolymer (COC) that provides both a chemically inert and an optically clear ($n = 1.65$) smooth surface. The plate can be brought down very close to the focusing optics of the fluorescence detector, so that bottom reading provides an unobstructed high numerical aperture sampling of the fluorescence emanating from each well. The circular well bottom is 0.95 mm in diameter, the diameter of the well at the top is 1.3 mm, and the well depth is 3 mm. The interstitial material between the wells consists of black dye mixed with COC polymer. The opacity minimizes the contamination of fluorescence measurements of each well by skew light originating from adjacent wells. The NanoWell plate bottom is optically planar to within 0.25 mm across its length, so that sphericity and astigmatism are reduced. Circular wells, in contrast to square-shaped wells, provide for the uniform distribution of cells across the bottom of the wells.

Chemical inertness results in the surface at the bottom of each well being difficult to derivatize with typical covalent reagents. This has both advantages and drawbacks. The advantage is that the surface composition is always known. In addition, the material is essentially nontoxic to cells introduced into the wells. The drawback is that cells need to interact with the surface in some normal physiological manner for survival (i.e., expression of metabolic phenotype, or entrance into a particular phase of the growth cycle). Chemical inertness thus requires some level of derivatization to facilitate cell-substrate adhesion (Figure 77). The well bottoms are easily treated to create an artificial extracellular matrix (poly-L-lysine, collagen, gelatin, fibro-/vitronectins, etc.). Nonpolarity of the well material favors adsorption of hydrophobic reagents, potentially reducing their bioavailability. This reduction in bioavailability is mitigated by inclusion of extracellular serum factors that provide carrier capabilities. In general, bioavailability scales as the ratio of hydrophobic surface area to aqueous volume, which is approximately 50-fold greater for a well in the 96-well plate compared with a well in a NanoWell plate.

Figure 76 The Aurora NanoWell assay plate. The plate is constructed to have the same total-size ‘footprint’ as industry-standard microplates. The plate contains an array of 3456 reaction wells, each with a maximum volume of 2.7 μL . The reaction well arrangement comprised a 1.5 mm center-to-center distance and is scaled as a 6×6 well subdivision of the 9 mm center-to-center distance between the wells in the industry-standard 96-well microplate. The plate thickness is 3 mm. The plate is mounted in a custom-designed caddy. A close-fitting special lid covers the top of the plate, and effectively seals each well against evaporation.

Figure 77 Phase contrast micrograph of CHO cells grown in a single well of a NanoWell plate. The micrograph was obtained 6 h after seeding 2 μL of $106 \text{ cells mL}^{-1}$. The well bottom was coated with poly-L-lysine.

The inert plastic material also provides a very high electrical resistance. This effectively isolates each well from stray electrical currents created in ungrounded robotic positioning platforms. This also makes the plate susceptible to accumulation of static charge, which ultimately is not deleterious to the assay cells but may affect liquid dispensing.

2.12.13.4 Microfluidic Technology

2.12.13.4.1 Sample distribution robot system

The Piezo Sample Distribution Robot (PSDR) is designed for delivery to assays of liquid volumes in the subnanoliter range. The conceptual framework within which the need for subnanoliter dispensing was developed is that the individual compounds in the chemical library were synthesized in limited quantity and that replication of the synthetic run would not be efficacious if no useful leads were generated by the run. Hence, it is important to maximize the information derived from the limited quantity of each compound that is produced. The PSDR was designed to enable miniaturization of assays to submicroliter volumes by enabling the delivery of materials present in only limited quantity, such as the constituents of chemical compound libraries, or those that are prepared in solutions with relatively high concentrations. The PSDR dispenses by piezo-actuated compression of a liquid–vapor interface. This results in the ejection of a single drop of liquid from the interface with a drop volume of 300–700 pL. The PSDR enables the construction of microliter scale volumes by adding negligible quantities of concentrates.

To appreciate the value of the PSDR, it is useful to determine the number of molecules in a 2 μL reaction volume for various concentrations and then to calculate the stock concentration required if these molecules are delivered in a

single bolus of liquid. For example, a 1 nM final concentration in 2 μL requires 1.2×10^9 molecules or 2 fmol. To contain this number of molecules in a single drop of 500 pL volume, the concentration of substance in the stock solution must be 4 μM . It is noteworthy that many compounds, such as small peptides and heterocyclic hydrocarbons, have aqueous solubility limits below this value. For a 1 μM final concentration, the situation is even more difficult in that the concentration of material in a single delivered drop must be 4 mM. The PSDR enables the delivery of these small amounts of compounds in extremely small volumes. This permits the use of stock concentrations within the solubility limit, and overcomes one of the significant limitations to assay miniaturization.

Each piezo-actuated compression dispenser (Figure 78) consists of a 1 mm diameter vertical glass microcapillary with a small ($<100\text{ }\mu\text{m}$ diameter) orifice at the bottom end. The top portion of the microcapillary is connected to a hydraulic system that allows liquid to be moved from the system into the dispenser microcapillary during washes or into the microcapillary through the orifice when external liquid is aspirated prior to dispensing. About midway up, the glass tube is surrounded by an annular radially polled piezoelectric ceramic element. When a voltage pulse is applied between the inner and outer faces of the piezoelectric annulus, the element increases in volume and radially compresses the liquid-filled glass tube. At the liquid-vapor interface that spans the discharge orifice of the glass tube, the compression creates a transient capillary wave. If the voltage pulse is of sufficient amplitude, the capillary wave possesses enough energy to move liquid from the microcapillary to a wave crest to create a forming drop. Because the formation of a capillary wave requires a fixed energy, each generated drop has fixed energy. Thus, each drop generated has the same volume and is ejected with the same velocity. One square-wave electrical pulse to the piezoelectric element produces one drop. Since the amount of piezo-induced compression is contingent on the amplitude of the voltage pulse, the volume of a single drop is controlled by the pulse height. The number of pulses controls the total volume delivered to a well.

The PSDR consists of four parallel heads, each consisting of 96 dispensers arrayed in the industry-standard 12×8 format. In operation, the dispensers are filled with chemical compounds to be delivered to assay plates by removing a 96- or 384-well master compound plate from the store and transporting it to the PSDR. The plate is robotically placed under a 96-dispenser head and raised, so that the microcapillary tips are submerged in the compound solutions. The pressure control system is used to aspirate several microliters of test compound into each dispenser. The master compound plate is then lowered and transported back to the store, and a 3456-well NanoWell plate, in which an assay is being staged, is brought up to the head. Each dispenser is filled with a single compound from a chemical library. A total of 36 wells can be addressed, to create a formatted experimental grid in which the compound concentration is varied (by the number of drops delivered) and in which the experimental conditions are covered (e.g., a test compound without agonist or modulator). The test compound is then dispensed to one or more of the 36 wells that can be addressed by each dispenser. Each dispenser contains more than enough material to deliver more than 20 nL of test compound to each of the addressable 36 wells. Dispensing is uniform across the 96 dispensers in each head

Figure 78 The piezo-actuated liquid dispenser. The glass tip is a microcapillary with an opening at the bottom end that serves as a discharge orifice. The glass microcapillary extends all the way through the dispenser, and at the top is connected with the liquid-filled pressure control system. The microcapillary is surrounded by an annular-shaped, radially polled piezoelectric ceramic material in the portion covered by the housing. The electrical stimulating leads to the piezoelectric material are exposed to the external electrical control system at the connections.

(Figure 79). The number of drops elicited in each visit of a dispenser tip to a well is controllable. Delivery to each well is reliably varied (Figure 80).

The spatial accuracy of dispensing can be affected by static charge that attaches to the nonconductive plate material surrounding each well. The charge has the effect of attracting the small drops of ejected material because the liquid is fairly conductive and the liquid–vapor surface is a site of dielectric discontinuity. The effect of this static potential is to deflect the discharged drop toward the site of accumulated charge. This is avoided by bringing the plate to within 0.25 mm of the tip bottoms. In addition, the static charge can be neutralized by grounding the robotic element chassis and by deionization. These treatments decrease the plate potential difference down to about 20 V cm^{-2} . At this level, no spatial errors in dispensing are made when the dispenser tips are 0.5 mm above the well rims.

Figure 79 Dispensing accuracy. A few microliters of 5 mM stock fluorescein were aspirated into each of 96 dispenser tips in a head, and then 20 drops were delivered by each tip to a 96-well plate filled with 0.2 mL sodium borate buffer, pH 9.2. The height of each bar denotes the average volume of each drop. The average drop volume for the population of dispensers is 472 ± 46 pL.

Figure 80 Linearity. In these experiments, three separate buffer-filled plates were used for each drop count. Each point shows the fluorescence of the borate buffer-diluted fluorescein averaged over all 96 dispenser tips in a head, and for all three plates. This confirms that each request for a delivered drop results in the subsequent dispensing of a drop. The implementation of the PSDR enables drop requests to range from 1 to 256 drops. Bars are \pm standard deviation.

2.12.13.5 Solenoid-Based Dispenser Technology

2.12.13.5.1 The reagent distribution robot

2.12.13.5.1.1 Solenoid-controlled liquid dispensing

For dispensing volumes that are larger than the subnanoliter volumes dispensed by the piezo-actuated dispensers, more traditional fluid-handling technologies have been miniaturized to deliver the microliter-sized liquid volumes. These dispensers, termed reagent dispensers, utilize a solenoid-controlled valve to enact and disengage physical blockade of a hydraulic pathway in order to regulate liquid flow (**Figure 81**). The dispensing tube (vertically oriented) is divided into two parts by a solenoid-controlled valve. At the lower end of the tube below the valve is the discharge orifice with a specially fabricated nozzle (<1 mm diameter). Above the valve, the entire hydraulic system is maintained at a fixed positive pressure of about 10 psi (0.7 bar) when the pathway is filled with liquid. The solenoid valve consists of a metal core wrapped by an insulated wire that is, in turn, surrounded over a portion by an annular conductor that is clamped at a fixed current (detent). When current flows through the wire wrapped around the core, the newly generated magnetic field forces the solenoid core into alignment with the field established around the annular conductor (active). The solenoid is mechanically fixed to obstruct the flow path in the detent field, so that when the solenoid is activated, the flow path toward the discharge orifice becomes contiguous with the pressurized hydraulic system, and liquid moves out through the orifice. Because of the time course of the valve movement, the activating and deactivating electrical currents can only be incremented on a millisecond time-scale. This confines the linear range of volumes to 0.1–5 μL , which can be achieved by varying the duration over which the valve remains open. At short times, volume precision is limited by the inertia of the volume that must be moved in order to obtain any liquid dispensing into the target well, and at long times, the volume moved is sufficient to cause a drop in system pressure. Nonetheless, this range of volume is all that is required for dispensing reagent volumes to the miniaturized reaction wells (**Figure 82**).

2.12.13.5.1.2 High-throughput liquid dispensing to multiple reaction wells

The reagent dispensers are used to deliver the major components of the assays to the reaction wells. These constituents typically consist of the dispersed assay cells in cell growth media, fluorogenic precursor substrates, and agonists and other physiological modulators. The reagent dispensers are arrayed linearly in a head assembly that enables reagent delivery to each well in a single row of 48 wells in a high-density NanoWell assay plate at a single positioning of the plate relative to the dispenser. Because each dispenser solenoid is individually addressable, discharge through each outlet can be individually controlled, and each well could, in theory, receive entirely different reaction constituents.

In practice, each linear array of 48 dispensers is fed by a common supply line at fixed pressure that, in turn, is connected to a single large-volume bottle of one reagent (see **Figure 81**). Assays are constructed using multiple linear arrays, each supplied with a different reagent. An assay is staged by sequential visits of each well to the dispensing position under each orifice serving a column of wells. Thus, each linear array dispenses a reagent to each of the 48 wells in a column at a time. The plate is moved under the dispenser head 72 times, to position each of the 72 wells in a row under the orifice servicing the row. The plate is then moved to the next linear array of dispensers, to receive the next reagent. In this way, reactions can be mixed directly in each well over a short time course. This avoids the necessity of mixing reagents together in the supply volumes, with possible deleterious effects due to reaction, oxidation, and so forth.

In general, solenoid-based dispensers provide the major improvement to dispensing technology – over mechanical (plunger)-based delivery – with respect to the construction of microliter scale volume assays. Solenoid-actuated valves

Figure 81 (a) Filling and (b) dispensing from the linear array. The common hydraulic line is connected to the supply volume of liquid to be dispensed on the left, while the right line goes to a disposal container. The common hydraulic line is subjected to a constant hydrostatic pressure. With both left and right valves open, the common line is filled with fluid to be dispensed. The outlet valve is closed to equalize pressure across the common line. The solenoid valves are then opened to enable dispensing. The volume is controlled by the duration for which the orifice valves are open.

Figure 82 Linearity of dispensation of microliter volumes by solenoid-controlled dispensers. The supply line to a linear array of 48 orifices was filled with 105 mL^{-1} GFP-expressing CHO cells. A single NanoWell plate was passed under the orifice array, and eight sequential columns of 48 wells each received the same volume. The volume was set by adjustment of the duration for which the solenoid-gated valve was activated. The dispensed volume is directly proportional to the valve open time for volumes between 0.2 and $2.0 \mu\text{L}$.

are useful in regulating small-diameter (0.1–1 mm) flow pathways due to the length scale over which relatively small electromagnets can produce forces sufficient to rapidly move the dead weight of the occlusion. Because the small outlets can be used in arrays that match the formats of high-density reaction well arrays, the solenoid-based valves are one of the most important technologies enabling miniaturization, and are used to deliver the bulk of the reagents to the assay wells.

2.12.13.6 Fluorescence Detection

The miniaturized assay technologies under development by Aurora all utilize measurement of FRET fluorescence. This requires measurement of the emission intensities of two fluorophores nearly simultaneously (or at least in close temporal sequence) in two reasonably well-separated spectral wavebands. This multiple-wavelength emission quantification is thus a subset of the broader domain of multicolor measurement. Because only two fluorophores are needed in a FRET measurement, the selection of a single waveband for the measurement of each dye that is relatively uncontaminated by fluorescence from the other probe (i.e., avoidance of ‘spillover’) obviates the requirement for continuous spectrometry. Instead, miniaturization creates challenges at the level of the optical interface between the sample and light collection, to enable the measurement of light from as few fluorophores in as few cells as possible. The NanoWell assay plate provides a useful cellular reaction platform that brings the cells to a distance from the optics that is essentially fixed. This enables the maximization of numerical aperture in such a way that the depth of field includes the entire layer of cells settled on the bottom of the well. Thus, the observation optics can be brought very close to the well bottom, and, moreover, each well is read with the same numerical aperture optics.

The major challenges of miniaturization are several in fluorescence detection:

- delivery of sufficient excitation light to the donor fluorophore to produce significant acceptor sensitization, so that changes in donor and acceptor emission are meaningful;
- collection of sufficient light from the sample from each fluorophore for measurement;
- separation of the light into the relevant wavebands; and
- reproducibly replicating the excitation emission optics at each assay well.

Aurora fluorescence measurement exploits the high internal reflectivity of fused-silica waveguides to accomplish delivery of light to and from the assay well bottom ([Figure 83](#)). An objective lens is interposed between the well bottom and the front of the light guide. For excitation of the donor, light from a high-intensity arc discharge lamp is directed through heat suppression and bandpass filters, to select the proper wavelengths. This filtered light is then focused by a condenser onto one end of a resin-clad fiber bundle that is brought to a lens positioned very close to the bottom of the well. Excitation light can either be focused on the cells at the bottom of the well (confocality) or allowed to remain nonconvergent (by using the condenser to focus the excitation beam at the back-focal plane of the objective

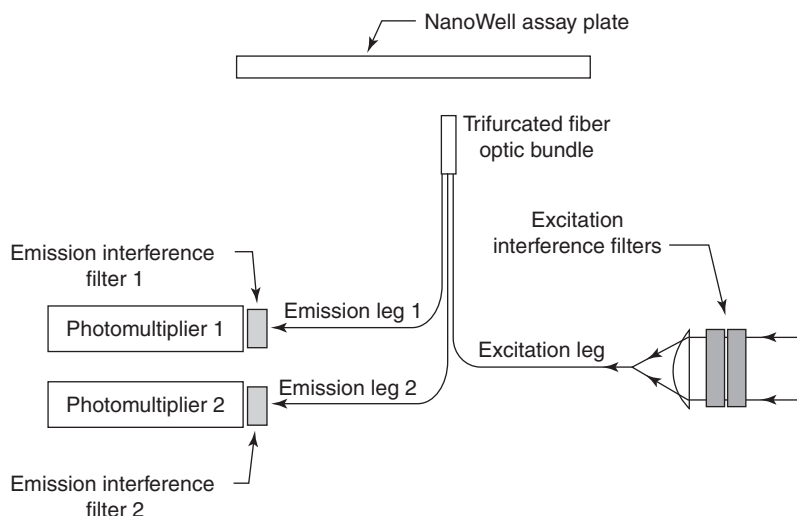

Figure 83 Schematic of the optical pathway in the NanoPlate fluorescence plate reader. The assay plate is scanned by the optical reader head by moving the plate. Excitation light is delivered to each well, and emission light is collected from each well by an optical reader head and a trifurcated fiber-optic bundle. The emission filter stacks are used to separate the emission light into the two wavebands originating primarily from the donor and acceptor fluorophore probes. With two photomultiplier tubes, one for each emission waveband, both donor and acceptor fluorescence intensities are measured simultaneously.

Figure 84 Raw data from the NanoWell plate reader illustrating the continuity of the digitized data. All 3456 wells are scanned in less than 2 min. The trace shows the digitized output of one photomultiplier tube during a scan of six wells in a single row. The raw data are processed to corrected fluorescence data originating from each well by averaging the fluorescence intensities in the integration window. The integration window is determined by the locations of local minimum and maximum fluorescence intensities and their values. The illustrated scan was obtained with 100 nM fluorescein in borate buffer pH 9.2 through the green emission channel.

lens). Confocal excitation delivers more light to fewer fluorophores. A duplicate paired set of light guides is used to collect the emitted light focused by the objective lens. One set leads to a stack of interference filters that isolates the light emitted by the donor fluorophores, and the other set leads to a stack that isolates the acceptor emission. Each stack sits atop the photocathode faceplate of a photomultiplier tube. Thus, the emissions from both fluorophores are obtained simultaneously.

In order to maximize the throughput of the miniaturized, high-density format system, the NanoWell plate is scanned relative to the optical fluorescence detector (Figure 84). In the Aurora instrument, the plate is moved by

high-resolution motorized screws, and the optical system is fixed in place. This results in each well being represented as a set of discrete integrated intensities obtained for the scan. The interstitial material between the wells attenuates the fluorescence, so that the raw output of each photomultiplier resembles a periodic wave. Nearest-neighbor analysis is used to isolate the intensity peaks corresponding to the well centers in each scan of a row of wells. The well array format is used to isolate wells containing no fluorescent material. Furthermore, statistical analysis enables the exclusion of the rare, extremely intense yet spatially small fluorescent objects that are dust particles. Data acquisition must keep up with the rate of plate scanning and the amount of data that the two photomultipliers are capable of generating. In any case, fluorescence measurement requires a very small fraction of the time needed to construct and measure miniaturized cell-based physiological reactions in high density.

2.12.13.7 High-Throughput Functional Biology

Ultrahigh-throughput screening utilizing microliter volume assays is made possible with the types of instrumentation described for the manipulation of replicated small liquid volumes and for simultaneous two-color measurements repeated many times. This is demonstrated using a standard cell-based assay that is amenable for testing signal transduction pathways mediated by GPCRs. In this assay, Jurkat cells are transfected with an expression vector in which a gene encoding β -lactamase is under the control of a set of nuclear factor of activated T cells (NFAT) nuclear transcription activation sites. β_2 -adrenergic receptor activation by isoproterenol or muscarinic activation by carbachol results in the heterotrimeric G-protein-dependent activation of phospholipase C. The resulting inositol triphosphate-activated release of calcium ions from intracellular stores activates calcineurin, a phosphatase that activates the NFAT transcription regulator, and promotes expression of β -lactamase. The activity of β -lactamase is determined by the use of the cephalosporin-linked coumarin-fluorescein dye pair (CCF2). Thus, the expression level of β -lactamase in these transfected Jurkat cells provides a direct indication of the extent of β_2 -adrenergic activation. The enzyme activity is directly indicated by the amount of coumarin fluorescence, resulting from CCF2 cleavage and dequenching of the coumarin fluorescence by the disruption of FRET with fluorescein, relative to the amount of fluorescein fluorescence, which is sensitized by FRET with the directly excited coumarin. Distinguishing receptor activation in these cells is unambiguous (Figure 85).

To construct the assays shown in Figure 86, the NanoWell assay plate well was seeded with 2000 detached (spinner culture) cells in serum-free growth medium using a single array of the solenoid-based reagent-dispensing robot (RDR). The plate was then incubated at 37 °C for 6 h to allow the cells to attach to the well bottom. The carbachol was added after a second pass through the RDR, and, after a 2 h incubation, the CCF2 fluorogenic reagent was added. Fluorescence was measured after 4 h in CCF2 at room temperature. The receptor activation is clearly revealed as an inversion in the amount of blue fluorescence relative to green. In quantitative studies, the donor–acceptor fluorescence intensity ratio depends on the agonist concentration, indicating the pharmacological validity of the FRET sensitization ratio.

This relatively simple fluorescent assay for receptor activation consists of a significant number of operations, such as cell seeding in a medium, the addition of agonist, the addition of fluorogenic reagent, and several incubations at different temperatures. The steps needed to construct the assay must be performed within the constraints of time and physical condition. Nonetheless, the construction and measurement of the assay consist of relatively simple steps – fluid addition, incubation, and fluorescence reading – that are amenable to automation. The precision of the automation enables the assay to be miniaturized.

Further utility of the miniaturized assay is provided by a different set of transformed Jurkat cells that are activated by carbachol, and provide a convenient cell-based assay for screening chemical compounds for possible effects on signal transduction processes mediated by muscarinic receptors and heterotrimeric G-proteins (in addition to NFAT and NF- κ B-activated gene transcription).

2.12.13.8 Overview

The technologies of liquid handling, assay construction, and fluorescence detection provide a set of operational modules that can be configured to perform a wide variety of assays. The key features are that they enable cell-based fluorescence measurements, and so are adapted to screening for effects on potentially intricate physiological pathways in intact living cells. In addition, the liquid handling can be parceled so that a particular instrument is specialized for a range of volumes that are consistent with the physical methodologies used to obtain control of the dispensed volume. Solenoid-based hydrostatic delivery is required for the range and precision of control of microliter-volume dispensing. At the subnanoliter level, more transient pressure control mechanisms are necessary, and so piezoelectric technology is useful. These technologies are fully amenable to the design of new assays for new physiological pathways and for the determination of gene product functions.

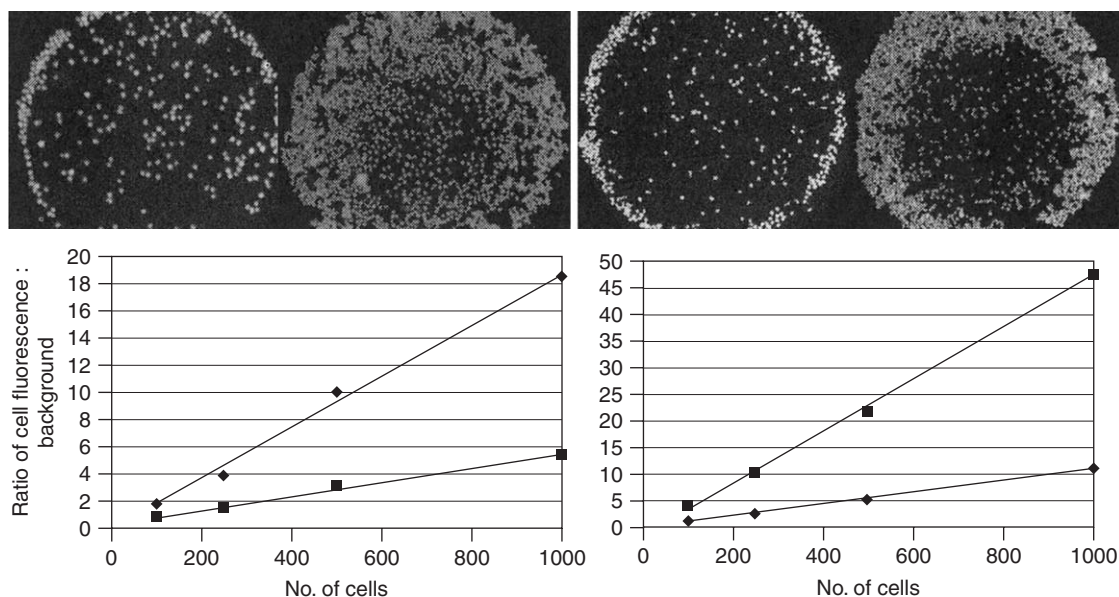

Figure 85 Isoproterenol stimulation of Jurkat cells transfected with NF-AT- β -lactamase vector. The upper panel shows fluorescence micrographs of individual wells seeded with Jurkat cells after 4 h incubation in the dual-FRET fluorophore CCF2. The pair of panels of cells on the left shows cells that were not treated with isoproterenol. The fluorescence originates by direct excitation of the coumarin and sensitization of fluorescein fluorescence by FRET in the intact CCF2 molecule. The leftmost panel was obtained by seeding 250 cells in the well, whereas the adjacent panel to the right shows 1000 cells. The plots show the quantitative relation between coumarin and fluorescein fluorescence intensities as a function of cell density. In unstimulated cells, green fluorescence predominates. The pair of panels on the right shows Jurkat cells after stimulation with isoproterenol. The expressed β -lactamase has cleaved the dual-FRET fluorophore, relieving the quenching of the coumarin fluorescence.

Figure 86 Dose-response curve for Jurkat cells transfected with a β -lactamase reporter gene and stimulated with carbachol. The emission intensity ratio at 460–520 nm was normalized by the sensitization ratio obtained at 10^{-5} M agonist concentration.

2.12.14 Data Management for High-Throughput Screening

2.12.14.1 Introduction

2.12.14.1.1 Background

Data management is an integral requirement of any HTS effort. Ultimately, the purpose of any screening program is to acquire information that can be turned into knowledge in the drug discovery process. In order to achieve this goal, the results of all tests, along with all appropriate contextual information, must be reliably captured by a data management system and made available to researchers throughout an organization. The tracking of sample locations, test conditions,

the capture of raw results, and the transformation of raw results into calculated and meaningful information requires robust and flexible information systems with effective user interfaces, as well as links to inventory and other information systems. This section will highlight some of the issues involved in developing and maintaining an informatics system to support HTS.

2.12.14.1.2 Issues in high-throughput screening data management

2.12.14.1.2.1 Large volumes of data

The introduction of automation to biological screening has resulted in an increase in the volume of data of many orders of magnitude. In the early 1990s a large pharmaceutical research organization might screen tens of thousands of samples in a year. By the late 1990s some large research organizations were screening as many as 22 million samples in a single year. Clearly, in order to achieve this type of volumes, informatics systems must be a part of the overall strategy, both to aid with the logistics of HTS and to support decision-making.

2.12.14.1.2.2 Addition of automation

The defining feature of HTS is the application of automated systems to biological testing, greatly increasing the number of samples that can be tested in any time period. The increase in the number of samples being tested has a number of complicating side effects. First, since the goal of increasing throughput is to gain knowledge regarding the interactions of molecules and targets, results data must be collected, analyzed, and made accessible to researchers. Information processes that are possible by hand with small volumes of data require automated systems when large volumes of data are involved. Second, the use of automation introduces the possibility of mechanical error. Finding the error and isolating the results is a major issue for HTS informatics systems.

2.12.14.1.2.3 Variability inherent in biological experiments

Early in the days of HTS, many comparisons were made between the application of automation to biological screening and that in other industries, such as manufacturing. Many presentations and papers of the time talked about the 'industrialization of research.' While certain aspects of the process, particularly inventory and logistics, did become more industrialized, the predictions underestimated the rapid changes in the research process, as well as the variability inherent in biological systems. The nature of discovery research dictates rapid change. By comparison, the basic principles of double-entry accounting have not changed since the 1500s. While there have been, and will continue to be, changes in the details, such changes pale in comparison to those in scientific research, where even many of the leading scientists today cannot tell you where the process will be going 5 years from now.

2.12.14.2 Acquisition of Data

In almost all cases, the endpoint of a HTS experiment is a change in the state of the contents of a well that may be detected by an automated device, typically referred to as a reader or a plate reader. The change in state may be an increase in fluorescence, radioactivity, or absorption. The plate reader will measure the state of the sample at a set time or over a period of time. In some experiments, the detector takes multiple readings. In almost all cases, the output of the reader is a series of raw results, which must be either normalized or reduced, and combined with other information, in order to produce meaningful results.

2.12.14.2.1 Integration with automation equipment

Plate readers most often produce one or more text files, which contain the raw results of the experiment. These results are often expressed in terms of counts per minute, optical density, or fluorescence. These results can be extremely difficult for scientists to interpret in their raw form for several reasons. An example of such a file is shown in [Figure 87](#). There are several things that we can see regarding this file. First, we can see that besides the raw result, there is other potentially valuable information contained in the header section, such as the filters used and the temperature. Next, we see the results in a 'data block.' These are the raw results, but we can quickly surmise that reviewing the raw results would not be an efficient way to analyze the experiment. For one thing, there is no indication of what was in each well that was tested. While many readers today can accept the input from a bar code and will include the bar code plate identifier in the reader file, there is no indication of what sample was in the plate, what concentration was used for the test, or other information required. In addition, to make sensible decisions on the basis of these data, the scientist must perform other analyses, such as stability of the controls, and overall level of activity for the assay. While looking at a single plate of raw results might give an indication of the answer, one would have to keep a fair amount of information in one's head. For example: Where were the controls for this experiment located? What ranges of numbers indicate

Figure 87 Raw output of an LJL Analyst plate reader. Automated plate readers can produce a great deal of information; however, the information is not always formatted in a way that is straightforward or easy for data systems to capture. Most modern plate readers can be programmed to produce data in desired formats. The 8×12 block of numbers in the center contains the raw results for this plate. Other information, such as filters used and temperature, may be included. Typically, the information system parses the information out of this type of file, processes the raw results, and stores all the information in appropriate fields in the database. Note also that ancillary information, such as sample ID or well type, is not included in this file.

activity versus inactivity? Are the results seen on this plate in line with what should be expected from this type of assay? While it may be possible for a scientist to manually analyze one plate's worth of data, imagine trying to do this for 1000 plates run in a single day. It may be possible, but it certainly would not be a good use of the researcher's time.

2.12.14.2.2 Integration with other information systems

In order to present the data to the scientist in a format that can aid in efficient decision-making, the raw results in the reader file must be parsed and brought into an information system, where the results will be integrated with information such as the sample tested, the kind of well (sample, control, reference, or other), and other conditions, then calculated and presented to the scientist so that decisions can be made. This integration can be challenging for a number of reasons:

- The plate read by the detection device is almost never the inventory plate. It is usually a copy made at the time of the test. Therefore, the information system must associate the ID of the assay plate with the inventory plate that was the source.
- The layout of the reader file can vary dramatically from one reader to the next. In fact, most readers have several programmable modes that allow them to create files with a number of different formats. Information systems must properly parse the information.
- The layout and configuration of the test plate is different for different experiments. In fact, sometimes within a single experiment multiple plate layouts may be used. The information system must be able to associate the correct layout with each plate.
- Finally, when making decisions, the scientist will frequently want to see results from other tests for the same samples. This means that the system should have the capability to query other databases.

2.12.14.2.3 Well types and plate layouts

One key piece of information that is not captured in either inventory systems or by the reader file is the plate layout. The plate layout describes the contents of each well in a plate. Plate layouts typically include information such as sample concentration, and the location of control wells or standards. While this is typical information, plate layouts can include any variable that the scientist has under his or her control, such as pH or salinity. In some cases, the scientist will even place different targets (enzymes, receptors, or cell lines) in the wells. This information is crucial for a meaningful calculation and interpretation of the results. Most HTS information systems have specialized input screens to support the definition of plate layouts. The variety of plate layouts used for different types of experiments requires that any general-purpose information system be extremely flexible.

2.12.14.2.4 Calculation, reduction, and normalization of data

Once the raw results are brought into the data system, some form of calculation is needed to make the data meaningful to the scientist. This is important because the raw numbers coming out of the reader file can vary widely based on the type of detection used as well as the specifics of the assay. Using just the raw numbers, it would be almost impossible for the scientist to quickly determine the quality of the assay run or to determine if any samples displayed unusual activity. Even within a single assay, results coming from plates taken at different times may vary substantially. So, unless the raw results are somehow normalized, the scientist can be easily misled. The most common calculated results are as follows:

- percent inhibition;
- percent of control;
- IC_{50} or EC_{50} ;
- K_i ; and
- ratios.

2.12.14.2.4.1 Percent inhibition and percent of control

Percent inhibition and percent of control are perhaps the two most commonly used calculations in the HTS environment. In both cases, the calculations show the activity of the sample(s) being studied relative to the activity shown by a known set of controls or standards after accounting for systematic noise as expressed in the low controls. The percent inhibition calculation is

$$1 - (\text{sample} - \text{average of low controls}) / (\text{average of high controls} - \text{average of low controls})$$

The percent of control calculation is

$$(\text{sample} - \text{average of low controls}) / (\text{average of high controls} - \text{average of low controls})$$

Note that these two calculations are the inverse of the other. In many cases, researchers will calculate both and use the one that is most familiar to them. For the remainder of this chapter, we will use only percent inhibition, but we will mean both.

2.12.14.2.4.1.1 Variations In many cases, experimentalists will attempt to reduce experimental error by using two or more wells to test each sample. The replicates are averaged, and then the averages compared. If there is a high deviation within the sample responses (e.g., if one replicate shows an inhibition of 80%, and the other replicate shows an inhibition of 5%), we have a good indication that one of them is wrong. Sometimes the replicates are on the same plate, and sometimes the entire plate is replicated. Again, the information system needs to be able to tell where the samples are, find the replicate, and perform the appropriate calculation.

In the most common application of percent inhibition tests, control wells are placed on each plate. However, in many cases experimentalists will choose to place the control wells on a designated control, reference, or quality control plate. The controls from this plate are then used to calculate results of samples on other plates.

Percent inhibition tests represent a good first-pass indication of the activity of a sample. When dealing with a large number of samples, where you are looking for 10-fold or better differences in activity level, these tests give you a fast, reasonable indication of which samples are worth following up. However, there are several shortcomings to these measurements. First, they are single-point measurements, so we only learn the activity level of a compound at a certain concentration. It may be impossible to make reasonable comparisons regarding the relative activity of different samples

Figure 88 A set of fitted dose-response curves. The dashed line shows the IC_{50} concentration (i.e., the concentration level where 50% inhibition is observed). Furthest to the left is the sample with the lowest IC_{50} , and in most cases would be indicative of the most potent sample.

if they were tested at different concentrations. In addition, these measurements give no indication of the nature of the activity. To obtain this type of information, other types of tests have to be run. The most common of these tests are the dose-response and the kinetics tests, described in the following sections.

2.12.14.2.4.1.2 Dose-response tests All dose-response tests measure the activity of a sample over a range of concentrations. The results of these tests are usually computed using one of many nonlinear curve fitting algorithms to find a measure called either the IC_{50} or the EC_{50} . In both cases, these measures tell us the concentration at which the compound shows an activity level of 50%. This measure is superior to percent inhibition for several reasons. First, it allows reasonable comparisons between different compounds. Second, it is a much finer measure of activity because it also shows information about the nature of the activity. For example: How rapid is the response to changes in concentration? What is the concentration level at which activity maximizes? At what concentration is there no activity? (See [Figure 88](#).)

2.12.14.2.4.1.3 Kinetics experiments Kinetics experiments measure the rate of change in activity of a sample over time. The usual measure of activity for a kinetics experiment is K_i , the maximum rate of change. A wide variety of models are used to calculate K_i . One of the most popular models is the Michealis-Menten model, which typically takes the form

$$v = V[A]/(K_{mA} + [A])$$

where V and K_{mA} are constants at a given temperature and a given enzyme concentration. A deeper explanation of kinetics and other calculations used in biochemical screening is published by the Nomenclature Committee of the International Union of Biochemistry.^{596a}

2.12.14.2.4.1.4 Ratios A large number of experiments require that several results be compared. For example, in some tests we are interested in both protein growth and cell survival. In other tests, the exact level of activity is not considered as important as the change in activity from a baseline. In these and several other types of test, the results are typically reported as a ratio.

2.12.14.3 Validation of Experimental Results

2.12.14.3.1 Detection of experimental error

In any experiment, there is a chance of error. The addition of automation and the increased number of samples tested at any given time increase the probability of error. So, before the scientist even begins to look for meaning in the results of an experiment, he or she must determine if the results are useful at all, or if experimental error means that the results are invalid.

2.12.14.3.2 False positives versus false negatives

There are two types of experimental error that are generally to be accounted for: false positives and false negatives. False positives look like hits but are not, whereas false negatives are hits that are never revealed. In many cases, scientists care very little about these errors if they are random occurrences, impacting a small number of samples. The assumptions are that false positives will be found with relatively inexpensive follow-up tests, and that there is enough overlap in the chemical space that for any false negative there will be other similar compounds tested that will yield the correct answers. In short, given the nature of biological systems, the assumption is that there will be some level of random error, and most scientists will deal with that. The bigger concern for most HTS scientists is the detection of systematic error, which may invalidate the entire experiment or a large portion of the experimental results. These errors can be very expensive and difficult to recover from. Typically, most scientists depend on the use of controls, or known positives and negatives, to avoid experimental errors.

2.12.14.3.3 Sources of error

2.12.14.3.3.1 Automation equipment failure

Equipment failure is one of the most common sources of experimental error in the automated environment. Typical automation failures include improper dispensing of reagents, physical mishandling of plates, and the failure of incubators and detection devices. Computer systems and software that control the automation equipment are also subject to failure. It should be noted that each increase in throughput and/or plate density comes with a period of increased automation error. This is to be expected, as many of the issues become more problematic, and tolerances become tighter. As an example, a typical well in a 96-well plate can contain 200 μL . On a 1536-well plate, a typical well contains 10 μL . A variation of 1 μL will be 0.5% of a 96-well plate but 10% of a 1536-well plate.

2.12.14.3.3.2 Stability of reagents or targets

Many HTS tests involve the use of radioactive labels, which are subject to decay. Most involve the use of enzymes, receptors, proteins, or live cells, all of which are subject to degradation or contamination. Needless to say, if an enzyme breaks down, or if the cells die before the test, the results of the test are invalid.

2.12.14.3.3.3 Environmental issues

Most biological tests are designed to be performed within some range of conditions. Failure to maintain these conditions may result in invalid test results. As an example, in low-humidity environments, evaporation can be an extreme problem. If the liquid in a well evaporates before the test is completed, clearly the results will not be valid.

2.12.14.4 Decision Support

2.12.14.4.1 Finding systematic error

Given the possibility of some kind of systematic error and the dramatic effect that such errors can have on the results of a test, it makes sense for the scientist to validate that the experiment ran properly before searching for active compounds. The major methods of detecting systematic error are (1) the use of controls and standards and (2) the search for patterns within the data.

2.12.14.4.1.1 Use of controls and references

The most common way to detect systematic error is by the use of control wells on each plate. Control wells contain samples with a known activity or no sample at all. At the conclusion of the test, the scientist's first action will typically be to check the controls. Did they run as expected? How tightly did the results cluster? Was there wide variation in the results over time? Was there an acceptable difference in activity between the high and low controls (the signal-to-noise ratio)?

2.12.14.4.1.2 Search for patterns

The results of most HTS experiments should be random, with a small number of hits randomly distributed over the library tested. If the results indicate that one area (such as a specific row, column, or well location) had an unusual level of activity, it is usually indicative of some kind of systematic error. As with almost anything else in HTS, there are exceptions to this. For example, if screening a combinatorial library, where all members of a row contain a common substructure, increased activity for an entire row would not be uncommon, and might be exactly what you are looking for.

2.12.14.4.2 Locating hits quickly

In most HTS environments, the difference between a hit and other samples is somewhat dramatic, often of the order of 10-fold. Under these circumstances, it is fairly easy to locate the hits and move forward. There are a number of methods for locating hits, ranging from graphical display of the data to simple database queries, such as ‘find the top $x\%$ in terms of activity.’ Many organizations use standard deviation (σ), looking for samples that are 2σ more active than average. In many cases, locating the most active samples and producing a list of the identifiers is all that is required. This list is sent to a sample room (or back to the automation equipment) for replating and confirmation or secondary tests.

2.12.14.4.2.1 Evaluating a single run or an entire campaign

Often, the HTS laboratory will run an organization’s entire library of compounds through a screen over a period of several weeks to several months. This is often referred to as a campaign. Many organizations will wait until the entire campaign is completed before evaluating samples. They do this because they have found that their libraries have sections (sublibraries) that are more or less active than the norm. If one of these sublibraries is run early, the threshold for activity may be set improperly. Therefore, it is more effective to wait until the entire library has been tested to make threshold evaluations.

2.12.14.4.3 Integration of other data

Sometimes it is desirable to consider information other than the results. Most often this information is used to narrow down the number of hits and to eliminate hits that are not worthy of further study. Some of the key information used to eliminate hits includes the following:

- Results from other tests. If a compound is found to be active against a number of other targets, it is likely to have undesirable side effects.
- Physicochemical data. The most common filtering method is the Lipinski ‘rule of five.’ This set of rules looks for compounds that are likely to have reasonable absorption characteristics and eliminates those that do not.

At this point, some people ask, ‘Why run those compounds in the first place?’ If, after all, they are just going to be eliminated after the primary screen, does it not make sense to remove them in the first place? There are two reasons why these compounds are typically run in primary screens. First, many companies maintain their entire libraries in 96-well plates. It is easier and less expensive to simply test everything than to pick out certain compounds. Second, in some cases these may be the only active compounds in a screen. While none of them will be drugs, the information gathered will give medicinal chemists a starting point in terms of how to develop compounds further.

2.12.14.4.4 Graphical display versus tabular display

There are many fine books on the subject of human interaction with and comprehension of data, and a detailed discussion of the subject is beyond the scope of this section. For now, we will simply say that both tabular and graphical displays of data have their place, and most systems provide a combination of displays. We will discuss some of the common graphical displays used, as well as some of the basic requirements for effective tabular displays.

2.12.14.4.4.1 Tabular display

A tabular display is basically a spreadsheet, showing the data in columns and rows. The most common spreadsheet in use today is Microsoft Excel. Most systems specifically designed for HTS data management try to offer an ‘Excel-like’ spreadsheet capability. Commercial examples of these systems include CSAP from Accelrys, Inc., and Assay Explorer from Elsevier MDL Information Systems. A very popular HTS package, ActivityBase from IDBS uses Excel as the front end. Tabular displays are useful in that they give scientists a detailed and precise view of specific results. Typically, tabular displays will need to sort and filter the results so that a meaningful subset can be displayed. It is unrealistic to assume that any scientist can find meaningful data in a tabular display of 100 000 records; however, scientists can raise a query such as ‘Show me the 50 most active compounds from this test,’ and a tabular report can be useful. Tabular reports could also be useful for statistical summaries of a large experiment.

2.12.14.4.4.2 Graphical display

Properly designed graphical displays allow scientists to quickly analyze large amounts of data, as well as to spot trends and outliers. Some of the typical graphs used in HTS include scatter charts and control charts. Scientists would generally request that any graphical display be interactive so that it can be used as a query device.

2.12.14.4.5 Reporting

In addition to display of the data, most organizations will want a hard copy of at least a summary of the results. Often the hard copy contains statistical data regarding the experiment and a summary of interesting results. These reports are usually stored in a laboratory notebook. Again, it is unlikely that anyone would want to create a hard-copy report showing the results of hundreds of thousands of compounds, 99% of which are inactive.

2.12.14.5 Data Analysis and Mining

Up to now, we have been discussing display and reporting of the results for a single experiment. The key decisions made at the single-experiment level include the following: (1) Did this experiment run as expected? (2) Were there any hits, or interesting compounds? While these are interesting and useful questions to ask, other questions can require even deeper analysis, and place an increased strain on information systems. For example: (1) Of the compounds that were active in this test, which were active (or not active) in other tests? (2) Are there structural components of the hits that would account for the activity? (3) Do any of the hits have physicochemical properties that would indicate that bioavailability, solubility, or potential toxic effects?

2.12.14.5.1 Cross-assay reports

2.12.14.5.1.1 Pivoted data

In most data management systems, results data are stored in some variant of a long, skinny table. This means that a single column in the table can hold multiple result types and that other columns are required to describe the results. An example of a simplified long, skinny table is shown in [Table 26](#). Long, skinny tables make for efficient and flexible data storage because they do not require new columns or other modifications to define new variables. However, they do not present the data in a manner that is intuitive to the scientist. Most scientists prefer to see data in a short and wide format, in which each variable associated with a compound is represented as a column. An example of a short, wide table is given in [Table 27](#). Note that each test is now a column, so the scientist can quickly answer questions such as ‘Which compounds were active in this test, but not in others?’ or, for the compounds of interest, ‘Are there tests that were not run?’ Converting data representation from tall/skinny, as it is stored, to short/wide is known as pivoting the data. The data pivot can take place in many different ways, and many biological information management systems have a data-pivoting function built in.

In [Table 27](#), note how easy it is to tell which samples have been run in which tests, and which samples were active in one test but inactive in other tests. Unfortunately, this type of table makes for very inefficient storage, especially if there are sparsely populated columns. Also, this type of table is also very inflexible, since the addition of a new test requires the addition of new columns.

2.12.14.5.1.2 Classical structure activity

One of the goals of pharmaceutical research has been to find the relationship between small-molecule chemical structure and biological activity. One simple, but widely used, method of analysis is the structure–activity relation report. This report shows a chemical structure and pieces of information describing the activity on each row. The addition of quantitative measures of physicochemical properties (quantitative structure–activity relationships) is the province of molecular modelers. Structure–activity relationship reports are very useful, particularly for small numbers of compounds; however, the amount of data rapidly becoming available in most large life science companies will completely overwhelm the cognitive ability of most scientists to view and analyze the data. As we move into higher volumes of data, data reduction and visualization techniques become more important.

2.12.14.5.2 Visualization of data

When working with large volumes of data, humans tend to respond to visual cues much more rapidly than textual displays of the data. Several data visualization tools in use today allow users to simultaneously view multiple attributes. It has been established that by using a combination of size, shape, color, position, and texture, it is possible to perceive up to eight dimensions simultaneously. A popular data mining tool is Spotfire Pro, which allows the user to graphically reduce the data set to the results of interest; for example, displaying the results of multiple tests as dimensions, and the physicochemical properties of the samples as colors, shapes, and sizes.

2.12.14.6 Logistics

2.12.14.6.1 Plate handling

HTS is almost entirely performed in microplates, each containing between 96 and 3456 wells. During the past several years, the 384-well plate has supplanted the 96-well plate as the primary HTS vehicle. Tracking the contents of each well in each plate and associating the results with the proper sample is of crucial importance for a HTS system, but several factors must be overcome.

The detected plate (the assay plate) is rarely the plate stored in the inventory. Often, the process of detection itself is destructive. Whether detection is destructive or not, the addition of the biological reagents would make the assay plate unusable for future tests. The usual process has the automation equipment copy a plate taken from the inventory, to create the new assay plate. Reagents are then added to the assay plate, and the detection is performed. At some point, the data management system must be told what is in the assay plate or how to associate the assay plate with the information in an inventory plate. This can be done in several different ways. Two examples follow:

(1) The liquid-handling device, which actually makes the assay plate, keeps a running list of the assay plates that it makes as well as the inventory plates from which it makes each one. In this case, the data management system will have to look up the inventory plate for each assay plate and then get the appropriate inventory information.

(2) When making an assay plate, the liquid handler applies a bar code identifier that includes the inventory plate ID plus an extension. When the data system reads the plate ID (usually in the reader file), it needs to parse out the inventory plate ID and retrieve appropriate inventory information.

2.12.14.6.2 Special cases

2.12.14.6.2.1 Consolidation

An increasing percentage of HTS experiments are being performed on 384-well plates. However, most storage is still done using 96-well plates. During the process, four 96-well plates are typically combined into a single 384-well plate. So, as the sample is transferred from each of the 96-well plates to a different location on the 384-well plate, the information system must be informed about the new location of the sample.

2.12.14.6.2.2 Format changes

Often, samples are purchased from outside suppliers or are stored in the inventory in a format that is not compatible with the format used for the test. For example, many suppliers provide compounds in 96-well plates with all the wells filled; however, most tests require that one or two columns of wells be left blank for controls. In these cases, once again, samples must be moved to different locations on the new plates, and the information system must keep track of which samples are moved where.

2.12.14.6.2.3 Pooling/deconvolution

Some laboratories, in an effort to increase throughput, intentionally mix 8–12 samples per well. When a well displays activity, the samples contained in that well are tested individually to find the ‘hot’ sample. Assuming that 1% or less of all samples are active, this will result in a dramatic decrease in the number of wells tested, thus increasing throughput and decreasing costs. A special case of pooling is called orthogonal pooling. In this case, each sample is put into two wells, but the combination of samples is unique in each well, and any two wells will only have one sample in common. Therefore, when any two wells are active, the common sample can be located and retested for confirmation.

2.12.14.7 Future Technologies

Predicting the future in any case is a perilous thing to do. In the case of a rapidly changing field, such as HTS, it is downright foolhardy, but that will not keep us from trying. Most of the predictions we are making are just extrapolations of technologies under way. There is always the possibility that a major technological innovation will change the course of screening dramatic changes in HTS processes, or perhaps even obviating the need for HTS. Even in the absence of such dramatic discontinuities, we can see several new technologies that will have an impact on the practice of screening.

2.12.14.7.1 Higher densities and ultrahigh-throughput screening

First, the drive toward higher and higher densities will continue. The economics of HTS make a compelling case. Increases in speed of throughput are a secondary issue to reduction in the cost of reagents used. We fully expect the HTS standard to move from 96-well plates to 384, on to 1536, and possibly as high as 3456. The effect that this will have on informatics systems is fairly obvious. First, as noted earlier, smaller wells require much tighter tolerances; hence, the need for the capability to detect systematic errors will become even more acute. In addition, as we move to higher densities, new visualization tools will become a requirement, as many of the visualizations designed for 96- and 384-well plates will simply not be usable for 3456-well plates. Finally, the need for users to be able to quickly locate information for single samples will become more acute. Higher densities and faster instrumentation together are allowing throughput to increase dramatically. The increased throughput levels, referred to as ultrahigh-throughput screening, will put additional strain on information systems, forcing the systems to process more information at a higher rate.

2.12.14.7.2 Wider use of high-throughput screening techniques

One of the effects of the adoption of HTS throughout the pharmaceutical industry has been to move the bottleneck in the discovery pipeline downstream. Essentially, this means that HTS laboratories are producing hits at a faster rate than the therapeutic areas and development can absorb them. One strategy for dealing with this new bottleneck is to adapt HTS-style techniques for metabolism, toxicity, and other secondary and development assays. This change will have a dramatic effect on information systems, as the data produced by these tests are usually far more complex than those produced in classical HTS assays. For one thing, these tests can often have more than one endpoint. For example, some toxicity tests measure the effects of exposing a specific type of cell to different samples. The scientist may want

to record the percentage of cells that died (or survived), the reproduction rate, the growth rate, and if any specific types of proteins were expressed. Some tests go as far as measuring specific types of damage to the cell. The challenge to the information system is to be able to collect all of the relevant information so as to allow the scientist to declare all of the appropriate variables for the experiment and record the appropriate contextual information (e.g., how was the test run?).

2.12.14.7.3 High-throughput screening kinetics and high-content screening

Until recently, the goal of all HTS programs was simply to increase throughput, the sheer number of samples processed, and hence the volume of data produced. Many HTS scientists believe that this goal has been largely accomplished and that further investment in increasing throughput will bring diminishing returns. The next goal is to increase the quality of the data produced. Essentially, this means that the goal is no longer to simply test more samples but rather to learn more about each sample tested. Some organizations call this 'high-content screening' (HCS). HCS involves tests where multiple endpoints are achieved for each sample. In addition, many kinetics experiments (where multiple readings are taken for each sample over a course of time) have been adapted for automation. Now, instead of a single reading for a well, there can be up to 100 readings for each well. There is a great debate concerning what to do with this raw data. Should it be stored at all? Can it be archived? Should it be available for on-line queries? Most organizations have (to date) decided that it is impractical to attempt to store all the raw data on-line but that it can be archived in off-line storage, and the reduced data (such as K_i) can be stored on-line.

2.12.14.8 Overview

While it may not be possible to predict what HTS will look like in the future, several points are clear:

- The volume of data will continue to increase. Whether it is from higher throughput or higher content, or both, more data will be available to scientists. The challenge to the information system designer, then, is to create tools that allow the scientist to store all the relevant data and then retrieve it in such a way that information can be extracted quickly. The goal is to help the scientist find 'actionable' data, or data that cause the scientist to make a decision, such as 'this sample is worthy of further study' or 'the results of this test should be rejected.'
- As the volume of data increases, data storage systems will come under increasing pressure. Currently, most major pharmaceutical companies store all chemical or biological data in Oracle databases from Oracle Corporation. Oracle is migrating technology to object orientation, which can provide increased performance. It will be up to the developers of chemical and biological information management systems to utilize advances in the underlying core technologies as they become available.
- Data-mining tools are being developed for industries ranging from retail to financial services. While the volume of data being produced by HTS and related technologies calls for data-mining and statistical solutions, and there is a great deal of work going on in this area, it is unclear at the time of writing whether general-purpose data-mining tools can be adapted for drug discovery.
- Science will continue to evolve, and information systems must also continue to evolve to support the science.

2.12.15 Combinatorial Chemistry: The History and the Basics

2.12.15.1 Definition

What is combinatorial chemistry? There have been several opinions, some formulated very sharply, but most expressing what combinatorial chemistry is not. At the end of the conference 'Combinatorial Chemistry 2000' in London, a discussion session was organized to answer this question and make sure that our understanding of the term reflects the fact that at least some operations in the synthesis of the group of chemical compounds is performed in combinatorial fashion. Unfortunately, when it came to the public vote, the scientists in the audience voted for a much broader definition of combinatorial chemistry. The majority expressed the opinion that combinatorial chemistry is defined by the design process – that compounds designed by the combination of building blocks (and synthesized by whatever means) are the subject of combinatorial chemistry. In the literature, the term 'combinatorial chemistry' is used very often; however, the definition is found rarely. Seneci⁵⁹⁷ says that "combinatorial chemistry refers to the synthetic chemical process that generates a set or sets (combinatorial libraries) of compounds in simultaneous rather than a sequential manner." The *Journal of Combinatorial Chemistry* defines combinatorial chemistry as "a field in which new

chemical substances – ranging from pure compounds to complex mixtures – are synthesized and screened in a search for useful properties.”

But do we really need to define combinatorial chemistry before discussing the history of this branch of science? Must we have consensus about the term ‘combinatorial chemistry’ before we start a new journal with the term in its title? (There are already several journals with the term on their covers.) Apparently not, and the precise definition is probably not as important as the fact that the novel techniques are being widely accepted and applied as needed for a variety of projects, starting from finding new drug candidates and ending in the discovery of new inorganic materials.

2.12.15.2 History

Maybe the best introduction to combinatorial chemistry is through its brief history. In 1959, the young chemist Bruce Merrifield had the idea that it would be extremely beneficial to modify the sometimes unpredictable behavior of growing peptide chain intermediates by attaching the chain to the polymeric matrix, the properties of which would be very uniform from step to step.^{598–601} His invention of solid phase synthesis, for which he was awarded the Nobel Prize,⁶⁰⁰ changed the field of peptide synthesis dramatically. The synthesis of oligonucleotides followed immediately⁶⁰²; however, the solid phase synthesis of organic molecules was pursued basically only in the laboratory of Professor Leznoff.^{603,604} Even though solid phase synthesis was more or less accepted in the chemical community, it took another 20 years before the new ways of thinking about the generation of a multitude of compounds for biological screening brought combinatorial chemistry to life. Pressure from biologists motivated the development of combinatorial chemistry. Chemists could not keep up with the demand for new chemical entities. Big pharmaceutical companies started to screen their entire collections of chemical compounds against new targets, and the rate at which these collections grew seemed unsatisfactory. Ronald Frank in Germany,⁶⁰⁵ Richard Houghten in California,⁶⁰⁶ and Mario Geysen in Australia⁶⁰⁷ devised ways to make hundreds of peptides or oligonucleotides simultaneously by segmenting the synthetic substrate–solid support. Frank used cellulose paper as the support for the synthesis of oligonucleotides. Cutting the circles of the paper and reshuffling the labeled circles for each cycle of the coupling was a very simple way to generate hundreds of oligos. Houghten enclosed classical polystyrene beaded resin in polypropylene mesh bags, later called ‘tea-bags’ or ‘T-bags,’ and used them for parallel synthesis of hundreds of peptides. The principle was the same: combine the bags intended for coupling the same amino acid and re-sort the bags after each cycle of coupling. Geysen used functionalized polypropylene pins arranged in the fixed grid. Each pin was then immersed in a solution of activated amino acid pipetted into the individual wells of microtiter plate. Pins were not re-sorted after each step, but the common steps of the synthesis (washing and deprotection) were done by the introduction of the pins into the bath containing appropriate solvent. These techniques cleared the way for the arrival of real combinatorial techniques applied to general organic chemistry and not only to the specific arena of peptides and oligonucleotides.

For biologists and biochemists, working with mixtures was absolutely natural – well, it was natural also for natural products chemists – however, organic chemists were (and still are) horrified when mixtures were mentioned. Therefore, the development of specific binders selected from the astronomically complex mixtures of RNA by selective binding and amplification of selected molecules by PCR was accepted enthusiastically, and papers describing it were published in *Science*⁶⁰⁸ and *Nature*,^{609,610} (Larry Gold and his colleagues were adventurous enough to build a company around this technology – NeXstar, subsequently merged with Gilead.) Relatively fast acceptance was given to the techniques generating specific peptides on the surface of the phage, panning for the binding sequences and amplification of the phage,^{611,612} described by Smith. Again, the approach was basically biological. However, earlier attempts to publish papers describing the use of synthetic peptide mixtures for determination of epitopes in *Nature* were unsuccessful; the world was not ready for chemical mixtures. Geysen’s seminal paper was eventually published in *Molecular Immunology*,⁶¹³ and did not find a large audience. In this paper, the mixture of amino acids was used for the coupling at the defined positions, thus generating large mixtures of peptides. Mixtures showing significant binding were ‘deconvoluted’ in several steps to define the relevant binding peptide sequence at the end.

The pioneer in development of the methods for creating the equal mixtures (of peptides) was Arpad Furka in Hungary. His method of ‘portioning–mixing’ was invented in 1982, and presented as posters in 1988 and 1989.^{614,615} The method was not noticed until 1991, when it was reinvented and published in *Nature* by two independent groups, Lam *et al.* in Arizona (the ‘split-and-mix’ method)⁶¹⁶ and Houghten *et al.* in California (the ‘divide–couple–recombine’ method).⁶¹⁷ The technology of deconvolution of mixtures was the basis of the formation of Houghten Pharmaceuticals, later renamed Trega Biosciences and now known as LION Biosciences. Finding the active molecule requires synthesis of the second (and third, and fourth, etc.) generation mixtures of lower complexity based on the activity evaluation of the most active mixture from the first round of screening. An alternative method is positional scanning, in which mixtures of the same complexity with defined building blocks in all positions of the sequence are screened, and the

importance of individual blocks is ascertained. The combinations of all 'important' residues are then assembled in the possible 'candidate sequences,' which are then tested individually.⁶¹⁸ The use of mixture-based libraries has been reviewed.⁶¹⁹

Portioning–mixing (split-and-mix or divide–couple–recombine) is a simple but powerful method that not only allows the generation of equimolar mixtures of compounds but is also the basis of one-bead-one-compound technology for the screening of individual compounds (as recognized by Lam^{616,620,621}). In this modification, the synthetic compounds are not cleaved from the resinous bead, and binding is evaluated by assay performed directly on the bead. The structure of a compound residing on a positively reacting bead is then established by direct methods or by reading 'the code' associated with that particular bead. The one-bead-one-compound technique can be modified for the release of the compound to solution,⁶²² or to semisolid media,⁶²³ to allow for the use of assays not compatible with solid phase limitations. Again, this technology jump started the first combinatorial chemistry company, Selectide (now part of Aventis).

2.12.15.3 Small Organic Molecules

Libraries of peptides and oligonucleotides were relatively easy to handle both in the mixture and in the individual one-bead-one-compound format. The determination of the structure of peptides and/or oligonucleotides is made relatively easy by sequencing requiring picomolar or even lower amounts of material. At the same time, synthetic methodologies for their synthesis are well developed. However, good candidates for new successful drugs are being sought between 'small organic molecules.' Libraries containing nonoligomeric organic compounds were obviously the next step in the development of combinatorial chemistry. Jonathan Ellman recognized this need, and developed a method for the solid phase parallel synthesis of benzodiazepines.⁶²⁴ His publication, together with published results from Parke-Davis⁶²⁵ and Mimotopes,^{626,627} started a flood of communications about the application of solid phase synthesis to the preparation of enormous numbers of different categories of organic compounds, with the major focus on heterocyclic molecules. (Numerous compilations of solid phase syntheses were published; e.g., see the examples in the reference list,^{628–631} and a dynamic database of all relevant publications is available on the internet.¹¹⁰⁵).

Transformation of one-bead-one-compound libraries to the arena of small organic molecules requires methods allowing simple and unequivocal determination of the structure from the individual bead containing picomolar amounts of analyzable material. This problem was addressed by the inclusion of 'tagging' into the synthetic scheme.^{632–635} The structure of the relevant molecule is determined by reading the 'tag.' A most elegant method for tagging was developed by Clark Still.⁶³³ Again, as a rule in this field, the result was the formation of a new company, Pharmacopeia. In this method, the tagging of the organic molecule is achieved by a relatively small set of halogenated ethers attached to the bead as a defined mixture in each step of the synthesis, forming digital code (each molecule of the tagging substance is either present (1) or absent (0)), evaluated after the detachment from the bead by gas chromatography. It did not take long before the combinatorial techniques were applied to material science.^{636–640} These libraries are produced usually in a spatially addressable form and were used to find new supraconductive, photoluminescent, or magnetoresistive materials.

2.12.15.4 Synthetic Techniques

Although the pressure to produce more compounds was visibly coming from pharmaceutical companies, some of the new techniques were developed at academic institutions. Big companies still did not embrace the new techniques, possibly due to the fact that they are quite simple and inexpensive to implement. Pharmaceutical companies do not want simple solutions; they would rather invest in enormous automation projects. Managers are judged by the budget they are able to invest, and a big room full of robotic synthesizers definitely looks impressive. Another major factor is the 'visibility' of the compound produced. The production of 100 nmol of the compound (about 50 µg of an average organic compound), which can make 100 mL of 1 µM solution (enough for 1000 biological assays), is unacceptable – simply because it is not 'visible.' Companies usually require 5–50 mg of the compound (more than enough for 1 million assays) just to 'have it on the shelf.' And techniques providing 100 nmol are definitely cheaper and require less automation than techniques needed to make milligram quantities of the compound.

A very elegant technique for synthesizing numerous organic compounds in parallel was introduced by Irori. This company was based on the idea that it is possible to label individual polymeric beads with a readable radiofrequency tag, which will be built during the split-and-mix synthesis of any type of molecule. The technique of 'Microkants' – small containers made from polymeric mesh material inside which are beads used for solid phase synthesis together with a radiofrequency tag^{641,642} – is used in numerous laboratories.⁶⁴³ The most recent incarnation of this technique

(based on the original principle of the 'tea-bag' synthesis of Houghten⁶⁰⁶) is the labeling of small disks containing 2–10 mg of synthetic substrate, called 'NanoKans,' by a two-dimensional bar code on a small ceramic chip.⁶⁴⁴

On the other hand, thousands of compounds can be synthesized relatively inexpensively in polypropylene microtiter plates using either 'surface suction'⁶⁴⁵ or 'tilted centrifugation.'⁶⁴⁶ However, nothing can be more economical and versatile for the synthesis of up to couple of hundred compounds than disposable polypropylene syringes equipped with polypropylene frits, as introduced by Krchnak.⁶⁴⁷ A syringe is charged with the solid support of choice, and all steps of the synthesis are performed by aspirating appropriate reagents using needles and (if needed) septum-closed bottles. The operation of syringes can be simplified by the use of domino blocks.⁶⁴⁸

2.12.15.5 Philosophy and Criteria

The different approaches to the synthesis of libraries illustrate the different philosophies of laboratories and companies. The same difference in thinking can be found in the value given to the purity of prepared compounds. Different companies apply different criteria. However, the only really important information that the chemist should be able to provide to the biologist is whether he or she can guarantee the preparation of the same sample tomorrow or a year from now. Does he or she have the stable, well-rehearsed protocol and reliable source of starting materials? If the biological activity is found in the impure sample, the likelihood that the active component of the mixture can be found after isolation of all components is pretty high. The probability that the activity is higher than observed in the mixture is also high. Occasionally, the active species might not be the one that was targeted but, rather, the side product of unexpected (and hopefully novel) structure.

We could go on discussing combinatorial chemistry, but because this text is intended to be an introduction to the history of the fields, we will stop here and refer readers to the published literature. The histories and personal recollections of the pioneers in this field were compiled in the inaugural issue of *Journal of Combinatorial Chemistry*,⁶⁴⁹ and a similar format was used for a history of solid-supported synthesis.^{650,651} In addition to books on the subject of combinatorial chemistry and solid phase synthesis,^{652–670} we recommend attendance at the biannual symposia on solid phase synthesis and combinatorial techniques,⁶⁷¹ organized by Roger Epton. Reading of review articles^{628–631,672–684} is also helpful. We also direct readers to the internet website compiling all papers published in this exciting and rapidly growing field.¹¹⁰⁵

2.12.16 New Synthetic Methodologies

The synthesis of libraries of diverse drug-like molecules is dependent on the availability of reliable and general synthetic methods. This section is intended to give the reader an overview of the latest developments in solid phase and solution phase syntheses directed to constructing libraries of compounds for biological screening. The brevity of this review with respect to some of the more established synthetic methods is by no means meant to diminish their importance, but rather to maintain the focus of this section on the most recent synthetic methodology advances. The reader is encouraged to consult the extensive literature cited in this section for complete details of these new synthetic methods.

2.12.16.1 Introduction

The development of high-throughput screening (HTS) technology in the late 1980s and early 1990s and the dramatic increases in the number of biological targets available from the Human Genome Project has fueled the desire of pharmaceutical companies for larger numbers of compounds to screen against these new biological targets. The solid phase synthesis of benzodiazepines was first demonstrated in 1977 by Camps Diez and co-workers.⁶⁸⁵ Around this same time, several other organic chemists, including Leznoff and Frechet, also synthesized small molecules on solid supports.^{686–688} However, little general notice was taken of these accomplishments until the early 1990s, when Ellman and Hobbs-Dewitt published their syntheses of benzodiazepines, and solid phase synthesis was recognized as an ideal method for the construction of large compound libraries.^{689,690} Multiple parallel synthetic techniques first described by Geysen (using multipin arrays⁶⁹¹) and Houghten (using 'tea-bag' methods⁶⁹²) and combinatorial synthesis by the split-and-mix method initially described by Furka *et al.* made possible the synthesis of vast numbers of diverse compounds for biological screening.^{693,694} The rapid medicinal chemistry optimization of lead compounds discovered from these collections by analogous parallel synthesis methods promised to shorten the time required to advance these compounds to clinical trials. Although in 1992 it was clear that solid phase synthesis methods could significantly enhance the drug

discovery process, the lack of robust solid phase synthetic methodologies severely limited its utility. The race was then begun to discover new synthetic methods, invent new robotics and instrumentation, develop computer-assisted library design and analysis software, and integrate these tools into the drug discovery process. The plethora of publications in combinatorial organic synthesis and the establishment of journals dedicated to combinatorial chemistry (e.g., the *Journal of Combinatorial Chemistry*, *Molecular Diversity*, and *Combinatorial Chemistry and High Throughput Screening*) demonstrates the commitment of the synthetic organic community to these endeavors.^{695–723}

2.12.16.1.1 Strategies for combinatorial library syntheses

The efficient combinatorial synthesis of quality compound libraries can be reduced to a few basic principles: (1) compound libraries must be amenable to high-throughput synthesis; (2) the scope of chemistry must be sufficiently broad; (3) the building blocks must be readily available; (4) library purities must be excellent (>85% on average); and (5) the yield must be adequate (>25% on average). The ideal library synthesis thus consists of short chemical sequences composed of highly optimized synthetic reactions to ensure adequate yields and high purities of the library members. A variety of building blocks used in the synthesis would be available from commercial sources or one- to two-step syntheses, allowing for the rapid synthesis of large compound libraries.

Solid phase synthesis is one of the most powerful methods for construction of large compound libraries. It is amenable to ‘split-and-pool’ methods for extremely large ($>10^4$ – 10^7 members), single-compound-per-bead libraries, mixture libraries, or discrete compound syntheses. The ability to drive reactions to completion using excess reagents and simple removal of impurities from the crude reactions by washing the resin permits the multistep synthesis of complex scaffolds in excellent purities and yields. Recent advances in solution phase scavenging and solid-supported reagents are also proving to be effective in multistep synthesis of libraries. A comparison of the advantages and disadvantages of solid phase versus solution phase synthesis described by Coffin in an article by Baldino is provided in [Table 28](#) (refer to the article for clarification of the ‘issues’ discussed in the table). The obvious synergies of these two methods are apparent from the table. A proficient combinatorial chemistry laboratory is capable of utilizing either solution phase or solid phase high-throughput methods, and the decision of which method to use is based on a variety of factors. These factors include the type of chemistry to be performed, the size and scale of the library, and the intended use of the library (i.e., a lead discovery library versus a lead optimization or a structure–activity relationship library).

2.12.16.2 Solid Phase Synthesis Methodologies

Numerous advances in solid phase synthesis methodologies have been published in the literature in the past decade. In fact, most solution phase synthetic transformations have now been performed in some form on solid supports. This section presents brief descriptions of many of the most recent solid phase synthesis advances, and attempts to explain the importance of these methods for the rapid synthesis of compound libraries. The reader can expect to gain from this section a good overview of the current state of the art and where the field of solid phase synthesis is headed at the beginning of the twenty-first century.

2.12.16.2.1 Introduction to polymer-supported synthesis

2.12.16.2.1.1 Pros and cons of synthesis on a support

The concept of polymer-supported synthesis was popularized by Bruce Merrifield, with the publication in 1963 of his seminal paper describing the solid phase synthesis of peptides.⁷²⁴ In this work, Merrifield covalently attached an amino acid to an insoluble polymer bead made from polystyrene cross-linked with 1–2% divinylbenzene ([Figure 89](#)). When placed in a reaction solution, the polystyrene beads swell and allow solvent to penetrate the bead, permitting a dissolved reagent access to the linked amino acid. Because the beads do not dissolve, they can be isolated from the solution by simply filtering them on a fritted funnel. The power of this method is the trivial isolation of the polymer (and thus the polymer-bound compound) from a reaction solution by filtration after the addition of each new reagent. This method completely eliminates the need for the isolation and purification of the intermediate products, each of which usually requires an aqueous extraction and chromatographic purification. This procedure is particularly useful in the synthesis of peptides, where the addition of each amino acid in solution requires two chemical steps (deprotection and coupling), as well as a separate time-consuming purification after the addition of each new amino acid (for more details, see [Figure 134](#) and [Section 2.12.16.3.1.1](#) on peptide synthesis on a solid support). Using the solid phase procedure an entire peptide can be assembled while attached to the polymer bead, and only a single purification step at the end of the synthesis is necessary. Peptides of unprecedented length and purity were synthesized in a much shorter time using the Merrifield procedure than was previously possible using traditional solution phase peptide synthesis methods. The success of

polymer-bound peptide synthesis also resulted in the development of similar technology for the construction of other biopolymers, including oligonucleotides, which are now routinely constructed in a completely automated fashion.

The concept of polymer-supported synthesis for molecules other than peptides was investigated in the late 1960s and early 1970s by a number of investigators who helped to define the scope and limitations of polymer-bound synthesis of organic molecules.^{686,687} There are a number of advantages to polymer-bound synthesis. As mentioned

above, the main advantage of an insoluble polymer support is that the insoluble polymer may be isolated from a reaction solution by filtration, making conventional purification of the desired compound unnecessary. This simplified purification procedure allows the use of a large excess of reagents to drive a reaction to completion while minimizing the time needed to purify and isolate the desired product from the complex reaction solution. Linkage of a molecule to a polymer support also facilitates encoding; an identifying tag of some kind can be linked to the polymer bead containing a particular molecule. Systems have been developed to allow the screening of millions of compounds followed by the identification of active structures by decoding tags attached to the polymer bead during the synthesis of the particular compound.⁷²⁵ Although solid phase organic synthesis remains one of the most powerful techniques for parallel synthesis, it has drawbacks. Disadvantages of this method may include diminished reaction rates for certain reactions, formation of support-bound impurities that are released along with the desired molecule during cleavage, and the necessity of developing a method for linkage of the desired compound to the support. The analysis of resin-bound intermediates can also be complicated, and additional time is often required to develop robust and versatile chemistry for multistep syntheses on a solid support. A variety of tools have been developed or adapted to aid in the analysis of compounds on a solid support, including solid-state nuclear magnetic resonance (NMR), Fourier transform infrared and mass spectroscopies, as a number of color tests for the presence or absence of certain functional groups.^{726–730} New technologies have been designed to try to retain the benefits of solid phase chemistry while minimizing the drawbacks (see Section 2.12.16.4.1 on solution phase polymer-supported synthesis).

2.12.16.2.2 Synthetic transformations on solid supports

2.12.16.2.2.1 Carbon–heteroatom coupling reactions on solid supports

Carbon–heteroatom coupling reactions are the most widely used synthetic transformations for the construction of compound libraries. *N*-Acylation, *N*-alkylation, *N*-arylation, *O*-acylation, *O*-alkylation, and *O*-arylation are just a few examples of these ubiquitous reactions performed on solid supports (Scheme 1). Nearly all reported multistep solid phase syntheses incorporate one or more of these reactions. In general, these reactions tend to be easily optimized, occur at or near room temperature, and are not particularly sensitive to air or moisture. These mild reaction conditions simplify tremendously the automation of the library synthesis, since reagents and reactions do not need to be cooled, heated, or kept under an inert atmosphere. Recent engineering advances in instrument design do permit the high-throughput synthesis of compound libraries under these more demanding conditions. Thousands of the reagents used in these syntheses are available from commercial sources. Diverse or focused sets of reagents can therefore be readily purchased for incorporation into diversity-oriented or target-directed compound libraries.

Scheme 1

Figure 90 Examples of resin-bound amines.

2.12.16.2.2.1.1 *N*-Acylation, *N*-alkylation, and *N*-arylation Many synthetic methods for the derivatization of resin-bound amines have been optimized for the construction of diverse compound libraries. The ease of amine incorporation and subsequent derivatization, along with the large and diverse set of amine building blocks that are commercially available, has driven the exploitation of this functionality. A wide variety of resin-bound amines are thus readily available, since they can be incorporated onto the support in high yields and purities via standard amino acid chemistry, reductive amination of aldehyde-functionalized resins, or amine displacement of resin-bound halides, to name just a few synthetic methods (Figure 90).

Derivatization of resin-bound amines can be accomplished by many different synthetic transformations, thus allowing the generation of diverse product libraries. Several examples are given in Scheme 1. *N*-Acylation is a particularly useful diversity forming reaction, since thousands of building blocks (acids, acid chlorides, sulfonyl chlorides, isocyanates, chloroformates, carbamoyl chlorides, and others) are commercially available, and each can be performed in high yield (Scheme 1). *N*-Alkylation of resin-bound amines is another useful reaction sequence, since it affords basic secondary or tertiary amine products with dramatically different chemical and physical properties. The aldehyde, alkyl halide, or alcohol building blocks necessary for the synthesis of these *N*-alkylamine compounds (via reductive amination or *N*-alkylation, respectively) are also readily available, allowing large, diverse libraries of these compounds to be synthesized. A general method for the *N*-arylation of resin-bound amines is a relatively new addition to the optimized solid phase reactions.^{731–734} A complete description of these transformations can be found in Section 2.12.16.2.2.3 on transition metal-mediated coupling reactions.

2.12.16.2.2.1.2 *O*-Acylation, *O*-alkylation, and *O*-arylation The carbon–oxygen bond is a ubiquitous motif found in many drugs. Therefore, solid phase synthetic methods for carbon–oxygen bond formation (*O*-acylation, *O*-alkylation, and *O*-arylation) have been utilized many times in compound library synthesis (Scheme 1). The robust nature of this chemistry with respect to the ease of synthesis and variety of building blocks that undergo efficient chemical reaction make these methods very attractive for diverse compound library construction. While the resultant esters can be somewhat unstable to proteases under physiological conditions, the ether and carbamate linkages are typically stable.

The hydroxyl functional group also offers a handle for linking a scaffold to a suitable polymer support. This technique has been a useful synthetic strategy for those libraries where a free hydroxyl group is desired in all members of the library. The solid phase syntheses of hydroxyethylamine aspartyl protease inhibitor libraries and prostaglandin libraries are excellent examples of this strategy (Figure 91).^{735–737} The hydroxyl group is an integral part of the aspartyl protease inhibitor and prostaglandin pharmacophores. The linkage at the conserved hydroxyl group not only binds the core to the resin for subsequent derivatization but also protects the hydroxyl from undesired reactions during the library synthesis. The free hydroxyl group is only revealed upon cleavage of the final products from the solid support.

2.12.16.2.2.2 Carbon–carbon bond-forming reactions on solid supports

The biopolymer syntheses described in Section 2.12.16.3.1 involve the formation of a carbon–heteroatom bond (an amide bond for peptides, a glycosidic ether linkage for oligosaccharides, and a phosphate ester bond for

Figure 91 Use of a support/linker as a hydroxyl protecting group in the synthesis of (a) hydroxyethylamines and (b) prostaglandins.

oligonucleotides). While the ability to form these bonds is crucial to the synthesis of biopolymers, an expanded set of reactions is required to allow chemists to access more complex organic structures. A key tool for synthetic organic chemists is the ability to synthesize carbon–carbon bonds. There are numerous methods available for the generation of carbon–carbon bonds in normal solution chemistry (which in most cases translate well into soluble polymer chemistry). However, these methods must often be modified for reactions in the presence of a solid support, where factors such as polymer solubility (or ‘swelling’ ability), reagent solubility, and compatibility of any linker or previously existing functionality must be taken into consideration. Extensive effort has gone into developing conditions for a variety of carbon–carbon bond-forming reactions on solid supports, a number of which are now available to the chemist for use in the parallel synthesis of small organic molecules.⁷³⁸ Several examples of these reactions are shown below. Numerous other carbon–carbon bond-forming reactions have been described, including metal-mediated coupling reactions (such as the Stille, Suzuki, and Heck reactions)⁷¹¹ and multiple-component condensations (e.g., the Passerini, Ugi, and Biginelli reactions).⁷³⁹ Many of these other reactions are described briefly elsewhere in this section, and in-depth discussions can be found in several recent reviews of solid phase synthesis.^{698,701,710,711,713,738,740} The Grignard reaction involves the attack of a carbon nucleophile (for Grignard reactions, a carbon–magnesium halide salt) on an electrophilic carbon such as an imine, Weinreb amide, or ketone, as shown in the examples in Figure 92.⁷⁴¹ While the examples above show classical magnesium bromide Grignard salts acting as nucleophiles, similar reactions have been demonstrated on supports using organolithium and organocuprate reagents. (Cuprates are traditionally used to introduce a carbon nucleophile to an α,β -unsaturated carbonyl group at the β position of the double bond.) When performing reactions with strong nucleophiles/bases such as Grignard reagents, consideration must be given to factors such as the other functional groups present on the support, whether the linker can withstand reaction conditions involving strong nucleophiles, and so on. There exist in the literature numerous examples of Grignard reagents being successfully applied in a library format to a support-bound reactant.

The Wittig and Horner–Emmons reactions (Figure 93) are often used to install carbon–carbon double bonds into a target molecule, and have been readily applied to support-bound synthesis. The Baylis–Hillman reaction (Figure 93) involves the coupling of an aldehyde to an electron-poor alkene. Unlike most other carbon–carbon bond-forming reactions, it does not require an inert atmosphere, and can usually be conducted at room temperature. These mild reaction conditions make the Baylis–Hillman reaction well suited for combinatorial and parallel synthetic applications.⁷⁴² In an enolate alkylation, the enolate is generated by the reaction of a carbonyl-containing compound with a strong base (shown in Figure 93). The enolate is then reacted with an electrophile, resulting in the formation of the carbon–carbon bond. There have been various reports of enolates being generated and alkylated on a support to

Figure 92 Carbon–carbon bond formation on a solid support: carbon nucleophiles (Grignard and cuprate additions).

install a carbon–carbon bond adjacent to a carbonyl group. Chiral auxiliaries have been attached to a support adjacent to the reacting center to influence the stereochemistry of the chiral center that is formed, with diastereoselectivities that were found to be comparable to those obtained via the analogous solution phase reaction.

2.12.16.2.2.3 Transition metal-mediated coupling reactions

Transition metal-mediated coupling reactions have been utilized extensively in solid phase syntheses.⁷¹¹ Palladium-mediated Heck, Suzuki, and Stille reactions are particularly useful for diversifying compound libraries due to their generality and efficiency of coupling (Figure 94). These biaryl- and arylalkene-forming reactions have been effected in high yield with either the metallated arene/alkene or the arylhalide bound to the solid support.

Transition metal-mediated olefin metathesis has been utilized in a number of solid phase syntheses for the construction of rings of various sizes, including several examples of macrocycles that would be inaccessible by other solid phase synthetic methods (Figure 95).^{743–745} The generality of the method has made olefin metathesis a useful tool for the synthesis of various macrocycles. The resulting cyclic scaffolds are preferred over their linear counterparts since they often bind more tightly to proteins, due in part to their reduced entropy of binding. Medicinal chemists also glean additional structural information from leads discovered from these compound libraries, since their mode of binding can be predicted with greater precision due to decreased conformational flexibility of the molecules.

Figure 94 Support-bound Heck, Suzuki, and Stille reactions.

Figure 95 Three examples of transition metal-catalyzed ring-closing reactions on solid support.

Advances in palladium-mediated and copper-mediated *N*-arylation reactions have been demonstrated on solid supports (Figure 96).^{731–734} These synthetic methods are particularly useful due to the omnipresent nature of the *N*-aryl bond in biologically active compounds. *N*-Arylation of support-bound amines by copper-acetate-mediated coupling of boronic acids afford *N*-arylated amines, while suitably substituted arylhalides on solid supports can be *N*-arylated with a variety of primary and secondary amines using palladium catalysis. These complementary reactions provide new synthetic avenues for the generation of diverse structures not previously available to the combinatorial chemist.

2.12.16.2.2.4 Intramolecular cyclization–resin-cleavage strategies

When conducting syntheses on a support, whether that support is a soluble polymer or an insoluble (‘solid’) phase, it is desirable to minimize the number of reaction steps required to obtain the final products. The time and material saved in such combinations of steps (e.g., by not having to wash a library on a solid support between reactions) is often worth the price of a small decrease in yield or purity. The two steps of cyclization to form a ring and cleavage of the product from the support have been combined in a number of reaction sequences. In the situation where cyclization directly

N-arylation

Figure 96 Two examples of *N*-arylation chemistry on a solid support.

Pyrrolidinones

Hydantoins

Quinazoline-2,4-diones

Figure 97 Three examples of simultaneous cyclization and cleavage reactions.

results in cleavage from the support, product purity is excellent. Typically, only the desired completed sequence is capable of cleavage, whereas any incomplete sequences remain on the support. When the cyclization and cleavage reactions occur sequentially (such as in the cyclopentapiperidinone case shown below, where acidic cleavage and cyclization are not necessarily simultaneous), and the cyclization does not proceed to 100% completion, both the cyclized and uncyclized material are released into solution. Both cyclization to release product and 'one-pot' cleavage followed by cyclization of product have been successfully applied to a number of small-molecule syntheses on a polymeric support, as shown in [Figures 97 and 98](#).

Three examples of syntheses where cleavage from the support occurs as a direct result of cyclization (such that only the desired cyclized material is isolated) are shown in [Figure 97](#).^{746,747} In all three cases, only the cyclized product is obtained in high purity, though in varying yields, after the cyclization/cleavage step. All impurities are either washed from the resin prior to the final step or remain attached to the solid phase.

Two examples where cleavage and cyclization are not necessarily linked events are shown in [Figure 98](#). The reaction conditions result in cleavage of material from the support, whether or not cyclization occurs. In the dihydrobenzodiazepine-2-one case, the product ester is generated after reaction with sodium methoxide at the terminal carboxylic acid/ester, while cyclization takes place via amine attack at the unsaturated carbon adjacent to

Figure 98 Two examples of cleavage from a support, followed by nonsimultaneous cyclization.

the amide.⁷⁴⁸ In the cyclopentapiperidinone case, trifluoroacetic acid cleaves the free amine from the resin, then subsequently catalyzes the observed cyclization.⁷⁴⁹ In these two cases, if cyclization could not occur, the molecules are still cleaved from support, and hence an additional impurity (the uncyclized material) may be present in the final product.

2.12.16.2.2.5 Cycloadditions

Carbocyclic and heterocyclic cores are frequently used to display pharmaceutically interesting functional groups. The cyclic core allows for the specific orientation of functional group side chains, often resulting in improved binding affinity or specificity versus more flexible linear cores. One method for obtaining cyclic and heterocyclic cores that has been exploited to a great extent in parallel and combinatorial synthesis is the cycloaddition reaction. Cycloadditions are very attractive to the chemist synthesizing a compound library, since in one step multiple bonds can be formed, introducing a carbocycle or heterocycle while concurrently installing one or more side chains in specific positions on the cyclic core. Strategies have also been developed whereby cyclization to provide the desired molecule and cleavage from the solid support occur simultaneously (see the previous section on intramolecular cyclization/cleavage strategies). A number of different support-bound cycloadditions have been reported, usually resulting in the formation of four-, five-, and six-membered rings with varying displays of side chains around the cores.^{701,713,720,738,750} Several examples of cycloadditions on solid support are shown in [Figure 99](#).

2.12.16.2.2.6 Multiple-component reactions on solid supports

Multiple-component reactions simultaneously condense three or more components to generate new complex molecules in a single synthetic transformation ([Figure 100](#)). Relatively few such synthetic transformations are known when compared with bimolecular reactions. Even so, these unique reactions are particularly desirable for generating libraries of complex molecules, since only a single step need be optimized and performed to bring together as many as five different components. These solid phase syntheses thus require substantially less time to optimize reaction conditions and are easier to perform in a high-throughput manner for large-compound library construction. Many of these reactions are also tolerant of a variety of functionalities on the individual components, and thus allow the combinatorial chemist to synthesize structurally diverse compound libraries. Although multiple-component reactions offer substantial efficiencies in the time and effort required to construct single-compound-per-well libraries, they do not allow for 'split-and-pool' synthesis strategies due to the inherent nature of the multiple-component condensation process.

The first multiple-component reaction to be performed both in solution and on a solid support was a three-component Passerini reaction, affording a library of azinomycin analogs ([Figure 101](#)).^{705,739,751–753} A variety of multiple-component reactions have since been effected where one of the components is bound to the solid support, including the Ugi reaction, the Mannich reaction, the Biginelli reaction, the Grieco three-component reaction,

and a thiazolidinone synthesis, to name but a few.^{739,754} Recent advances in the use of multiple-component reactions have focused on the subsequent synthetic manipulation of the generic multiple-component scaffold to reduce the peptide-like nature of the products. The solid phase or solution phase synthesis of lactams,⁷⁵⁵ pyrroles,⁷⁵⁶ imidazoles,^{757,758} imidazolines,⁷⁵⁹ and ketopiperazines⁷⁶⁰ from Ugi products are a few examples of such multiple-component reactions and subsequent synthetic elaboration to afford libraries of heterocycles (Figure 102).

2.12.16.2.3 Resin-to-resin transfer reactions

A synthetic method that would enable a chemist to synthesize a novel reagent on one resin and subsequently transfer it to another derivatized resin (i.e., resin-to-resin transfer) would be a useful tool for the convergent construction of diverse compound libraries. A report by Scialdone *et al.* demonstrates such a transformation, where an isocyanate was

Scheme 2

Scheme 3

generated from one resin, then diffused into and reacted with another appropriately functionalized resin to generate novel ureas (Scheme 2).⁷⁶¹

Another example of resin-to-resin transfer, used in a Suzuki reaction, has been reported. In this case, the support-bound boronic ester is released from one resin via mild hydrolysis, and reacted with a resin-bound aryl iodide to yield the biaryl product on the support (Scheme 3).⁷⁶² The ability to synthesize increasingly complex building blocks by solid phase methods and subsequently utilize them as building blocks for a new solid phase synthesis is an important step toward the construction of structurally complex compound libraries.

2.12.16.3 Complex Multistep Synthesis on Solid Supports

2.12.16.3.1 Oligomers – natural and unnatural

Many of the synthetic techniques used for the synthesis of libraries of small organic molecules were originally developed for the chemical synthesis of biopolymers. Extensive research has gone into the required activating protocols and the wide array of protecting groups needed to synthesize large (20–100 steps) biopolymers in high yields and purities. The three major classes of biopolymers, peptides, oligosaccharides, and oligonucleotides, have all been chemically synthesized on supports, and each of these classes is discussed below.

2.12.16.3.1.1 Peptide synthesis

The chemical synthesis of peptides was performed by Merrifield in 1963, and represents the original application of the solid phase synthesis of organic molecules.⁷⁶³ Whereas very large peptides and proteins are often synthesized by biochemical methods (e.g., overexpression in *E. coli*⁷⁶⁴), synthesis on a solid support is frequently used when peptides (typically lower than 50 amino acids) or peptides containing unnatural amino acids are desired (Figure 103). (Peptides containing unnatural amino acids can be expressed using Schultz's modified tRNA technique.⁷⁶⁵ However, for short peptides or in cases where a significant amount of peptide is desired, chemical synthesis is still preferred.) While there have been a number of different routes developed for support-bound peptide synthesis, two techniques are used most frequently. One of these is the 9-fluorenylmethoxycarbonyl (Fmoc)-based approach, using amino acids that are protected at the backbone nitrogen with the base-labile Fmoc group and at side chain functional groups with acid-labile protecting groups. In the Fmoc-amino acid approach, side chain nitrogens are protected using *t*-butoxycarbonyl (t-Boc) groups. Amino acids are coupled to the amino terminus of the growing peptide on a solid support via the use of an activating agent to boost the reactivity of the reacting carboxylate.^{766,767} After each coupling step, the amino terminus is prepared for the next reaction by removal of the Fmoc protecting group. When completed, the peptide is

Figure 103 Solid phase peptide synthesis. Side chains are represented by R groups, and PG indicates a protecting group.

removed from the support by a strong acid cleavage step, which simultaneously removes all of the acid-labile side chain protecting groups, resulting in the desired peptide. Coupling conditions and reagents have been refined to provide high efficiency while minimizing racemization of the amino acid stereocenters.

Peptide libraries numbering in excess of 1 million compounds have been generated using standard Fmoc-based chemistry in a split-and-mix library synthesis format. For example, a 6.25 million member mixture-based library of tetrapeptides synthesized using Fmoc-based chemistry was used to identify several 0.4–2.0 nM agonists of the mu opioid receptor.⁷⁶⁸ Synthesis of peptides on a solid support via the Fmoc-based strategy is easily automated, and a variety of peptide synthesizers that apply this chemistry have been developed. Many of the concepts and reagents that have been applied to Fmoc-amino acid peptide synthesis are used in combinatorial organic small-molecule synthesis as well, including various resins and linkers, coupling reagents, and protecting groups. In particular, a wide variety of the coupling reagents used to make amide and ester linkages in peptides have found extensive application in the generation of small-molecule libraries.

The second frequently applied support-bound peptide synthesis strategy is the t-Boc-protected amino acid approach, where the acid-labile t-Boc protecting group protects peptide backbone amines during coupling.⁷⁶⁹ In this approach, side chains are protected using benzyl groups. These protecting groups are stable to the mildly acidic conditions used during deprotection of the peptide terminus. The support-bound t-Boc-protected amino terminus is deprotected by exposure to acid (typically trifluoroacetic acid in dichloromethane), and the next residue is added to the peptide via use of an activating agent, as described above. The completed peptide is cleaved from the support by a very strong acid, usually hydrofluoric acid or trifluoromethane sulfonic acid. A variation of the t-Boc-amino acid strategy is widely applied for solution phase synthesis of small peptides (i.e., free of polymeric support). The t-Boc-amino acid peptide synthesis technique is often used in industrial settings. However, it is applied less frequently than the Fmoc-amino acid strategy in academic or research settings. This most likely is due to the special equipment and extraordinary care that must be used with the t-Boc-amino acid strategy as a result of the extremely harsh cleavage conditions required to cleave the finished peptide.

2.12.16.3.1.2 Oligonucleotide synthesis

The synthesis of oligonucleotides on a solid support has been developed to such an extent that it is now readily automated; the synthetic steps are typically high yielding, and extremely long oligonucleotides can be synthesized. The protection and reactivity of only four different nucleotides had been considered in the optimization of DNA synthesis.⁷⁷⁰ Molecular biology techniques, such as PCR, have increased the need for chemically synthesized oligonucleotides (e.g., to act as primer sequences in PCR). The demand for methods to chemically synthesize oligonucleotides is especially strong when synthetic, or 'unnatural,' nucleotides are to be incorporated, when milligram quantities of an oligonucleotide are needed, or when a library of relatively short oligonucleotides (less than 30 nucleotides) is desired. The technique most commonly used for oligonucleotide synthesis on a support is the phosphoramidite coupling method, a general outline of which is shown in Figure 104. In this technique a nucleotide is coupled to the free hydroxyl of a support-bound nucleotide, forming a phosphite triester. The phosphite is then oxidized to a phosphate triester, the protecting group (PG^2) is removed from the primary hydroxyl of the terminal nucleotide, and the coupling process is repeated. This method has been successfully applied in automated oligonucleotide synthesizers due to the high yields and purity of products typically observed for each step of the sequence.

Figure 104 Support-bound oligonucleotide synthesis. PG¹ and PG² indicate two different protecting groups.

Figure 105 Representation of oligosaccharide synthesis using a support-bound glycosyl acceptor. PG indicates protecting groups, and OA indicates the glycosyl acceptor in the elongation reaction.

2.12.16.3.1.3 Oligosaccharide synthesis

Oligosaccharides were one of the last biopolymers to succumb to automated solid phase or solution phase chemical synthesis. They present a special challenge to chemical synthesis, either on a support or in solution, due to both the number of hydroxyl groups of similar reactivity that must be protected and the selective deprotection of a specific hydroxyl group that is required for glycosidic bond formation (**Figure 105**). Added to these issues is the requirement that glycosidic bond formation proceeds in a stereospecific manner, ideally with accessibility to either stereoisomer. The synthetically demanding requirements of obtaining regiospecific and stereospecific bond formation at each coupling step balances the advantages of support-bound synthesis (the ease of purification of intermediates and the ability to drive reactions to completion using excess reagents). While the oligosaccharide area of biopolymer synthesis is not as fully developed as the areas of peptides or oligonucleotides, many significant advances have been made in recent years.^{771–773}

The parallel synthesis of oligosaccharides has been accomplished using both soluble and insoluble polymers. Glycoside elongation has been accomplished by either chemical or enzymatic bond formation. Glycopeptides have also been synthesized on a support, where the peptide is elongated after glycosylation; then the saccharide is attached to a peptide side chain and elongated, or, alternatively, the completed oligosaccharide is attached to the completed support-bound peptide.^{772,774,775} Glycopeptides fall into two classes; *O*-linked glycopeptides and *N*-linked glycopeptides (examples of which are shown in **Figure 106**).

Oligosaccharides have been synthesized on a polymeric support using two approaches: either the glycosyl donor is on the support and the acceptor is in solution, or the glycosyl acceptor is on the support and the donor is in solution. An example of a support-bound glycosyl donor strategy applied to the synthesis of a β -linked oligosaccharide is shown in **Figure 107**.⁷⁷⁶

Figure 106 Examples of (a) O-linked and (b) N-linked glycopeptides.

Figure 107 Tetrasaccharide synthesis using a support-bound glycosyl donor, as described by Zheng *et al.*⁷⁷⁶ Bn indicates a benzyl protecting group, and Piv indicates a pivaloyl protecting group.

2.12.16.3.1.4 Synthesis of hybrid oligomers

The advances in techniques for the chemical synthesis of the three major classes of biopolymers discussed above have allowed scientists to explore hybrids of the biopolymers. As mentioned above, glycopeptides have been synthesized on a solid phase, with the oligosaccharide segment being elongated after coupling to a support-bound peptide. A related approach, where the completed oligosaccharide is coupled to the support-bound peptide, has also been reported. Likewise, peptide–DNA hybrids, or peptide nucleic acids (PNAs), have been synthesized.^{777,778} In a PNA, the phosphate–sugar backbone of the oligonucleotide has been replaced by a peptide amide backbone (**Figure 108**). PNAs have received considerable attention as potential antisense and antigene drugs, as well as tools for probing DNA structure and helix stability.^{779,780}

2.12.16.3.1.5 Unnatural oligomers

The proper orientation of pharmacologically important side chains around a central core is fundamental to medicinal chemistry. Nature accomplishes this orientation in peptides and proteins by displaying amino acid side chains around

Figure 108 Base pairing of a segment of a DNA molecule with a PNA molecule, where C, G, A, and T represent the corresponding nucleic acids.

the peptide backbone. Libraries of peptides are often used to identify the proper side chains and orientation for binding to a receptor or enzyme active site. However, peptides (amino acid oligomers) have significant pharmacological drawbacks that typically make them unsuitable as orally bioavailable drugs. A number of unnatural oligomers have been reported in recent years, many of which have been synthesized on a solid phase or soluble polymer support. In their attempts to mimic the display of side chains by a normal peptide backbone, chemists have developed these various oligomers, while endeavoring to overcome some of the liabilities of peptides (susceptibility to proteolysis, poor bioavailability, etc.). Several examples of unnatural oligomers are shown in [Figure 109](#), along with a natural peptide backbone for comparison.^{781–789} This figure is not meant to represent an inclusive set, as several other unnatural oligomers (e.g., the PNAs mentioned in the previous section) have also been synthesized.

2.12.16.3.2 Heterocycle/pharmacophore synthesis

As the number of different chemical transformations available to chemists has expanded, the complexity of molecules that may be synthesized in parallel has likewise increased. Chemists have taken advantage of the new tools available to them to synthesize molecules of significant complexity. Several interesting examples of solid phase small-molecule synthesis are shown in [Figures 110–115](#). Relatively early yet significant examples of small molecule combinatorial synthesis are the 1,4-benzodiazepine libraries, synthesized on a solid phase in the early 1990s.^{689,790,791} Benzodiazepines are known to have a wide range of biological activities. The 1,4-benzodiazepine scaffold represents a versatile pharmacophore (or core structure), of which multiple diverse elements may be displayed. The synthesis shown in [Figure 110](#) allows for the incorporation of four diverse elements (represented as R^1 – R^4) around the central benzodiazepine core. Another example of the synthesis of an important pharmacophore on a solid phase is that of the quinolones ([Figure 111](#)).⁷⁹² Quinolones compose a class of broad-spectrum antibiotics discovered relatively recently. In their demonstration of quinolone solid phase synthesis, MacDonald and co-workers included the known antibiotic ciprofloxacin in order to highlight the ability of their quinolone library to generate pharmaceutically relevant compounds.

Four recent pharmacophore syntheses on supports are shown in [Figures 112–115](#). In all four cases, at least three diversity elements may be displayed around a central core. The bicyclic guanidines derive their diversity elements from amino acids; an acylated dipeptide is synthesized on a support, the amide carbonyl groups are reduced, and the resulting triamine is then cyclized ([Figure 112](#)).⁷⁹³ The benzopiperazinones ([Figure 113](#)) also derive side chain diversity (at two positions) from amino acids, and a postcyclization alkylation on support introduces functionality at the R^4 position.⁷⁹⁴ The oxopiperazine core is assembled via a tandem *N*-acyliminium ion cyclization–nucleophilic addition, resulting in the construction of both rings in a single step ([Figure 114](#)).⁷⁹⁵ Finally, the prostaglandin synthesis shown in [Figure 115](#) is an excellent example of the application of a variety of solid phase reactions, including enantioselective carbon–carbon bond formation, and oxidation of an alcohol to a ketone.^{737,796}

The Schreiber group has developed ‘complexity-generating’ reactions to access diverse compounds. One example of this approach is shown in [Figure 116](#), where the 7-5-5-7 ring system was generated in six steps on a support. The synthesis involves two key complexity-generating steps: an Ugi reaction (followed by an intramolecular Diels–Alder

Figure 109 Peptide backbone, followed by various unnatural oligomer structures, indicating display of side chains (R groups).

reaction) and a ring-closing metathesis. The final product contains five stereocenters, and was isolated as a single stereoisomer. The authors report that the optimization of the support-bound reactions is underway, with the goal of generating a library via split-pool synthesis.

2.12.16.3.3 Natural product total syntheses on a solid support

The total synthesis of complex natural products offers formidable synthetic challenges even without the added difficulties involved with the optimization of solid phase synthesis.⁷⁹⁷ These challenges have been met by several different research laboratories with the synthesis of such natural products as epothilones A and B,⁷⁴³ the fumiquinazoline alkaloids,⁷⁹⁸ and analogs of indolactam V⁷⁹⁹ (Figure 117). The degree of difficulty of these

Figure 114 Solid phase synthesis of oxapiperazines.

Figure 115 Solid phase synthesis of prostaglandins.

syntheses and proficiency with which they have been achieved are evidence that solid-supported synthesis has matured into an applicable method for the generation of complex molecules.

Ganesan's solid phase synthesis of (+)-glyantrypine and several close analogs (fumiquinazoline alkaloids) from readily available starting materials demonstrates the potential of this technology to rapidly access natural product structures.⁷⁹⁸ The synthesis began with Fmoc-protected L-tryptophan on a solid support. Subsequent elongation to a linear tripeptide was followed by a cyclative cleavage from the support, resulting in the desired fumiquinazoline alkaloids. The versatility of this approach was demonstrated by the synthesis of 17 unnatural fumiquinazoline analogs, where L-alanine, L-leucine, and L-phenylalanine were used in place of L-tryptophan. The final products were obtained in moderate to good yields and high purity.

Nicolaou's total synthesis of epothilones A and B reveals the potential synergies between solution and solid phase synthesis.⁷⁴³ Complex subunits were synthesized in solution and then combined on the solid support to achieve a highly convergent method for the rapid construction of the uncyclized scaffold (Scheme 4). A strategic olefin linkage of the acyclic precursor to the solid support allowed for simultaneous macrocyclization and cleavage of the reaction product from the resin via ring-closing metathesis. A subsequent epoxidation in solution, followed by the resolution of diastereomers, led to the desired natural product. This type of hybrid solution phase and solid phase approach is particularly attractive to the medicinal chemist, since it allows for the rapid generation of analogs of these biologically active natural products.

Schreiber and co-workers have described the synthesis of a library of 'natural product-like' compounds. The library contained over 2 million compounds, and was derived from two cores that vary in the nature of the R group in the template (Figure 118).⁸⁰⁰ Several other groups are also looking at cores related to natural products in order to access structural classes that were previously inaccessible by parallel synthesis.^{744,801} This application of solid phase synthesis begins to bridge the gap between the relatively simple small molecules traditionally made via combinatorial methods and very complicated natural products, as chemists seek more sophisticated cores for their libraries.

2.12.16.4 Solution Phase Synthesis Methodologies

2.12.16.4.1 Solution phase polymer-supported synthesis

While the majority of reports of parallel and combinatorial synthesis still involve the attachment of reactants (either reagent or substrate) to an insoluble support, there have been numerous publications describing parallel synthesis using

Figure 116 Solid phase synthesis using 'complexity-generating' reactions to produce a 7-5-5-7 ring system.

Figure 117 Natural products and natural product analogs synthesized on solid supports.

Scheme 4

Figure 118 Core template (boxed) and representative synthesis of the ‘natural-product-like’ library from the benzyl-derived core and alkyne, amine, and carboxylic acid building blocks. For the core template, R represents either benzyl or phenyl side chains.

soluble polymers.^{704,721,722} The major advantage that the use of a soluble polymer holds over a ‘classical’ insoluble polymer (e.g., polystyrene beads) is that reactions occur entirely in the solution phase, so that little or no modification of a traditional non-polymer-supported synthesis is necessary. A second advantage is that the reaction kinetics are often faster with the soluble polymer than with a two-phase system. Upon completion of the reaction, the desired product

Figure 119 Examples of soluble polymer supports.

Figure 120 Dendrimer-supported synthesis.

(attached to the soluble polymer) is isolated by precipitation of the polymer, by extraction (e.g., into a fluorous solvent when using a fluorous polymer), or by means of separation based on molecular weight (such as equilibrium dialysis or size exclusion chromatography). Some examples of soluble polymers include polyethyleneglycol (PEG), polyvinyl alcohol, non-cross-linked polystyrene, and polyacrylic acid (Figure 119). Since the polymer-bound component can be separated from the other reagents at the end of the reaction, excess reagents may still be used to drive reactions to completion, affording high yields and purities of the products.

When using soluble polymer supports, such as PEG, consideration must be given to the size and solubility properties of the polymer to be used, as well as to the size of the desired product molecule. As the size of the attached molecule increases, its solubility properties can often moderate or dominate the solubility properties of the polymer, potentially resulting in loss of product due to incomplete crystallization or extraction. A number of different polymers have been applied to solution phase parallel synthesis, selected for their solubilizing characteristics and compatibility with reaction chemistry.

Chemistry has been developed to take advantage of the unique properties of highly fluorinated hydrocarbons. It has been recognized that solvents comprising these fluorinated hydrocarbons are immiscible with water and with many organic solvents, resulting in a 'fluorous' phase.⁸⁰² Compounds attached to highly fluorinated 'tags' may be reacted in solution in pure organic solvents or solvents containing a fluorous co-solvent, then extracted into a fluorous phase upon completion of the reaction. Likewise, reagents may be attached to highly fluorinated tags and extracted into a fluorous phase and away from the product. To selectively bind and separate the fluorous-tagged material from the reaction mixture, a third option is to combine a fluorinated solid phase (such as silica) with a fluorinated, bonded phase. Techniques involving the use of fluorinated tags have the advantages of allowing reactions to be run in solution, followed by straightforward separation of the product or reactant (depending on which contained the fluorous tag). No translation of solution phase procedures is necessary. However, such fluorous tagging has yet to find widespread use in parallel and combinatorial chemistry, due in part to the poor commercial availability of several of the required reagents.

Dendrimers have been suggested for use as soluble polymer supports for combinatorial libraries (Figure 120).⁸⁰³ Separation from reactants is accomplished by methods such as size exclusion chromatography or ultrafiltration, where the larger dendrimer is isolated from the smaller reactants. Dendrimers typically have considerably higher loading (more molecules of product per gram of support) than insoluble polymers, and again there is no need to translate solution phase procedures for use with dendrimer supports. While it would appear that there are several advantages for the use of dendrimers over insoluble polymer supports, there have been relatively few reports of dendrimer-supported parallel or combinatorial syntheses. Only a few dendrimers are commercially available, and the methods of purification required between steps (size exclusion chromatography or ultrafiltration) have not yet been developed in a readily accessible high-throughput format.

2.12.16.4.2 Solution phase reactions involving scavenging resins

It was first recognized by Kaldor and co-workers that solid-supported nucleophiles and electrophiles could be used for rapid purification of compound libraries synthesized in a standard solution phase reaction.^{702,804} The advantages of this

technique include standard solution phase kinetics and easy analysis of reactions using conventional methods, and it also obviates the need for the development of linker chemistry. The largest incentive to pursuing this methodology is that the development time for the synthesis of new compounds can be much shorter than the time necessary to develop a new solid phase synthesis. This reduction in time is critical, particularly when medicinal chemists are developing methods for the exploration of structure–activity relationships in the intensely competitive pharmaceutical industry. Sequestering agents allow the most straightforward type of parallel synthesis; standard reactions are carried out in solution in parallel, and the replacement of the normally time-consuming work-up by simply mixing the reaction solutions with an appropriate scavenger on a support and filtering to provide the pure products eliminates purification.

There are several potential drawbacks to solution phase synthesis involving either scavenging resins or resin-bound reagents (discussed in [Section 2.12.16.4.3](#)). For example, it is not possible to design split-and-pool syntheses, as the reaction products are free in solution and not associated with any tag or bead to separate. This can limit the size of the library (number of compounds) produced. In addition, while several examples of longer syntheses involving scavenging or resin-bound reagents are shown below, reaction sequences using these reagents are typically very short, of the order of one to three steps. This is in contrast to syntheses on solid supports, which are often five or six steps long, and occasionally much longer. (For examples of longer sequences, see the preceding sections on complex multistep synthesis on solid supports.)

Support-bound scavengers have been developed for a variety of common reagents. There are two common varieties of scavengers: ionic reagents that remove impurities by forming salts, and reaction-based scavengers that react chemoselectively with an undesired excess reagent. Ionic reagents were the first such resins to be reported.⁸⁰⁴ Amines can be removed by forming salts with support-bound sulfonic or carboxylic acids (sulfonic acid resins such as Dowex are common), and acids can be removed with support-bound amines, such as high-loading trisamine resins. Acid-functionalized resins are also commonly employed to scavenge excess metals and metal alkoxides from organometallic reactions, including Grignard and alkyllithium additions.⁸⁰⁵ These reactions are relatively selective, as the unreacted polar reagents are usually removed from uncharged products. Although conceptually simple, these procedures are extremely powerful, and are used routinely in parallel synthesis.

Chemists have also used ion exchange resins to ‘trap’ products instead of impurities. In this inverse application of scavenger resins (often termed ‘catch and release’ purification), the charged product is captured by an appropriate ion exchange resin. The reaction impurities are then washed away, and the pure product is released from the ion exchange resin by elution with an appropriate buffer ([Figure 121](#)). This technique has also been applied in cases where the product is selectively reacted with a resin-bound reagent, to form a covalent link to the support. The impurities are then washed away, and the product is released via a second reaction or cleavage step.

Most reactivity-based scavengers are functionalized polystyrene resins. Nucleophilic impurities such as amines or thiols can effectively be removed by the use of electrophilic resins. Some examples of these reagents include polymer-bound isocyanates, sulfonyl chlorides, anhydrides, aldehydes, and chloroformates. Excess electrophiles, such as acid chlorides, isocyanates, aldehydes, alkyl halides, α,β -unsaturated carbonyl compounds, and sulfonyl chlorides, can be sequestered using polymer-bound nucleophiles such as amines and thiols.^{806–808} Examples of several different classes

Figure 121 Outline of ‘catch and release’ purification: a cationic product is captured on an anionic ion exchange resin, the neutral and anionic impurities are washed away, and the pure product is eluted from the resin.

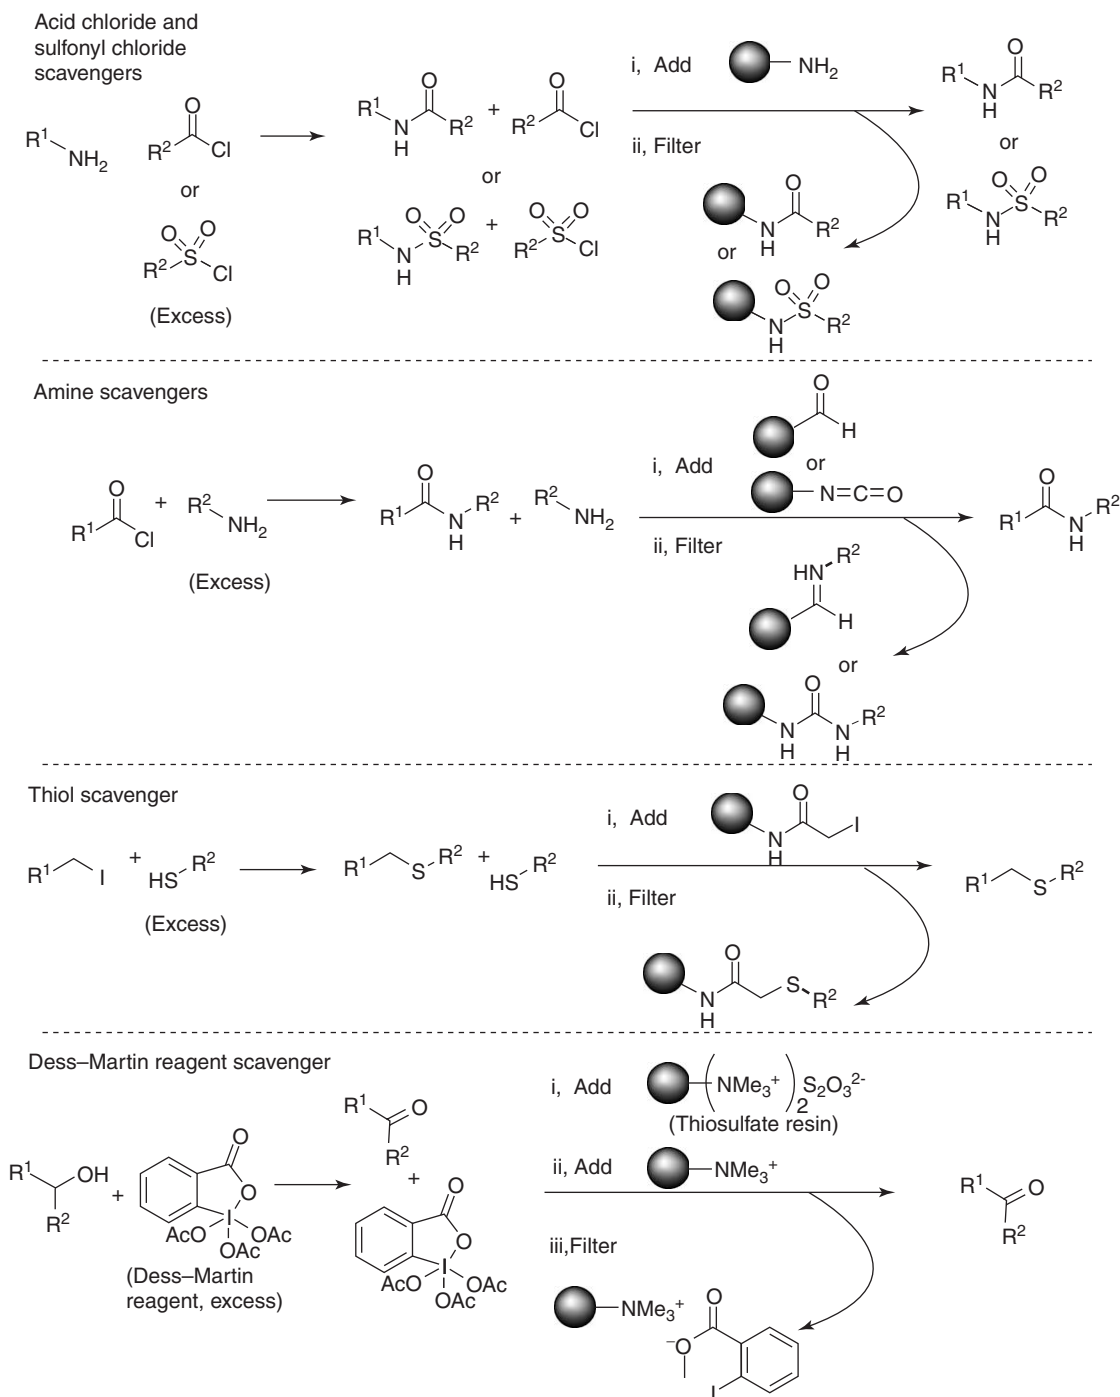

Figure 122 Reactivity-based scavenger resins.

of reactivity-based scavengers are shown (being used for purification of products) in [Figure 122](#).^{806–810} The large number of different reagents available for these purification techniques allows ‘tuning’ of the reactivity of a scavenger. For example, a thiol can be removed from a solution containing an amine by use of an α -iodoamide resin as an electrophile. This reagent will selectively react with the more nucleophilic thiol over the desired amine-containing product.⁸⁰⁹ The loading levels of polymer-bound scavengers are important; the swelling of resins requires the use of large solvent volumes, such that higher resin loading levels of scavenger are desirable to minimize dilution of the

Scheme 5

reaction mixture and the amount of resin required. The following section highlights some more advanced scavengers that have been developed to remove specific impurities and demonstrate the power of this technique.

Parlow and co-workers have developed a scavenging method for the versatile Dess–Martin oxidation procedure.⁸¹⁰ Reaction of a primary or secondary alcohol with an excess of the Dess–Martin reagent in solution produces an aldehyde or ketone. The excess reagent is usually removed in solution phase reactions by reduction of the unreacted reagent with sodium thiosulfate followed by aqueous extraction. Parlow and co-workers have developed a thiosulfate resin by simply washing commercial chloride-form Amberlyst A-26 ion exchange resin with thiosulfate (Figure 122). Treating a crude reaction solution from a Dess–Martin oxidation with the thiosulfate resin reduces the unreacted Dess–Martin reagent to *o*-iodobenzoic acid, which can then be efficiently sequestered by any of a number of basic resins. This chemistry was demonstrated on a number of alcohols, to produce the corresponding aldehydes or ketones in good yields and excellent purities (>99% in almost all cases as measured by gas chromatography/mass spectrometry and ^1H NMR).

Ion exchange sequestering is an efficient procedure to remove excess impurities from reaction mixtures; however, in the pharmaceutical industry the use of sulfonic acid resins is limited by the presence of basic amines on a large number of desired products. Parlow and co-workers have devised a strategy to make possible the sequestration of a reactive amine from a solution containing a desired basic but nonnucleophilic amine.⁸¹¹ By adding tetrafluorophthalic anhydride to such a reaction mixture, the excess reactive amine is consumed, leading to the formation of the phthalamide with a pendant carboxylic acid (Scheme 5). Both the resulting carboxylic acid and any excess anhydride can be sequestered using a basic resin, leaving only the desired basic amine in the reaction solution. This procedure is effective for removing relatively poor nucleophiles, such as anilines, that do not react completely with most support-bound electrophiles.

In another example of material design, Kirkland and co-workers prepared functionalized porous silica microspheres for use as scavengers in combinatorial chemistry.⁸¹² The silica microspheres are more than 99.995% pure, and have a uniform particle size and shape that provide superior mass transfer properties. The microsphere beads are easy to handle, do not swell, and are efficient scavengers in both polar and nonpolar solvents. The microspheres can be functionalized with the same functional groups as polystyrene beads, and therefore can be used in many of the same situations as conventional scavengers. These silica-based materials have been evaluated for the ability to sequester a number of acids, acid chlorides, and amines from typical reaction solutions.

2.12.16.4.3 Solution phase reactions involving resin-bound reagents

A complementary approach to removing excess reagents from a reaction solution using a support-bound sequestering agent is to immobilize the reagent on an appropriate solid phase. The addition of an excess of this solid-supported reagent to a suitable substrate in solution provides a product that can be purified by simple filtering off of the support-bound reagent. This approach is conceptually relatively old but has been recently revitalized, as is evident by the vast number of support-bound reagent classes that have been developed for solution phase parallel synthesis. There are now commercial resins available that deliver support-bound equivalents of many types of reagents, including acids, bases

(tertiary amine, 4-dimethylaminopyridine, phosphazine, etc.), acylating agents (see below), coupling agents (carbodiimides), reducing agents (borohydride, cyanoborohydride, silylhydrides), oxidizing agents (permanganate, chromium, ruthenium, osmium), catalysts (palladium, asymmetrical catalysts), a wide variety of protecting groups, and many other reagent classes. A discussion of all of the reagents currently available is beyond the scope of this section. The interested reader is directed to the review articles mentioned in the introduction to the solution phase chemistry (see Section 2.12.16.4.1).^{702,717,807} Several classes of these reagents are described in detail below.

Amide formation is a reaction of fundamental importance in medicinal chemistry; consequently, many techniques to form amides using polymer-assisted solution phase (PASP) chemistry have been developed. A convenient method is to utilize a support-bound alcohol that is functionalized using either a carboxylic acid and coupling agent or an acid chloride to provide a support-bound activated ester. These reagents can then be stored, and are typically stable for months. Simply stirring an excess of the support-bound activated ester with an amine provides (after a filtration step to remove the support) a high yield of a desired amide. Adamczyk and co-workers have developed an *N*-hydroxysuccinimide-functionalized resin for this purpose, utilizing a Michael addition of a support-bound thiol to *N*-hydroxymaleimide to provide the functionalized resins **1** (Figure 150).⁸¹³

A resin similar to that discussed above has been reported by Salvino and co-workers whereby the reaction of aminomethyl resin with 4-carboxytetrafluorophenol provides a support-bound pentafluorophenyl ester equivalent (**2**, Figure 123).⁸¹⁴ Loading of the resin with a carboxylic acid or sulfonyl chloride provides a support-bound activated ester. This tetrafluorophenyl alcohol resin has the advantage that solid phase ¹⁹F NMR can be utilized to quantitatively determine the loading level of the polymer-bound active ester reagents.⁸¹⁵ Other support-bound reagents for transformations of this type have been previously reported, including support-bound 1-hydroxybenzotriazole (HOBt) equivalents, a polymer-bound *o*-nitrophenol equivalent (**3**, Figure 123),⁸¹⁶ and the Kaiser oxime resin.⁸¹⁷ Chang and Schultz have analyzed resins **1**, the *o*-nitrophenyl ester resin, the Kaiser oxime resin, and commercial HOBt resin for their relative abilities to act as support-bound acylating agents.⁸¹⁸ By acylating all four resins with a carboxylic acid containing a dye and monitoring the rate of amide formation with benzylamine, the relative order of reactivity of the resins was determined to be as follows (P denotes the resin): P-HOBt ≫ P-*N*-hydroxysuccinimide > P-*o*-nitrophenyl ≫ P-oxime.

Several groups have developed 'safety catch' linkers whereby the linking unit is stable to a variety of acidic and basic conditions. The term 'safety catch' arises from the fact that the resins normally must be activated prior to release of the product (so the linker is 'safe' until intentionally modified to provide an activated ester equivalent). Kenner and Ellman have reported sulfonamide-based linkers that are stable under most reaction conditions.^{819–821} Upon chemical activation, the linker serves as an activating group, and the product can be released by reaction with amines or alcohols to produce amides or esters (Figure 124). Scialdone and co-workers have published several applications of

Figure 123 Support-bound activated esters that can be directly reacted with an amine nucleophile.

Figure 124 Support-bound reactants requiring activation prior to reaction with an amine nucleophile.

Scheme 6

Scheme 7

phosgenated oxime (phoxime) resin (**4**, [Scheme 6](#)).⁸²² The phoxime resin also serves as a reactive equivalent, requiring thermal rather than chemical activation. This polymer-bound reagent traps amines as support-bound urethanes that are thermally labile and can be cleaved by thermolysis to provide isocyanates. The released isocyanate reacts with amines present in the cleavage solution producing highly substituted ureas ([Scheme 6](#)) (see also the previous section on resin-to-resin transfer).

A number of laboratories have investigated the synthesis and use of polymer-bound ¹H-benzotriazole as both a support-bound reagent and a traceless linker for library synthesis. It is fitting that the Katritzky group published the first report of such a reagent for the synthesis of amine libraries, as that same group pioneered the use of this reagent in traditional solution phase chemistry.⁸²³ Treatment of any of the benzotriazole resins with an aldehyde and an amine under conditions suitable for formation of the Schiff base produces the polymer-bound benzotriazole–Schiff base adduct **6** ([Scheme 7](#)). Cleavage is then effected by substitution with a suitable nucleophile, such as a hydride, Grignard, or Reformatsky reagent, to produce a new, substituted amine (**7**) in good yield. Given the utility of benzotriazole in the synthesis of substituted heterocycles, it is certain that polymer-supported benzotriazole equivalents will be useful for many different heterocycle syntheses in the future.

Cycloaddition reactions utilizing support-bound substrates are popular due to the large increase in complexity of the final products afforded by these reactions. Smith has utilized a commercially available alkyldiethylsilane-functionalized polymer (PS-DES resin) activated as the triflate to prepare resin-bound silyl enol ethers of enones ([Scheme 8](#)).⁸²⁴ These resin-bound intermediates then provide access to a variety of cycloaddition products. Smith has investigated the Diels–Alder chemistry of these intermediates, and Porco and co-workers⁸²⁵ have demonstrated the utility of these precursors in providing functionalized esters from Claisen rearrangement chemistry. Given the utility of trimethylsilyl triflate and related silyl triflate catalysts in a variety of traditional solution phase transformations, such as glycosylation, PS-DES triflate is likely to be a useful reagent for many transformations in library synthesis.

Scheme 8

Scheme 9

2.12.16.4.4 Multistep synthesis with resin-bound scavengers and reagents

The development of a large number of strategies for PASP chemistry has allowed the synthesis of increasingly complex molecules using only fast PASP purification. This section details some of these advances, which provide a strong base for the future of the field.

One important synthetic target of the Ley group has been the hydroxamate inhibitors of the matrix metalloproteinases.⁸²⁶ Inhibitors similar to the known inhibitor CGS-27023A (Scheme 9, 12 ($R^1 = \text{Pr}^i$, $R^2 = 4\text{-MeO-phenyl}$, $R^3 = 3\text{-pyridyl}$)) were prepared from amino acid *t*-butyl esters. The synthesis involved the use of support-bound amines to scavenge excess sulfonyl chloride and alkyl halide reagents, the use of a support-bound base in an alkylation, and the use of support-bound triphenylphosphine to generate an acid bromide in solution. Condensation with aromatic sulfonyl chlorides followed by work-up with P-NH_2 and desalting with ion exchange resin provides the sulfonamides **9**. Alkylation of the sulfonamide with P-BEMP (a resin-bound base) and a benzyl halide yields compounds **10** after removal of excess halide with P-NH_2 . The *t*-butyl ester is cleaved with acid, and the hydroxamic acid functionality is introduced by preparing the acid bromide, followed by condensation with *O*-benzylhydroxylamine hydrochloride in the presence of base. Hydrogenation provides the final products **12** (27 examples). No chromatography was necessary, and the products were isolated in high (90–98%) overall purity and variable (39–100%) yields.

The Ley group has extended these concepts to include the multistep synthesis of natural products as well as the solution phase preparation of libraries. The synthesis of racemic oxamaritidine and epimaritidine (Scheme 10) was accomplished starting with 3,4-dimethoxybenzyl alcohol.⁸²⁷ All six steps of the reaction sequence involve the application of a resin-bound reagent. Oxidation with polymer-supported perruthenate to the aldehyde followed by reductive amination with amine **15** using P-borohydride (a resin-bound reducing agent) gave the secondary amine **16**, which was then trifluoroacetylated using P-DMAP . Oxidative spirocyclization to **18** was achieved using polymer-bound (diacetoxyiodo)benzene. After removal of the trifluoroacetate protecting group with P-carbonate , the resulting amine

Scheme 10

spontaneously undergoes 1,4-addition to provide racemic crystalline oxamaritidine. Reduction with polymer-supported borohydride provides epimaritidine. Both natural products were prepared in excellent overall yield and purity.

A final example is the multistep synthesis of the analgesic natural product epibatidine, an alkaloid isolated from the Ecuadorian poison dart frog *Epidobates tricolor*.⁸²⁸ The 10-step synthesis involves support-bound reagents being used in oxidations, reductions, basic catalysis, and catch-and-release purification of the final product. The sequence begins with reduction of the acid chloride **19** with support-bound borohydride followed by oxidation with polymer-bound perruthenate to afford the aldehyde **20** (Scheme 11). A Henry reaction catalyzed by basic resin is followed by elimination to the styrene **22**. A Diels–Alder reaction with the diene **23** occurs smoothly in a sealed tube to yield the cyclohexanone **24**, which is then reduced with support-bound borohydride to the alcohol. Mesylation with P-DMAP affords the mesylate. Reduction of the nitro group without concomitant dehalogenation proved to be difficult; however, the modification of polymer-bound borohydride with nickel(II) chloride provided an impressive solution to this problem, and the desired product (**26**) was isolated in 95% yield as a 7:1 mixture of diastereomers. The critical transannular cyclization of **26** to *endo*-epibatidine occurred in 71% yield upon treatment with P-BEMP, and the unreacted *cis* isomer of **26** could be removed by reaction of the remaining mesylate using P-NH₂ (a nucleophilic support-bound amine). Finally, the natural product was prepared by isomerization to the desired *exo* isomer, followed by catch and release purification using a polymer-bound sulfonic acid. The natural product **27** was released from the support by eluting with ammonia in methanol, and was isolated as a 3:1 *exo:endo* mixture in more than 90% purity by ¹H NMR and liquid chromatography/mass spectrometry analysis.

2.12.16.5 Conclusion

Since Furka's and Geysen's seminal work on peptide library synthesis in the late 1980s, combinatorial chemistry has matured into its own discipline. Today, combinatorial chemistry encompasses an extremely broad range of technologies and methodologies that have brought many seemingly unrelated scientific fields together. The meshing of high-throughput synthesis, computational design, robotics, and informatics has provided a framework for modern research. The combinatorial chemistry laboratory is now highly automated, allowing hundreds of reactions to be performed in parallel. This new paradigm for discovery is transforming the way scientists think about setting up experiments. The basis of the scientific method is being retooled for the twenty-first century chemists, who are equipped to solve problems by asking not one question at a time but many. The development of new synthetic methods to create the desired libraries of molecules for the study of their specific function is critical, and will continue to determine one's ultimate success. Recent advancements in the field of combinatorial organic synthesis on solid phase and in solution phase are providing powerful tools to the chemist seeking to apply these new principles. The continued development of novel methodologies and technologies in combinatorial chemistry promises a new and bright future for science in general.

Scheme 11

2.12.17 Supports for Solid Phase Synthesis

Since the introduction by Merrifield of support-based peptide synthesis,⁸²⁹ insoluble polymer supports have been widely used for numerous synthetic processes to accelerate synthesis and product purification.^{830,831,831a} The original small-molecule solid phase efforts by Leznoff,⁸³² and more recent efforts, demonstrated the synthetic advantages of solid phase methods and have led to solid phase chemistry now playing a substantial role within most pharmaceutical companies, in part due to the ease of automation as well as the inherent advantages of solid phase chemistry. The increasing familiarity of synthetic chemists with solid phase synthesis has led research groups to investigate a wide variety of supports in combinatorial synthesis.^{833,834} The main purpose of this section is to review the different types of supports used in solid phase synthesis, a crucial issue if any synthesis is ever to be successful and an area often ignored in a solid phase campaign.

The recent activity in solid phase organic chemistry has focused almost entirely on gel-type resins due to their prior impact in solid phase peptide synthesis. However, the more diverse chemistry that must be achieved nowadays has persuaded many groups and companies to investigate a wider range of solid supports compatible with different reaction conditions. Automation within pharmaceutical companies is also an issue in combinatorial chemistry, in so far as solid phase supports must be developed to facilitate automation and handling issues.

2.12.17.1 Resin Beads

2.12.17.1.1 Polystyrene gel-based resins

In practice, gel-based spherical resin beads of 50–200 μm diameter are commonly used in solid phase organic chemistry (SPOC). These can be easily synthesized or bought from a range of commercial suppliers. The size, shape, and uniformity are important features, and the uniformity of cross-linked polymer particles is vital for reproducible SPOC. Robust spherical beads with a uniform size are preferred for reproducible chemistry, with irregularly shaped particles being much more sensitive to mechanical destruction, often falling apart in the course of the chemistry. Bead size is also important, since reaction rates are inversely proportional to bead size. The technique of suspension polymerization is almost universally used for resin synthesis, and provides regular particles in a highly reproducible manner. Typically,

Figure 125 Synthesis of DVB-cross-linked PS resins and derivatization.

styrene and divinylbenzene (DVB) mixtures are dispersed as spherical droplets in an excess of an immiscible phase (water) containing the polymerization initiator. The aqueous phase generally contains a low level of some dissolved suspension stabilizer, a surface-active species, which prevents the organic monomer droplets from conglomerating. In the course of the polymerization, these droplets are converted to hard, glassy beads. Then the resin particles can be collected by filtration; unreacted monomers, initiator, and other by-products removed by solvent extraction; and the beads vacuum dried and sieved. The introduction of functionality onto a polymer support is usually achieved by direct chloromethylation, to give the classic Merrifield resin. However, an alternative approach is to use a co-monomer that already bears the desired functionality in the free polymerization mixture or some precursor that can subsequently be transformed. This second strategy can be useful in producing a structurally well-defined resin network with control of functional group ratios (Figure 125). So-called Merrifield resin and related polystyrene (PS) based analogs (e.g., aminomethyl resin) are the most widely used resins in SPOC today. They are characterized as being a gel-type polymer typically containing 1–2% of the cross-linking agent DVB, which provides the links between the linear PS chains, with the whole polymer solvated and with reactions taking place throughout the polymer network, controlled by diffusion into the bead.

The percentage of DVB used in bead synthesis is very important for the mechanical strength and insolubility of the support, but should not prevent swelling of the resin beads when immersed in an organic solvent. Indeed, swelling is an essential feature of gel resins. At low cross-linkings, sufficient swelling occurs in so-called good solvents to allow the diffusion of reagents within the PS network. Merrifield resin swells in solvents with a solubility parameter similar to the polymer (e.g., toluene), with swelling inversely related to the ratio of the DVB content. On the other hand, Merrifield resins are not compatible with highly polar solvents such as water and methanol. The swelling and shrinking process always occurs from the outside to the inside of the resin network; thus, very low levels of DVB (<1%) give mechanically weak networks that can be damaged by heating, handling, or solvent shock. On the other hand, a highly cross-linked resin network may not swell even in a ‘good swelling’ solvent, but clearly will offer much greater mechanical stability. If a PS network is fully swollen in a so-called good solvent and then shrunk in a bad solvent (e.g., during resin-washing steps), mechanical shock takes place and the bead may disintegrate. This effect (osmotic shock)⁸³⁴ and the degree of cross-linking must thus be considered in any solid phase synthesis where many cycles of swelling and deswelling may be involved to reduce mechanical damage to the beads. Besides osmotic shock, PS supports have limitations when used with highly electrophilic reagents and at excessive temperatures (200 °C). Impurities from commercially available Merrifield resin can arise from incomplete polymerization and/or from trapped solvents, which contaminate the final products or decrease the actual loading. It should also be borne in mind that very high levels of initiator (sometimes 5%) are used in bead synthesis, which, depending on the initiator used, will undoubtedly have an influence on bead structure and chemistry. Although various methods have been investigated⁸³⁵ to overcome resin-based impurities, such as prewashing of the resin beads, the main method appears to be based on

final library purification, as being the best way to readily remove impurities from library compounds, although perhaps not ideal (the advent of automated HT purification means that low levels of impurities can be readily removed from the cleaved compounds at the end of the synthesis).

2.12.17.1.2 Macroporous resins

Macroporous resins have been used for many years in ion exchange applications, as polymeric adsorbents and for reverse-phase chromatography purifications. Macroporous resins are defined as a class of resins having a permanent well-developed porous structure even in the dry state (if they survive in this form). These resins are typically prepared by suspension polymerization of styrene–DVB mixtures containing a porogen or diluent (an organic solvent in general) at a well-defined ratio, providing resin beads with a defined pore structure. Removal of the porogen at the end of polymerization provides a heterogeneous PS matrix with some areas completely impenetrable and others free of polymer. Macroporous resins are characterized by a hard, rough surface having a defined total surface area. Unlike Merrifield resins, these materials do not need to swell to allow access of reagents through the PS network, as they possess a permanent porous structure that can be accessed by, essentially, all solvents; even solvents such as water can penetrate the macroporous PS–DVB matrix. When a solvent penetrates a macroporous resin, the polymer matrix tends to swell to some extent, and often rapidly, because the permanent holes provide rapid access through the network. However, due to the nature of the beads, swelling takes place in the pores and little swelling of the beads takes place. Due to the nature and speed of diffusion, macroporous resins show much better resistance to osmotic shock during swelling and deswelling processes.

Comparisons between macroporous resins and a 2% cross-linked gel-based Merrifield resin have been undertaken.⁸³⁶ Resin washing efficiency is, not unexpectedly, much more efficient with macroporous resins due to the rigid pores speeding up the migration of material from the interior of the polymer to the bulk solvent. The kinetics for esterification between standard Merrifield resin and three macroporous resins from Rohm & Haas are shown in Table 29. This seems to show that a large number of sites are more accessible in the gel-based resins, while reaction rates are comparable. However, since reaction rates are bead size dependent for the gel-based resins, it is hard to draw any real conclusions from these data.

2.12.17.1.3 Polyethyleneglycol-containing resins

The development of polymer supports having both polar and nonpolar features has been of great interest for peptide synthesis. Although Merrifield resin has been widely used in solid phase peptide synthesis, the rate of incorporation of particular amino acid residues was found to decrease with increasing chain length. This decrease in yield was thought to be due to the unfavorable conformation adopted by the growing peptide chain and peptide aggregation. Thus, to improve the physicochemical compatibility of PS supports, polar hydrophilic acrylamide-based copolymers were introduced as an attractive alternative to all PS–DVB supports, most notably by Atherton and Sheppard.⁸³⁷ However, an alternative approach, which leads to the second most popular support type in solid phase chemistry, after the PS gel-based resins, is the modification of PS resin by the addition of polyethyleneglycol (PEG) to generate PS-PEG-based materials. These hydrophilic solid supports were developed in theory to remove the reaction sites from the bulk ‘rigid’ PS matrix, to give a more solution-like environment as well as to broaden the solvent compatibilities of the support. However, another driving force was the need to prepare a solid support for continuous solid-flow solid phase peptide synthesis, which did not undergo dramatic volume changes during synthesis and arose at least in part from the early soluble PEG-based chemistries in the 1970s and 1980s. Various popular PEG-containing synthetic polymers as solid supports are summarized in Table 30.

Table 29 Kinetics for esterification between standard Merrifield resin and three macroporous resins

CLEAR ⁸⁴⁴	Poly(trimethylolpropane ethoxylate triacrylate- <i>co</i> -allylamine)

**Figure 126** The two main PS-PEG supports used in solid phase synthesis.

2.12.17.1.3.1 Polystyrene-polyethyleneglycol supports

A preliminary approach to the synthesis of PS-PEG supports relied on covalent anchoring via amide linkages of defined PEGs onto amino-functionalized PS resins.⁸³⁸ Later, a new version of PS-PEG was introduced by Bayer and Rapp,^{839,840} obtained by ethylene oxide grafting, to give the material now known as TentaGel (Figure 126). Optimized TentaGel-grafted resins generally have PEG chains of about 3 kDa ($n = 68$ units, 70–80% by weight). PS-PEG beads display uniform swelling properties in a variety of solvents, from medium- to high-polar media, ranging from toluene to water.

The solution-like environment has an impact on reaction kinetics, allowing rapid access of reagents through the swollen resin to active sites. Rapp⁸⁴¹ has demonstrated that the kinetics of certain reactions on PS-PEG beads were similar to those in solution. However, TentaGel resin is far from being the perfect solid support due to (1) a low loading capacity, (2) Lewis acid complexation onto the PEG chain, and (3) instability of the PEG chain to acidic media, generating PEG contamination after trifluoroacetic acid cleavage. To overcome these problems, new families of PS-PEG resins with higher loading capacities, good acid stabilities, and low linear PEG impurities have been developed.⁸⁴² Thus, assuming that the acid instability of TentaGel resin was due to the benzylic ether PS-graft linkage, improved stability was obtained by using a longer linkage, while enhanced loading capacity has been obtained via bifurcation of functional groups prior to ethylene oxide grafting (Figure 126) and reduced PEG graftings.

It is worth noticing that at the end of the polymerization material must be contaminated by linear or cyclic PEG, and this removal may be the source of repeated claims of contamination. A series of graft copolymers have been elaborated by varying the ethylene oxide/initiator ratio, providing well-defined graft lengths with predictable loadings ($0.3\text{--}0.55\text{ mmol g}^{-1}$). Some swelling properties of PS and PS-PEG resins are summarized in Table 31.

2.12.17.1.3.2 Cross-linked ethoxylate acrylate resins

CLEAR resins (cross-linked ethoxylate acrylate resins), introduced by Barany,⁸⁴³ are a unique family of supports that are highly cross-linked polymers (>95% by weight of cross-linker) yet show excellent swelling properties, contrary to the general expectation of the time. These supports are prepared by radical polymerization of the tribranched cross-linker trimethylolpropaneethoxylate-triacrylate **29**, with various amino-functionalized monomers, such as allylamine

(**30**), or 2-aminoethyl methacrylate (**31**) (Figure 127). The CLEAR supports differ from other polymers in that they are synthesized from a branched cross-linker used in a high molar ratio. The fact that the amino functionality can be introduced into the bead in the polymerization process ensures that the required substitution level can be obtained.

A number of different formulations were tested and prepared by bulk suspension to obtain the optimal material. These supports swell in a wide range of hydrophobic and hydrophilic solvents, such as water. Although these materials showed great chemical and mechanical stability in acidic and weakly basic conditions, the resins will dissolve in the presence of ammonia or aqueous bases, due to the ammonolysis of the three ester linkages in the cross-linker.

2.12.17.1.3.3 Tetraethylene glycol diacrylate cross-linked polystyrene support (TTEGDA-PS)

A number of groups^{844,844a,845} have developed resins based on varying the cross-linker to change the properties of the resin but maintaining the excellent chemical nature of the PS support. Pillai^{844,844a} investigated the use of polyacrylamide and PS supports cross-linked with *N,N*-methylenebisacrylamide (NNMBA), TTEGDA, and DVB. It was shown that the polymer derived from TTEGDA-polyacrylamide had a significant increase in reaction kinetics when compared with NNMBA-polyacrylamide and DVB-polyacrylamide supports. Gel phase reaction kinetics with polyacrylamide-DVB supports showed that the first 90% reaction sites were homogeneously distributed throughout the bead and had equal reactivity, while the remaining 10% were less available to external reagents. The major problems with polyacrylamide supports is the lack of mechanical stability when compared with PS, and chemical reactivity when used in an organic chemistry sense, although there is an optimal hydrophobic-hydrophilic balance. TTEGDA-PS provides these two essential features in a single matrix with a hydrophobic PS backbone and a flexible hydrophilic cross-linker,^{844,844a} thus being insoluble but highly solvated. PS supports with 4% TTEGDA (Figure 128) show good mechanical properties and good swelling characteristics, rendering this support suitable for long-chain peptide synthesis.

As mentioned earlier, the swelling properties of a solid support are a crucial feature in solid phase synthesis, and a measure of the scope of a new support. The difference between 1% DVB-PS and 4% TTEGDA-PS was investigated. As expected, TTEGDA-cross-linked PS had enhanced swelling properties in polar solvents compared with the DVB-PS support (Table 32), which renders maximum accessibility of reagents throughout the hydrophobic network.

2.12.17.1.3.4 Polyethyleneglycol-poly-(*N,N*-dimethylacrylamide) (PEGA) copolymer

Polar acrylamide supports were introduced successfully by Sheppard⁸³⁷ and co-workers as an alternative to PS resin, and used as a versatile cross-linked support for peptide syntheses. Meldal^{846,846a} introduced PEGA, a similar resin that

Figure 128 Hybrid PS- and PEG-based resins via PEG-based cross-linkers.

Table 32 Comparison of DVB-PS and TTEGD-PS swelling properties (mL g^{-1})

<i>Solvent</i>	<i>1% DVB-PS</i>	<i>4% TTEGDA-PS</i>
Chloroform	4.3	6.5
Tetrahydrofuran	5.2	8.7
Toluene	4.7	6.9
Pyridine	4.2	6.0
Dioxane	3.5	8.8
Dichloromethane	4.3	8.8
Dimethylformamide	2.8	5.5
Methanol	1.8	2.2

contains a PEG component. PEGA is superior to many other existing supports for peptide synthesis in terms of the solution-like nature of the structure, although it is associated with handling problems, and lacks chemical inertness. The PEG chain is the major constituent, providing a highly flexible and biocompatible matrix. The polymer backbone was designed to allow macromolecules, such as enzymes, to penetrate the polymer network, thereby facilitating solid phase enzymatic reactions.

Typically, preparation of PEGA resins is carried out by an inverse suspension polymerization reaction in a mixture of *n*-heptane and carbon tetrachloride (6:4 v/v) due to the water solubility of the monomers (Figure 129). Meldal and co-workers anticipated that PEGA 1900 ($n = 45$) had pores large enough to allow enzymes up to 50 kDa to penetrate the PEGA network.^{847,847a} In order to identify new enzyme inhibitors for matrix metalloproteinase 9, which in its proform has a molecular weight of 92 kDa, longer cross-linked PEGs were used (4000–8000 Da, $n = 89, 135$, and 180) to increase the

Figure 129 Monomers used for PEGA resin synthesis.

apparent ‘pore size’ of these supports. Bis-amino-PEGs were used to form partially or bis-*N*-acryloylated PEG as a macromonomer. These resins have high swelling properties, and are suited for enzyme reactions, despite initially low loading capacities ($0.08\text{--}0.13\text{ mmol g}^{-1}$). The introduction of acryloyl sarcosine with bis-acrylamido-PEG-1900, -4000, -6000, and -8000 and dimethylacrylamide resulted in PEGA copolymer-type resins with a much higher loading capacity.

2.12.17.1.3.5 Enhancing bead loading: dendrimers as powerful enhancers of functionality

One of the most powerful tools available to the combinatorial chemist is the process of split and mix in terms of the number of compounds that can be made and the economics of synthesis, with resin beads being used as the ultimate microreactor in synthesis. However, this method results in tiny amounts of compound being available, typically less than 1 nmol per bead. This might be enough to identify an active bead, but it is not enough to conduct numerous biological assays or to validate the compound as a lead. More importantly, it is insufficient to determine the compound’s structure using conventional techniques such as ^1H NMR. Such a low loading requires a tagging system to identify the compound, and necessitates resynthesis on a larger scale either in solution or on the solid phase for rescreening. However, though elegant, the introduction of a tag during the library synthesis is very time-consuming. One solution to this problem is to increase the size of the beads. A larger bead will obviously bear more sites, although size is limited by bead stability, susceptibility to fracturing, and bead synthesis, as well as by poor reaction kinetics. Another approach is to multiply the functionalities on a bead by dendrimerization, using the hyperbranched nature of the dendrimer to amplify loading. Solid phase lysine-based dendrimers were published by Tam⁸⁴⁸ as a means of generating a high density of peptide functionality for antigen presentation (the multiple antigen presentation system), but resins with low loading were deliberately used to avoid possible steric problems. However, the development of solid phase polyamidoamine (PAMAM) dendrimers has provided to be a powerful tool in increasing the loading of single beads.⁸⁴⁹ The development of highly symmetrical dendrimers allows an extremely high loading to be obtained on the resin beads.

The efficiency of synthesis for the PAMAM dendrimers (Michael addition onto methyl acetate and ester displacement with a diamine) is achieved by using a large excess of reagent compared with the loading of the resin as in any normal solid phase synthesis, and produces dendrimers cleaner than those from the solution approach. The multiplication of the terminal amino functionalities makes possible the analysis of compounds cleaved from single beads.⁸⁵⁰ Using a Tris-based monomer,⁸⁵¹ a loading of 230 nmol per bead was obtained for a second-generation dendrimer, which becomes a very acceptable loading for using the beads in a split-and-mix manner (Figure 130). The NMR spectrum and high-performance liquid chromatography (HPLC) data of material from one bead are shown. This is the Suzuki product formed between 4-methylphenylboronic acid and resin-attached 4-iodobenzoic acid. Using this method, dendrimers have been synthesized on a range of other solid supports, either to be used as such or to modify the surface properties of the support.

2.12.17.2 Synthesis on Surfaces

2.12.17.2.1 Pins and crowns

The limitations of linear ‘solitary’ peptide synthesis were first overcome by Houghten,⁸⁵² with the use of the ‘tea-bag’ methodology, and Geysen, with the ‘pin’ methodology.^{853,853a} The pin method was a revolutionary approach to peptide synthesis and moved away from traditional PS-based resins, allowing the synthesis of peptides on the surface of

Figure 130 (a) Resin amplification via dendrimerization. (b) Single-bead cleavage analysis.

polyethylene supports (rod-like materials termed ‘pins’ (4 mm diameter \times 40 mm)) in a multiple parallel manner. These derivatized materials were prepared by radiation grafting, in which the pins were placed in a γ -radiation source in the presence of an aqueous solution of acrylic acid. Radiation (initially 10^6 rad) activated the surface by radical formation to a depth of several micrometers, which reacted with the acrylic acid to give rise to a polyacrylic acid derivatized pin (Figure 131). It was this (immobilized) graft that could then be used as a support for peptide synthesis, initially by coupling to a suitably protected lysine residue (Boc-Lys-OMe). Due to the discrete and handleable nature of the pins, they could be arranged in an array format akin to the microtiter plates used for biological screening, with synthesis taking place by dipping the tips of the pins into the appropriate solutions. Although the whole pin was derivatized, only the tip was actually used synthetically. The major problems were thus logistical, due to compound numbers, rather than chemical. This basic procedure allowed the synthesis in 1984 of 208 overlapping peptides covering the entire peptide sequence of the coat protein VP1 of foot-and-mouth disease virus. This was accomplished using *t*-butoxycarbonyl (*t*-Boc) chemistry, with the peptide directly attached to the pin as shown in Figure 131. Two assumptions made by the authors in this original work were that an initial loading of at least 1 nmol would be sufficient for even a low-efficiency synthesis to allow antibody binding, and that high purity was not necessary.

Developments and improvements on this original method took place at the end of the 1980s and in the 1990s, with three main driving forces: (1) the development of linkers to allow cleavage from the pins;^{854,854a} (2) an improvement in their loading;⁸⁵⁵ and (3) alterations in the grafting polymer to alter the physical and accessibility properties of the graft.⁸⁵⁶ (Figure 132). Thus, in 1990 and 1991, derivatization of the pin by acrylic acid was followed by saturation coupling with *t*-Boc-1,6-diaminohexane, and coupling to the most accessible sites with a limited amount of Fmoc- β -Ala-OH followed by capping of the remaining sites, to give a loading of 10–100 nmol per pin.⁸⁵⁷ Linkers could then be added to the derivatized pins. The first approach was to use diketopiperazine (DKP) formation as a driving force for peptide release, allowing a ‘safety catch’-based cleavage from the solid support. The second method used hydroxymethylbenzoic acid as a linker, which allowed the peptide to be subsequently cleaved from the pin with ammonia vapor.⁸⁵⁸ Both methods allowed the release and analysis of peptides by HPLC and mass spectrometry.

Figure 131 Initial method used for pin derivatization.

Figure 132 Radiation-grafted materials: Mimotopes crowns and removable pin heads.

Subsequent developments led to the removable crown (although confusingly also called pins or detachable pinheads in the literature) (Figure 132).⁸⁵⁹ Crowns were prepared by injection molding of granular polyethylene. They were 5.5 mm high and 5.3 mm in diameter, but, importantly, had a surface area of 1.3 cm², much improved over that of the pins. The second improvement involved the use of alternative monomers (Figure 133). Variations in the vinylic monomer allowed higher grafts weights to be obtained (the graft weight increased from 1% to 15%).⁸⁵⁹ Thus, these materials could be esterified under normal dicyclohexylcarbodiimide/4-*N,N*-dimethylaminopyridine (DCC/DMAP) coupling conditions with Fmoc- β -Ala-OH and controlled reaction timings, allowing only the most reactive/accessible sites to be derivatized before the capping of all remaining sites. This procedure allowed crowns with loadings of 1.0–2.2 μ mol per crown

Figure 133 Second-generation pin/crown derivatization and loading.

to be prepared for solid phase peptide synthesis. Later papers used a variety of monomers, including methacrylic acid and dimethylacrylamide,⁸⁵⁸ while PS grafts also became available. The crowns/pins thus became available with aminomethyl-PS functionalities, thereby allowing a wide range of linkers, including the acid-labile Wang and Rink type of linkers, to be introduced onto these supports via the aminomethyl group, thus permitting the straightforward cleavage, analysis, and screening of micromolar quantities of compound. The ease of handling these small discrete crowns, which could be prepared in a variety of different colors as an inbuilt coding mechanism, and the broad range of loadings available (1–40 μmol), obviously made them very user-friendly to the synthetic chemist for multiple parallel synthesis.

The potential of these crowns was demonstrated in a series of papers from Mimotopes^{860,860a} and Ellman,^{861,861a–d} including reductive aminations and Mitsunobu chemistries, and a large series of β-turn mimetics (using pins with a loading of 5.9 μmol) and 1680 1,4-benzodiazepines were prepared. Numerous groups have now used these materials in either an MPS- or a transponder-encoded defined split-and-mix synthesis. An addition to this area has been reported by Irori.⁸⁶² Radiation grafting was carried out as in the case of Mimotopes crowns, although in this case it was done on so-called microtubes (small plastic tubes) made of either polypropylene or a more chemically resistant fluoropolymer. However, they have not found widespread use.

2.12.17.2.2 Sheets

Sheet-type materials have been used for many years in the area of oligonucleotide and peptide synthesis. Early examples include the use of radiation-grafted polyethylene sheet, akin to Geysens pins, polypropylene membranes coated with cross-linked polyhydroxypropylacrylate, and derivatized glass or paper. Planar surfaces have a big advantage over beads used in the combinatorial manner in that the structure of the compound can be directly deduced by its location on the support. The first of these methods used low-density polypropylene sheet that was γ-irradiated while immersed in a solution of styrene, a method commonly used at the time for the radiation grafting of surfaces.⁸⁶³ Graft weights of some 440% were obtained with the PS attached to the surface having a molecular weight of some $6 \times 10^6 \text{ g mol}^{-1}$.

Figure 134 Spot array synthesis on paper.

Aminomethylation of the PS graft allowed linker attachment and peptide synthesis in good yield, with the sheet having a loading of about 29 μmol cm⁻². However, as far as we are aware, no more has been reported on the use of this material. At the same time, another approach was reported, although in this case the potential applications suggested were epitope mapping, affinity purification, and diagnostic testing as well as continuous-flow synthesis. The membrane used in this case was polypropylene coated with cross-linked hydroxypropylacrylate, which had a pore size of 0.2 μm.^{864,864a} Unfortunately, no details of the coating process or of the material loading were given, but four peptides were prepared on this membrane with good purities. More recently, amino-functionalized polypropylene sheets have been used in DNA array synthesis, but the nature of the derivatization was not given.^{865,865a}

In 1990, Frank⁸⁶⁵ introduced the concept of spot array synthesis of peptides, the basic premise being the suitability of cellulose paper as a support for standard Fmoc/Bu^t peptide synthesis (Figure 134). Numerous peptides could be rapidly prepared by manual spotting of reagents, with up to 100 peptides prepared on an area of 4 cm², although 96 peptides based around a microtiter type of format became a standard format. Peptides were either screened on the paper (e.g., when looking for continuous epitopes), or released by DKP formation, analogous to the Mimotopes method, for solution screening, analysis, and characterization. Synthesis and screening of peptides was subsequently carried out on Nimobilon-AV from Millipore in an identical spot manner.

A new material and concept were developed by Kobylecki⁸⁶⁶ in which 1% PS resin beads were sandwiched between two layers of polypropylene sheet, giving a loading of approximately 5–10 nmol cm⁻². This material was used in a defined split-and-mix synthesis, using three sheets of material. Thus, in the first step a different amino acid was added to each sheet. The material was then cut into three strips, and one strip from each sheet appended together. A different amino acid was added to each bundle of strips. The strips were lined up again as in the original three sheets, and cut into squares, with nine squares per sheet. The squares from each row were joined together, and again functionalized with another amino acid. Thus, this method uses the spatial nature of the material to define the synthetic sequence. In this case, it was used to prepare 27 (3³) peptides.

Other sheet-like materials have been used in peptide/DNA synthesis.⁸⁶⁷ Thus, amino-functionalized sintered polyethylene (Porex X-4920, nominal pore size 30 μm) has either been used directly for DNA synthesis (0.07 mmol g⁻¹ loading) or derivatized with a chloromethylated styrene-based colloid having a diameter of 0.46 μm, to increase the loading to 9–12 μmol g⁻¹ in an approach similar to that of the dendrimer methods described above. Another approach was described by Luo,^{868,868a} in which porous polyethylene disks were oxidized to generate carboxylic acids on the surface that were subsequently derivatized with a diamine followed by carboxymethyl dextran. The acid sites were then loaded with diamines ready for synthesis. Thus, the polyethylene surface was, in essence, coated with derivatized dextran, making it highly hydrophilic and suitable for biological screening. However, accessibility to proteins might be very limited on these materials, depending on the pore size of the polyethylene used. However, these last two methods are anecdotal.

2.12.17.2.3 Glass

In 1991, an extension of 'spot' peptide synthesis was reported, with the introduction by Affymax of peptides and oligonucleotides synthesis on glass.^{869,869a} In this process, light-based protecting groups were used for synthesis in conjunction with photolithographic masks, similar to those used in chip manufacture. The basic principle for photolithographic chemistry relies on a functionalized solid surface (glass/silica) that is treated with a photocleavable-protected linker or spacer to coat the surface (Figure 135). A laser or photolithographic mask allows the light-induced deprotection of a well-defined (size and position) portion of the slide (Figure 136). The disadvantage of this method is that it requires relatively complex instrumentation and the development of a new array of synthesis tools.

In the reported cases, a binary masking strategy was used, although later the permutational 'stripe' masking strategy was used to increase the library size. Using this method, peptide arrays of 1024 peptides could be prepared in an area of

Figure 135 The concept of synthesis on glass using light-based protecting groups.

Figure 136 Masks for use in array synthesis.

1.28 cm², which could then be screened directly (each peptide site being 400 nm²). In a similar way, oligonucleotides could be prepared. Thus, the synthesis of short oligonucleotide probes and hybridization onto glass was published in 1994 by Fodor and co-workers, who demonstrated the synthesis of a 1.28 × 1.28 cm array of 256 nucleotides, and hybridized it toward the sequence 5'-GCGTAGGC-fluorescein.⁸⁷⁰ The sequence specificity of the target hybridization was demonstrated by the fabrication of complementary probes differing by only one base, with the targets hybridizing almost totally specifically to its complementary sequence. However, a concern with all this chemistry, especially for oligonucleotide synthesis, is the efficiency of protecting-group removal.

In 1996, McGall^{871,871a} published the preparation of DNA arrays (using standard solid phase oligonucleotide synthesis) using polymeric photoresist film as a physical barrier to mask selected regions of the surface; exposure to light reveals the surface, and allows the coupling of the first nucleoside. However, the harsh conditions required for deprotection could damage the library, and a bilayer process was developed. An inert polymeric film was introduced prior to the photoresist coat, with the underlayer functioning as both a barrier to the chemical deprotection step and as a protective layer to insulate the substrate surface from the photoresist chemistry and processing conditions. This was a direct application borrowed from the microelectronics industry, allowing, it was claimed, more precise deprotection of the surface, thereby permitting the creation of denser arrays. An array of 256 decanucleotides was synthesized and tested. For additional information, Wallraff and Hinsberg⁸⁷² published an overview of the lithographic imaging techniques. Southern⁸⁷³ also reported using a physical masking approach to prepare DNA arrays, with the chemistry taking place on activated glass (Figure 137), with areas being masked or separated from each other by physical 'gaskets,' in this case silicon rubber. The advantage with this method is that well-developed chemistry could be used, the limitations being the number of positions available for synthesis, which is limited by the accuracy of masking. In 1994, the striped method was replaced by the regular shape of a diamond or disk mask in which linear translation of the

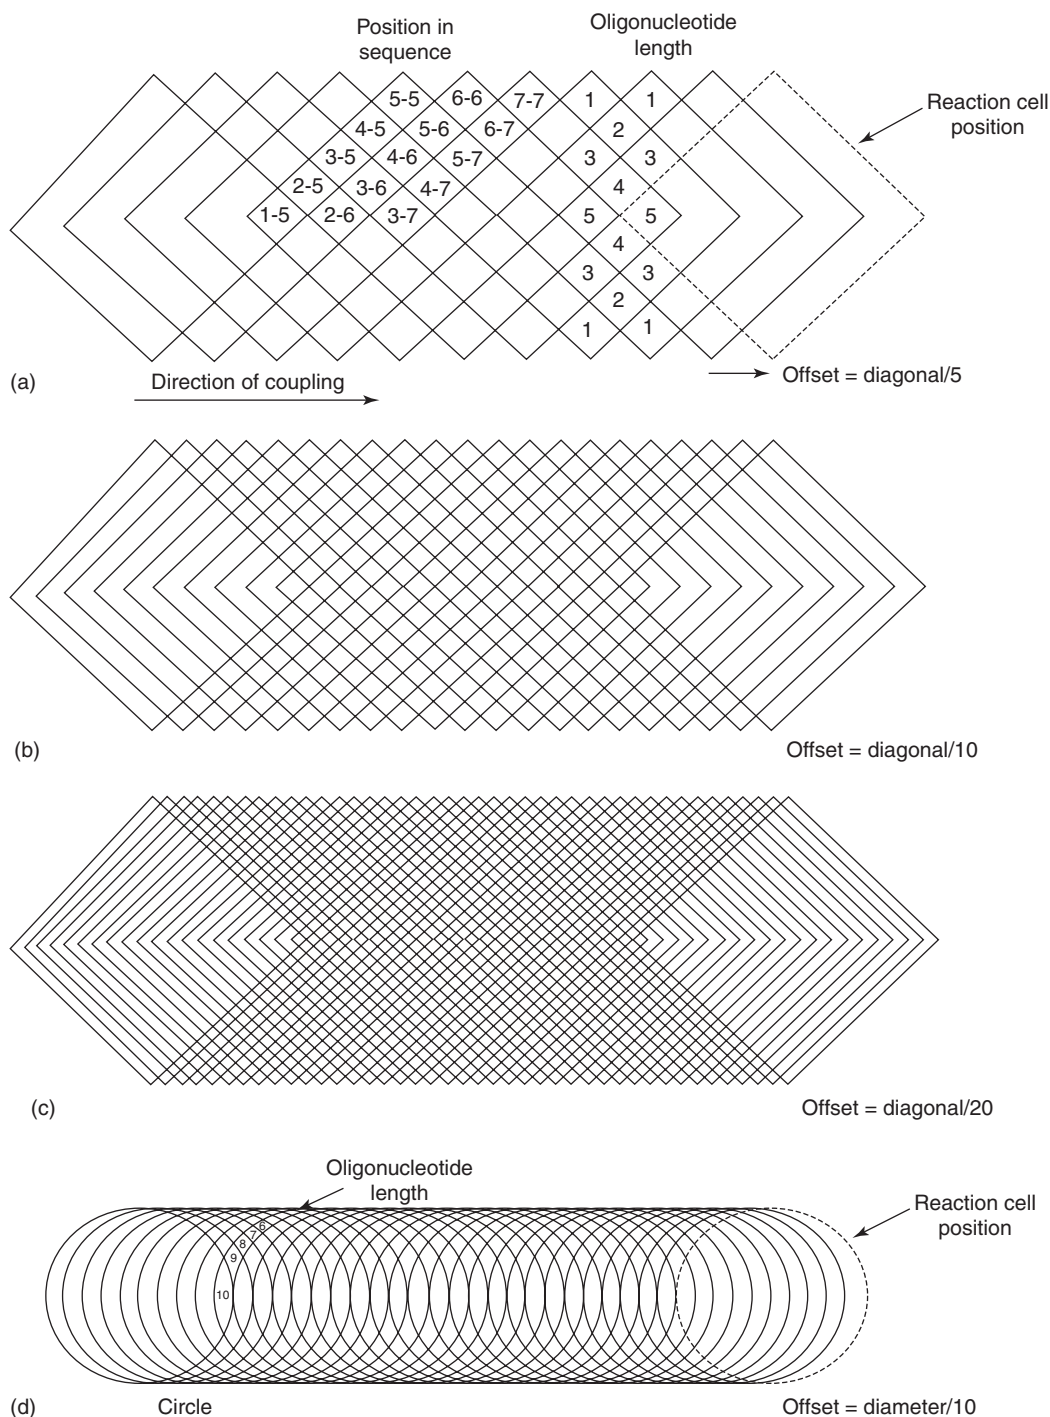

Figure 137 Physical masks for oligo array synthesis.^{873,874}

mask allows the generation of a well-defined library,⁸⁷⁴ since a small translation of the mask allows defined parts of the slide to be deprotected and reacted.

A library of decamers was synthesized, as an application of the technique, and used to study the hybridization behavior of the corresponding synthetic deca-nucleotide in solution. However, this approach is much less practical and much more cumbersome than the light-based masking strategy.

2.12.17.3 Overview

In conclusion, a wide range of materials have been used and continue to be used for solid phase synthesis. A number of these are very specific in application, such as synthesis on glass for DNA array synthesis. However, supports such as PS resins are undoubtedly the workhorse of the industry, with others, such as the pins and PS-PEGs, having a much narrower role. There is clearly much scope for improved resin design and the generation of new supports for solid phase synthesis.

2.12.18 The Nuclear Magnetic Resonance 'Toolkit' for Compound Characterization

2.12.18.1 Introduction

This section discusses the application of various NMR spectroscopy techniques to the process of drug discovery. To make it easier to understand how drug discovery incorporates NMR data, all drug discovery-related activities have been categorized into one of the following six disciplines: (1) natural products research; (2) medicinal chemistry; (3) rational drug design (protein structure and modeling); (4) metabolism; (5) combinatorial chemistry; and (6) drug production and quality control. Although this classification process may initially appear to be somewhat artificial, its use makes it easier to understand the applications and advantages of each NMR technique. However, readers should recognize that most drug discovery programs involve a blend of these six disciplines, and therefore usually benefit from using a combination of different NMR techniques.

Most advances in NMR technology have occurred when someone tried to address a particular limitation in one of these six disciplines. However, once a new tool is developed, it can sometimes solve a different problem in a different discipline or create a whole new field of NMR. An example of the former is the use of magic-angle spinning (MAS) first for solid state NMR, then for small-volume solution state NMR for natural products, and then for solid phase synthesis (SPS) resin NMR for combinatorial chemistry. An example of the last technique is the development of indirect detection, which helped spawn the use of isotopically labeled proteins and triple-resonance NMR for determining the structures of biomolecules in rational drug design programs.

In addition to the simple migration of NMR techniques from one discipline to another, two or more NMR techniques can often be synergistically combined. A good example of this is the combination technique of high-performance liquid chromatography–NMR (HPLC–NMR). Its current implementation involves the use of indirect detection, shaped pulses, broadband decoupling, pulsed-field gradient (PFG) sequences, PFG shimming, automation, and small-sample probe design.

The purpose of this section is to examine some of these NMR tools and to see how they have influenced drug discovery programs. First, we will see how they were initially used to solve a particular problem. Then we will see how some have been used to solve problems in other disciplines. Finally, we will see how others have been synergistically combined to develop much more powerful tools.

[Section 2.12.18.2](#) covers the basic tools in NMR, which include multidimensional NMR, high-field NMR, broadband decoupling, spin locks, shaped pulses, indirect detection, and PFGs. [Section 2.12.18.3](#) introduces some additional applications of NMR and the more specialized tools in use, most of which are based on the technologies introduced in [Section 2.12.18.2](#). These include protein structure determinations and the multiple-channel indirect-detection experiments they spawned ([Section 2.12.18.3.1](#)), water suppression techniques ([Section 2.12.18.3.2](#)), and hardware and probe developments ([Section 2.12.18.3.3](#)). The probe developments that are covered include small-volume probes and high-resolution (HR)-MAS probes in [Section 2.12.18.3.3.1](#), as well as flow probes and cryogenic probes, which are sufficiently important to be treated separately (*see* [Sections 2.12.18.3.5](#) and [2.12.18.3.7](#), respectively). Detailed information about combinatorial chemistry applications can be found in the discussions on solid phase resin analysis using MAS ([Section 2.12.18.3.4](#)) and the analysis of libraries stored in titer plates using flow NMR (*see* [Section 2.12.18.3.5.2](#)). Lastly, there are individual discussions on analyzing mixtures, combined NMR techniques, quantification by NMR, and the automation of NMR in [Section 2.12.18.3.11](#).

2.12.18.2 Basic Nuclear Magnetic Resonance Tools

2.12.18.2.1 One-, two-, three-, and multidimensional nuclear magnetic resonance

One of the first tools to be developed was multidimensional NMR. The first NMR spectra to be observed contained only one frequency axis, and so were termed 1D (even though they actually contain two dimensions of NMR information: frequency and amplitude). 1D spectroscopy was the only real option for the early generations of

continuous-wave (CW) spectrometers, but with the advent of pulsed Fourier transform NMR (FT-NMR) spectrometers some 20 years later, it was soon recognized that additional dimensions of NMR information could be obtained. Because some 1D NMR spectra had a crowded frequency axis (especially large molecules such as proteins) or coincidental or overlapping chemical shifts (especially poorly functionalized molecules such as some steroids), methods to simplify these spectra were needed.

In the early 1970s, the first papers on 2D NMR spectroscopy began to appear.⁸⁷⁵ Because 2D NMR allowed the NMR information to be spread in two dimensions, each of which could encode different kinds of information, most kinds of spectral overlap could be resolved. As an example, one dimension could contain chemical shift data while the other dimension could encode information about spin–spin couplings.

Different pulse sequences were then developed to select all kinds of information. The 2D correlations could arise from homonuclear or heteronuclear couplings, through-bond (scalar) or through-space (dipolar) couplings, or single-quantum or multiple-quantum couplings. They could also be designed either to detect the presence of or to actually measure the magnitude of a given kind of coupling. Experiments exploiting all of the various combinations of these possibilities were eventually developed, and remain in use today. These include experiments that generate 2D data to measure the presence of homonuclear scalar coupling (homonuclear correlation spectroscopy (COSY) and total correlation spectroscopy (TOCSY)); the magnitude of homonuclear scalar couplings (homonuclear 2D J spectroscopy (HOM2DJ)); the presence of heteronuclear scalar couplings (heteronuclear correlation spectroscopy (HETCOR), heteronuclear multiple-quantum correlation (HMQC), and heteronuclear multiple-bond correlation (HMBC)); the magnitude of heteronuclear scalar couplings (heteronuclear 2D J spectroscopy (HET2DJ)); the presence of homonuclear dipolar coupling (nuclear Overhauser effect (NOE) spectroscopy (NOESY)); the presence of heteronuclear dipolar coupling (heteronuclear NOE spectroscopy (HOESY)); and double-quantum, double-quantum-filtered, and multiple-quantum-filtered homonuclear scalar coupling correlation spectroscopy (DQ-COSY, DQF-COSY, and MQF-COSY, respectively). Many good books and reviews about 2D NMR can be found.^{876–878}

It is useful to understand that a 2D pulse sequence generates data that contain both a direct (F_2) and an indirect (F_1) dimension. The direct dimension, sometimes called the ‘real-time’ dimension, consists of a series of one-dimensional experiments; each spectrum is completely acquired during one intact time interval, usually within a few minutes. However, the indirect dimension is generated by a ‘ t_1 ’ delay in the pulse sequence that is incremented many hundreds of times during a 2D experiment. A direct-dimension spectrum is acquired for each of these several hundred delay times, then the data are subjected to Fourier transformation a second time – along this indirect dimension – to produce the 2D data set. Each spectrum along the indirect dimension is reconstructed from hundreds of direct-dimension spectra, and each data point in an indirect-dimension spectrum arises from a different direct-dimension spectrum. This means that each indirect-dimension spectrum is composed of data points acquired over many minutes (or hours or days). Any time-dependent instabilities (in the spectrometer, the environment, the sample, the electrical power, etc.) can cause a corruption of data points, and therefore cause noise; since this noise runs parallel to the t_1 axis, it is called ‘ t_1 noise.’ We will see later how t_1 noise, which is ubiquitous, can be troublesome enough that some NMR techniques, such as PFG, were developed to suppress it.

After a wide range of 2D NMR pulse sequences were developed, it was recognized that they could be effectively combined to create 3D, 4D, and even higher ‘ n D’ spectroscopies.^{879,880} Each additional dimension is created by appending to the pulse sequence certain pulse sequence elements (that contain an incrementing delay) that generate the desired effect. A 3D pulse sequence has one direct dimension and two incrementing delays, whereas a 4D data set has three incrementing delays. Each dimension of an n D data set usually encodes for different information, so 3D HETCOR-COSY would have three distinct chemical shift axes (one ^{13}C and two ^1H) and three distinct faces. (If the data within the 3D cube are projected onto each of the three distinct faces, they would display 2D HETCOR, 2D COSY, and 2D HETCOR-COSY data, respectively.) These hyphenated experiments, combined with the power of 3D and 4D NMR, are proving to be very useful for elucidating the structures of large molecules, particularly for large (150–300 residue) proteins.⁸⁸¹

Since a 2D data set contains three dimensions of information (two frequency axes and a signal amplitude), a contour plot presentation is usually used to represent the data on paper. A 3D data set is a cube in which each data point contains amplitude information. Since all this information is difficult to plot simultaneously, 3D data are usually plotted as a series of 2D planes (contour plots). 4D (and higher) experiments are easy to acquire (aside from the massive data storage requirements), but plotting and examining the data becomes increasingly difficult; as such, 3D spectroscopy is often the upper limit for routine NMR. We will see later how multidimensional NMR can be combined with multinuclear (triple-resonance) NMR experiments.

Although multidimensional NMR can provide more information, it also has some disadvantages. Its experimental time is longer; it usually requires more samples; set up of the experiment and processing and interpretation of the data
