

# Comprehensive Medicinal Chemistry II

## Volume 5 : ADME-Tox Approaches

Elsevier, 2006

*Editors-in-Chief: John B. Taylor and David J. Triggle*  
ISBN: 0-08-044513-6 (set)

### Introduction

**5.01 The Why and How of Absorption, Distribution, Metabolism, Excretion, and Toxicity Research**, Pages 1-9, H. Van de Waterbeemd and B. Testa

### Biological and In Vivo Aspects of Absorption, Distribution, Metabolism, Excretion, and Toxicity

**5.02 Clinical Pharmacokinetic Criteria for Drug Research**, Pages 11-30, J.-P. Tillement and D. Tremblay

**5.03 In Vivo Absorption, Distribution, Metabolism, and Excretion Studies in Discovery and Development**, Pages 31-50, T. Laveé and C. Funk

**5.04 The Biology and Function of Transporters**, Pages 51-85, J.-M. Scherrmann

**5.05 Principles of Drug Metabolism 1: Redox Reactions**, Pages 87-132, W.F. Trager

**5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions**, Pages 133-166, B. Testa

**5.07 Principles of Drug Metabolism 3: Enzymes and Tissues**, Pages 167-191, R.A. Totah and A.E. Rettie

**5.08 Mechanisms of Toxification and Detoxification which Challenge Drug Candidates and Drugs**, Pages 193-214, B. Oesch-Bartlomowicz and F. Oesch

**5.09 Immunotoxicology**, Pages 215-229, C. Esser

### Biological In Vitro Tools in Absorption, Distribution, Metabolism, Excretion, and Toxicity

**5.10 In Vitro Studies of Drug Metabolism**, Pages 231-257, Y. Parmentier, M.-J. Bossant, M. Bertrand and B. Walther

**5.11 Passive Permeability and Active Transport Models for the Prediction of Oral**

- Absorption**, Pages 259-278, P. Artursson, S. Neuhoff, P. Matsson and S. Tavelin
- 5.12 Biological In Vitro Models for Absorption by Nonoral Routes**, Pages 279-299, P. Colombo, S. Cagnani, F. Sonvico, P. Santi, P. Russo and G. Colombo
- 5.13 In Vitro Models for Examining and Predicting Brain Uptake of Drugs**, Pages 301-320, N.J. Abbott
- 5.14 In Vitro Models for Plasma Binding and Tissue Storage**, Pages 321-340, P. Barton, R.P. Austin and R.E. Fessey
- 5.15 Progress in Bioanalytics and Automation Robotics for Absorption, Distribution, Metabolism, and Excretion Screening**, Pages 341-356, J. Wang and B. Faller

#### **Physicochemical tools in Absorption, Distribution, Metabolism, Excretion, and Toxicity**

- 5.16 Ionization Constants and Ionization Profiles**, Pages 357-397, J.E.A. Comer
- 5.17 Dissolution and Solubility**, Pages 399-423, A. Avdeef, D. Voloboy and A. Foreman
- 5.18 Lipophilicity, Polarity, and Hydrophobicity**, Pages 425-452, G. Caron, G. Ermondi and R.A. Scherrer
- 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery**, Pages 453-487, K. Sugano
- 5.20 Chemical Stability**, Pages 489-507, E.H. Kerns and L. Di
- 5.21 Solid-State Physicochemistry**, Pages 509-530, D. Giron

#### **In Silico Tools in Absorption, Distribution, Metabolism, Excretion, and Toxicity**

- 5.22 Use of Molecular Descriptors for Absorption, Distribution, Metabolism, and Excretion Predictions**, Pages 531-554, S. Winiwarter, M. Ridderström, A.-L. Ungell, T.B. Andersson and I. Zamora
- 5.23 Electrotopological State Indices to Assess Molecular and Absorption, Distribution, Metabolism, Excretion, and Toxicity Properties**, Pages 555-576, L.H. Hall, L.B. Kier and L.M. Hall
- 5.24 Molecular Fields to Assess Recognition Forces and Property Spaces**, Pages 577-602, G. Vistoli and A. Pedretti
- 5.25 In Silico Prediction of Ionization**, Pages 603-626, R. Fraczekiewicz
- 5.26 In Silico Predictions of Solubility**, Pages 627-648, J. Taskinen and U. Norinder
- 5.27 Rule-Based Systems to Predict Lipophilicity**, Pages 649-668, I.V. Tetko and D.J. Livingstone
- 5.28 In Silico Models to Predict Oral Absorption**, Pages 669-697, H. Van de Waterbeemd
- 5.29 In Silico Prediction of Oral Bioavailability**, Pages 699-724, J.V. Turner and S. Agatonovic-Kustrin
- 5.30 In Silico Models to Predict Passage through the Skin and Other Barriers**, Pages

725-744, M.T.D. Cronin and M. Hewitt

- 5.31 In Silico Models to Predict Brain Uptake**, Pages 745-766, M.H. Abraham and A. Hersey
- 5.32 In Silico Models for Interactions with Transporters**, Pages 767-794, M. Wiese and I.K. Pajeva
- 5.33 Comprehensive Expert Systems to Predict Drug Metabolism**, Pages 795-807, D.R. Hawkins
- 5.34 Molecular Modeling and Quantitative Structure–Activity Relationship of Substrates and Inhibitors of Drug Metabolism Enzymes**, Pages 809-825, M.J. De Groot, D.F.V. Lewis and S. Modi
- 5.35 Modeling and Simulation of Pharmacokinetic Aspects of Cytochrome P450-Based Metabolic Drug–Drug Interactions**, Pages 827-846, M. Dickins, A. Galetin and N. Proctor
- 5.36 In Silico Prediction of Plasma and Tissue Protein Binding**, Pages 847-866, G. Colmenarejo
- 5.37 Physiologically-Based Models to Predict Human Pharmacokinetic Parameters**, Pages 867-884, T. Laveé, N. Parrott and H. Jones
- 5.38 Mechanism-Based Pharmacokinetic–Pharmacodynamic Modeling for the Prediction of In Vivo Drug Concentration–Effect Relationships – Application in Drug Candidate Selection and Lead Optimization**, Pages 885-908, M. Danhof, P.H. Van der Graaf, D.M. Jonker, S.A.G. Visser and K.P. Zuideveld
- 5.39 Computational Models to Predict Toxicity**, Pages 909-932, N. Greene
- 5.40 In Silico Models to Predict QT Prolongation**, Pages 933-955, A.M. Aronov
- 5.41 The Adaptive In Combo Strategy**, Pages 957-969, D.A. Smith and L. Cucurull-Sanchez

## **Enabling Absorption, Distribution, Metabolism, Excretion, and Toxicity Strategies and Technologies in Early Development**

- 5.42 The Biopharmaceutics Classification System**, Pages 971-988, H. Lennernäs and B. Abrahamsson
- 5.43 Metabonomics**, Pages 989-1007, I.D. Wilson and J.K. Nicholson
- 5.44 Prodrug Objectives and Design**, Pages 1009-1041, B. Testa
- 5.45 Drug–Polymer Conjugates**, Pages 1043-1068, F.M. Veronese and G. Pasut

# 5.01 The Why and How of Absorption, Distribution, Metabolism, Excretion, and Toxicity Research

## 5.01.1 Evolving Paradigm in Drug R&D

Not so very long ago, pharmacokinetics, drug metabolism, and toxicology of selected clinical candidates were studied mainly during preclinical and clinical development. In those days the mission of medicinal chemistry was to discover and supply very potent compounds, with less interest being given to their behavior in the body. However, the R&D paradigm in the pharmaceutical industry has undergone dramatic changes since the 1970s and particularly since the mid-1990s. High-throughput biological assays were developed that have enabled large series of compounds to be screened. This was driven by the increasing size of proprietary depositories and the availability of new reagents and detection technologies.

Simultaneously, medicinal chemists have developed new synthetic strategies such as combinatorial chemistry and parallel synthesis. The number of compounds synthesized increased dramatically. In addition, specialized biotech companies as well as universities began offering compound collections and focused libraries. As a result, much attention is currently being paid to the design and/or purchase criteria of lead- and drug-like compounds.<sup>1–3</sup> Increasingly, this includes considerations on ADME-related physicochemical properties as well as ADME properties themselves. The concept of property-based design,<sup>4</sup> in addition to structure-based design where target structures are available, is now commonly used to address ADME issues as early as possible. Thus, the former traditional in vivo animal ADME evaluation could no longer cope with the demand and in vitro ADME screens became widely used. Despite rapid advances in the use of automation and robotics to increase the throughput of the in vitro ADME assays,<sup>5</sup> screening all available compounds was not necessarily the most efficient and cost-effective strategy. It thus became reasonable and even essential to develop in silico tools to predict and simulate various physicochemical and ADME properties and to balance these in decision-making processes together with combined in vivo and in vitro approaches (in combo).

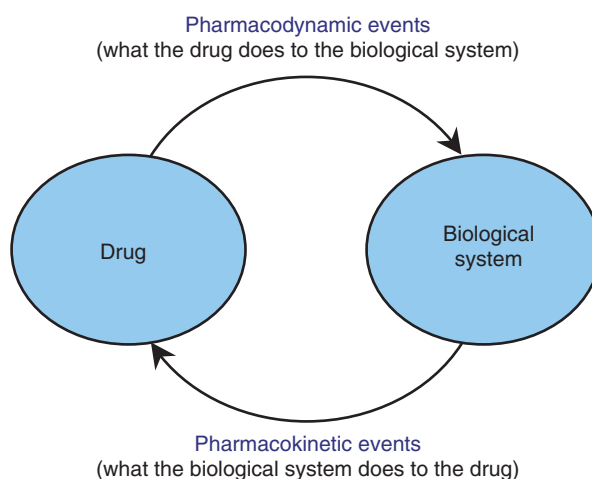

Rigorous analyses of the root causes of attrition during development revealed that lack of efficacy, toxicity, as well as inappropriate absorption, distribution, metabolism, and excretion (ADME) are among the major determinants of the failure of candidates.<sup>6,7</sup> Lack of efficacy, in addition to insufficient response of the target, may of course be caused by poor absorption, inadequate distribution, and/or rapid metabolism, leading to drug concentrations at the target site that are too low.<sup>8</sup> And since toxicity is also a major factor of attrition, the development of compounds is often halted even before a detailed human pharmacokinetics or efficacy study can be performed. Hence, the real impact of absorption, distribution, metabolism, excretion, and toxicity (ADMET) processes remains somewhat hidden in (incomplete)

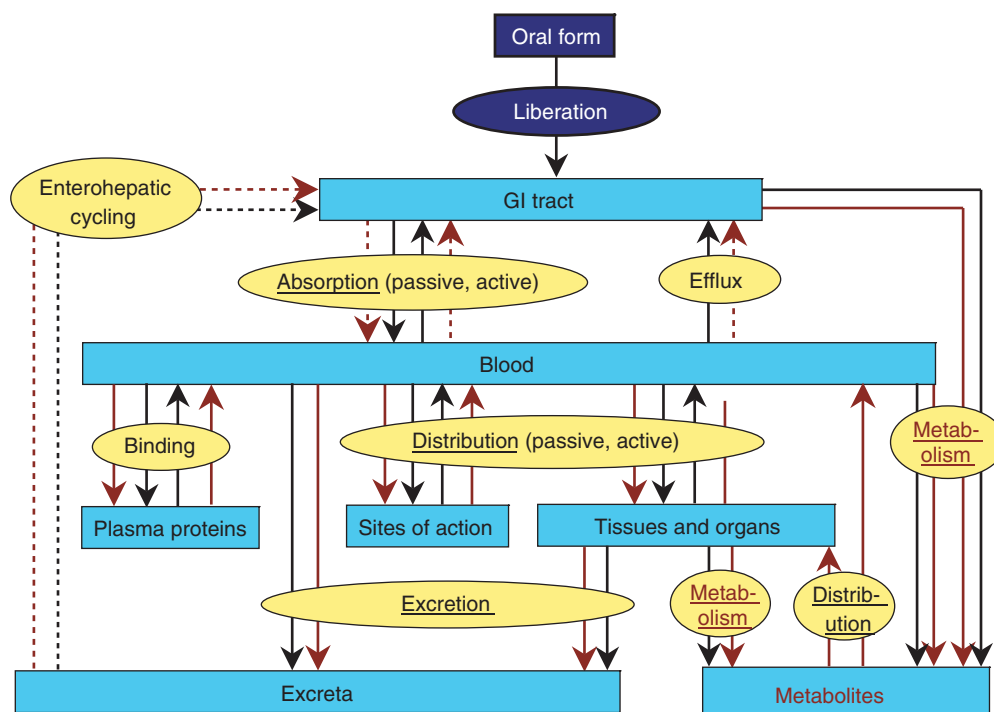

attrition data. During the 1990s, it became good practice to collect ADME and toxicity data during the drug discovery stage in order to use them in decision making to select the best clinical candidates.<sup>9</sup> Today, the drug discovery process has also become strongly dependent on departments providing data, guidance, and insight on issues of drug metabolism and pharmacokinetics (DMPK), toxicology, and safety.

Yet, the success of this move to early involvement of DMPK has been questioned. According to some practitioners the main contribution of a discovery (research) department of drug metabolism and pharmacokinetics has been to enable the design of pharmacokinetically adequate rather than optimal compounds and thus to make it possible to work on difficult targets.<sup>10</sup> However, despite all preclinical efforts there will always remain an essential need for extensive clinical pharmacokinetics to lay the ground for safe prescription once the drug is on the market.<sup>10</sup>

This bird's-eye view of ADMET research can be summarized in two statements. First, and in a more industrial perspective, it is now entirely clear that ADMET profiling must be initiated as early as possible in the discovery process, using high-throughput and in silico methods characterized by the best possible balance between good relevance to clinical properties on the one hand, and high speed, efficiency, and capacity on the other. Second, and in a more fundamental perspective, it took decades for pharmacologists and biologists to realize that there is an unseverable relation between pharmacodynamic effects (what the drug does to the organism) and pharmacokinetic effects (what the organism does to the drug) (Figure 1).<sup>11–13</sup> [A word of caution is necessary here about the meaning of the noun 'pharmacokinetics' and the adjective 'pharmacokinetic.' In its first meaning, the adjective refers to everything 'the organism does to the drug,' in other words to its disposition (absorption, distribution, metabolism, and excretion = ADME) in the body. This meaning is seen in the expression 'pharmacokinetic effects.' However, such effects can be investigated and described at the qualitative level (e.g., drug D yields metabolite M but not metabolite N), at the quantitative level (e.g., the oral availability of drug D in humans is in the range 70–90%), and at the kinetic (quantitative versus time) level (e.g., the half-life of drug D in humans is in the range 3–4 h). In its second meaning, the adjective refers strictly to the kinetic levels (e.g., when one speaks of 'pharmacokinetic parameters'). In contrast, the noun 'pharmacokinetics' refers exclusively to the kinetic aspects of drug disposition, at least in the English language. Unfortunately, this unambiguous and restrictive meaning is not found in all languages; witness the French language where 'la pharmacocinétique' can mean either disposition or pharmacokinetics.] For well over a century, these two components of the interaction between drug and organism were investigated separately and in complete ignorance of any influence the other component might have. The importance now given to early ADME screening is a belated recognition of the interdependence of pharmacodynamic and pharmacokinetic effects. Indeed, the influence of pharmacokinetic effects on a drug's actions is common knowledge, be it in the duration and intensity of these actions, or even in their nature when active metabolites are produced. As for the changes in its disposition that result directly from a drug's pharmacodynamic effects, these may be due to modifications in blood flow, gastrointestinal transit time, or enzyme responses, to name a few.

**Figure 1** The two basic modes of interaction between bioactive agents and biological systems, namely pharmacodynamic events (activity and toxicity) and pharmacokinetic events (ADME). (Reproduced with modifications from Testa, B.; Vistoli, G.; Pedretti, A. *Chem. Biodiv.* **2005**, 2, 1411–1427 with the kind permission of the copyright owner, Verlag Helvetica Chimica Acta in Zurich.)

**Figure 2** A schematic description of the major processes of drug disposition showing absorption (passive and active), distribution (passive including binding, and active including efflux), metabolism (= biotransformation), and excretion (passive and active including efflux). Elimination is not indicated explicitly, since metabolism is chemical elimination and excretion is physical elimination.

### 5.01.2 The Increasing Role of Absorption, Distribution, Metabolism, Excretion, and Toxicity (ADME-Tox) in Pharmaceutical R&D

ADME studies aim at obtaining an early estimate of human pharmacokinetic and metabolic profiles.<sup>14</sup> However, drug behavior in the body is a highly complex process involving numerous components, as presented in very simplified form in **Figure 2**.<sup>15</sup> This diversity and complexity is reflected in the ADME studies themselves, which include absorption, bioavailability, clearance and its mechanism, volume of distribution, plasma half-life, involvement of major metabolizing enzymes, nature and level of metabolites, dose estimates, dose intervals, potential for drug–drug interactions, etc.

Early toxicology and safety studies should weed out compounds before they enter lengthy and costly clinical trials. As a result of the recent withdrawal of a number of marketed drugs, more pressure is now being put on pharmaceutical companies by regulatory agencies such as the Food and Drug Administration (FDA) and the European Agency for the Evaluation of Medicinal Products (EMA) with regard to safety evaluations including pharmacological and toxicological safety. Investigation of the potential to cause QT prolongation is now routine. However, the interpretation of data is not straightforward, since many marketed drugs can prolong the QT interval.<sup>16</sup>

The increased role of early and preclinical ADME and safety/tox studies has led to an important growth of the supporting departments and a considerable development of various technologies to address the key issues. A short overview of the hot issues is given below<sup>17</sup>; the important challenges in investigating the disposition of new chemical entities (NCEs) and candidates are highlighted first, followed by some technological issues.

#### 5.01.2.1 Issues in Absorption, Distribution, Metabolism, Excretion, and Toxicity

##### 5.01.2.1.1 Transporters

Transporter proteins constitute a significant fraction of membrane-bound proteins. They are typically expressed in all organs involved in the uptake, distribution, and elimination of drugs, including the gastrointestinal tract, the blood–brain barrier, the liver, and the kidneys. The sequence of many transporters is known (*see* 5.04 The Biology and Function of

Transporters; 5.32 In Silico Models for Interactions with Transporters). There is hope that in the near future the experimental 3D structures of the key transporters will be elucidated. Interaction of drugs with transporters can alter their behavior in membrane transport, which may result in, for example, active uptake, efflux, and rapid elimination. In other words, the pharmacokinetics of a drug may be influenced by transporters. Apart from a metabolic component (see Section 5.01.2.1.3), drug–drug and drug–nutrient interactions may involve transporters.<sup>18,19</sup> However, while the basic knowledge on transporters is rapidly growing, their real clinical significance remains open to debate despite some convincing theories.<sup>20</sup> A number of P-glycoprotein (P-gp) assays have been developed, as well as some double- and triple-transfected assays. More transporter assays will be available in the near future. The challenge will be to translate the flood of experimental data into relevant information for drug design projects.

#### 5.01.2.1.2 Metabolite identification

With increasing resolution of mass spectrometry and nuclear magnetic resonance (NMR), it is now feasible to detect minute amounts of metabolites. Debate is ongoing as to how to define major versus minor metabolites. Some metabolites might be pharmacologically active and contribute to the overall pharmacokinetics (PK). Reactive metabolites might bind to proteins and cause idiosyncratic reactions.<sup>21</sup> The challenge remains to detect these metabolites as early as possible. It has been suggested that time-dependent inhibition should become routine in vitro screening protocols.<sup>22</sup> Good progress has been made in computational (in silico) metabolite prediction.<sup>23–25</sup>

#### 5.01.2.1.3 Drug–Drug interactions

Regulatory authorities require information to be submitted on the potential for interactions to cause adverse effects. Thanks to the availability of in vitro systems this aspect is often considered during the early stages of discovery, including hit evaluation. Oxidative metabolism by cytochromes P450 (CYPs) is the major route of elimination of most drugs. Since CYPs are also able to metabolize multiple substrates, their inhibition is the major focus of drug–drug interaction (DDI) studies. Thus, CYP3A4 is not only the most abundant hepatic CYP, but is also present in the gut wall and is responsible for the metabolism of 50–60% of all drugs. Therefore, this enzyme is highly susceptible to both reversible and irreversible (mechanism-based) inhibition.<sup>26</sup> Most CYP3A4 substrates or inhibitors are also P-gp substrates or inhibitors. It is believed that CYP3A4 and P-gp in the gastrointestinal tract work in concert to limit uptake of xenobiotics including drugs.<sup>27</sup> Current inhibition studies are based on  $K_i$  or  $IC_{50}$  values,<sup>28</sup> but more kinetic approaches would be of benefit.<sup>29</sup> Great progress has been made in the reliable simulation of DDIs, even taking into account variability in the population.<sup>30</sup> A further question is how metabolites contribute to DDIs; a better understanding of the allosteric kinetics of CYPs is also needed.<sup>31</sup>

Although clinically somewhat less important than enzyme inhibition, enzyme induction is also an inescapable issue and adequate protocols are being developed for its characterization. It remains to be agreed when to carry out such assays or screens during the discovery process.<sup>22</sup>

#### 5.01.2.1.4 Toxicology and safety prediction

Drug safety is of great concern to patients, medical professionals, and regulatory bodies. As a result, early toxicity predictions and safety estimates are receiving ever-increasing attention in all drug discovery programs. Simple in vitro screening assays, e.g., for hERG and other cardiac ion channels, genetic toxicology, and cytotoxicity, are now routinely added to the growing battery of biology, ADME, and tox/safety screens. Despite encouraging progress,<sup>32</sup> in silico predictive toxicology is still in its infancy.<sup>33</sup> A promising tool is the integration of ADME-Tox, and pharmacology data to predict side effects, as in the BioPrint approach.<sup>34</sup>

### 5.01.2.2 Technological Issues

#### 5.01.2.2.1 In vitro screening

Based on the experience gained with pharmacodynamic high-throughput screening, many in vitro ADME screens can now run in medium or high-throughput modes using automation, robotics, and miniaturization.<sup>35–37</sup> Physicochemical properties are now recognized to play a key role in modulating DMPK properties,<sup>4,38–40</sup> and their assessment and understanding are therefore receiving greater attention. Owing to the nature of many high-throughput physicochemistry and ADME assays, the typical analytical endpoint is often liquid chromatography–mass spectrometry (LC/MS). Cell-based assays such as the Caco-2 screen for permeability/absorption are quite expensive due to considerable reagent costs, particularly when run in screening mode with many compounds. The trend is to invest in either cheaper in vitro

alternatives such as the PAMPA (parallel artificial membrane permeability assay) method or in silico approaches. A proper synergistic hybrid combination of in vitro and in silico methods,<sup>41</sup> which has been called the ‘in combo’ approach,<sup>42</sup> may be the most cost-effective approach to ADME screening in drug discovery.

#### 5.01.2.2.2 In silico absorption, distribution, metabolism, and excretion

Prediction and simulation of various ADME properties is considerably cheaper than in vitro screening. Therefore, great efforts have been made to turn all available data into predictive computational models using quantitative structure–activity relationship (QSAR) methods and molecular modeling.<sup>42,43</sup> In vitro data are now generated for many ADME and physicochemical endpoints and can be used to build more robust models. Model updating will need to be automated and fitted in the data generation cycle. There is a need for both local (project-specific) as well as global (general, encompassing a wide range of chemotypes) models. Unfortunately, there is still a paucity of human in vivo data, and thus models based upon these will need to be handled with care. Of course interindividual variability within the population is another key factor to take into account for human predictions. Predictions will be ranges rather than hard numbers. Many drug companies have web-based cheminformatics and ADME predictions deployed via their intranet giving the medicinal chemist easy access to ‘web screening.’<sup>44</sup> For the development of potential drugs, predictions may also contribute to high-throughput pharmaceuticals and rational drug delivery.<sup>45</sup>

#### 5.01.2.2.3 Simulations: physiologically-based pharmacokinetic (PBPK) and pharmacokinetic/pharmacodynamic (PK/PD)

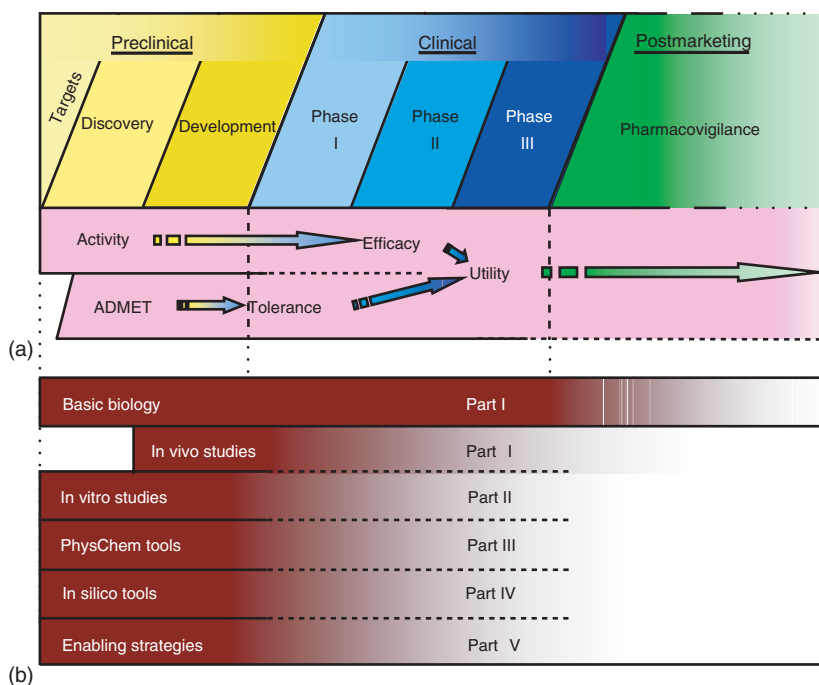

Physiologically-based pharmacokinetic (PBPK) models rely on principles well known in chemical engineering and describe the human or animal body as a series of pipes and tanks.<sup>46,47</sup> Convenient software packages are now available and make PBPK modeling more accessible to drug discovery and development to predict various PK parameters and concentration–time profiles in the body. Population variability<sup>48</sup> and specific groups such as children and the elderly can also be taken into account. The more experimental data that are available, the better the simulations, making these approaches of interest in drug discovery and clinical development. Some commercial programs have put considerable effort into simulating the absorption process, which is of interest in optimizing pharmaceutical formulations.

Pharmacokinetic/pharmacodynamic (PK/PD) modeling links dose–concentration relationships (PK) to concentration–effect relationships (PD). This approach helps to simulate the time course of drug effects depending on the dose regimen.<sup>49</sup> Specialized software and a better understanding of the applications may help to speed up clinical development. As a whole the pharmaceutical industry lags behind engineering-based industries such as car and airplane manufacturers in using prediction, modeling, and simulation. Often, resources remain allocated to producing experimental data rather than developing the information technology (IT) tools to move toward in silico pharma; in other words, toward web screening rather than wet screening and to a ‘will do’ rather than a ‘can do’ attitude.

### 5.01.3 Concept of the Volume

ADME-Tox issues were far from the forefront in the first edition of *Comprehensive Medicinal Chemistry*, being implicit rather than explicit in a number of chapters on ‘drug design.’ Numerous and fast developments since the early 1990s now fully justify a complete volume being devoted to the strategies and technologies currently aimed at evaluating and assessing biotransformation, pharmacokinetics, toxicology, and safety of new chemical entities in the preclinical phases. A schematic diagram of drug discovery, development, and clinical assessment is shown in [Figure 3a](#). Pharmacodynamics (i.e., activity) is obviously the first object of study, but the new paradigm of drug R&D now dictates that ADMET screening must be initiated rapidly. Activity (PD) and ADMET (PK) screening and evaluation thus run in parallel throughout the preclinical phases, and this is when medicinal chemists find themselves in close collaboration with pharmacologists, biologists, biochemists, bioanalysts, physicochemists, computer scientists, and other experts. Assessment of efficacy and tolerance, to merge into utility assessment, then become the objectives of clinical trials.

The present volume is organized mainly according to the methodologies and technologies available to researchers, with due consideration being given to the biochemical/biological background underlying them. However, such a concept taken per se offers a necessary but not sufficient rationale for a logical and mission-oriented organization of this volume. The second concept underlying the organization of the volume is the overwhelming fact that the ultimate ‘target’ of medicinal chemistry and drug discovery is the human patient, and that all methodologies, technologies, and tools used during the preclinical phases to screen, assess, and understand the biological behavior of hits, leads, and candidates must be relevant to this ultimate ‘target.’ In other words, each and every biological model, physicochemical method, and computer software package used in drug discovery and development must demonstrate a useful degree of predictivity to behavior in the human patient.

**Figure 3** A schematic representation of modern drug research and development (a), presented in parallel with the layout of this volume (b). (a) The major steps in drug R&D, showing target validation, discovery, and development, followed by the clinical phases and the postmarketing phase. Note the overlaps, which reflect the fact that many knowledge-expanding investigations are carried out after the next phases have begun, e.g., in vivo research in animals continues during the clinical phases, and clinical studies continue postmarketing for confirmatory and indication-enlarging purposes. Preclinical R&D has two objectives: activity and ADMET. These translate as efficacy and tolerance in the early clinical phases, to merge subsequently into the global objective of utility. (b) This part of the figure shows the content of this volume and how its parts correspond to the ADMET methodologies and technologies used in drug discovery and development. (The upper part is reproduced from Testa, B.; Krämer, S. D. *Chem. Biodiv.* (in press) with the kind permission of the copyright owner, Verlag Helvetica Chimica Acta in Zurich.)

As a result of this dual rationale, this volume has been organized to begin with the human patient; concretely with the clinical pharmacokinetic criteria good candidates are expected to fulfill. The first chapter (5.02 Clinical Pharmacokinetic Criteria for Drug Research), written by two renowned clinical pharmacologists, is thus the platform on which the volume is built. Part I (see [Figure 3b](#)) then examines in vivo animal models used in discovery and development (see 5.03 In Vivo Absorption, Distribution, Metabolism, and Excretion Studies in Discovery and Development). This is followed by a number of chapters presenting the biochemical bases of drug metabolism and toxification/detoxification.

Part 2 is dedicated to in vitro biological tools used to investigate the absorption, distribution, and metabolism of lead candidates, leads, and clinical candidates. As stressed above, relevance to in vivo and clinical behavior is a major concern. Part 3 covers the major physicochemical tools used in discovery and mainly in development to characterize ionization profile, solubility and dissolution, lipophilicity and permeation, and stability of leads and clinical candidates. Relevance to biological and clinical behavior is considered.

Part 4 is dedicated to in silico tools. The term ‘in silico’ was coined by the molecular biologist Antoine Danchin, whose quotation below offers a concise and cogent justification to our decision to dedicate the largest part of the volume to this methodology:

[I]nformatics is a real aid to discovery when analyzing biological functions.... [I] was convinced of the potential of the computational approach, which I called *in silico*, to underline its importance as a complement to in vivo and in vitro experimentation.<sup>50</sup>

Indeed, in silico tools have gained an irreplaceable significance in virtual experimentation by allowing medicinal chemists to predict physicochemical and ADMET properties of projected and existing molecules. But here again, relevance to ‘wet’ physicochemistry, biological properties, and clinical behavior is of paramount importance.

The volume ends with the short Part 5 where global tools (the biopharmaceutics classification system and metabonomics) and enabling strategies are presented.

With 45 chapters, this volume aims at informing by providing data and examples, and instructing by presenting a conceptual and logical framework. As such, careful students of this volume may find in it a didactic value even greater than that of the sum of its individual chapters. The hope is that this volume will retain its usefulness for many years to come, and we thank our contributors for their dedication and enthusiasm.

## Biographies

**Han Van de Waterbeemd** studied physical organic chemistry at the Technical University of Eindhoven, the Netherlands, and then took a PhD in medicinal chemistry at the University of Leiden, the Netherlands. After carrying out postdoctoral research with Bernard Testa at the School of Pharmacy of the University of Lausanne, Switzerland, he took up a position at the same institution for 5 years. He also taught medicinal chemistry to pharmacy students at the universities of Berne and Basel in Switzerland from 1987 to 1997. In 1988 Han joined F Hoffmann-La Roche Ltd in Basel as head of the Molecular Properties Group. In 1997 he moved to Pfizer Central Research UK (now Pfizer Global Research and Development), and held various positions in the Department of Drug Metabolism, later called PDM (Pharmacokinetics, Dynamics, and Metabolism), including Head of Discovery and Head of Automation and In Silico ADME Technologies. In 2005 he moved to AstraZeneca to become global project leader of their Molecular Properties and In Silico ADMET Modeling system.

He has published more than 135 peer-reviewed papers and book chapters, and has (co)-edited 11 books. His research interests include physicochemical and structural molecular properties and their role in drug disposition, as well as the in silico modeling of ADMET properties. Han was secretary of The QSAR and Modeling Society between 1995 and 2005.

**Bernard Testa** studied pharmacy because he was unable to choose between medicine and chemistry. Because he was incapable of working in a community pharmacy, he undertook a PhD thesis on the physicochemistry of drug-macromolecule interactions. Because he felt himself to be not gifted enough for the pharmaceutical industry, he applied for a postdoctoral research position at Chelsea College, University of London, where he worked for 2 years under the supervision of Prof Arnold H Beckett. And because these were easy times, he was called upon to become assistant professor at the University of Lausanne, Switzerland, becoming full professor and Head of Medicinal Chemistry in 1978. Since then, he has tried to repay his debts by fulfilling a number of local and international commitments, e.g., Dean of the Faculty of Sciences (1984–86), Director of the Geneva-Lausanne School of Pharmacy (1994–96 and 1999–2001), and President of the University Senate (1998–2000). He has written four books and edited 29 others, and (co)-authored 450 research and review articles in the fields of drug design and drug metabolism. During the years 1994–98, he was the Editor-Europe of *Pharmaceutical Research*, the flagship journal of the American

Association of Pharmaceutical Scientists (AAPS), and he is now the co-editor of the new journal *Chemistry and Biodiversity*. He is also a member of the Editorial Board of several leading journals (e.g., *Biochemical Pharmacology*, *Chirality*, *Drug Metabolism Reviews*, *Helvetica Chimica Acta*, *Journal of Pharmacy and Pharmacology*, *Medicinal Research Reviews*, *Pharmaceutical Research*, and *Xenobiotica*). He holds Honorary Doctorates from the Universities of Milan, Montpellier, and Parma, and was the 2002 recipient of the Nauta Award on Pharmacochemistry given by the European Federation for Medicinal Chemistry. He was elected a Fellow of the AAPS, and is a member of a number of scientific societies such as the French Academy of Pharmacy, the Royal Academy of Medicine of Belgium, and the American Chemical Society. His recently granted Emeritus status has freed him from administrative duties and gives him more time for writing, editing and collaborating in research projects. His hobbies, interests, and passions include jogging, science fiction, epistemology, teaching, and scientific exploration.

## 5.02 Clinical Pharmacokinetic Criteria for Drug Research

### 5.02.1 Introduction

Combinatorial chemistry and in silico approaches have created an avalanche of new chemical entities (NCEs), which will compete to become drug candidates. Most of these NCEs will be rejected following a thorough selection process, which must be carried out as early as possible for obvious reasons of cost and time.<sup>1</sup> The criteria of selection of a drug candidate involve many diverse aspects such as required pharmacological activity, an absence of toxicity at least within a large range of doses including the active ones, and pharmacokinetic characteristics that enable it to develop its activity in human disease.<sup>2</sup> These criteria should be weighted simultaneously and balanced. Indeed, the selected agent is not obviously the most powerful one, but the one that satisfies efficacy, safety, and appropriate kinetics. A highly powerful agent that is eliminated from the body too quickly would not be of therapeutic interest. Similarly, a molecule that exhibits a very long half-life ( $t_{1/2}$ ) may be difficult to monitor and may lead to accumulation in the body. As a result, the selected drug candidate is often a compromise between the needed activity and the toxicological and pharmacokinetic

characteristics. The latter allow the fulfillment of this activity and they facilitate prescription, safe use, comedication, and monitoring.

This chapter describes the pharmacokinetic criteria a drug must meet, the principles of their evaluation, and the information needed for rational and safe use in humans, and highlights some new trends in pharmacokinetics.

### 5.02.2 Pharmacokinetic Requirements for Drug Development

The pharmacological characteristics of a drug involve its pharmacodynamic (PD) and pharmacokinetic (PK) properties. The former include its effects, their mechanisms, and intensity, while the latter include the conditions of the drug's effectiveness, namely its ability to reach and bind to its receptors at pharmacological concentrations over a period of time sufficient for its effects to develop.

Pharmacokinetic studies observe and measure the variations of drug levels in the body as a function of time. They enable the corresponding parameters to be calculated in order to draw models of the fate of the drug allowing for prediction under various conditions. Pharmacokinetics involves studying the concentrations in various parts of the body, namely organs, tissues, blood, and excreta (urine, bile, feces, sweat, saliva, etc.). It involves not only the parent drug (the administered agent) but also its metabolites, be they active, partly active, or inactive.

Drug disposition consists of four phases (Figure 1):

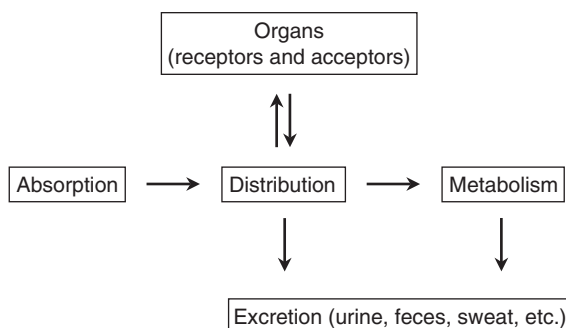

- absorption;
- distribution;
- metabolism (i.e., chemical elimination); and
- excretion (i.e., physical elimination).

These four phases are not successive but can occur more or less simultaneously in vivo. However, they can be investigated separately in in vitro assays.

Appropriate pharmacokinetic characteristics are needed to fulfill the following therapeutic objectives:

1. To reach the selected targets in amounts high enough to produce pharmacological effects. This objective supposes a body distribution selective enough to avoid high concentrations in tissues or organs where the drug does not act (no receptors) or may lead to toxic effects.
2. To maintain the drug concentrations at sufficient levels over a period of time for the effect to develop.
3. To excrete the parent drug and its metabolites according to stable and predictable processes, avoiding as much as possible interindividual variations due to genetic factors and/or pathophysiological conditions such as diseases that alter drug distribution or excretion. Both in vitro and in vivo assays are needed during drug research and development in order to select a pharmacologically effective agent that will exhibit the best profile for human use.

A number of properties must be assessed during preclinical studies, for example, stability at physiological pH, ability to cross cell membranes by passive diffusion or active transfer, blood distribution, and metabolic stability and profiles. These studies also allow selection of the compulsory second animal species for toxicological testing (the first one often being the rat), since its metabolic profile needs to be close to the human one. This can be done in vitro before long-term toxicological studies begin and the first administration to humans. Metabolic profiles are checked using

**Figure 1** The simplest model of drug disposition inside the body.

microsomes, S9 fractions, animal and human hepatocytes, etc. These assays may also be used to check the possible formation of toxic reactive metabolites and the conditions of their production, for instance, when biotransformation processes are saturated or genetically limited.

Each pharmacodynamic effect will then be correlated with the concentrations in the corresponding organ and blood, including those of the active metabolites. This step initiates the fundamental pharmacokinetic–pharmacodynamic (PK/PD) evaluation of the drug and an assessment of its dose–concentration–effect relationships.<sup>3</sup> Toxic effects are also correlated with the relevant concentrations measured during toxicological studies (toxicokinetics).<sup>4</sup> In humans, PK/PD evaluations will be made using the corresponding data, quantified effects, and relevant drug levels. They will be used to define the administered dose, the number of daily administrations, drug dosage regimens, duration of treatment, etc.

Variations in drug concentrations, in parallel with a quantification of effects, may also bring to light drug–drug interactions, potentiation or antagonism, metabolic induction or inhibition, and the effects of pathological states, as discussed throughout this volume.

## 5.02.3 The Fate of Drugs in the Body: The Absorption, Distribution, Metabolism, and Excretion (ADME) Paradigm

### 5.02.3.1 An Overview of Kinetics

The fate of a drug in the body is related to the efficacy of clearing organs and to the fact that most of its interactions in the body (effects, storage, and metabolism) involve reversible binding to specific proteins, receptors, acceptors, and enzymes. Covalent bonds may sometimes be involved, which prolong effects or cause toxicity.

The fate of a drug in the body depends on a series of transfers through and between membranes and into, out of, or between cells during which it may be transformed. Kinetics of transfer and transformation result from either passive or active processes. Passive transfers are described according to Fick's law:

$$\frac{dM}{dt} = k_f \frac{S}{d\sqrt{MW}} \Delta C \quad [1]$$

where  $dM/dt$  is the amount of drug transferred during time  $dt$ ,  $\Delta C$  is the gradient of concentration,  $MW$  is the molecular weight of the transferred solute, and  $k_f$  is a constant related to its lipophilicity (solubility in membranes) and hydrophilicity (solubility in water). As a general rule, drugs transferred by this process have a  $MW$  below 500.  $S$  is the surface available for transfer and  $d$  is the thickness of this surface or membrane.

This equation is valid for linear kinetics where rate and concentration are directly related. The membrane transfer depends also on other parameters (*see* 5.12 Biological In Vitro Models for Absorption by Nonoral Routes; 5.13 In Vitro Models for Examining and Predicting Brain Uptake of Drugs; 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery; 5.28 In Silico Models to Predict Oral Absorption; 5.29 In Silico Prediction of Oral Bioavailability; 5.30 In Silico Models to Predict Passage through the Skin and Other Barriers; 5.37 Physiologically-Based Models to Predict Human Pharmacokinetic Parameters; 5.42 The Biopharmaceutics Classification System).

Active transfers are energy consuming as defined in Michaelis kinetics by the general equation:

$$\frac{dM}{dt} = \frac{V_{\max} \times C}{K_m + C} \quad [2]$$

where  $dM/dt$  is the amount of drug transferred or metabolized during time  $dt$ ,  $C$  is the drug concentration,  $V_{\max}$  is the maximum rate of kinetics, and  $K_m$  is the Michaelis constant. Since drug concentrations are generally very low,  $C$  is often negligible compared to  $K_m$  and the equation becomes:

$$\frac{dM}{dt} \approx \frac{V_{\max}}{K_m} C \quad [3]$$

This approximation yields linear kinetics.

### 5.02.3.2 Absorption

Absorption is the early phase of distribution when the drug enters the bloodstream from its site of administration. Two main parameters describe absorption: the ratio of absorbed dose over given dose and the rate of absorption. Both parameters influence the initial concentrations of the drug in blood, hence its concentration gradient and intensity of effects (when concentration dependent).

The main sites of absorption are the gut (oral route), connective tissues (subcutaneous route), muscles (intramuscular route), skin, eyes, nose, and various mucosa. These routes of administration are extravascular. The intravascular routes (intraarterial or intravenous) bypass the absorption phase as the drug is administered directly into the blood.

### 5.02.3.3 Distribution

Distribution is the next phase, when the drug is transferred from the blood into tissues.<sup>5</sup> To do so, it exits the vessels and enters the extravascular circulation, first into interstitial fluids, then into cells. Distribution may be subdivided into two successive phases. The first phase involves dilution of the absorbed dose in the whole blood as a free fraction, and binding to plasma proteins and circulating cells (e.g., erythrocytes). In the second phase, the drug distributes to organs. When the drug is injected intravenously as a bolus, a high local concentration occurs in blood before dilution, thus creating a high transitory gradient that reaches organs immediately downstream. This high gradient is sometimes required in order to obtain a quick and intense effect in well-irrigated organs (e.g., in the brain for general anesthetics). In many other cases, it may be dangerous as it promotes over dosage and possible toxic effects in heart and lungs.

In the blood, drugs are bound to plasma proteins according to the law of mass action (reversible equilibrium). The binding to a plasma protein may have two different meanings, either pharmacokinetic or pharmacodynamic. In the first case, the amount of bound drug and the characteristics of binding can alter the overall drug distribution. In the second, the drug is bound to its circulating receptor.

Many plasma proteins can bind drugs according to eqns [4] and [5]:

$$K_a = [C_b]/[C_u \cdot (C_p - C_b)] \quad [5]$$

which gives:

$$f_u = 1/[1 + K_a \cdot (C_p - C_b)] \quad [6]$$

where  $K_a$  is the association constant,  $C_p$  is the protein concentration,  $C_b$  is the concentration of protein-bound drug,  $C_u$  is the free (unbound) drug concentration (with  $C_b + C_u = C$ , the total drug concentration in plasma),  $f_u$  is the free fraction of drug in plasma (with  $f_u = C_u/C$ ), and  $100(1 - f_u)$  is the percentage of bound drug.

According to eqn [6],  $f_u$  is not constant but increases when  $C_b$  increases. But when  $C_b$  is negligibly small compared to  $C_p$  ( $C_b \ll C_p$ )  $f_u$  will be constant if the protein concentration is constant. Then:

$$f_u = 1/[1 + K_a \cdot C_p] \quad [7]$$

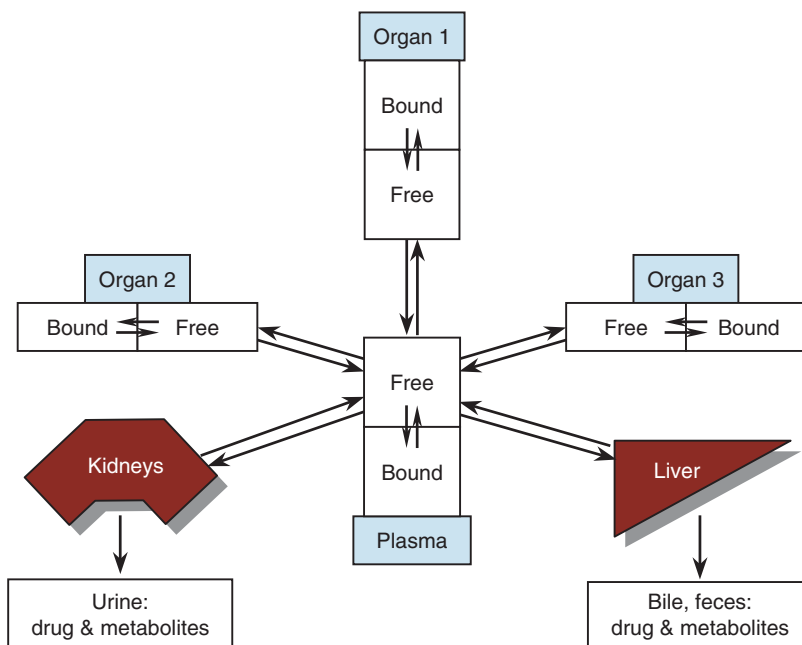

Human serum albumin (HSA) and  $\alpha_1$ -acid glycoprotein (AGP) bind significant amounts of drugs as a consequence of their concentration and affinities. HSA concentration is high (ca. 630  $\mu\text{M}$ ), implying that  $C_b \ll C_p$  is generally fulfilled, and HSA binding capacity for acidic drugs is generally high. In contrast, AGP concentrations are low (ca. 10  $\mu\text{M}$ , except in some genetic or pathological states),<sup>6</sup> and its affinity is mainly toward basic drugs, with the result that condition  $C_b \ll C_p$  is not always fulfilled, binding is quickly saturated, and  $f_u$  increases when drug concentration increases and binding percentage decreases.

Significant amounts of a drug may also be taken up by red cell membranes, or in the case of basic drugs in red cell cytosol at pH 7.20. Generally, uptake and binding to red cells are nonsaturable processes. When they are saturable, saturating concentrations will induce nonlinear kinetics.

Lipophilic drugs may also interact with lipoproteins,<sup>7</sup> their dissolution in the lipid core of lipoproteins being roughly proportional to their lipid content (VLDL > LDL > HDL). Binding to the protein core has also been described but its pharmacokinetic significance is not yet established. The design of these various binding modes to plasma proteins has been described elsewhere.<sup>8</sup> Other plasma proteins of pharmacokinetic interest are fibrinogen,  $\alpha_2$ -glycoprotein, and gamma globulins.

From the blood, drugs will distribute into organs at different rates corresponding to different membrane structures and different local blood flow rates. Schematically, drug distribution inside an organ is superimposable to the rate of blood flow. This observation explains why the blood cannot selectively distribute a drug into a given organ.

In every organ and every cell, a drug is partly free and partly bound to functional proteins, both forms being in reversible equilibrium. According to Brodie,<sup>9</sup> it is assumed that at any time and in every tissue, an instantaneous equilibrium exists between blood and organ concentrations. This equilibrium is characterized by the same free drug

**Figure 2** Equilibria between blood and various organs, with liver and kidneys as excretion pathways. It is assumed that each binding is governed by a reversible equilibrium. At any one time, the free drug concentrations are assumed to be rapidly exchangeable. The liver (by biotransformation and bile excretion) and kidneys (by urine excretion) continuously disrupt the general equilibrium by removing some of the free drug. At steady-state, the free drug concentration is assumed to be identical in plasma and organs.

concentration ( $C_u$ ) in all organs, which is considered to be instantaneously exchangeable with the plasma. However, this equilibrium is disrupted since clearing organs excrete a fraction of the free drug. The decrease in  $C_u$  is quickly compensated, and a new equilibrium is reached with a decrease in overall drug concentration (Figure 2). At the end of this cascade of equilibria, the entire dose is cleared from the body.

#### 5.02.3.4 Metabolism

Drug metabolism is the phase of biochemical transformation of the drug. It is highly variable among drugs and depends on biological conditions. The metabolism phase is absent for the few drugs that are not transformed. As explained in great detail in other chapters (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions; 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions; 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues; 5.08 Mechanisms of Toxicification and Detoxification which Challenge Drug Candidates and Drugs; 5.09 Immunotoxicology; 5.10 In Vitro Studies of Drug Metabolism; 5.33 Comprehensive Expert Systems to Predict Drug Metabolism; 5.43 Metabonomics), biotransformations may involve one or more successive reactions:

- Phase 1 transformations (reactions of functionalization) involve the creation of a functional group or the modification of an existing one by oxidation, reduction, or hydrolysis.
- Phase 2 transformations (reactions of conjugation) couple a drug or a metabolite to an endogenous conjugating molecule such as glucuronic acid, sulfuric acid, acetic acid, glutathione, etc.

From a physicochemical point of view, drug metabolism is expected to yield metabolites of lower lipophilicity relative to the parent drug, e.g., by adding an ionizable group. As a result, metabolites are often excreted faster than the parent drug, but there are exceptions. From a pharmacological point of view, it is essential to check the pharmacodynamic consequences of these metabolic reactions. Often but far from always, biotransformation involves inactivation or detoxification. Activation concerns prodrugs, but also active compounds (drugs) giving rise to active metabolites. The latter may exhibit a PK profile different from that of the parent drug, and/or a qualitatively different activity. Prodrugs receive specific treatment in Chapters 5.44 and 5.45.

Some enzymes involved in metabolism present a genetic polymorphism, which separates populations of patients according to their phenotypes (i.e., very fast, 'normal,' and poor metabolizers). This is the field of pharmacogenetics. Independently of any pathological state, individuals who are very fast or poor metabolizers need to be identified and have their dosages adjusted.<sup>10</sup> Specific monitoring must also be applied for drugs with a low therapeutic index resulting in a low safety margin due to relatively vicinal effective and toxic doses.

### 5.02.3.5 Excretion

The kidneys and the liver are the main organs that clear drugs from the body, and the only ones that elicit active excretion processes provided the compounds are ionized. Rates of excretion are always faster for hydrophilic than for lipophilic compounds, however, metabolites cannot be excreted more rapidly than the parent drug, as their excretion is limited by their formation from the parent drug.

#### 5.02.3.5.1 Renal excretion

Three separate processes are involved in renal excretion, namely, glomerular filtration, active tubular excretion, and passive tubular reabsorption.

Glomerular filtration is a simple filtration of plasma through the pores of the glomeruli, whose size allows only the plasmatic free drug and metabolites to be cleared. The amount of compound eliminated is restricted by the glomerular filtration rate and as a result by the renal blood flow. Thus, it may be modified by comedications that increase the rate of elimination of other drugs (e.g., diuretics), and obviously by various pathophysiological conditions.

Active tubular excretion is the process by which tubules excrete ionized compounds, a process requiring energy supply and specific transporters. P-glycoprotein and multidrug resistance-associated proteins (type 2) transfer amphiphilic anions and most of the conjugates. Other transporters transfer organic cations. Most of the renal transporters work from plasma to urine and to a lesser extent back from urine to plasma. The fact that this process involves only ionized compounds underlines the prominent role of plasma pH as a factor influencing the degree of ionization.

Passive tubular reabsorption takes place at proximal and distal tubules. Following filtration, nonionized compounds may return to capillaries provided that a favorable gradient exists. This process involves mostly the more lipophilic parent compounds. It is directed by the pH of elementary urine as a determinant of percentage of the reabsorbed nonionized form.

The total elimination of a parent compound and metabolites requires the integrity of these three separate processes, which themselves depend on plasma pH, urine pH, and renal blood flow. All active processes may be restricted by the amount of available transporters and energy supply, which may lead to competitive drug–drug interactions.

#### 5.02.3.5.2 Hepatic elimination

Three main processes may be involved in the hepatic elimination of a drug and its metabolites, namely uptake, metabolism, and biliary secretion. These processes can be minor or even lacking depending on the physicochemical properties of the drug (e.g., its hydrophilicity). As in the kidney, hepatocytes excrete unchanged drugs and metabolites by active processes involving transporters. As a result, competition for biotransformation and excretion may also take place in the liver. Following bile secretion, the excreted compounds reach the duodenum where they may be either excreted from the body via the feces, partly reabsorbed in enterohepatic recycling, or partly metabolized by the intestinal flora (as an example, conjugated morphine is partly deconjugated). Metabolites may also be excreted in plasma from which they are cleared by kidneys.

In conclusion, prescribing of drugs in a rational way requires a knowledge of what causes pharmacological activity to stop, namely:

- in which organs (liver, kidneys, or others);
- by which processes (biotransformation to inactive metabolites, biliary secretion without reabsorption, or urinary excretion); and
- at which rates (clearance and half-life).

An alteration in any of these processes may necessitate a dosage adjustment or even a drug change.

#### 5.02.3.5.3 Other routes of excretion

Fecal excretion of drugs can result from incomplete intestinal absorption following oral administration, biliary elimination, or direct excretion by enterocytes. Pulmonary excretion is found for volatile agents, even lipophilic ones, but in situ

transformation may also occur. Excretion in saliva, sweat, and tears results from passive diffusion processes. Assaying concentrations in saliva may be useful to monitor some drugs or toxins as they reflect free plasma concentrations.

Special attention should be given to the secretion of drugs in breast milk, which, being more acidic than blood plasma, can concentrate basic compounds. Milk also contains a high proportion of lipids, a factor favoring the secretion of lipophilic drugs. The amount of drug transferred by this route from mother to baby is usually low, but it can be sufficient to induce side effects in the newborn, especially in the CNS since the blood–brain barrier is lacking at birth.

Drug disposition in hair has no pharmacokinetic relevance but may indicate drug intake.

## 5.02.4 Pharmacokinetic Parameters

### 5.02.4.1 Introduction

Pharmacokinetic parameters are assessed by monitoring variations in concentration of the drug and/or its metabolites in physiological fluids that are easy to access (i.e., plasma and urine). Plasma concentrations are usually checked, and in addition biopsies can be taken from animals and sometimes from humans. Pharmacokinetic parameters give an overall indication of the behavior of the drug in the body; the basic parameters are listed in [Table 1](#).<sup>11–13</sup> ([Figures 3 and 4](#))

Since the kinetics of absorption, distribution, metabolism, and excretion of a drug are usually linear, a poly-exponential function may be adjusted to the plasma concentrations allowing the calculation of pharmacokinetic parameters. However, adjustment is not always feasible and is not mandatory. It is sufficient to consider the terminal part of the concentrations-versus-time curve, assuming that absorption and distribution, being almost complete, would have no significant influence on both metabolism and excretion. A monoexponential function can then be fitted, according to eqn [8]:

$$C = C_0 \times e^{-\lambda_1 t} \quad [8]$$

The logarithmic transformation gives eqn [9]:

$$\ln C = \ln C_0 - \lambda_1 t \quad [9]$$

which is the equation of a straight line.  $C$  and  $\lambda_1$  can be calculated by linear regression,  $C$  being the concentration at time  $t$ ,  $C_0$  the concentration extrapolated to the origin, and  $\lambda_1$  the apparent elimination constant.

### 5.02.4.2 Calculation of Individual Parameters

The lag time ( $t_l$ ) is the time between administration and the first measurable concentration. In the case of oral administration, for instance, it is not nil but corresponds to the time needed for the tablet to disintegrate in the gastrointestinal tract, the drug to dissolve, and absorption to occur.  $C_{\max}$  is deduced from the observation of time-related plasma concentrations. After intravascular bolus administration,  $C_{\max}$  is obviously the first concentration measured, however rapidly the first sampling was taken. After an infusion,  $C_{\max}$  is the concentration measured at the end of the infusion. The time that corresponds to  $C_{\max}$  is  $t_{\max}$ .

**Table 1** Basic pharmacokinetic parameters

#### *Parameters obtained from plasma concentrations*

After an intravascular administration ([Figure 3](#))

AUC = area under the curve of a plasma concentration versus time profile

CL = total plasma clearance

$V_D$  = volume of distribution

$t_{1/2}$  = elimination half-life

After an extravascular administration ([Figure 4](#))

$t_l$  = lag time

$C_{\max}$  = maximum concentration

$t_{\max}$  = time to reach  $C_{\max}$

AUC = area under the curve of a plasma concentration versus time profile

$t_{1/2}$  = elimination half-life

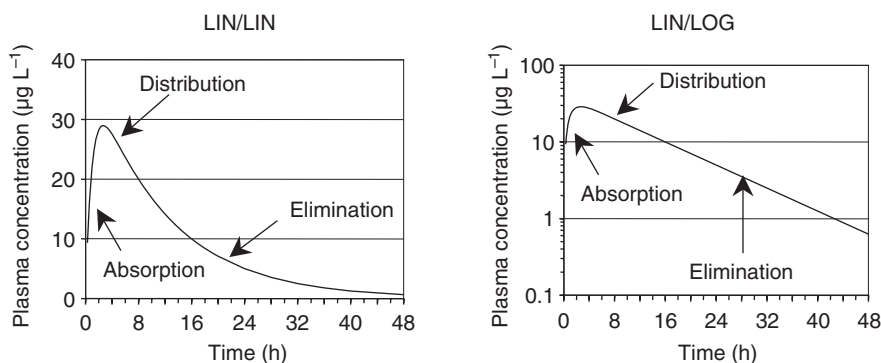

#### *Parameters obtained from urine concentrations (whatever the route of administration)*

$M_U$  = amount excreted in urine

$CL_R$  = renal clearance when plasma concentrations are known

**Figure 3** Time course of plasma concentration following administration by the intravenous (iv bolus) route. The same data are displayed as linear (LIN/LIN) and semilogarithmic (LIN/LOG) plots.

**Figure 4** Time course of the plasma concentration of a drug administered by the extravascular route. The same data are displayed as linear (LIN/LIN) and semilogarithmic (LIN/LOG) plots. Dose: 5 mg,  $C_{max}$ :  $30 \mu\text{g L}^{-1}$ , AUC:  $420 \text{ h } \mu\text{g L}^{-1}$ , and  $t_{1/2}$  8 h. No lag time is observed here.

The AUC (area under the curve of a plasma concentration versus time profile) from time 0 to the last sampling is calculated directly from concentrations  $C$  and their corresponding  $t$  by using eqn [10] (trapezoidal rule):

$$\text{AUC}_{0-t} = \frac{1}{2} \sum (C_n + C_{n-1})(t_n - t_{n-1}) \quad [10]$$

The extrapolation to infinite may be done as per eqn [11]:

$$\text{AUC}_{0-\infty} = \text{AUC}_{0-t} + \text{AUC}_{t-\infty} = \text{AUC}_{0-t} + \frac{C_{\text{last}}}{\lambda_1} \quad [11]$$

AUC is expressed as time multiplied by concentration. When the kinetics is linear, AUC is proportional either to the amount of drug that reaches the body without any transformation, or to the amount of metabolite when its concentrations have been measured.

The total plasma clearance indicates the elimination of the drug from the body whatever the process involved (metabolism, urinary excretion, bile secretion, pulmonary elimination).<sup>14</sup> It is the part of the distribution volume ( $V_D$ ) cleared by time unit (eqns [12–15]).

$$\text{CL} = V_D \frac{\text{amount of drug metabolized and/or excreted per unit of time}}{\text{amount of drug in the body}} \quad [12]$$

$$\text{CL} = V_D \frac{dM/dt}{V_D C} = \frac{dM/dt}{C} \quad [13]$$

$$\frac{dM}{dt} = \text{CL} \times C \quad [14]$$

$$dM = \text{CL} \cdot C \cdot dt \quad [15]$$

Making the assumption that CL is constant, the integration as a function of time gives eqn [16]:

$$M = CL \cdot AUC \quad [16]$$

And making the further assumption that: (1) the drug is administered by the intravascular route; (2) the drug is eliminated from the plasma without any reintroduction (no enterohepatic cycling, no reversible biotransformation regenerating the parent drug from metabolites); and (3) the total amount  $M$  of excreted drug is equal to the dose, then:

$$CL = \frac{\text{Dose}}{AUC} \quad [17]$$

When the drug is administered by an extravascular route, the total amount reaching the body is unknown and CL cannot be calculated.

The product of urinary concentration and urinary volume gives the amount eliminated in urine ( $M_U$ ). When the compound measured in plasma and urine is the same (parent or metabolite), eqns [14] and [15] apply and become eqns [18] and [19]:

$$\frac{dM_U}{dt} = CL_R \times C \quad [18]$$

$$dM_U = CL_R \cdot C \cdot dt \quad [19]$$

where  $CL_R$  is the renal clearance, which can be calculated from urine fractions collected during  $\Delta t$  (eqns [20] and [21]):

$$\Delta M_U = CL_R \cdot C \cdot \Delta t \quad [20]$$

$$CL_R = \frac{\Delta M_U}{\Delta AUC} \quad [21]$$

$\Delta M_U$  is the amount eliminated in urine during  $\Delta t$  and  $\Delta AUC$  is the area corresponding to  $\Delta t$ . The calculation can be made using the global kinetics; therefore, eqn [17] becomes eqn [22]:

$$CL_R = \frac{M_U}{AUC} \quad [22]$$

The only assumption here is that  $CL_R$  remains constant.

Hepatic and renal clearances are additive; lung clearance is multiplicative since it acts upstream of liver and kidneys. When neither the lungs nor any other organ plays a significant role in the overall clearing process, the total plasma clearance is the sum of hepatic and renal clearances:

$$CL = CL_R + CL_H \quad [23]$$

and  $CL_H$  can be obtained by difference.

Clearance of drugs occurs by blood perfusing the organ of extraction. Extraction refers to the proportion of the drug arriving at the organ and removed irreversibly by excretion or metabolism. Hepatic intrinsic clearance ( $CL_{int}$ ) refers to the global capacity of the hepatocytes to contribute to the processes of the hepatic elimination.  $CL_{int}$  can be estimated from in vitro studies using hepatocytes and the drug as substrate and scaling up to whole liver dimensions:

$$CL_{int} = \frac{V_{max}}{K_m} \times \frac{\text{number of hepatocytes in the liver}}{\text{number of cultured hepatocytes}} \quad [24]$$

For drugs highly extracted by the liver (high  $CL_{int}$ ), clearance depends on the blood flow perfusing the liver, and causes a large hepatic first-pass effect. Conversely, for a drug with a low  $CL_{int}$ , clearance depends on  $C_u$ , the free concentration of the drugs, which is only available for extraction, and on enzymatic activity. Equation [14] then becomes eqn [25]:

$$\frac{dM}{dt} = CL_H \times C = CL_{H,u} \times C_u \quad [25]$$

in which  $CL_{H,u}$  is the clearance based on unbound concentration. When  $CL_{int}$  is low,  $CL_{int} \approx CL_{H,u}$ .

From eqn [25], one obtains eqn [26]:

$$CL_H = CL_{H,u} \frac{C}{C_u} = CL_{H,u} \times f_u \quad [26]$$

Changes in  $f_u$  (e.g., due to saturation or displacement) and/or in  $CL_{H,u}$  (e.g., by enzymatic inhibition or induction) will induce changes in  $CL_H$ .

Protein binding is one of the factors that influences  $CL_R$ . Filtration and secretion depend on  $f_u$  and change in the same way.<sup>15</sup>

At steady-state, increase of  $f_u$  will decrease  $C$ , but  $C_u$  will be the same, as  $CL_u$  should not be affected and the activity of the drug should not change, despite the decrease of  $C$ .

The distribution volume  $V_D$  represents the theoretical body volume inside which the drug would be distributed if it had the same concentration everywhere in the body and in plasma.  $V_D$  equals the amount of drug in the body divided by the plasma concentration:

$$V_D = \frac{M}{C} \quad [27]$$

This definition is simple to use but not sufficient. Indeed, according to this equation  $V_D$  increases between the moment the drug reaches the body and the moment its distribution is complete. A condition must be added, that the drug be in equilibrium in all parts of the distribution volume, a variation in one part being immediately reflected in all other parts. This condition is fulfilled during the elimination phase when plasma and tissue concentrations decrease in parallel, which means that the ratio of tissue concentration over plasma concentration is constant.

With this condition, the amount of drug remaining in the body ( $M_t$ ) at time  $t$  after an intravascular administration is equal to the initial dose minus the amount eliminated:

$$M_t = \text{Dose} - CL \cdot (AUC_{0-\infty} - AUC_{t-\infty}) \quad [28]$$

$$M_t = \text{Dose} - CL \cdot AUC_{0-\infty} + CL \cdot AUC_{t-\infty} = \text{Dose} - \text{Dose} + CL \frac{C_t}{\lambda_1} = CL \frac{C_t}{\lambda_1} \quad [29]$$

Coming back to the definition of  $V_D$  according to the eqn [27]:

$$V_D = \frac{M_t}{C_t} = \frac{CL \frac{C_t}{\lambda_1}}{C_t} \quad [30]$$

$$V_D = \frac{CL}{\lambda_1} \quad [31]$$

After an extravascular administration, the amount of drug that reaches the body can be different from the administrated dose, thus in that case the calculation of  $V_D$  cannot be done.

The distribution volume of a drug depends on: (1) its respective affinities for plasma proteins and blood circulating cells that retain it in plasma; (2) its ability to leave the vessels; and (3) its affinities for the tissues that can attract it. Consider the following mass balance relationship<sup>12</sup>:

$$V_D \cdot C = V_P \cdot C + V_T \cdot C_T \quad [32]$$

where  $V_P$  is the plasma volume and  $V_T$  and  $C_T$  are the tissue volume and the tissue concentration, respectively. Knowing that  $f_u = C_u/C$  and similarly for tissues  $f_{u,T} = C_u/C_T$ ,  $C_u$  at steady-state being the same in all parts of the body, eqn [32] becomes:

$$V_D \times \frac{C_u}{f_u} = V_P \times \frac{C_u}{f_u} + V_T \times \frac{C_u}{f_{u,T}} \quad [33]$$

Dividing by  $C_u/f_u$  yields eqn [34]:

$$V_D = V_P + V_T \times \frac{f_u}{f_{u,T}} \quad [34]$$

This approach shows that  $V_D$  depends on  $f_u$  and  $f_{u,T}$ . The distribution volume does not correspond to a physiological one. However, it is interesting to compare it to the volume of exchangeable water as related to body weight,  $V_D = 0.6 \text{ L kg}^{-1}$ . A smaller  $V_D$  indicates that the distribution of the drug is quantitatively limited inside the body due to several possible causes ( $f_u$  is small and/or  $f_{u,T}$  is large). Either the drug is not transferable because it is not lipophilic enough (e.g., many antibiotics) or its molecular weight is too high. The drug may also be able to diffuse

through membranes but is retained in the blood flow because of a high affinity to plasma proteins (restricted distribution).<sup>16</sup>

A larger  $V_D$  ( $> 1 \text{ L kg}^{-1}$ ) indicates an important distribution linked to a high tissue affinity ( $f_{u,T}$  is small). When  $V_D$  is large, the corresponding  $C_T$ s of the drug are large. If we consider now  $C_u$ , eqn [27] and eqn [33] give:

$$V_{D,u} = \frac{M}{C_u} = \frac{M}{f_u \times C} = \frac{V_D}{f_u} = \frac{V_P}{f_u} + \frac{V_T}{f_{u,T}} \quad [35]$$

The distribution volume  $V_{D,u}$  represents the theoretical body volume inside which the unbound drug would be distributed. The smaller the free fractions  $f_u$  and  $f_{u,T}$ , the larger  $V_{D,u}$  will be.

The half-life ( $t_{1/2}$ ) is the time needed for a plasma concentration to decrease by one-half. During elimination, when the decrease in plasma concentrations follows a nonexponential process,  $t_{1/2}$  is a constant, which can be calculated as follows from the apparent elimination constant:

$$t_{1/2} = (\ln 2)/\lambda_1 = (\ln 2) \cdot V_D/CL \quad [36]$$

The half-life  $t_{1/2}$  may be deduced directly from the graph of concentrations-versus-time, whereas  $V_D$  and  $CL$  are calculated. However,  $t_{1/2}$  also depends on  $V_D$  and  $CL$  as shown above.

#### 5.02.4.3 Clinical Considerations

Most drugs are administered chronically at a constant dose and at regular time intervals. When the next dose is given before complete elimination of the previous one, the drug accumulates until elimination compensates absorption. When kinetics is linear,  $CL$ ,  $V_D$ , and thus  $t_{1/2}$  are constant. Hence, a steady state is reached after repeated administration and can be predicted from a unique administration. The time needed to reach the steady state usually represents 4–6 half-lives (Figure 5).

In the simplest case (intravascular bolus injection), distribution and elimination follow a nonexponential process, and  $C_{\max}$  at steady state is:

$$C_{\max,ss} = \frac{\text{Dose}}{V_D(1 - e^{-\lambda_1 \tau})} \quad [37]$$

and  $C_{\min}$  at steady state is:

$$C_{\min,ss} = C_{\max,ss} \cdot e^{-\lambda_1 \tau} \quad [38]$$

where  $\tau$  is the time between two doses.

**Figure 5** A typical curve of the variation of plasma concentration following repeated administrations by the extravascular route ( $t_{1/2} = 24 \text{ h}$ ).

If accumulation of the drug induces a saturation or an inhibition of its own elimination process, i.e., if its CL decreases with the amount of drug in the body, the steady-state concentrations may be higher than expected. In the worst-case scenario, accumulation proceeds without reaching a steady state and elicits toxic effects. More information about the determination of pharmacokinetic parameters can be found elsewhere.<sup>17</sup> In contrast, if the drug induces an increase of its own elimination process, the steady-state levels will be lower than predicted.

Inhibition and induction can be caused by a coadministered drug. It is thus necessary to verify whether a steady state is reached after repeated administration and to compare the relevant calculated and measured concentrations. If they are not in accordance, the discrepancy must be explained and the drugs changed or dosed differently.

## 5.02.5 Bioavailability and Bioequivalence

The concept of bioavailability (biological availability) has been created to evaluate the pharmacological effects of a drug in humans when these effects are delayed (e.g., with antidepressants, digitalis) or not easily measured (e.g., for hormones, glucocorticoids). Instead of measuring more or less precisely the corresponding clinical effects, it was proposed: (1) to evaluate the concentration of drug in the receptor compartment (making the assumption of concentration-related effects); (2) to measure the maximal plasma concentration and the time needed to reach it; and (3) to develop a pharmacokinetic approach to predict the intensity of effects.

### 5.02.5.1 Bioavailability

Bioavailability means the extent and rate to which a drug becomes available in the general circulation. The extent is measured by the fraction ( $F$ ) of the administered dose which reaches intact the general circulation. When the drug is administered by the intravascular route,  $F = 1$  and the relevant rate is that of the injection. When extravascular routes are used, for instance, the oral route,  $F \leq 1$  and depends on the absorbed fraction of the ingested dose and on the lost part of the dose metabolized in the gut during absorption or in the liver before reaching the general blood flow. These latter possibilities are named first-pass effects (intestinal and/or hepatic).

The amount of drug  $M$  that reaches the general circulation is given by eqn [16]. Thus:

$$F = \text{CL} \cdot \text{AUC}/\text{Dose} \quad [39]$$

The rate of absorption is estimated by two parameters,  $C_{\max}$  and  $t_{\max}$ , with  $C_{\max}$  being related to: (1) total plasma clearance; (2) the fraction of dose that reaches the general circulation without being metabolized; (3) the rate of absorption; and (4) the rates of distribution and elimination. As for  $t_{\max}$ , it depends on: (1) the rate of absorption; and (2) the rates of distribution and elimination.

After oral administration, bioavailability may be estimated by comparison with either the intravascular route, yielding the absolute bioavailability, or with another pharmaceutical form of the drug by the same route, yielding the relative bioavailability. Absolute bioavailability can be measured after intravascular administration:

$$\text{Dose} = \text{CL} \cdot \text{AUC}_{\text{iv}} \quad [40]$$

or after oral administration:

$$F \cdot \text{Dose} = \text{CL} \cdot \text{AUC}_{\text{po}} \quad [41]$$

If the doses used for both routes are identical, assuming a linear and identical kinetics (i.e., a constant CL), then:

$$F = \frac{\text{AUC}_{\text{po}}}{\text{AUC}_{\text{iv}}} \quad [42]$$

This test is of interest for several reasons. When a drug has not been previously investigated by the i.v. route, the i.v. results allow the calculation of CL and  $V_D$  and can lead to a basic understanding of the drug's kinetics. Moreover, they yield the characteristics of oral absorption, which are needed when oral administration follows i.v. injection. A typical example of such a test is given in Figure 6.

The relative bioavailability ( $F_{\text{rel}}$ ) is used to compare two different pharmaceutical forms, one serving as a reference:

$$F_{\text{rel}} = \frac{\text{AUC}_{\text{test}}}{\text{AUC}_{\text{ref}}} \quad [43]$$

This equation may be used if the respective doses of the two pharmaceutical forms are the same and if the clearance is constant. It also allows a comparison of  $C_{\max}$  and  $t_{\max}$ .

**Figure 6** Absolute bioavailability of a drug administered at the same dose by the intravascular (red) and extravascular (blue) route. Assuming CL to be constant and identical for the two administrations, the ratio of the AUC is 0.7, meaning that 70% of the administered dose reaches the systemic circulation intact.

### 5.02.5.2 Bioequivalence

The concept of bioequivalence was born from the following observation. Digoxin, administered orally at the same dose of 1 mg but as a tablet made by two different pharmaceutical companies using different components, induced quantitatively different pharmacological effects. The two tablets were considered as being nonbioequivalent, their nonbioequivalence being a consequence of the difference in formulation between the two tablets, which released digoxin at different rates and in different amounts. Thus, one tablet could not replace the other.

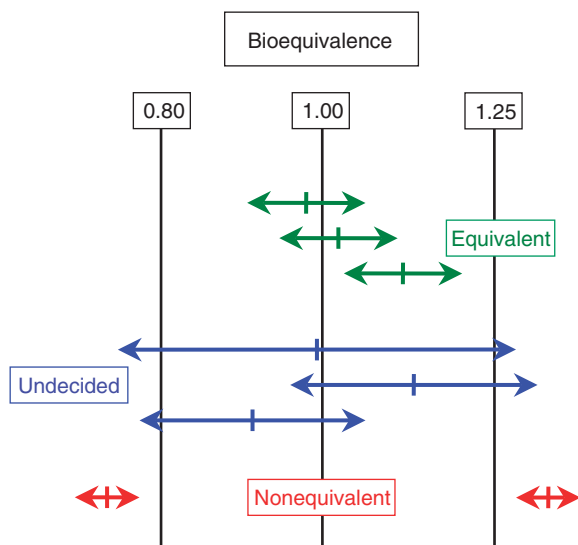

The many pharmaceutical forms of the same drug that are now available, either during its development or as generics, need to be checked to see whether they will produce the same quantitative effects; in other words, that one may be substituted for another without any change in therapeutic effects. Making the likely assumption that the same plasma concentrations develop the same clinical effects, bioequivalence may be assessed by the equivalence of the relative bioavailabilities of the two pharmaceutical forms of a drug. Such equivalence is checked by comparing AUC,  $C_{\max}$ , and  $t_{\max}$ , assuming that pharmacokinetic parameters remain constant during the comparison.<sup>13</sup> These tests are carried out in healthy volunteers, using a randomized two-period, two-sequence crossover design. The statistical method for testing bioequivalence is based upon the 90% confidence interval for the ratio of the means for the parameters under consideration (test/reference). Concerning  $C_{\max}$  and AUC, the confidence interval is calculated using the residual of the analysis of variance (ANOVA), the data should be transformed prior to analysis using a logarithmic transformation. The analysis for  $t_{\max}$  should be nonparametric and should be applied to untransformed data. Bioequivalence is concluded when confidence intervals are within 0.8 and 1.25 (Figure 7).

This procedure is required for any generic of a drug that has already been marketed in its original pharmaceutical form. More information about the requirements on bioavailability and bioequivalence can be found in the guidances of the European Community,<sup>18</sup> FDA,<sup>19</sup> and ICH.<sup>20</sup>

### 5.02.6 Which Pharmacokinetic Profiles for Drugs?

The overall objective of a pharmacokinetic design is to harmonize the effects of the active compounds (parent and/or active metabolites). It has to allow the drug to develop its effects under the best conditions of efficacy, intensity and duration, interindividual predictability, safety, and comfort to the patient. These requirements are obviously difficult to fulfill simultaneously, although many drugs come very close.

Specific designs are needed according to the medical use of the drug. For instance, some antibiotics are designed to target intracellular germs and must therefore be extensively distributed to tissues, whereas others are targeted to cure vascular infections.  $V_D$  in the former case must be larger than in the latter. Thus, the design may be done in accordance with the specifications of the treatment. Only some general proposals in the design of pharmacokinetics are presented here based on observations of the evolution of the characteristics of recent drugs.

**Figure 7** Acceptance or rejection of bioequivalence according to the confidence intervals of ratio of transformed  $C_{\max}$  and AUC of test and reference medicine calculated from residual of variance analysis.

#### 5.02.6.1 A Limited Distribution in the Body

This simple idea is based on the fact that drugs can distribute throughout the whole body whereas their targets are limited to some organs. As an example, the liver receives almost 100% of the amount of the drug absorbed after oral administration and about 50% after the drug has reached the general circulation. Thus, a significant amount of drug is lost as a fraction distributed in organs where it is useless at best and toxic at worst. Considering that most effects, either pharmacological or toxic, are concentration dependent, the first option is to restrict as much as possible the distribution of the drug to the nontargeted organs. This can be achieved by decreasing its  $V_D$  to the lowest value compatible with activity. A limited lipophilicity may also fulfill this goal by decreasing transfer through membranes.

Another possibility is to design chemical structures ionized at physiological pH, i.e., poorly transferable by passive diffusion, but such compounds should retain good oral absorption. An elegant solution is obtained with zwitterionic molecules, which are mostly ionized at plasma pH yet well absorbed from the gut. This is possible when the isoelectric pH of the compound falls within the range of pH variations inside the gut (e.g., cetirizine).<sup>21,22</sup>

Another way to avoid an extensive distribution is to design agents that are bound to plasma proteins (mostly to HSA or to AGP) with an association constant high enough to retain a large amount of drug inside the compartment of distribution of the protein. This design creates the conditions for a restricted distribution (the drug is characterized by a low  $V_D$ ) avoiding an extensive and ubiquitous distribution of the drug in the body but delivering it only to sites of high affinity.

Such a design redirects the quantitative distribution to selective targets provided that they have a higher retention power for the drug. More precisely, the leading parameter is the binding capacity ( $C_a$ ) of the protein:

$$C_a = N \cdot K_a \quad [44]$$

where

$$N = n \cdot C_p \quad [45]$$

$n$  being the number of available binding sites per mole of protein.

The right solution is to design a compound whose plasma  $C_a$  is high enough to prevent the drug from an extensive distribution, but lower than the  $C_a$  of the targeted sites. Another example adds to this design the transfer of the plasma-binding carrier and its bound drug to the pathological sites. This is illustrated by the kinetics of many nonsteroidal anti-inflammatory drugs (e.g., profens, mefenamic acid, and oxicams), all of which are acidic drugs ionized at plasma pH and extensively bound to HSA, their corresponding  $V_D$  ranging between 0.1 and 0.4 L kg<sup>-1</sup>. The early inflammation process induces a vasodilatation and an increase in the capillary permeability followed by a plasma transudation including HSA and its bound drug. As a result, the distribution of the drug is directed to its target by the pathological process. When inflammation stops, the impermeability of the capillaries is restored and no further drug is transferred to the previously inflamed tissue.

The best solution to limiting drug distribution in the body remains the discovery of very effective and selective agents. This allows the use of small doses, and limits their amounts in nontarget tissues. Unfortunately, agents with optimal *in vitro* behavior rarely have the kinetic characteristics necessary to become a drug. Favorable cases are those encountered when the pathological process induces specific enzymes not found in healthy tissues, e.g., the pathological increases in dihydrofolate reductases (DHFRs) and tyrosine kinases (TKs). DHFR inhibitors include trimethoprim (an antibacterial agent), chloroguanide (an antimalarial agent), and methotrexate (an antitumoral agent) while TK inhibitors include the antitumoral agents imatinib, erlotinib, and gefitinib. Other specific inhibitors of cell enzymes are the statins and the coxibs.

Specific markers of pathological states, especially of cancers, are generally used as tests for the diagnosis of the disease and the prognosis of its evolution. As they are secreted by the tumor, they may be considered as drug targets. Antibodies are generated against these markers; in some cases they are effective by themselves, and in other cases active drugs are linked to them and thus targeted to the tumor.

A limited distribution may be obtained when the selected targets of a drug and its potential toxic sites are located in separated organs. This is a likely possibility when the target cells are more easily reached from the blood flow than the toxic sites. This is seen with the H1-antihistamines whose therapeutic targets are always on the external sides of intravascular cells, on circulating eosinophils and neutrophils, or on the internal wall of veins and smaller vessels, or in perivascular tissues (connective tissue and basophils).<sup>23</sup> Thus, the kinetics of cetirizine and that of its eutomer levocetirizine<sup>24</sup> show that one can avoid most intracellular side effects of H1-antihistamines, namely inside the heart, brain and liver, by limiting their distribution to their therapeutic target sites. The  $V_D$  of cetirizine, for example, is  $0.4 \text{ L kg}^{-1}$ , i.e., less than the exchangeable water volume. In other words, the idea is to avoid organ toxicity by limiting the access of the drugs to these organs.<sup>25</sup> Other examples include  $\alpha_1$ -antagonists (antihypertensive agents acting on vascular targets), inhibitors of angiotensin-converting enzyme, and angiotensin II receptor antagonists. In these cases, an intravascular distribution is enough to reach their targets, whereas their distribution to tissues serves no purpose.

To summarize, the kinetics of drugs can be improved by developing molecules whose affinity for and activity toward their targets are as high as possible, with a significant but smaller affinity for plasma proteins and the lowest possible tissue affinity.

### 5.02.6.2 Stable and Predictable Elimination Processes

The effects of a drug are limited in time by the efficacy of physiological clearing functions, namely:

- metabolism when the metabolites are inactive;
- bile secretion of active compounds (parent drug and/or metabolites) when they are excreted fecally without enterohepatic cycling; and
- urinary excretion of active compounds (parent drug and active metabolites).

The liver, kidneys, and lungs (mainly for volatile agents) are the major organs of elimination whose overall clearing activities are expressed by clearance. The respective roles of these organs are investigated by means of two parameters: the first is the fraction of administered dose that they inactive or excrete; and the second is the rate of these processes. Such data are needed for rational prescription of drugs and should be carefully observed by those who prescribe.

For many drugs, target and clearing organs are different. With the exception of some drugs such as diuretics and urinary antibiotics, most are cleared by the liver and/or the kidneys where they have no role to play. The liver and kidneys fulfill their elimination function by very different mechanisms. Metabolic transformations are mainly hepatic and are carried out by enzymes whose activity varies among humans (interindividual variability) and as a function of time for the same individual (intraindividual variability). The fact that these enzymes act on chemically very diverse drugs explains the occurrence of drug interactions when two drugs compete for the same enzymes. Frequently, a competitive interaction ensues where the metabolism of one is decreased by the other (potentiation). On the other hand, enzymatic induction or inhibition may also occur following administration of some drugs or intake of some foods (e.g., grapefruit). All these potential causes of variation explain why the duration of action of drugs when controlled by hepatic enzymes may differ among patients. Such a route of elimination thus brings a certain degree of uncertainty in the duration of action.

When a drug is excreted mainly unchanged in urine, the margin of uncertainty is lessened if renal functions are normal and the pH of urine is controlled. The most likely explanation of the differences between hepatic degradation and kidney excretion is linked to identical renal functions among individuals (creatinine clearance is a stable parameter,  $120 \text{ mL min}^{-1}$ ), whereas the activities of normal hepatic enzymes differ to a large extent. This observation remains true when renal functions are impaired. If the pathological process is stable with a decreased but stable creatinine

clearance, it is possible to adjust drug dosage knowing the relationship between the clearance of the drug and creatinine clearance. This relationship is determined by specific pharmacokinetic studies including normal volunteers and patients with various degrees of renal insufficiency. This is done for instance for digoxin and aminoglycoside antibiotics.

When a choice is possible, physicians are thus likely to prefer a drug excreted mainly unchanged in urine. To avoid hepatic metabolism as much as possible, one needs a low lipophilicity and sterically protected target groups in the molecule, inasmuch as these features are compatible with activity. This objective is valid for all drug classes for which no benefit can be expected from hepatic extraction. This is the case for drugs acting in peripheral organs, for example anti-inflammatory drugs, most antibiotics, antihypertensive agents, and H<sub>1</sub>-antihistamines. However, it appears that this proposal cannot be applied to drugs acting in the CNS, which must be able to cross the blood–brain barrier and require a sufficient lipophilicity also synonymous with liver uptake (e.g., psychotropic drugs).

### 5.02.6.3 Linear Pharmacokinetic Parameters

The main interest of pharmacokinetic parameters ( $CL$ ,  $V_D$ ,  $t_{1/2}$ ,  $t_{max}$ ) is that they are constants applicable to all doses. This argument, however, is restricted to drugs whose kinetics is linear. With nonlinear pharmacokinetics, the corresponding parameters vary according to dose. Nonlinearity may be the consequence of two main processes, namely, plasma binding or liver transformation. When the overall plasma concentrations of a drug increase beyond the upper limit of protein binding capacity, the excess of drug cannot be bound. Being free and completely distributed (saturation of the restricted distribution process), it induces an increase of  $f_u$  which leads to a modification of pharmacokinetic parameters:  $V_D$  increases (see eqn [34]) and  $V_{D,u}$  decreases (see eqn [35]). Moreover,  $CL_R$  increases and when  $CL_{int}$  is low,  $CL_H$  increases (see eqn [26]) but  $CL_{H,u}$  is not affected. Another cause is a quickly saturated reaction of transformation, which leads to a decrease of  $CL_H$  because  $CL_{H,u}$  decreases,  $f_u$  being constant (see eqn [26]) and either results in accumulation or is replaced by an untoward transformation, for instance, into a toxic reactive metabolite (e.g., acetaminophen).

Nonlinear pharmacokinetics is a handicap for drug prescription. Schematically, infra- and suprasaturating doses exhibit different pharmacokinetic parameters due to different kinetics at enzymes or transporters. Changing doses from infra to supra will induce an increased effect, the intensity of which may be higher than expected.

In summary, the therapeutic use of drugs exhibiting nonlinear pharmacokinetics is not easy but cannot be rejected a priori. Indeed, the threshold concentration beyond which nonlinear processes begin varies among individuals according to their plasma binding capacity and liver enzymatic activities. A simple solution is to use only low, infrasaturating doses, a drug with linear kinetics remaining the best option when a choice exists.

### 5.02.6.4 One Oral Dose Once a Day

The oral route is obviously the best route of administration especially when chronic treatment is needed. The rule ‘one tablet once a day’ is very well known, but it requires some specifications. Thus, absorption has to be almost complete, unmodified by food intake, stable according to time, and produce an effect of constant intensity for 24 h meaning that  $t_{1/2}$  should be adequate, close to 24 h. Specific formulations may fulfill this objective.

A pharmacokinetic solution to prolonging effects is to design a drug with a restricted distribution that is bound to HSA, and whose release from this protein is delayed. This is achieved with a low dissociation rate of the drug–protein complex, as successfully shown by some sulfonamides, which are active for 2 weeks after a single administration.

### 5.02.7 Which Pharmacokinetics for Populations at Risk?

Populations at risk involve apparently healthy people as well as those with health problems. The latter group includes the extremes of age, namely embryos, fetuses, newborns, children, and elderly persons. The second group includes patients presenting with either a disease that affects drug elimination or rapidly evolving multipathological processes. It is not possible here to propose specific pharmacokinetic profiles according to the encountered risk, but guidelines can be given to obtain the best benefit/risk ratio, as exemplified below.

During pregnancy, the amount of drug transferred through the placenta to the fetus is limited to the free drug plasma concentration of the mother. The rate of transfer follows Fick’s law (eqn [1]). In this specific case,  $S$  is the placenta surface available for drug transfer,  $d$  is the thickness of this surface, and  $\Delta C$  represents the gradient of plasma free drug concentrations between the mother and the fetus. During pregnancy,  $S$  increases and  $d$  decreases, and both modifications favor the transfer of drugs to the fetus. The consequence is that more drug is transferred to the fetus at the end of the pregnancy with a maximum at the time of delivery,  $S$  being then maximal and  $d$  minimal. From a

pharmacological point of view, where extensive drug diffusion to the fetus needs to be avoided, one can reduce its transfer by decreasing the maternal–fetal gradient. This can be achieved by oral administration in small repeated doses distributed over the course of a day. In some specific and rare circumstances, the intravenous route may be used to reach a high gradient, i.e., when the drug must be administered to the fetus via the mother. But in most cases transfer of drug to the fetus is not wanted and can be limited by binding to maternal plasmatic proteins (restricted distribution). Use of such binding can also limit drug transfer to breast milk after delivery. Moreover, as the newborn will not have a functional blood–brain barrier (BBB) until 3 weeks after birth, a strong binding to plasma proteins can be useful to limit CNS distribution when not required therapeutically.

At birth, renal excretion and liver metabolism are not immediately functional but they improve progressively. Unfortunately, many drugs are not adapted to this age group, and clearly the physicians must favor drugs known to be quickly eliminated in adults. Special efforts to design adapted drugs should be encouraged.<sup>26</sup>

In the elderly, several physiological alterations can be observed.<sup>27</sup> The adipose mass is increased even in lean people and liquid volumes are decreased. As a result, hydrophilic drugs will reach higher plasma concentrations and doses must be decreased accordingly. In contrast, lipophilic drugs are stored for longer periods inducing a longer duration of effects in the elderly as compared to adults, also increasing the risk of drug interactions. Moreover, the liver mass is reduced in elderly people and the number of functional hepatocytes is decreased accordingly; hence, metabolic processes are usually slower and hepatic clearance decreased especially when cytochrome P450 dependent since these enzymes are very sensitive to decreased protein synthesis. Conjugation reactions that occur in the cytosol appear to be less modified. This is why, for instance, hydroxylated benzodiazepines are preferred for elderly patients over those that are oxidized in vivo. More generally, drugs having a short  $t_{1/2}$  are preferable.

Elderly people frequently develop a chronic renal insufficiency (decreased renal clearance), a situation which must be taken into account when setting the doses of drugs excreted renally.

Hepatocellular insufficiency<sup>28</sup> and chronic renal disease<sup>29</sup> are the two main pathological states that induce a significant alteration of the kinetics of drugs (mainly decreased total plasma clearance). The knowledge of PK parameters in healthy subjects, and more precisely the respective roles of liver and kidneys in overall elimination processes, allows it to be anticipated whether drug elimination will be normal or decreased in a given pathological state. Thus, it is usual to prefer extensively metabolized drugs in cases of renal insufficiency and urine-excreted, unmetabolized drugs in those of hepatic diseases. This procedure is now questioned, as it appears that it is easier to adjust the dosage of a drug excreted in urine during renal insufficiency than to use a drug inactivated by liver enzymes. The best example of this is shown by digoxin and its alternative digitoxin. Digoxin is excreted mainly in urine without transformation (85%) and secondarily as hepatic metabolites (15%). Digitoxin is excreted mainly as inactive metabolites (85%) and partly in urine as the parent drug (15%). However, their  $t_{1/2}$  are  $1.6 \pm 0.5$  and  $6.7 \pm 1.7$  days for digoxin and digitoxin, respectively. Both have a low therapeutic index (2 or so) and a dose-dependent toxicity. Digoxin is selected despite renal insufficiency, as the risk of accumulation is lower with this drug than with digitoxin. Here again, renal excretion appears to be more easily controlled than liver metabolism.

It is not possible to define drug kinetics for emergency situations as the encountered pathological states differ vastly and evolve quickly. The selection of the intravenous route bypasses the absorption phase, which is a pharmacological lag phase. Emergency wards tend to use drugs whose effects are immediate and brief. These drugs are mainly hydrophilic, a requisite to intravenous injections, and are excreted by the kidneys.

## 5.02.8 Conclusion

Besides efficacy and safety, there is now a growing interest in other qualities expected from a new drug. Regularity of effects and facility of use are important factors that improve the quality of life. Adequate pharmacokinetic parameters help to achieve this. Considering the relevance of current pharmacokinetic tools, it is obvious that methodological progress is needed in the screening and evaluation of new chemical entities. One advance is a more precise evaluation of drug distribution in and between organs;  $V_D$  affords an idea of drug concentrations in blood and organs, but it cannot establish in which of them the drug is predominantly located. Improvements will probably be afforded by new techniques such as imaging, which allows the respective locations of drugs and their specific targets to be observed using labeled markers and positron emission tomography (PET) scans. The location of a drug inside cells should also be studied, and the following need to be considered: binding to nuclei, which are the starting point of many pharmacological effects; binding to the endoplasmic reticulum as a regulator of  $\text{Ca}^{2+}$  homeostasis; and binding to mitochondria as the main source of energy transmission (ATP). Subcellular pharmacokinetics should also be developed.

A more ambitious yet realistic research trend involves avoiding the phase of vascular transfer by going directly to the site of action. One solution may be the direct application of drugs inside the targeted organs, permitting the use of high

doses and limiting blood transfer and nonspecific distribution. Such projects need new technologies such as nanoparticles and probably new modes of administration adapted to each patient. These are some of the challenges for the near future.

## Biographies

**Jean-Paul Tillement** is MD, PharmD MSc, Professor of Pharmacology. From 1985 to 2003 he held the position of Full Professor of Fundamental and Clinical Pharmacology and Head of Department at the Faculty of Medicine Paris-XII. His responsibilities during this time included teaching and research at the Faculty, as well as activities in clinical pharmacology as part of drug treatments of patients at the University Hospital as a qualified biologist Head of the Hospital Department of Pharmacology. He held various national appointments as an expert at the French Ministry of Health (still ongoing) and public research structures (INSERM, INRA), and at the French Ministry of Justice (still ongoing). Prof Tillement was also involved as an expert in the COST project, Brussels, Belgium (Criteria for the choice and definition of healthy volunteers and or patients for phase I and II studies in drug development, 1995). He has organized international scientific meetings especially on drug–protein interactions, his first recognized field of expertise, which he has in parallel broadened to include the pharmacological preservation of mitochondrial functions. He is past-president of the Société Française de Pharmacologie Clinique et Thérapeutique; past member of the jury of Prix Galien (1988–2005); current member of 10 medical and scientific societies; of the board of 9 international journals; current referee of 7 international journals; full member of the French National Academy of Pharmacy and corresponding member of the French National Academy of Medicine; Adjunct Professor at the Georgetown University Medical Center (Washington DC, USA) since 2002. He serves as a consultant in pharmacology to pharmaceutical companies. He has published more than 560 scientific works (December 2005) consisting in Research & Educational papers, Reviews and Books, Communications and Posters, and conducted 35 theses.

**Dominique Tremblay**, PhD (Pharmacy), has obtained certificates in General and Human Biochemistry, and in Statistics Applied to Medical Biology, Clinical Pharmacology and Pharmacokinetics. From 1991 to 1998, he held the position of director of Preclinical Development at Hoescht-Marion-Roussel in Romainville (France). In this position he was in charge of the departments of Toxicology, Pharmacokinetics (preclinical and clinical), Quality, Pharmaceutics, Quality Assurance and Scientific Coordination and Documentation. He actively participated in the development and introduction of various drugs (antibiotics, hormones and antihormones, nonsteroidal antiinflammatory drugs, and cardiovascular drugs) into the international market. After he left Hoescht-Marion-Roussel, he became an expert in Pharmacokinetics, Toxicokinetics and Toxicology at the French medical agency (Agence Française de Sécurité Sanitaire des Produits de Santé, AFSSaPS). At present, he is a member of the Marketing Committee Authorization and chairman

of the Preclinical Working Party at the AFSSaPS, and a member of the Safety Working Party at the European Agency for the Evaluation of Medicinal Products (EMA). He gives lectures at the University of Paris on toxicokinetics and pharmacokinetics. He participates as a tutor in the Pharmacokinetic Workshop under the guidance of Professors Malcolm Rowland and Thomas Tozer. Dominique Tremblay's interests are in experimental and applied pharmacokinetics. He has published about 50 scientific publications, abstracts and posters in this area. His main field of interest is how pharmacokinetics and toxicokinetics can be best used to predict and/or understand the effects of drugs on both man and animal in terms of efficacy and safety.

### 5.03.1 Objectives of Absorption, Distribution, Metabolism, and Excretion (ADME) Studies

In recent years, there has been an increased awareness about the importance of pharmacokinetics and metabolism data in all stages of the drug discovery and development process. In order to understand better the impact of in vivo drug metabolism and pharmacokinetic studies, it is important to first outline the major objectives of drug metabolism and pharmacokinetics (DMPK) when applied at the discovery and nonclinical development stages.

#### 5.03.1.1 Support to Drug Discovery

DMPK is now a routine part of the lead identification, lead optimization, and clinical candidate selection processes. At these different stages an appraisal of DMPK issues alongside other 'developability' factors is performed. Thus, the deployment of available in vivo and in vitro methods is based on a sound understanding of the relevant DMPK issues and not simply on the capacity to process large numbers of compounds.

#### 5.03.1.2 Support to Drug Metabolism

The main goal of drug metabolism or biotransformation for the body is to eliminate potentially harmful xenobiotics via urine and/or bile. This is typically realized in a stepwise process: the often lipophilic drug molecules are metabolized (biotransformation) to typically inactive, nontoxic, and more hydrophilic products, which can then be readily excreted in urine or bile.<sup>1</sup> In some cases, however, drug metabolites might be toxic or might represent activated products (e.g., acylglucuronides), which can potentially lead to organ toxicity or immune-mediated toxicity. Therefore, an extensive knowledge of drug metabolism is required for an overall understanding of the pharmacological and safety properties of new drug molecules.<sup>2</sup>

#### 5.03.1.3 Support to Pharmacodynamics

The monitoring of pharmacodynamic studies for exposure and the rigorous design of pharmacokinetic/pharmacodynamic (PK/PD) studies in animals are key to a number of questions that need to be addressed during preclinical development. These questions include: (1) identification of potential pharmacodynamics endpoints for efficacy in animal models; (2) development of mechanism-based models for efficacy; (3) determination of in vivo potency and intrinsic activity and prediction in humans; (4) dosage form and dosage regimen optimization; and (5) supporting dose selection for phase 1 studies.

Thus, the use of PK/PD modeling in early preclinical development to define the dose-concentration-pharmacological effects and dose-concentration-toxicity relationships, as well as the extrapolation of these results to humans using a combination of in vitro and in vivo data, can be particularly helpful in determining the appropriate dosing regimen for phase 1 studies. Preclinical PK/PD studies may also prompt a series of important mechanistic studies to explore any dissociation between plasma concentration and duration of pharmacological effect (i.e., active metabolites or long half-life in the effect compartment, etc.). For PK/PD models and their use in drug discovery (*see* 5.38 Mechanism-Based Pharmacokinetic-Pharmacodynamic Modeling for the Prediction of In Vivo Drug Concentration-Effect Relationships – Application in Drug Candidate Selection and Lead Optimization).

#### 5.03.1.4 Support to Toxicology

An important function of animal DMPK studies is in support of preclinical safety evaluation. Thus, determination of pharmacokinetics and exposures during the course of a toxicological experiment is key to interpreting toxicological findings. For example, it is essential to compare exposures in toxicological studies with the exposures expected or achieved in humans to ensure sufficient safety margin. Furthermore, metabolite profiles obtained from the species used in toxicology studies are compared to those in humans. In this case, emphasis is placed on qualitative similarity in metabolite profiles between humans and species used in toxicology studies in order to ensure that both are exposed to the parent drug as well as the same metabolites, any of which may contribute to toxicity.

#### 5.03.1.5 Support to Formulation Testing

During the discovery and development process, the formulation scientist develops formulations to ensure appropriate dosing of the test compound during early DMPK, safety, and pharmacodynamics studies. Various formulations also

should be investigated when the in vivo plasma concentration versus time profiles need, for example, to be extended with controlled release dosage forms and when oral bioavailability needs to be improved. In this context, formulations with a desirable pattern in vitro are submitted to in vivo oral absorption studies in animals. Once a favorable plasma concentration versus time profile in animals is achieved, the formulations are developed for testing in humans.

The judicious selection of animal species to support formulation testing is of key importance at this stage. To this end it is important to understand the similarities and differences of the physiology of the gastrointestinal (GI) tract between animals and humans. These issues are discussed in detail later in this chapter. However, it is a fact that the dog has become the most commonly used species for bioavailability studies in the context of formulation testing. Because of some species differences between humans and dogs, the findings in dogs and in other animal species have to be interpreted cautiously for their relevance to humans.

### 5.03.2 In Vivo Drug Metabolism and Pharmacokinetics Screening Studies

In recent years, several pharmaceutical companies have published reports on the simultaneous administration of several compounds to a single animal (cassette dosing or 'N-in-One' dosing)<sup>3-7</sup> as a means to rapidly rank order compounds on the basis of their in vivo pharmacokinetic properties. Compared with conventional pharmacokinetic studies, this method has the advantage of speed, because the slow steps of animal dosing, blood collection, and sample analysis are minimized. Another advantage is that animal usage is greatly reduced. The enabling technology for cassette dosing is liquid chromatography coupled to tandem mass spectrometry (LC/MS), which allows many compounds to be analyzed simultaneously.

Although cassette dosing has been reported to yield useful results when used as a screen, especially to rank order drug candidates, the potential for large errors was shown recently both theoretically and experimentally.<sup>4</sup> Consequently, it is recommended that the pharmacokinetic parameters derived from cassette dosing are interpreted very cautiously.

### 5.03.3 Pharmacokinetic Studies

A pharmacokinetic study involves dosing and sampling of animals or subjects, bioanalysis of the biological samples (e.g., blood, plasma, tissues) and analysis of the resulting blood, plasma, or serum concentration versus time data using for example noncompartmental or compartmental pharmacokinetic methods. Low aqueous solubility of molecules often necessitates significant formulation work prior to dosing. The bioanalytical or assay phase typically involves sample extraction with organic solvents and LC/MS or LC/MS/MS separation and detection of analytes. During drug discovery, pharmacokinetic studies are most commonly conducted in rodents and/or the species used for the assessment of in vivo efficacy. Subsequently, experiments in larger animal species such as dog or monkey are performed to further characterize the compound of interest, to support toxicology studies, and to generate data useful in predicting human pharmacokinetics (see discussion on scaling below). The most common routes of compound administration are oral and intravenous.

### 5.03.4 Metabolism Studies

Two aspects are of importance in the context of drug metabolism studies. The first aspect is the chemical nature of the metabolites formed in respect to their safety profile. All metabolites that are formed and are systemically available in man should ideally also be formed and reach at least similar systemic exposure in one animal species used in the preclinical toxicity program.<sup>8</sup> Second, the enzymes mainly responsible for the primary metabolic clearance steps might exhibit species-specific expression patterns, inducibility, or inhibition potential. Many of the clinically relevant drug-drug interactions are based on an induction or inhibition of enzymes or other active processes involved in drug metabolism and elimination (e.g., transporters).

While numerous in vitro tools are available to study the main processes involved in drug metabolism and the metabolites formed, quantitative correlations between in vitro and in vivo metabolism are often difficult to make.<sup>9</sup> In the early lead optimization process, the metabolic stability, biotransformations, and metabolite structures of new chemical entities (NCEs) are typically studied first using appropriate in vitro tools such as expressed human enzymes or cellular systems (e.g., hepatocytes).<sup>9</sup> Often a ranking of compounds in terms of metabolic stability and metabolites formed is sufficient as output from these in vitro studies.<sup>9</sup> Later on during drug development, differences in the systemic exposure to metabolites and the overall excretion pathways have to be addressed. As compounds are increasingly optimized for metabolic stability, extrahepatic metabolic routes and direct excretion of unchanged drug

molecules are often seen, requiring in vivo studies in animals and man. The completeness of excretion, the excretory pathways, and the metabolite patterns in plasma and excreta are studied sequentially in the animal species involved in toxicity studies and finally in man using radiolabeled drugs. This chapter will focus on in vivo metabolism studies; in vitro studies are discussed in detail in Chapter 5.10.

#### 5.03.4.1 The Use of Radiolabeled Compounds

Radiolabeled drug molecules are useful for most in vitro and in vivo drug metabolism studies. The total sum of all drug-related molecules can be easily quantified in different biological matrices and the recoveries of sample work-up procedures can be determined. Also, chromatographic separation of the individual metabolites with easy quantification and detection of unknown metabolites for which no chemical standard is available is greatly facilitated by radiolabeled isotopes.<sup>10</sup> Therefore, radiolabeled drugs are used in most in vivo ADME studies;  $^{14}\text{C}$ -labeled compounds are preferred for these studies due to the higher metabolic stability of this isotope in the molecule as compared to the  $^3\text{H}$  label. The isotope is typically placed on the metabolically stable core group of the molecules. However, for more specific questions or depending on the metabolic steps involved, the label might be placed both on stable and labile moieties. Furthermore, double-labeled compounds with different isotopes ( $^{13}\text{C}/^{14}\text{C}$  or  $^3\text{H}/^{14}\text{C}$ ) might be synthesized to aid in metabolite identification and quantification of the individual moieties.<sup>10</sup>

#### 5.03.4.2 Chromatographic Separation and Quantification of Drug Metabolites

High-performance liquid chromatography (HPLC) is the method of choice to analyze and quantify the parent drug and any metabolites, both from in vitro drug metabolism assays or in vivo animal studies using radiolabeled compounds. A new technique with a much higher sensitivity for the detection of  $^3\text{H}$  and  $^{14}\text{C}$  isotopes is accelerated mass spectroscopy (AMS), which has potential especially in human ADME studies.<sup>10–12</sup> ADME studies in man can be performed with radioactive doses of very low specific activity, the total amount of radioactivity being in the range of nanocuries. Information on the completeness of excretion (mass balance), the excretion pathways, and also limited information on metabolites formed can be obtained very early on in drug development.

#### 5.03.4.3 In Vivo Animal Models Used for Absorption, Distribution, Metabolism, and Excretion Studies

A number of different animal models are used for in vivo drug metabolism studies. Nonoperated, naive animals are used for excretion balance studies and to assess the metabolite profiles in plasma, urine, and feces. For compounds with a high proportion of biliary elimination of total drug-related material, bile duct-cannulated animals are often used in addition. The total gastrointestinal drug absorption, the importance of first pass metabolism, and also secretion of drug and metabolites into the gastrointestinal tract (after intravenous administration) can be evaluated in this animal model.<sup>10</sup> However, operated rats often show inflammatory reactions leading to induced or repressed phase I and phase II enzyme systems (cytochrome P450 and glucuronyltransferases) thereby significantly altering metabolic capacity. For specific questions, knock-out animals or strains with deficiencies in certain metabolic enzymes or transporters can be used to complement in vitro findings. P-glycoprotein knock-out mice are used to study the contribution of this transporter for limitations in brain uptake and to a minor degree also drug absorption in the GI tract. Humanized mice can be used to study the impact of the respective cytochrome P450 isoenzymes on the metabolism and the drug–drug interaction potential in an in vivo environment.<sup>13</sup>

#### 5.03.4.4 Mass Balance and Route of Excretion Studies

In animals the full urinary and fecal balance is typically assessed at different developmental stages in the main species involved in safety studies, e.g., rats and dog or monkey.<sup>8</sup> The nonrodent species used for teratology studies, typically the rabbit, and the second species used for carcinogenicity studies, typically the mouse, are not routinely investigated to this extent.<sup>14</sup> The results are used for the preparation of the ADME study using a radiolabeled dose in man, which is typically initiated during clinical development phase I.

The mass balance study in rats is most often performed prior to initiation of clinical phase I studies<sup>14</sup> in order to evaluate the kinetics and completeness of excretion and the excretion routes in this species. Both oral and intravenous administration are studied for most compounds and three to five animals are typically used per administration mode. The doses selected are within the pharmacologically relevant range and typically about 20  $\mu\text{Ci}$  of radiolabel are used per animal

enabling enough sensitivity for quantification. A 1:1 mixture of cold and radiolabeled drug is ideal for later metabolite identification by LC/MS/MS. If the excretion is incomplete within 5 to 7 days (<90–95% recovery), the remaining carcasses are analyzed after dissolution for any remaining radiolabel. For the second species used (dogs or monkeys) the excretion balance study is often performed later, in parallel to the phase I studies, in preparation for the human mass balance study. Urine and feces samples from both rat and nonrodent studies can be further used for the analysis of metabolite patterns. Plasma samples are typically not taken from rats, so as not to interfere with the main objective of the study, the completeness of mass balance; for larger animals, however, samples can be taken for additional analyses.

#### 5.03.4.5 Metabolite Profiling in Animal Species and Man

One of the main goals of in vivo ADME studies is the evaluation of metabolite profiles in plasma and excreta and to investigate any species differences.

##### 5.03.4.5.1 Systemically available metabolites in plasma

The plasma exposure of parent drug and major metabolites along with any related interspecies differences are of special interest for interpretation of toxicology or carcinogenicity studies. However, it is only data from the radiolabeled human ADME study that allows safety margins for all the relevant metabolites to be finally established, as only then the systemic availability of the metabolites formed in man is known. It is possible to detect known or postulated metabolites early on in plasma samples from the first clinical studies in man with newer, more sensitive, and selective technologies such as LC/MS/MS. This technology, however, does not allow the quantification of all those metabolites for which no reference material is available. Furthermore, it is extremely difficult to detect all unknown metabolites.

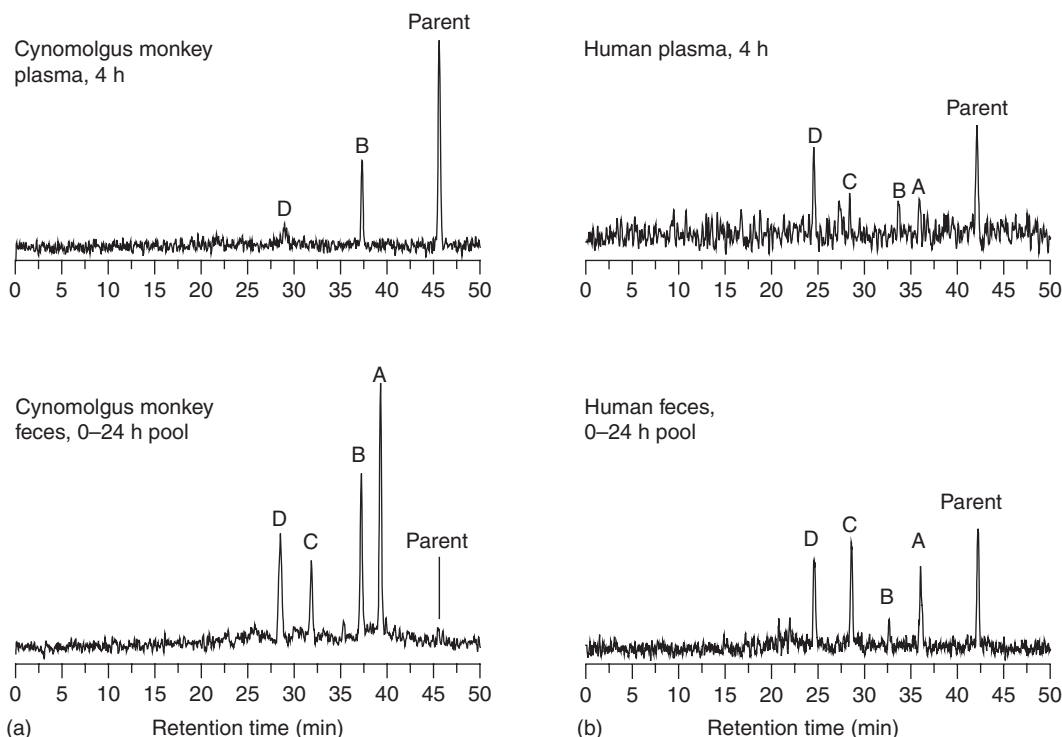

Special attention should be drawn to major human metabolites, which account for a considerable amount of the AUC (area under the plasma concentration–time curve) relative to the parent drug, and metabolites, that are only seen in man.<sup>15</sup> For both types of metabolites, a quantitative analytical assay should be set up in order to establish their kinetics and exposure in animals and man. For the human-specific metabolites and metabolites that do not reach comparable systemic exposure in at least one animal species used in the different toxicity studies, separate toxicity studies should be considered.<sup>15</sup>

Major metabolites in plasma are not necessarily major metabolites of the overall metabolism, as both the rates of formation and elimination as well as other kinetic parameters are important factors. An example of species-specific differences in the exposure of a major metabolite is given in [Figure 1](#). Most of the radiolabeled test drug was eliminated in the feces in both man and cynomolgus monkey. The oxidative metabolite D was formed in addition to other oxidative metabolites in both the monkey and man to a similar extent (~15% of the dose) based on analysis of pooled feces samples. However, this metabolite was only a minor peak in cynomolgus monkey plasma, while in man it reached systemic plasma exposures comparable to, or even exceeding, that of the parent drug. Species-specific differences in the rates of elimination of this metabolite might be one reason for this observation, which was only apparent once human plasma samples were analyzed quantitatively for these metabolites.

##### 5.03.4.5.2 Metabolites found in excreta

The main aim of analyzing metabolites in excreta is to quantitatively evaluate the contribution of the different excretion routes and metabolic pathways to the overall elimination and metabolism of a test drug. This information is used to estimate the fraction metabolized by various pathways. Furthermore, metabolites can be purified from urine for elucidation of their structures. Purification from bile and feces, although more difficult, can also be successful.

For mostly renally cleared drug-related material, typically smaller molecular weight entities or some phase II metabolites, analysis and quantification is in most cases easy to accomplish. For compounds that are mainly eliminated via bile and feces, the metabolite patterns should be studied in both bile and feces for an overall evaluation of the nature and route of drug metabolites excreted. A feasible approach in the rat is to analyze urine and feces samples from nonoperated animals. This can easily be done with samples from the excretion balance study, allowing an overall quantitative assessment of the individual metabolites in excreta. In parallel studies bile and feces samples from bile duct-cannulated animals after intravenous and oral drug administration should be analyzed. This helps to understand the nature of biliary eliminated metabolites, their stability in feces, the fraction absorbed, the effect of first pass metabolism and bioavailability, and the potential for direct secretion of drug/metabolites into feces.<sup>10</sup> A similar approach can be taken for dogs and monkeys, while for man the analysis of excreta is typically limited to urine and feces. It must be emphasized, however, that bile duct-cannulated animals often show altered metabolic activities or incomplete excretion within the study period. Therefore, it is very important to compare these observations with those in naive animals.

**Figure 1** Metabolite patterns in plasma and feces collected from cynomolgus monkey (a) and human (b) excretion balance studies. The identity of parent drug and metabolites A, B, C, and D were confirmed by LC/MS/MS analysis.

#### 5.03.4.5.3 Limitations of animal models for drug metabolism

Species differences in drug metabolism limit the value of preclinical in vivo studies. Such differences can be either of a quantitative (same metabolic route although at different relative rates) or qualitative (different metabolic routes, different metabolites formed) nature.<sup>16</sup> No single in vivo animal model can be said to be most suitable for man. Species differences are discussed in more detail at the end of this chapter.

A different type of limitation of animal models is caused by inflammatory reactions often observed in operated animals. Upon cannulation acute phase response markers, such as  $\alpha_1$ -acid glycoprotein and tumor necrosis factor (TNF), can be observed.<sup>17,18</sup> As a consequence of this different groups of drug-metabolizing enzymes are either induced or repressed, resulting in significantly altered drug kinetics and metabolic pathways (see for example Figure 2).

In nonoperated rats, the parent drug was metabolized by cytochromes P450 (CYPs) to M1 and both parent drug and M1 were conjugated with glucuronic acid. M1 and M1-glucuronide were the main peaks observed in a liver homogenate prepared from naive rats 5 min after dosing. However, in bile duct-cannulated rats, 4 days after the operation, metabolization to M1 was hardly observed, while the main product of metabolism was parent drug conjugated with glucuronic acid. The significantly reduced activity of the CYP enzyme involved could be demonstrated in vitro using liver microsomes prepared from bile duct-cannulated rats (Figure 3).

#### 5.03.4.6 Covalent Binding Studies: Reactive Metabolites

Although most drug metabolites formed are stable and can be readily detected, some metabolites are short lived and are reactive intermediate products. For these metabolites other detection methods have to be used, such as trapping with glutathione or measuring stable degradation products.<sup>19</sup> In cells these reactive products are typically trapped by glutathione. These very reactive metabolites can readily react with proteins resulting in covalent drug-protein adducts that can potentially trigger immune-mediated idiosyncratic toxicity.<sup>20</sup> These reactions might also occur in situations where glutathione is depleted. Such underlying processes are typically addressed early on in the drug discovery and

**Figure 2** Metabolite patterns from plasma and liver homogenate of naive (a) and bile duct-cannulated (b) rats, compared to in vitro metabolite patterns.

**Figure 3** Cytochrome P450-dependent in vitro metabolism using liver microsomes prepared from nonoperated rats and animals 5 days after bile duct cannulation.

development process using appropriate in vitro assays.<sup>19</sup> In vivo studies can help to assess the relevance of these findings for the in vivo situation. The radiolabeled drug, covalently bound to plasma, liver, or microsomal proteins can be quantified and the binding can be compared relative to the dose and in relation to the binding of positive test compounds under the same conditions.<sup>10</sup>

#### 5.03.4.7 Enzyme Induction and Inhibition Studies

Studies addressing the enzyme induction and inhibition potential for new test drugs are typically performed in specific in vitro studies, since studies with animals are of limited predictive value for man for these two mechanisms.

The inhibition of major drug-metabolizing enzymes of the cytochrome P450 family by a test drug is studied using human liver microsomal preparations or the recombinantly expressed human enzymes. Based on the result, *in vivo* studies are then performed to study the relevance of the *in vitro* findings. The affected enzymes can be studied using selective marker substrates for the inhibited isoenzyme, or by using a ‘cocktail’ addressing all major cytochrome P450 enzymes in one study.<sup>21,22</sup> Animal experiments are generally not considered as an alternative to human studies due to significant differences in substrate specificities.<sup>21,23</sup> Simulation of drug–drug interactions are reviewed elsewhere in this book (*see* 5.35 Modeling and Simulation of Pharmacokinetic Aspects of Cytochrome P450-Based Metabolic Drug–Drug Interactions).

Enzyme induction by a new test drug might have already been observed in multiple dose toxicity studies by decreasing drug exposure over time. However, the regulation of drug-metabolizing enzymes in animals and man is different, making animals a poor model for enzyme induction studies. In addition induction of a number of isoenzymes might be overlooked if the test compound is not significantly metabolized by these isoenzymes. Therefore, the enzyme-inducing properties of a new test drug are typically studied using human hepatocytes.<sup>23</sup> Such information is usually required early on in drug development to exclude potentially harmful comedications from the first phase of clinical studies.

### 5.03.5 Mechanistic Pharmacokinetic Studies

#### 5.03.5.1 Intestinal Absorption Studies

Absorption studies can be carried out using a variety of dosing routes. In this chapter we will focus on intestinal absorption since oral dosing is the most common route of administration for drugs. Models for absorption by nonoral routes are in Chapter 5.12.

There are a number of different approaches to estimate absorption. Artificial membranes such as parallel artificial membrane permeability assay (PAMPA) or cell-based assays using Caco-2 and Madin–Darby canine kidney (MDCK) cell lines are commonly utilized for assessing the intestinal permeability of a drug. These methods are well suited to high- or medium-throughput screening and have been shown to produce permeability values that correlate with intestinal absorption in man.<sup>24–27</sup> However, these cell lines are mostly used to predict passive absorption, and the results obtained are greatly affected by experimental parameters such as pH and co-solvents. *In silico* and *in vitro* transport models for oral absorption are discussed in detail elsewhere in this book (*see* 5.28 *In Silico* Models to Predict Oral Absorption; 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption). The *in situ* perfusion approaches described in this section provide experimental conditions closest to those encountered following oral administration, with a lower sensitivity to pH variations due to a preserved microclimate above the epithelial cells.<sup>28</sup> In this model, the animal is anesthetized and a segment of gut is cannulated and perfused with a solution containing the test drug. The concentrations measured in the perfusate before and after perfusion are used to quantify the absorption of the compound. These techniques maintain an intact blood supply to the intestine, and can be used to estimate the impact of clearance pathways, such as enzymes and transporters, that are present in the gut. Moreover, drug permeability<sup>29</sup> and expression of drug-metabolizing enzymes and transporters have been shown to vary along the intestinal tract, which can be investigated using intestinal perfusion of the various regions. In addition, intestinal permeability measured in rats with this perfusion technique was recently reported<sup>28</sup> to correlate very closely with that obtained in man (Figure 4).

#### 5.03.5.2 Liver and Intestinal First Pass Studies

The use of hepatic portal vein-cannulated animals can be helpful in determining specific causes of poor bioavailability. Numerous factors contribute to the low and erratic oral bioavailability of drugs such as low aqueous solubility, poor dissolution properties, and poor apparent permeability due to intrinsically low absorptive membrane permeability. Extensive CYP3A-mediated metabolism in the liver and, to some extent, in intestinal tissues is also considered a significant factor. More recently, secretory membrane transporters (e.g., P-glycoprotein (P-gp) and MRP2) have also been implicated in controlling the oral bioavailability and variability of drug absorption. The oral bioavailability ( $F$ ) can be described as:

$$F = f_a \cdot (1 - f_g) \cdot (1 - f_h) \quad [1]$$

where  $f_a$  is the fraction of dose absorbed from the gastrointestinal lumen and  $f_g$  and  $f_h$  are the fractions of drug metabolized by the gut wall and liver, respectively, during the first pass. In order to gain insights into the absorption

**Figure 4** Percentage of drug dose absorbed in man (A%) versus rat  $P_{eff}$  (effective intestinal permeability) value. 1, Sulfasalazine; 2, aciclovir; 3, nadolol; 4, atenolol; 5, furosemide; 6, terbutaline; 7, hydrochlorothiazide; 8, cefalexin; 9, metoprolol; 10, propranolol; 11, antipyrine; 12, ketoprofen; 13, dexamethasone; 14, naproxen.

processes and the main factors limiting the oral bioavailability it is possible to perform dosing and/or sampling of the hepatic portal vein in animals in addition to the traditional methods of oral and intravenous dosing coupled with intravenous sampling. Thus, for example,  $f_g$  and  $f_h$  can be easily derived from these experiments and the respective contribution of gut and liver first pass effects can be easily quantified. Studies to investigate the relative contributions of the gut and liver to the first-pass loss of a number of compounds have been performed using in vivo intestinal-vascular access port models in various species including rat, dog, and rabbit. In order to assess and differentiate the roles of the intestine and liver with respect to metabolism and secretion, test compounds needed to be coadministered with specific P-gp and CYP3A inhibitors.

### 5.03.5.3 Studies to Assess Blood–Brain Barrier Permeation

Drugs that are effective against diseases in the central nervous system and reach the brain via the blood compartment must pass the blood–brain barrier (BBB). This is considered to be the most important barrier for drug transport to the brain because its surface area is 5000 times larger than the blood-cerebrospinal fluid barrier located at the choroid plexus.<sup>30</sup> Compounds can cross the BBB by passive processes including paracellular transport for small hydrophilic compounds and transcellular transport for lipophilic compounds. Other possibilities include transcytosis with involvement of transporters. A number of transporters have been studied. Among these, the discovery of the presence of P-gp has greatly contributed to our understanding of the transport of compounds into the brain.<sup>30</sup>

Various methods are available to study the transport of compounds into the brain including in silico (see 5.31 In Silico Models to Predict Brain Uptake), in vitro (see 5.13 In Vitro Models for Examining and Predicting Brain Uptake of Drugs), and in vivo methods. The in vivo methods available to study brain transport include the single carotid injection technique, the internal carotid artery perfusion technique, the intravenous injection technique with brain tissue of cerebrospinal fluid (CSF) sampling, and in vivo brain microdialysis. These methods have been reviewed recently<sup>31</sup> and are summarized in this section.

#### 5.03.5.3.1 Carotid artery injection technique

With this technique the test compound is rapidly injected or perfused into the carotid artery.<sup>32</sup> This technique has been applied to various animal species including rats, mice, and guinea pigs. The brain is collected 5–15 s after administration of the compound to assess brain permeability. This technique has been widely used to study BBB permeability and the role of protein binding and transport in penetration to the brain.

#### 5.03.5.3.2 Intravenous injection technique with brain collection

In this case, the compound is usually administered in the femoral vein through bolus injection or through infusion. Then, animals are sacrificed at different time points to allow brain and blood collection. The concentrations measured in brain and plasma are then used to assess brain permeability or determine the brain:plasma ratio at steady-state.

#### 5.03.5.3.3 Cerebrospinal fluid sampling technique

The determination of CSF concentration has been attractive because of its low protein content and analysis of CSF samples is simple. Furthermore, there have been a number of examples indicating that CSF exposure might be related

to exposure at the site of action. However, these observations cannot be generalized as a number of examples have also shown that the permeability at the blood-CSF barrier (the choroid plexus) could also be different from the BBB permeability.

For drugs that are passively transported, the CSF concentration may approximate unbound concentration in plasma. Jezequel<sup>33</sup> compared the CSF to plasma concentration ratio with the free fraction in plasma for 50 drugs. About 50% of the compounds had a CSF to plasma concentration ratio similar to free fraction in plasma. For the other compounds, the unbound concentration in CSF was usually lower than the corresponding unbound concentration in plasma, most likely as a result of the involvement of active transport processes at the blood-CSF barrier.

#### 5.03.5.3.4 Intracerebral microdialysis

These techniques have been reviewed recently.<sup>30</sup> Intracerebral microdialysis involves the stereotactic implantation of a microdialysis probe in the brain. The probe comprises a semipermeable membrane partly covered with impermeable coating. The probe can be positioned at a specific site in the brain and may be used to sample extracellular fluid but also to deliver compound to the brain. One important issue of microdialysis experiments is the careful determination of in vivo concentration recovery for each experiment to characterize the relation between brain extracellular concentration and dialyzate concentration.

Intracerebral microdialysis is particularly suitable to estimate extracellular unbound drug concentration as a function of time. In addition unbound concentrations can be measured at the same time in blood and compared to unbound brain concentration to characterize drug transport across the BBB. The microdialysis technique offers the possibility to take multiple samples from individual animals and to sample from different brain regions including diseased brain sites for example.

A number of examples illustrate the applicability of microdialysis to study drug transport to the brain.<sup>34</sup> Thus, the extracellular concentrations of atenolol and acetaminophen were shown to follow very closely the corresponding plasma concentrations. As a result of higher lipophilicity leading to larger lipophilic diffusion across the BBB, the extracellular fluid concentrations of acetaminophen were much larger than those of atenolol.<sup>34</sup>

### 5.03.6 Interspecies Differences in Pharmacokinetics

#### 5.03.6.1 Species Differences in Absorption

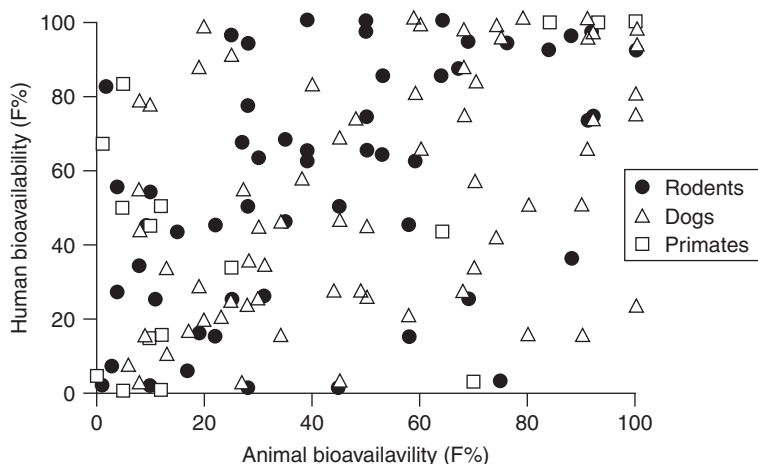

Drug absorption is influenced by a variety of physiological and physicochemical factors. The physiological factors are species dependent and include gastric and intestinal transit time, blood flow rate, gastrointestinal pH and first-pass metabolism, while the physicochemical factors correspond to drug-specific and species-independent properties, such as  $pK_a$ , molecular size, solubility, and lipophilicity. The oral bioavailability of a drug is defined as the fraction of an oral dose that reaches the systemic circulation unchanged. The oral bioavailability ( $F$ ) can be described by eqn [1]. The  $f_a$  is determined mainly by solubility and stability of the drug in the gastrointestinal tract and its permeability across the intestinal membrane. Models for human bioavailability are given in Chapter 5.29.

In comparing oral bioavailability across animal species, it is not unusual to observe marked interspecies differences (Figure 5).

For many compounds, these differences reflect presystemic (intestinal and/or hepatic) drug metabolism. By contrast to presystemic metabolism and oral bioavailability, some similarities across species<sup>35–38</sup> have been reported for fraction absorbed ( $f_a$ ) as described below in more detail.

##### 5.03.6.1.1 Physiology of the gastrointestinal tract

A recent review article has highlighted a number of similarities and differences in anatomy and physiology of the GI tract in rats and humans, which need to be taken into consideration in the interpretation of species differences in oral absorption.<sup>39</sup> For example, the human GI tract is capable of absorbing materials faster and to a greater extent than that of the rat. Such differences are likely to influence the extent to which drugs are absorbed. Overall, the rat's gastrointestinal tract is organized in the same way as the human's, but with a few important differences. For example, the relative lengths of the small intestine in the rat differ from those in man, in that the jejunum makes up nearly the entire small intestine in the rat. Another important difference is that the human intestinal tract is only about 5.5 times the length of that in the rat, despite man's much larger body size (70 kg) compared to the rat (0.25 kg). The absolute surface area of the human intestinal tract is about 200 times that of the rat, which when normalized on the basis of body surface area amounts to a factor of 4 times. The physiological consequences of these anatomical differences are twofold.

**Figure 5** Species differences in oral bioavailability. (Reproduced from Grass, G. M.; Sinko, P. J. *Adv. Drug Deliv. Rev.* **2002**, 54, 433–451.<sup>80</sup>)

First, well-absorbed substances are likely to be absorbed more quickly in humans (i.e., man will exhibit a higher absorption rate). Second, substances that are poorly or incompletely absorbed by both species are likely to be absorbed to a greater extent in man.<sup>39</sup>

With regard to interspecies differences in secretions into the intestinal tract, an important anatomical difference between rats and humans is the absence of a gall bladder in rats. This means that in the rat, bile enters the duodenum continuously as it is made. By contrast the bile in humans is released only when chyme is present. These anatomical differences can be responsible for pronounced species differences in the concentration versus time profile of drugs that undergo enterohepatic recycling.

There are also some important similarities and differences in gastrointestinal physiology<sup>40–42</sup> between dogs and humans, which are discussed below. The physiology of the stomach is relatively similar under fasting conditions in both dog and man. The higher intestinal pH observed in the dog is the main difference between the species under fasting conditions. This could lead to species differences in the absorption of compounds for which solubility is a function of pH in the region of 5–7 and for enteric-coated formulations with dissolution in this pH range. Dogs also exhibit short intestinal transit time, which could lead to lower absorption for compounds slowly absorbed in the colon and for compounds in slow-release dosage forms. Postprandially, differences occur in both the gastric and intestinal physiology. For example, meal emptying rates are much slower in the dog. Furthermore, gastric and intestinal pH appears to be more acidic in dogs than in humans. These lower pH values may result in different absorption rates between dog and man for compounds whose intestinal permeability or solubility are affected by fraction ionized. These species differences in physiology between fasted and fed state might also result in different food effects on pharmacokinetics between human and dog.

Solubilization of lipophilic drugs is a critical step in ensuring its bioavailability. This solubilization process is highly dependent upon the presence and nature of the bile salts contained within the intestinal fluids. However, the marked interspecies differences in bile flow and composition can significantly affect the nature of this solubilization process.

The solubility of poorly soluble compounds was recently compared in dog and humans. For danazol, felodipine, and griseofulvin, the solubility in dog intestinal fluid was significantly higher than in human intestinal fluid, indicating that dog might not be a suitable species to predict human absorption for these poorly soluble compounds.<sup>43</sup> This higher solubility in dog intestinal fluid reflects the influence of higher bile salt concentration in dog as compared to man.

#### 5.03.6.1.2 Interspecies comparison of fraction absorbed

Despite the differences in physiology, nearly identical oral absorptions in humans and rats have been reported for 64 drugs with markedly varying physicochemical properties and a wide range of intestinal permeabilities (Figure 6).<sup>38</sup>

In addition, similar oral bioavailabilities in rats and humans have been reported for 16 PEG compounds with molecular weights ranging from 280 to 950.<sup>44</sup>

The monkey may be another excellent animal model for predicting oral absorption in humans.<sup>35</sup> Chiou and Buehler found that absorption values in monkeys were similar or identical to those in humans (Figure 7). In contrast to rat and monkey, the dog appears to be less predictive for man. In general there is a tendency for dogs to absorb compounds

**Figure 6** Oral absorption in rat versus human of 64 drugs with markedly different physicochemical properties. (Reproduced from Chiou, W. L.; Barve, A. *Pharm. Res.* **1998**, *15*, 1792–1795.<sup>38</sup>)

**Figure 7** Oral absorption in cynomolgus monkey versus human of 43 drugs with markedly different physicochemical properties. (Reproduced from Chiou, W. L.; Buehler, P. W. *Pharm. Res.* **2002**, *19*, 868–874.<sup>35</sup>)

better than man. For the 16 PEG compounds the absorption in dogs was better than in humans.<sup>44</sup> Also for 43 drugs, the correlation coefficient between the fraction absorbed in humans and dogs ( $r^2 = 0.51$ ) was much lower than that ( $r^2 = 0.97$ ) reported between humans and rats<sup>36,38</sup> (Figure 8).

For acyclovir and nadolol, the fraction absorbed in dogs was about 100% while humans only absorbed about 20% of the dose. Great differences were also found for atenolol (50% in man versus 100% in dogs), methyldopa (43% in man versus 100% in dogs), ranitidine (63% in man versus 100% in dogs), sumatriptan (60% in man versus 97% in dogs), and xamoterol (8.6% in man versus 36% in dogs).

A number of hypotheses have been proposed to explain the higher absorption in dog as compared to man. For example, the dog has longer villi, which may compensate for a shorter intestinal transit time. Furthermore, the higher bile salt secretion rate in the dog could increase the permeability of the intestinal membrane and might, through a solubilizing effect, also facilitate the absorption of poorly water-soluble drugs.<sup>36,38</sup> In addition the size and frequency of the tight junction for paracellular transport may be greater in dogs than in humans, which might explain the greater extent of absorption of small hydrophilic compounds, such as polyethylene glycol oligomers.<sup>44</sup>

### 5.03.6.2 Interspecies Differences in Distribution

The PK parameter that is most commonly used to characterize the distribution of a drug is its volume of distribution at steady state ( $V_{D,ss}$ ).  $V_{D,ss}$  represents the equivalent volume into which a given dose of drug is apparently distributed

**Figure 8** Oral absorption in dog versus human of 43 drugs with markedly different physicochemical properties. (Reproduced from Chiou, W. L.; Jeong, H. Y.; Chung, S. M.; Wu, T. C. *Pharm. Res.* **2000**, *17*, 135–140.<sup>36</sup>)

within the body and, as such, it includes the extent to which the drug is bound to tissue and/or plasma proteins. The numerical value of  $V_{D,ss}$  that is recorded can be as small as the blood volume or, for compounds that are extensively bound to tissues, can exceed the volume of total body water. The following equation has been proposed to relate  $V_{D,ss}$  to plasma and tissue binding:

$$V_{D,ss} = V_P + f_{u,p} \cdot V_E + V_P \cdot R_{e/i} \cdot (1 - f_u) + V_R \cdot f_{u,p}/f_{u,t} \quad [2]$$

where  $V_P$ ,  $V_E$ , and  $R_{e/i}$  are the plasma and extracellular volumes and the ratio of extravascular to intravascular proteins, respectively.  $V_R$  is the volume in which the drug distributes minus the extracellular space.  $f_{u,p}$  and  $f_{u,t}$  are the fractions of unbound drug in plasma and tissue.<sup>45</sup>

$V_{D,ss}$  can also be represented in terms of tissue/plasma partition coefficients ( $K_p$ ) and plasma volume ( $V_P$ ):

$$V_{D,ss} = V_P + V_{ery} \cdot ery/plasma + \sum V_T \cdot K_p \quad [3]$$

Models for plasma protein binding and tissue storage are given in Chapter 5.14. Plasma protein binding of drugs often differs considerably across species, and more so than tissue binding. This might be because plasma binding frequently involves the interaction of a drug with a specific binding site on a specific protein, which differs structurally from one species to another, whereas tissue binding involves interaction with many constituents, thereby reflecting an average value.<sup>46,47</sup> This is supported by the observation that using the same  $K_{pu}$  ( $K_p/f_{u,p}$ ) value for a tissue across species and correcting for differences in plasma protein binding tends to produce better prediction of tissue distribution than when no correction is made.<sup>48</sup> This is illustrated with the example of propranolol for which the large species differences in free fraction are responsible for species differences in volume of distribution derived from total plasma concentrations. When the volume is derived from unbound plasma concentrations, the volume is very similar across species (Figure 9).

Along these lines, in a study with a series of 40 drugs with widely differing physicochemical characteristics, Fichtl and coworkers demonstrated close interspecies correlations in binding to muscle tissue<sup>49</sup> (Figure 10).

However, some differences in tissue binding have also been reported. Thus, for lipophilic compounds that distribute into and bind more extensively to tissues, interspecies differences in  $K_{pu}$  values have been reported.<sup>50</sup> These may be due to differences between rodents and humans in the lipid content and composition of certain tissues, such as muscle<sup>50,51</sup> (Table 1) where the fraction of neutral lipids is about 10-fold higher in humans compared to rats.

Some studies demonstrated interspecies differences of up to threefold in  $K_{pu}$  values of heart muscle and lung determined in rat and rabbit.<sup>50,51</sup> For drugs whose distribution is diffusion rate limited, species differences in membrane permeability could also influence the  $K_{pu}$  values. In addition, a different degree of active transport processes

**Figure 9** Interspecies differences in volume of distribution and protein binding for propranolol.

**Figure 10** Correlation among different species in binding of drugs to muscle tissue in vitro. B/F represents the ratio between bound (B) and free (F) concentrations. (Reproduced from Fichtl, B.; Nieciecki, A.; Walter, K. In *Advances in Drug Research*; Mordenti, C. A., Ed.; Academic Press: London, 1991, pp 117–177.<sup>49</sup>)

(e.g.,  $\text{Na}^+/\text{K}^+$  ATPase) in animals and humans can lead to significant interspecies differences in  $V_{D,ss-u}$ . For example,  $V_{D,ss-u}$  (volume of distribution of the unbound concentration) of digitoxin is  $2.1 \text{ L kg}^{-1}$  in rat but  $9.1 \text{ L kg}^{-1}$  in man.<sup>51</sup>

Overall, however, species differences in tissue binding seem to be less pronounced than the corresponding differences in plasma binding.

### 5.03.6.3 Species Differences in Elimination

#### 5.03.6.3.1 Interspecies differences in metabolic clearance

Hepatic clearance can be described by theoretical models that relate the intrinsic clearance ( $CL_{int}$ ) to the other physiological parameters that influence clearance, namely hepatic blood flow and blood binding. Hepatic clearance in the well-stirred model is described by:

$$CL_H = [Q_H \cdot f_{u,b} \cdot CL_{int}] / [Q_H + f_{u,b} \cdot CL_{int}] \quad [4]$$

**Table 1** Physiological parameters for tissue composition in the adult male human and in rat

| Tissue  | Neutral lipids ( $V_n$ ) (fraction of wet tissue weight) |         | Phospholipids ( $V_{ph}$ ) (fraction of wet tissue weight) |         | Water ( $V_w$ ) (fraction of wet tissue weight) |       |

where  $Q_H$  is the liver blood flow,  $f_{u,b}$  is the fraction unbound in the blood, and  $CL_{int}$  (the intrinsic clearance) is a measure of the maximal ability of the liver to metabolize a drug in the absence of protein binding or blood flow limitations.

For drugs that are rapidly metabolized (i.e., very high  $CL_{int}$  leading to  $f_{u,b} \cdot CL_{int} \gg Q_H$ ) the value of CL approaches  $Q_H$  and hepatic clearance is limited by the liver blood flow. For these compounds, interspecies differences in clearances will reflect interspecies differences in liver blood flow. One such example is propranolol. This drug is mainly eliminated by the liver, and the intrinsic clearance is so rapid that CL is limited by hepatic blood flow. Its CL is  $90 \text{ mL min}^{-1} \text{ kg}^{-1}$  in the rat,  $34 \text{ mL min}^{-1} \text{ kg}^{-1}$  in the dog,  $18 \text{ mL min}^{-1} \text{ kg}^{-1}$  in the monkey, and  $15 \text{ mL min}^{-1} \text{ kg}^{-1}$  in man.<sup>52</sup> The CL value in each species approximates their hepatic blood flow rate.

For drugs with low extraction ratios ( $f_{u,b} \cdot CL_{int} \ll Q_H$ ) the value of CL is directly related to  $f_{u,b}$  and  $CL_{int}$  ( $CL = f_{u,b} \cdot CL_{int}$ ). Thus, the clearance of such compounds is mainly determined by their plasma protein binding and intrinsic clearance, which can both be subject to large species differences. Species differences in rate of metabolism ( $CL_{int}$ ) have been shown with many different drugs undergoing both phase I and phase II metabolism. In general, drug metabolism in mammalian species is lower than in nonmammalian species<sup>53</sup> and decreases with increasing body weight. These species differences are the result of differences in the amino acid sequence, substrate specificity, and levels of the enzymes (e.g., cytochrome P450). For example, the hepatic levels of CYP1A, CYP2C and CYP3A in rats are approximately 28, 638, and  $165 \text{ pmol mg}^{-1}$  microsomal protein, respectively,<sup>54</sup> and the corresponding values for humans are 37, 55, and  $87 \text{ pmol mg}^{-1}$  microsomal protein.<sup>55</sup>

In general, deficiencies are well known for some animal species often used in experimental studies. Such deficiencies are for example a lack of acetylation of some compounds in dogs and guinea pigs, glucuronidation deficiency in cats, and some deficiencies in sulfotransferase activities in pigs.<sup>16</sup> In addition to these species differences in phase II conjugation reactions, differences are well known in phase I cytochrome P450 isoenzyme activities. However, for this group of enzymes it is more the altered substrate specificities and quantitative differences that lead to differences in metabolite patterns. The relevance of animal species depends on the cytochrome P450 isoenzyme involved. While dog seems to be a good species for CYP 2D-dependent reactions, CYP2E1 and CYP1A1/2 appear more appropriately represented in rats, (mini)pigs, and rhesus monkey.<sup>56</sup> In addition to species differences significant gender differences are apparent, especially in rats. In general, male rats metabolize many drugs faster than female rats, while the opposite is reported for mice. In rats many of these differences are due to the male-specific cytochrome 2C11,<sup>57</sup> which is often involved in the metabolism of compounds in man via CYP3A. New, humanized mouse models might overcome some of these limitations.<sup>13</sup> Mice expressing human CYP2D6 and CYP3A4 have been successfully generated; however, many other components of human drug metabolism and transport might be important for consideration in such a holistic model to adequately represent the interplay of drug metabolism in man.

Large species differences in hepatic metabolic clearance have been reported for many drugs and have made extrapolation of metabolic clearance from animal to man highly questionable. Bosentan is one example of a drug characterized by large interspecies differences in clearance.<sup>58</sup> Bosentan, exhibits a high blood clearance in rabbits, which approximates the liver blood flow. Intermediate to high clearance values were observed in mice, marmosets, and rats, while dogs exhibited a low blood clearance, which represented less than 5% of the corresponding liver blood flow. From these examples, it appears that it is not recommended to predict human metabolic clearance based on animal data. Fortunately, the availability of in vitro models in humans allows predictions of clearances to be performed based on physiologically-based scaling methods with satisfactory prediction accuracy.<sup>59,60</sup>

Comprehensive expert systems to predict drug metabolism are discussed in 5.33 Comprehensive Expert Systems to Predict Drug Metabolism.

#### 5.03.6.3.2 Interspecies differences in renal clearance

Many drugs and drug metabolites are excreted by the kidneys. Renal clearance is the net result of three interrelated processes: glomerular filtration, tubular secretion, and tubular reabsorption. Both glomerular filtration and active tubular excretion eliminate a drug from the blood, while tubular reabsorption allows drug that has entered the renal tubules to re-enter the circulation.

A mechanistic relationship, in which the contributions of tubular secretion and glomerular filtration are additive, has been proposed by Levy.<sup>61</sup> This describes renal clearance ( $CL_R$ ) in the following terms:

$$CL_R = (1 - f_r) \cdot f_u \cdot GFR + (1 - f_r) \cdot Q_R [f_u \cdot CL_{int,us}] / [Q_R + f_u \cdot CL_{int,us}] \quad [5]$$

where  $CL_R$  represents renal clearance,  $f_r$  is the fraction of drug reabsorbed in the tubules,  $f_u$  is the free fraction in plasma, GFR the glomerular filtration rate,  $Q_R$  the renal blood flow, and  $CL_{int,us}$  is the intrinsic tubular secretion rate. This model assumes that tubular secretion and glomerular filtration are fully independent processes.

If tubular secretion is absent then  $CL_R$  is directly proportional to GFR and the free fraction in plasma. For compounds with these characteristics, the unbound renal clearance in different species will reflect species differences in GFR. Similarly, if the secretory pathway is very efficient at removing drug then  $CL_R$  approximates  $Q_R$ , and in this case species differences in the  $CL_R$  will reflect species differences in renal blood flow. *para*-Aminohippuric acid is one example of a compound whose renal clearance is limited by blood flow.

Lin<sup>62,63</sup> recently provided a number of examples where mechanisms of renal excretion were compared across species. Based on these examples, depending on whether renal clearance is less than, equal to, or greater than the GFR, it may be possible to predict the mechanisms for renal elimination in man. Thus, famotidine has a renal clearance in rats of  $1.68 \text{ L h}^{-1} \text{ kg}^{-1}$  which exceeds its GFR ( $0.522 \text{ L h}^{-1} \text{ kg}^{-1}$ ), indicating that a net tubular secretion is occurring. In humans, the renal clearance of famotidine is  $0.266 \text{ L h}^{-1} \text{ kg}^{-1}$ , which is also greater its GFR ( $0.108 \text{ L h}^{-1} \text{ kg}^{-1}$ ). The ratio of renal clearance to GFR is 2.5 and 3.2 in humans and rats, respectively. Therefore, for famotidine, there is reasonably good agreement between renal clearance in humans and that expected from animal models. Extending this approach to the data for the six compounds published by Sawada<sup>64</sup> tends to support this observation. Comparing the unbound renal clearance to GFR in the rat and human gave comparable ratios for cefoperazone (0.5 and 0.9), moxalactam (1.7 and 1.8), and cefazolin (7.7 and 3.6). For cefmetazole, the mechanism of renal excretion was similar in rat and human but the net secretion was much more pronounced in human (ratios of 1.6 in rat and 6 in human). For cefpiramide the ratios in rat (1.1) and human (0.7) were similar but the values indicated different excretion processes, namely a net secretion in rat and a net reabsorption in human.

Nevertheless, important species differences might arise when active transport is involved in the renal disposition of compounds. For example, Giacomini and colleagues<sup>65</sup> have shown that the human organic cation transporter (hOCT1) system is functionally different from the OCT1 homolog in other mammals, and it is reasonable to assume that these differences will modify their interactions with drugs. In this context, Dresser and co-workers<sup>66</sup> determined the kinetics and substrate selectivity of the OCT1 homologs from mouse, rat, rabbit, and human, and found that the human homolog is functionally different from that of the rodent and rabbit.

Species differences in renal clearance might also occur through differences in urinary pH.<sup>67</sup> Such effects might influence not only the extent of diffusion and reabsorption across the renal tubule, but could also result in artificial differences due to changes in the stability at different urinary pHs.<sup>67</sup>

#### 5.03.6.3.3 Interspecies differences in biliary clearance

In general, mice, rats, and dogs are good biliary excretors, while guinea pigs, monkeys, and humans are relatively poor biliary excretors. The species differences in biliary excretion become less marked when the molecular size of the drug

being excreted exceeds 700 Da.<sup>53</sup> Species variation in the efficiency of the transport systems is the more probable cause. However, as discussed earlier, differences in biliary anatomy (i.e., presence or absence of a gallbladder) can give rise to species differences in pharmacokinetics.<sup>53</sup>

The role of active transport processes and their impact on species differences in drug disposition have been reviewed recently.<sup>68</sup> Species differences in active transport may result from differences in the nature, levels, and/or regulation of the various transport proteins, as well as from their sequence substrate/inhibitor specificities. Where data are available on rat and human orthologs, sequence identity is reasonably high (70–80%) for the OATP,<sup>69</sup> OCT,<sup>70,71</sup> and MDR<sup>72</sup> transporter families. There is some evidence to suggest that the rate of transport in rat is greater than in humans. For example, some basic compounds were shown to be taken up ~10-fold faster in rat than human hepatocytes<sup>73</sup>. Also  $K_m$  and  $K_i$  for a range of bases were significantly lower for rat OCT1 than human OCT1,<sup>70,71</sup> suggesting a greater substrate affinity in rat. Species differences in the transport across the bile canalicular membrane of certain organic anions (temocaprilat, 2,4-dinitrophenyl-*S*-glutathione and taurocholate, which are specific substrates of MRP2 and BSEP transporters) were shown to be due mainly to differences in  $V_{max}$  rather than  $K_m$ .<sup>74</sup>

### 5.03.7 Prediction to Humans

Preclinical in vivo studies are helpful to guide the design of the first clinical studies. A number of approaches including empirical methods and physiologically-based models are being used to predict human pharmacokinetics based on preclinical data (see 5.37 Physiologically-Based Models to Predict Human Pharmacokinetic Parameters). Among the empirical methods, allometric scaling explores the mathematical relationships between pharmacokinetic parameters from various animal species in order to make predictions in humans. Such methods are relatively easy to apply but place demands on resources for the collection of in vivo data in animals. Nevertheless, their application has led to useful predictions of individual pharmacokinetic parameters (e.g., clearance, fraction absorbed, volume of distribution). In general, however, such methods can only take account of ‘passive’ transport differences between species.

Allometric scaling is based on a power function of the form:

$$y = a \cdot W^x \quad [6]$$

where  $y$  is the dependent variable (e.g., clearance, volume of distribution, half-life),  $W$  (body weight) is the independent variable, and  $a$  and  $x$  are the allometric coefficient and exponent, respectively. The values of  $a$  and  $x$  can be estimated by linear least squares regression of the log transformed allometric equations, i.e.,

$$\log(\text{clearance, volume of distribution, half-life, etc.}) = \log(a) + x \cdot \log(W) \quad [7]$$

The sign and magnitude of the exponent indicate how the physiological or pharmacokinetic variable is changing as a function of  $W$ <sup>75–77</sup>: for  $b < 0$ ,  $y$  decreases as  $W$  increases; for  $0 < b < 1$ ,  $y$  increases as the species get larger, but does not increase as rapidly as  $W$ ; when  $b = 1$ ,  $y$  increases in direct proportion to the increases in  $W$ ; and when  $b > 1$ ,  $y$  increases faster than  $W$ .

The allometric equations for the pharmacokinetic parameters tend to be of the same order of magnitude as those for the corresponding physiologic variables, i.e.:

1. half-life (min)  $\sim aW^{0.2}$  to  $aW^{0.4}$ ;
2. clearance ( $\text{mL min}^{-1}$ )  $\sim aW^{0.6}$  to  $aW^{0.8}$ ; and
3. volume of distribution (mL)  $\sim aW^{0.8}$  to  $aW^{1.0}$ .

The allometric approach can be particularly useful for compounds that are primarily eliminated by physical transport processes and when distribution occurs through passive processes. In such cases, when their values depend upon underlying physical or physiological processes that scale according to body weight, parameters such as clearance and volume of distribution do lend themselves well to allometric scaling. However, it may be less reliable for compounds that exhibit marked species differences in distribution, metabolism, or excretion mechanisms and a number of authors have cautioned against its use for selecting doses for the first phase of human studies.<sup>78,79</sup>

Physiologically-based models (PBPK) can be used to explore, and help to explain, the mechanisms that lie behind species differences in pharmacokinetics and drug metabolism. Physiologically-based models are discussed in more details in Chapter 5.37. Such models can provide a rational basis for interspecies scaling of individual parameters, which can then be integrated to provide quantitative and time-dependent estimates of both the plasma and tissue concentrations in humans. Furthermore, being mechanistically based they can be used diagnostically to generate

information on new compounds and to understand the sensitivity of the in vivo profile to compound properties. Recent developments of in silico and in vitro models, which can provide estimates of the input parameters for PBPK models, have dramatically reduced the amount of experimental work required to make use of them.

## Biographies

**Thierry Lavé** received his PharmD and PhD in Pharmaceutical Sciences from the University of Strasbourg in 1992 and 1993. He also received a statistical degree from the University of Paris in 1992 and did an internship in Hospital Pharmacy from 1988 to 1992 in Strasbourg. He joined Roche's Department of Preclinical Pharmacokinetics and Drug Metabolism in 1992 where he served for 2 years as a postdoctoral fellow. Thierry Lavé is currently a Scientific Expert at F Hoffmann-La Roche and took responsibility for the global modeling and simulation group in preclinical research in 2002. His main area of research is in preclinical modeling of safety, pharmacokinetics and formulation, physiologically based pharmacokinetics, interspecies scaling, drugdrug interactions, and all aspects related to early predictions of pharmacokinetics/pharmacodynamics in man during drug discovery and early drug development. He has published a number of papers in these areas and also teaches pharmacokinetics at the Universities of Basel, Strasbourg, Helsinki, and Besançon.

**Christoph Funk** studied Biology at the Swiss Federal Institute of Technology (ETH) in Zürich, Switzerland in the early 1980s. Following graduation in 1985, he then completed his PhD thesis at the same University on the metabolism of several natural products in plants and plant tissue cultures. Dr Funk continued these studies between 1990 and 1993 as a postdoctoral fellow at the Institute of Biological Chemistry at Washington State University in Pullman, USA). His research focused on the metabolism of several mono- and diterpenoids in plants, including the characterization of several cytochrome P450 monooxygenases and other metabolic enzymes involved in secondary product formation.

Dr Funk returned to Switzerland where he took up a post-doctoral post at the Botanical Institute of the University of Basel. In 1994 he became Laboratory Head of Drug Metabolism in the Nonclinical Drug Development unit of F Hoffmann-La Roche in Basel. Besides the metabolic characterization of many new drug molecules, the research focused on the setup of in vitro drug transport assays and their characterization. The goal is to understand the relevant enzymatic steps involved in drug distribution and elimination. Since 2000, Dr Funk has been responsible for the drug metabolism and pharmacokinetics (DMPK) technologies group, bringing together the disciplines of drug metabolism, drug transport, kinetics, and mechanistic toxicology, with the aim of better characterization of the absorption, distribution, metabolism, excretion, and toxicity (ADMET) properties of potential new drugs.

### 5.04.1 Introduction

Pharmacokinetics has been defined over the past several decades as the study of drug absorption, distribution, metabolism, and excretion (ADME) when the drug is introduced into a biological system such as the human body. Most of the molecular processes responsible for the fate of a drug in the body were attributed to the passive crossing of the bilayer cell membranes. These explained a large part of how a drug was believed to be absorbed, distributed, and

eliminated. Several drug descriptors, such as molecular weight, degree of ionization, and solubility, were used to explain how a drug crossed biological membranes. Other pharmacokinetic effectors were considered, such as the metabolizing enzymes, that played an important role in drug biotransformation and the circulating plasma proteins defining the so-called ‘fraction of free drug’ available for tissue distribution. Elimination was also defined as the endpoint of all pharmacokinetic events, by which the more hydrophilic drugs or their metabolites were excreted in urine or bile.

Pharmacokineticists learned quite early that the overall renal clearance of a drug results from a combination of three processes: glomerular filtration, tubular secretion, and reabsorption. These last two processes have long been known to be mediated by carrier systems. In these systems, membrane proteins transport solutes in oriented directions. It was gradually realized that drugs could cross biological membranes by these carrier-mediated processes as well as by passive diffusion. This view of pharmacokinetics is now challenged by the growing importance of transporters, a relatively new and potentially major contributor. The impact of drug transporters on pharmacokinetics has suffered from the fact that less is known about them than about drug-metabolizing enzymes. Schwenk<sup>1</sup> published a review in 1987 that stated that “drug transport in the intestine occurs mainly by diffusion and the contribution of intestinal drug carriers seems to be of minor importance.” He also pointed out that “the liver is the organ where carrier-mediated drugs predominate” and that there may be four hypothetical carrier systems, called “carrier 1, 2, 3 and 4,” for drug uptake by hepatic cells. At the same time, the main enzymes implicated in drug metabolism were identified and the factors causing variations, such as the regulation and genetic polymorphism of these enzymes, were extensively studied. We are now in a position to complete the list of drug transporters, the tissues in which they occur and function, how they are regulated, and the clinical relevance of their presence in normal and diseased tissues. Nevertheless, despite the tremendous efforts that have been made in recent years, we still lack a significant amount of information about the fundamental contributions that transporters make to the pharmacokinetic processes that regulate the disposition of drugs in the body.

## 5.04.2 Membrane Transport Proteins in Biological Systems

### 5.04.2.1 Passive and Active Permeation

The exchange of solutes between body compartments depends to a considerable extent on the properties of the body that allow easy communication between tissues and compartments via pores and fenestra on the walls of the blood vessel or gap junctions between cells. These features allow free solutes to move in both directions through biological membranes by the so-called ‘paracellular pathway.’ But the organs of the body and pharmacological targets are not readily accessible to exogenous molecules because of the integrity of the lipid bilayer membranes that protect the interiors of cells. Some physiological barriers like the blood–brain barrier (BBB), the blood–placenta barrier, and the blood–testis barrier are so impermeable that solutes can only cross the lipid bilayer by a transcellular pathway. It has been established for some time that with advantageous gradient conditions only small nonpolar, uncharged molecules, such as oxygen, carbon dioxide, water, and ethanol, can diffuse easily through the membranes, whereas charged small ions, such as sodium and potassium, and large molecules, such as glucose (180 Da), are considerably less able to permeate than water (Figure 1). As the delivery of many polar molecules, such as anions and cations, vitamins, sugars, nucleosides, amino acids, peptides, bile acids, and porphyrins, to cells is essential for life, essential transporter proteins anchored in the lipid bilayer have evolved to permit their exchange between cells and their environment.

There are two principal classes of transport proteins: the proteins that form channels or pores, and the transporters. Channels are responsible for the facilitated diffusion of ions and small nutrient molecules down their electrochemical gradients. The flow of ions or solutes through channels is controlled by the opening of the channels via gating mechanisms and the single-channel conductance (number of charges per second at a given voltage). Some channels are more selective and have specific binding sites; they undergo changes of conformation and these changes regulate their opening to solute traffic.<sup>2</sup> The second class of transporters or carriers undergoes a conformational change during the translocation of a solute across the membrane. Transporters that facilitate the movement of solutes into the cell are called influx (import) transporters, while those that remove substances from the cytosol of the cell are efflux (export) transporters.

### 5.04.2.2 Transport Modes

Influx and efflux transporters can be further classified on the basis of their energy requirements.<sup>3</sup> Like protein channels, passive transporters, or facilitated transporters or uniporters, allow net solute flow down an electrochemical concentration gradient.

In contrast, active transport leads to the movement of solutes against an electrochemical gradient across the membrane. Active transport always occurs in a specific direction because it is coupled to an energy source. Several types of transporters have been identified; they differ by their energy source and the direction of transport (Figure 2). The

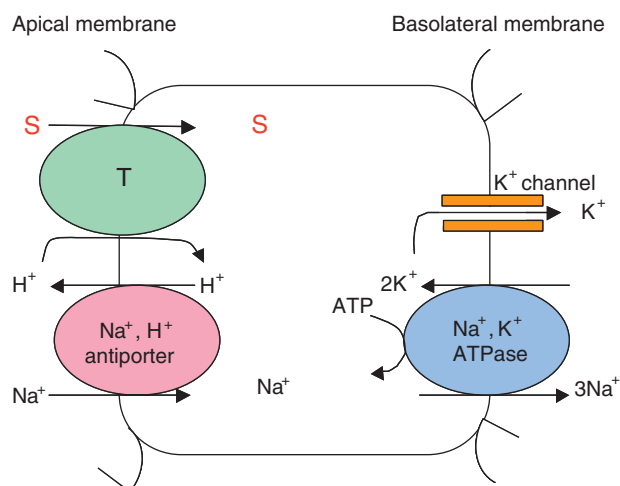

**Figure 1** Permeation of ions and molecules through the membrane lipid bilayer. Small, lipophilic molecules with no charge are more likely to cross the membrane by passive diffusion. Ions and high molecular weight hydrophilic compounds cannot cross the lipid bilayer in the absence of pores, channels, or specific transporters.

**Figure 2** The classification of modes of solute (S) transport translocation between the extracellular (*out*) and intracellular (*in*) compartments. A few examples of transporter families are included.

primary active transport systems are coupled to an energy source that results in solar, electrical or chemical reactions, such as the hydrolysis of ATP by ion pumps (ATPases) and the ATP-binding cassette (ABC) transporters that transport the substrate in one defined direction. They are called primary transporters because no additional biochemical step is needed for solute transport. The combination of an energy-yielding reaction and transport occurs within a single catalytic cycle of the protein. The second group of transporters are the co-transporters; these use a voltage or/and ion gradient to transport both ions and solutes together. They are uniporters when only one species is transported, and symporters when both species are transported in the same direction, whereas the antiporters transport solutes and ions in opposite directions. The  $\text{H}^+$  ion is the most common form of energy in prokaryotes, while  $\text{Na}^+$  is more frequently

**Figure 3** This model shows how solutes (S) are transported in a mammalian epithelial cell having K<sup>+</sup> channels and three types of transporters at the apical or basolateral membranes. The Na<sup>+</sup>, K<sup>+</sup>-ATPase (the primary active transporter) generates a Na<sup>+</sup> gradient, which provides the driving force for activating Na<sup>+</sup> and H<sup>+</sup> fluxes via the Na<sup>+</sup>, H<sup>+</sup> antiporter (the secondary active transporter). T is the tertiary active transporter, which transports S molecules down the H<sup>+</sup> gradient in symporter mode.

encountered in eukaryotic cells.<sup>3</sup> For example, several secondary transporters are involved in the entrance and exit of Na<sup>+</sup> at both apical and basolateral membranes of intestinal and renal epithelial cells. Thus the rate of transport of solutes like sugars or amino acids depends on the extracellular concentration of Na<sup>+</sup>. The main role of the Na<sup>+</sup>, K<sup>+</sup>-ATPase system is to activate the cascades of multiple co-transport processes. These co-transporters are also called secondary or even tertiary transporters because the machinery of ion transport must be activated by one or two pumps before solute transport occurs (Figure 3). Thus the energy component is clearly critical and the consequence of a lack of ATP in cells, as occurs in ischemia, leads to a loss of all transport by the ABC transporters. Other sources of energy involve glutathione (GSH), HCO<sub>3</sub><sup>-</sup>, and dicarboxylate  $\alpha$ -ketoglutarate ( $\alpha$ -KG).

The biological significance of these proteins is highlighted by their universal distributions in both prokaryotes and eukaryotes. Transporters are involved in the biology of yeasts, plants, bacteria, and parasites, so that it is possible that these molecules in bacteria and parasites may raise resistance to drug therapy. Many of the major body functions in mammals, like gut absorption, glucose uptake by tissues, bile acid secretion into the gut from the liver, and the renal secretion or reabsorption of nutrients, are linked to the presence of protein transporters on both the plasma membranes of cells and in intracellular organelles like the endoplasmic reticulum, mitochondria, and endosomes. Therefore, the extracellular and intracellular trafficking of any solute, including exogenous compounds like drugs, depends directly on this network of protein transporters.<sup>4</sup>

### 5.04.3 Biology of Membrane Transport Proteins

#### 5.04.3.1 Genes and Classification

Following the determination of the prokaryotic and eukaryotic genomes, Paulsen *et al.*<sup>5</sup> determined the distribution of membrane transport proteins for all those organisms whose genomes had been completely sequenced. Paulsen predicted that 15% of the 23 000 genes in the human genome code for transport proteins; this would result in nearly 3500 transporters. Ward *et al.*<sup>6</sup> assumed that 3–12% of the genes in bacterial genomes encode membrane transport proteins that can be vital for the efflux of antibiotics, the secretion of proteins or toxins, and other functions. But only about 10% of these proteins with known physiological function have been identified in mammalian cells, and only the members of two superfamilies are presently known to affect drug transport. They are the ABCs and solute carriers (SLCs). ABC proteins are widespread in all organisms, from bacteria to mammals, with about 600 referenced transporters, but only 48 genes have been identified in humans and no more than around nine ABCs have been shown to affect drug pharmacokinetics and pharmacodynamics.<sup>7</sup> The SLC family, which may contain about 2000 members, is presently known to have 46 families, including 362 transporter genes with documented transport functions.<sup>8</sup>

The current status of transporter nomenclature and classification is in the same disarray as was that of the metabolizing enzymes in the early 1980s. However, the Human Genome Organization (HUGO) Nomenclature

Committee Database has provided a list of the ABC and SLC genes and defined families of these transporters.<sup>8a</sup> There are other classification systems, such as the Transport Classification Data Base (TCDB). This is analogous to the Enzyme Commission system for the classification of enzymes but also incorporates phylogenetic information.<sup>8b</sup> This review uses the HUGO as the primary reference for identifying genes and proteins. Human proteins (*genes*) are shown in capitals (e.g., ABCB1 (*MDR1*)), while rat and mouse proteins (*genes*) are indicated by an initial capital followed by small letters (proteins) and small letters (genes) (e.g., Abcc1 (*mdr1*)). Some transporter databases provide only certain properties of a specific class or group of membrane transporter proteins. But, altogether, they contain information on cDNA and amino sequences, gene family, putative membrane topology, driving force, transport direction, lists of substrates, inhibitors, inducers, transport kinetic data, tissue distribution in both humans and mice and rats, drug–drug interactions involving transporters, and altered functions caused by mutations or polymorphisms and the influence of associated diseases.<sup>9</sup>

### 5.04.3.2 Basic Structure

The primary and secondary structures of many transporters are known. The structures of many ABCs and SLCs remain to be determined due to the inherent difficulties in crystallizing transporters for the x-ray crystallographic analyses needed to prepare high-resolution three-dimensional (3D) structures. This needs to be addressed. Biochemical analyses of transporter proteins are more challenging than studies on soluble proteins because they are hydrophobic, high molecular weight proteins and represent a small percentage of the total cell proteins. They are also rather inaccessible because they are tightly inserted into the lipid bilayer. Nevertheless, considerable progress has been made in the past 10 years by combining several biophysical approaches to determine the structure and topology of membrane transporters in the absence of a crystal structure. For example, several homology models predicting the pharmacophore pattern for the transporter binding site(s) are now available tools for 3D structure–activity relationship (3D-QSAR) analyses (*see* 5.32 In Silico Models for Interactions with Transporters).

Drug transporters are integral membrane proteins that typically have 12 transmembrane domains (TMDs), although there are exceptions with 6, 8, 10, 11, 13, or even 17 TMDs. The TMDs are folded in  $\alpha$ -helical structures within the membrane and linked at both sides by amino acid sequences floating in the internal or external cell environment. The amino acids in the external loop domains are frequently *N*-glycosylated, while those of the intracellular loops of both SLC and ABC proteins bear phosphorylation sites and one or two ATP binding domains in the ABCs. When observed in 3D structure, TMDs form a crown and look like a channel allowing communication between the two fluid spaces separated by the lipid bilayer. Many SLC transporters have 300–800 amino acid residues and a molecular mass of 40–90 kDa, while the ABC transporters are larger, with 1200–1500 residues and a mass of 140–190 kDa.<sup>10,11</sup> Knowledge of the amino acid sequence can be used to classify transporters by family and subfamily according to the degree of amino acid homology. For example, a transporter protein is assigned to a specific SLC family if it has an amino acid sequence that is at least 20–25% identical to those of other members of that family. A new nomenclature system was recently proposed that is based on the classification of drug-metabolizing enzymes; the transport proteins of a superfamily are arranged in clusters of families ( $\geq 40\%$  identity) and subfamilies ( $\geq 60\%$  identity).<sup>12</sup> Knowledge of the amino acid sequences is also extremely helpful for assessing the effect of a single mutation within the sequence that can induce a change in the conformation of the transport protein and alter its transport functions.

### 5.04.3.3 Transport Kinetics

Transport proteins may have one or more binding sites formed by amino acid sequences of the TMDs or the extracellular loops. Environmental factors, such as the extracellular or intracellular pH or the lipid bilayer fluidity, may influence the transport process. For example, the probability of a solute interacting with a membrane transport protein can depend on the permeability coefficient ( $P_e$ ), which determines how fast a solute diffuses passively across the lipid bilayer. This condition is particularly relevant when solute molecules interact with the transport binding sites of the TMD inserted in the plasma membrane. The higher the  $P_e$  ( $< 10^{-6} \text{ cm s}^{-1}$ ) the lower the probability of the binding site interacting with the substrate because the residence time of the substrate molecules within the membrane space is too short. In contrast, a long substrate residence time within the membrane domain may facilitate the interaction between the transporter and the substrate.

Like drug-metabolizing enzymes, transporters are substrate specific and the kinetics of transport obey the capacity limit rules described by the Michaelis–Menten equation. The influx or efflux flux rate ( $J_{\text{in}}$  or  $J_{\text{ex}}$ ) for a single permeation process mediated by one transporter depends on the affinity of the transporter for its substrate ( $K_m$ ), which is the concentration at the half-maximal transport rate ( $V_{\text{max}}$ ):

$$J_{\text{in}} \text{ or } J_{\text{ex}} = V_{\text{max}} C / (K_m + C) \quad [1]$$

**Figure 4** Transport kinetics: relationships between the transport flux ( $J$ ) and the concentration of substrate  $[S]$  in (a) influx and (b) efflux modes. Multiple components (diffusion and one or more forms of active transport) participate in the overall transport process. Kinetic parameters such as  $K_m$  and  $V_{max}$  ( $J_{max}$ ) can be derived from these plots.

The active process is more often coupled to a passive diffusion component, which is directly, proportional to the substrate concentration by a rate constant ( $k_d$ ) leading to an additional term in eqn [1]:

$$J_{in} \text{ or } J_{ex} = [V_{max}C/(K_m + C)] + k_dC \quad [2]$$

The permeation of a solute through biological membranes may be more complex than that described by the above equations, and results from the combination of several components associating more than one active process with the diffusion component. In this case, the net flux of the transport ( $J_{net}$ ) is calculated by adding all influx components and subtracting the efflux ones:

$$J_{net} = J_{diff} + J_{in} - J_{ex} + \dots \quad [3]$$

This last feature is not simply hypothetical; more and more examples of multicomponent permeation are now known. The impact of all these kinetic processes of varying complexity is illustrated in [Figure 4](#). It can be seen that the superimposing passive diffusion and active influx and/or efflux processes leads to nonlinear relationships between  $J_{net}$  and the substrate concentration. These relationships can be dissected into their diffusion and active component processes. This can be used to calculate the kinetic parameters of active transport ( $K_m$  and  $V_{max}$ ) and to anticipate the risks of permeation saturation in situations such as exposure to a high dose of a drug or following drug–drug interactions.

#### 5.04.4 Transporters in Drug Disposition

This section covers only those transporters that influence the A, D, or E of drugs and xenobiotics. They belong to either the ABC or the SLC superfamilies and are often classified according to the chemical nature of their substrates. Hence, they translocate organic anions or cations, peptides, or nucleosides. Most of them were first named according to their specific chemical substrate, such as the organic cation transporters (OCTs), or the organic anion transporters (OATs), before they were named using the HUGO nomenclature rules. They all have some common general properties: a broad specificity with frequent overlaps of substrate recognition, making them ‘polyspecific transporters,’ and they are present in several body tissues and organs. They frequently differ in the type of energy mechanism that catalyzes the transport reaction.

#### 5.04.4.1 Adenosine Triphosphate-Binding Cassette Transporter Superfamily

The transporters of the ABC superfamily have one of three types of structure, but they all have one or two nucleotide-binding domains (NBDs) (Figure 5). Two sequence motifs located 200 amino acids apart in each NBD, designated Walker A and Walker B, are conserved among all ABC transporter superfamily members. The lysine residue in the Walker A motif is involved in the binding of the  $\beta$ -phosphate of ATP while the aspartic acid residue in the Walker B motif interacts with  $Mg^{2+}$ . An additional element, the signature (C) motif with a highly conserved amino acid sequence, lies just upstream of the Walker B site. The precise function of this sequence has not yet been determined although it is directly implicated in the recognition, binding, and hydrolysis of ATP.<sup>13</sup> The two NBDs are located in the cytoplasm and transfer the energy from ATP hydrolysis to transport the substrate. The main differences between the ABC transporters is in the number of TMDs in the hydrophobic membrane-spanning domain (MSD). The MSD itself consists of several transmembrane  $\alpha$ -helices. The ABC transporters ABCB1 (MDR1) and ABCC4, 5, 8, and 9 (multidrug resistance associated proteins (MRPs)) have a classical 12-TMD body. The structures of ABCC1, 2, 3, 6, and 7 are similar in that they possess two ATP binding sites, but they also contain an additional MSD with five TMDs at the amino-terminal end, giving them a total of 17 TMDs (see Figure 5). At the other extreme, ABCG2, also called a 'half-transporter', contains six TMDs and one ATP binding region on the amino-terminal side, but this half-transporter is thought to homodimerize to form a functional transporter. Most of the ABC transporters in eukaryotes move compounds from the cytoplasm to the outside of the cell or into intracellular organelles, such as the endoplasmic

**Figure 5** Topological models of the best characterized ABC transporters that confer drug resistance and transport drugs and toxicants. (a) The model of MRP1 resembles MRP2, 3; (b) the model of MDR1 (P-gp) resembles MRP4, 5, 8; and (c) the model of BCRP. MSD, membrane-spanning domain; NBD, nucleotide binding domain. Transmembrane  $\alpha$ -helical domains (TMDs) are represented by red rectangular bars; N-glycosylation sites (indicated by branches) are present on extracellular protein loops. Cytoplasmic (in) and extracellular (out) orientations are indicated.

reticulum, mitochondria, and peroxisomes. This means that they are frequently called efflux pumps.<sup>14,15</sup> Phylogenetic analysis has grouped the eukaryotic ABC genes into seven subfamilies (A–G).<sup>7</sup> Only three of these subfamilies, B, C, and G, contain transporters that influence drug disposition. Table 1 shows the main properties of the nine single ABC transporters belonging to these three subfamilies.

#### 5.04.4.1.1 ABCB subfamily

These full transporters include ABCB1 (MDR1), ABCB4 (MDR3), and ABCB11 (sister P-gp or BSEP). ABCB1 is also called P-glycoprotein (P-gp); it is a 170-kDa protein which was the first human ABC transporter cloned and has been shown to be responsible for the multidrug resistance (MDR) phenomenon that occurs with such anticancer agents as the anthracyclines, vinca alkaloids, and taxanes.<sup>16,17</sup> P-gp is the product of two MDR genes in humans, *MDR1* and *MDR2* (also called *MDR3*), and only the MDR1 protein is involved in the MDR phenotype; the human *MDR2* gene functions as a phospholipid translocase at the canalicular membrane of hepatocytes where it is important for the secretion of phosphatidyl choline into the bile. Two genes, *mdr1a* and *1b*, result in a similar MDR phenotype in rodents.

P-gp is present mainly on the apical membrane of many secretory cells, including those of the intestine, liver, kidney, choroid plexus, and adrenal gland. In the placenta, P-gp is found on the apical surface of syncytiotrophoblasts, where it can protect the fetus from toxic xenobiotics. P-gp is also abundant on hematopoietic stem cells, where it may protect the cells from toxins, and on the luminal surface of endothelial cells forming physiological barriers such as the blood–testis barrier and the BBB.<sup>18</sup>

P-gp transports not only antineoplastic agents, but also a wide variety of substrates that are not structurally closely related: they are mostly hydrophobic compounds that are either neutral or positively charged, and are probably presented to the transporter binding sites directly from the lipid bilayer. The range of substrates that P-gp recognizes overlaps with those of the main drug-metabolizing enzymes CYP3A4/5. These enzymes are known to metabolize about 50% of the drugs currently on the market. Immunosuppressive agents (cyclosporin A and its analog PSC833), cardiac glycosides (digoxin), protease inhibitors (saquinavir and indinavir), antibiotics (rifampicin), calcium channel blockers (verapamil), and quinoline (quinidine) have been found to interact with P-gp as both substrates and inhibitors.<sup>19</sup> It is now well accepted that P-gp has several drug-binding domains lying within the TMDs (see 5.32 In Silico Models for Interactions with Transporters). This helps to clarify why so many substrates are transported by P-gp. A complete catalytic cycle includes the hydrolysis of two ATP molecules, but the two events do not occur simultaneously, although both are needed to transport one substrate molecule. The substrate becomes bound to P-gp and the first ATP hydrolysis causes a change in the conformation of P-gp that releases the substrate to either the outer leaflet of membrane or the extracellular space. The second ATP hydrolysis allows the ‘re-set’ of P-gp so that it can bind another molecule of substrate.<sup>20</sup>

The use of P-gp inhibitors to improve bioavailability of P-gp substrate drugs taken orally and their brain penetration has many clinical interests and is not limited to anticancer therapy. Extensive pharmacotherapy programs have tested three generations of chemical inhibitors. The first-generation inhibitors of P-gp were drugs like verapamil and cyclosporin A that act as competitive inhibitors. They failed in clinical application because they were bound poorly by P-gp; this meant that high doses had to be used, and that led to the concomitant inhibition of the main drug-metabolizing enzyme, CYP3A4, and hence pharmacokinetic interactions. The second-generation P-gp inhibitors, like the cyclosporin A analogue valspodar (PSC 833), are more potent but they also inhibit CYP3A4, again limiting their clinical application. The third-generation inhibitors, such as elacridar (GF120918), zosuquidar (LY335979), and tariquidar (XR9576), are more clinically useful as they are potent inhibitors of P-gp and do not interact with CYP3A4.<sup>21</sup>

The combination of P-gp on the apical or luminal membranes of epithelial or endothelial cells with its capacity to extrude compounds from the cell cytosol or to impede their entry into cells makes this transporter a strategic pharmacokinetic effector that limits absorption of a drug by the intestine, its distribution to the brain, testis, placenta, and stem cells, and enhances its elimination in the bile and urine. The pharmacological and toxicological effects of active drug transport by P-gp have been demonstrated in knockout mice that lack one or both of the murine homologs of the genes encoding human MDR1, *Mdr1a*, and *Mdr1b*.<sup>22</sup> The two murine isoforms have approximately 30% amino acid identity with MDR1. Murine P-gps confer resistance to a similar spectrum of anticancer agents as does MDR1. Nevertheless, the two rodent isoforms differ in their tissue distribution. *Mdr1a* is relatively abundant in the BBB, placenta, liver, and kidney, while *Mdr1b* is found in the adrenal gland, uterus, ovary, placenta, liver, and kidney. Studies using the *Mdr1a* or *1b* or *Mdr1a/1b* knockout-mice, which are viable and fertile but more susceptible to developing colitis than wild-type mice, have made a marked contribution to elucidation of the function of P-gp in pharmacology and toxicology.<sup>21</sup>

The discovery in recent years of *MDR1* polymorphisms has amplified the question of the importance of P-gp in the response to drugs and their toxicity in humans. A total of 29 single nucleotide polymorphisms (SNPs) have been reported in the *MDR1* gene.<sup>23</sup> SNPs in exons 26 (C3435T), 21 (G2677T/A), and 12 (C1236T) are the most frequent genotypic combinations and the allele frequencies of the three variant sites differ markedly between populations of

**Table 1** Current human ABC protein, *gene* nomenclature and properties

| <i>Human gene name</i> | <i>Protein name</i> | <i>Common name (aliases)</i> | <i>Predominant substrates</i>   | <i>Transport mode energy source</i> | <i>Tissue distribution (cellular expression)</i>  | <i>Predominant transport impact</i> |

different ethnic origin. The effect of *MDR1* polymorphisms on the pharmacokinetics of drugs such as digoxin, fexofenadine, cyclosporin A, and tacrolimus remains very controversial, but it seems to involve mainly their absorption by the gut.<sup>23</sup> The C3435T SNP is most frequently associated with nortriptyline-induced postural hypotension in patients with major depression who are being treated with nortriptyline and fluoxetine.<sup>24</sup> However, other studies have shown no association between antidepressant-induced respiratory depression and the *MDR1* C3435T variation.<sup>25</sup> These studies are considerably hampered by the lack of *MDR1* haplotype analysis. A recent study by Yi *et al.*<sup>26</sup> examined exons 12, 21, and 26 of the three most frequent SNPs and showed that the distribution of fexofenadine varied considerably among healthy Korean male volunteers. These subjects were allocated to one of six groups, depending on their drug pharmacokinetics. *MDR1* polymorphism may also influence the susceptibility of an individual to diseases. The exon 26 allele is significantly more frequent in subjects with drug-resistant epilepsy, and the same exon seems to protect patients with parkinsonism, especially those with a history of exposure to pesticides (which are frequently substrates of P-gp).<sup>27,28</sup> Additional studies that focus on haplotypes, environmental factors, and patient size and selection are needed to demonstrate just how *MDR1* polymorphisms influence drug pharmacokinetics.

*MDR1* activity can also be altered by a modulation of gene transcription. Transcription of the *MDR1* gene can be modulated by exposure to xenobiotics or mediators of inflammation, as well as by cell stress. The pregnane X receptor (PXR) controls the transcription of *MDR1* and is activated by several steroids, dietary compounds, toxicants, and a number of currently used drugs. PXR regulates several genes encoding phase I and II metabolism enzymes and transporters, like the ABC proteins MRP2 and MRP3 in the liver and intestine.<sup>29</sup> This raises the question of whether there is a coordinated defense system. The body seems to have at least three lines of defense that can be activated in response to xenobiotics. P-gp could be the first reducing the uptake of substrates; phase I and II enzymes producing metabolites could be the second; while the third line of defense could be other transporters, like the MRPs, that excrete the metabolites.

ABCB11 is a second member of this family that can affect drug disposition. This transporter was first reported as the sister of P-gp and called SPGP, or BSEP (bile salt export pump). It is found mainly in the bile canicular membranes and participates in the secretion of bile salts, such as taurocholate, but it can confer resistance to paclitaxel and vinblastine.<sup>30</sup> BSEP appears to be a key target of drug-induced cholestasis, which results in the intracellular accumulation of bile salts, whose detergent actions promote hepatocellular damage by interfering with mitochondrial functions. Cyclosporin A, rifampin, glibenclamide, and bosentan have been shown to inhibit rat BSEP-mediated transport of bile salts.<sup>31</sup> This pump also influences drug absorption by modulating the production of bile salts. These combine with biliary cholesterol and phospholipids to form the micelles that facilitate the solubilization of drugs and their absorption by the intestine.

#### 5.04.4.1.2 ABCC subfamily

Although P-gp is considered to be the major transporter responsible for drug export at the plasma membrane of many cells, MDR phenotypes that are not P-gp-mediated have been linked to several MRPs or ABCCs. The MRP subfamily of proteins was first described in 1992 when Cole and Deeley cloned ABCC1.<sup>32</sup> Other MRPs followed in 1996, and several isoforms of the 12 members of the ABCC subfamily have now been found at various sites in the body. At least four of them, MRP2, 3, 4, 5, and recently MRP8, are likely to be involved in mediating drug resistance and to affect drug pharmacokinetics. Although several molecules are substrates of P-gp when the unconjugated cationic (vincristine and doxorubicin) and neutral (etoposide) compounds are transported, these MRPs preferentially transport anions (like many phase II metabolites of drugs) conjugated to GSH, glucuronate, or sulfate. The MRP4 and MRP5 proteins mainly confer resistance to cyclic nucleosides and purine analogs. They transport substrates by a different mechanism from P-gp; there may even be multiple mechanisms that include co-transport with GSH. All these isoforms are concentrated on specific areas of polarized cells, like the epithelial cells of the gut and kidney, and probably also in the brain microvessel endothelial cells. MRP2 and MRP4 are, like P-gp, found in the apical (luminal) membrane, while MRP1, MRP3, and MRP5 are found in the basolateral (abluminal) membrane.<sup>33,34</sup>

##### 5.04.4.1.2.1 ABCC1 (MRP1)

The 190-kDa MRP1 is the founding member of this subfamily. Despite its modest degree of sequence similarity with P-gp (approximately 15%), MRP1 confers similar degrees of resistance to anthracyclines, vinca alkaloids, camptothecins, and methotrexate, but not to taxanes, which are an important component of the P-gp profile. The substrate specificities of the two pumps differ markedly; MRP1 can transport lipophilic anions, including structurally diverse conjugates of GSH, glucuronate, and sulfate, such as the cysteinyl leukotriene LTC<sub>4</sub>, an important mediator of inflammatory responses, the estradiol 17 $\beta$ -D-glucuronide (E<sub>2</sub>17 $\beta$ GG), and sulfated bile acids. LTC<sub>4</sub> is the substrate for

which MRP1 has the highest affinity, with a  $K_m$  of about 100 nM. The ability of MRP1 to transport GSH conjugates indicates that it is a ubiquitous GS-X pump.<sup>35</sup> The precise mechanism by which GSH participates in MRP1-mediated efflux is still unsettled. At least four different mechanisms have been proposed.

The predominant idea is that GSH is a direct, low-affinity substrate for MRP1, or a co-substrate that allows the co-transport of substrates like vincristine, daunorubicin, and aflatoxin B<sub>1</sub>. Alternatively, GSH may stimulate the transport of certain compounds by MRP1, but is itself not translocated across the membrane. Conversely, GSH transport can be enhanced by certain substances, like verapamil, that are not themselves substrates of MRP1.<sup>35</sup> Thus, the exact mechanism by which GSH is transported and interacts with MRP1 is quite complex. Although there are several potent inhibitors of P-gp, there are only a few inhibitors of MRP1. One of the more potent is the leukotriene antagonist MK571.<sup>36</sup> Indomethacin and the isoflavonoid genestein have been reported to inhibit the transport function of MRP1 *in vitro*.<sup>37</sup> Unfortunately, we have no specific inhibitors for each MRP homolog, so that it is quite possible to misinterpret results obtained using inhibitors in whole-cell systems that contain multiple isoforms of MRP.

The murine ortholog of MRP1, Mrp1, is 88% amino acid identical to human MRP1, but shows some differences in substrate specificity despite this great identity. Mouse and rat Mrp1 confer negligible resistance to anthracyclines compared with the human MRP1.<sup>38</sup> Mrp1 (–/–) knockout mice were developed and found to be viable, healthy, and fertile, but they have altered immune responses that are attributed to decreased LTC<sub>4</sub> secretion.<sup>39,40</sup> Studies on Mrp1 (–/–) mice indicate that Mrp1 is involved in the defense against xenobiotics and the regulation of GSH. The GSH concentration is elevated in the tissues of Mrp1 (–/–) mice that normally contain high concentrations of Mrp1, whereas the GSH concentrations in tissues normally containing little Mrp1 are the same as in those of wild-type mice. The capacity of Mrp1 to function as an *in vivo* resistance factor is supported by the finding that Mrp1-deficient mice are hypersensitive to etoposide and the penetration of etoposide into the cerebrospinal fluid (CSF) is increased 10-fold resulting from the lack of Mrp1 at the choroid plexus.<sup>41</sup>

#### 5.04.4.1.2.2 ABCC2 (MRP2, cMOAT)

Prior to the identification of the MRP2 molecule, this protein was known as the canalicular multispecific organic anion transporter (cMOAT). MRP2 has 48% amino acid identity with MRP1 and lies at the apical membranes of epithelial cells. Its function was deduced from investigations in humans and rats that were genetically deficient in the pump.<sup>42</sup> Dubin–Johnson syndrome, the Sprague–Dawley Eisai hyperbilirubinuric rat (EHBR), the Wistar transport deficient (TR<sup>–</sup>) rat, and Groningen yellow (GY) rats have all been used to assess the role of MRP2 in the excretion of conjugates in the bile.<sup>35</sup> These rat strains have reduced biliary excretion of methotrexate and irinotecan.<sup>43</sup> The drug resistance profile of MRP2 is similar to that of MRP1, but it is less potent. MRP2 also transports uncharged and cationic substrates such as saquinavir, rifampicin, sulfinpyrazone, and ceftriaxone, the flavonoids epicatechin (found in tea) and chrysin, and the meat-derived heterocyclic amine PhIP, a carcinogen with genotoxic properties.<sup>44</sup> The MRP1 inhibitor MK-571 also blocks transport by MRP2. GSH plays a critical role in the MRP2-mediated transport of etoposide, vincristine, and vinblastine, as it does in MRP1, and GSH itself is actively transported into the bile by MRP2. Like MRP1, the transport protein has at least two binding sites that give rise to cooperative binding of substrates or modulators. Thus, the transport of E<sub>2</sub>17βG is stimulated 30-fold by adding sulfamitran and sixfold by adding indomethacin.<sup>45</sup>

High concentrations of MRP2 mRNA are present in the human liver, and lower ones in the duodenum, brain, placenta, and kidney.<sup>46</sup> These findings indicate that MRP2 plays a major role in the hepatobiliary excretion of drugs and conjugates. MRP2 is also an important component of the detoxification system of hepatocytes. Recent immunohistochemical and confocal microscopy studies showed that Mrp2 lies in the luminal membranes of the endothelial cells isolated from the brain capillaries of fish, rats, and pigs.<sup>47</sup> This group also demonstrated that the luminal accumulation of the substrate sulforhodamine 101 was inhibited by other MRP substrates, implicating Mrp2 in the transport of drugs from the brain to blood. MRP2 has also been found in the luminal side of the human BBB and is overproduced in patients with resistant epilepsy.<sup>48</sup> Potschka *et al.*<sup>49</sup> showed that the concentrations of phenytoin and its anticonvulsant activity were significantly higher in the brains of Mrp2-deficient TR<sup>–</sup> rats than in normal rats. The authors suggest that MRP2 is involved, like P-gp, in the efflux of a wide spectrum of drugs, sometimes overlapping with that of P-gp. Thus MRP2 might play an important role in the detoxification and protection of the brain, similar to its action in hepatocytes. MRP2 is most abundant in the duodenum of rats and humans, and its concentration decreases toward the terminal ileum and colon, where there is very little. The production of MRP2 in the duodenum is inducible; it responds to signals from several nuclear receptors, including the retinoid X receptor (RXR), the retinoic acids receptor (RAR), and the farnesoid X receptor (FXR). FXR is also involved in bile acid homeostasis in the liver and gut.<sup>45</sup>

#### 5.04.4.1.2.3 ABCC3 (MRP3, MOAT-D)

MRP3 is the human MRP that is most like MRP1, with 58% of amino acid identity. The concentration of *MRP3* mRNA is high in the liver, duodenum, colon, and adrenal glands, and lower in the lung, kidney, bladder, spleen, and ovary.<sup>46,50</sup> Despite the high concentration of MRP3 transcripts in the liver, the protein concentration is relatively low and *MRP3* immunostaining is found in the bile duct epithelial cells and in the basolateral membrane of hepatocytes.<sup>46</sup> The basolateral membranes of hepatocytes of cholestatic patients and those with Dubin–Johnson syndrome contain high concentrations of MRP3, suggesting that there is a compensatory induction of MRP3 in hepatocytes. MRP3 is mainly a GSH S-conjugate transporter that probably does not transport GSH itself. Its presence in hepatocytes and enterocytes indicates that MRP3 is involved in the enterohepatic circulation of nonsulfated and sulfated bile salts such as glycocholates and taurocholates. Thus MRP3 protects hepatocytes and enterocytes against endogenous bile salts and provides an efflux pump that can compensate for a deficient MRP2. The MRP3 substrate profile overlaps with that of MRP1 and MRP2, but the affinity of MRP3 and its capacity to produce drug resistance are not as great as those of either MRP1 or MRP2. MRP3 has a high affinity for glucuronidated compounds like etoposide-glucuronide, E<sub>2</sub>17βG, and the glucuronides of morphine. A recent study demonstrated that *Mrp3* (–/–) mice are unable to excrete morphine-3-glucuronide (M3G) from the liver into the bloodstream.<sup>51</sup> This results in increased concentrations of M3G in the liver and bile and a 50-fold reduction in its plasma concentration. These data, plus the fact that the expression of MRP3 varies greatly from one human to another because of genetic variations and its induction by other compounds, raise questions about its function, particularly its influence on the differences in the pharmacokinetics and pharmacodynamics of morphine seen among individual patients.<sup>52,53</sup>

#### 5.04.4.1.2.4 ABCC4 (MRP4, MOAT-B), ABCC5 (MRP5, MOAT-C), and ABCC8 (MRP8)

MRP1, 2, and 3 all have a third MSD, but MRP4, 5, and 8 do not (Figure 5). Thus their functions might be distinct from those of the previous members of the MRP family.

MRP4 and MRP5 do not confer resistance to anthracyclines or vinca alkaloids, but transport organic anions like typical MRP1 substrates (E<sub>2</sub>17βG, methotrexate and reduced folates). Both pumps also selectively transport the nucleotides cAMP and cGMP, but the extent to which they influence cyclic nucleotide homeostasis seems to be limited by the highly efficient phosphodiesterase system, and they are probably more effective at mediating the extrusion of cAMP and cGMP.<sup>54</sup> Certain nucleoside analogues, such as PMEA (9-(2-phosphonylmethoxyethyl adenine)), employed in the treatment of hepatitis B, and anticancer derivatives like 6-mercaptopurine (6MP) and 6-thioguanine, are also transported by both pumps. Neither transporter translocates uncharged purine and pyrimidine base analogues, but they do carry their metabolites. For example, 6MP is metabolized to its monophosphate intracellular cytotoxic metabolite, which is effluxed by MRP4 and MRP5. It remains to be determined whether these pumps are induced in treated patients, and if they contribute to the resistance of cells to the anticancer agents used in the maintenance therapy of childhood acute lymphoblastic leukemia or to antivirals such as PMEA and zalcitabine (ddc). GSH appears to be a substrate for both MRP4 and MRP5 and the co-transport of bile salts with GSH has been reported.<sup>55</sup> However, the co-transport mechanism is not necessary for all substrates of MRP4.

MRP4 is found in the lung, kidney, bladder, liver, prostate, testis, ovary, and brain. Although the concentration in the liver appears to be low in most species, a recent study found MRP4/*Mrp4* at the basolateral membrane in human, mouse and rat hepatocytes.<sup>56</sup> Unlike MRP4, MRP5 is ubiquitous, with high concentrations of its mRNA in the brain, skeletal muscle, lung, and heart.<sup>46,50</sup>

The recent development of *mrp4*-deficient mice has shown that the anticancer drug topotecan, an *Mrp4* substrate, accumulates in the brain parenchyma and CSF of these mice.<sup>57</sup> Immunocytochemical analyses showed that *Mrp4* is concentrated at the luminal membrane of the brain capillary endothelial cells and the basolateral membrane of the choroid plexus. This dual distribution of *Mrp4* suggests that *Mrp4* protects the brain from cytotoxins at both BBBs.

The human *MRP8* (*ABCC8*) gene is very similar to *MRP5* and is expressed in various tissues, including the liver and kidney. Like MRP4 and MRP5, MRP8 enhances the extrusion of cyclic nucleotides from cells and confers resistance to nucleoside analogues. LCT4, dehydroepiandrosterone sulfate (DHEAS), E<sub>2</sub>17βG, monoanionic bile salts, and methotrexate were shown recently to be transported by MRP8.<sup>35</sup>

#### 5.04.4.1.3 ABCG subfamily

The members of the ABCG subfamily differ from the more common ABC transporters, like P-gp and MRPs, in that they are half-transporters that are composed of a single NBD followed by one MSD with six transmembrane α-helices. The domains of P-gp and MRP1 are arranged in an opposite fashion, with the MSD followed by the NBD (Figure 5).

The second unique feature of the ABCG proteins is that they may work as homodimers or homo-oligomer or hetero-oligomer held together by disulfide bonds.

There are presently four known human members in the G subfamily: ABCG1, ABCG2, ABCG5, and ABCG8. They are all implicated in lipid transport, except ABCG2, which is important for drug resistance and drug disposition. This transporter was cloned independently by three different groups and called breast cancer resistance protein (BCRP), mitoxantrone-resistance protein (MXR), and placenta-specific ABC protein (ABCP), before it was designated ABCG2.<sup>58–60</sup> This second member of the G subfamily confers resistance to anticancer agents by ensuring their energy-dependent efflux. The drug substrates include anthracyclines, mitoxantrone, the camptothecins, topotecan and irinotecan, and flavopiridol, a flavonoid-like cell cycle inhibitor, but not paclitaxel, cisplatin, or vinca alkaloids. BCRP also actively transports structurally diverse organic molecules, both conjugated and unconjugated, such as SN38, the metabolite of irinotecan and its glucuronide conjugate SN38-G, estrone-3-sulfate, 17 $\beta$ -E<sub>2</sub>G, DHEAS and organic anions like methotrexate.

Hence, BCRP seems to transport sulfated conjugates of steroids and xenobiotics rather than GSH and glucuronide metabolites. Other BCRP substrates include tyrosine kinase inhibitors like imatinib mesylate (Gleevec), which has also been proposed as a potent inhibitor of BCRP, nucleotide reverse transcriptase inhibitors, zidovudine (AZT), its active metabolite AZT5'-monophosphate, lamivudine (3TC), and the proton pump inhibitor pantoprazole.<sup>61</sup> BCRP can transport chemical toxins, in addition to chemotherapeutic agents and conjugated or unconjugated organic anions. These chemicals include pheophorbide a, a breakdown product of dietary chlorophyll that is phototoxic, and the small heterocyclic amine carcinogen PhIP, which induces mammary and prostate cancers. Bcrp1-knockout mice suffer from diet-induced ear phototoxicity that results from accumulation of pheophorbide a in the brain. This occurs because these mice lack the Bcrp1 needed to export pheophorbide a at both the intestine and BBB.<sup>62</sup>

The third-generation P-gp inhibitor, elacridar (GF120918), was recently found to be an efficient inhibitor of human BCRP and mouse Bcrp1. More specific BCRP inhibitors include the fungal toxin derivative fumitremorgin C (FTC); some analogs like KO143 are less toxic than FTC in vivo, but are more potent inhibitors than FTC. Several dietary flavonoids are also potent inhibitors of BCRP. Both 6-prenylchrysin and tectochrysin are more potent inhibitors than elacridar, and are promising new specific inhibitors for the reversal of ABCG2-mediated drug transport.<sup>63</sup> BCRP is found in many hematological malignancies and solid tumors, where it confers resistance to chemotherapeutic agents. BCRP lies primarily in the plasma membrane and at the apical membrane of polarized epithelia, as does P-gp. High concentrations of BCRP are found in the placental syncytiotrophoblasts, the apical membrane of the epithelium of the small intestine, the liver canalicular membrane, and at the luminal surface of the endothelial cells of the brain microvessels that form the BBB. Thus ABCG2 is found mainly in organs that are important for absorption (proximal part of the small intestine), distribution (placenta and the BBB), and elimination (liver and small intestine). Its tissue distribution overlaps considerably that of P-gp.<sup>21</sup>

Orally administered topotecan is much more bioavailable when it is given together with elacridar to either mice or humans. This is due to its more efficient intestinal uptake when BCRP is inhibited by elacridar, and its decreased hepatobiliary excretion since canalicular BCRP is also responsible for excretion into the bile.<sup>64</sup> These data suggest that BCRP plays a major role in drug absorption and elimination.<sup>21</sup> BCRP inhibitors might also be used to improve the penetration of BCRP anticancer drugs into the central nervous system (CNS). BCRP might be an important component of the efflux activity of the BBB. Recent studies of the P-gp and BCRP substrate imatinib in Bcrp1 knockout mice and Mdr1a and Mdr1b double-knockout mice show that BCRP, together with P-gp, is involved in the efflux of imatinib at the BBB.<sup>65</sup> The chemotherapy treatment of primary or metastatic brain tumors could be improved by increasing the distribution of anticancer agents into the CNS by adding P-gp and BCRP inhibitors to the chemotherapy cocktail.<sup>21</sup>

BCRP has been found in stem cells and progenitor cells from the interstitial spaces of mammalian skeletal muscle, human pancreas islets, the human liver and heart, and the hematopoietic compartment.<sup>66</sup> The BCRP in stem cells seems to protect them from cytotoxic substrates; this is consistent with the physiological role attributed to BCRP at other sites in the body. BCRP was also recently shown to secrete drugs or toxins into milk.<sup>67</sup> BCRP lies in the apical membrane of the mammary gland alveolar epithelial cells, at the main site of milk production. It is present in the mammary glands of mice, cows, and humans and its concentration increases greatly during late pregnancy, and particularly during lactation in mice. The milk-to-plasma ratios of several drugs, such as aciclovir, cimetidine, and nitrofurantoin, were found to be high even before they were known to be BCRP substrates.<sup>68</sup> Experimental studies with wild-type and Bcrp1 knockout mice have demonstrated that topotecan, the PhIP carcinogen and the hepatocarcinogen aflatoxin B1 become concentrated in milk.<sup>66</sup> As the substrates transported by mouse and human BCRP are very similar, various types of compounds, such as drugs, pesticides, and carcinogens, are very likely to be concentrated in milk, placing infants and consumers of dairy products at risk of dangerously increased exposure. The secretion of xenobiotics into milk by BCRP is puzzling because this function exposes the suckling infant to a range of

drugs and toxins. BCRP appears to protect against xenobiotics everywhere else in the body. Its physiological function in the mammary gland remains intriguing.

BCRP seems to have a large number of polymorphic variants, unlike other ABC proteins, and these may yield important functional differences. The first cloned *BCRP* cDNA was later found to encode a mutant BCRP that deviated from the 'wild type' BCRP at Arg 482 (R482); it was replaced by either threonine (R482T) or glycine (R482G). Mutations in BCRP alter its capacity to transport doxorubicin, rhodamine 123, topotecan, and methotrexate, but not the transport of mitoxantrone.<sup>69</sup> However, these mutants have only been detected in cell lines overexpressing BCRP, and never in any normal human population or cancer specimens. Since the oral bioavailability and clearance of drugs that are BCRP substrates, such as topotecan, varies greatly from one individual to another, analysis of the *BCRP* gene for SNPs can provide interesting data. Several mutations have been identified in the coding region of *BCRP* from healthy individuals and patients.<sup>69</sup> Two of them, V12M and Q141 K, are polymorphic in several populations, with significant differences in allele frequencies between different populations around the world. The allele Q141 K is most frequent in Asian populations (approximately 30–60%) and relatively rare in Caucasians and African-Americans (approximately 5–10%). This variant of BCRP is less abundant at the plasma membrane of transfected cells, and therefore confers lower resistance to drugs than the wild-type protein.<sup>69,70</sup> A recent clinical study correlated the Q141 K polymorphism with changes in the pharmacokinetic properties of diflomotecan. The plasma concentrations of diflomotecan in five heterozygote patients were much higher (299%) than those of 15 patients with wild-type alleles, while 11 known variants in the *ABCB1*, *ABCC2*, *CYP3A4*, and *CYP3A5* genes did not affect diflomotecan disposition.<sup>71</sup>

Thus, BCRP can transport a structurally and functionally wide range of organic substrates, and this range overlaps extensively with those of P-gp, MRP1, and MRP2. The tissue distribution of BCRP varies greatly, but overlaps that of P-gp. We infer from this that BCRP has a very similar role to P-gp in the pharmacology and toxicology of substrates.

#### 5.04.4.2 Solute Carrier Transporter Superfamily

While the transporters of the ABC superfamily are mainly concerned with the efflux of substrates from cells, the transporters of the second superfamily, the SLCs, are influx transporters. Unlike the ABC transporters, the physiological roles of which are seldom clearly understood, the SLC proteins are indispensable for the uptake of many essential nutrients by cells. They also play a critical role in the absorption, excretion and toxicity of many xenobiotics. Several inherited diseases, like the glucose-galactose and bile acid malabsorption syndromes, are attributed to mutations of SLC transporters.<sup>72,73</sup>

A total of 362 mammalian genes have, to date, been assigned to the SLC superfamily, divided into 46 families.<sup>8a</sup> The system for naming members of the SLC superfamily differs somewhat from the ABC nomenclature. The genes are usually named using the root symbol *SLC*, followed by a number corresponding to the family (e.g., *SLC22*, solute carrier family 22), the letter A, and finally the number of the individual transporter (e.g., *SLC22A2*). But there may be differences between families. The *SLC21* family encoding the organic anion transporting proteins (OATPs) has been reclassified as a superfamily with families and subfamilies much like the classification of drug-metabolizing enzymes. The gene symbol then becomes *SLCO* (i.e., the '21' and the 'A' have been replaced by the letter 'O' for organic transporter) and the 'OATP' symbol has been kept for protein nomenclature (e.g., *SLCO1A2* for the gene and OATP1A2 for the protein).

Tables 2–6 list the main characteristics of many of the SLC proteins implicated in pharmacology and toxicology. The *SLC21* and *SLC22* families contain several members that transport a variety of structurally diverse organic anions, cations, and uncharged compounds. Most of the members of the *SLC21* family of OATPs transport anionic amphipathic compounds. The *SLC22* family includes OCTs, the carnitine OCTs novel type (OCTNs), the urate anion-exchanger (URAT1), and several OATs. Other families that may be involved in pharmacology and toxicology include transporters with more restricted substrate specificities. These include the hexose transporters (*SLC2* and *SLC5*), the amino acid (*SLC7*) transporters, which may be used for drug delivery, and the *SLC16* that transport monocarboxylic acids. The main transporters include the *SLC15* proteins that carry di- and tripeptides, and the *SLC28* and *SLC29* proteins that transport nucleoside analogues.

##### 5.04.4.2.1 OATP (*SLC21/SLCO*) transporters

The nomenclature of the OATP is the most confusing of all the drug transporter families because different names have been coined for individual proteins and no orthologous human *OATP* genes have been identified for many rodent *Oatp* genes, indicating no one-to-one relationship between rodent Oatps and human OATPs. All Oatps/OATPs contain 12 TMDs; their structural features include a large extracellular domain between TMDs 9 and 10, *N*-glycosylation sites in

CT, carnitine transporter; EMT, extraneuronal monoamine transporter.

the extracellular loops 2 and 5, and the OATP ‘superfamily signature’ at the border between extracellular loop 3 and TMD6 (**Figure 6**); 13 rat, 11 mouse, and 11 human Oatps/OATPs have been identified to date. The amino acid contents of the mammalian proteins are 31–82% identical, and these similarities have been used to arrange individual proteins into families and subfamilies. The amino acid profiles of the rat, mouse, and human OATP-3 proteins (r Oatp11, m Oatp11, and OATP3A1) are almost identical (97% and 98%).<sup>12</sup>

The OATPs were originally characterized as uptake transporters, although some may function primarily for efflux.<sup>74</sup> The driving force for OATP-mediated transport is still not clear, but it is independent of ATP or sodium gradients. There is experimental evidence that bidirectional transmembrane transport can be mediated by anion (HCO<sub>3</sub><sup>−</sup>) or GSH exchange. The GSH gradient may be a powerful driving force. It is due to the high intracellular GSH concentration (approximately 10 mM), the low extracellular concentration (approximately 0.01 mM), the negative charge on GSH at physiological pH, and the negative intracellular potential (−30 to −60 mV).<sup>75</sup> This is well documented for rat Oatp 1 and Oatp 2, but many other OATPs remain to be checked. Oatp 1 (Oatp1a1) was first cloned as a bromosulphophthalein (BSP) and taurocholate uptake system of the rat liver. It has now been shown that many OATPs are polyspecific OATs with partially overlapping substrate specificities for a wide range of solutes, including bile salts, organic dyes (BSP), steroid conjugates (DHEAS, 17βE<sub>2</sub>G estrone-3-sulfate (E-3-S)), thyroid hormones, neuroactive peptides ((D-penicillamine-2,5) enkephalin (DPDPE), Leu-enkephalin and deltorphin II), and numerous drugs and toxins such as the cardiotonic digoxin, the angiotensin-converting enzyme inhibitors enalapril and temocaprilat, and the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor pravastatin (**Table 2**). OATP substrates are mainly high molecular weight (> 450 Da) amphiphatic molecules, mostly bound to albumin, that have a steroid nucleus or linear and cyclic peptides.<sup>76</sup> Most OATPs, mainly those of the OATP1 family, are found in many tissues and though to be part of the overall body detoxification system, helping to remove xenobiotics from the systemic circulation (e.g., drug uptake into hepatocytes). Others, those of families 2–4, may act more specifically in selected organs, such as transporting thyroid hormones or steroids. The rat Oatp1a1, Oatp1a4, and Oatp1b2, and human OATP1B3, OATP1B1, and OATP2B1 are found in the sinusoid membrane of hepatocytes, where they are responsible for the uptake of xenobiotics for hepatic clearance. The hepatic OATPs may have a strategic role in

NLT, novel liver-specific transporter; PAH, *p*-aminohippurate transporter; RST, renal-specific transporter.

drug–drug interactions and hepatotoxicity. For example, rifampicin is a potent inhibitor of both OATP transporters and CYP3A4. Thus giving it together with OATP substrates may reduce hepatic first-pass clearance and increase the bioavailability and decrease the efficacy of an intrahepatically active drug like pravastatin.<sup>77</sup> On the other hand, induction of *OATP* gene expression could increase the hepatic uptake and the total body clearance of the substrate. Expression of the rat *Slco1a4* gene is induced by phenobarbital and pregnenolone-16 $\alpha$ -carbonitrile (PCN), a well-known inducer of CYP3A4, via the PXR nuclear receptor pathway.<sup>72</sup>

OATPs have also been found at the two brain–blood interfaces. Oatp1a4 and OATP1A2 were found at the luminal and abluminal membranes of the BBB, where they could mediate the efflux of conjugated metabolites and the brain uptake of drugs like digoxin and DPDPE.<sup>72</sup> Oatp1a1 and Oatp1a4 are present in the epithelium of the rat choroid plexus, Oatp1a1 at the apical membrane and Oatp1a4 at the basolateral membrane, where they can account for the secretion of GSH and the removal of LTC4 from the CSF and the uptake of thyroid hormones into the brain.

Only a few OATPs (rat Oatp1a1 and OAT-K1/2, human OATP1A2 and OATP4C1) have been found in the kidney, where they could be responsible for the reabsorption of organic anions.<sup>76,78</sup> The human proteins OATP2B1, OATP3A1, and OATP4A1 and the rat transporters Oatp2b1 and Oatp4a1 have been found at the trophoblast epithelium between the fetal and maternal circulations. The OATP system may facilitate the transport of bile acids and steroid hormones, which are extensively synthesized by the fetal liver in utero, across the trophoblast epithelium from the fetus to the maternal circulation.<sup>79</sup>

No Oatp knockout mice have yet been generated, but studies on several disease models, such as cholestatic liver diseases or cholate feeding, have shown downregulation of hepatocellular *Oatps*. Hence, the loss of basolateral hepatocellular Oatps during cholestasis and massive liver regeneration can explain the impaired transport under these pathological conditions.

#### 5.04.4.2.2 OCT (*SLC22*) transporters

The OCTs of the human *SLC22* family include three potential sensitive proteins (OCT1, OCT2, and OCT3) and three H<sup>+</sup>-driven transporters of carnitine and/or cations (OCTN1, OCTN2, and CT2, also known as *SLC22A4*, *SLC22A5*, and either *FLIPT2* or *SLC22A16*, respectively). Like most members of the *SLC22* family they have 12 TMDs. The amino and carboxyl termini are cytoplasmic and the proteins have glycosylated extracellular loops and intracellular loops that contain phosphorylation sites (Figure 6).

OCT1 and OCT2 were originally cloned from the rat kidney<sup>80,81</sup>; the human homologs were then isolated and OCT3 cloned.<sup>82</sup> Both OCT1 and OCT2 lie in the basolateral membranes of epithelial cells, but there is no conclusive evidence as to whether OCT3 is located in the basolateral or apical membrane of polarized cells. The substrate and inhibitor specificities of OCT1, OCT2, and OCT3 overlap extensively, but the OCT subtypes differ significantly in their affinity and maximal transport rates. All three OCTs recognize a variety of organic cations (OCs), including endogenous bioactive amines such as acetylcholine, choline, epinephrine, norepinephrine, dopamine, and serotonin, and drugs like cimetidine, quinine, quinidine, prazosin, desipramine, verapamil, and morphine. Some uncharged compounds and anions are also transported, such as some anionic prostaglandins.<sup>83</sup> The nitrogen moiety of the weak bases bears a net positive charge at physiological pH, allowing electrostatic interaction with the binding sites of the OCTs. The ‘type 1’ and ‘type 2’ classifications of OCs were developed to study their uptake by the liver.<sup>84</sup> Type 1 OCs are small (60–350 Da), monovalent, hydrophilic compounds such as tetraethylammonium (TEA) and the parkinsonian neurotoxin 1-methyl-4-phenyl pyridinium (MPP<sup>+</sup>). In contrast, type 2 OCs are usually bulkier (>500 Da; e.g., anthracyclines) and polyvalent (e.g., d-tubocurarine). This classification helps to differentiate the mechanisms by which they are transported across polarized cells. Type 2 OCs are believed to diffuse across the basolateral membrane and to be exported across the apical membrane by MDR1. In contrast, the basolateral entry of type 1 OCs involves one or more transporters, including OCT1, 2, and 3, and their efflux at the apex may be mediated by OCTN 1 and 2.<sup>85</sup> The OCTs generally mediate bidirectional transport of substrate molecules, and this depends mainly on the membrane potential and not directly on the transmembrane gradients of Na<sup>+</sup> or H<sup>+</sup>. There is thus an electrogenic facilitated diffusion of the monovalent cations in a direction that is defined by the prevailing electrical and chemical (i.e., substrate concentration) gradients across the membrane.<sup>86</sup>

Both OCT1 and OCT2 are found primarily in the major excretory organs (the kidney and the liver) and to a lesser extent in the intestine and the brain. OCT1 is highly species-specific. Human OCT1 is most abundant in the liver, where it mediates the uptake of type1 OCs across the sinusoidal membrane of hepatocytes; it is less abundant in the

ND, not determined; SPNT, sodium-dependent purine nucleoside transporter.

intestine and kidney, where it is less than 1% of that of OCT2.<sup>85</sup> There is enough OCT1 in the kidneys of rats, mice, and rabbits for it to play a significant role in substrate transport. OCT2 is mainly found in the kidneys of rats and humans. The amount of OCT2 in the kidney depends on gender and age. The kidneys of males contain more *oct2* mRNA and protein than do those of females, whereas the concentrations of OCT2 in young male and female rats are similar.<sup>87</sup> Although the physiological relevance of this gender dimorphism is unknown, it might be responsible for differences in the renal elimination of OCs and responses and sensitivity to drugs. OCT2 is also present at the choroid plexus and in various dopamine-rich regions of the brain (substantia nigra, nucleus accumbens, and striatum), where it might act as a ‘background’ transporter in the removal of monoamine neurotransmitters that have escaped reuptake by high-affinity monoamine transporters.<sup>83</sup>

OCT3, unlike OCT1 and OCT2, is much more widely distributed. *hOCT3* mRNA has been detected in the aorta, skeletal muscle, prostate, adrenal gland, and placenta.<sup>88</sup> OCT3 is also abundant in the mammalian brain, where it has been identified as an extraneuronal monoamine transporter like OCT2.<sup>89</sup> OCT3 also plays a very limited role in the transport of type 1 OCs (TEA) in the human and rodent kidney. Nevertheless, OCT3 seems to play a significant role in the handling of amantadine, a putative dopaminergic compound, by the rat and rabbit kidneys.<sup>86</sup>

The quantitative significance of the OCTs in drug pharmacokinetics was clearly established in studies with mice lacking the three Ocs. All three knockout strains are viable, fertile, and display no physiological abnormalities.<sup>83</sup> However, the knockout of Ocs markedly affects the pharmacokinetics of OC substrates. For example, the knockout of both Oct1 and Oct2 transporters eliminates the renal tubular secretion of TEA and reduces the hepatic uptake and clearance of TEA by about 80% in the Oct1 knockout mice due to the lack of Oct1 at the sinusoidal membrane of the hepatocytes.<sup>89</sup> The intestinal secretion of TEA is reduced by about 50%, indicating that Oct1 also mediates the basolateral uptake of TEA into enterocytes. Similar observations were made with the liver uptake of several biguanides (metformin and buformin); these antidiabetes drugs are sometimes responsible for lactic acidosis. The accumulation of metformin in the liver was

**Figure 6** Topological models of the human *SLC22*; (a) organic cation transporters (OCT), organic anion transporters (OAT), and *SLCO*; (b) the organic anion polypeptide transporter (OATP). Features common to all members of the OCT, OAT, OATP transporter family include 12 transmembrane-spanning domains (TMDs) with intracellular amino and carboxyl termini. Transmembrane  $\alpha$ -helical domains (TMD) indicated by red rectangular bars; *N*-glycosylation sites (indicated by branches) are present on extracellular protein loops. Cytoplasmic (*in*) and extracellular (*out*) orientations are indicated.

more than 30-fold lower than in wild-type mice. The metformin-induced blood lactate concentration is also decreased in the knockout mice, suggesting that Oct1 is involved in the hepatotoxicity of biguanides.<sup>90</sup>

The OCTNs differ markedly in their mode of action, unlike the OCTs, which have a common energy-supply mechanism (Table 3). OCTN1 supports electroneutral OC/H<sup>+</sup> exchange, OCTN2 supports both Na<sup>+</sup>-dependent co-transport (e.g., carnitine) and electrogenic-facilitated diffusion (e.g., TEA and type 1 OCs), and OCTN3 mediates the electrogenic transport of carnitine. OCTN3 and CT2 are present only in the testes of mice and humans,<sup>91</sup> where transported carnitine improves sperm quality and fertility. OCTN1 and OCTN2 were originally cloned from human fetal liver and placenta.<sup>92,93</sup> OCTN1 is most abundant in the kidney (at the apical membrane of the tubular cells), small intestine, bone marrow, and fetal liver (but not in the adult liver).<sup>92</sup> OCTN2 is mainly found in the heart, placenta, skeletal muscle, kidney, and pancreas.<sup>93</sup> Both OCTN1 and OCTN2 have a low affinity for MPP<sup>+</sup>, cimetidine, and TEA, and OCTN2 plays a major role in carnitine homeostasis.<sup>85,93</sup>

#### 5.04.4.2.3 OAT (*SLC22*) transporters

As their name implies, small organic anions (300–500 Da) possess a net negative charge at physiological pH and their transepithelial transport into the negatively charged environment of the cell requires energy. This is largely to the OATs (*SLC22* family) that are found mainly in cells playing a critical role in the excretion and detoxification of xenobiotics. The OAT family contains six members (OAT1, OAT2, OAT3, OAT4, OAT5, and URAT1), present mainly in the liver, kidney, placenta, brain capillaries, and choroid plexus (Table 4). Their topological structures are very similar to those of the OCTs (Figure 6), but they have more complex energy requirements.<sup>94</sup> The members of the OAT1, OAT2, and OAT3 group form a tertiary active system, with the first driving element being a Na<sup>+</sup> gradient furnished by the Na<sup>+</sup>,

K<sup>+</sup>-ATPase pump. The inward movement of Na<sup>+</sup> drives the uptake of dicarboxylate  $\alpha$ -ketoglutarate ( $\alpha$ -KG) by a second transport protein, the Na<sup>+</sup>/dicarboxylate co-transporter 3 (NaDC3). This, in conjunction with mitochondrial  $\alpha$ -KG production, maintains an outward  $\alpha$ -KG gradient.<sup>95</sup> Finally, the third transporter in the chain is one of the three OATs; it functions like an  $\alpha$ -KG/organic anion exchanger for translocation of organic anion substrates into the cell. This differs slightly from the mechanism depicted in Figure 3. As a result, a negatively charged molecule can enter the cell against its chemical concentration gradient and the negative electrical potential of the cell. While these three OATs are present at the basolateral membrane and function mainly as influx systems, OAT4 and URAT1 are found at the cell apex and may function as either Na<sup>+</sup>-independent organic anion exchangers or membrane potential-facilitators allowing the bidirectional transport of organic anions.<sup>96</sup>

The first OAT, rat and mouse Oat1, was cloned by several groups in 1997, and its orthologs were subsequently isolated from the kidneys of rabbits, humans, and pigs.<sup>97</sup> OAT1 is mainly a kidney-specific transporter, found at the basolateral membrane of the renal proximal tubular cells. OAT1 was earlier known as the *p*-aminohippurate (PAH) transporter. As PAH is almost completely extracted during a single pass through the kidney, it has been used as the prototypical substrate for the renal organic anion transport system and as a biological marker of renal plasma flow, which is equal to the renal clearance of PAH.<sup>98</sup>

OAT2 was originally isolated from the rat liver as a novel liver-specific transporter (NLT) labeling the sinusoidal membrane of rat hepatocytes; it was later found in the kidney and choroid plexus.<sup>95</sup> The concentration of Oat2 is higher in the kidney than in the liver of female rats, but the concentrations are reversed in male rats. *OAT3* gene expression has been detected in mammalian kidneys and in the apical membrane of the choroid plexus and basolateral membrane of the endothelial cells at the BBB from rodents. No orthologs of human OAT4 have been identified. OAT4 is present in the kidney, liver, and placenta.<sup>96</sup> Oat5 is the first rodent Oat to be detected in the kidney, but not in the choroid plexus, in marked contrast to Oat1, Oat2, and Oat3. URAT1 is expressed in the luminal membrane of the kidney proximal tubules, and was originally identified in the mouse as a renal specific transporter (RST). URAT1 is involved in renal reabsorption of urate and helps to maintain blood levels of uric acid. It is the *in vivo* target for the uricosuric acid drugs probenecid and benzbromarone and the antiuricosuric acid drug pyrazinamide.<sup>96</sup>

The OAT proteins play a critical role in the excretion and detoxification of a wide variety of drugs, toxins, hormones, and neurotransmitter metabolites. Uremic toxins, which accumulate in the blood during chronic renal failure, inhibit renal transport, hepatic drug metabolism and serum protein binding. Several uremic toxins (indoxyl sulfate, indoleacetic acid, hippuric acid, etc.) are substrates or inhibitors of both rat and human OAT1 and OAT3; this could explain changes in the pharmacokinetics of other OAT substrates, including drugs.<sup>96</sup> Several acidic metabolites of neurotransmitters are excreted into the CSF via OAT transporters, which is consistent with the presence of OATs in the choroid plexus. A number of common nonsteroidal anti-inflammatory drugs (NSAIDs), including acetyl salicylate and salicylate, acetaminophen, diclofenac, ibuprofen, ketoprofen, indomethacin, and naproxen, are substrates of one or more OAT isoforms, so that there can be significant interactions between NSAIDs and other drugs. The  $\beta$ -lactam antibiotics (penicillins, cephalosporins, and penems) and the antiviral nucleosides adefovir, cidofovir, aciclovir, and AZT are also substrates of one or more OAT isoforms and are actively excreted in the urine.<sup>98</sup> Toxins like chlorinated phenoxyacetic acid herbicides, mercuric conjugates, cadmium, and ochratoxin A are also transported either into renal tubular or hepatocyte cells via the OAT network, and this predisposes these tissues to nephrotoxicity or hepatotoxicity.<sup>95</sup>

#### 5.04.4.2.4 PEPT1 (*SLC15A1*) and PEPT2 (*SLC15A2*) transporters

Peptide transporters 1 and 2 (PEPT1 and PEPT2, *SLC15A1* and *SLC15A2*, respectively) are H<sup>+</sup>-coupled oligopeptide symporters (Figure 3) whose predicted membrane topology anticipates the 12 TMDs of the SLC family (Figure 6). More recently, two new type 1 (PHT1, *SLC15A4*) and type 2 (PHT2, *SLC15A3*) peptide/histidine transporters have been identified in mammals. PEPT1 and PEPT2 translocate dipeptides and tripeptides produced by protein catabolism. Considering all possible combinations, they can transport 400 dipeptides and 8000 tripeptides derived from the 20 L- $\alpha$  amino acids present in proteins.<sup>99</sup> Their pharmacological importance results from their ability to transport a wide variety of peptide-mimetic drugs, such as  $\beta$ -lactam antibiotics of the cephalosporin and penicillin classes and drugs like captopril, enalapril, and fosinopril. Other drugs include the dopamine D2 receptor antagonist sulpiride and the peptidase inhibitor bestatin.<sup>99</sup> PHT1 and PHT2 transport histidine and certain di- and tripeptides, but their location on the cell or lysosomal membranes remains as questionable as their implication in pharmacotherapy.<sup>100</sup> PEPT1 and PEPT2 differ in their transport properties and tissue distributions (Table 5). PEPT1 is the low-affinity (millimolar range), high-capacity transporter that is mainly found in the apical membranes of enterocytes in the small intestine, in renal proximal tubular cells of the S1 segment, and in bile duct epithelial cells. In contrast, PEPT2 is a high-affinity (micromolar range), low-capacity transporter that is more widely distributed in the apical membranes of

kidney tubular cells of the S2 and S3 segments, brain astrocytes, and epithelial cells of the choroid plexus. They are involved in the uptake of their substrates, leaving a basal transporter(s) to account for the exit. This basal transporter could be PHT1 and/or PHT2, or the amino acid transporters of the *SLC1* and *SLC7* families.<sup>99</sup> Both PEPT1 and PEPT2 can mediate the renal reabsorption of the filtered compounds in kidney tubules, whereas PEPT2 may be responsible for the removal of brain-derived peptide substrates from the CSF via the choroid plexus.<sup>101</sup> Recent studies on *pept2*-deficient mice (which are viable and have no kidney or brain abnormalities) have confirmed that Pept2 is involved in the uptake role of peptides into the cells of the choroid plexus and the proximal tubule.<sup>102</sup> The pharmaceutical relevance of these peptide transporters is closely linked to the design of drug delivery strategies mediated by the intestinal PEPT1. One successful approach has been to produce peptide derivatives of parent compounds as substrates for PEPT1. The pharmacophoric pattern for the transporter includes the rules that the peptide bond is not a prerequisite for a substrate and that 5' amino acid esterification, mostly using L-valine or L-alanine, markedly improves recognition by PEPT1.<sup>103</sup> This prodrug strategy was used to improve the bioavailability of oral enalapril from 3–12% to 60–70% for the ester enalaprilat, which resembles the structure of the tripeptide Phe-Ala-Pro. The oral bioavailability of the nucleoside antiviral aciclovir (22%) was similarly improved by adding a valine residue to give valaciclovir (70%).<sup>103</sup> Current studies on the regulation of PEPT1 and PEPT2 synthesis in inflammatory intestinal diseases may provide helpful information on the variations in bioavailability of oral PEPT1 drug substrates.<sup>99</sup>

#### 5.04.4.2.5 CNT (*SLC28*) and ENT (*SLC29*) transporters

The members of the human *SLC28* and *29* families catalyze mainly the transport of purine and pyrimidine nucleosides.<sup>104</sup> The hydrophilic nucleosides, like the purine adenosine, are important signaling molecules that control both neurotransmission and cardiovascular activity. They are also precursors of nucleotides, the constitutive elements of DNA and RNA, and are the basic elements of a variety of antineoplastic and antiviral drugs. The *SLC28* proteins in the apical membranes of polarized cells work in tandem with the *SLC29* proteins found in the basolateral membrane. Thus, the members of these two families are critical for the transepithelial transport of nucleosides – they form a coordinated transport system.

The *SLC28* family consists of three dependent concentrative nucleoside transporters, CNT1, CNT2, and CNT3 (*SLC28A1*, *SLC28A2*, and *SLC28A3*, respectively). They co-transport Na<sup>+</sup> and the substrate in a symporter mode and are considered to be a high-affinity, low-capacity transporter.<sup>105</sup> The members of the *SLC28* family have 13 TMDs, unlike the 12 TMDs of most of the SLC, with the Na<sup>+</sup> and substrate recognition sites in the carboxyl half of the protein. The three subtypes differ in their substrate specificities. CNT1 transports naturally occurring pyrimidine nucleosides plus the purine adenosine. Several antiviral analogues, like AZT, lamivudine (3TC), and ddC, are substrates of CNT1. The cytotoxic cytidine analogues, cytarabine (AraC) and gemcitabine (dFdC) are also transported by CNT1.<sup>106</sup> CNT1 is primarily found at the apical membrane in epithelial tissues including the small intestine, kidney, and liver (Table 6).

Human CNT2 is widely distributed in the kidney, liver, heart, brain, intestine, skeletal muscle, pancreas, and placenta. CNT2 transports purine nucleosides and uridine. Pharmaceutical substrates include the antiviral didanosine (ddI) and ribavirin.<sup>107</sup>

Human CNT3 has, like CNT2, a wide tissue distribution with high concentrations in the pancreas, bone marrow, and mammary gland. CNT3 is broadly selective and transports both purine and pyrimidine nucleosides in a 2:1 Na<sup>+</sup>/nucleoside coupling ratio, in contrast to the 1:1 ratio employed by CNT1 and CNT2. CNT3 transports several anticancer nucleoside analogues, including cladribine, dFdC, fludarabine, and zebularine.<sup>108</sup>

A number of coding region SNPs have been reported for human CNT1 and CNT2,<sup>108a</sup> and the determination of their function is an important goal for future investigations.<sup>105</sup>

The human *SLC29* family contains four members. These equilibrative nucleoside transporters (ENTs) include the well-characterized, low-affinity facilitators ENT1 (*SLC29A1*) and ENT2 (*SLC29A2*), but the cation-dependence, and the tissue and subcellular distribution of ENT3 have not yet been fully evaluated. The ENT proteins have 11 TMDs, in which the amino-terminus is in the cytoplasm and the carboxyl-terminus is extracellular. ENT1 and ENT2 can both transport adenosine, but differ in their abilities to transport other nucleosides and nucleobases.<sup>109</sup> ENT1 is almost ubiquitously distributed in human and rodent tissues and transports purine and pyrimidine nucleosides with *K<sub>m</sub>* values of 50 μM (adenoside) to 680 μM (cytidine). The antiviral drugs ddC and ddI are also poorly transported.<sup>110</sup> ENT2 is present in a wide range of tissues, including the brain, heart, pancreas, prostate, and kidney, and is particularly abundant in skeletal muscle. ENT2 differs from ENT1 in that it can also transport nucleobases like hypoxanthine and AZT.<sup>111</sup> ENTs also mediate the uptake and efflux of several nucleoside drugs because of their bidirectional transport property. Selective inhibition of ENTs may be a strategy for improving therapy with nucleoside drugs. For example, the vasodilator drafazine increases and prolongs the cardiovascular effects of adenosine by inhibiting nucleoside uptake into endothelial cells. Dipyridamole, dilazep, and imatinib all selectively inhibit ENTs and modulate the toxic or therapeutic effects of the endogenous nucleosides.<sup>104</sup>

## 5.04.5 Expression and Function Properties of Transporters in Tissues

About 40 transporters belonging to the ABC and SLC superfamilies are presently known to influence the pharmacokinetics, pharmacodynamics, and toxicity of drugs and xenobiotics. While there are still many gaps in our knowledge of the function of transporters, it is possible to outline their main properties.

### 5.04.5.1 Transporters at the Plasma Membrane and Within Cells

There are about 200 different types of cells in human tissues, and all their plasma membranes and the membranes of their organelles contain transporters. As outlined above, they can import or export endogenous and exogenous compounds, thereby regulating intracellular ions and essential nutrients and controlling the traffic of exogenous compounds into, from, and within cells. They are thus the fundamental effectors of physiological and pharmacological processes. The drug transporters at the organelles may well become most important in future studies. This was recently documented during a dramatic phase II trial in which the nucleoside antiviral fialuridine (FIAU) caused the death of subjects as a result of severe toxicity, including hepatotoxicity, pancreatitis, neuropathy, or myopathy.<sup>112</sup> These toxic events were clearly linked to mitochondrial damage due to the inactivation of the mitochondrial DNA polymerase  $\gamma$  by FIAU or its triphosphorylated metabolite. Before this can happen, FIAU must be transported into the cytosol, and then it, or its phosphorylated metabolite, must be transported into the mitochondria. Molecular and imaging techniques were used to show that FIAU is transported by ENT1, which is located in both the plasma and mitochondria membranes, but not in the nuclear envelope, endosomes, lysosomes or Golgi complex. But the mitochondrial membranes of rodents do not contain Ent1, and they are not affected by this toxic action. This variation in FIAU toxicity and ENT1 expression between species dramatically highlights the inability of preclinical studies on rodents to predict the toxicity of nucleoside analogs for human mitochondria. It also shows how the toxicity of antiviral drugs like AZT, stavudine, and ddI for mitochondria is linked to the role of a transporter.<sup>112</sup>

### 5.04.5.2 Tissue Specificity

The distribution of certain transporters may be restricted to a limited range of cells or tissues. Thus, MRP2, and MRP3, OCT1, and OATPs are mainly found in the liver, while OAT1 is restricted to the kidney. In contrast others, like MRP1, the CNTs, and ENTs, are ubiquitous, being present throughout the human body. This indicates that the transporters with a limited distribution are more specialized. For example, MRP2 and MRP3 are concerned with the export of conjugated metabolites from hepatocytes, while the ubiquitous transporters are implicated in essential physiological functions such as the export of LTC<sub>4</sub> and GSH (MRP1) and uptake of nucleosides (CNTs and ENTs), and their influence on pharmacokinetics may be less organ-specific.<sup>35,104</sup>

### 5.04.5.3 Polarized Cellular Distribution

The cellular location of transporters at the plasma membrane is a critical issue because most of the cells involved in the A, D, and E pharmacokinetic processes are polarized. Hence their apical (luminal) and basolateral (abluminal) membranes do not have the same populations of transporters. The same transporter is found at both the apical and basolateral membranes in only a few cases. Good examples are the glucose transporter GLUT1 (*SLC2*) and the monocarboxylic transporter MCT1 (*SLC7*), and they ensure the efficient transepithelial transport of their substrates.<sup>8</sup> However, most of the ABC and SLC transporters are found at either the apical or the basolateral epithelial membranes, and their location helps define the direction of substrate transport and the resulting pharmacokinetic event. Efflux transporters are usually found in the apical membrane of epithelial cells, where their main function is to reduce the uptake of substrates. Most of the ABC efflux transporters (P-gp, BCRP, MRP2, and MRP4) lie in the apical membrane, although MRP1, MRP3, and MRP5 are more usually found in basolateral membranes.<sup>55</sup> In contrast, influx transporters are more equally distributed on both apical and basolateral membranes. Although the great majority of transporters are specific to the apical or basolateral sides, there are exceptions. One is the rat Oatp1a1, which is found on the basolateral membrane of hepatocytes, where it takes up substrates from the blood, and on the apical membrane of renal tubular cells, where it reabsorbs substrates from the urine.<sup>113</sup> Another is MRP4, which is localized in the basolateral membrane in prostatic glandular cells and in apical membrane in rat kidney tubule cells.<sup>114</sup> The basolateral segment of the epithelial cells of the small intestine and the kidney renal tubules face the blood, while the apical sides are in contact with the gut lumen or urine. However, the blood (luminal) side of the BBB is in contact with the apical side of the brain endothelial cells, while their basolateral sides face the brain. Thus, each tissue must be carefully

examined to determine the apical/basolateral distributions of transporters and the correlation between this and the cell's environment (blood, CSF, extracellular fluid, urine, etc.). The mode of transport, such as bidirectional facilitated diffusion or one-directional active transport, must also be considered before assigning a direction to the transport of the substrate.

#### 5.04.5.4 Coordinated and Vectorial Transports

The net pharmacokinetic effect of active transport processes is frequently due to the involvement of several transporters that may not always belong to the same superfamily or subfamily. For example, the OATPs (*SLCO*) on the sinusoidal (basolateral) membrane of hepatocytes take up organic anions, while the MRP2 (*ABC*) on the apical bile canicular membrane excrete them. The combined activities of these two transporters thus results in the vectorial transport of drugs from the blood to the bile.<sup>113</sup> Similarly, the basolateral transporters OCT1, OCT2, and OCT3 of the kidney tubular cells act in a coordinated, vectorial manner with the apical transporters OCTN1 and OCTN2 to secrete OCs from the blood to the urine, whereas the basolateral OAT1, OAT2, and OAT3 are coupled to the apical OAT4, and URAT1 for transporting organic anions in the same tissue.<sup>85,95</sup> Unfortunately, the apical or basolateral partners of several coordinated systems have not yet been identified. Two examples are the apical peptide transporters PEPT1 and PEPT2; their basolateral partners have not yet been found.<sup>99</sup>

#### 5.04.5.5 Coordination between Transporters and Enzymes

Drug metabolism was considered to be one of the main processes of removing xenobiotics prior to the emergence of transporters. The CYP isoenzymes catalyze the first step of biotransformation and this function was called phase I metabolism. The subsequent conjugation step was called phase II metabolism. We now know that these two phases occur in specialized cells like the hepatocytes and enterocytes, and that they are preceded and followed by two other phases controlled by transporters. Efflux or influx transporters reduce or increase the uptake of substrates, and these actions help regulate the amounts of xenobiotics reaching the enzyme binding sites or the rate at which the metabolites produced are eliminated. The first step has been called 'phase O' and the second 'phase III,' indicating a close relationship between transporters and enzymes. They provide the cell with a suite of events and operate both in parallel and in series. This integrated biological function of combined transport and metabolic processes is strongly supported by the presence of common regulation pathways that act via similar nuclear receptors, such as PXR, RXR, and others, to induce or repress the genes encoding enzymes and transporters.<sup>45,115</sup>

#### 5.04.5.6 Polyspecific Transport and Inhibition

The substrate specificities of transporters are often very broad, as indicated by the many overlaps of substrates and inhibitors, much like the specificity of the drug metabolism enzymes. Thus, probenecid was initially known to produce many drug interactions by blocking the secretion by the kidney of many drugs, including the penicillins and the antiviral Tamiflu.<sup>116</sup> Probenecid is today known to be a polyspecific inhibitor of several MRPs, OATs, OATPs, and even OCTs.<sup>117</sup> Similarly, MRP1, MRP2, and MRP3 have broad, overlapping substrate specificities, while OCT1, OCT2, and OCT3 transport a wide range of similar OCs. P-gp interacts with a multitude of xenobiotics, many of which are metabolized by CYP3A4/5, and some of them are also substrates of MRP1 and BCRP.<sup>21</sup> The tyrosine kinase inhibitor imatinib is effluxed by both P-gp and BCRP, and imported by OCT1.<sup>118</sup> Thus all ionized chemicals, peptides, and nucleosides that cannot diffuse freely across membranes are very likely to interact with one or more transporters. A review of the entry and export of 14 antiretroviral nucleoside agents into and from cells found that 14 distinct transporters of the *ABC* and *SLC* superfamilies were involved in translocating these drugs, illustrating this unique property of polyspecificity.<sup>104</sup>

#### 5.04.5.7 Variations in Transport Kinetics

As each transporter has a limited capacity, it can be saturated by substrate concentrations greater than its  $K_m$ . The  $K_m$  of transporters can vary from nanomolar to millimolar values and the risk of saturating transport will depend on the amount of substrate in the transporter environment. It was mentioned above that the efflux of P-gp at the BBB can be saturated with a taxane derivative, leading to its nonlinear penetration into the brain parenchyma.<sup>119</sup>

Transport can also be inhibited in a competitive or noncompetitive manner, in the same way as the drug-metabolizing enzymes, so that transporters can promote drug-drug interactions that were initially thought to be due to

the drug-metabolizing enzymes alone. The calcium channel blocker mibefradil, which was first believed to be only a CYP3A4 inhibitor, is now known to inhibit P-gp.<sup>120</sup> Similarly, the effect of grapefruit juice on the disposition of fexofenadine, which was attributed to the inhibition of CYP3A4, is now known to result from its ability to inhibit the OATP-mediated uptake of fexofenadine.<sup>121</sup> In vitro transporter assays are increasingly being used to assess the potential risks of drug–drug interactions mediated by transporters. The in vitro inhibition constant ( $K_i$ ) can be measured and used to predict changes in the clearance or systemic exposure by measuring the area under the curve (AUC).<sup>122</sup> Transport kinetics may also depend on the amount of transporter, which will depend on the actions of drugs, nutrients, and disease states on the nuclear receptor pathways mentioned above. The most recent area of variation concerns the presence of genetic polymorphisms; these have been described for MDR1, BCRP, and nucleoside transporters. However, studies on the pharmacogenetics of most drug transporters have only recently begun. SNPs have been identified in drug-uptake transporters such as OCT1 and OATP1B1, and those in OATP1B1 may have an impact on the therapeutic efficacy and toxicity of HMG-CoA reductase inhibitors such as pravastatin.<sup>123</sup>

#### 5.04.6 Roles of Transporters in Pharmacokinetics

Transporters are now recognized to be as important as the metabolizing enzymes in the modulation of the main steps controlling the fate and action of xenobiotics in the body. They affect all the main pharmacokinetic events, such as the oral bioavailability, distribution, and clearance of any substrates. As most drugs, toxicants, and carcinogens are taken orally, we focus here on their impact on the enterocytes, as these are the main intestinal cells involved in the passage of compounds from the intestine to the blood. The absorbed compounds are then cleared by the liver, where the hepatocytes may produce, like the enterocytes, coordinated transporter–enzyme systems that influence the overall availability of compounds taken via the mouth before they can be distributed throughout the body. Tissue distribution depends on many factors, such as the degree to which a drug is bound to plasma proteins, the organ perfusion rate, and the rate at which the drug permeates biological membranes. Here too, transporter-mediated effects are particularly important at the so-called barriers between the blood and specific organs, like the BBB, the blood–CSF barrier at the choroid plexus, and the blood–testis, blood–prostate, and blood–placenta barriers. All these barriers protect tissues from external agents, and transporters are now considered to be the predominant actors in this defense system. They are frequently described as the gatekeepers of these physiological barriers between the exterior and interior environments. Finally, the last step concerns the elimination of parent compounds and their metabolites. The two most frequent routes for the removal of xenobiotics that do not require their metabolism are excretion in the bile or urine. **Figure 7** illustrates all these steps from the absorption to the elimination of a xenobiotic, including the key organs in drug disposition and the networks of transporters at the apical or basolateral poles of their cells.

##### 5.04.6.1 Intestinal Absorption

Drugs can be absorbed from the intestine by passive transcellular, paracellular, and carrier-mediated transport. The development of various in vitro experimental techniques in the 1980s, such as the human colon adenocarcinoma cell line Caco-2, which forms confluent monolayers of well-differentiated enterocyte-like cells, facilitated the characterization of intestinal transepithelial transport. Numerous SLC transporters translocating a wide range of natural and essential nutrients were found on both the intestinal brush border and the basolateral membrane.<sup>124</sup> Some of them, like the amino acid (*SLC7*) and monocarboxylic acid transporters (MCT, *SLC16*), may also transport drugs and xenobiotics.<sup>125</sup> Both influx and efflux transporters modulating drug absorption are present in the epithelium of the various segments of the intestine.<sup>126</sup> PEPT1, OATP2B1, OATP3A1, and OATP4A1 are all on the apical membrane and mostly import substrates from the lumen to the circulation (**Figure 8**). PEPT1 is the best-characterized drug transporter in the small intestine of mammals, and is widely used to improve the absorption of poorly absorbed oral drugs using a prodrug strategy (see **Section 5.04.4.2.4**). ABC transporters, including MDR1, MRP2, and BCRP, are also found on the apical membrane, where they either limit the intestinal uptake of their substrates or contribute to the active secretion of drugs from the blood to the intestinal lumen.<sup>127</sup> For example, the antineoplastic agent, paclitaxel, a P-gp substrate, is poorly absorbed when taken orally in humans (only 5% is bioavailable), but when it is administered with the P-gp competitor cyclosporin A, its bioavailability is increased to 50%.<sup>127</sup> The roles of basolateral transporters are much less well known. Oct1 is present on the basolateral sides of cells, and studies using Oct1 knockout mice indicate that Oct1 is important for the secretion of OCs into the lumen of the small intestine. The intestinal distribution of human OCT1 and OCT3 is still poorly documented, whereas the functional activity of OCT1, 2, and 3 has been demonstrated using Caco-2 cells.<sup>128</sup> The network of OCTs in the small intestine remains to be identified.

**Figure 7** Drug absorption, distribution, and elimination: the ABC and/or SLC transporter network mediate vectorial transport in each of the key body organs, with transporters at the basolateral or apical membranes of the organ-specific cells indicated in brackets.

**Figure 8** Distribution of the main drug ABC (blue) and SLC (red) transporters on the apical and basolateral membranes of intestinal enterocytes. All apical transporters (except MRP1) lie at the top of the villi.

The ABC transporter MRP3 is concentrated in the basolateral membranes, where it mediates the transfer of bile acids to the blood; its role in the intestinal absorption of drugs needs further clarification. The mRNAs of *MRP4* and *MRP5* were recently detected in the human intestine, suggesting that they are involved in the transport of nucleosides.<sup>127</sup> The intestinal transporters are not identically distributed along the crypt–villus axis. Many of those

implicated in the absorption of drugs, like PEPT1, MDR1, BCRP, MRP2, and MRP3, are villus-specific.<sup>113</sup> This restriction of transporters to the villus is also correlated with the presence of CYP3A in intestinal cells, suggesting coordinated phase 0 and 1 activities of MDR1 and CYP3A4 in the so-called intestinal first-pass effect.<sup>115</sup> By contrast, MRP1 is predominantly found on the membranes of crypt cells in the small intestine, the site of enterocyte renewal, where it can protect these cells from toxins. The function and interplay of all these intestinal transporters must be very carefully considered when looking at their roles in drug absorption. A major concern is the way in which their densities vary along the gastrointestinal tract. For example, MRP3 is the most abundant ABC protein throughout the human intestine, except for the terminal ileum where MDR1 is most abundant. Similarly, the concentration of MDR1 increases from the duodenum to the colon, whereas BCRP is found throughout the small intestine and colon, and MRP2 is most prevalent in the duodenum and becomes undetectable toward the terminal ileum and colon.<sup>45,113</sup> MCT1 has also been detected throughout the intestinal tract from the stomach to the large intestine, but it is most abundant in more proximal regions of the duodenum–ileum.<sup>129</sup> These diverse densities of the intestinal transporters may have dramatic pharmaceutical consequences. The pharmaceutical form of an oral drug can vary from a simple solution to a solid, controlled-release complex, and this can influence the gastrointestinal site (stomach, duodenum, jejunum, ileum, or colon) at which the active compound is released. Such differences may also influence the efficacy of the carrier-mediated transporters, as these may vary from one region of the intestine to another.

This raises the question of how useful *in vitro* Caco-2 cells are. They are representative only of the colon, whereas the majority of drugs are absorbed more proximally. Caco-2 cells can also bear some OCTs, as indicated above, although these have not yet been identified *in vivo*, but they lack BCRP and CYP3A4, which are now known to be important for effluxing drugs. The great risk of saturating active transport can also affect the kinetics of drug absorption. This can occur when a large amount of drug is rapidly dissolved in the intestinal lumen and ready to be absorbed by a relatively small area of intestine. Active transport can be saturated by a relatively high concentration of substrate (Figure 4a and b), so shifting absorption toward diffusion. Here, too, the properties of the oral preparation, like its rate of dissolution, may influence the contribution of active transport to drug absorption.

In summary, the intestinal drug transporters play two major roles. First, they take part in drug influx – the absorption of drugs such as PEPT1 may be used to develop drug-delivery strategies for poorly absorbed drugs. Second, they are very important for drug efflux, either limiting the intestinal uptake of xenobiotics or mediating the secretion into the intestine of substrates circulating in the blood.

#### 5.04.6.2 Liver and Hepatic Clearance

The liver is the most important drug-metabolizing organ in the body and acts as an apparently ‘homogeneous’ pool of enzymatic activity. Its parallel sinusoids lined with fenestrated endothelial cells form a freely accessible extracellular space surrounded by plates of hepatocytes. The hepatocyte plasma membrane is the only barrier to the entry of drugs into the hepatocytes. Hepatocytes are polarized cells with basolateral (sinusoidal and lateral) and apical (canicular) membranes (Figure 9). Molecules may be excreted from the hepatocytes across their canicular membrane into the

**Figure 9** Distribution of the main drug ABC (blue) and SLC (red) transporters on the basolateral (sinusoid) and apical (bile canaliculus) membranes of hepatocytes.

bile, or across the basolateral membrane into sinusoidal blood, from which they are subsequently removed by other organs (e.g., the kidney). Hepatic clearance is a combination of metabolic (phase I and II) and biliary clearance. As previously indicated, hepatocytes can take up drugs by diffusion or active transport (phase 0).

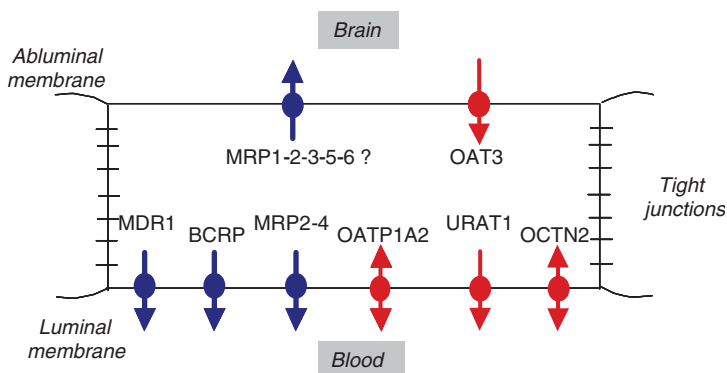

The basolateral membrane OATs include OAT2, OAT4, OATP1A2, -1B1, -1B3, and -2B1, the organic cation transporter OCT1 and the Na-taurocholate co-transporting polypeptide NTCP (*SLC10A1*).<sup>130</sup> They are responsible for the uptake of a wide variety of drugs by the liver because of their broad, overlapping substrate specificities. Phase III, which follows phases 0, I, and II, results in the elimination of the intact drug and/or metabolite(s) via efflux transporters on the apical and basolateral membranes. The hepatobiliary transporters include several ABC proteins (MDR1, MDR3, MRP2, BSEP, and BCRP) that are the main mediators of the excretion of numerous endogenous conjugated and unconjugated bile salts and drugs via the bile. Phase III also includes the efflux of compounds from hepatocytes back into the systemic circulation via basolateral membrane efflux transporters. Some of the OATPs, OATs, and OCT1 are bidirectional and may facilitate efflux, but the main exporters are the ABC proteins, which transport a wide range of glucuronides, and sulfated and GSH conjugates. The main ones are MRP1 and MRP3, the synthesis of which is readily induced, and the cyclic nucleoside transporters MRP4 and MRP5.<sup>113,130</sup>

This huge network of hepatobiliary transporters can give rise to variations in drug disposition between individuals by modulating the uptake or the exit of drugs and their metabolites from hepatocytes. A change in hepatic uptake may have clinical consequences. It may modulate the pharmacological activity of drugs that act via the intrahepatocellular transduction pathways, it may cause hepatotoxicity, or give rise to drug–drug interactions. The concentration of the cholesterol-lowering HMGCoA inhibitors in hepatocytes must be adequate for their pharmacological activity, and most of the statins (e.g., pravastatin, simvastatin, lovastatin, cerivastatin, and pitavastatin) enter hepatocytes via OATP1B1, and to a lesser degree via OAT1B3.<sup>131</sup> Recently identified genetic polymorphisms like the *SLCO1B3* haplotype \*17 are associated with reduced statin clearance by the liver and lower concentrations in hepatocytes; they thus have less effect on cholesterol synthesis.<sup>132</sup> Large-scale clinical studies are needed to confirm the impact of OATP1B1 polymorphisms on the considerable variation between individuals to therapy with hypolipidemic agents. The clinical efficacy and adverse effects of oral antidiabetic drugs similarly vary greatly between individuals. Polymorphisms of CYP2C8/2C9, the main enzymes catalyzing the transformation of sulfonylureas, and the meglitinide-class drugs, such as repaglinide and nateglinide, have been advanced to explain these variations, but one *SLCO1B1* genotype was recently shown to affect markedly the pharmacokinetics of repaglinide and its effect on blood glucose.<sup>133</sup> The clinical efficacy of the antidiabetic drug metformin, which is not significantly metabolized, mainly depends on its hepatic uptake by OCT1 (see Section 5.04.4.2.2), which can also be affected by several SNPs.<sup>134</sup>

Transporters can also mediate hepatotoxicity. For example, the sulfate conjugate of the antidiabetic troglitazone can cause troglitazone hepatotoxicity by inhibiting OATP1B1 and OATP1B3.<sup>135</sup> Phalloidin, the major toxin of the mushroom *Amanita phalloides*, enters hepatocytes via OATP1B1 and -1B3, and cyclosporin A is reported to be the most potent competitive inhibitor of OATP1B1-mediated phalloidin transport in the liver.<sup>136</sup> Several other drugs also inhibit the basolateral OATPs. The fibrate gemfibrozil interacts with statins by inhibiting OATP1B1.<sup>137</sup> Thus drug–drug interactions do not concern only the inhibition of metabolic enzyme, but may involve the first line of hepatocyte transporters. These hepatic impacts of the basolateral transporters have their counterpart at the apical pole. The multiple ABC transporters may also be responsible for variable drug disposition. For example, giving patients receiving digoxin the P-gp inhibitor verapamil decreases the biliary clearance of digoxin by 43% and increases its plasma concentration by 44%.<sup>138</sup> Furthermore, each of the apical ABC proteins contains several genetic polymorphisms and is very sensitive to liver diseases.<sup>139</sup> Both the influx and efflux hepatic transporters are thus critical influences on drug efficacy and toxicity. They are also very important for selecting the appropriate in vitro system for evaluating hepatic clearance and predicting hepatic clearance in vivo. The absence of transporters from the hepatic microsomal assays widely used to assess the metabolism of xenobiotics means that both suspensions and sandwich-cultures of primary hepatocytes are presently the most relevant in vitro models for studying hepatic uptake, biliary excretion, and drug–drug interactions, because they integrate the entire hepatobiliary transporter network.<sup>130</sup>

### 5.04.6.3 Blood Barriers and Tissue Distribution

The tissue distribution of a drug can be affected by transporters because they lie on either the luminal or abluminal membranes of the endothelial cells of the tissue blood vessels, or on the membranes of the specific cells of the underlying organ. The transporters on the membranes of the blood vessels may be several key physiological components of the blood barriers throughout the human body if tight junctions seal adjacent cells and prevent the paracellular exchange of solutes. In contrast, solutes can freely communicate between extracellular spaces when blood vessels are fenestrated, as in the liver sinusoids, and transporters on the plasma membranes of the tissue cells (e.g., the

**Figure 10** Distribution of the main drug ABC (blue) and SLC (red) transporters on the abluminal (facing brain extracellular fluid) and luminal membranes of the brain microcapillary endothelial cells constituting the BBB.

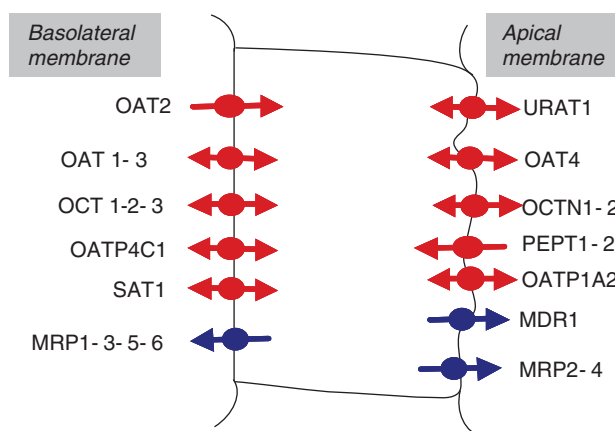

hepatocyte membranes) become the first barrier regulating the import and export of solutes. Several organs, including the brain, nose, eyes, testes, prostate, and placenta, are protected by endothelial barriers that contain extensive networks of transporters.<sup>79,140–143</sup>

**Figure 10** illustrates the luminal and abluminal distributions of several transporters at the BBB. The two ABC proteins MDR1 and BCRP are most abundant on the luminal side of the endothelial cells and are most important for protecting the brain from numerous xenobiotics (see Sections 5.04.4.1.1 and 5.04.4.1.3).<sup>144</sup> Most of the MRPs have been also identified in the brain microvessel endothelial cells, but their luminal or abluminal location remains questionable and no important functional effects on drug transport across the BBB have been documented, except in a few cases for MRP2 and MRP4 (see Section 5.04.4.1.2). Few SLCs have been characterized in the rat BBB, except for the important network of SLC transporters that allows the blood–brain exchange of amino acids and sugars. Rat Oatp1a4 is found on both the luminal and abluminal membranes of the brain capillaries.<sup>145</sup> The human isoform OATP1A2 is also present, but its membrane location has not been determined. Both OATPs can mediate uptake or efflux transport because of their bidirectional transport characteristic (see Section 5.04.4.2.1). The members of the *SLC22*, OAT3, OCTN2, and URAT1, have been found in the BBB.<sup>146</sup> OAT3 is abluminal and effluxes benzylpenicillin, cimetidine, PAH, and several acidic metabolite of neurotransmitters from the brain to the blood. The luminal position of URAT1 enables this vectorial transport of the OAT3 substrates. OCTN2, which is believed to be luminal, can simultaneously transport carnitine into the brain and efflux OCs from the brain to the blood.

The other BBB, the blood–CSF barrier (BCSFB), which regulates the solute exchanges between the blood and the CSF, is a monolayer of epithelial cells at the choroid plexus floating in the brain ventricles. The apical and basolateral locations of ABC and SLC transporters makes this second barrier an important interface for brain homeostasis and drug disposition.<sup>147</sup> Here, too, drug transporters on the membranes of physiological barriers or on specific membranes of the tissue cells can affect drug distribution and, consequently, the fraction of the drug available for binding to intracellular receptors or other biological targets.

#### 5.04.6.4 Kidney and Renal Clearance

The presence of a drug in the urine is the net result of filtration, secretion, and reabsorption. Filtration occurs by passive glomerular filtration of unbound plasma solutes, whereas secretion and reabsorption are generally carrier mediated. They can occur in the proximal tubule, which has three segments (S1, S2, and S3): the loop of Henle, the distal tubule, and the collecting tubule. These specific anatomical and functional regions of the kidney must be carefully considered, just like the regions of the intestine, because region-specific distributions of transporters define their action in renal clearance. Most renal transporters lie on the apical and basolateral membranes of the proximal tubule cells, with fewer on the epithelial membrane of the other components of the nephron. The resulting vectorial transport from the peritubular capillaries to the tubule lumen, or vice versa, can produce either secretion or reabsorption. **Figure 11** shows the locations of the major drug transporters in the human proximal renal tubule cells. Multiple SLC transporters at their basolateral membrane (close to peritubular capillaries) mediate drug uptake into the tubule cells. Although by nature bidirectional, the direction of the transmembrane driving gradients favors tubular uptake rather than the efflux of organic anions and cations. Organic anions enter these cells via OAT1, OAT2, and OAT3 – and probably via OATP1A2 and OATP4C1, which was recently identified, and transports digoxin and

**Figure 11** Distribution of the main drug ABC (blue) and SLC (red) transporters on the basolateral (peritubular fluid) and apical (glomerular filtrate) membranes of the kidney proximal tubule cells.

methotrexate.<sup>148</sup> OCs are similarly transported by OCT 1, OCT2, and OCT3; the efflux transporters MRP1, MRP3, MRP5, and MRP6 mediate their efflux back into the systemic circulation.<sup>114,134</sup> The sulfate-anion antiporter 1 (SAT-1; *SLC26A1*) is responsible for the sodium-dependent movement of sulfate across the basolateral membrane of the proximal tubule in exchange for  $\text{HCO}_3^-$ , but organic anions can also be substrates or inhibitors of SAT-1.<sup>98</sup> At the apical membrane, OAT4 and URAT1, OCTN1, and OCTN2 can mediate drug transport with bidirectional properties, either secretion or reabsorption. For example, OCTN2 secretes OCs and reabsorbs zwitterions. OATP1A2, PEPT1, and PEPT2 mediate the reabsorption of their substrates from the tubule lumen (see Section 5.04.4.2.4).

The ABC transporters MDR1, MRP2, and MRP4 are also present on the apical membrane and efflux compounds by secretion. As indicated above, transporters are not evenly distributed along the nephron: MDR1, MRP2, MRP4, and MRP6 are found mainly within the three segments of the proximal tubule; MRP3 lies in the distal convoluted tubule; and MRP1 is found in the epithelial cells of the loop of Henle and the distal and collecting duct tubule cells, but not in proximal tubule cells.<sup>114</sup> The regional distributions of the SLC transporters are also specific. OAT1 is found only on the basolateral membrane of the S2 segment cells of the proximal tubule, whereas OAT3 is present on the cells of the S1, S2, and S3 segments. Once again, this raises the question of the most appropriate in vitro kidney models containing the whole transport network. As with Caco-2 intestinal cells, the Madin–Darby canine kidney (MDCK) cell lines are widely used in wild-type or transfected cell systems for examining particular transport processes.<sup>149,150</sup> They are useful in vitro tools for assessing the risks of drug–drug interactions, nephrotoxicity, and drug efficacy mediated by the reabsorptive and secretory capacities of the kidney.

If the renal clearance of a drug is equal to or more than the overall body clearance, renal transporters can be important in clinical efficacy or toxicity. For example, the cephalosporin antibiotics are primarily eliminated via the kidney. Creatinine clearance is normally  $100\text{--}140\text{ mL min}^{-1}$ , but the renal clearance of cephalosporins is  $16.8\text{--}469\text{ mL min}^{-1}$ , suggesting that some of them, like cefotaxime and cefadroxil, are excreted into the urine by tubular secretion, whereas others, like ceftriaxone and cefazodin, the renal clearance of which is less than that of creatinine, are reabsorbed.<sup>151</sup>

OAT1, OAT2, and OAT3 are located on the basolateral side of the proximal tubule and mediate the uptake of most of the cephalosporins into the proximal tubule from the peritubular capillary. The apical OAT4 mediates both the uptake (reabsorption from the tubular lumen) and the efflux (secretion) of these anionic antibiotics.<sup>95</sup> Like the basolateral transporters of hepatocytes, which can modulate the pharmacological activity of drugs acting via intrahepatocyte targets or induce hepatotoxicity, the basolateral OATs can make some cephalosporins cause nephrotoxicity, which may lead to acute proximal tubular necrosis. This toxicity is mainly due to the accumulation of cephalosporin in the renal cortex because of the lack of efficient vectorial transtubular transport.<sup>95,98,152</sup> This transport-mediated nephrotoxicity also results in the adverse effect of cisplatin drugs via their basolateral uptake in the proximal tubule by OCT2 and the toxic effects depend on the platinum complex used, as does the structure-dependent nephrotoxicity of cephalosporins.<sup>153</sup> Nephrotoxicity also limits the use of the nucleoside phosphonates, adefovir and cidofovir, in the treatment of human immunodeficiency virus. The toxicity of these drugs appears to be a function of both OAT1-mediated proximal tubular accumulation and decreased efflux at the luminal membrane by MRP2. A small dose of the OAT1 inhibitor, probenecid, may reduce the nephrotoxicity of cidofovir.<sup>154</sup>

The use of transporter inhibitors to reduce nephrotoxicity suggests that drug–drug interactions affecting anionic and cationic drugs can be mediated via competition at the basolateral and luminal tubular transporters. Multiple drug–drug interactions have been reported with probenecid and cimetidine, and there have been fatal cases with methotrexate and NSAIDs following the inhibition of the basolateral OAT1 and OAT3.<sup>155</sup>

Finally, renal transporters can be critical for the action of diuretics. Tubular secretion is the main route by which diuretics act in the kidney and are excreted. The diuretic drugs, such as the thiazides, the loop diuretics bumetanide and furosemide, and the carbonic anhydrase inhibitors, are all competitive inhibitors of the renal OATs, although their affinities and specificities vary.<sup>156</sup>

#### 5.04.6.5 Transporters and the Biopharmaceutics Classification System

Amidon *et al.*<sup>157</sup> have devised a biopharmaceutics classification system (BCS) that divides drugs into four classes according to their solubility and permeability (*see* 5.42 The Biopharmaceutics Classification System). The BCS has produced rates and extents by which oral drugs are absorbed. Extended versions of the BCS have been proposed by associating the four classes with the main routes of elimination and the effects of efflux and influx transporters. Their objectives were to predict the pharmacokinetic performance of a drug product in vivo from measurements of permeability and solubility. Figure 12 combines the first elements of the original BCS and additional information on the main pathways of drug elimination and the impact of drug transporters.<sup>158</sup> Most class 1 and class 2 compounds, which are highly permeable, are eliminated via metabolism, whereas class 3 and 4 compounds, which are poorly permeable, are primarily eliminated unchanged into the urine and/or bile. The effect of intestinal transporters is expected to be minimal for class 1 compounds, even if they interact with transporters, as their great permeability and solubility allows high concentrations in the gut lumen to saturate any transporter. In contrast, many large (> 500 Da), lipophilic and poorly water-soluble new BCS class 2 molecules that deviate the crude Lipinski filter rule of 5 are often the target of gut efflux transporters such as MDR1 and BCRP.<sup>158</sup> Sufficient amounts of class 3 drugs will be available for gut absorption because of their great solubility, but their poor permeability requires an absorptive transporter. The poor oral bioavailability and transporter effects are likely to determine the oral absorption of class 4 compounds.

The postabsorptive pharmacokinetics can also be anticipated with the BCS. Most of the drugs with high hepatic extraction ratios and clearances approaching the hepatic blood flow are class 1 compounds, and the target mediating drug–drug interactions is primarily metabolic. In contrast, both uptake and efflux transporters are critical determinants of the disposition of class 2, 3, and 4 compounds, the biliary secretion and renal secretion or reabsorption-mediated transport of which can dramatically modulate the systemic concentrations of these drugs. Thus, transporters may be the primary mediators of drug–drug interactions.

|                   | High solubility  | Low solubility   |
|-------------------|--|--|
| High permeability | <p>Class 1<br/>(high solubility, high permeability)</p> <p><i>Metabolism</i><br/><i>‘High hepatic extraction’</i></p> <p>Transporter effects minimal</p> | <p>Class 2<br/>(low solubility, high permeability)</p> <p><i>Metabolism</i></p> <p>Efflux transporter effects predominate</p>  |
| Low permeability  | <p>Class 3<br/>(high solubility, low permeability)</p> <p><i>Renal and/or biliary elimination</i></p> <p>Absorptive transporter effects predominate</p>  | <p>Class 4<br/>(low solubility, low permeability)</p> <p><i>Renal and/or biliary elimination</i></p> <p>Absorptive and efflux transporter effects could be important</p> |

**Figure 12** The biopharmaceutics classification system (BCS), as defined by Amidon *et al.*<sup>157</sup> and extended by Wu and Benet,<sup>158</sup> showing the predominant routes of drug elimination and the transporter effects on drug disposition.

There was very little interest in the importance of drug transporters in drug bioavailability when the BCS was first developed. But the involvement of drug transport at all steps of the pharmacokinetic processes has provided a clearer correlation between the solubility and permeability of a drug and its fate within the human body. Hence the action of transporters is now included in ADMET predictive models.

## 5.04.7 Conclusion

The recent expansion of our knowledge of the involvement of drug transporters in pharmacokinetics has added a new layer of complexity to our understanding of the mechanisms underlying the absorption, distribution, and elimination of drugs. New transporters undoubtedly remain to be identified, and the functions of some identified transporters remain poorly understood. Nevertheless, it is clear that the drug transporters in organs such as the intestine, liver, brain, and kidney are significant determinants of variations in drug responsiveness between individuals. Together with the drug-metabolizing enzymes, they determine drug–drug interactions, drug-induced organ toxicities, and diseases. Detailed knowledge of genetic polymorphisms in transporters and how they affect transporter function will help to optimize drug therapies and identify unknown, residual factors that influence intersubject variations.

Transporters are now an integral part of the drug discovery and development processes. They are attractive markers in the creation of drugs that are readily absorbed and accurately targeted. The incorporation of transport properties into structure–activity models should help medicinal chemists design more efficient and safer new medicines.

A few years ago, the body factors governing the main phases of drug pharmacokinetics were believed to be completely understood. The transporter adventure has now opened up a new horizon for pharmacokinetics that focuses on the cells and molecules that govern the main events in the body, so promoting pharmacokinetics to a discipline that integrates multiple interacting biological systems.

## Biography

**Jean-Michel Scherrmann**, PharmD, PhD, is Professor and Chair at the Department of Clinical Pharmacy and Pharmacokinetics, Faculty of Pharmacy, the University of Paris 5. He received his PharmD and PhD in analytical radiochemistry from the University René Descartes at Paris. He currently leads the Neuropsychopharmacology Unit at the French Institute of Health and Medical Research (INSERM) and the National Center of Scientific Research (CNRS). Professor Scherrmann has made major contributions to the development of drug radioimmunoassay, drug detoxification by immunotherapy, and drug redistribution concepts in pharmacokinetics. He pioneered the first clinical application of colchicine immunotherapy in acute colchicine overdose, and is now focusing his research on the role of drug transporters in neuropharmacokinetics and drug delivery strategies to the brain. His work has resulted in two patents, 290 scientific articles, 45 book chapters, and more than 300 presentations. He has served on the editorial boards of several journals in the analytical and pharmaceutical sciences. He has mentored over 30 postgraduate and 44 doctoral students. Professor Scherrmann has been a recipient of the 1992 American Academy of Clinical Toxicology Award and the 1999 French National Academy of Medicine Achievement Award. He is a Fellow of the American Association of Pharmaceutical Scientists and a member of the French National Academy of Pharmacy.

### 5.05.1 Introduction

Environmental exposure to foreign compounds that might be harmful to normal biological function has necessitated the development of a generalized defense system in virtually all higher life forms. To cope with the challenges that exposure brings requires that the system be sophisticated enough to effectively operate on chemical entities to which the living organism has never been exposed. This has been partially achieved by the evolution of the group of enzyme systems outlined in [Table 1](#). Virtually any organic molecule can be transformed by one or more of the enzymes in this group. Most are oxidoreductases, and thus have dual reaction modes. They can activate and utilize molecular oxygen to oxidize xenobiotics or utilize electrons supplied by cofactors to reduce xenobiotics. For a few, reduction is the preferred course of reaction. The products invariably have altered biological properties since they are structurally distinct from the parents. Their increased polarity results in their increased water solubility and more rapid elimination from the body. An excellent discussion of the role these enzymes play in drug metabolism can be found in the book by Testa.<sup>1</sup>

**Table 1** General properties of the major oxidoreductases that catalyze the metabolism of xenobiotics in the human

| <i>Enzyme system</i>                                   | <i>Size (kDa)</i>   | <i>Location</i>   | <i>Cofactors</i>                            | <i>Primary substrates</i>              | <i>Site of attack</i>                      |
|--|---------------------|---|---|--|--|
| CYP <sup>a</sup> (multiple isoforms in three families) | ~ 50                | Endoplasmic reticulum; primarily liver                  | NADPH <sup>b</sup> , heme, CYP reductase    | Lipoidal organics                      | Primarily C also S and N                   |
| FMO <sup>c</sup> (six isoforms)                        | ~ 60                | Endoplasmic reticulum; primarily liver                  | FAD <sup>d</sup> , NADPH                    | Heteratom-containing lipoidal organics | Nucleophilic heteroatoms N, S, P, Se, etc. |
| MAO <sup>e</sup> (two forms; A and B)                  | ~ 60                | Outer mitochondrial membrane; liver, brain, gut, kidney | FAD   | Arylalkylamine neurotransmitters       | N  |
| XOR <sup>f</sup> (two interconvertible forms)          | ~ 300 (homodimeric) | Cytosol primarily; primarily liver and intestine        | Molybdopterin, two iron–sulfur centers, FAD | Purines, N-containing heterocycles     | Ring C                                     |
| Aldehyde oxidase                                       | ~ 300 (homodimeric) | Cytosol   | Molybdopterin, two iron–sulfur centers, FAD | Aldehydes purines, N heterocycles      | Carbonyl C, ring C                         |
| Aldehyde dehydrogenase (many isoforms)                 | ~ 50–60             | Cytosol, microsomes, mitochondria                       | NAD, NADP                                   | Aldehydes                              | Carbonyl C                                 |

| AKR <sup>g</sup> (superfamily)                         | ~ 35–40             | Cytosol primarily liver                                 | NADPH                                       | Aldehydes, ketones                     | Carbonyl C                                 |
| Carbonyl reductase (superfamily)                       | ~ 30                | Cytosol   | NADPH, NADH                                 | Aldehydes, ketones                     | Carbonyl C                                 |

<sup>a</sup> Cytochrome P450.<sup>b</sup> Reduced form of nicotinamide adenine dinucleotide phosphate.<sup>c</sup> Flavin-containing monooxygenase.<sup>d</sup> Flavin adenine dinucleotide.<sup>e</sup> Monoamine oxidase.<sup>f</sup> Xanthine oxidoreductase (xanthine oxidase and xanthine dehydrogenase).<sup>g</sup> Aldo-keto reductase.

The organism's defense mechanism is completed by two additional classes of enzymes. The conjugating enzymes catalyze covalent bond formation between highly polar species (e.g., glucuronic acid) and a suitable functional group (usually hydroxyl) of the xenobiotic. The hydrolytic enzymes operate primarily on esters and amides, generating alcohols and acids or amines and acids, respectively. Both classes serve as mechanisms to enhance the elimination of highly lipoidal target molecules by increasing their water solubility through chemical modification.

The content of this chapter is focused on the metabolic reactions catalyzed by the enzyme systems listed in [Table 1](#). Conjugation and hydrolytic reactions are the subjects of Chapter 5.06.

## 5.05.2 Oxidations

### 5.05.2.1 Cytochromes P450

#### 5.05.2.1.1 Occurrence, multiplicity, catalytic cycle, oxygen activation, and selectivity

As components of a biological defense system the cytochrome P450 enzymes<sup>2</sup> are by far the most dominant and important ([Table 1](#)). They embody a superfamily of monooxygenases that are found in living organisms, ranging from bacteria to humans.<sup>3</sup> In humans and other mammals the cytochromes P450 are found in highest concentration in the endoplasmic reticulum of the liver, and in lower concentration in other tissues (e.g., brain, lung, kidney, and intestine). In addition to defense, some cytochromes P450 play a significant role in normal physiology. In the human, for example,

specialized cytochromes P450 found in the adrenal cortex are involved in the syntheses of steroid hormones, while others are involved in the oxidative transformation of fatty acids and the production of prostaglandins. However, the focus of this chapter will be on the cytochromes P450 involved in drug metabolism. These specific cytochromes P450 are found primarily in three families,<sup>4</sup> CYP1, CYP2, and CYP3 (see 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions; 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues, for an extensive discussion of the biological and structural properties of the cytochromes P450). Of the cytochromes P450, CYP3A4 is, arguably, the most important, as it has been found to contribute significantly to the metabolism of approximately half of all drugs that have been administered to humans or are in current use.<sup>5</sup>

All the cytochromes P450 work by activating  $O_2$ . In the cycle<sup>6,7</sup> that describes the catalytic role,  $O_2$  is split into two oxygen atoms; one atom is reduced to water, while the second is transferred to the substrate (Figure 1).

In the resting state the charge of heme  $Fe^{3+}$  is counterbalanced by two negatively charged nitrogen atoms from the porphyrin ring plus a negatively charged cysteine thiolate group that anchors heme to the protein. Heme  $Fe^{3+}$  is primarily in the low-spin form characterized by hexacoordinated heme  $Fe^{3+}$  in which  $Fe^{3+}$  lies in the plane of the porphyrin ring. Four of the ligand sites are occupied by the four imidazole nitrogen atoms, and the fifth by cysteine thiolate. The sixth is presumed to be occupied by a molecule of water.

- Step 1 – the substrate, RH, associates with the active site of the enzyme, and perturbs the spin state equilibrium. Water is ejected from the active site, and the high-spin pentacoordinated substrate-bound form becomes dominant.  $Fe^{3+}$  is puckered out and above the plane in the direction of the sixth ligand site. The change in spin state alters the redox potential of the system. Substrate bound enzyme is now more easily reduced.
- Step 2 – NADPH-dependent cytochrome P450 reductase transfers an electron to heme  $Fe^{3+}$ .

**Figure 1** The cytochrome P450 catalytic cycle.

- Step 3 –  $O_2$  binds, but can also dissociate, causing the enzyme to revert to the heme  $Fe^{3+}$  resting state while generating the superoxide radical anion.
- Step 4 – a second electron, via cytochrome P450 reductase or in some instances cytochrome *b5*, is added to the system, generating a heme-bound peroxide dianion formally equivalent to  $FeO_2^{1-}$ .
- Step 5 –  $H^+$  adds to the system, generating a heme-bound hydroperoxide anion complex formally equivalent to heme  $FeO_2H^{2-}$ .
- Step 6 – a second  $H^+$  is added. If  $H^+$  adds to the inner oxygen of heme  $FeO_2H^{2-}$ , decoupling occurs,  $H_2O_2$  is released, and the enzyme reverts to the heme  $Fe^{3+}$  form.
- Step 7 – the second  $H^+$  adds to the outer oxygen atom of heme  $FeO_2H^{2-}$ ; water is formed and released. Residual heme  $FeO^{3+}$  bears an oxygen atom (oxene) complexed to heme  $Fe^{3+}$ , a species considered to be analogous to compound 1 (heme in which  $Fe^{IV}O$  is complexed to a porphyrin  $\pi$  radical cation), the active oxidant of the peroxidases. Decoupling can again occur via a two-electron reduction of  $FeO^{3+}$  plus the addition of two protons. This generates a molecule of water and the heme  $Fe^{3+}$  resting state of the enzyme. The degree to which this process occurs depends on the relative rates of heme  $FeO^{3+}$  reduction versus oxygen atom transfer to the substrate, as outlined in the next step.<sup>8,9</sup>
- Step 8 – an oxygen atom is transferred from heme  $FeO^{3+}$  to the substrate, forming the oxidized product, which is then released. The enzyme reverts to its heme  $Fe^{3+}$  resting state.

#### 5.05.2.1.2 Oxidation of $sp^3$ carbon–hydrogen bonds

##### 5.05.2.1.2.1 Mechanism

Unlike other enzymes, which are generally highly specific, the cytochromes P450 are of necessity general oxidants that must be able to oxidize an unlimited array of organic compounds of divergent structure. This is achieved by their ability to generate a species, an oxygen atom, that is reactive enough to oxidize virtually any organic molecule that it comes in contact with.<sup>10,11</sup> This high reactivity suggests that the importance of protein composition and active site architecture to catalysis is fundamentally different for the cytochromes P450 than it is for most other enzymes. Cytochromes P450 have the ability to control access to the active site oxidant. In most other enzymes the active site architecture promotes a specific active site binding orientation that approaches the transition state geometry for the reaction and thereby lowers the necessary energy of activation.<sup>10,11</sup> Since all cytochromes P450 have the same heme cofactor and the same active oxidant, it is the spectrum of specific substrates that are able to access the active site of a given cytochrome P450 that distinguishes one cytochrome P450 from another.

The consensus mechanism for the cytochrome P450-catalyzed oxidation of covalent C–H bonds of simple normal hydrocarbons has been the two-step hydrogen atom abstraction–oxygen rebound mechanism where heme  $FeO^{3+}$  abstracts a hydrogen atom from the substrate to form heme  $FeOH^{3+}$  and a carbon-based substrate radical in the first step. In the second step, a hydroxy radical from heme  $FeOH^{3+}$  combines with the substrate radical to form the hydroxylated product and regenerate the resting state of the enzyme.<sup>12–16</sup>

While the evidence for a radical rebound mechanism is strong, it is not without problems,<sup>14,15,17,18</sup> and has been challenged by Newcomb and co-workers,<sup>18–25</sup> who suggest a single-step direct insertion mechanism.

A potential resolution to this dilemma has been offered by Shaik and co-workers,<sup>26–32</sup> based on theoretical calculations. These investigators describe a two-state reactivity paradigm for heme  $FeO^{3+}$  that rationalizes the properties of a two-step radical recombination mechanism<sup>12,13</sup> and those of a single-step direct insertion mechanism.<sup>20,22</sup> An excellent review that focuses on the mechanisms of O–O bond activation and assesses the potential role of multiple active intermediates has recently appeared in the literature.<sup>33</sup>

##### 5.05.2.1.2.2 Primary, secondary, and tertiary carbon atoms

Despite the complexity of the mechanism for cytochrome P450-catalyzed oxidation of  $sp^3$  C–H bonds, the electrophilic character of a carbon-based radical or radical-like species generated by the two-state reactivity paradigm state suggests that the ease of formation of either of these species by the two states should in general mirror the relative ease of formation of carbonium ions, that is, hydroxylated product formation should follow the order tertiary ( $3^\circ$ ) > secondary ( $2^\circ$ ) > primary ( $1^\circ$ ). Experimentally, this is indeed what is found when simple normal- or branched-chain hydrocarbons are exposed to cytochrome P450. Even though they are the most sterically hindered,  $3^\circ$  carbons tend to be preferentially hydroxylated as are  $\omega$ -1  $2^\circ$  carbons (i.e.,  $2^\circ$  carbons immediately adjacent to terminal methyl groups).

It is important to note that while  $3^\circ$ ,  $2^\circ$ , and  $1^\circ$  is the order usually followed by members of the CYP1, CYP2, and CYP3 families, the CYP4 family contains specialized cytochromes P450 only marginally involved in drug metabolism that are selective for  $\omega$ -hydroxylation, particularly in relation to the metabolism of fatty acids. For example,

Powell *et al.*<sup>34</sup> have identified CYP4A11 as the major lauric acid  $\omega$ -hydroxylase found in human liver, while Alexander *et al.*<sup>35</sup> report that rat brain tissue has high fatty acid  $\omega$ -hydroxylase activity, leading to the formation of dicarboxylic acids. Sawamura *et al.*<sup>36</sup> found that CYP4A7 hydroxylates the prostaglandins PGA<sub>1</sub> (**1**) and PGA<sub>2</sub> (**3**) exclusively in the  $\omega$ -position (eqns [1] and [2]).

These results not only emphasize the capacity of heme  $\text{FeO}^{3+}$  to selectively oxidize a C–H bond as unreactive as a methyl group attached to a saturated aliphatic chain but they also highlight the importance of active site architecture in dictating what part of the substrate molecule is exposed to the oxygen atom of heme  $\text{FeO}^{3+}$ . Members of CYP families 1, 2, and 3, as major drug-metabolizing enzymes, would be expected to have relatively open active and less constraining active sites to accommodate a greater variety of molecules. Conversely, members of CYP families, such as CYP4, that are involved in the metabolism of endogenous bioactive molecules, such as the prostaglandins or the steroids, would be expected to have active sites that confine the oxidation of specific molecules to specific sites within the molecule. This indeed appears to be the case.

That nature has demonstrated the possibility of constructing cytochromes P450 that can selectively oxidize sites within complex molecules that are neither energetically nor statistically favored suggests that it may be possible to bioengineer cytochromes P450 to obtain catalysts for the production of important intermediates or end products that can only be obtained with great difficulty or at great expense. Catalysts could also be engineered for processing recalcitrant environmental pollutants such as polychlorinated aromatic compounds (e.g., dioxin). Such possibilities have provoked a great deal of interest within the scientific community, and their exploration is beginning to meet with some success. While a thorough discussion of the area is beyond the scope of this chapter, a few examples are worth noting.

Fisher *et al.*<sup>37</sup> covalently linked rat cytochrome P450 reductase to rat CYP4A1, a cytochrome P450 responsible for the  $\omega$ -hydroxylation of lauric acid (**5**) (eqn [3]). The new fusion protein is extremely active, and catalyzes this reaction at the remarkable turnover rate of  $300 \text{ nmol (nmol P450)}^{-1} \text{ min}^{-1}$ .<sup>38</sup> The exceptional rate is presumably achieved by compelling the reductase and cytochrome P450 to maintain close proximity by covalently linking the two proteins. Thus, the price of entropy is paid as the reductase is always in position to supply reducing equivalents to the cytochrome P450 and fuel the reaction.

Purging the environment of polychlorinated aromatics has proven to be a major problem because of their toxicity, widespread presence, chemical inertness, and resistance to bacterial degradation. To address the problem, Jones *et al.*<sup>39</sup> genetically altered the bacterial enzyme cytochrome P450<sub>cam</sub> (CYP101), one of the most well-characterized and

Scheme 1

well-studied of all known cytochromes P450. While wild-type CYP101 can oxidize dichloro- and trichlorobenzenes to chlorophenols, it is not able to metabolize the more highly substituted pentachlorobenzene (7) and hexachlorobenzene (8). Polychlorinated phenols do not present a significant hazard, as they are degraded by microorganisms in the environment. Thus, finding or constructing an enzyme that would metabolize highly chlorinated aromatics such as 7 and 8 would represent a significant advance toward a solution. Once constructed, the genes encoding the CYP101 system could be genetically incorporated into chlorophenol-degrading microorganisms to convert chlorobenzenes to chlorophenols that would then be further degraded by the host.<sup>39</sup> The authors' challenge then was to bioengineer CYP101 so it would be able to hydroxylate 7 and 8 to form 9 (Scheme 1). Reasoning that changes that increased hydrophobicity and decreased the size of the active site would be beneficial to that end, three specific mutations were introduced. The mutant enzyme was not only able to metabolize 7 and 8, but exceeded the hydroxylase activity of wild type by three orders of magnitude.

#### 5.05.2.1.2.3 Benzylic and allylic carbon atoms

If cytochrome P450-catalyzed hydroxylation of benzylic or allylic C–H bonds proceeds by the same mechanism operative for the simple saturated systems discussed above, they would be expected to be favored processes. Resonance stabilization of a radical intermediate would lower the activation energy for both benzylic and allylic hydroxylation. This is generally what is found in drug metabolism studies.

White *et al.*<sup>40</sup> reinvestigated the stereochemistry of hydroxylation of the prochiral benzylic carbon atom of phenylethane (10), using enantiomerically pure (*R*)- and (*S*)-phenylethane-1-d as substrates (Scheme 2). General findings of particular note were (1) hydroxylation occurs almost exclusively, greater than 99%, at the benzylic position to give the isomeric  $\alpha$ -methylbenzyl alcohols (11), a result consistent with the benzylic position being a favored site of attack, and (2) the percentage yield of the minor metabolites, 2-phenylethanol (12) and 4-ethylphenol (13), more than triples when phenylethane-1-d<sub>2</sub> is used as the substrate. The isotopically driven switching to other sites of metabolism not only indicates the operation of a significant isotope effect but the tripling of such metabolites, particularly 4-ethylphenol, also indicates that the substrate has considerable freedom of motion within the active site and the potential to form multiple catalytically productive active site binding orientations.<sup>8,41,42</sup> It is not uncommon for a single cytochrome P450 to catalyze the formation of multiple regioisomeric products from the same substrate.<sup>43,44</sup> where the primary metabolite is often formed by oxidation at the energetically most favored position.<sup>45</sup>

An early example of allylic hydroxylation was provided by Licht and Coscia,<sup>46</sup> who reported that the CYP2B 4-catalyzed hydroxylation of the terpenes geraniol (14) and nerol (16) occurred almost exclusively at the C-10 (*E*)-methyl group of both compounds (eqns [4] and [5]). What is informative about this example is that the adjacency of a double bond converts the methyl group to a major site of oxidative attack.

Scheme 2

The mechanism of cytochrome P450-catalyzed allylic hydroxylation was found to be consistent with a hydrogen abstraction–oxygen rebound mechanism by Groves and Subramanian.<sup>47</sup> A consequence of generating a radical intermediate, as the mechanism requires, is the possible production of a rearranged product. This is seen in the metabolism of (*R*)-pulegone (18), the major constituent of pennyroyal oil, a volatile plant oil that has been used as an abortifacient and causes major toxicity at high doses. Menthofuran (19), previously identified as a metabolite of pulegone, appeared to arise from initial cytochrome P450-catalyzed oxidation of one of the allylic methyl groups.<sup>48</sup> To probe the mechanism of the reaction, the (*E*)-methyl-d<sub>3</sub> analog of pulegone (18) was synthesized and incubated with

**Scheme 3**

microsomal cytochrome P450, to form **19** (Scheme 3).<sup>49</sup> Isolated **19** contained a furano-trideuteromethyl group, indicating that a labile intermediate must have been formed during the course of the reaction to allow interchange of the positions of the two allylic methyl groups prior to hydroxylation, ring closure, and aromatization.

#### 5.05.2.1.2.4 Carbon atoms $\alpha$ to a heteroatom (N, O, S, and X)

*N*-Dealkylation is a frequently encountered metabolic reaction. It is often responsible for the production of the major metabolite obtained from an *N*-alkyl containing drug. Its prominence does not simply derive from the commonality of an alkyl-substituted amino group as an important part of the structural motif of many drugs. It arises primarily as a consequence of *N*-dealkylation being energetically favored.<sup>10</sup> Typical examples include the *N*-demethylation of methamphetamine (**20**)<sup>50</sup> (eqn [6]), the *N*-deethylation of lidocaine (**22**)<sup>51</sup> (eqn [7]), and the *N*-deisopropylation of propranolol (**24**)<sup>52</sup> (eqn [8]), to form the secondary amines **21**, **23**, and **25**, respectively.

There are two competing mechanisms for oxidative *N*-dealkylation: the single-electron transfer (SET) mechanism, championed by Guengerich and McDonald,<sup>53–59</sup> and the hydrogen atom transfer (HAT) mechanism, advocated by Dinnocenzo and Jones.<sup>60–64</sup> Both mechanisms postulate the intermediacy of a carbon-based radical, but differ in the mechanistic events leading to its formation (Figure 2). The HAT pathway postulates direct formation of the radical by transfer of a hydrogen atom from the  $\alpha$ -carbon atom to heme  $\text{FeO}^{3+}$ , to form heme  $\text{FeOH}^{3+}$ . In contrast, the SET pathway requires two steps, initiated by single-electron transfer from the nitrogen lone pair to heme  $\text{FeO}^{3+}$ , to form heme  $\text{FeO}^{2+}$ , followed by transfer of  $\text{H}^+$  from the  $\alpha$ -carbon atom to heme  $\text{FeO}^{2+}$ , forming heme  $\text{FeOH}^{3+}$  and the  $\alpha$ -carbon radical. Oxygen rebound by either mechanism then forms the carbinolamine. Carbinolamines are chemically unstable, and dissociate to generate the secondary amine and aldehydes as products, or eliminate water to generate the iminium ion. The iminium ion if formed can reversibly add water to reform the carbinolamine, or add a different nucleophile if present (Figure 2). If the nucleophile is within the same molecule and four or five atoms removed from the iminium carbon atom, cyclization can occur and form a stable five- or six-membered ring system. For

**Figure 2** Mechanisms for oxidative *N*-dealkylation: SET and HAT.

Scheme 4

example, the 4-imidazolidinone **26** is a major *in vivo* metabolite of lidocaine (**22**) (Scheme 4). It can also be formed upon isolation of the *N*-deethyl metabolite of lidocaine (**23**), if a trace of acetaldehyde happens to be present in the extraction solvent<sup>51</sup> (Scheme 4). A related example<sup>65</sup> is the formation of the stable 3,3-diphenylpyrrolidine **29** that is generated by the intramolecular cyclization of *N*-desmethylnmethadone (**28**), the major metabolite of methadone (**27**) (Scheme 5).

Since iminium ions are reactive electrophiles, it is not surprising that they have been associated with toxicity. An interesting example is provided by the psychotomimetic agent phencyclidine (**30**), whose use can lead to long-term psychoses. When phencyclidine is incubated with rabbit liver microsomes, a reactive intermediate is formed that can be trapped by the addition of cyanide ions (Scheme 6). The structure of the cyanide adduct (**32**) is consistent with being formed from reaction of cyanide with the phencyclidine iminium ion (**31**).<sup>66,67</sup> Further NADPH-dependent metabolism of the iminium ion leads to the production of the conjugated pyridone **33**, a reactive electrophile that is the likely species responsible for stable covalent binding with critical bio-macromolecules and toxicity (Scheme 6).<sup>68</sup>

Oxidative attack on a C–H bond of an alkyl group  $\alpha$  to a nitrogen atom is not restricted to saturated aliphatic amines. In fact, X in an X–N–CH– structural subunit can be virtually any common atomic grouping that can be found in stable organic molecules. For example,  $\alpha$ -carbon hydrogen atoms of *N*-alkyl-substituted aromatic cyclic amines (**34**),<sup>69</sup> aryl amines (**36**),<sup>60</sup> amides (**38**),<sup>70,71</sup> amidines (**41**),<sup>72</sup> and *N*-nitrosoalkylamines (**43**)<sup>73</sup> (eqns [9]–[13]), are all subject to oxidative attack, carbinolamine formation, and, in most cases, release of an aldehyde or ketone, depending on the substitution pattern (1° or 2°) (eqns [11]–[13]). In some cases (e.g., *N*-alkyl aromatic cyclic amines), carbinolamines are stable enough to be isolated (e.g., **35**) (eqn [9]).

Scheme 5

Scheme 6

Cytochrome P450 can also catalyze hydroxylation of a C–H bond  $\alpha$  to the oxygen atom in both alcohols and ethers. However, in contrast to ethers, the primary oxidants of alcohols appear to be the dehydrogenase enzymes and not the cytochromes P450, as will be discussed later.

The *O*-dealkylation of ethers, while not encountered as frequently as *N*-dealkylation, is still a common metabolic pathway. Mechanistically, it is less controversial than *N*-dealkylation. It is generally believed to proceed by the HAT pathway (Figure 3). The product of the reaction is unstable, being a hemiacetal or hemiketal, which dissociates to generate an alcohol and an aldehyde or ketone.

Energetically, *O*-dealkylation is less favored than *N*-dealkylation.<sup>44</sup> This is not surprising, as the greater electronegativity of oxygen relative to nitrogen would make abstraction of an  $\alpha$ -hydrogen atom more difficult. Examples of drugs in which *O*-dealkylation plays a significant role are phenacetin (**45**),<sup>74</sup> dextromethorphan (**47**),<sup>75</sup> codeine (**49**),<sup>76</sup> and metoprolol (**51**)<sup>77</sup> (eqns [14]–[17]).

A methylene dioxy group in aromatic compounds is subject to *O*-dealkylation (e.g., 3,4-methylenedioxyamphetamine (53)<sup>78</sup>) (eqn [18]). The process generates formic acid and the catechol metabolite 54 as final products. However, in the course of the reaction a portion of the enzyme can be inactivated by formation of what has been termed a metabolic intermediate (MI) complex<sup>79,80</sup> characterized by an absorption peak maximum at 455 nm in the difference spectrum of reduced cytochrome P450. The complexing species is believed to be a carbene that associates with heme  $\text{Fe}^{2+}$  (55), in much the same way that carbon monoxide<sup>81,82</sup> does. The complex is of moderate stability, and thus a quasi-irreversible inhibitor of the enzyme. It ultimately dissociates to generate ferric cytochrome P450, carbon monoxide, and the catechol 54.<sup>83</sup>

*S*-Dealkylation, unlike *N*- or *O*-dealkylation, is uncommon, generally not a major metabolic pathway, and in some cases does not even contribute to the metabolic profile of a sulfide-containing drug. This is probably due to two factors: (1) sulfide-containing drugs represent a small percentage of available drugs and (2) the sulfur atom itself is more

**Figure 3** Mechanism for the *O*-dealkylation of ethers.

susceptible to oxidation than is the adjacent  $\alpha$ -C-H bond. Nevertheless,  $\delta$ -dealkylation does occur, but whether it is driven by cytochrome P450 or some other enzyme system is not clear.

Halogen dealkylation mirrors *O*-dealkylation both in terms of mechanism and the commonality of the process, that is, while an aliphatic halogen substituent is not a common structural component, virtually any drug that contains a C-H bond adjacent to a halogen atom will be subject to cytochrome P450-catalyzed oxidative dehalogenation. Halogen atoms can also be removed either reductively, as will be discussed later, or by glutathione displacement, and as such represent a chemical group that is fairly labile in a biological environment.

Aliphatic halogen atoms are present in a number of common solvents and industrial chemicals to which people are exposed. For example, the fuel additive and suspected human carcinogen 1,2-dibromoethane (**56**) is oxidatively transformed to bromoacetaldehyde (**57**) by CYP2E (eqn [19]).<sup>84</sup> Aliphatic halogen atoms are also a major structural component of most inhalation anesthetics.

Since many of these compounds contain two halogen atoms on a terminal methyl group, their metabolism can lead to serious toxicity because of the generation of reactive intermediates such as acyl halides.<sup>85</sup> For example, chloroform (**58**)-induced nephrotoxicity in mice has been correlated with the ability of the animals to metabolically convert

chloroform to the highly reactive acid chloride phosgene (**59**)<sup>86–88</sup> (eqn [20]). Similarly, the inhalation anesthetic halothane (**60**) is converted to trifluoroacetyl chloride (**61**) (eqn [21]), which in turn can covalently bind to protein, generating liver protein neo-antigens.<sup>89,90</sup> In susceptible individuals these neo-antigens stimulate the production of anti-trifluoroacetyl-protein antibodies, which can cause fatal halothane hepatitis upon re-exposure to the anesthetic. The related anesthetics enflurane (**62**) and isoflurane (**63**) are also subject to acyl halide formation and an ensuing hepatic dysfunction similar to that caused by halothane.<sup>91–93</sup>

#### 5.05.2.1.3 Oxidation of $\text{sp}^2$ carbon atoms

##### 5.05.2.1.3.1 Isolated or exo-ring double bonds

The cytochrome P450-catalyzed oxidation of a  $\text{C}=\text{C}$  bond results in the formation of an epoxide. For example, the major metabolite of the anticonvulsant carbamazepine (**64**) is carbamazepine-10,11-epoxide (**65**)<sup>94</sup> (eqn [22]), and the potential carcinogen butadiene (**66**) is converted to the mono-epoxide **67**, by human liver microsomes (eqn [23]).<sup>95</sup>

Mechanistically, the reaction is bounded by two extremes. At one extreme,  $\text{FeO}^{3+}$  adds to the double bond in a single step, while at the other a two-step reaction involving the generation of an intermediate is operative. Evidence exists for both pathways, but again the two-state reactivity paradigm of Shaik and co-workers appears to resolve the dilemma.<sup>96,97</sup>

##### 5.05.2.1.3.2 Aromatic rings

The frequency of aromatic hydroxylation as a metabolic event is undoubtedly a reflection of the commonality of an aromatic ring as a structural component of many drugs. While a phenol is usually not the major metabolite of such a drug, it often is found as a significant contributor to the metabolism of that drug. In general, phenol formation follows the rules of electrophilic aromatic hydroxylation established by the linear free energy relationships of physical organic chemistry (i.e., *para* > *ortho* > *meta*). This order prevails unless the system is deactivated by a substituent that on balance withdraws electron density from the ring (e.g., nitro group). In such a case, *meta* substitution predominates, since it is the site that is the least deactivated toward electrophilic attack. In the case of cytochrome P450 catalysis, an exception would occur if the steric demands of the active site architecture of the enzyme for a specific substrate favored *meta* hydroxylation.

These general observations suggest that if the enzyme has a sterically permissive active site that is not overly restrictive to substrate motion, the electronic properties of the substrate should determine regioselectivity of hydroxylation. Thus, the development of computational models for predicting aliphatic hydroxylation, aromatic hydroxylation, or a combination of the two, pioneered by Jones, Korzekwa, and colleagues,<sup>10,45,98,99</sup> is not only promising but has already met with considerable success.

Establishing the exact mechanism for aromatic hydroxylation has proved to be difficult. If deuterium is present in the substrate at the site of hydroxylation, a fractional amount of deuterium will almost always be retained in the product owing to migration to the adjacent carbon atom during the process of phenol formation. This is the well-known NIH shift.<sup>100</sup> It was believed to occur upon ring opening of an initially formed epoxide (arene oxide) (pathway 1 in [Figure 4](#)). Mechanistically, epoxide formation can occur either by a concerted addition of oxygen to form the epoxide in a single step or by a stepwise process. The stepwise process would involve: (1) the initial addition of oxygen to a

**Figure 4** Mechanism for aromatic hydroxylation.

specific carbon atom, to form a tetrahedral intermediate; (2) electron transfer from the aryl group to heme, to form a carbonium ion adjacent to the oxygen adduct; followed by (3) ring closure, to form the epoxide (pathway 2, [Figure 4](#)). From this point on to the formation of the final product phenol, both mechanisms are identical: the ring opens, generating an adjacent carbonium ion, and the hydride moiety shifts to satisfy the adjacent carbonium ion, as a pair of electrons from the oxygen atom moves in to satisfy the positive charge being developed as the hydride leaves; this overall process leads to the formation of a ketone, which then tautomerizes to generate the phenol. The stepwise mechanism does not necessarily have to close to epoxide. At step 2 it can bypass epoxide formation, to form the ketone directly, then the phenol (pathway 3, [Figure 4](#)), or it can form the phenol directly by proton transfer to a pyrrole nitrogen atom (pathway 4, [Figure 4](#)).

A concerted mechanism would require obligatory epoxide formation on the path to phenol, whereas a stepwise mechanism would not necessarily have to pass through the epoxide. Since epoxides can be toxic or even carcinogenic (e.g., epoxides of some polycyclic aromatic hydrocarbons), the question of whether their formation is obligatory is significant for drug design and development.

A theoretical study<sup>101</sup> and several experimental studies<sup>102–105</sup> have provided strong evidence for the stepwise mechanism, and, most recently, de Visser and Shaik<sup>106</sup> examined the problem using density functional calculations, and came to the same basic conclusion.

#### 5.05.2.1.3.3 Carbonyl carbon atoms

The conversion of acetaldehyde to acetic acid by cytochrome P450 has been clearly established.<sup>107</sup> But of the aldehydes that have been shown to be metabolized by cytochrome P450, allylic or aryl aldehydes appear to be the best substrates.<sup>108</sup> For example, retinal (**68**)<sup>109</sup> and the 11-oxo metabolite of tetrahydrocannabinol (**70**)<sup>110</sup> are oxidized to carboxylic acids (eqns [24] and [25]).

Selective cleavage of an unactivated C–C bond is chemically difficult. However, the highly specialized steroidogenic cytochromes P450 aromatase and lanosterol-14 $\alpha$ -demethylase accomplish this difficult transformation with relative ease. In the case of aromatase, androstenedione (**72**) is converted to estrone (**73**) by three sequential oxidations of the C-19 methyl group, culminating in the elimination of formic acid and the aromatization of the A ring (eqn [26]). While the first two steps (sequential hydroxylations of C-19 to form a hydrated aldehyde) are well understood, the final oxidation leading to loss of formic acid and aromatization is not. An attractive possibility suggested by Akhtar *et al.*<sup>111</sup> is that an O<sub>2</sub>-derived peroxide might be involved in the final C–C bond cleavage step.

To investigate this possibility, Vaz *et al.*<sup>112</sup> used cyclohexanecarboxaldehyde (**74**) as a simple model of the C-19 aldehyde of androstendione. Upon treatment with CYP2B4, NADPH, and cytochrome P450 reductase, the aldehyde–cyclohexyl ring C–C bond of **74** was cleaved, forming cyclohexene (**75**) and formic acid (eqn [27]). The reaction was supported if hydrogen peroxide replaced NADPH and cytochrome P450 reductase, but was not supported if other oxidants such as iodosobenzene, *m*-perchlorobenzene, and cumyl hydroperoxide were used. The authors propose that an O<sub>2</sub>-derived heme-iron-bound peroxide attacks the carbonyl carbon, to form an enzyme-bound peroxyhemiacetal-like intermediate (**76**). The intermediate rearranges either by a concerted or sequential mechanism, to yield the observed products.

In a subsequent paper, Roberts *et al.*<sup>113</sup> found that CYP2B4 would selectively deformylate a number of simple  $\alpha$ - or  $\beta$ -branched-chain, but not normal-chain, aldehydes, to generate alkenes. Still later, Vaz and co-workers<sup>114–117</sup> provided strong evidence that cytochrome P450 heme FeO<sub>2</sub><sup>1+</sup>, or FeO<sub>2</sub>H<sup>2+</sup>, rather than FeO<sup>3+</sup>, is the active oxidant in deformylation reactions.

#### 5.05.2.1.4 Oxidation of sp carbon atoms

The oxidation of terminal aryl alkynes by cytochrome P450 forms the corresponding substituted aryl acetic acid. Early on it was shown<sup>118</sup> that if the alkyne hydrogen atom of 4-ethynylbiphenyl was replaced with deuterium (**77**), it would be quantitatively retained on the  $\alpha$ -carbon of the acid metabolite (**79**) (Scheme 7). The reaction proceeds by heme FeO<sup>3+</sup> addition to the terminal acetylenic carbon, with concerted migration of the hydrogen atom to the adjacent carbon atom, leading to the formation of a substituted ketene (**78**). The reactive ketene is hydrolyzed, to generate the final product (**79**). If heme FeO<sup>3+</sup> adds to the inner carbon of the acetylene group, the reaction takes an entirely different course. This latter reaction pathway leads to alkylation of a heme nitrogen, and destruction of the enzyme.<sup>119,120</sup>

Scheme 7

## 5.05.2.1.5 Oxidation at a heteroatom

## 5.05.2.1.5.1 Mechanism for oxidation at a nitrogen atom

It is clear from the literature that while *N*-oxides and *N*-hydroxylated compounds are observable metabolites, they are minor relative to the products of *N*-dealkylation. They appear to only become more significant when *N*-dealkylation is not an option.<sup>57</sup> A caveat, however, is that *N*-hydroxy compounds are not all that stable, particularly in vivo, where they can be reduced back to the amine or further oxidized to even less stable compounds. The degree to which they contribute to nitrogen metabolism may be underestimated because of their relative instability.

5.05.2.1.5.2 *N*-Hydroxylation

*N*-Hydroxylation is most frequently found occurring with primary and, to a lesser extent, secondary alkyl and aryl amines or with aryl amides. For example, the  $\beta$ -phenethylamine phentermine (**80**),<sup>121</sup> the arylamine dapsone (**82**),<sup>122</sup> and the aryl amide 2-acetoaminofluorene (**84**)<sup>123</sup> are all oxidized, to yield significant amounts of the corresponding *N*-hydroxy metabolite (eqns [28]–[30]).

*N*-Hydroxylamines as a class of compounds are problematic. The alkyl-*N*-hydroxylamines tend to be toxic, and many of the hydroxylamines of arylamines and arylamides are carcinogenic.<sup>123–125</sup> Alkyl- and aryl-*N*-hydroxylamines are readily oxidized to chemically reactive nitroso compounds that are at least as toxic as the parent. They form quasi-irreversible inhibitors of the enzyme that produces them,<sup>126</sup> through generation of tightly bound heme Fe<sup>2+</sup> complexes characterized by an ultraviolet spectrum with an absorbance maximum at around 455 nm, analogous to the MI complexes generated from methylenedioxy substrates. The phenomenon is general, and encompasses many widely used drugs,<sup>127</sup> including major antibiotics such as troleandomycin and erythromycin,<sup>128–130</sup> thereby raising its potential as a source of drug–drug interactions.

*N*-Hydroxylation is not restricted to amines or amides. Other nitrogen-based functional groups that have at least one N–H bond are susceptible to cytochrome P450-catalyzed *N*-hydroxylation. Examples include the amidino group of the antiprotozoal drug pentamidine (**86**)<sup>131</sup> (eqn [31]), the guanidino group of the antihypertensive debrisoquine (**88**)<sup>132</sup> (eqn [32]), or the iminoguanidino group of the antihypertensive guanabenz (**90**)<sup>133</sup> (eqn [33]).

The oxidation of alkyl and aromatic tertiary nitrogen-containing substrates by flavin-containing monooxygenase (FMO) and, to a lesser extent, by cytochrome P450, generates *N*-oxide metabolites. Since FMO is the primary driver of *N*-oxidation, specific examples will be presented in the section on FMO-catalyzed reactions that follows.

#### 5.05.2.1.5.3 Mechanism for oxidation at a sulfur atom

Where *N*-hydroxylation and *N*-oxide formation are minor pathways relative to *N*-dealkylation, the exact opposite is true of sulfur oxidation. *S*-Dealkylation is a minor pathway of metabolism, while direct oxidation of sulfur to a sulfoxide and/or a sulfone is a major pathway. Both FMO and cytochrome P450 can catalyze sulfur oxidation, but cytochrome P450 is often the major contributor. If the reaction is initiated by electron abstraction to generate a sulfur radical cation (the SET mechanism), it could serve as a common intermediate for both sulfoxidation and *S*-dealkylation. Product formation would reflect competition between the two pathways. However, independent mechanisms, a SET mechanism for sulfoxidation versus a HAT mechanism for *S*-dealkylation, could account for the data, since the energy required for ionization is much lower for sulfur than it is for nitrogen.

#### 5.05.2.1.5.4 S-Sulfoxidation and sulfone formation

Several examples of drugs that are subject to *S*-oxidation follow. Tazofelone (**92**) is a new drug that has been shown to be highly effective in the treatment of inflammatory bowel disease in animal models but has poor bioavailability because of rapid turnover. Determination of the metabolic profile of **92** revealed that a mixture of tazofelone sulfoxide diastereoisomers (**93**) was a major metabolite of the drug, and that CYP3A4 was primarily responsible for its formation (eqn [34]).<sup>134</sup>

The major human metabolites<sup>135</sup> of SNI-2011 (**94**), a new agent being developed to treat a chronic autoimmune disorder known as Sjögren's syndrome, are a mixture of sulfoxide diastereoisomers (**95**) and, to a lesser extent, the *N*-oxide (**96**) (Scheme 8). Interestingly, while **95** arises from the action of cytochrome P450, **96** is formed by FMO in the kidney.

A major human metabolite of sulfapyrazone (**97**), a sulfoxide-containing uricosuric agent, is the sulfone<sup>136</sup> **98** (eqn [35]). Similarly, a sulfone is a significant human metabolite of the proton pump inhibitor omeprazole<sup>137</sup> (**99**) (eqn [36]).

Scheme 8

#### 5.05.2.1.6 Other cytochrome P450 oxidative reactions

##### 5.05.2.1.6.1 Oxidative dehydrogenation

The anticonvulsant valproic acid (**101**) undergoes normal cytochrome P450-catalyzed transformation, to generate the  $\omega$  and  $\omega$ -1 hydroxylated metabolites, (**102** and **103**, respectively; [Scheme 9](#)). However, the unsaturated substrate, 4-ene valproic acid (**104**), is also produced, suggesting product partitioning between the alcohol and alkene. While **104** is a minor metabolic product, its formation is important both from a mechanistic perspective and from the fact that it is toxic. Using selectively deuterated valproic acid analogs, Rettie *et al.*<sup>138,139</sup> established that **104** forms in competition with **103** after initial abstraction of a hydrogen atom from the  $\omega$ -1 carbon, to form the radical **105**. Abstraction of a  $\omega$ -hydrogen atom to form the radical **106** only leads to **102**.

Similarly, testosterone (**107**) is oxidized by CYP2A1 to four metabolites,<sup>140,141</sup> 7 $\alpha$ -hydroxy- and 6 $\alpha$ -hydroxytestosterone (**108** and **109**, respectively),  $\Delta^6$ -testosterone (**110**), and  $\Delta^6$ -testosterone epoxide (**111**) ([Scheme 10](#)), the epoxide being formed from further oxidation of **110**. Again using selectively deuterated analogs, Korzekwa *et al.*<sup>141</sup> established that **110** was formed in competition with **109** after initial hydrogen atom abstraction from C-6 to form the radical **112**. Little if any **108** formed upon initial hydrogen abstraction from C-7.

Scheme 9

Scheme 10

**Scheme 11**

A third example can be found with ezlopitant (**113**), a drug being developed as a potential substance P receptor antagonist. Metabolism of **113** yields two major metabolites, the benzyl alcohol **114** and the corresponding alkene<sup>142</sup> **115** (Scheme 11).

#### 5.05.2.1.6.2 Oxidative cleavage of esters and amides

If esters and amides are also susceptible to oxidative attack, one would expect that the site of attack to be the carbon atom  $\alpha$  to an oxygen atom (esters) or  $\alpha$  to a nitrogen atom (amides) by analogy to *O*- and *N*-dealkylations. This is indeed the case. Guengerich *et al.*<sup>143</sup> demonstrated that the pyridine diester **116** was oxidatively cleaved, to yield the mono-acid **117** (eqn [37]). Subsequently, Peng *et al.*<sup>144</sup> established that oxidative cleavage is a general cytochrome P450 reaction for commonly used esters and amides. The reaction has largely gone unrecognized, probably because of being obscured by hydrolysis, the expected mode of reaction.

#### 5.05.2.1.6.3 Oxidative transformation of nitriles

Cytochrome P450-catalyzed C–C bond cleavage is a relatively rare event. The conversion of aldehydes to alkenes<sup>112,113</sup> was presented earlier. A second example is the conversion of a nitrile to a cyanide ion and an aldehyde or ketone. Grogan *et al.*<sup>99</sup> modeled the reaction using a set of 26 structurally diverse nitriles. They found that acute toxicity in the mouse correlated with the ease of hydrogen abstraction  $\alpha$  to the nitrile (cyanide release) relative to oxidative attack at other intramolecular sites (no cyanide release).

Cytochrome P450 also appears to generate nitriles from alkyl and arylaldoximes by catalyzing their dehydration.<sup>145,146</sup> The reaction was first reported for the conversion of *n*-butyraldoxime (**118**) to butyronitrile (**119**), and found to require reduced cytochrome P450 (heme  $\text{Fe}^{2+}$ ) and be inhibited by excess  $\text{O}_2$  (eqn [38]).<sup>145</sup> Subsequently, the reaction was established for both alkyl- and arylaldoximes<sup>146</sup> (e.g., benzaldoxime (**120**) (eqn [39]), and phenylacetaldoxime (**122**) (eqn [40])), suggesting that while it is apparently restricted to the (*Z*) isomer, it might be general.

Nitriles can also be oxidized to amides. Zhang *et al.*<sup>147</sup> found that CYP3A4 would convert the cyano group of the potassium channel-opening agent pinacidil (**124**) to the corresponding amide (**125**) (eqn [41]).

#### 5.05.2.1.6.4 Oxidative transformation of a tertiary carbon atom adjacent to a nitrogen atom

The CYP3A4-catalyzed oxidation of the synthetic opioid alfentanil (**126**) follows two major pathways<sup>148</sup>: *N*-dealkylation, to form noralfentanil (**127**), and cleavage of the spiro center, to generate *N*-phenylpropionamide (**128**) (Scheme 12). Moreover, **128** is found to come directly from alfentanil and not **127**. The mechanism of how the C–N bond of the spiro center is cleaved is unknown.

The treatment of 1-phenylcyclobutylamine (**129**) with cytochrome P450 results in ring expansion and the production of 2-phenyl-1-pyrroline (**130**). Presumably, the mechanism involves sequential formation of the aminium radical cation, homolytic ring opening, ring closure, then, finally, a second one-electron oxidation to form the pyrroline (Scheme 13).<sup>149</sup>

#### 5.05.2.1.6.5 Ipsso substitution

A relatively new aspect of cytochrome P450-catalyzed aromatic hydroxylation is the replacement of the substituent of a *para*-substituted phenol with a hydroxy group; a phenomenon termed ipso substitution. In 1994, Ohe *et al.*<sup>150</sup> reported that cytochrome P450 catalyzed the partial conversion of both *p*-methoxyphenol (**131**) and *p*-phenoxyphenol (**132**) to hydroquinone (**133**) (Scheme 14). In a subsequent paper, the scope of the reaction was investigated, and found to require the phenolic group.<sup>151</sup> Nine *p*-substituted phenols (F, Cl, Br, NO<sub>2</sub>, CN, CH<sub>2</sub>OH, COCH<sub>3</sub>, CPh, CO<sub>2</sub>H) of diverse structure were incubated with rat liver microsomes, and the amount of **133** formed from each substrate was determined. All substrates gave measurable or significant levels of **133**, except perhaps for *p*-tolylphenol (**134**). In the case of **134**, the reaction stopped at the formation of the ipso adduct, *p*-toluquinol (**135**) (eqn [42]).

Scheme 12

Scheme 13

Scheme 14

[42]

### 5.05.2.2 Flavin Monooxygenases

#### 5.05.2.2.1 Occurrence, multiplicity, catalytic cycle, oxygen activation, and selectivity

The oxidative activity of the NADPH and  $O_2$ -dependent FMOs are largely complementary to that of the cytochromes P450.<sup>152</sup> Like the cytochromes P450, the FMOs are widely distributed in nature, have multiple family members, with six (FMO1–FMO6) having been characterized.<sup>153</sup> In humans they are found in close association with cytochrome P450 in the endoplasmic reticulum of most tissues, with the greatest concentration being in liver (FMO3)<sup>154,155</sup> FMO1 is the major form in human fetal liver,<sup>156</sup> but it localizes in the kidney in the adult.<sup>157</sup> The FMOs display broad substrate selectivity, and like cytochrome P450 the primary criterion for reaction is substrate access to the active oxidizing species.<sup>152,158</sup>

Unlike the cytochromes P450 the FMOs appear not to be inducible, and operate by the two-electron oxidation characteristic of peroxides. Nature seems to have designed the FMOs to be selective for a class of compounds that the cytochromes P450 are less efficient at oxidizing: xenobiotics that contain electron-rich polarizable nucleophilic groups. These are largely compounds containing the elements sulfur, nitrogen, selenium, and phosphorus (thiols, sulfides, disulfides, amines (1°, 2°, and 3°), imines, hydrazines, hydroxylamines, selenols, selenides, phosphines, etc.).<sup>152</sup>

The active oxygen species utilized by the FMOs is the C(4a)-hydroperoxyflavin **136**, generated from  $O_2$  addition to  $FADH_2$ , formed upon reduction of flavin adenine dinucleotide (FAD) by enzyme-bound NADPH (Figure 5). The substrate is oxidized, water eliminated from the residual C(4a)-hydroxyflavin, and FAD regenerated to complete the catalytic cycle.<sup>159–161</sup>

**Figure 5** The FMO catalytic cycle.

Since the FMOs and cytochromes P450 are closely associated and can catalyze some of the same reactions, it is important to be able to determine which enzyme is primarily responsible for the formation of a given metabolite. This is of particular importance for in vitro–in vivo correlation and drug interaction studies. Experimentally, the enzymes can be distinguished<sup>136</sup> by heat and by running the reactions at higher pH. If the microsomal preparation is heated (45 °C for 5 min) before NADPH is added to initiate the reaction, cytochrome P450 maintains its activity while that of FMO is lost. If in a separate experiment the pH of the incubation mixture is raised to 9, FMO maintains activity but cytochrome P450 activity is virtually abolished, particularly in the presence of a detergent.

#### 5.05.2.2.2 Oxidation at a nitrogen atom

FMO *N*-hydroxylates both amphetamine (21) and methamphetamine (20), to generate the hydroxylamines 137 and 138, respectively (Scheme 15).<sup>162</sup> It then catalyzes a second *N*-hydroxylation in both metabolites. The two *N,N*-dihydroxy intermediates eliminate water, to generate the oxime in the case of 139 and the nitrone in the case of 140.

Both FMO3 and extra-hepatic FMO1 have been shown to be effective in oxidizing the nonsteroidal anti-inflammatory agent benzydamine (141)<sup>163</sup> to benzydamine *N*-oxide (142), with only a minor contribution from cytochrome P450 (eqn [43]). FMO is also the major catalyst for the conversion of the antipsychotic clozapine (143)<sup>164</sup> and the anticancer agent tamoxifen (145),<sup>165</sup> and for the cerebral metabolism of the psychoactive drug imipramine (147),<sup>166</sup> to their corresponding *N*-oxides (144, 146, and 148, respectively) (eqns [44]–[46]).

Scheme 15

#### 5.05.2.2.3 Oxidation at a sulfur atom

Sulindac sulfide (**149**), a metabolite of the nonsteroidal anti-inflammatory agent sulindac, is re-oxidized by FMO<sup>167</sup> with a high degree of stereoselectivity toward the (*R*) enantiomer back to enantiomerically enriched sulindac (**150**) (eqn [47]).

Metabolic activation of the antitubercular pro-drug ethionamide (**151**) occurs within the organism *Mycobacterium tuberculosis*. FMO<sup>168</sup> has been identified as the enzyme that activates **151** by catalyzing two sequential oxidations. The

Scheme 16

first is to the inactive *S*-oxide **152**, while the second oxidation generates the active agent, but a stable, noncytotoxic amide **153** is the only product isolated (Scheme 16). These results imply that the cytotoxic agent is a reactive intermediate that can break down to **153**. It has been postulated<sup>168</sup> that the reactive intermediate is a sulfinic acid **154**, which upon hydrolysis yields **153**.

### 5.05.2.3 Monoamine Oxidase (MAO)

#### 5.05.2.3.1 Occurrence, multiplicity, distribution, oxygen activation, and selectivity

MAO, like FMO, is an enzyme that relies on the redox properties of FAD for its oxidative machinery. The enzyme exists as two isoforms, MAO-A and MAO-B, that share a sequence homology of approximately 70%.<sup>169</sup> They are found in the outer mitochondrial membrane, and are widely distributed in mammalian tissues. The isoforms differ in substrate selectivity<sup>170</sup> and tissue distribution.<sup>171</sup> MAO-A is located primarily in the placenta, gut, and liver, while MAO-B is predominant in the brain, liver, and platelets. In humans, MAO-B constitutes about 80% of the enzyme found in the liver.<sup>172</sup> The primary function of both isoforms appears to be to catalyze the oxidative deamination of the arylalkylamino neurotransmitters, to form the corresponding aldehydes. MAO-A is selective for serotonin and norepinephrine, and is selectively inhibited<sup>173</sup> by the mechanism-based inhibitor clorgyline (**155**). MAO-B is selective for  $\beta$ -phenethylamine and tryptamine, and is selectively inhibited<sup>173</sup> by the mechanism-based inhibitors deprenyl (**156**) and pargyline (**157**). Recently, both MAO-A<sup>174</sup> and MAO-B<sup>175</sup> were structurally characterized by x-ray crystallography.

The role of MAO-A and MAO-B in regulating the concentration of the amine neurotransmitters offered a strategy for treating pathologies that involve these critical biomolecules. Thus, drugs have been developed that are used to treat the symptoms of depression by inhibiting MAO-A<sup>176</sup> or neurodegenerative diseases such as parkinsonism by inhibiting MAO-B.<sup>177</sup>

### 5.05.2.3.2 Mechanism of monoamine oxidase oxygen activation and oxidation of substrate

Overall, the catalytic activity of MAO can be characterized as two half-reactions.<sup>171</sup> In the first the amine substrate is oxidized, and the FAD cofactor is reduced to FADH<sub>2</sub>, while in the second the imine product is released, and the FADH<sub>2</sub> cofactor is re-oxidized to FAD, generating peroxide in the process. The released imine chemically hydrolyzes to the corresponding aldehyde.

A mechanism involving a SET has generally been accepted<sup>178</sup> (Figure 6a), although evidence for a HAT mechanism<sup>179,180</sup> exists (Figure 6b), and a polar nucleophilic mechanism has also been advanced<sup>181,182</sup> (Figure 6c).

### 5.05.2.3.3 Oxidation of xenobiotic amines

The most well-documented case of a MAO-B-catalyzed oxidation of a nonbiogenic amine<sup>183</sup> is the conversion of *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (158) to *N*-methyl-4-phenyl-2,3-dihydropyridine (MPDP<sup>+</sup>)

**Figure 6** Mechanisms for the catalytic activity of MAO: (a) SET, (b) HAT, and (c) via a polar nucleophile.

(159), on the path to formation of *N*-methyl-4-phenylpyridine (MPP<sup>+</sup>) (160), the neurotoxin that causes a parkinsonism-like syndrome. The reaction is not restricted to MPTP alone but will oxidize a number of MPTP analogs in which the *N*-methyl group<sup>184,185</sup> and/or the 4-aryl substituent<sup>172,185</sup> has been altered. A structure–activity relationship study<sup>185</sup> suggested that the maximum size of MPTP analogs acceptable as substrates by MAO-B is 12 Å, as measured along the N-1–C-4 axis.

While MAO does not appear to be a major catalyst in the metabolism of amine-containing drugs, it can contribute. The extent to which it does remains to be determined.

#### 5.05.2.4 Xanthine Oxidoreductase

Xanthine oxidoreductase is a complex homodimeric 300 kDa cytosolic enzyme. Each subunit contains a molybdopterin cofactor, FAD, and two nonidentical iron–sulfur centers.<sup>186–188</sup> It is widely distributed, and exists in two interconvertible forms in mammals: xanthine dehydrogenase and xanthine oxidase. Xanthine dehydrogenase predominates *in vivo*, while xanthine oxidase is the form that is generally isolated.<sup>186–188</sup> Maximum concentrations of xanthine oxidoreductase have been found in liver, intestine, and lactating mammary gland.<sup>189</sup> In patients with liver disease, xanthine oxidoreductase activity has been found to be 10–20-fold higher than that found in healthy liver tissue.<sup>190</sup>

Its primary role appears to be in the metabolism of purines (e.g., it catalyzes the sequence of oxidations that convert hypoxanthine (161) to xanthine (162), then to uric acid (163) (Scheme 17)). Excess uric acid production can lead to flare-ups of symptomatic gout. One of the effective treatments for gout is the administration of allopurinol (164). Allopurinol is both a competitive inhibitor of xanthine oxidoreductase and a substrate, as xanthine oxidoreductase slowly oxidizes 164 to alloxanthine (165) (eqn [48]). Since 165 is also an inhibitor of xanthine oxidoreductase, the therapeutic effectiveness of 164 is not significantly compromised by its conversion to 165. However, if 164 and the anticancer agent 6-mercaptopurine (166) are coadministered, inhibition of xanthine oxidoreductase can be problematic. If the extensive first-pass metabolism of 166 to 6-mercaptopuric acid (167), catalyzed by xanthine oxidoreductase (eqn [49]), is inhibited by 164, it can result in potentially toxic plasma concentrations of 166 fivefold higher than normal.<sup>191</sup>

Scheme 17

[48]

Since xanthine oxidoreductase is a ready source of electrons that can be transferred to molecular oxygen to form reactive oxygen species such as superoxides and peroxides, it is thought to be involved in free radical-generated tissue injury. It has been implicated in the pathogenesis of ischemia–reperfusion damage and, more recently, in the production of peroxynitrite (168)<sup>187</sup> and the carbonate radical anion 169,<sup>195</sup> both potent biological oxidants. Since xanthine oxidoreductase is present in high concentrations in the liver, it may be released into the circulation if the liver is injured, and bind to vascular endothelium, causing vascular dysfunction.<sup>196</sup>

While much has been learned about xanthine oxidoreductase, much remains to be uncovered. Understanding its exact role in lipid peroxidation, inflammation, and infection is particularly important. Its significance to drug metabolism remains to be determined.

**Figure 7** Mechanism of action for xanthine oxidoreductase.

### 5.05.2.5 Aldehyde Oxidase (AOX)

AOX is closely related to xanthine oxidoreductase, and like xanthine oxidoreductase is a member of the structurally related molybdoflavoenzymes. AOX and xanthine oxidoreductase have overlapping substrate selectivities, and operate by the same chemical mechanism.<sup>196</sup> As the name implies, one of the primary reactions that AOX catalyzes is the oxidation of aldehydes to carboxylic acids. For example, it contributes to the oxidation of acetaldehyde resulting from alcohol ingestion. Unfortunately, it also seems to be implicated in alcohol-induced liver injury because of the free radicals it generates in the process of oxidizing acetaldehyde.<sup>197</sup>

In oxidizing aldehydes, AOX appears to operate by the same mechanism it utilizes to oxidize purines. This is illustrated for the conversion of 2,5-dihydroxyacetaldehyde (**170**) to 2,5-dihydroxybenzoic acid<sup>193</sup> (**171**) (Figure 8).

AOX is also effective in metabolizing a wide range of nitrogen-containing heterocycles, such as purines, pyrimidines, pteridines, quinolines, and diazanaphthalenes.<sup>198,199</sup> For example, phthalazine (**172**) is rapidly converted to 1-phthalazinone (**173**) (eqn [50]),<sup>200</sup> the prodrug 5-ethynyl-2-(1*H*)-pyrimidone (**174**) is oxidized to the dihydro-pyrimidine dehydrogenase mechanism-based inhibitor 5-ethynyluracil (**175**) (eqn [51]),<sup>201</sup> and the prodrug famciclovir (**176**) is first hydrolyzed to 6-desoxypanciclovir (**177**), before being oxidized to the active antiviral agent panciclovir (**178**) by AOX (Scheme 18).<sup>202</sup>

**Figure 8** Mechanism for the oxidation of aldehydes by xanthine oxidoreductase.

Scheme 18

As more information becomes available, it is becoming increasingly probable that the contributions of AOX and xanthine oxidoreductase to the metabolism of drugs that incorporate aryl nitrogen-containing heterocycles have been largely unrecognized and underestimated.

#### 5.05.2.6 Aldehyde Dehydrogenases

The aldehyde dehydrogenases are members of a superfamily of pyridine nucleotide (NAD(P)<sup>+</sup>)-dependent oxidoreductases that catalyze the oxidation of aldehydes to carboxylic acids, are widely distributed in mammals, and are found in cytosol, mitochondria, and microsomes.<sup>203–205</sup> Seventeen genes have been identified in the human genome that code for aldehyde dehydrogenases, attesting to the importance of these enzymes to normal physiological function.

Aldehyde dehydrogenases can be placed in two broad categories: (1) those that are highly substrate-selective and are critical for normal development, and (2) those that are less substrate-selective and protect the organism from potentially toxic aldehydes contained in food or generated from xenobiotics.<sup>204</sup> An example of aldehyde dehydrogenases that fall into the first category are those that oxidize retinal (68) to retinoic acid (69) (eqn [24]), a molecule important for growth and development.<sup>206</sup>

Aldehyde dehydrogenases that fall into the second category are almost invariably detoxifying. The most common example is the oxidation of alcohol-derived acetaldehyde to acetic acid. However, sometimes it is advantageous to inhibit their detoxifying effects. For example, inhibition of acetaldehyde oxidation by the administration of disulfiram (179) is a common treatment for alcohol abuse.<sup>207</sup> In vivo, 179 is converted to diethylthiomethylcarbamate (180), the active inhibitor (eqn [52]). Inhibition results in potentially toxic levels of acetaldehyde upon ingestion of alcohol by the abuser.

A second example is provided by the anticancer agent cyclophosphamide (181).<sup>208</sup> Upon administration of 181, cytochrome P450 catalyzes hydroxylation at the 4-position, to produce 182, leading to the formation of the ring-opened aldehyde 183, or further oxidation to the cyclic amide 184 (Scheme 19). In the absence of aldehyde dehydrogenase, the aldehyde spontaneously eliminates to generate acrolein (185) and the phosphoramidate mustard 186, both of which are cytotoxic species responsible for the anticancer effects. In the presence of aldehyde dehydrogenase, the ring-opened aldehyde is converted to the acid carboxyphosphamide (187), a species that no longer eliminates 185 and has no anticancer affect.

The major set of substrates for aldehyde dehydrogenase include the aldehydes generated in MAO-catalyzed deamination reactions, cytochrome P450-catalyzed *N*- and *O*-dealkylation, oxidative dehalogenation, and oxidation of aryl and alkyl methyl groups.

Scheme 19

### 5.05.2.7 Alcohol Dehydrogenases (ADHs)

ADHs, a subset of the medium-chain dehydrogenases/reductases,<sup>209</sup> constitute a highly complex superfamily of widely distributed zinc containing cytosolic  $\text{NAD}^+$  dependant enzymes that are presently divided into seven classes<sup>210</sup> and numerous isozymes and allelic variants.<sup>211</sup> While they can reversibly catalyze the oxidation of the alcohol/aldehyde redox pair in a variety of substrates, including ethanol,<sup>212</sup> retinol,<sup>206</sup> and other aliphatic alcohols,<sup>212</sup> they function primarily as oxidative catalysts.

## 5.05.3 Reductions

### 5.05.3.1 Cytochrome P450

#### 5.05.3.1.1 Reductive dehalogenation

Under certain conditions, particularly anaerobic conditions, cytochrome P450 can function as a reductase. The most well-recognized reaction in this regard is probably reductive dehalogenation. In a series of papers in the early 1980s, Ullrich and co-workers<sup>213–215</sup> established that cytochrome P450 could catalyze the reductive removal of halogens from polyhalogenated alkanes such as hexachloroethane (188), to yield the corresponding carbon-based radical (Scheme 20). The radical would then undergo a second one-electron addition, to yield the carbanion. Elimination of a chloride ion or the addition of a proton yielded the observed products, tetrachloroethylene (189) and pentachloroethane (190), respectively.

Carbon tetrachloride (191) is a solvent that is chemically inert and highly resistant to oxidation, but biologically toxic. Despite its chemical stability, cytochrome P450 is able to convert 191 to a reactive species (Figure 9). Reduced cytochrome P450 transfers an electron to 191, to form a chloride anion and the reactive trichloromethyl radical 192,<sup>216</sup> in accordance with the mechanism proposed by Ullrich.<sup>213–215</sup> The trichloromethyl radical has a number of

Scheme 20

Figure 9 Mechanism for reductive dehalogenation.

pathways open to further reaction. It can adduct to the protein,<sup>217</sup> to give **193**, react with molecular oxygen, to form the trichloromethylperoxy radical (**194**),<sup>216</sup> or undergo a second one-electron reduction, to generate the trichloromethyl anion (**195**), which protonates to yield chloroform (**58**), or eliminates a second chloride anion, to generate dichlorocarbene (**196**).<sup>218</sup>

Both oxidative and reductive metabolism of the general anesthetic halothane (**60**) have been associated with hepatotoxicity (Scheme 21). Both processes lead to covalent adduction of a reactive metabolite to various proteins. In the case of oxidative metabolism, it is the trifluoroacetylated protein **197**, formed by reaction with the trifluoroacetyl chloride metabolite of halothane, as discussed earlier, while in the case of reductive metabolism it is the 2,2,2-trifluoro-1-chloroethylated protein **198**, formed from reaction with the 2,2,2-trifluoro-1-chloroethyl radical, which in turn is generated from the reductive elimination of a bromide anion from halothane.<sup>214,219</sup>

#### 5.05.3.1.2 Reduction of nitrogen-containing functional groups

Cytochrome P450 is also capable of reducing nitrogen-containing functional groups of various oxidation states back to the corresponding saturated nitrogen-containing functional group (amine, hydrazine, etc.). So, *N*-oxides, imines,

Scheme 21

Scheme 22

hydroxylamines, nitroso groups, nitro groups, and azo dyes can all be reduced by cytochrome P450, especially under anaerobic conditions.

*N*-Oxide metabolites are generally nontoxic or less toxic than the parent drug. Their lack of toxicity coupled to the likely regeneration of the parent in a hypoxic bio-environment suggested a prodrug strategy for treating solid tumors (for an extensive discussion of prodrugs, *see* 5.44 Prodrug Objectives and Design). Administration of an *N*-oxide-containing anticancer agent should reduce systemic toxicity but maintain the effectiveness of the drug, since reduction of the *N*-oxide back to the parent compound at the tumor site would be highly probable. This strategy has been successfully employed<sup>220,221</sup> with the anthraquinone derivative AQ4N (**199**), which is currently in clinical trials (Scheme 22). After reaching the hypoxic regions of the solid tumor, the drug undergoes two sequential two-electron reductions. The reductions (CYP3A4) generate AQ4M (**200**), the mono-*N*-oxide, followed by AQ4 (**201**), the di-tertiary amine, and active anticancer agent. The cytotoxic potency of **201** is of the order of 1000-fold greater than that of **199**.<sup>220</sup>

The reduction of an aromatic nitro group to an amine, a process that is frequently associated with toxicity, proceeds through the nitroso compound and the hydroxylamine. Early on it was established<sup>222</sup> that nitrobenzene (**202**), nitrosobenzene (**203**), and phenylhydroxylamine (**204**) could all be reduced to aniline (**205**) by cytochrome P450 (Scheme 23). Cytochrome P450 under anaerobic conditions also appears to play a central role in the reductive

Scheme 23

Scheme 24

metabolism of the carcinogens 1-nitropyrene,<sup>223</sup> 2-nitropyrene, 4-nitrobiphenyl, and 1-nitronaphthalene<sup>224</sup> to the corresponding hydroxylamines and amines. In a somewhat similar vein, the 3'-azido group of the anti-HIV drug zidovudine (206) has been shown to be susceptible to reduction to its toxic 3'-amino metabolite 207 under anaerobic conditions both by cytochrome P450 and by cytochrome *b5* and its reductase (Scheme 24).<sup>225</sup>

#### 5.05.3.1.3 Benamidoxime reductase

A cytochrome P450-dependent, oxygen-insensitive reducing system that catalyzes the efficient reduction of strongly basic primary *N*-hydroxylated functional groups such as amidines, guanidines, and amidinohydrazone was isolated from pig liver and characterized by Clement *et al.*<sup>226</sup> The reconstituted system, termed benamidoxime reductase, is composed of NADH, cytochrome *b5*, its reductase, phosphatidylcholine, and a cytochrome P450 from the 2D family.

In subsequent investigations this enzyme system was found to be an efficient reductant of aliphatic hydroxylamines (e.g., amphetamine hydroxylamine (208)), in liver microsomal preparations,<sup>227</sup> mitochondria, and other organs and organelles.<sup>228</sup> Its reducing efficiency in conjunction with the wider bio-distribution of the activity suggested its potential usefulness in a pro-drug strategy for administering strongly basic drugs. Such drugs are generally poorly adsorbed because they are virtually 100% protonated throughout the gastrointestinal tract. Administration of the less basic hydroxylamine analogs should increase adsorption, allowing the pro-drug to reach the systemic circulation, where it could be reduced to generate the parent drug.<sup>228</sup> This approach was tried with ximelagatran (209), a pro-drug of the thrombin inhibitor melagatran (210), and was found to increase the oral bioavailability of 210 from 3–7% to 18–24% (Scheme 25).<sup>229</sup> While the hydroxylamine was efficiently and rapidly reduced in humans, the specific cytochrome P450 that catalyzed the reaction could not be identified.<sup>230</sup>

Scheme 25

The benzamidoxime system has recently<sup>231</sup> been found capable of reducing the *N*-hydroxylamines of sulfamethoxazole (**211**) and dapsone (**82**), without cytochrome P450. The notion that the reductase system between the human and pig might differ with regard to the relevance of cytochrome P450 has been proposed by Andersson *et al.*<sup>232</sup> They concluded that neither cytochrome P450 nor FMO is an essential element of the reductase system in the human, based on selective inhibitors, while cytochrome *b5* reductase and nonheme iron probably are.

### 5.05.3.2 Xanthine Oxidoreductase and Aldehyde Oxidase

Cytochrome P450-containing enzyme systems are not the only ones capable of reducing nitrogen-containing functional groups. In fact, the cytosolic molybdenum-containing enzymes xanthine oxidoreductase and, in particular, AOX are often the major contributors. For example, they are major contributors in the reduction of aromatic nitro compounds,<sup>222–224</sup> and perhaps *N*-oxides.<sup>233</sup>

### 5.05.3.3 Aldo-Keto Reductases (AKRs)

The AKRs are a superfamily of dehydrogenases/reductases.<sup>234</sup> Unlike the ADHs, they require NADP<sup>+</sup>(H) as a cofactor, and generally catalyze reductive<sup>235</sup> rather than oxidative reactions. While they operate on the same kinds of endogenous substrates as the ADHs (e.g., ketosteroids,<sup>236</sup> retinal,<sup>237</sup> and lipid peroxidation products),<sup>238</sup> they also tend to operate on xenobiotics.

At least three AKR isoforms (1C1, 1C2, and 1C4) have been isolated from human liver cytosol that contribute to the reduction of the tobacco-specific carcinogen 4-methylnitrosoamino-1-(3-pyridyl)-1-butanone (**212**) to the less toxic 4-methylnitrosoamino-1-(3-pyridyl)-1-butanonol (**213**), which is susceptible to conjugation and elimination.<sup>239</sup>

Yanmano *et al.*<sup>240</sup> have isolated and purified two AKRs of the 1C subfamily from rabbit liver cytosol that will reduce the opioid receptor antagonist naloxone (**214**) to the  $\alpha$ - and  $\beta$ -diastereomeric alcohols **215** and **216**, respectively (Scheme 26). Interestingly, one AKR, termed NR1, stereospecifically produces **215**, while the second, termed NR2, stereospecifically produces **216**. Naltrexone (**217**) and dihydromorphinone (**218**) were good substrates for NR2 but not NR1. Both enzymes reduced aliphatic and aromatic aldehydes, cyclic and aromatic ketones, and quinones. They also catalyzed the dehydrogenation of 17 $\beta$ -hydroxysteroids with low  $K_m$  values. The main human AKRs have been cloned and expressed, and their substrate reactivity profiles and tissue and organ distribution determined.<sup>241</sup>

Scheme 26

### 5.05.3.4 Carbonyl Reductases (CBRs)

CBRs are a subset of short-chain dehydrogenase/reductases<sup>242,243</sup> that belong to a superfamily of oxidoreductases.<sup>244</sup> They are found in cytosol, have broad substrate selectivity, and encompass both endobiotic and xenobiotic carbonyl compounds, including prostaglandins, steroids, and quinones, plus a wide array of aromatic and aliphatic aldehydes and ketones. For recent reviews, see Oppermann and Maser<sup>235</sup> and Rosemond and Walsh.<sup>245</sup> Typical examples of CBR-catalyzed reduction of quinone carbonyls or keto groups contained in a xenobiotic include the reduction of the anthracycline antibiotic doxorubicin (**219**),<sup>246</sup> halopyridol (**220**),<sup>247</sup> metyrapone (**221**),<sup>247</sup> acetohexamide (**222**),<sup>247</sup> and warfarin (**223**).<sup>248</sup>

### 5.05.4 Conclusion

The explosion of metabolic information since the 1990s has served to accentuate the importance of drug metabolism to clinical pharmacology and therapeutics. This new knowledge emphasizes the need for a common understanding among investigators of the different disciplines that impact drug development. To help meet that need, my goal in writing this chapter was to provide a comprehensive overview of the scope of the chemistry and major enzyme systems involved in drug metabolism. Many of the topics could not receive the detailed coverage they merit because of the constraints of space. However, it is hoped that nothing of importance has been missed, and that the references provided serve as a key to deeper exploration by the interested reader.

## Biography

**William F Trager** is currently Emeritus Professor of Medicinal Chemistry of the School of Pharmacy, University of Washington, Seattle, Washington. He is a naturalized citizen from Winnipeg, Canada. In 1960, he received his BS in Chemistry from the University of San Francisco, San Francisco, California and in 1965 his PhD in Medicinal Chemistry from the University of Washington under the direction of Professor Alain C Huitric working in the area of conformational analysis using NMR. After receiving his PhD, he spent 2 years as a Postdoctoral Fellow with Professor Arnold H Beckett at the Chelsea School of Science and Technology in London, England. His postdoctoral studies involved the structural analysis of mitragyna alkaloids of unknown structure by spectral means (NMR, CD, IR, and UV).

In 1967 Dr Trager joined the faculty of the School of Pharmacy, University of California at San Francisco as an Assistant Professor of Medicinal Chemistry. While at the University of California he was responsible for the High Resolution Mass Spectral Facility and developed his on-going interest in drug metabolism. In 1972 he returned to the University of Washington as an Associate Professor of Medicinal Chemistry. In 1977 he was promoted to full Professor and received a Career Development Award from the National Institutes of Health. In 1978 spent 3 months at the NIH working in the Laboratory of Chemical Pharmacology with Dr James Gillette. In 1980 he was appointed as Science Advisor to the FDA, Seattle District, Chairman of the Department of Medicinal Chemistry in the School of Pharmacy and Adjunct Professor of Chemistry in the Department of Chemistry. In 1984 he left the Chair and returned to his academic positions. From 1983 to 1987, Dr Trager served as a committee member of the Pharmacological Sciences Review Committee of the National Institutes of General Medical Sciences and in subsequent years he frequently served as an ad hoc member of various study sections and site visit teams.

Dr Trager's primary research interests are in drug metabolism and he was the PI. of an NIH Program Project Grant for the past 20 years investigating the molecular basis of the phenomena of drug interactions. More specific interests include quantitative mass spectrometry using stable isotopes, stereoselective metabolism, and the use of deuterium isotope effects to study mechanisms of cytochrome P450-catalyzed reactions and active site structure. In 2004 Dr Trager retired from the University and was converted to Emeritus status.

## 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions

### 5.06.1 Introduction

Reactions of xenobiotic metabolism are traditionally categorized into phase I and phase II reactions. Such a nomenclature is based on the fact that phase I reactions generally precede phase II, but it conveys no biochemical information whatsoever, and it neglects the very many examples of phase II reactions occurring without prior phase I reactions and even preceding them. This had led a number of authors to use the less euphonic but more informative terms of functionalization and conjugation reactions.<sup>1,2</sup>

Functionalization (phase I) reactions involve the creation of a functional group in the substrate molecule or the transformation of an existing functional group. The majority of such metabolic reactions are oxidations, but numerous

**Table 1** Classification of reactions of xenobiotic metabolism according to the chemical entity being transferred to or from the substrate

| <i>Functionalizations (phase I)</i> |                   | <i>Conjugations (phase II)<sup>a</sup></i>                            |   |

<sup>a</sup> Except for boxes with the superscript *b*, the right column lists endogenous conjugating moieties (endocons).

<sup>b</sup> Conjugation is the necessary initial step in these metabolic reactions, which cannot be considered as conjugations from the point of view of the final metabolite.

<sup>c</sup> Not discussed in the text.

reactions of reduction are also known. In the simplest and broadest perspective, metabolic redox reactions involve the transfer of one oxygen atom (monooxygenations), two oxygen atoms (dioxygenations), one or two electrons, or a hydride anion (Table 1).<sup>3,4</sup> This vast topic of metabolic redox reactions receives comprehensive coverage in Chapter 5.05.

There is, however, an additional class of functionalizations, namely, the reactions of hydrolysis.<sup>4,5</sup> Here, the degree of oxidation of the substrate remain unchanged, hence the term ‘nonredox’ reactions, which is sometimes found in the literature. A few authors like to consider hydrolyses as conjugation reactions, an unfortunate and confusing viewpoint given that they fulfil none of the criteria by which conjugations are recognized (see later).

Reactions of conjugations are by far the most varied when considering the chemical entities being transferred to the substrate, or better here, coupled to the substrate. For example, the endogenous conjugating moiety (the ‘endocon,’ as it has been termed) can be a small and hydrophobic fragment (the methyl group), a large and hydrophobic molecule (cholesterol or a diglyceride), or a large and hydrophilic one (glucuronic acid or glutathione). Table 1 is offered here to help the reader acquire a synthetic and schematic understanding of the reactions of drug metabolism.

## 5.06.2 Reactions of Hydrolysis and Hydration

The two terms of hydrolysis and hydration both imply bond breakage with addition of a molecule of H<sub>2</sub>O. In this text, we prefer to apply the term ‘hydrolysis’ to the cleavage of esters (carboxylesters, lactones, inorganic esters), amides (carboxamides, sulfamates, phosphoamides, lactams, etc.), and glycosides. In contrast, the term ‘hydration’ will be restricted to epoxides, although the enzymes catalyzing this reaction are also classified as hydrolases (see below). Readers in search of a much more extensive treatment of hydrolases and their metabolic reactions of hydrolysis and hydration might want to consult a recent book coauthored by this writer.<sup>5</sup>

### 5.06.2.1 Hydrolases

The classification adopted by the Nomenclature Committee (NC) of the International Union of Biochemistry and Molecular Biology (IUBMB) classifies all hydrolases as ‘EC 3.’ and divides them into classes and subclasses according to

the group they hydrolyze and the nature of their substrates. A further criterion in the classification of peptidases is based on the nature of their catalytic site. A constantly updated version with supplements is available online,<sup>6</sup> as are all available PDB (Protein Data Bank) entries classified as recommended by the NC-IUBMB.<sup>7</sup>

A small and somewhat subjective selection of hydrolases of known or potential activity toward drugs and other xenobiotics is presented in [Table 2](#). The objective of this table is first and foremost to testify to the impressive variety of functional groups that hydrolases can cleave. Also, the table illustrates the huge variety of enzymes that have evolved to cleave chemical bonds by comparatively simple nucleophilic mechanisms necessitating no high-energy electron transfer. But only a limited number of entries are of foremost significance in drug metabolism, namely:

- carboxylesterases (EC 3.1.1.1), whose sequence is encoded by a superfamily of genes (e.g., *CES1A1*, *CES1A2*, *CES1A3*, *CES1B*, *CES1C*, *CES2*, *CES3*, *CES4*)<sup>5,8,9</sup>;
- cholinesterases (EC 3.1.1.8, also known as butyrylcholinesterase);
- paraoxonases (EC 3.1.8.1, also known as arylalkylphosphatase), whose sequence is encoded by the *PON1*, *PON2*, and *PON3* genes<sup>10,11</sup>;
- epoxide hydrolases (EC 3.3.2.3), to be discussed separately in [Section 5.06.2.3](#); and
- amidases and peptidases in general, although their individual roles in xenobiotic metabolism remain very poorly understood.

The enzymatic hydrolysis of carboxylic derivatives is far more effective than chemical hydrolysis. For example, subtilisin (EU 3.4.21.62) accelerates the hydrolysis of amide bonds at least 10<sup>9</sup>- to 10<sup>10</sup>-fold. All hydrolases include the following three catalytic features in their active site, which enormously accelerate rates of hydrolysis ([Figure 1](#)). First, they contain an electrophilic component, which increases the polarization of the carbonyl group in the substrate ( $Z^+$  in [Figure 1](#)). Second, they use a nucleophile (Y: in [Figure 1](#)) to attack the carbonyl carbon, leading to the formation of a tetrahedral intermediate. And finally, they use a proton donor (H–B in [Figure 1](#)) to transform the –OR' or –NR'R' moiety into a better leaving group.<sup>5,12</sup>

## 5.06.2.2 Substrates of Hydrolases

### 5.06.2.2.1 Esters

Several examples of hydrolysis of esters, lactones, and amides are discussed elsewhere in this Volume (*see* 5.44 Prodrug Objectives and Design). To complement this, we present here a few examples of (active) drugs whose metabolism is catalyzed to a large extent by hydrolases and which serve to illustrate some important concepts.

(–)-Cocaine (**1**, [Figure 2](#)) has led to unexpected insights into relations between metabolism and molecular toxicology (reviewed in<sup>5</sup>). This xenobiotic is metabolized by various routes including *N*-demethylation (to form norcocaine), *N*-oxygenation, aromatic hydroxylation, and hydrolysis of its two ester groups. The latter route is particularly important since it is globally a route of detoxification that accounts for as much as 90% of the dose in humans, who excrete high urinary concentrations of benzoylecgonine (**2**), ecgonine methyl ester (**3**), and ecgonine (**4**).

Studies using human serum and liver showed enzymatic hydrolysis of the benzoyl ester bridge, whereas the hydrolysis of the methyl ester group occurs both nonenzymatically and enzymatically. Furthermore, marked tissue differences in the formation of benzoylecgonine from cocaine were seen in the rat, with more than one enzyme activity being involved. Three human enzymes are now known to be involved in the hydrolysis of cocaine. One is a liver carboxylesterase (designated hCE-1), which catalyzes the hydrolysis of the methyl ester group. As for the benzoyl ester group, it is hydrolyzed by the liver carboxylesterase hCE-2 and serum cholinesterase. Natural (–)-(2*R*;3*S*)-cocaine (**1**) is a relatively poor substrate of hepatic carboxylesterases and plasma cholinesterase (EC 3.1.1.8), and also a potent competitive inhibitor of the latter enzyme. In contrast, its unnatural enantiomer (+)-(2*S*;3*R*)-cocaine is a good substrate of carboxylesterases and cholinesterase. Because hydrolysis is a route of detoxification for cocaine and its stereoisomers, such metabolic differences have a major impact on their monooxygenase-catalyzed toxification, a reaction of particular effectiveness for (–)-cocaine.

There is an additional factor that contributes to the toxicity of cocaine, namely its interaction with ethanol.<sup>13,14</sup> Many cocaine abusers simultaneously ingest ethanol probably to experience a potentiation of effects and a decrease in headaches. It is now known that ethanol interferes in two ways with the metabolism of cocaine, first by inhibiting its hydrolysis and second by allowing a transesterification to form benzoylecgonine ethyl ester (**5**, [Figure 2](#)). This reaction of transesterification is also catalyzed by hCE-1. The benzoylecgonine ethyl ester is commonly known as cocaethylene, and it is of clear significance since it retains the pharmacological and toxicological properties of cocaine, in particular its CNS and hepatic effects.

#### 5.06.2.2.2 Amides

Lidocaine (**6**, **Figure 3**) is a local anesthetic and antiarrhythmic drug in wide use since over five decades. The compound is very resistant to chemical hydrolysis even in strongly acidic or basic media. Yet, despite this high chemical stability, metabolic hydrolysis to 2,6-xylidine (**7**, **Figure 3**) represents a major pathway in mammals, with considerable interspecies differences in its extent. This may be due in part to the fact that *N*-dealkylated and *para*-hydroxylated metabolites of lidocaine also undergo enzymatic hydrolysis, and do so with differing substrate selectivities. In humans, hydrolysis of the amide bond represents the major metabolic pathway, accounting for about 75% of the amount excreted in urine.<sup>5</sup> Investigations using human liver slices have shown that 2,6-xylidine is produced by direct hydrolysis of lidocaine.<sup>15</sup> Furthermore, a liver microsomal carboxylesterase very effectively hydrolyzed lidocaine and its mono-*N*-deethylated metabolite, but not its di-*N*-deethylated metabolite.<sup>16</sup> These findings prove the different substrate selectivities of the oxidized metabolites of lidocaine toward hydrolases. More importantly, the demonstration that carboxylesterases are able to

**Figure 3** The structure of lidocaine (6), 2,6-xylidine (7), and levetiracetam (8). The figure also shows thalidomide (9) and some of its products of spontaneous hydrolysis observed in vivo and in vitro.

efficiently hydrolyze some amides points to the near impossibility of correctly assessing their full range of potential substrates.

Another interesting amide is levetiracetam (8, [Figure 3](#)), a recent antiepileptic agent whose metabolism in humans is almost exclusively CYP-independent (oxidative metabolites represent  $\leq 2.5\%$  of a dose).<sup>17</sup> Indeed, this hydrophilic compound was excreted renally unchanged for two-thirds of the dose, whereas a quarter of the dose was accounted for by its acidic metabolite resulting from hydrolysis of the primary carboxamide group. In vitro investigations have confirmed that the reaction was catalyzed by a serine hydrolase, most probably a carboxylesterase found in human liver, red cells, and most likely other tissues.

Thalidomide (9, [Figure 3](#)) is well known for its high teratogenicity and for causing the greatest drug-related tragedy in history. Recently, new clinical uses have been discovered that render thalidomide useful in alleviating symptoms in leprosy and even HIV infections. Although the underlying mechanisms are only poorly understood, some of the activities of thalidomide may be related to its capacity to inhibit the production of tumor necrosis factor alpha (TNF- $\alpha$ ).<sup>5,18</sup>

Parallel to rapid inversion of configuration and very low rates of hydroxylations, thalidomide is rapidly hydrolyzed to ring-opened products.<sup>18–21</sup> All four amide bonds of the molecule are susceptible to hydrolytic cleavage at pH > 6, and the reactions are nonenzymatic and base-catalyzed. The main urinary metabolites in humans were shown to be 2-phthalimidoglutaramic acid (10, about 50% of a dose) and  $\alpha$ -(*o*-carboxybenzamido)-glutarimide (11, about 30% of a dose). Metabolites 12 and 13 were minor. Metabolite 11 was the main product in rats and dogs. Toxicological investigations revealed that of the 12 hydrolysis products of thalidomide only the three containing the intact phthalimido moiety retained teratogenic activity, namely metabolites 10, 12, and 13.

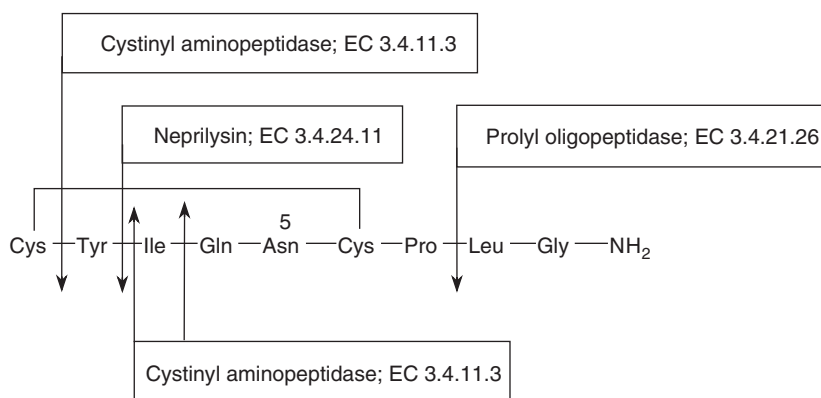

#### 5.06.2.2.3 Peptides

A huge amount of information is known about peptidases,<sup>22</sup> but much remains to be understood regarding their interactions with xenobiotic substrates. This is rendered all the more imperative by an ever increasing interest in therapeutic peptides and peptidomimetics. A number of such peptidases (EC 3.4) are listed in [Table 2](#), but this list is based on indirect evidence and hypotheses much more than on solid data. As a reminder, we show in [Figure 4](#) the classification of peptidases based on the bonds they cleave along the polypeptide chain. Two examples have been selected for presentation here: one (oxytocin) to illustrate the multiplicity of enzymes acting on clinically used natural peptides, and the other (cetorelix) to hint at the impossibility of predicting the metabolites of a synthetic peptide containing nonproteinogenic acids.

**Figure 4** Classification of peptidases according to the bonds they cleave along the polypeptide chain. (Reproduced from Testa, B.; Mayer, J. M. *Hydrolysis in Drug and Prodrug Metabolism – Chemistry, Biochemistry and Enzymology*; Wiley-Verlag Helvetica Chimica Acta: Zurich, Switzerland, 2003, with the kind permission of the copyright owner, Verlag Helvetica Chimica Acta in Zurich.)

**Figure 5** Major peptidases acting on oxytocin. Descending arrows represent primary cleavage reactions, whereas ascending arrows indicate secondary reactions, i.e., cleavage sites in shorter peptides. (Reproduced from Testa, B.; Mayer, J. M. *Hydrolysis in Drug and Prodrug Metabolism – Chemistry, Biochemistry and Enzymology*; Wiley-Verlag Helvetica Chimica Acta: Zurich, Switzerland, 2003, with the kind permission of the copyright owner, Verlag Helvetica Chimica Acta in Zurich.)

Oxytocin (**Figure 5**) is a potent and specific stimulant of myometrial contractions commonly used to induce labor. This peptide is of interest here due to it being a natural peptide and being degraded by a variety of peptidases. Thus, cleavage of the N-terminal cysteine is catalyzed by an aminopeptidase now known as cystinyl aminopeptidase (EC 3.4.11.3; oxytocinase), an enzyme found in the placenta and in the serum of pregnant women.<sup>23</sup> The enzyme acts efficiently to hydrolyze the Cys1-Tyr2 bond, thus opening the ring structure of oxytocin, and then cleaves successive residues from the N-terminal end. At the C-terminus, prolyl oligopeptidase (EC 3.4.21.26; postproline endopeptidase) cleaves the C-terminal dipeptide.<sup>24</sup> The resulting oxytocin-(1–7) is also a substrate for aminopeptidase activity. Furthermore, neprilysin (EC 3.4.24.11) can also play a role in oxytocin degradation, although it seems to act with less efficiency than the two other enzymes.

Our last example here is cetorelix (**Figure 6**), a potent antagonist of LHRH receptors. The compound is an N- and C-protected decapeptide containing D-Nal, D-(*p*-chloro)Phe, D-(3-pyridyl)Ala, D-Orn and D-Ala as D- or artificial residues. Following subcutaneous administration, the plasma half-life was 35–40 h in rats and 100–130 h in dogs, indicating a remarkable metabolic stability.<sup>25</sup> In both species, only unchanged compound was found in urine, whereas the bile contained up to four metabolites, namely the (1–9)-nonapeptide, the (1–7)-heptapeptide, the (1–6)-hexapeptide, and the (1–4)-tetrapeptide. This indicates that peptidase-related products were the only products identified. Interestingly, the relative abundance of the metabolites changed between bile and feces, indicating additional intestinal breakdown by enteral peptidases or bacteria.

### 5.06.2.3 Epoxide Hydrolases and Their Reactions

#### 5.06.2.3.1 Epoxide hydrolases

Epoxide hydrolases (see **Table 2**) belong to the ether hydrolases and are a group of related enzymes sharing a similar catalytic mechanism but differing in substrate specificity and biochemical characteristics.<sup>5,26–28</sup> These enzymes are

**Figure 6** The structure of cetrorelix, an N- and C-protected decapeptide containing D- and artificial residues in addition to natural amino acids. The arrows indicate the sites of attack by peptidases leading to the four identified metabolites.<sup>25</sup>

**Figure 7** A simplified model showing that the nucleophilic attack of the substrate is mediated by a carboxylate group in the catalytic site to form an ester intermediate. Only in the second step is the intermediate hydrolyzed by an activated water molecule, leading to enzyme reactivation and product liberation. (Reproduced from Testa, B.; Mayer, J. M. *Hydrolysis in Drug and Prodrug Metabolism – Chemistry, Biochemistry and Enzymology*; Wiley-Verlag Helvetica Chimica Acta: Zurich, Switzerland, 2003, with the kind permission of the copyright owner, Verlag Helvetica Chimica Acta in Zurich.)

located in many organs and tissues. They play essential physiological roles, e.g., vitamin K1 oxide reductase, and are also major modifiers of biological activity in the metabolism of xenobiotics. In mammals, epoxide hydrolases (EH) of broad and complementary substrate specificity are the microsomal EH and the soluble EH.

The microsomal epoxide hydrolases (mEH) are predominantly found in the endoplasmic reticulum. They catalyze the hydration of both alkene and arene oxides, including oxides of polycyclic aromatic hydrocarbons, and do so with regio- and stereoselectivity. The human mEH contains 455 amino acids (52.5 kDa) and is the product of the *EPHX1* gene. The human soluble epoxide hydrolase (sEH, also known as cytosolic EH, cEH) has 554 amino acids (62.3 kDa) and is the product of the *EPHX2* gene. Its specific substrate is *trans*-stilbene oxide, and it appears unable to hydrate epoxides of bulky steroids or polycyclic aromatic hydrocarbons.<sup>5</sup>

The overall reaction catalyzed by epoxide hydrolases is the addition of a water molecule to an epoxide. Alkene oxides thus yield diols whereas arene oxides yield dihydrodiols. As shown in Figure 7, the nucleophilic attack of the substrate is recognized to be mediated by a catalytic carboxylate group to form an ester intermediate. In a second step, this intermediate is hydrolyzed by an activated water molecule, leading to enzyme reactivation and product liberation. This mechanism involves a catalytic triad consisting of a nucleophile, a general base, and a charge relay acid, in close analogy with many other hydrolases (see Section 5.06.2.1).

#### 5.06.2.3.2 Arene oxide substrates

Together with glutathione conjugation, hydration is a major pathway in the inactivation and detoxification of arene oxides. As a rule, these are good substrates of microsomal epoxide hydrolase. But when reading the literature, the

variety of intertwined metabolic pathways centered around arene oxides is not always easy to grasp. The general scheme presented in [Figure 8](#) should contribute to clarify the metabolic context of arene oxides. These arise by CYP-catalyzed oxidation of arenes (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions) and are a crossroads to a number of metabolic routes, namely: (1) conjugations, (2) adduct formation, (3) proton-catalyzed isomerization to phenols followed by oxidation to diphenols and even to quinones, and (4) EH-catalyzed hydration to *trans*-dihydrodiols. The latter reaction is the topic of this section.

In phenyl and naphthyl rings, the proton-catalyzed isomerization of epoxides to phenols is an extremely fast reaction that markedly reduces the likelihood of the epoxide being hydrated by epoxide hydrolase. This chemical instability decreases for chemicals with three or more fused rings, but such compounds are no longer of medicinal interest and will not be discussed here. Yet, despite the high reactivity of benzene epoxides, the characterization of a dihydrodiol metabolite has been achieved for a limited number of phenyl-containing drugs, and particularly for neurodepressant drugs such as hypnotics (e.g., glutethimide) and antiepileptics (e.g., ethosin and phenytoin).

For example, phenytoin (diphenylhydantoin) is a good substrate of cytochrome P450. Incubations with rat liver 9000 g supernatant produced the *para*-phenol (4'-hydroxy-phenytoin) as the major metabolite, and the dihydrodiol in smaller proportions. Interestingly, aromatic oxidation of phenytoin in humans and other mammals except the dog occurs almost exclusively at the *pro-S* phenyl ring, the *para*-phenol having the (*S*)-configuration at C5, i.e., (5*S*)-5-(4-hydroxyphenyl)-5-phenylhydantoin. The dihydrodiol similarly has the (*S*)-configuration at its C5, while its C3' and C4' atoms in the oxidized phenyl ring have the *trans*-(*R,R*)-configuration, i.e., (5*S*)-5-[(3*R*;4*R*)-3,4-dihydroxy-1,5-cyclohexadien-1-yl]-5-phenylhydantoin (**14**, [Figure 9](#)) (for a review *see* <sup>5</sup>).

A more recent example is that of rofecoxib, a potent and selective cyclooxygenase-2 (COX-2) inhibitor. In rats and dogs, phenyl oxidation produced 4'-hydroxy-rofecoxib and rofecoxib-3',4'-dihydrodiol (**15**, [Figure 9](#)) as urinary metabolites of intermediate quantitative importance.<sup>29</sup>

#### 5.06.2.3.3 Alkene oxide substrates

Alkene oxides are generally quite stable chemically, indicating a much reduced chemical reactivity compared to arene oxides. Under physiologically relevant conditions, they have little capacity to undergo rearrangement reactions and are resistant to uncatalyzed hydration. As a result, many alkene oxides formed as metabolites are stable enough to allow their isolation in the absence of degrading enzymes.

Some drugs contain an unconjugated alkene group undergoing CYP-catalyzed epoxidation followed by EH-catalyzed hydration. Thus, the anti-inflammatory agent alclophenac contains an *O*-allyl group. Its epoxide (**16**, [Figure 9](#)) was found as a stable metabolite in the urine of mice and humans, and so was the diol, proving the involvement of the epoxide-diol pathway in the metabolism of this drug. The epoxide proved mutagenic, but only in the absence of a rat liver S-9 suspension (which contains EH).<sup>30</sup> A few old barbiturates also contain an allylic group in the 5-position, e.g., allobarbitol (**17**, [Figure 9](#); R = allyl), and secobarbitol (**17**, [Figure 9](#); R = 1-methylbutyl). These compounds were substrates of the epoxide-diol pathway in rats and guinea pigs. The relative importance of this metabolic route was species dependent, but was also markedly influenced by the nature of the other C5-substituent.<sup>31</sup>

Cycloalkenes are found particularly among natural products (i.e., terpenoids) and as such are of medicinal interest. Limonene (**18**, [Figure 9](#)) undergoes epoxidation to the C1-C2 and C8-C9 double bonds. The two epoxide groups are then hydrated by epoxide hydrolase, but at a different rate. Indeed, incubations in rat liver microsomes showed that the hydrolysis of limonene 1,2-epoxide was 70 times slower than that of the 8,9-epoxide, a result explained by steric hindrance on the basis of these and other findings.<sup>32</sup>

A number of neurotropic agents contain a conjugated alkene group incorporated in an iminostilbene (**19**, [Figure 9](#); X = >NR) or dibenzosuberene (**19**, [Figure 9](#); X = >CHR or >C=CHR) ring system. Examples include the anticonvulsant carbamazepine and the antidepressants protriptyline and cyclobenzaprine. As a rule, these drugs are oxidized by cytochrome P450 to the corresponding epoxide (**20**, [Figure 9](#)), but hydration to the dihydrodiol (**21**) is usually low for reasons of unfavorable positioning in the catalytic site (for a review *see* <sup>5</sup>).

As a result, related tricyclic drugs yield modest or very low proportions of dihydrodiols, despite the 10,11-oxides being consistently formed. For example, both the epoxide and the dihydrodiol were characterized in the urine of rats given protriptyline (**19**, in [Figure 9](#); X = >CHCH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NHMe), whereas cyclobenzaprine (**19**, [Figure 9; X = >C=CHCH<sub>2</sub>CH<sub>2</sub>NMe<sub>2</sub>\) did not yield the dihydrodiol despite the epoxide and other oxygenated metabolites being formed \*in vivo\* and \*in vitro\*.<sup>5</sup>](#)

Carbamazepine (**19**, [Figure 9](#); X = >NCONH<sub>2</sub>) is a major antiepileptic drug whose metabolism has interested biochemists and clinical pharmacologists for many years. Well over 30 metabolites of this drug have been characterized

**Figure 8** Metabolic reactions centered around arene oxides. (Reproduced from Testa, B.; Mayer, J. M. *Hydrolysis in Drug and Prodrug Metabolism – Chemistry, Biochemistry and Enzymology*; Wiley-Verlag Helvetica Chimica Acta: Zurich, Switzerland, 2003, with the kind permission of the copyright owner, Verlag Helvetica Chimica Acta in Zurich.)

**Figure 9** Alkenes, epoxides, and dihydrodiols of medicinal interest discussed in the text.

in vivo and/or in vitro. Thus, the 10,11-epoxide and the 10,11-dihydrodiol are urinary metabolites in humans and rats given the drug. In epileptic patients, the range of plasma concentrations of the epoxide and the diol was approximately 0.8–17  $\mu\text{M}$  and 0.8–36  $\mu\text{M}$ , respectively, i.e., a predominance of the latter.<sup>33</sup> A number of studies have also addressed the origin of toxic reactions seen in some patients, e.g., CNS symptoms, gastrointestinal and hepatic disturbances, and hypersensitivity. Whereas no single factor seems to account for such toxic effects, the pharmacologically active 10,11-epoxide appears to contribute to clinical toxicity.<sup>34</sup> In this perspective, the EH-catalyzed hydrolysis of the epoxide appears as a reaction of detoxification.

Interestingly, there is a marked species difference in the in vitro hydrolysis of carbamazepine 10,11-epoxide, such that the reaction was observable only in human liver microsomes but not in liver microsomal or cytosolic preparations from dogs, rabbits, hamsters, rats, or mice.<sup>35</sup> Thus, carbamazepine appears to be a very poor substrate of epoxide hydrolases, in analogy with its simpler analogs (**19**, Figure 9;  $\text{X} = >\text{NR}$ ,  $>\text{CHR}$  or  $>\text{C}=\text{CHR}$ ). The human enzyme is exceptional in this respect.

### 5.06.3 Reactions of Conjugation

The reactions of conjugation listed in Table 1 are of different quantitative importance in drug metabolism, some involving a very large number of xenobiotic substrates (e.g., glucuronidation) and others a comparatively modest number (e.g., methylation). But their toxicological significance does not necessarily parallel the number of their known substrates, some reactions being particularly effective in quenching reactive intermediates whereas others may lead to toxic conjugates. Before examining in turn major and lesser reactions of conjugation, it appears useful to discuss the criteria that allow conjugation reactions to be recognized as such.<sup>4,36–40</sup>

### 5.06.3.1 Criteria of Conjugation

Conjugation reactions are characterized by a number of criteria, namely:

1. The substrate is coupled to an endogenous conjugating molecule or moiety (sometimes called an 'endocon'), producing a metabolite known as a conjugate.
2. This endogenous molecule or moiety is highly polar (hydrophilic) and has a molecular weight (MW) in the 100–300 Da range.
3. Conjugation reactions are catalyzed by enzymes known as transferases.
4. They involve a cofactor that binds to the enzyme in close proximity to the substrate and carries the endogenous molecule or moiety to be transferred.

The first criterion is an essential one, and it is the criterion of decision. The other criteria are neither sufficient nor necessary to define conjugation reactions. They are not sufficient, since for example in hydrogenation reactions (i.e., typical reactions of functionalization), the hydride is also transferred from a cofactor (NADPH or NADH). And they are not necessary, since they show some important exceptions, which will become apparent below.

### 5.06.3.2 Reactions of Methylation

#### 5.06.3.2.1 Mechanism and multiplicity of methyltransferases

Reactions of methylation imply the transfer of a methyl group from the cofactor *S*-adenosyl-L-methionine (**22**, Figure 10; SAM) to the substrate. It is important to note that the methyl group in SAM is bound to a sulfonium center, giving it a marked electrophilic character and explaining its reactivity. Furthermore, it becomes pharmacokinetically relevant to distinguish methylated metabolites in which the positive charge has been retained or lost.

A number of methyltransferases are able to methylate small molecules.<sup>41–43</sup> Thus, reactions of methylation fulfil only three of the four criteria defined above, since the methyl group is small compared to the substrate.

**Figure 10** Structure of the cofactor *S*-adenosyl-L-methionine (**22**; SAM); generic reactions of O- and S-methylation (a) and of N-methylation (b).

Methyltransferases involved in xenobiotic metabolism include:

- the main enzyme responsible for *O*-methylation, namely catechol *O*-methyltransferase (EC 2.1.1.6; COMT), which is mainly cytosolic but also exists in membrane-bound form;
- various enzymes involved in *N*-methylation and characterized by different substrate specificities, e.g., nicotinamide *N*-methyltransferase (EC 2.1.1.1), histamine *N*-methyltransferase (EC 2.1.1.8), phenylethanolamine *N*-methyltransferase (EC 2.1.1.28), and a nonspecific arylamine *N*-methyltransferase (EC 2.1.1.49); and
- enzymes catalyzing *S*-methylation, namely the membrane-bound thiol methyltransferase (EC 2.1.1.9) and the cytosolic thiopurine methyltransferase (EC 2.1.1.67).

This classification makes explicit the three types of functionalities undergoing biomethylation, namely hydroxy (phenolic), amino, and thiol groups.

#### 5.06.3.2.2 Substrates of methyltransferases

**Figure 10** also shows the main methylation reactions seen in drug metabolism. *O*-Methylations (**Figure 10a**) are common reactions of compounds containing a catechol moiety, with a usual regioselectivity for the *meta* position. The substrates can be xenobiotics and particularly drugs, L-DOPA being a classic example. More frequently, however, *O*-methylation occurs as a late event in the metabolism of aryl groups, after they have been oxidized to catechols (see **Figure 8**). This sequence was seen, for example, in the metabolism of the anti-inflammatory drug diclofenac, which in humans yielded 3'-hydroxy-4'-methoxy-diclofenac (**23**, **Figure 11**) as a major metabolite with a very long plasma half-life.<sup>44</sup> The rates of *O*-methylation of about 50 substrates in recombinant human soluble COMT has been published and analyzed by partial least squares (PLS) QSAR and 3D-QSAR.<sup>45,46</sup> The compounds examined were natural products. The results showed that increased acidity of the catechol group and a larger size of the adjacent substituents strongly decreased the rate of methylation.

*S*-Methylation of thiol groups (**Figure 10a**) is documented for such drugs as 6-mercaptopurine (**24**, **Figure 11**) and captopril. More recently, it has been shown to be one of the major routes of human metabolism of the vasoepitidase inhibitor omapatrilat (**25**, **Figure 11**).<sup>47</sup> Other substrates are metabolites (mainly thiophenols) resulting from the S-C cleavage of (aromatic) glutathione and cysteine conjugates (see later). Once formed, such methylthio metabolites can be further processed to sulfoxides and sulfones before excretion (see 5.05 Principles of Drug Metabolism 1: Redox Reactions).

Three basic types of *N*-methylation reaction have been recognized (**Figure 10b**). A number of primary amines (e.g., amphetamine) have been shown to be in vitro substrates of amine *N*-methyltransferase. The same is true of some

**Figure 11** Compounds discussed in the text in connection with reactions of *O*-, *S*-, and *N*-methylation.

secondary amines such as tetrahydroisoquinolines produced in plants and animals. Examples of tetrahydroisoquinolines are isosalsoline and salsolidine; their *N*-methylation by bovine liver amine *N*-methyltransferase has been shown to be substrate enantioselective, the preferred substrates being (+)-(*R*)-isosalsoline and (–)-(*S*)-salsolidine (26 and 27, respectively, in Figure 11).<sup>48</sup> Some phenylethanolamines and analogs are also *N*-methylated, in this case by phenylethanolamine *N*-methyltransferase. However, such reactions are seldom of quantitative significance in vivo, presumably due to effective oxidative *N*-demethylation. A comparable situation involves the N-H group in an imidazole ring, as exemplified by histamine.<sup>49</sup> A therapeutically relevant example is that of theophylline (28, Figure 11) whose reaction of *N*(9)-methylation to caffeine is very effective in newborn humans with the danger of caffeine intoxication, whereas in adults it is masked by a comparatively fast *N*-demethylation (futile cycling).

*N*-Methylation of pyridine-type nitrogen atoms appears to be of greater in vivo pharmacological significance than the two other types of *N*-methylation, and this is for two reasons. First, the resulting metabolites, being quaternary amines, are more stable than tertiary or secondary amines toward *N*-demethylation. Second, these metabolites are also more polar than the parent compounds, in contrast to all other products of methylation. Good substrates are pyridine itself, whose *N*-methylation is a genuine reaction of detoxification, nicotinamide, and a number of monocyclic and bicyclic derivatives.<sup>49</sup>

From Figure 10, methylation reactions can clearly be subdivided into two classes:

1. those where the substrate and the product have the same electrical state, a proton in the substrate having been exchanged for a positively charged methyl group; and
2. those where the product has acquired a positive charge, namely has become a pyridine-type quaternary ammonium.

Looking back at Table 1 and at the criteria discussed above for conjugation reactions, it is apparent that the methyl group being transferred is the smallest of all endocons. Furthermore, and with the exception of pyridine-type substrates, the metabolites formed by methylation are less hydrophilic than the corresponding substrates.

### 5.06.3.3 Formation of Sulfate and Phosphate Conjugates

#### 5.06.3.3.1 Mechanism and multiplicity of sulfotransferases

Sulfation reactions consist in a sulfate being transferred from the cofactor 3'-phosphoadenosine 5'-phosphosulfate (29, Figure 12; PAPS) to the substrate under catalysis by a sulfotransferase. All criteria of conjugation are met in these reactions, since they are enzymatic and the moiety transferred (sulfuric acid or rather sulfate) is of medium MW, ionized and highly hydrophilic, and is carried by a coenzyme.

In PAPS, the sulfate and phosphate moieties are linked by an anhydride bond whose cleavage is exothermic and supplies enthalpy to the catalytic reaction. The nucleophilic hydroxy group (phenols, alcohols, and hydroxylamines, Figure 12a) or primary or secondary amino groups (Figure 12b) in the substrate will react with the leaving  $\text{SO}_3^-$  moiety, forming an ester sulfate or a sulfamate (Figure 12).<sup>50</sup> Some of these conjugates are unstable under biological conditions and may undergo heterolytic cleavage to form electrophilic intermediates of considerable toxicological significance, as discussed later.

Sulfotransferases involved in the metabolism of small endogenous and exogenous molecules are soluble (cytosolic) enzymes. Following major advances in molecular biology, they are now recognized as being encoded by a gene superfamily of which about 50 mammalian genes are known and whose products are classified into families (>45% residue identity) and subfamilies (>60% residue identity) according to their degree of homology. Thus, human sulfotransferases include:

- the SULT1A subfamily, which contains the enzymes 1A1, 1A2, and 1A3 (phenol[ = aryl] sulfotransferases, with some correspondence with EC 2.8.2.1);
- the subfamily SULT1B with the enzyme 1B1 (thyroid hormone sulfotransferase);
- the subfamily SULT1C with the enzymes 1C1 and 1C2;
- the subfamily SULT1E with 1E1 (estrogen sulfotransferase, EC 2.8.2.4);
- the subfamily SULT2A with 2A1 (alcohol[ = hydroxysteroid] sulfotransferase, EC 2.8.2.2);
- the subfamily SULT2B with the two transcript variants 2B1a and 2B1b; and
- the family SULF4 with 4A1.<sup>51–60</sup>

A number of other sulfotransferase activities are recognized by the NC-IUBMB, including steroid sulfotransferase (EC 2.8.2.15) and cortisol sulfotransferase (glucocorticosteroid sulfotransferase; EC 2.8.2.18). An important family is

**Figure 12** Structure of the cofactor 3'-phosphoadenosine 5'-phosphosulfate (**29**; PAPS); generic reactions of *N*-sulfation (b) and of *O*-sulfation (a).

SULT3, which is involved in amine sulfation and should correspond to amine sulfotransferase (EC 2.8.2.3). However, there are marked and condition-dependent overlaps in the substrate specificity of all these sulfotransferases, a fact that prevents any strong and one-to-one correspondence between the IUBMB and the homology-based nomenclatures. Nevertheless, it is well established that the enzymes of greatest significance in the sulfation of xenobiotics are the aryl sulfotransferases, the alcohol sulfotransferases, and the amine sulfotransferases.

#### 5.06.3.3.2 Substrates of sulfotransferases

Sulfotransferases act on a very large variety of compounds bearing a phenolic, alcoholic, hydroxylamino, or amino function. These substrates include endogenous compounds (e.g., catecholamines, steroids, and bile acids), dietary constituents (e.g., flavonoids), procarcinogens (e.g., benzylic alcohols and heterocyclic aromatic amines, see below), and drugs.

Phenols form stable aryl sulfate esters (Figure 12a). The reaction is usually of high affinity (i.e., rapid), but the limited availability of PAPS restricts the amounts of conjugate being produced. Given that phenols are also substrates of glucuronyltransferases (see Section 5.06.3.4), a competition for the two reactions is frequently seen, with the high-affinity but low-capacity sulfation predominating at lower doses, and the lower affinity but higher capacity glucuronidation predominating at higher doses. This typical situation is aptly exemplified by contrasting the relative sulfation and glucuronidation of the high-dose drug paracetamol (**30**, Figure 13), whose major metabolite is an aryl glucuronide, with those of the low-dose drug troglitazone (**31**), whose major metabolite in human plasma is the aryl sulfate rather than the aryl glucuronide.<sup>61</sup> Sulfation, like glucuronidation (discussed in Section 5.06.3.4), is also a route of significance in the conjugation of phenols generated as phase I metabolites of aromatic drugs, e.g., 4-hydroxypropranolol.<sup>62</sup>

Quantitative structure–activity relationship (QSAR) investigations based on sulfation rates obtained with recombinant human SULT enzymes have uncovered some valuable trends for SULT1A3.<sup>46</sup> Factors favoring the rate of sulfation were, for example, lipophilicity and a basic amino group or a zwitterionic nature of the compound; unfavorable factors included a carboxy group and the number of H-bond acceptor groups.

The sulfoconjugation of alcohols (Figure 12a) leads to metabolites of different stabilities. Endogenous hydroxysteroids (i.e., cyclic secondary alcohols) form relatively stable sulfates, while some secondary alcohol metabolites of allylbenzenes (e.g., saffrole and estragole) form highly genotoxic carbocations.<sup>63</sup> Primary alcohols, e.g., methanol and ethanol, can also form sulfates whose alkylating capacity is well known and results from the heterolytic cleavage of the C–O bond. Similarly, polycyclic hydroxymethylarenes yield reactive sulfates believed to account for their mutagenicity and carcinogenicity.<sup>52</sup> The reaction is not without medicinal relevance, since, for example, the sulfate ester (**32**, Figure 13) of  $\alpha$ -hydroxytamoxifen, a well-known metabolite of the antiestrogen tamoxifen, has been

**Figure 13** Compounds discussed in the text in connection with reactions of O- and N-sulfation.

shown to be highly reactive toward 2'-deoxyguanosine.<sup>64</sup> While this study only afforded indirect evidence, its results become meaningful in view of the propensity of tamoxifen to induce endometrial cancers in tumor patients.

Aromatic hydroxylamines and hydroxylamides are good substrates for some sulfotransferases and yield unstable sulfate esters (Figure 12a). Indeed, heterolytic N–O cleavage produces a highly electrophilic nitrenium ion. This is a mechanism believed to account for part or all of the cytotoxicity of arylamines and arylamides (e.g., phenacetin). An intriguing and very rare reaction of conjugation occurs for minoxidil (33, Figure 13), a hypotensive agent also producing hair growth. This drug is an N-oxide, and the actual active form responsible for the different therapeutic effects is the stable N-O-sulfate ester (34).<sup>65</sup>

In contrast to the unstable hydroxylamine sulfates, significantly more stable products are obtained upon N-sulfoconjugation of amines (Figure 12b). Some alicyclic amines, and primary and secondary alkyl- and arylamines can all yield sulfamates in the presence of human SULT2A1.<sup>66</sup> However, the clinical significance of these reactions in humans remains poorly understood.

One medically relevant example is that of trovafloxacin (35, Figure 13; R = H), a quinolone antibacterial agent. Human volunteers who had been given the drug excreted it partly unchanged and partly as three major conjugates (see Section 5.06.3.5).<sup>67</sup> One of these was the sulfamate (35, Figure 13; R =  $\text{SO}_3\text{H}$ ), which accounted for about 10% of the dose and was excreted fecally, indicating its stability against biodegradation by the gut microflora.

### 5.06.3.3.3 Formation of phosphate conjugates

Phosphate conjugates are rare compared to sulfates, yet they are of primary significance in the metabolism of anticancer and antiviral agents impacting on endogenous nucleotides. Indeed, phosphorylation is an essential metabolic step in the bioactivity of these agents, and numerous *in vitro* and *in vivo* studies document their stepwise phosphorylation to mono-, di-, and triphosphates. Such reactions are sometimes, and correctly, labeled as anabolic (i.e., biosynthetic) ones.<sup>68,69</sup> They are known or postulated to be catalyzed by some among the very many phosphotransferases (EC 2.7), for example adenosine kinase (EC 2.7.1.20), thymidine kinase (2.7.1.21), uridine kinase (2.7.1.48), deoxycytidine kinase (EC 2.7.1.74), deoxyadenosine kinase (EC 2.7.1.76), nucleoside phosphotransferase (EC 2.7.1.77), creatine kinase (EC 2.7.3.2), adenylate kinase (EC 2.7.4.3), nucleoside-phosphate kinase (EC 2.7.4.4), guanylate kinase (EC 2.7.4.8), and (deoxy)nucleoside-phosphate kinase (EC 2.7.4.13).

A therapeutically relevant example is afforded by the well-known anti-HIV agent zidovudine (AZT) (36, Figure 14). The concentrations of its phosphate anabolites were measured in the peripheral blood mononuclear cells of AIDS patients treated with the drug.<sup>70</sup> The monophosphate was the predominant compound, and the diphosphate and triphosphate were present in comparable amounts.

**Figure 14** Compounds discussed in the text in connection with reactions of phosphorylation.

The unexpected (and mostly unexplored) activity of phosphotransferases toward xenobiotic substrates is forcefully illustrated by the recently reported activation of FTY720 (37, [Figure 14](#)), a novel immunomodulator showing great promise in transplantations and to treat autoimmunity.<sup>71</sup> The agent itself appears inactive, being phosphorylated in rats and humans to the active monophosphate. Recent studies have implicated spingosine kinases as the catalysts and have shown that the reaction is highly product enantioselective. Indeed, FTY720 itself is prochiral (it bears two enantiotopic  $-\text{CH}_2\text{OH}$  groups), and the enzymatic reaction results exclusively in the phosphorylated enantiomer of (*S*)-configuration (38), which is also the only active one.

#### 5.06.3.4 Conjugations with Glucuronic Acid

Glucuronidation is considered by many to be the most important reaction of conjugation; qualitatively for the diversity of functional groups to which glucuronic acid can be coupled, and quantitatively for the vast number and diversity of its substrates.

##### 5.06.3.4.1 Mechanism and multiplicity of UDP-glucuronyltransferases

Glucuronidation consists in a molecule of glucuronic acid being transferred from the cofactor uridine-5'-diphospho- $\alpha$ -D-glucuronic acid (39, [Figure 15](#); UDPGA) to the substrate. This cofactor is produced endogenously by C6 oxidation of UDP- $\alpha$ -D-glucose, and it is recognized that about 5 g are synthesized daily in the adult human body, hence the high capacity of this metabolic route.

Glucuronic acid exists in UDPGA in the  $1\alpha$ -configuration, but the products of conjugation are  $\beta$ -glucuronides (40, [Figure 15](#)). This is due to the mechanism of the reaction being a nucleophilic substitution with inversion of configuration. Indeed, all functional groups able to undergo glucuronidation are nucleophiles, a common characteristic they share despite their great chemical variety. As a consequence of this diversity, the products of glucuronidation are classified as *O*-, *N*-, *S*-, and *C*-glucuronides. Practically all functional groups that are glucuronidated are shown in [Figure 15](#). The hydroxy groups (phenols, alcohols, carboxylic acids, carbamic acids, hydroxylamines, and hydroxylamides) form *O*-glucuronides and are grouped in [Figure 15a](#) together with strongly acidic enolic acids, a very few of which are known to form *C*-glucuronides. The *N*-glucuronides are grouped in [Figure 15b](#) and are generated from amides, sulfonamides, aromatic amines, heterocyclic amines, and aliphatic amines; also shown in [Figure 15b](#) are the thiols, which lead to *S*-glucuronides.

The enzymes catalyzing these highly diverse reactions are known as UDP-glucuronyltransferases (UDP-glucuronosyltransferases; EC 2.4.1.17; UDPGT) and consist in a number of proteins coded by genes of the *UGT* superfamily ([Table 3](#)). The human UDPGT known to metabolize xenobiotics are the products of two gene families, *UGT1* and *UGT2*. Their major substrates classes are also summarized in [Table 3](#).<sup>72–78</sup>

##### 5.06.3.4.2 Substrates of UDP-glucuronyltransferases

Phenols are important substrates of UDP-glucuronyltransferases, be they drugs, drug metabolites, natural products, industrial chemicals, or metabolites thereof. An example of an extensively glucuronidated drug is paracetamol (30 in [Figure 13](#); see [Section 5.06.3.3.2](#)); the major catalysts of the reaction are UGT1A6 and mainly 1A7.<sup>79</sup> Interesting QSARs have been published for the glucuronidation of a variety of natural, medicinal, and model phenols catalyzed by UGT1A1, 1A6, 1A9, 2B7, and 2B15.<sup>46</sup>

**Figure 15** Structure of the cofactor uridine-5'-diphospho- $\alpha$ -D-glucuronic acid (39; UDPGA); generic reactions of O- and S-glucuronidation (a) and of N- and S-glucuronidation (b).

Another major group of substrates are alcohols, be they primary, secondary, or tertiary (Figure 15a). Medicinal examples include oxazepam (UGT1A9, 2B7, and 2B15) and zidovudine (36, Figure 14; UGT2B7).<sup>80,81</sup> Another important example is that of morphine (41, Figure 16), which is conjugated on its phenolic and secondary alcohol groups to form the 3-O-glucuronide (a weak opiate antagonist) and the 6-O-glucuronide (a strong opiate agonist), respectively.<sup>82</sup>

Hydroxylamines and hydroxylamides may also form O-glucuronides (Figure 15a). Thus, a few drugs and a number of aromatic amines are known to be N-hydroxylated and then O-glucuronidated. A recent example has been found in the metabolism of a new oral hypoglycemic agent 9-[(1S;2R)-2-fluoro-1-methylpropyl]-2-methoxy-6-(1-piperazinyl) purine.<sup>83</sup> When administered to monkeys, more than half of a dose was recovered as a compound found to be the O-glucuronide of the N-hydroxylated metabolite (42, Figure 16).

An important pathway of O-glucuronidation is the formation of acyl-glucuronides (Figure 15a). Substrates are numerous nonsteroidal anti-inflammatory arylacetic and 2-arylpropionic acids (e.g., ketoprofen, 43 in Figure 16) and aliphatic acids (e.g., valproic acid, 44 in Figure 16). More recent drug classes such as statins and endothelin receptor antagonists may also yield acyl-glucuronides. Aromatic acids do not appear to be good substrates, but there are exceptions. The significance of acyl-glucuronides has long been underestimated. Indeed, these metabolites are quite reactive, rearranging to positional isomers and binding covalently to plasma and seemingly also tissue proteins.<sup>84,85</sup> Thus, acyl-glucuronide formation cannot be viewed solely as a reaction of inactivation and detoxification.

Second in importance to O-glucuronides are the N-glucuronides (Figure 15b) formed from carboxamides and sulfonamides, aromatic and pyridine-type amines, and basic amines.<sup>86</sup> The glucuronidation of primary and secondary amides and amines yields the 'plain' N-glucuronides; these will be discussed first, followed by the quaternary N-glucuronides derived from tertiary amines.

The N-glucuronidation of carboxamides is exemplified by the primary amide carbamazepine (19, Figure 9;  $\text{X} = >\text{NCONH}_2$ ) and by the secondary amide phenytoin (45, Figure 16). The reaction has beneficial significance for

**Table 3** Human UDP-glucuronyltransferases and their preferred substrates<sup>72–78</sup>

<sup>a</sup>Flavonoids, coumarins, etc.<sup>b</sup>No data or very weak activities.

antibacterial sulfonamides such as sulfadimethoxine (**46**, [Figure 16](#)) since it produces highly water-soluble metabolites that show no risk of crystallizing in the kidneys.

*N*-Glucuronidation of aniline-type aromatic amines has been observed in a few cases only (e.g., benzidine). Similarly, there are a few observations that primary and secondary basic amines can be *N*-glucuronidated, for example, imidazole derivatives such as atipamezole (**47**, [Figure 16](#)), a substrate of UGT1A4.<sup>87</sup> *N*-Glucuronidations of particular significance in humans are seen in the formation of quaternary glucuronides, also known as  $N^+$ -glucuronides.<sup>86–89</sup> More and more lipophilic, basic tertiary amines containing one or two methyl groups (e.g., antihistamines and neuroleptics)

**Figure 16** Compounds discussed in the text in connection with reactions of hydroxy, carboxy, carboxamido, sulfamido, and amino glucuronidation.

are found to undergo this reaction to a marked extent in humans, as exemplified by the  $N^+$ -glucuronide of imipramine (48, Figure 16). The same is true for pyridine-type tertiary amines, as exemplified by two important conjugates of nicotine in humans, namely the  $N^+$ -glucuronide of nicotine (49;  $X = 2H$ ) and cotinine (49;  $X = O$ ).

UGT1A4 plays a particularly important role in  $N$ -glucuronidation, but there are extensive overlaps in the specificity of the various UGT enzymes toward the various classes of substrates discussed above (Table 3). QSAR, 3D-QSAR, and pharmacophore modeling are beginning to clarify these specificities and offer preliminary predictive models.<sup>46,90,91</sup>

### 5.06.3.5 Reactions of Acetylation

The factor involved in the acetylation reaction is acetyl-coenzyme A (50, Figure 17;  $R = COCH_3$ ; acetyl-CoA). The acetyl moiety is in activated form, being bound to CoA by a thioester bridge of increased reactivity compared to an oxoester. This endocon is transferred to a nucleophilic function in the substrate, namely an amino, hydroxy, or thiol group. As discussed below, weak amino groups are by far the best targets of acetylation in xenobiotic substrates.

Various enzymes are known to catalyze acetylation reactions:

- arylamine  $N$ -acetyltransferase (arylamine acetylase; EC 2.3.1.5; NAT) is the major enzyme system involved in xenobiotic acetylation; two enzymes have been characterized in humans, namely NAT1 and the highly variable NAT2<sup>92–94</sup>;
- aromatic-hydroxylamine  $O$ -acetyltransferase (EC 2.3.1.56) and  $N$ -hydroxyarylamines  $O$ -acetyltransferase (EC 2.3.1.118) are also involved in the acetylation of aromatic amines and hydroxylamines (see below); and
- other acetyltransferases include diamine  $N$ -acetyltransferase (putrescine acetyltransferase; EC 2.3.1.57) and aralkylamine  $N$ -acetyltransferase (serotonin acetyltransferase; EC 2.3.1.87), but their involvement in xenobiotic metabolism does not appear to be sufficiently characterized.

**Figure 17** Structure of the cofactor acetyl coenzyme A (**50**; acetyl-CoA; R = acetyl), and generic reactions of *N*- and *O*-acetylation shown by drugs and other xenobiotics (box).

**Figure 18** Medicinal substrates discussed in the text in connection with reactions of *N*- and *O*-acetylation.

The xenobiotic substrates of acetylation (box in [Figure 17](#)) are mainly primary amines of medium basicity, namely arylamines, hydrazines (R = H or aryl), and hydrazides (R = COR'). Medicinal examples include *para*-aminosalicylic acid (**51**, [Figure 18](#)), sulfamethazine (**52**) and first-generation sulfonamides, isoniazid (**53**) and hydralazine (**54**). Xenobiotics of toxicological interest include hydrazine itself, and many carcinogenic arylamines such as benzidine. Few basic primary amines of medicinal interest have been reported to form *N*-acetylated metabolites, but a noteworthy recent example is that of trovafloxacin (**35**, [Figure 13](#); R = H). Human volunteers who had been given the drug excreted it partly unchanged and partly as the sulfamate (*see* [Section 5.06.3.3.2](#)), the acyl-glucuronide (the major circulating metabolite), and the *N*-acetyl conjugate (**35**, [Figure 13](#); R = COCH<sub>3</sub>), which accounted for about 6% of the dose.<sup>67</sup>

Xenobiotic arylhydroxylamines can also be acetylated, but the reaction is one of *O*-acetylation (box in [Figure 17](#)). This is the reaction formally catalyzed by EC 2.3.1.118 with acetyl-CoA acting as the acetyl donor, the *N*-hydroxy metabolites of a number of arylamines being known substrates. The same conjugates can be formed by intramolecular *N,O*-acetyl transfer, when an arylhydroxamic acid is *N*-acetylated.<sup>95</sup>

A very different type of reaction is represented by the conjugation of xenobiotic alcohols with fatty acids, yielding highly lipophilic metabolites accumulating in tissues. Thus, ethanol and haloethanols form esters with, e.g., palmitic acid, oleic acid, linoleic acid, and linolenic acid; enzymes catalyzing such reactions are cholesteryl ester synthase (EC 3.1.1.13) and fatty-acyl-ethyl-ester synthase (EC 3.1.1.67).<sup>96</sup> Larger xenobiotics such as tetrahydrocannabinols and codeine are also acylated with fatty acids, possibly by sterol *O*-acyltransferase (EC 2.3.1.26).

### 5.06.3.6 Conjugations with Coenzyme A and Subsequent Reactions

#### 5.06.3.6.1 Xenobiotic acyl-CoA conjugates as metabolic crossroads

For at least four reasons, the conjugation of xenobiotic acids (R-COOH) with coenzyme A (CoA-SH) is an exception among phase II reactions. First, the reaction begins with the activation of the substrate to a transient enzyme-bound acyl-adenylate intermediate. This intermediate is then reacted with CoA-S- to form an acyl-CoA conjugate (50, Figure 17; R = xenobiotic acyl group).<sup>97</sup> Second, these R-CO-SCoA conjugates are never excreted and can only be observed transiently in vitro and be inferred indirectly. Third, and most importantly, the R-CO-SCoA conjugates are a crossroads for a number of anabolic or catabolic reactions, which are discussed later. Fourth, and as a consequence of this, it is in the formation and processing of CoA-conjugates that drug metabolism mostly interferes with endogenous metabolic pathways, specifically lipid biochemistry. Such interactions may be of pharmacological or toxicological significance,<sup>97,100</sup> as insufficiently appreciated.

A number of enzymes involved in lipid biochemistry can catalyze the conjugation of xenobiotic acids to coenzyme A. They belong to the ligases forming carbon-sulfur bonds (EC 6.2), and more precisely to the acid-thiol ligases (EC 6.2.1)<sup>6</sup>:

- short-chain fatty acyl-CoA synthetase (EC 6.2.1.1; acetyl-CoA ligase);
- propionate-CoA synthetase (EC 6.2.1.17);
- medium-chain acyl-CoA synthetase (EC 6.2.1.2; butyrate-CoA ligase), which acts on C4 to C11 acids;
- long-chain acyl-CoA synthetase (EC 6.2.1.3), which acts on C6 to C20 and sometimes even C24 acids;
- cholate-CoA ligase (EC 6.2.1.7; cholate thiokinase);
- benzoyl-coenzyme A synthetase (EC 6.2.1.25; benzoate-CoA ligase), which acts on various benzoic acids; and
- phenacyl-CoA synthetase (EC 6.2.1.30; phenylacetyl-CoA ligase), which acts on a variety of arylalkanoic acids.

This list is based for the most part on the recognition of endogenous substrates. There has been a growing interest in xenobiotic-CoA ligases for a number of years, with numerous enzymes of overlapping substrate specificity being discovered.<sup>97–99</sup>

Given that xenobiotic-CoA conjugates are metabolic intermediates characterizable in in vitro studies only, it is of great importance to be aware of the secondary metabolites likely to be seen in in vivo and clinical investigations. As shown in Table 1, xenobiotic-CoA conjugates may undergo a variety of secondary reactions resulting in the formation of stable metabolites, some of which are conjugates (Figure 19) and others not. The secondary routes open to xenobiotic-CoA conjugates depend primarily on their molecular structure, and in part also on biological conditions. Below, we focus on amino acid conjugation and formation of hybrid triglycerides, and briefly discuss cholesteryl ester formation, chiral inversion, and  $\beta$ -oxidation.

#### 5.06.3.6.2 Amino acid conjugation

Amino acid conjugation is a significant metabolic route for a number of carboxylic acids and involves the formation of an amide bond between the xenobiotic acyl-CoA and the amino acid. Glycine is the amino acid most frequently used for conjugation of small aromatic acids (reaction A in Figure 19), while a few glutamine conjugates (reaction B in Figure 19) have been characterized in humans. In addition, taurine (reaction C in Figure 19) and perhaps a few other amino acids and dipeptides can be used for conjugation in various animal species.<sup>37</sup> The enzymes catalyzing these transfer reactions are known or believed to be various *N*-acyltransferases, for example:

- glycine *N*-acyltransferase (EC 2.3.1.13);
- glutamine *N*-phenylacetyltransferase (EC 2.3.1.14);
- glutamine *N*-acyltransferase (EC 2.3.1.68);
- glycine *N*-benzoyltransferase (EC 2.3.1.71); and
- bile acid-CoA:amino acid *N*-acyltransferase (EC 2.3.1.65; glycine-aurine *N*-acyltransferase).

The xenobiotic acids undergoing glycine conjugation are mainly substituted benzoic acids, e.g., benzoic acid itself (55, Figure 20); the discovery of hippuric acid, its glycine conjugate, in the urine of horses over 150 years ago marks the birth of the science of drug metabolism. Salicylic acid (56) similarly yields salicyluric acid, which accounts for about 3/4 of a dose of aspirin in humans. Similarly, *m*-trifluoromethylbenzoic acid (57), a major metabolite of fenfluramine, is excreted as the glycine conjugate. A number of studies have been published on the structure-metabolism relationships of benzoic acid derivatives and analogs in glycine conjugation.<sup>98,101</sup>

**Figure 19** Metabolic conjugations involving acyl-CoA intermediates of xenobiotic acids, namely conjugation to glycine (reaction A), glutamine (reaction B), taurine (reaction C), and cholesterol (reaction D), and formation of hybrid triglycerides (reaction E).

**Figure 20** Medicinal substrates discussed in the text in connection with conjugation to amino acids and the unidirectional chiral inversion of profens.

Some phenylalkanoic acids can yield glycine and glutamine conjugates (reactions A and B in [Figure 19](#)), as illustrated by 4-phenylbutyric acid (**58**, [Figure 20](#)), a drug used to treat patients with inborn errors of ureagenesis.<sup>102</sup> In humans and rats, this drug undergoes  $\beta$ -oxidation (*see* [Section 5.06.3.6.4](#)) to phenylacetic acid (**59**) via a number of identified oxygenated metabolites. 4-Phenylbutyric acid and phenylacetic acid both yielded the corresponding

acyl-glucuronide. Of relevance to the present context is the fact that phenylacetylglutamine was formed in the rat, whereas both phenylacetylglutamine and 4-phenylbutyrylglutamine are excreted as the major metabolites in the urine of normal subjects treated with 4-phenylbutyric acid.

Valproic acid (44, [Figures 16](#) and [21](#)) is of major interest in the context of lipid biochemistry. Coupling of this antiepileptic drug to coenzyme A opens the door to  $\beta$ -oxidation, as discussed later, and to amino acid conjugation. Indeed, epileptic patients treated with valproic acid produced and excreted trace amounts of valproyl glycine, and more significant amounts of valproyl glutamine and the unexpected glutamic acid conjugate, i.e., valproyl glutamate.<sup>103</sup>

There have been a number of reports in recent years of medicinal carboxylic acids yielding taurine conjugates (reaction C in [Figure 19](#)). This is exemplified by the withdrawn nonsteroidal anti-inflammatory drug (NSAID) benoxaprofen, which in bile duct-cannulated rats gave both the acyl-glucuronide and taurine conjugate.<sup>104</sup> Only the (*R*)-enantiomer (60, [Figure 20](#)) formed the acyl-CoA intermediate leading to the taurine conjugate, but racemization of this acyl-CoA conjugate (see [Section 5.06.3.6.4](#)) ultimately led to minor amounts of the (*S*)-benoxaprofen taurine conjugate also being excreted in the bile.

Another interesting example is that of MRL-II (61, [Figure 20](#)), an agonist of the  $\alpha$ -peroxisome proliferator-activated receptor ( $\alpha$ PPAR). When administered to dogs, dose-dependent amounts of the acyl-glucuronide and taurine conjugates were excreted in the bile.<sup>105</sup> Low doses favored the taurine conjugate, whose proportion decreased at higher doses. It is interesting to note that MRL-I, a closely related compound, yielded exclusively the acyl-glucuronide and no taurine conjugate. This fact, together with literature data showing the taurine conjugation of some retinoic acids and synthetic prostaglandins, suggests the involvement of a physiological enzyme such as bile acid-CoA:amino acid *N*-acyltransferase (EC 2.3.1.65).

#### 5.06.3.6.3 Formation of hybrid triacylglycerides and cholesteryl esters

Incorporation of xenobiotic acids into lipids forms highly lipophilic metabolites that may burden the body as long-retained residues. In the majority of cases, cholesterol esters or triacylglycerol analogs are formed. Candidate enzymes for such reactions are respectively:

- sterol *O*-acyltransferase (EC 2.3.1.26; acyl coenzyme A-cholesterol-*O*-acyltransferase, ACAT);
- diacylglycerol *O*-acyltransferase (EC 2.3.1.20); and
- 2-acylglycerol *O*-acyltransferase (EC 2.3.1.22) and other *O*-acyltransferases.

Some phospholipid analogs, as well as some esters to the 3-hydroxy group of biliary acids, have also been characterized.<sup>4,106</sup>

The number of drugs and other xenobiotics known to form glyceryl or cholesteryl esters is currently limited. To the best of our knowledge, only a few nonmedicinal xenobiotics but no drugs have been reported to form cholesteryl esters (reaction D in [Figure 19](#)). In contrast, results are accumulating on many acidic drugs and other xenobiotics forming triacylglycerol analogs, also called hybrid triglycerides (reaction E in [Figure 19](#)).<sup>107</sup> One telling example is that of ibuprofen (62, [Figure 20](#); see [Section 5.06.3.6.4](#)), a much used NSAID whose (*R*)-enantiomer forms hybrid triglycerides detectable in rat liver and in human and rat adipose tissues.<sup>100</sup> A similar formation of hybrid triglycerides has been reported for, e.g., the NSAID ketoprofen (43, [Figure 16](#)) and the antihyperlipidemic agent lifibrol (63, [Figure 20](#)).<sup>108</sup> The covalent incorporation of valproic acid (44 in [Figure 16](#) and [Figure 21](#)) into phospholipids in neurons is also of note.<sup>109</sup>

#### 5.06.3.6.4 Chiral inversion and $\beta$ -oxidation

Ibuprofen (62, [Figure 20](#)) and other arylpropionic acids (i.e., profens) are chiral drugs existing as the (+)-(*S*)-enantiomer and the (–)-(*R*)-diastomer. Some of these compounds undergo an intriguing metabolic reaction such that the inactive (*R*)-enantiomer is converted to the active (*S*)-enantiomer, while the reverse reaction is negligible. This unidirectional chiral inversion is thus a reaction of bioactivation, and its mechanism is now reasonably well understood.<sup>100</sup> The initial step is the formation of an acyl-CoA conjugate, a reaction that is highly substrate stereoselective since only the (*R*)-form but not the (*S*)-form produces the acyl-CoA conjugate, indicating a high enantiospecificity of the ligase. The (*R*)-acyl-CoA conjugate then undergoes a reaction of epimerization believed to be catalyzed by 2-methylacyl-CoA 2-epimerase (EC 5.1.99.4), resulting in a mixture of the (*R*)-profenoyl-CoA and (*S*)-profenoyl-CoA conjugates. Both epimers can then be hydrolyzed or undergo other reactions such as hybrid triglyceride formation (see [Section 5.06.3.6.3](#)). This reaction of chiral inversion is not limited to profens, and a few other structurally related xenobiotics are known to undergo this metabolic route.

**Figure 21** Mitochondrial  $\beta$ -oxidation of valproic acid (44).

In some cases, acyl-CoA conjugates formed from xenobiotic acids can also enter the physiological pathways of fatty acids catabolism or anabolism. A few examples are known of xenobiotic alkanolic and arylalkanoic acids undergoing two-carbon chain elongation. Other cases involve the opposite, namely two-, four-, or even six-carbon chain shortening by  $\beta$ -oxidation. An example of two-carbon chain shortening is mentioned in [Section 5.06.3.6.2](#) for 4-phenylbutyric acid (58, [Figure 20](#)).

In addition, intermediate metabolites of  $\beta$ -oxidation may also be seen, as illustrated by valproic acid (44, [Figure 21](#)). Approximately 50 metabolites of this drug have been characterized; they are formed by cytochrome P450-catalyzed hydroxylations, dehydrogenations,  $\beta$ -oxidation, glucuronidation, and other routes of conjugation (*see* [Sections 5.06.3.4.2, 5.06.3.6.2, and 5.06.3.6.3](#)). [Figure 21](#) shows the  $\beta$ -oxidation of valproic acid seen in mitochondrial preparations.<sup>110,111</sup> The resulting metabolites have also been found in unconjugated form in the urine of humans or animals dosed with the drug.

### 5.06.3.7 Conjugations with Glutathione

#### 5.06.3.7.1 Glutathione and glutathione transferases

Glutathione (64, [Figure 22](#); GSH) is a thiol-containing tripeptide of major significance in the detoxification of drugs and other xenobiotics. In the body, it exists in a redox equilibrium between the reduced form (GSH) and an oxidized form (GSSG). The metabolism of glutathione (i.e., its synthesis, redox equilibrium, and degradation) is quite complex and involves a number of enzymes.<sup>112–115</sup>

Glutathione reacts in a variety of ways, one of which is its redox capacity. Indeed, GSH can reduce peroxides (a reaction catalyzed by glutathione peroxidase) and organic nitrates; in its GSSG form, glutathione can oxidize the superoxide anion radical. Of major significance in detoxification reactions is the capacity of GSH (and other endogenous thiols including albumin) to scavenge free radicals, in particular radical oxygen species (e.g.,  $R^\bullet$ ,  $HO^\bullet$ ,  $HOO^\bullet$ ,  $ROO^\bullet$ ). As such, glutathione and other thiols have a critical role to play in cellular protection.<sup>116</sup> The reactions involved are highly complex and can be simplified as follows:

- $GSH + X^\bullet \rightarrow GS^\bullet + XH$
- $GS^\bullet + GS^\bullet \rightarrow GSSG$
- $GS^\bullet + O_2 \rightarrow GS-OO^\bullet$
- $GS-OO^\bullet + GSH \rightarrow GS-OOH + GS^\bullet$

In this chapter, we focus on the conjugation reactions of glutathione as catalyzed by glutathione transferases. The glutathione transferases (EC 2.5.1.18; GSTs) are multifunctional proteins coded by two multigene superfamilies ([Table 4](#)).<sup>117–123</sup> They can act as enzymes as well as binding proteins. The microsomal superfamily contains the homotrimer GST enzymes, whereas the cytosolic GST enzymes are homodimers and heterodimers. Seven classes are now known in humans, e.g., the alpha class with the following dimers: A1–1, A1–2, A2–2, A3–3, A4–4, and A5–5. The

**Figure 22** The structure of glutathione (**64**; GSH), its conjugation with substrate R to yield a glutathione conjugate (**65**), and the processing of such conjugates to cysteine conjugates (**66**), mercapturic acids (**67**), and further metabolites discussed in the text.

**Table 4** The glutathione transferase gene superfamilies and the corresponding human glutathione transferase enzymes<sup>117–123</sup>

| <i>GST genes</i>   | <i>Human enzymes (EC 2.5.1.18)</i>                  |
|--|---|
| Microsomal GST superfamily (⇒ homotrimers)                         |   |
| <i>MGST1, MGST2, MGST3</i>   | GST1, GST2, GST3                                    |
| Cytoplasmic GST superfamily (⇒ homodimers, and a few heterodimers) |   |
| <i>GST A1, A2, A3, A4, A5</i>                                      | Alpha class: GST A1-1, A1-2, A2-2, A3-3, A4-4, A5-5 |
| <i>GST K1</i>  | Kappa class: GST K1-1 (peroxisomal)                 |
| <i>GST M1, M2, M3, M4, M5</i>                                      | Mu class: GST M1-1, M2-2, M3-3, M4-4, M5-5          |
| <i>GST O1, O2</i>  | Omega class: GST O1-1, O2                           |
| <i>GST P1</i>  | Pi class: GST P1-1                                  |
| <i>GST T1</i>  | Theta class: GST T1-1, T2                           |
| <i>GST Z1</i>  | Zeta class: GST Z1                                  |

GST A1–2, A2–2, and P1–1 display selenium-independent glutathione peroxidase activity, a property also characterizing the selenium-containing enzyme glutathione peroxidase (EC 1.11.1.9). The GST A1–1 and A1–2 are also known as ligandin when they act as binding or carrier proteins, a property also displayed by mu class GSTs. In the latter function, these enzymes bind and transport a number of active endogenous compounds (e.g., bilirubin, cholic acid, steroid and thyroid hormones, and hematin), as well as some exogenous dyes and carcinogens.

The conjugating reactivity of glutathione is due to its thiol group (pK<sub>a</sub> 9.0), which makes it a highly effective nucleophile. The nucleophilic character of the thiol group is greatly enhanced by deprotonation to a thiolate. In fact, an essential component of the catalytic mechanism of glutathione transferases is the marked increase in acidity (pK<sub>a</sub> decreased by 2–3 units) experienced by the thiol group upon binding of glutathione to the active site of the enzyme.<sup>118</sup> As a result, GSTs transfer glutathione to a very large variety of electrophilic groups; depending on the nature of the substrate, the reactions can be categorized as nucleophilic substitutions or nucleophilic additions. And with compounds of sufficient reactivity, these reactions can also occur nonenzymatically.<sup>118,124,125</sup>

Once formed, glutathione conjugates (**65**, Figure 22; R-SG) are seldom excreted as such (they are best characterized in vitro or in the bile of laboratory animals), but usually undergo further biotransformation prior to urinary or fecal excretion. Cleavage of the glutamyl moiety by glutamyl transpeptidase (EC 2.3.2.2) and of the glycyl moiety by cysteinylglycine dipeptidase (EC 3.4.11.2; aminopeptidase M) leaves a cysteine conjugate (**66**; R-S-Cys), which is further *N*-acetylated by cysteine-*S*-conjugate *N*-acetyltransferase (EC 2.3.1.80) to yield an *N*-acetylcysteine conjugate (**67**; R-S-CysAc). The latter type of conjugates are known as mercapturic acids, a name which clearly indicates that they were first characterized in urine. This, however, does not imply that the degradation of unexcreted glutathione conjugates must stop at this stage, since cysteine conjugates can be substrates of cysteine-*S*-conjugate β-lyase (EC 4.4.1.13) to yield thiols (R-SH). These in turn can rearrange, be oxidized, or be *S*-methylated and then *S*-oxygenated to yield thiomethyl conjugates (R-S-Me), sulfoxides (R-SO-Me), and sulfones (R-SO<sub>2</sub>-Me).

### 5.06.3.7.2 Substrates of glutathione transferases

Most known cases of glutathione conjugation are nucleophilic attacks of electron-deficient carbon atoms, but attack of a nitrogen atom (e.g., in an aromatic nitroso group) or a sulfur atom (in thiols) is also documented. Very often, the target carbon atom is  $sp^3$ - or  $sp^2$ -hybridized, but a few examples document the reactivity of  $sp$ -hybridized carbons. From a mechanistic viewpoint, it may be convenient to subdivide glutathione conjugations into nucleophilic additions and nucleophilic substitutions (i.e., addition-eliminations).<sup>4,37,40</sup>

*Nucleophilic additions* can involve metabolites arising from oxidation reactions, but they can also occur as primary metabolic reactions. Frequent cases of GSH addition are to  $\alpha,\beta$ -unsaturated carbonyls, a typical xenobiotic substrate being the toxin acrolein ( $CH_2=CH-CHO$ ). Attack occurs at the activated  $CH_2$  group. The mechanism of GSH addition to  $\alpha,\beta$ -unsaturated carbonyls is summarized in **Figure 23** with the diuretic drug ethacrynic acid (**68**), whose glutathione conjugate (**69**) has been known for many years. As shown, the exomethylene is electron deficient and is thus the obvious target of glutathione.

Quinones (*ortho*- and *para*-) and quinoneimines are structurally very similar to  $\alpha,\beta$ -unsaturated carbonyls. They react with glutathione by two distinct and competitive routes, one of which is a reduction to the hydroquinone or aminophenol, where GSH does not react covalently with the substrate but emerges in the oxidized form (GSSG). The other route is relevant to the present context, being a nucleophilic addition to form a conjugate. The reaction has physiological significance since endogenous metabolites such as quinone metabolites of estrogens are conjugated to glutathione. A medicinal example is provided by the toxic quinoneimine metabolite (**71**, **Figure 23**; see 5.05 Principles of Drug Metabolism 1: Redox Reactions; 5.08 Mechanisms of Toxication and Detoxification which Challenge Drug Candidates and Drugs) of paracetamol (**30**). Its glutathione conjugate (**71**) is not excreted as such in humans dosed with the drug, but as the mercapturic acid (**67**, **Figure 22**). The reaction is one of major detoxification, the quinoneimine being extremely hepatotoxic and resulting in liver necrosis, liver failure, and even death when produced at levels and rates that oversaturate the GSH conjugation pathway. Nevertheless, the GSH conjugation of quinones and quinonimines is not always a reaction of detoxification, as some of these conjugates are known to undergo further transformations leading to reactive products.<sup>126</sup>

The addition of glutathione to isocyanates and isothiocyanates (**72**, **Figure 23**;  $X=O$  and  $S$ , respectively) has received some attention due in particular to its reversible character.<sup>127</sup> Substrates of the reaction are xenobiotics such as the infamous toxin methyl isocyanate, whose glutathione conjugate (**73**) behaves as a transport form able to carbamoylate various macromolecules, enzymes, and membrane components. The reaction is also of interest from a

**Figure 23** Examples of glutathione conjugation by nucleophilic addition involving ethacrynic acid (**68**), the quinoneimine (**70**) reactive metabolite of paracetamol (**30**), and toxic isocyanates (**72**;  $X=O$ ) and isothiocyanates (**72**;  $X=S$ ).

**Figure 24** The metabolic pathway from arene oxides (**74**) to aromatic mercapturic acids (**77**) is presented here; the first product of addition is **75**, which dehydrates and aromatizes to **76** before being cleaved and N-acetylated. Also shown here is the logical pathway leading from valdecoxib (**78**) to its methyl sulfone conjugate (**79**).

medicinal viewpoint since anticancer agents such as methylformamide appear to work by undergoing activation to isocyanates and then to the glutathione conjugate.

An important role of GSH is in the conjugation of arene oxides, particularly those with slower rearrangement to the phenol and which are poor substrates of epoxide hydrolase (see Section 5.06.2.3.2 and Figure 8). The first reaction is again a nucleophilic addition to the epoxide (**74**, Figure 24), the target carbon atom here being  $sp^3$ -hybridized state. The resulting nonaromatic conjugate (**75**) then dehydrates to an aromatic GSH conjugate (**76**), followed by a cascade leading to the mercapturic acid (**77**) as also shown in Figure 22. This is a common reaction of metabolically produced arene oxides, as documented for naphthalene and numerous drugs and xenobiotics containing a phenyl moiety. Note that the same reaction can also occur readily for epoxides of olefins.

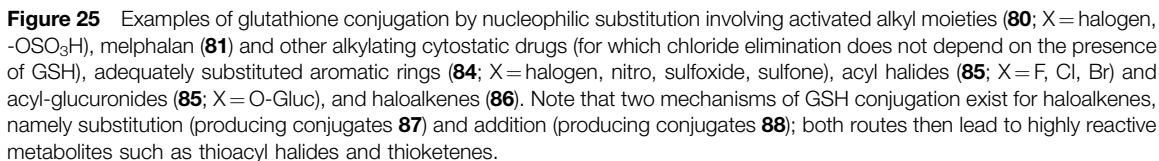

An interesting example of GSH addition to an arene oxide is found in the metabolism of the COX-2 inhibitor valdecoxib (**78**, Figure 24).<sup>128</sup> When administered to mice, the compound was almost completely metabolized by phase I and phase II reactions, with 16 metabolites being identified in blood, urine, and feces. One of these was the methyl sulfone derivative **79**, whose formation can only be understood by epoxidation, GSH conjugation, mercapturic acid formation,  $\beta$ -lyase C-S cleavage to form the free thiol, S-methylation, and finally S-oxygenation (Figure 22).

Glutathione conjugation by a mechanism of *nucleophilic substitution* (addition-elimination) appears more frequent with industrial xenobiotics than with drugs. Thus, compounds having an activated alkyl moiety of general structure **80** (Figure 25) become electrophilic when X is an electron-withdrawing leaving group such as a halogen atom or a sulfate ester group of metabolic origin. Such a reaction occurs for example at the  $-\text{CHCl}_2$  group of chloramphenicol. At first sight, the reaction of glutathione with alkylating cytostatic drugs having a nitrogen mustard group (e.g., melphalan **81**, Figure 25) to yield a conjugate such as **83** occurs by a substitution reaction. However, this is true only if one neglects the intermediate aziridinium ion (**82**), which is formed by chloride elimination independently of the presence of GSH. In other words, the real reaction is again one of nucleophilic addition.<sup>129</sup>

With good leaving groups (e.g., halogen, nitro, sulfoxide, sulfone), nucleophilic aromatic substitution reactions also occur at aromatic rings containing additional electron-withdrawing substituents and/or heteroatoms (i.e., compounds **84**, Figure 25).

Acyl halides (**85**; X = F, Cl, Br) are highly reactive industrial compounds, but some can also arise as toxic metabolic intermediate. Their detoxification by glutathione to yield a thioester type of conjugate is a highly effective mechanism of protection. A good example is provided by phosgene ( $\text{O} = \text{CCl}_2$ ), an extremely toxic metabolite of chloroform which is inactivated to the diglutathionyl conjugate  $\text{O} = \text{C}(\text{SG})_2$ .

While not nearly as reactive as acyl halides, acyl-glucuronides (**85**, Figure 25; X = O-Gluc) can nevertheless cause damage by forming adducts with proteins (see Section 5.06.3.4.2). Interestingly, they can also be conjugated with and detoxified by GSH. This has been demonstrated, for example, with zomepirac, an NSAID of the arylacetic acid class.

Haloalkenes (86, [Figure 25](#)) are a special group of substrates of GS-transferases since they may react with GSH either by substitution to form an alkene conjugate (87) or by addition to form an alkane conjugate (88). Formation of mercapturic acids occurs as for other glutathione conjugates, but in both routes S-C cleavage of the *S*-cysteinyl or *N*-acetyl-*S*-cysteinyl conjugates by renal  $\beta$ -lyase yields thiols of significant toxicity. Indeed, these thiols rearrange by hydrohalide expulsion to form highly reactive thioketenes and/or thioacyl halides.<sup>131,132</sup>

This chapter was written with a number of objectives in mind. As a priority, it was felt necessary to demonstrate to medicinal chemists the fact that metabolic reactions of hydrolysis and conjugation are not second in importance to the redox reactions comprehensively surveyed in 5.05 Principles of drug metabolism 1: Redox reactions. The variety of substrates and products presented here is just as ample as that discussed in 5.05 Principles of drug metabolism 1: Redox reactions, and the toxicological consequences (detoxification and toxification) of hydrolyses and conjugations are as important as those of redox reactions.

But differences do exist, and they may explain why hydrolyses and conjugations do not always receive the attention they deserve in drug discovery and development. First, numerous sites of potential enzymatic attack (think of Csp<sup>3</sup> and Csp<sup>2</sup> atoms) exist in substrates of oxidoreductases, most particularly in substrates of cytochrome P450s. As a result, about 90% or more of candidates, drugs, and other xenobiotics are substrates of CYPs. In contrast, hydrolyses and conjugations need specific target groups whose occurrence is less frequent than that of the target groups of CYPs. As a result, each of the metabolic reactions discussed in this chapter knows fewer substrates than CYP-catalyzed monooxygenations.

But this comparatively limited number of xenobiotic substrates per metabolic reaction is compensated by two important facts. The first is the impressive variety of existing transferases and the variety of endocons they transfer. In other words, the chemical nature of the functional groups introduced into substrates by conjugation reactions is markedly more diverse than that resulting from redox reactions. And the second compensating factor is the fact that while CYPs do indeed recognize more substrates than transferases during phase I metabolism, a more balanced situation prevails when considering the further processing of metabolites, in other words secondary metabolic reactions. Indeed, CYP-catalyzed monooxygenations do create the target groups for glucuronidation and other conjugations, meaning that there is markedly more scope for conjugation during phase II metabolism, particularly in *in vivo* investigations.

In closing, it appears from the above that the many distinct functionalities that differentiate substrates from their products of hydrolysis or conjugation offer a constant challenge to the expertise and intuition of pharmacochemists, bioanalysts, pharmacokineticists, pharmacologists, and toxicologists. The ultimate objective of this chapter is to appeal by providing enough factual evidence and educate by presenting a structured conceptual scaffold.

## Biography

**Bernard Testa** studied pharmacy because he was unable to choose between medicine and chemistry. Because he was incapable of working in a community pharmacy, he undertook a PhD thesis on the physicochemistry of drug–macromolecule interactions. Because he felt himself ungifted for the pharmaceutical industry, he went for 2 years to Chelsea College, University of London, for postdoctoral research under the supervision of Prof Arnold H Beckett. And because these were easy times, he was called as assistant professor to the University of Lausanne, Switzerland, to become full professor and Head of Medicinal Chemistry in 1978. Since then, he has tried to repay his debts by fulfilling

a number of local and international commitments, e.g., Dean of the Faculty of Sciences (1984–86), Director of the Geneva-Lausanne School of Pharmacy (1994–96 and 1999–2001), and President of the University Senate (1998–2000). He has written four books and edited 29 others, and (co)-authored 450 research and review articles in the fields of drug design and drug metabolism. During the years 1994–98, he was the Editor-Europe of *Pharmaceutical Research*, the flagship journal of the American Association of Pharmaceutical Scientists (AAPS), and he is now the co-editor of the new journal *Chemistry and Biodiversity*. He is also a member of the Editorial Board of several leading journals (e.g., *Biochemical Pharmacology*, *Chirality*, *Drug Metabolism Reviews*, *Helvetica Chimica Acta*, *Journal of Pharmacy and Pharmacology*, *Medicinal Research Reviews*, *Pharmaceutical Research*, *Xenobiotica*). He holds honorary doctorates from the universities of Milan, Montpellier, and Parma, and was the 2002 recipient of the Nauta Award on Pharmacology given by the European Federation for Medicinal Chemistry. He was elected a Fellow of the AAPS, and is a member of a number of scientific societies such as the French Academy of Pharmacy, the Royal Academy of Medicine of Belgium, and the American Chemical Society. His recently granted Emeritus status has freed him from administrative duties and gives him more time for writing, editing, and collaborating in research projects. His hobbies, interests, and passions include jogging, science-fiction, epistemology, teaching, and scientific exploration.

## 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues

## 5.07.1 Overview

The enzymes of drug metabolism mainly act to protect the cell from insult by foreign agents, such as drugs, industrial chemicals, and environmental pollutants. However, these versatile proteins also overlap with normal cellular function by participating in the anabolism and catabolism of a variety of endogenous compounds, including steroids, bile salts, vitamins, and products of the arachidonic acid cascade, to name but a few.<sup>1</sup>

In terms of their xenobiotic function, the drug-metabolizing enzymes can create or unmask hydrophilic moieties in such xenobiotics in order to facilitate their renal clearance (e.g., cytochrome P450 (P450), flavin-containing monooxygenase (FMO), esterases, glucuronyltransferases, sulfotransferases), or they can detoxify electrophilic species that may be damaging to the cell (e.g., epoxide hydrolase, carbonyl reductases and glutathione (GSH) transferases). This enzymatic division is not a strict one, as certain oxidative P450 reactions and conjugation reactions, for example, can be viewed as bioactivation processes that convert a relatively benign compound into a more reactive species.<sup>2</sup> Regardless, these diverse proteins can be divided operationally into three main categories: (1) redox enzymes, that catalyze oxidation and reduction reactions; (2) hydrolases, that catalyze reaction of water with esters, amides, and epoxides; and (3) transferases, that conjugate xenobiotics with relatively small polar molecules.

With regard to the metabolism of therapeutic agents, a survey of the top 200 prescribed drugs from 2002 indicated that more than two-thirds were cleared by metabolic processes, and that of this number about 75% owed their clearance mainly to metabolism by redox enzymes (mostly P450s), up to 15% were cleared by transferases (mostly UDP-glucuronyltransferases (UGTs)), and some 10% were cleared by hydrolase enzymes (mostly esterases).<sup>3</sup> Essential characteristics of each of these important enzyme groups are discussed below that highlight their diversity, structure–function relationships, tissue localization, and development. For additional information, *see* 5.08 Mechanisms of Toxicification and Detoxification which Challenge Drug Candidates and Drugs; 5.10 In Vitro Studies of Drug Metabolism.

## 5.07.2 Oxidases and Reductases

### 5.07.2.1 Cytochromes P450

The cytochromes P450 (EC 1.14.14.1) are a superfamily of heme-containing monooxygenases that catalyze a myriad of oxidative metabolic reactions upon generation of the high-valent iron-oxo species formed during the enzyme's catalytic cycle. Key characteristics of the P450s are presented in [Table 1](#) and compared with the other drug-metabolizing enzymes under discussion.

P450s are represented in every living organism examined to date, and as of January 2005, over 4500 unique P450 sequences had been identified from animals, bacteria, fungi, and lower eukaryotes.<sup>134</sup> The plant kingdom is particularly rich in P450 genes where they can comprise up to 1% of the plant genome.<sup>4</sup> Mammalian species exhibit less diversity, with humans possessing 57 functional P450s which are grouped into 18 structurally related families, termed CYP1–5, CYP7–8, CYP11, CYP17, CYP19–21, CYP24, CYP26–27, CYP39, CYP46, and CYP51.<sup>5</sup> These enzyme families are primarily associated with the metabolism of drugs and other xenobiotics or endogenous compounds such as sterols, bile acids, vitamins, and fatty acids. Several members of the CYP1, CYP2, and CYP3 families, present at relatively high concentrations in the endoplasmic reticulum of liver cells, exhibit the broadest substrate selectivity and collectively represent the ‘drug-metabolizing’ P450s ([Table 2](#)). *See* 5.05 Principles of Drug Metabolism 1: Redox Reactions for further details on redox reactions in drug metabolism.

| 2D6 (0–15)                                   | Dextromethorphan         | Quinidine                                     |
| 2E1 (10–50)                                  | Chlorzoxazone            | Disulfiram (diethyldithiocarbamate)           |
| 3A4 (50–350)                                 | Midazolam                | Ketoconazole, troleandomycin                  |

Parentheses indicate typical hepatic microsomal concentration ranges.

#### 5.07.2.1.1 Nomenclature

The current nomenclature for the P450s is the product of numerous iterations over the past 20 years that currently provides a structured and uniform mechanism for identifying, classifying, and discussing P450 enzymes, regardless of

their source.<sup>6</sup> A recent update also makes recommendations for nomenclature of P450 allelic variants and pseudogenes.<sup>7</sup> Key aspects of P450 taxonomy are summarized below:

- When describing a P450 gene, *CYP1A2* for example, *CYP* is italicized and designates the gene as a segment coding for cytochrome **P450**. The first arabic numeral designates the P450 family. This is followed by a capital letter designating the subfamily, and another arabic numeral to distinguish members within a subfamily. By 2005, the enormous biodiversity of P450s required consumption of P450 family 'space' out to *CYP748*!
- When describing a P450 enzyme, italics are not used and either CYP or P450 can be used in front of the family designation; for example, P450 1A2 or CYP1A2.
- P450 isoforms are assigned to specific families on the basis of amino acid sequence identity. If a novel form of the enzyme was discovered and its amino acid sequence found to be less than 40% similar to any of the known families, it would constitute the first member of a new gene family.
- If two P450 sequences have more than 55% homology, they would be placed in the same subfamily.
- The 40% and 55% sequence homology cut-offs for family and subfamily membership are useful guidelines that have been widely applied to the taxonomy of other drug-metabolizing enzyme superfamilies (see below).
- When considering genetic variants of a P450 gene, an asterisk is placed after the arabic numeral for subfamily designation, and each allelic form is assigned an arabic number, e.g., *CYP2C9*\*2 represents the first allelic form of this gene discovered (relative to the reference sequence, which usually has the \*1 designation). Again, when referring to the gene, italics should be used. When referring to the protein encoded by an allelic form of the enzyme, it is recommended that a period replace the asterisk (e.g., CYP2C9.2). However, this has not been widely adopted and most investigators simply use the asterisk designation without italics to denote a polymorphic form of the protein (e.g., CYP2C9\*2).

#### 5.07.2.1.2 Multiplicity and ligand selectivity

Within the human CYP1–3 families, some 23 functional forms of P450 can be identified.<sup>5</sup> However, arguably only CYP1A2, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, and CYP3A5 are critical to drug metabolism, as these enzymes constitute the bulk of the hepatic P450 complement and are known to have wide substrate selectivities. Other extensively studied human P450s, such as CYP1A1 and CYP1B1, have predominantly an extrahepatic location and are not significantly involved in the metabolic clearance of drugs, although they may be important for localized bioactivation reactions that can lead to xenobiotic toxicity.<sup>8</sup> Some newer members of the human P450 family, identified through large-scale sequencing projects, e.g., CYP2S1, CYP2U1, and CYP2W1, have unknown functions and have been referred to as 'orphan' P450s.

Diagnostic substrates and inhibitors for the major hepatic forms of human P450 are listed in [Table 2](#). These ligands, together with commercially available recombinant forms of all the major human P450s, are invaluable tools for dissecting the participation of specific human microsomal P450 isoforms that contribute to a given metabolic pathway.<sup>9</sup> Because highly specific substrates and inhibitors can be identified for certain P450s, it could be expected that each isoform would possess a unique active site architecture complementary to key hydrophobic, electrostatic, and steric features of their preferred ligands. Recent crystallization of mammalian forms of P450 is beginning to shed light on these interactions.

#### 5.07.2.1.3 Structure

In general, P450s are 450–500-amino-acid (55–60 kDa) proteins with a completely conserved C-terminal cysteine residue that provides the thiolate coordinate bond to the iron atom which tethers the heme prosthetic group. Intracellularly, P450s reside in the soluble fraction of the cell (bacterial enzymes), the inner membrane of the mitochondrion (several steroid-metabolizing P450s), or the endoplasmic reticulum (drug-metabolizing P450s); targeting is dependent on the nature of the N-terminal leader sequence.<sup>10</sup> Drug-metabolizing P450s contain a hydrophobic string of 20–30 amino acids that is inserted into the endoplasmic reticulum and anchors the enzyme to the membrane, with the bulk of the protein oriented towards the cytosol in a monotopic fashion.

Until 2000, P450 tertiary structure information was limited to the soluble bacterial forms of the enzyme (e.g., CYP101/P450cam and CYP102/P450 BM3). The availability of the first mammalian P450s structure, an N-terminally truncated form of rabbit CYP2C5 also engineered internally to limit additional membrane or oligomer interactions, confirmed that the global features of this enzyme evident for the early bacterial structures were conserved, viz., a heart-shaped protein with an alpha-helix-rich C-terminus and a beta-sheet-rich N-terminus.<sup>11</sup> At the time of writing, crystal structures for human CYP2C9, CYP2C8, CYP3A4, and CYP2A6 have been solved.<sup>12–15</sup> Notably, the structure for

**Figure 1** Crystal structures of CYP3A4 and CYP2C9. (a) The overall structural fold of CYP3A4 and location of the heme prosthetic group (ball and stick). Secondary structure elements are represented as coils for helices and arrows for strands. (b) and (c) contrast the solvent accessible molecular surfaces of the active sites of CYP3A4 (green) and CYP2C9 (magenta). These structures highlight differences in volume and shape of P450 active sites. (Reproduced with permission from Williams, P. A.; Cosme, J.; Vinkovic, D. M.; Ward, A.; Angove, H. C.; Day, P. J.; Vonrhein, C.; Tickle, I. J.; Jhoti, H. *Science* **2004**, 305, 683–686. Copyright (2004) AAAS.)

CYP2C9 with the flurbiprofen bound shows an important salt bridge interaction between an active site Arg108 residue and the charged carboxylate of this nonsteroidal anti-inflammatory drug, which helps explain this isoform's relative selectivity for acidic substrates.<sup>16</sup> A comparison of the active site of CYP3A4 and CYP2C9 is depicted in **Figure 1**. In some cases, ligands have been crystallized within the P450 active site in multiple conformations, highlighting the plasticity of mammalian P450 active sites. This is in accord with the long-held observations of the broad substrate specificity of these enzymes.<sup>11</sup>

#### 5.07.2.1.4 Tissue distribution

Early studies on P450 enzymes focused on the liver as the main drug-detoxifying organ and the adrenal gland for the metabolism of endogenous substrates, but it was soon recognized that other organs, notably those that serve as portals of entry to the body, such as the respiratory and the gastrointestinal tracts, also express P450s and other biotransformation enzymes. Each organ or tissue has its own profile of P450 enzymes that will determine the sensitivity of that tissue to a xenobiotic. It should be noted that most extrahepatic P450 enzymes are also present in the liver, often at a higher concentration, but can be regulated differently in different tissues, leading to altered xenobiotic exposures. **Table 3** summarizes the tissue distribution of P450 enzymes that are commonly detected at either the mRNA (or, less commonly, the protein) level in various human organs.

Although P450 enzymes have been found in all tissues except skeletal muscles (**Table 3**) and red blood cells,<sup>17</sup> the liver and intestine are organs of special significance with regard to drug metabolism. The liver is an impressive drug-metabolizing organ containing an abundance of P450s, UGTs, sulfotransferases (SULTs), and other drug-metabolizing enzymes. With regard to first-pass metabolism, P450s represent the most important hepatic enzymes.

**Table 3** Tissue expression of cytochrome P450 enzymes involved in human drug metabolism

| <i>Tissue</i>   | <i>Cytochrome P450 expression</i>  |
|-----------------|--|
| Liver           | 1A1, 1A2, 2A6, 2A13, 2B6, 2C8, 2C9, 2C18, 2C19, 2D6, 2E1, 2J2, 2S1, 3A4, 3A5, 3A7 (fetal), 3A43, 4A11, 4F2, 4F11 |
| Small intestine | 1A1, 1B1, 2C8, 2C9, 2E1, 2J2, 3A4, 3A5, 4F12   |
| Kidney          | 1B1, 2C8, 2J2, 3A5, 3A7 (fetal), 3A43, 4A11, 4B1   |
| Heart           | 1B1, 2J2, 4F12   |
| Lung            | 1A1, 1B1, 2A6, 2A13, 2B6, 2C18, 2D6, 2E1, 2F1, 2S1, 3A4, 4B1   |
| Brain           | 2A13, 2B6, 2C8, 2D6, 2E1   |
| Skin            | 2C18   |
| Placenta        | 1A1  |
| Ovary           | 1B1, 2C8   |
| Prostate        | 1B1, 2A13  |
| Spleen          | 1B1  |
| Thymus          | 1B1  |
| Nasal mucosa    | 2A6, 2A13, 2E1   |

Table is not exhaustive and reflects only P450 enzymes commonly identified in these organs.

Drug-metabolizing P450s are concentrated in the endoplasmic reticulum of the liver, which represents approximately 5% of adult body weight ( $\sim 1500$  g) and contains  $\sim 25\,000$  nmol of total P450. Amongst the P450s, CYP3A4 is the most abundant liver isoform ( $\sim 200$  pmol mg $^{-1}$   $\sim 40\%$  of total hepatic P450), but CYP1A2, CYP2C9, CYP2C19, and CYP2D6 also contribute significantly to hepatic drug metabolism (**Table 3**). CYP3A5, which possesses 83% sequence homology to CYP3A4, is expressed at much lower levels than CYP3A4 in the liver, but is the main CYP3A isoform expressed in the kidney.<sup>18</sup>

The gastrointestinal tract is an absorptive organ involved in the uptake of orally administered drugs, and also an important site for biotransformation. The average total P450 content of human intestine, about 20 pmol mg $^{-1}$  microsomal protein, is substantially lower than liver,<sup>19</sup> but nonetheless the intestine contributes significantly to the first-pass effect for some orally administered drugs.<sup>20,21</sup> This reflects both the large surface area of the organ and the fact that CYP3A4 accounts for the majority of total microsomal P450 found in the mucosal epithelium.<sup>22</sup> Other P450 isozymes, including CYP2C9, CYP2J2, and CYP4F12, are also expressed in the small intestine, but at much lower levels than CYP3A4 (**Table 3**). In contrast to the liver, in which the distribution of P450 enzymes is relatively homogeneous, the distribution of P450 enzymes is not uniform along the length of the small intestine, or along the villi within a cross-section of mucosa. CYP3A4 expression decreases down the intestinal tract.<sup>23</sup> The localization and distribution of CYP3A4 along the villi in human small intestine are also variable, with the columnar absorptive epithelial cells of the villi exhibiting the strongest immunoreactivity, whereas no protein is detectable in the goblet cells or the epithelial cells in the crypts.<sup>22</sup> Examples of drugs that undergo significant biotransformation by the gut wall include cyclosporine, nifedipine, midazolam, saquinavir, and verapamil, all of which are CYP3A4 substrates. In the case of midazolam, first extraction by the gut wall seems to be comparable to hepatic extraction.

#### 5.07.2.1.5 Ontogenic development

Organ maturation during fetal life and adulthood has a profound effect on the ability of that tissue to metabolize drugs.<sup>24,25</sup> Maturation of drug-metabolizing enzymes is perhaps the major factor accounting for age-associated changes in the nonrenal clearance of drugs. Individual variability in drug metabolism during different stages of infancy, childhood, and adolescence can partially be explained by the gradual development of drug-metabolizing enzymes, and failure to recognize this effect can have important consequences in therapeutics. For example, lack of awareness of the ontogenic regulation of UGT activity led to the therapeutic disaster in pediatrics known as 'gray-baby' syndrome caused by administration of chloramphenicol, a UGT substrate, to neonates and young infants with an underdeveloped UGT system.<sup>26</sup> In these young subjects, chloramphenicol accumulated to toxic concentrations and precipitated

cardiovascular collapse. **Table 4** contains a list of important hepatic drug-metabolizing enzymes known to be subject to developmental regulation.

In general, P450 expression is low, but detectable, in the developing human fetal liver, increases after birth, and reaches adult levels during the first 10 years of life.<sup>27</sup> CYP1A2 is typical in this regard, with fetal hepatic expression of CYP1A2 protein or mRNA essentially absent in samples from individuals in early gestational stages,<sup>28,29</sup> but steadily increasing in infants to reach 50% of levels seen in adults at 1 year of age.<sup>30</sup> However, temporal expression patterns of individual human liver P450s can vary widely, often among closely related isoforms with the same subfamily. Here the CYP3A family in humans is instructive. Whereas CYP3A4 is the predominant liver isoform in adults, CYP3A7 is the major P450 detected in human embryonic, fetal, and newborn liver. CYP3A7 activity is abundant during embryonic and fetal life and rapidly decreases during the first week of life. In contrast, CYP3A4 levels are very low before birth, but increase steadily thereafter and reach 50% of adulthood levels by 12 months.<sup>31</sup> Conversely, CYP3A5 activity and expression levels exhibit large interindividual variability throughout all stages of development and display no obvious developmental pattern.

In humans, the CYP2 subfamily is the most diverse P450 gene family, with the CYP2C and CYP2D subfamilies contributing substantially to xenobiotic metabolism. However, only the ontogenic development of CYP2C9 and CYP2C19 has been investigated in detail.<sup>32</sup> CYP2C9 protein levels and catalytic activity in first-trimester human fetal liver reflected only 1–2% of adult values, but increased gradually in later fetal life to reach approximately 30% of adult values. In contrast, CYP2C19 development was much slower, implying that different developmental regulatory mechanisms exist for these two closely related P450 isozymes.

The developmental regulation of P450 enzymes associated with the metabolism of endogenous compounds as well as xenobiotic bioactivation is also of interest. CYP1A1 has been closely associated with the bioactivation of polycyclic aromatic hydrocarbons and other chemical carcinogens. CYP1A1 mRNA levels are detectable in fetal liver, adrenal, and lung, but not the kidney, between 6 and 12 weeks of gestation.<sup>33</sup> In all cases mRNA levels decreased with increasing fetal age and were barely detectable in the adult liver, indicating that suppression of CYP1A1 activity occurs some time in the prenatal period, either at birth or during early childhood development.<sup>34</sup> CYP2A enzymes have been associated with the metabolism and bioactivation of tobacco-related xenobiotics. None of the human CYP2A enzymes (CYP2A6, CYP2A13, or CYP2A7) were detected in human fetal liver,<sup>35</sup> but by 1 year of age, hepatic CYP2A6 concentration was 50% of adult expression levels. In the fetal nasal mucosa, CYP2A6 and CYP2A13, but not CYP2A7, were identified (1–5% of adult expression levels) in fetal tissue samples.<sup>36</sup> CYP2J2 has been associated with the epoxidation of endogenous arachidonic acid to biologically active eicosanoids and is abundantly expressed in the adult heart.<sup>37,38</sup> This P450 enzyme appears to have a distinctive developmental pattern because CYP2J2 protein levels in fetal liver and olfactory mucosa samples from fetal tissues were comparable to adult levels.<sup>36</sup> The impact of ontogeny on P450 enzymes should be taken into account when prescribing drugs, whose clearance highly depends on this pathway, to neonates.

### 5.07.2.2 Flavin-Containing Monooxygenases

Like P450s, flavin monooxygenases (FMO, EC 1.14.13.8) are NADPH-dependent enzymes that couple a two-electron reduction of oxygen to water with two-electron oxidation of its substrates. With FMO, this chemistry occurs at the noncovalently bound flavin center of the molecule. During catalysis, the FAD prosthetic group is activated to a C4a-hydroperoxo species that carries out oxidative reactions on nucleophilic centers. FMOs have a restricted portfolio of reactions that they can catalyze because the activated FAD is a weaker oxidant than the activated perferryl species of P450. Consequently, their role in oxidative drug metabolism is much less pronounced than that of the P450s. FMOs typically form mostly N-oxide and S-oxide metabolites<sup>39</sup> from xenobiotics and also serve an important physiological function in converting trimethylamine to trimethylamine N-oxide.<sup>40</sup>

#### 5.07.2.2.1 Multiplicity and ligand selectivity

Historically, the FMO enzyme system was first characterized with regard to its substrate specificity and catalytic mechanism using the enzyme isolated in the 1970s from hog liver by Ziegler and associates.<sup>41</sup> Molecular biology techniques have now revealed the existence of up to 13 *FMO* genes, only five of which are functional and expressed in all mammalian species examined to date.<sup>42</sup> Compared to the P450s, FMO taxonomy is greatly simplified by the absence of gene family expansion, so, for example, there is only a single FMO1, as no subfamilies have been identified.<sup>43</sup> The five active forms of the enzyme are termed FMO1–FMO5. These enzymes exhibit only 50–55% sequence homology, whereas species orthologs (i.e., rat FMO, human FMO1, dog FMO1, etc.) share 80–90% homology. Human FMO6 is inactive due to alternative splicing that results in a nonfunctional protein.<sup>44</sup> Although five functional mammalian forms of the enzyme are recognized, in practice only two – FMO3 (major) and FMO1 (minor) – appear to be relevant to human drug metabolism.

**Table 4** Ontogeny of major hepatic drug-metabolizing enzymes

| Enzyme                | Prenatal trimester |     |     | Neonate (<4 weeks) | <1 year | 1–10 years | Adult |
|-----------------------|--------------------|-----|-----|--------------------|---------|------------|-------|
|                       | 1                  | 2   | 3   |                    |         |            |       |

Adapted and modified from<sup>24,25</sup>.

<sup>a</sup>Fetal-specific enzymes.

<sup>b</sup>Adult-specific enzymes.

FMO1 possesses a very broad substrate specificity and can metabolize most soft nucleophiles it encounters, but its extrahepatic location (see below) minimizes its impact on drug clearance. FMO3 is the major form of the enzyme present in human liver. While it too has a wide substrate specificity in vitro, the enzyme participates significantly in the metabolic clearance of only a few drugs and xenobiotics, e.g., itopride, ranitidine, moclobemide, nicotine.<sup>40</sup> However, FMO3 plays a major role in the conversion of the dietary breakdown product, trimethylamine, to trimethylamine N-oxide, and genetic defects in *FMO3* are responsible for the rare metabolic disorder, trimethylaminuria.<sup>45</sup> Genetic polymorphisms also render FMO2 largely nonfunctional in most human ethnic groups. Very little is known about the substrate specificity of FMO4 and FMO5.

#### 5.07.2.2.2 Structure

Human FMOs are FAD-containing flavoproteins comprising 532–558 amino acids (i.e., 60–65 kDa proteins). Two glycine-rich motifs forming part of the Rossmann folds for NADPH and FAD binding are found in the N-terminal half of the enzyme. The C-terminal portion is pronouncedly hydrophobic and may represent a membrane anchor domain. However, deletion of this hydrophobic region has generally been accompanied by loss of enzyme activity and crystallization of the protein has yet to be accomplished. Homology models based on soluble GSH reductase and/or phenylacetone monooxygenase may hold promise in the interim for visualizing some aspects of FMO structure.<sup>39</sup>

#### 5.07.2.2.3 Tissue expression and ontogenic development

As with P450, FMO isoforms are ubiquitously distributed in the animal kingdom and in the body where the highest concentrations are generally found in the liver, although certain species have high enzyme concentrations in the lung (rabbit) and kidney (mouse). FMO1 is the major liver form in most experimental animals, but is not detectable in adult human liver, where FMO3 and FMO5 are the major isoforms.<sup>46</sup> FMO1 is relatively abundant in human kidney and present at much lower levels in the intestine and the brain.<sup>47</sup> FMO5 and FMO2 are the major isoforms expressed, at the mRNA level, in human small intestine and lung respectively,<sup>48</sup> although the functional significance of these two enzymes in these organs is unclear.

Hepatic FMO1 is restricted to the fetus, peaking in the early embryo, and decreasing steadily within 3 days postpartum (Table 4).<sup>49</sup> Conversely, hepatic FMO3 protein is not detectable in the fetal state, and its onset of expression after birth can be slow. As noted above, FMO3 is necessary for the conversion of trimethylamine to its nonodoriferous N-oxide metabolite, so delayed onset of expression of this enzyme may contribute to cases of transient childhood trimethylaminuria.<sup>50</sup> The temporal switch for these FMO isoforms contrasts with that observed for CYP3A7 and CYP3A4/5, in which the suppression of CYP3A7 expression is accompanied by a simultaneous increase in CYP3A4/5, and the net hepatic CYP3A content remains constant.<sup>51</sup> The relatively high expression levels of FMO1 during prenatal development and the embryonic periods, in particular, might argue for a role for FMO1 in the metabolism of endogenous substrates that are important for development, but this remains to be determined.

### 5.07.2.3 Monoamine Oxidases

Monoamine oxidases (MAO, EC 1.4.3.4) are FAD-containing flavoproteins, recognized primarily for their physiological role in metabolically regulating levels of neurotransmitters in the brain. Unlike FMO, the FAD group functions only as an electron acceptor ( $\text{FAD} \rightarrow \text{FADH}_2$ ) during oxidative deamination of these biogenic amines. In addition to its physiological role, MAO can participate in the metabolism of certain xenobiotics, especially drug molecules that are structurally related to the endogenous substrates.<sup>52</sup>

#### 5.07.2.3.1 Multiplicity and ligand specificity

Two forms of the enzyme exist, MAO-A and MAO-B, that are encoded by separate genes.<sup>53</sup> These enzymes are ~80% similar, and possess overlapping, albeit sometimes distinctive, substrate specificities. Serotonin, norepinephrine, and epinephrine are the major endogenous substrates for MAO-A. The indoleamine nucleus of serotonin appears in a few drug classes, notably the triptan class of antimigraine drugs. These drugs are metabolized by MAO-A via pathways that ultimately generate carboxylic acid metabolites.<sup>40</sup> The acetylenic compound, clorgyline, is a selective mechanism-based inhibitor of MAO-A, and reversible inhibitors of the enzyme are under development as antidepressant drugs. Amongst the neurotransmitters, dopamine is selectively metabolized by MAO-B. Another acetylenic compound, deprenyl, is a selective mechanism-based inhibitor of MAO-B and the levo enantiomer, selegiline, is marketed as Eldepryl and used as an adjunct to L-DOPA in Parkinsonism. The rationale here is to minimize metabolism of dopamine and reduce the dose of L-DOPA required therapeutically. MAO-B is also implicated in the bioactivation of the environmental neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).<sup>54</sup>

### 5.07.2.3.2 Structure

Human MAO-A and MAO-B are FAD-containing flavoproteins containing 527 and 520 amino acids (~63 kDa), respectively. Models for the membrane topography of MAO suggests that it is monotonically localized in, and anchored to, the mitochondrial membrane by a hydrophobic C-terminus. In contrast to the FMOs, MAOs have their prosthetic group linked covalently to a cysteine residue located in the C-terminal half of the protein. Both human forms of the enzyme have been crystallized, revealing differences in the volume of the active site activity, 550 and 700 Å<sup>3</sup>, for human MAO-A and MAO-B, respectively.<sup>55</sup> The ligand specificity of the two enzymes is controlled, in part, by a tyrosine (MAO-B) to isoleucine (MAO-A) change in the C-terminal half of the protein.<sup>56</sup>

### 5.07.2.3.3 Tissue distribution and ontogenic development

MAO is mainly located in the outer membrane of mitochondria of presynaptic nerve terminals, where oxidative deamination of norepinephrine, epinephrine, and serotonin by MAO inactivates these neurotransmitters and abrogates the neural stimulus. Both MAO-A and MAO-B are expressed in several human tissues, with the highest concentrations evident in liver, followed by myocardium, renal cortex, and intestine.<sup>57</sup> MAO-A is selectively expressed in the placenta while MAO-B is selectively expressed in blood platelets.<sup>58</sup> Intestinal MAO is implicated in the breakdown of dietary amines, notably the indirectly acting sympathomimetic tyramine, which is present in high concentrations in aged cheeses and red wine. Normally, tyramine is metabolized by intestinal MAO before it enters systemic circulation. When MAOIs, like isoniazid and tranlycypromine and foods high in tyramine are taken concurrently, large amounts of dietary tyramine can reach the systemic circulation and precipitate a hypertensive crisis.<sup>59</sup>

Limited studies on the ontogenic development of MAO have been performed and most available data deal with developmental aspects of MAO in the human brain.<sup>58</sup> In the fetal brain, lung, aorta, and digestive tract, MAO-A activity is detected earlier than MAO-B, and in the fetal brain the levels of MAO-A are significantly higher than MAO-B (Table 4). Interestingly, during aging, in which a general decrease in most enzymatic activity is observed, MAO-B content and activity appear to increase, due perhaps to astroglial proliferation and the associated increased need to metabolize the resulting biogenic amines.<sup>58</sup>

### 5.07.2.4 Aldehyde Oxidases and Xanthine Oxidases

Aldehyde oxidases (AOX, EC 1.2.3.1) and xanthine oxidases (XOR, EC 1.17.3.2) are molybdo-flavoproteins, with complex structural and mechanistic features.<sup>60</sup> The enzymes principally carry out oxidation reactions on nitrogen heterocycles, ultimately inserting one atom of oxygen from water without the need for an external source of reducing equivalents. In the main, AOX and XOR target sp<sup>2</sup>-hybridized carbon atoms rendered electron-deficient by a nitrogen atom to which they are linked by a double bond (CH=N), with the resulting formation of lactam metabolites.<sup>61</sup> Historically, the majority of studies with these proteins have been carried out with the rabbit liver form of AOX, and XOR isolated from cow milk, because these are rich and readily available sources of the two enzymes, and because of difficulties in expressing recombinant forms of these complex enzymes in high yield.<sup>62</sup>

#### 5.07.2.4.1 Multiplicity and ligand specificity

Enzymes utilizing a molybdenum cofactor are known throughout evolution. In mammals, five distinct molybdo-flavoenzymes have been identified: XOR; AOX; and aldehyde oxidase homologs 1–3 (AOH1, AOH2, and AOH3). XOR and AOX have been characterized in a variety of species, including humans, whereas AOH1, AOH2, and AOH3 appear to be important only in rodent and bird species. These five enzymes are the products of distinct genes.<sup>63</sup> The substrate specificities of only AOX and XOR have been studied in detail and much less is known about the catalytic functions of AOH1–3. AOX and XOR exhibit ~50% amino acid homology and overlapping substrate specificities.

XOR catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid and represents a key enzyme in the metabolism of purines. In most tissues, XOR exists in its dehydrogenase form, where the physiological electron acceptor is NAD<sup>+</sup>. A number of factors, including ischemia and the purification process itself, promote facile conversion to the oxidase form where the electron acceptor is oxygen. Consequently, this enzyme is associated strongly with the production of reactive oxygen species (ROS), such as hydroxyl radical and superoxide. The enzyme can also produce nitric oxide by reduction of nitrites, which has further stimulated interest in the enzyme from a toxicological viewpoint.<sup>64</sup> Allopurinol is a diagnostic inhibitor of the enzyme. This drug is used clinically to treat hyperuricemia, following its metabolic conversion to oxypurinol, a tight binding inhibitor of XOR.<sup>61</sup>

Abundant levels of AOX are present in the liver where it metabolizes numerous drugs, including zaleplon and 6-mercaptopurine. Guanine derivatives based on aciclovir are useful antiviral agents, but are poorly absorbed after oral administration. Attempts to improve bioavailability have centered around 6-deoxy prodrugs, e.g., 6-deoxy penciclovir,

which are bioactivated by AOX (or XOR). AOX also plays an important role in the detoxification of potentially reactive iminium ions that can be generated by P450 or MAO, often from cyclic tertiary amines, e.g., nicotine.<sup>40</sup> Menadione, isovanillin, and raloxifene are useful diagnostic inhibitors of AOX.<sup>65</sup>

#### 5.07.2.4.2 Structure

AOR and XOR are large (~300 kDa) multimeric enzymes composed of two subunits. Each subunit contains one atom of molybdenum (Mo) in a pyranopterin complex, one FAD, and two Fe-S centers. All four centers can function as redox groups in the intramolecular transfer of electrons from a reducing substrate (electron donor) to an oxidizing substrate (electron acceptor). Several bacterial members of this enzyme family have been crystallized, indirectly lending insight into the structure and function of XOR and AOR.<sup>60</sup>

#### 5.07.2.4.3 Tissue distribution and ontogenic development

Limited information is available on the ontogenic development of XOR and AOX, except that both enzymes are expressed in fetal tissues at levels similar to those found in adults. Regarding tissue distribution, most studies on XOR have been conducted in experimental animals rather than humans. In rodents the highest expression levels of mRNA and protein of XOR are observed in the liver, lung, kidney, and in the epithelial lining of the duodenum on the proximal side of the small intestine, decreasing steadily towards the distal portion of the small intestine. Similar expression patterns in the intestine have also been reported in humans. The mouse lung also expresses XOR, in contrast to human lung, where the enzyme is barely detectable. Other studies have also reported expression of XOR in the human brain and heart. Intracellularly, XOR is almost always localized exclusively to the cytoplasm. Interestingly, intact XOR is found in milk and other body fluids, including blood.

Tissue expression of AOX is highly variable across species, with high hepatic concentrations present in rabbit and baboon, and low concentrations found in rat and dog liver. In humans, high concentrations are found in the liver and the enzyme has also been detected immunohistochemically in respiratory, urogenital, endocrine, and digestive tissues.<sup>66</sup> In these latter studies AOX was most abundant in the epithelial cells of the trachea and bronchium in addition to the alveolar cells of the respiratory system. In the digestive system, AOX is found in the surface epithelia of the small and large intestines. In the kidney, the proximal, distal, and collecting tubes but not the glomerulus expressed AOR. In mice, AOR exhibits gender differences where it is expressed at higher levels in males.<sup>60</sup> It has been proposed that AOX is induced by high levels of testosterone but this induction is tissue-specific as no gender differences in the levels of XOR were observed in mice lung. No gender differences in expression have been demonstrated in humans.<sup>60</sup>

### 5.07.2.5 Miscellaneous Dehydrogenases

#### 5.07.2.5.1 Aldehyde dehydrogenases

Aldehyde dehydrogenase (ALDH, EC 1.2.1.3) enzymes catalyze the NAD(P)<sup>+</sup>-dependent oxidation of aldehydes to carboxylic acids. Nineteen ALDH genes coding for enzymes with broad substrate specificities have been identified in the human genome. These enzymes cluster into nine families, ALDH1–9, with members of the ALDH1 and ALDH3 families most strongly associated with xenobiotic metabolism.<sup>67</sup> The nomenclature for this enzyme system follows closely that used for the P450s. ALDH1A1, 1A2, and 1A3 are cytosolic and mitochondrial enzymes that are involved in the biosynthesis of retinoic acid from retinal in humans. Retinoic acid is important for modulating cell differentiation, particularly during embryogenesis. ALDH1 forms are also implicated in the metabolic pathway leading to inactivation of antineoplastic agent, cyclophosphamide. ALDH2 is a mitochondrial enzyme that is mainly responsible for the metabolism of ethanol-derived acetaldehyde. An E487 K mutation (*ALDH2\*2*) results in a large increase in the  $K_m$  for NAD<sup>+</sup>, which almost inactivates the enzyme.<sup>68</sup> This polymorphism is responsible for alcohol flushing in up to 40% of Asians. Members of the ALDH3A subfamily are dioxin-inducible and are overexpressed in some tumors. These enzymes are involved in the metabolism of medium- to long-chain aliphatic and aromatic aldehydes. Individual members of gene families *ALDH4–9* metabolize a variety of usually endogenous aldehydes, although some may also have activity towards some xenobiotic substrates. Structurally, these enzymes are homotetramers, with subunit molecular weights of ~55 kDa.<sup>69</sup>

#### 5.07.2.5.2 Alcohol dehydrogenases

Alcohol dehydrogenase (ADH, EC 1.1.1.1) enzymes are zinc-containing dimeric enzymes, found in the cytosolic fraction of the cell, that catalyze the NAD(H)-dependent 'reversible' oxidation of low-molecular-weight alcohols to aldehydes. ADH enzymes perform numerous important metabolic functions, especially with endogenous substrates,

but the prototypic reaction is the oxidation of ethanol to acetaldehyde, during which they transfer the pro-R hydrogen from NADH to substrate. Globally, these enzymes constitute part of the medium-chain dehydrogenase/reductase superfamily.<sup>70</sup> In humans, five classes (classes I–V) of ADHs are known: members of different classes share less than 70% amino-acid sequence identity within a species.<sup>71</sup> Three genes found within the human class 1 enzymes – *ADH1*, *ADH2*, and *ADH3* are expressed in most adult tissue, with the exception of brain, kidney, and placenta. The absence of ADH1 enzymes, the most efficient ethanol-metabolizing enzymes among the ADH family, in the placenta and brain argues against a substantial contribution of this enzyme in local ethanol developmental central nervous system toxicity. On the other hand, polymorphisms in the human *ADH2* gene have been associated with alcoholism.<sup>72</sup>

### 5.07.2.6 Reductases

The reductive enzymology of drug metabolism is the most poorly characterized, but perhaps most complex, of the common drug metabolism processes. This is due, in part, to the host of enzyme systems that can catalyze this reaction, including, but not limited to, ADH, aldo-keto reductases (AKR), carbonyl reductases, quinone reductases, P450 reductase, and even P450 itself where conditions of low oxygen tension prevail. Moreover, reductase enzyme activity can be found throughout nature and in a variety of subcellular fractions, although NADPH-dependent cytosolic enzymes generally predominate. Another facet of the complexity of reductase enzymology is the reversible nature of many of the reactions, made possible by the redox behavior of the common nicotinamide cofactors, NADH and NADPH. For example, although ADHs can catalyze the (reductive) bioactivation of chloral hydrate to trichloroethanol by transferring a hydride from NADH to the substrate, the enzyme is more commonly associated with its important dehydrogenase (oxidative) function in the NAD<sup>+</sup>-dependent metabolism of ethanol to acetaldehyde. A common feature of carbonyl (and quinone) reductases is their two-electron reduction mechanism. In contrast, P450 and P450 reductase catalyze one electron reduction processes often associated with xenobiotic toxicity, but also productively in the bioactivation of some anticancer drugs.

#### 5.07.2.6.1 Carbonyl (and quinone) reductases

The carbonyl moiety of aldehydes, ketones, and quinones, often encountered in xenobiotic molecules, is the most common target of reductase enzymes, resulting in the formation of hydrophilic alcohols and hydroquinones that can readily undergo conjugation prior to excretion. This is an important biological function in that it provides a protective mechanism against a host of potentially reactive compounds that are formed intracellularly. Carbonyl-reducing enzymes belong to four main categories: (1) the short-chain dehydrogenase/reductase (SDR, EC 1.1.1) superfamily; (2) the AKR (EC 1.1.1.184) superfamily; (3) the ADH (EC 1.1.1.1) family; or (4) the nicotinamide quinone oxidoreductases (NQO1 and NQO2, EC 1.6.5.2).<sup>73</sup> These enzymes are all principally cytosolic and NADPH-dependent. Few recombinant forms of these enzymes are widely available, greatly complicating efforts to distinguish between the host of carbonyl-reducing enzymes in the cell for metabolism of a given xenobiotic. However, consideration of enzyme localization, cofactor preference, optimal reaction pH, and chemical inhibitor sensitivity, as outlined in a recent review,<sup>73</sup> provide a basis for distinguishing between the major enzyme classes that contribute to carbonyl reduction of xenobiotics.

##### 5.07.2.6.1.1 Short-chain dehydrogenase/reductase superfamily

SDRs are enzymes of great functional diversity found throughout nature. In humans, cytosolic carbonyl reductase (CBR1) is a major member of the SDR superfamily that metabolizes a wide variety of xenobiotics, including the anticoagulant warfarin, anthracycline derivatives like daunorubicin, and aldehyde and ketone products of lipid peroxidation.<sup>74</sup> A recent mouse knockout study demonstrated a critical role for CBR1 in the doxorubicin cardiotoxicity that is attributed to the reduced metabolite, doxorubicinol.<sup>75</sup> CBR3 is a second member of the cytosolic human carbonyl reductases, but its substrate specificity is not well documented. The major human microsomal carbonyl reductase, 11 $\beta$ -hydroxysteroid dehydrogenase, also belongs to the SDR family. Each enzyme demonstrates a cofactor preference for NADPH, transferring the *pro*-S hydrogen to the substrate, i.e., the opposite of ADH.

##### 5.07.2.6.1.2 Aldo-keto reductase superfamily

The AKRs perform oxidoreduction on a wide variety of natural and foreign substrates. A systematic nomenclature for the AKR superfamily similar to the P450 nomenclature has been adopted.<sup>76,135</sup> The superfamily contains several hundred proteins expressed in prokaryotes and eukaryotes that are distributed over 14 families (AKR1–AKR14). The AKR1 family contains aldehyde reductases (AKR1A), aldose reductases (AKR1B), dihydrodiol dehydrogenases, and 3 $\alpha$ , 17 $\beta$  and 20 $\alpha$  hydroxysteroid dehydrogenases (AKR1C) and keto steroid 5 $\beta$ -reductases (AKR1D). Another

family of drug metabolism interest is AKR7, the aflatoxin aldehyde reductases.<sup>77</sup> Crystal structures of many AKRs and their complexes with ligands are available.<sup>78</sup> Each structure has the characteristic ( $\alpha/\beta$ ) 8-barrel motif of the superfamily, a conserved cofactor binding site, and a catalytic tetrad comprised of conserved Tyr, Asp, His, and Lys residues.

#### 5.07.2.6.1.3 Quinone oxidoreductases

Two forms of cytosolic quinone oxidoreductase have been described. NQO1 (also known as DT-diaphorase) and NQO2 are FAD-containing enzymes that utilize NAD(P)H and dihydronicotinamide riboside, respectively, as electron donors.<sup>79</sup> From a functional standpoint, NQO1 has been more extensively studied, and is known to act as a chemoprotective enzyme cellular defenses against the electrophilic and oxidizing metabolites of a wide variety of xenobiotic quinones.<sup>80</sup> Obligatory two-electron reduction by the enzyme bypasses the formation of semiquinone radicals, which is important because the semiquinone radical can be reoxidized by molecular oxygen 'futile cycling' with concomitant production of ROS that can lead to cellular damage. NQO1 also participates in reduction of endogenous quinones, such as vitamin E quinone and ubiquinone, generating antioxidant forms of these molecules. Because NQO1 is overexpressed in some tumour types, its enzyme activity has been exploited in the design of anticancer drugs that require reductive bioactivation.<sup>81</sup>

#### 5.07.2.6.1.4 Miscellaneous reductases

Intestinal microflora present in the largely anaerobic environment of the lower gastrointestinal tract are well known to exhibit nitroreductase and azoreductase activities. In terms of specific reductase enzymes, P450 reductase (CPR, EC 1.6.2.4) is a 76 kDa membrane-bound flavoprotein, best recognized in the drug metabolism arena for its role as a coenzyme in P450-dependent oxidative reactions. There the enzyme's role is to transfer electrons, one at a time via its FAD and flavin mononucleotide (FMN) cofactors, from NADPH to P450. However, CPR can also directly reduce a variety of xenobiotics, notably quinones, by one-electron reduction. Under conditions of low oxygen tension, and depending on the redox potential of the ligands, substrates other than molecular oxygen can compete for ferrous cytochrome P450. Notable substrates for the reductive activity of P450 are halogenated hydrocarbons which can undergo reductive dehalogenation. P450-dependent reductive dehalogenation of carbon tetrachloride yielding a trichloroacyl radical that can react with molecular oxygen and initiate lipid peroxidation may be involved in the hepatotoxicity of this solvent.

#### 5.07.2.6.2 Tissue distribution and ontogenic development

As described above, reductase activity is distributed amongst a host of different enzymes, and systematic studies on many aspects of this diverse enzymology, including tissue distribution and developmental studies of the human enzymes, are lacking. However, carbonyl-reducing enzyme activity is generally present in most human tissues, including the liver, lung, brain, heart, kidney, spleen, testis, and blood, and intracellularly, with a few exceptions, most of these enzymes are cytosolic in origin.<sup>73</sup> Interestingly, NQO1, which has been associated with protection against carcinogenesis and mutagenesis, is expressed in many tissues, including epithelium of the thyroid, breast, colon, and eye, but is expressed at very low levels in the human liver. This contrasts with rat liver, which contains high levels of NQO1 and has been the enzyme's major source for purification.<sup>82</sup>

### 5.07.3 Hydrolases

Hydrolytic reactions in drug metabolism are commonly catalyzed by esterases, amidases, phosphatases, and epoxide hydrolases. While these reactions appear initially quite diverse, in fact each of these enzymes is linked structurally, by membership in the  $\alpha/\beta$  hydrolase-fold family of proteins, and mechanistically, by their reliance on a 'catalytic triad' of acidic and basic residues to effect hydrolysis.<sup>83</sup> Peptidases are not addressed in this chapter but are discussed in depth in 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions and a recent book.<sup>84</sup>

#### 5.07.3.1 Epoxide Hydrolases

Epoxide-containing compounds are cyclic ethers that can constitute a toxic hazard to the cell due to the reactivity of the strained three-membered ring. For example, some reactive polycyclic aromatic hydrocarbon epoxides bind to DNA, leading to mutagenic and carcinogenic effects.<sup>85</sup> In most cases, however, epoxides are of lower reactivity and often constitute intermediates in biological pathways, notably those involving arachidonic acid epoxides.<sup>86</sup> Regardless of the pathway involved, epoxide hydrolases (EC 3.3.2.3) catalyze the nucleophilic addition of water to the substrate.<sup>87</sup>

In most cases, reaction is initiated by attack of an enzyme nucleophile (usually Asp) on the epoxide to generate an acyl intermediate that is subsequently hydrolyzed by a water molecule that has been activated by the other members of the catalytic triad. This results in the formation of vicinal diols, except in the case of leukotriene A4 hydrolases, which catalyze formation of a 5,12-diol product due to the conjugated nature of the substrate.

#### 5.07.3.1.1 Multiplicity and ligand selectivity

Five types of mammalian epoxide hydrolase have been described: (1) microsomal epoxide hydrolase; (2) soluble epoxide hydrolase; (3) cholesterol epoxide hydrolase; (4) leukotriene A4 hydrolase; and (5) hepoxilin A3 hydrolase. The latter three enzymes have tight substrate specificities and do not appear to function in the metabolism of drugs and xenobiotics. The discussion below is, therefore, limited to microsomal epoxide hydrolase, also termed EPHX1, and soluble epoxide hydrolase, or EPHX2.

EPHX1 is a microsomal enzyme that exhibits about 90% sequence homology across species. This enzyme hydrates a variety of alkene and arene oxides, in most cases acting as a detoxifying enzyme by converting electrophilic epoxides to vicinal *trans*-dihydrodiol metabolites which are much less reactive.<sup>88</sup> The enzyme exhibits a broad substrate specificity with a preference for hydrophobic epoxides without extensive substitution. Styrene oxide and benzo(*a*)pyrene 4,5-oxide are common substrate probes for the *in vitro* determination of EPHX1 activity. Drug substrates are uncommon, but include carbamazepine 10,11-epoxide, an active metabolite of the anticonvulsant drug, carbamazepine, that is inactivated by microsomal epoxide hydrolase. Trichloropropene oxide and cyclohexene oxide are often used as diagnostic inhibitors of the enzyme, exhibiting  $IC_{50}$ s around 10  $\mu$ M. Valproic acid and valpromide are inhibitors of human EPHX1 at therapeutically relevant concentrations.

EPHX2 is found in high levels in the mouse cytosol, from which the enzyme was originally purified. The enzyme contains an imperfect peroxisome-targeting sequence at the C-terminus and so activity has also been detected in peroxisomes. Like EPHX1, EPHX2 is encoded by a single gene, but there is very little sequence similarity between the two enzymes. EPHX2 is a known hydrate range of aliphatic and extensively substituted, hindered arene oxides. However, current focus is on its physiological role, especially the metabolism of arachidonic, linoleic, and other fatty acid epoxides. These endogenous chemical mediators play an important role in blood pressure regulation and inflammation. It has been proposed that inhibitors of EPHX2 might be useful in the treatment of hypertension or as antiinflammatory agents and several potent and selective amide, carbamate, and urea-based inhibitors of EPHX2 have been developed.<sup>87</sup>

#### 5.07.3.1.2 Structure

Human EPHX1 and EPHX2 contain 455 (55 kDa) and 554 amino acids (65 kDa), respectively. Murine and human EPHX2 have been crystallized as a dimer, both with and without ligands bound.<sup>89</sup> The catalytic domain is located in the C-terminal region of the enzyme. The catalytic triad in EPHX2 is represented by Asp333, His523, and Asp495. In addition, from mutagenesis studies, Tyr381 and Tyr465 in the active site have been identified as essential and have been assigned as general acid catalysts that donate a hydrogen bond to the oxygen.

#### 5.07.3.1.3 Tissue distribution and ontogenic development

EPHX1 protein levels have been detected in a wide variety of tissues, including the liver, small intestine, kidney, lung, and urinary bladder. However, significant catalytic activities for styrene oxide hydrolysis were only demonstrated in the liver, lungs, kidneys, and gut.<sup>90</sup> EPHX2 has been detected in all tissues studied except the bile ducts, glomeruli, and the thyroid, and appears to be most abundantly expressed in the hepatocytes, endocrine, proximal tubules in the kidney, and the lymph nodes.<sup>37</sup> Expression of EPHX2 in the pituitary gland could be significant for drug metabolism because the pituitary lacks a blood-brain barrier but contains a high concentration of drug-metabolizing enzymes compared to other regions of the brain.

In the liver and adrenal gland, the activity of EPHX1 was three times higher than that observed in the kidney and lung and could be observed as early as 8 weeks' gestation (Table 4). At 22 weeks, EPHX1 activity had increased to about half that observed in adult liver.<sup>25</sup> EPHX2 is also expressed in the fetus, although fewer ontogenic studies have focused on this isoform. EPHX2 activity was demonstrated as early as 14 weeks in fetal liver with no change in activity occurring with time.<sup>25</sup> Adult hepatic activity of EPHX2 was fivefold higher than that observed in the fetus. However, additional studies are needed to examine the change in activity between 30 weeks' gestation and 30 years of age. EPHX2 is also observed in extrahepatic fetal tissue, including the kidney, adrenal glands, intestine, and lungs, but developmental expression in these tissues was less evident.<sup>90</sup>

### 5.07.3.2 Esterases

These proteins constitute a large and diverse group of enzymes that can hydrolyze peptides, amides, and halides, in addition to carboxylesters (EC 3.1.1), thioesters (EC 3.1.2), and phosphate esters (EC 3.1.3). Carboxylesterases (CESs) are important from a clinical viewpoint because ester derivatives of therapeutic agents are widely used as prodrugs to improve solubility, taste, absorption, bioavailability, and stability and to prolong duration of action.<sup>91</sup> The physiological function of the CESs is obscure, although recent work has shown that they may play a role in cholesterol and fatty acid homeostasis and affect the trafficking of other endoplasmic reticulum proteins such as C-reactive protein.<sup>92</sup> Certain esterases are also of toxicological interest, especially those involved in the metabolism of neurotoxic organophosphates (OPs).<sup>93</sup>

#### 5.07.3.2.1 Nomenclature

The broad early division into A and B esterase classes, proposed by Aldrich in 1953, occurred as a consequence of their differential interaction with OPs such as the insecticide, paraoxon. Whereas A-esterases hydrolyze (inactivate) OP substrates, OPs are mechanism-based inhibitors of B-esterases.<sup>94</sup> OP compounds are widely used as pesticides (mostly insecticides) and a few are nerve gases. The pesticides are usually applied as the relatively nontoxic sulfur derivatives which are bioactivated by microsomal monooxygenases to the oxon forms which are then substrates for the A-esterases. Nerve gases cause neurotoxicity by inhibiting acetylcholinesterase (a B-type esterase). Paraoxonase is an A-type serum esterase. The hydrolysis of neurotoxic OPs is a beneficial, fortuitous activity of serum paraoxonase. The greater toxicity of OP compounds towards birds compared to mammals is due to the absence of serum paraoxonase activity in avian species. B-esterases include the CES which catalyze the hydrolysis of drugs and many other xenobiotics,<sup>92</sup> and which are the focus of the sections below.

#### 5.07.3.2.2 Multiplicity and ligand selectivity

CESs are largely microsomal in origin, with molecular weights of 55–60 kDa. At least four families (CES1–CES4, EC 3.1.1.1) exist, based on sequence similarity, and in humans, the liver (CES1A1, hCE1) and intestinal forms (CES2, hCE2) appear to play the most important roles in detoxication/bioactivation of xenobiotics.<sup>95</sup> hCE1 metabolizes heroin and cocaine and is relatively selective for several of the angiotensin-converting enzyme inhibitors, such as delapril and imidapril, whereas hCE2 is more selective for irinotecan and oxybutynin. Therefore, hCE1 often appears to be associated with the removal of small (methyl, ethyl) groups, whereas hCE2 seems to prefer larger moieties, although this is far from a strict rule.<sup>92</sup>

Some broad-spectrum esterase inhibitors have been in use for many years. Liver and intestinal microsomal esterases can be inhibited by compounds such as bis-nitrophenyl phosphate (BNPP), which phosphorylates an active-site serine residue in the B-esterases. A-esterases can be inhibited by *p*-chloromercurobenzoate. More recently, aromatic diones, such as benzil, have been identified as general inhibitors of the CESs, and a series of benzene sulfonamides have been described that act as selective potent inhibitors of hCE2.<sup>96</sup>

#### 5.07.3.2.3 Structure

Microsomal CESs are typically about 60 kDa in size and glycosylated, with the carbohydrate modification seemingly necessary for activity. The crystal structure of hCE1 in complex with various ligands has been solved, revealing the serine hydrolase fold common to the esterase family (see [Figure 2](#) for an example). The enzyme exhibits a large, hydrophobic active site cavity some 15 Å deep, suitable for the binding of a wide variety of substrate molecules, as has been observed experimentally.<sup>97</sup>

#### 5.07.3.2.4 Tissue distribution and ontogenic expression

CES expression is low in the plasma, in contrast to the highly abundant cholinesterase, but high in liver, intestine, and kidney. The cellular localization of CES is predominantly microsomal, although lower levels have been reported in mitochondria, lysosomes, and cytosol (possibly artifactual). Few studies have been performed as yet on the ontogenic regulation of the individual CES isoforms.

### 5.07.4 Transferases

#### 5.07.4.1 UDP-Glucuronyltransferases

The UDP-Glucuronyltransferases (UGT, EC 2.4.1.17) superfamily is comprised of the *UGT1*, *UGT2*, *UGT3*, and *UGT8* gene families which code for enzymes that attach glycosyl groups to lipophilic substrates.<sup>136</sup> Xenobiotic glucuronidation

**Figure 2** Structural features of human CES 1. The enzyme exists in a trimer-hexamer equilibrium, and each protein monomer contains three ligand-binding sites. The active site (red) incorporates the catalytic triad of the enzyme and facilitates the docking of structurally distinct substrates; in some cases, substrates dock in more than one orientation simultaneously, as illustrated for the heroin analog naloxone (green and gold). The Z-site (blue) is a surface ligand-binding groove that might be allosteric and controls the trimer-hexamer equilibrium of the enzyme. It is relatively nonspecific, and is shown here with the anticancer drug tamoxifen (yellow) bound. The side-door site (magenta) is a secondary pore to the active site that could facilitate the release of product (as indicated here for a fatty acid (cyan)) or the entrance of substrate. (Reproduced from Redinbo, M.; Potter, P. *Drug Disc. Today* **2004**, 10, 313–325, copyright (2004), with permission from Elsevier.<sup>132</sup>)

is catalyzed by glucuronyltransferase enzymes that specifically utilize the cofactor UDPGA).<sup>98</sup> UGTs are ~60 kDa, microsomal (and nuclear) enzymes which, in contrast to the P450s, are localized to the luminal side of the endoplasmic reticulum. In addition to drugs and xenobiotics, there also many 'endogenous' glucuronide acceptors, e.g., bile acids and steroids. Regardless, a common endpoint is enhanced polarity of the original aglycone and facilitated renal excretion. In some cases, glucuronide conjugates may themselves be pharmacologically active. For example, morphine forms both 3-OH and 6-OH glucuronides, with the latter exhibiting more activity than parent drug, at least with some classes of opiate receptors. In addition, acyl glucuronides can have intrinsic chemical reactivity and have been associated with immune toxicities that can occur with some nonsteroidal antiinflammatory drugs.<sup>99</sup>

#### 5.07.4.1.1 Nomenclature

Human UGTs are composed of two gene families, *UGT1* and *UGT2*, and three subfamilies that are designated *UGT1A*, *UGT2A*, and *UGT2B*. Within each family, individual enzymes, e.g., *UGT2A1*, *UGT2B4*, share at least 45% sequence homology and subfamily members, e.g., *UGT1A1* and *UGT1A3*, share at least 60% homology. The human *UGT1* gene locus is located on the long arm of chromosome 2, and the *UGT2* genes are found on the long arm of chromosome 4. *UGT2* enzymes are each conventionally encoded by separate genes, but, unusually, *UGT1* enzymes share a common mRNA transcript that is differentially spliced. Consequently, all *UGT1A* isoforms share four common C-terminal exons and are distinguished by a variable exon 1 sequence. *UGT2* enzymes also share more sequence homology in their

C-termini, and so substrate selectivity is believed to reside largely in the hypervariable N-terminal regions of UGT enzymes.<sup>98</sup> The nomenclature for individual UGT isoforms follows the system established for the P450s, i.e., UGT1A1, UGT2B7, etc.

#### 5.07.4.1.2 Multiplicity and ligand selectivity

At present, 17 functional human UGTs have been identified: UGT1A1, 1A3, 1A4, 1A5, 1A6, 1A7, 1A8, 1A9, 1A10, 2A1, 2B4, 2B7, 2B8, 2B10, 2B11, 2B15, and 2B17. Numerous heterologous expression systems have been developed, and membrane preparations containing most of the recombinant human isoforms are commercially available.<sup>100</sup> Our knowledge of their substrate specificity comes largely from in vitro studies with the recombinant proteins, but also in some cases from clinical and pharmacogenetic studies performed in vivo.<sup>99</sup>

UGT1A1 is probably the most widely studied isoform because it is the most abundant UGT in liver, and it has long been recognized to be the primary enzyme responsible for the glucuronidation of bilirubin. A common genetic polymorphism in the promoter region of the gene (*UGT1A1*\*28) underlies the relatively benign hyperbilirubinemia or Gilbert's disease, whereas rare polymorphisms in the coding region of the *UGT1A* gene lead to the much more serious Crigler-Najjar syndromes.<sup>101</sup> In addition to bilirubin, an important substrate for UGT1A1 is SN-38, the active metabolite of the anticancer drug irinotecan. Accumulation of SN-38, prominent in carriers of *UGT1A1*\*28, causes dose-limiting toxicity. Human UGT1A4 and UGT2B7 have also attracted considerable attention because of their roles in amine glucuronidation and opiate metabolism, respectively. UGT1A4 is of particular interest because many drugs contain imidazoles and tetrazoles, and because aryl amine glucuronidation may be a modulating factor in colon and bladder cancer.<sup>102</sup>

Selective inhibitors of several human UGT isoforms are known, but these are generally low-potency compounds that are also used as selective substrates for the enzyme. Examples include bilirubin for UGT1A1, propofol for UGT1A9, and 3'-azido-3'-deoxythymidine for UGT2B7.<sup>103</sup>

#### 5.07.4.1.3 Structure

No crystal or solution structures have yet been solved for the UGTs. Evidence does exist that the recombinant proteins can be *N*-glycosylated and phosphorylated<sup>104</sup> but the relevance of these posttranslational modifications to enzyme function is not well understood. The UDPGA cofactor likely binds mainly to the conserved C-terminus of the protein, whereas binding determinants for the aglycone probably reside in the more variable N-terminus. An important step in the catalytic mechanism is activation of the xenobiotic substrate to an optimized nucleophile prior to displacement of glucuronic acid from UDPGA. Site-directed mutagenesis experiments implicate histidine residues in enzyme function,<sup>105</sup> but whether such basic residues are specifically involved in this substrate activation step remains to be determined.

#### 5.07.4.1.4 Tissue distribution

Most of the drug-conjugating UGT isoforms are expressed in the liver, but are also present at variable levels in extrahepatic tissues, particularly tissues that are responsible for the absorption or excretion of drugs, such as intestine, lung, and kidney. Human hepatic UGT enzymes include UGT1A1, UGT1A3, UGT1A4, UGT1A6, UGT1A9, UGT2B4, UGT2B7, UGT2B11, and UGT2B17.<sup>102</sup> The gastrointestinal tract contains UGT1A1, UGT1A8 (restricted to the colon) and UGT1A10, whereas UGT1A7 seems to be localized to in the esophagus, stomach, and lung. Human kidney UGT enzymes include UGT1A8, UGT1A9, UGT1A10, and UGT2B7. In fact, UGT2B7 levels in the kidney are similar to those found in the liver.<sup>106</sup> UGT2B transcripts are found in steroid-sensitive tissues, including the prostate (UGT2B17) and mammary tissues (UGT2B11 and UGT2B28).<sup>99</sup> Glucuronidation reactions are also readily detectable in the brain and placenta.<sup>102</sup>

Intracellularly, UGT enzymes are embedded in the internal membrane and face the luminal side of the endoplasmic reticulum which provides these enzymes ready access to the metabolic products of drug oxidation. However, this subcellular localization limits the access of substrates, cofactors, and glucuronidated products to and from the active sites of UGT enzymes. It is also responsible for the phenomenon known as 'latency' and contributes to difficulties in extrapolating in vivo effects of UGT enzymes from in vitro experiments using isolated tissue microsomes. To facilitate substrate access for in vitro studies of UGT activity, microsomes are often treated with low concentrations of detergent or a pore-former like allomethicin.

#### 5.07.4.1.5 Ontogenic development

Developmental changes in UGT activity have been extensively studied both in vivo and in vitro using morphine as a substrate. Morphine glucuronidation to both morphine-6-glucuronide and morphine-3-glucuronide is mediated mainly

by UGT2B7.<sup>107</sup> Morphine was found to undergo significant glucuronidation by the fetus liver. In vitro studies in hepatic microsomes obtained from fetuses (15–27 weeks) indicated that the glucuronidation rates were 10–20% of that observed in adult microsomes.<sup>108</sup> In addition, the mean rate of morphine glucuronidation in fetal livers obtained after hysterectomy was twofold higher than that obtained from induced abortion livers, suggesting a possible regulatory mechanism for UGT activity related to the birth process (Table 4).<sup>25</sup> The glucuronidation of morphine in vivo has also been demonstrated in premature neonates as young as 24 weeks of gestation. Studies with other substrates which are mainly or partially glucuronidated by UGT2B7, such as naloxone, an opiate agonist, benzodiazepines, and nonsteroidal antiinflammatory drugs are all suggestive of a reduced glucuronidation ability in neonates compared to adults.<sup>109</sup>

The developmental regulation of UGT enzymes was also demonstrated with acetaminophen, which is glucuronidated mainly by UGT1A6 and to some extent by UGT1A9.<sup>110</sup> Acetaminophen glucuronide formation is undetectable in the fetus; low levels are seen after birth and only reach adult levels of glucuronidation after 10 years of age.<sup>111</sup> This lack of UGT activity is compensated, however, by the high activity of sulfotransferases in infants and young children.<sup>112</sup>

#### 5.07.4.2 *N*-Acetyltransferases

Arylamine *N*-acetyltransferases (NAT, EC 2.1.1) transfer an acetyl group from the cofactor acetyl-CoA to lipophilic molecules that contain a primary amino group, notably hydrazines and arylamines.<sup>113</sup> Oftentimes, an arylamine function is first unmasked by *N*-dealkylation or nitro, azo, or amide hydrolysis prior to acetylation. All NATs contain a conserved active-site cysteine residue that is critical to catalysis, by activating the acetyl CoA cofactor. This cysteine forms part of an active-site catalytic triad composed of Cys-His-Asp that is conserved in all prokaryotic and eukaryotic NAT homologs.<sup>114</sup>

NAT activity has been found in most organisms and mammals, and NAT proteins have been isolated from bacteria, rats, hamsters, and humans. Human NATs are encoded at three separate loci on chromosome 8. One of the loci contains a nonexpressed pseudogene (NAT3). The other two loci contain genes for NAT1 and NAT2 which encode 35 kDa, cytosolic enzymes that share 87% nucleotide and 81% amino acid sequence identities. NAT1 is ubiquitously expressed and catalyzes the acetylation of so-called ‘monomorphic’ substrates such as *p*-aminosalicylic acid and *p*-aminobenzoic acid. NAT2 is expressed primarily in the liver and intestinal mucosa and catalyzes the acetylation of what have been termed ‘polymorphic’ substrates, including sulfamethazine, isoniazid, dapsone, sulfamethoxazole, procainamide, hydralazine, and caffeine. NAT polymorphisms underlie polymorphic *N*-acetylation in drug metabolism. For example, the antituberculosis drug isoniazid displays a bimodal distribution of elimination kinetics within several populations, due to ‘fast’ versus ‘slow’ acetylation NAT polymorphisms. This was one of the first documented examples of a polymorphic drug response.<sup>115</sup> Several adverse drug reactions have been linked to altered acetylator status, often related to redox cycling of hydroxylamine metabolites formed by an alternative P450 pathway. Functional polymorphism of NAT2 has also been associated with individual differences in susceptibility to occupational and smoking-related bladder cancer. Many epidemiological studies into NAT-related cancer susceptibility have been carried out and analysis of these combined studies has shown that the role of NAT2 in predisposition to cancer depends on the type of cancer, the ethnicity of the population, and probably also on the level of exposure to carcinogens.<sup>116</sup> Limited information is available on developmental aspects of the NATs.

#### 5.07.4.3 Methyltransferases

The *O*-, *S*-, and *N*-methyltransferases (EC 2.1.2) discussed below all catalyze the transfer of a methyl group from the cofactor *S*-adenosylmethionine to both endogenous and xenobiotic substrates.<sup>117</sup>

##### 5.07.4.3.1 Catechol *O*-methyltransferase

Catechol *O*-methyltransferase (COMT) typically metabolizes catecholamines and estrogens, forming mixtures of *ortho* and *para* methoxy metabolites.<sup>118</sup> Drug substrates include L-dopa, 2-hydroxy ethinylestradiol and isoproteranol and COMT inhibitors have therapeutic value in the treatment of Parkinsonism. The enzyme is the product of a single gene located on chromosome 22q11.2, but two forms of the protein exist: soluble COMT (S-COMT, ~25 kDa) and membrane-bound COMT (M-COMT, ~30 kDa), whose additional 50 amino acids provide the hydrophobic anchor for membrane localization. S-COMT predominates in peripheral tissues and M-COMT is the main form of the enzyme in brain tissue.<sup>119</sup> COMT activity is inherited in an autosomal recessive manner. Individuals with low activity inherit a form of the enzyme that is thermolabile. A single G to A transition at codon 108/158 of the cytosolic/membrane gene results in a Val to Met substitution which forms the molecular basis for the well-recognized interindividual variation in the metabolism and response to the antihypertensive drug,  $\alpha$ -methyldopa.<sup>117</sup>

#### 5.07.4.3.2 S-Methyltransferases

There are relatively few drugs that undergo *S*-methylation but the enzymes are important for the detoxication of xenobiotic thiol compounds which tend to be toxic, and clinically significant because of polymorphisms that occur in thiopurine methyltransferase (TPMT). The gene for human TPMT, located on chromosome 6p22, codes for a 28 kDa cytosolic enzyme that catalyzes the methylation of aromatic and heteroaromatic thiols.<sup>117</sup> Substrate groups include thiophenols and the oncolytic and immunosuppressive agents 6-mercaptopurine (6-MP) and azathioprine. Polymorphic disposition of these two latter drugs is important in cancer therapy, because a poor metabolizer phenotype is a major risk factor for severe hemotoxicity resulting from an exaggerated pharmacological effect of thioguanine nucleotides in nontarget hemopoietic cells. The distribution of TPMT activity is trimodal: approximately 1 in 300 individuals are poor metabolizers requiring substantial dose reduction of 6-MP and azathioprine. The TPMT polymorphism is as a paradigm for personalized medicine in the field of pharmacogenomics.<sup>120</sup>

#### 5.07.4.3.3 N-Methyltransferases

*N*-Methyltransferases are ~30 kDa cytosolic proteins that are localized in a number of tissues, including the gastrointestinal tract, bronchioles, kidney, and brain. There are only a few examples of drugs which undergo *N*-methylation, but two important endogenous substrates are histamine and nicotinamide. For more details on methyltransferases and *N*-acetyltransferases, see 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions.

### 5.07.4.4 Glutathione S-Transferases

Glutathione *S*-transferase (GST, EC 2.5.1.18) enzymes catalyze conjugation of xenobiotics and endogenous compounds with reduced GSH. Two superfamilies of GST proteins are recognized. Membrane-associated proteins involved in eicosanoid and GSH metabolism (MAPEG) family members are involved in several important physiological processes, including the synthesis of peptido-leukotrienes and the 5-lipoxygenase pathway, but do not seem to have a role in xenobiotic metabolism. Conversely, the cytosolic GSTs (cGSTs) metabolize a wide range of environmental agents and numerous drugs.<sup>121</sup> cGSTs have a particularly important toxicological role in scavenging reactive electrophilic species generated within the cell by various processes, and a large body of literature exists on the role of cGSTs in cancer.<sup>122</sup>

#### 5.07.4.4.1 Multiplicity and ligand specificity

cGST isoforms, like the other drug-metabolizing superfamilies we have already considered, are classified on the basis of sequence homology. However, cGST nomenclature is quite distinct because each of the six gene subfamilies is represented by a letter; i.e. A- (alpha-), M- (mu-), O- (omega), P- (pi), T- (theta), and Z- (zeta).<sup>123</sup> Within these six subfamilies there exist a total of 16 functional mammalian *cGST* genes, i.e., *GSTA1–GSTA5*, *GSTM1–GSTM5*, *GSTO1–GSTO2*, *GSTP1*, *GSTI1–GSTI2*, and *GSTZ1*.<sup>123</sup> Because cGSTs exist as dimers, a second number is added to the specific subfamily member to designate the dimer subunit composition, e.g., GSTA1-1. Finally, cGSTs usually exist as homodimers, but heterodimers are also known.

cGSTs are versatile catalysts that typically carry out nucleophilic addition and nucleophilic replacement reactions with GSH. However, these enzymes can also catalyze isomerization of double bonds without net consumption of GSH. 1-Chloro-2,4-dinitrobenzene (CDNB) is considered a ‘universal’ substrate for the cGSTs, although some T-isoforms have no activity. Class- and isoform-dependent substrate selectivity is broad and overlapping, as with the other detoxification enzymes. A few generalizations are: M-class GSTs have high activity toward planar aromatic hydrocarbon epoxides. T-class have high affinity for aryl sulfates and catalyze desulfation. A-class GSTs have relatively high activity toward organic peroxides. GSTA4-4 is selective for lipid hydroxy-enals (4-hydroxy-nonenal, HNE). GSTP1-1 may have a ‘unique’ function related to cancer cell response in that it inhibits c-Jun kinase, thereby regulating signal transduction pathways involved in apoptotic/proliferative responses.<sup>124</sup>

Given their functional versatility and anticipated role in a variety of biological processes, GST inhibitors could have the potential to impact a variety of therapeutic categories.<sup>125</sup> Historically, GST inhibitors have been *S*-linked conjugates of GSH with additional hydrophobic groups. In essence, these inhibitors are products of the reaction, and the fact that they are useful in vitro inhibitors reflects the product inhibition kinetics often observed for these enzymes. Such inhibitors tend not to be isoform-selective, which is not surprising because all isoforms have a GSH-binding site (G-site). Some progress has been made towards the development of isoform-selective inhibitors of GSTP1-1, wherein substitution of the GSH backbone is accommodated by this isoform, but not by others.<sup>126</sup>

#### 5.07.4.4.2 Structure

X-ray structures are available for human A-, P-, M-, T-, and S-class cGSTs.<sup>124</sup> The overall subunit structure is very similar across these classes and contains two distinct domains. The N-terminal domain possesses the G-site that binds nucleophilic GS-, which is stabilized, for example in GSTA, by hydrogen bonding to a conserved Arg residue. The much larger C-terminal domain contributes to the xenobiotic binding site (H-site) that lies between the domains. In some cases, the hydrophobic H-site includes an appropriate residue that can aid in the catalysis of specific substrates. For example, in GSTM an H-site Tyr provides a general base for the 'leaving' oxygen of epoxide substrates.

#### 5.07.4.4.3 Tissue distribution and ontogenic development

Human cGST enzymes are expressed in the cytosol of all organ tissues examined, although their involvement in xenobiotic metabolism is due principally to enzymes expressed in the liver, intestine, and kidney.<sup>127</sup>

Tissue-specific ontogenic expression of GST has been demonstrated for hepatic GSTA1 and GSTA2, both of which were detected as early as 10 weeks' gestation age, increasing to adult levels within the first 2 years of life.<sup>25</sup> GSTM(1–5) was also detected in fetal liver samples, albeit at lower levels, and increased to adult levels following birth. In contrast, GSTP1 expression has been detected in fetal liver samples (10–22 weeks' gestation age), but declined in the second and third trimester and was virtually undetectable in adult samples. In the fetal lung, GSTP1 is the major GST isozyme, detectable in lung tissue at less than 20 weeks' gestation, and decreased continuously in the developing fetus and infant after birth. In fetal kidney at less than 20 weeks' gestation, both GSTA1 and GSTA2 were detected and increased to adult levels within the first 2 years of life. GSTM levels, however, decreased between the fetal and postnatal samples, while GSTP1 levels remained constant during kidney development.

#### 5.07.4.5 Sulfotransferases

Sulfation of drugs and xenobiotics is catalyzed by cytosolic sulfotransferases (SULTs, EC 2.8.1) that utilize the cofactor 3'-phosphoadenosine 5'-phosphosulfate (PAPS).<sup>128</sup> Membrane-bound forms of the enzyme are known which sulfate heparins, tyrosines in proteins, and proteoglycans, but these enzymes have little or no activity toward drugs. The reactivity of cytosolic SULTs overlaps with the UGTs, but the substrate range is not as diverse. SULTs are mostly active with phenols, alcohols, and arylamines, but many endogenous substrates are also recognized, e.g., steroids, bile acids, neurotransmitters, and carbohydrates. As with the glucuronidation, sulfation reactions usually result in more polar species that are readily excreted in the urine. However, SULTs are also implicated in toxicological reactions if nonenzymatic loss of  $\text{SO}_4^{2-}$  occurs to generate a relatively stable carbocation, e.g., from *N*-arylamines and benzylic alcohols, that can react with proteins and DNA.<sup>129</sup>

##### 5.07.4.5.1 Multiplicity and ligand specificity

At least 10 human cytosolic SULT isoforms belonging to three SULT families are known. The human SULT1 family is the most diverse, being comprised of SULT1A1, 1A2, 1A3, 1B1, 1C2, 1C4, and 1E1. In addition, SULT2A1, 2B1, and 4A1 have been described in humans.<sup>130</sup> As with the UGTs, family members share at least 45% sequence homology, and subfamily members share at least 60% homology. This nomenclature system has replaced earlier, more confusing designations that usually reflected their substrate specificity, e.g., estradiol sulfotransferase, phenol sulfotransferase (PST), or hydroxysteroid sulfotransferase (HST). In terms of their substrate specificities, most information is available for the SULT1A and 1E isoforms which are recognized to metabolize preferentially a variety of simple phenols, estrogens, and catechols. Selective inhibitors for the various SULT isoforms are not available at present, although some general competitive inhibitors for the PAPS-binding site have been described.<sup>131</sup>

##### 5.07.4.5.2 Structure

Crystal structures for several SULTs are available. These enzymes are globular proteins with  $\alpha$ -helices on both sides of a characteristic 5 stranded  $\beta$ -sheet. Despite their discrete substrate specificities, crystallographic evidence indicates that membrane-bound and cytosolic SULTs share the same overall structural fold.<sup>128</sup> The PAPS-binding site is highly conserved between cytosolic and membrane SULTs, but the sulfate-acceptor binding site is very different. [Figure 3](#) depicts the crystal structure of SULT1A1 complexed with an inhibitor as well as PAPS.

Structural and site-directed mutagenesis data support the involvement of His107 as the active site base that activates the incipient nucleophilic substrate, with additional critical roles for Ser137 and Arg47 in the catalytic mechanism of the enzyme.

**Figure 3** The crystal structure of human SULT1A1 complexed with estradiol ( $E_2$ ) and the cofactor (a PAP analog). The  $C\alpha$  trace is colored blue (N-terminus) to red (C-terminus). Secondary structure elements are represented as coils for helices and arrows for strands. The bound ligands are shown as space-filling models: PAP, pink;  $E_2$ , dark gray. (Reproduced from Gamage, N. U.; Tsvetanov, S.; Duggleby, R. G.; McManus, M. E.; Martin, J. L. *J. Biol. Chem.* **2005**, 280, 41482–41486, copyright (2005) with permission from the American Society for Biochemistry & Molecular Biology.<sup>133</sup>)

#### 5.07.4.5.3 Tissue distribution and ontogenic development

The SULT1 family, which comprises at least 11 isoforms, is highly expressed in the liver, but is also present in other extrahepatic tissues.<sup>130</sup> SULT1A1 is mainly a liver form of the enzyme but is also detectable in the brain, breast, intestine, endometrium, kidney, lung, and platelets. Transcripts for the *SULT1B* subfamily, which is mainly involved in the sulfation of thyroid hormones, have been detected in the liver, colon, small intestine, and blood leukocytes, whereas human *SULT1C2* transcript is detected primarily in the thyroid, stomach, and kidney. *SULT1C4* transcripts are found predominantly in fetal kidney and lung and have been detected in the adult brain and ovary. Human SULT1E1 and 1E2 are found in steroid hormone-responsive tissues including the endometrium, testis, breast, adrenal gland, and

placenta, in addition to the liver and intestine. The SULT2 family, including transcripts for *SULT2A1* and *SULT2A2*, have been found in adrenal cortex, liver, brain, and intestine.

The ontogeny of SULTs was studied recently by Richard *et al.*<sup>112</sup> in the developing liver, lung, and brain. SULT1A1 enzymatic activity was higher in fetal tissues than in postnatal liver. Also SULT1A3 was expressed at higher levels in early stages of development, decreased gradually in the late fetal/early neonatal liver and was not observed in adult liver. In the lung, high SULT1A3 activity was observed in the fetus compared to neonatal levels. Therefore, the developing fetus clearly possesses significant sulfation capabilities. This could be a consequence of the important role sulfation plays in the homeostasis of hormones and other endogenous compounds that are important for development or because of the need for xenobiotic detoxification in the fetus where other conjugating enzymes, notably the UGTs, are not expressed at high levels until the neonatal stage.

### 5.07.5 Closing Remarks

The enzymology of drug metabolism has advanced considerably in the last 20 years, with the advent of molecular biology techniques that have provided detailed sequence information upon which to base rational nomenclature systems, and recombinant enzymes essential to the detailed study of enzyme–ligand interactions. Indeed, contemporary drug discovery and development rely heavily on this advancing lexicon of information to ensure that preclinical drug candidates are chosen with appropriate metabolic stabilities and interaction liability characteristics. Central to these activities is the identification of the specific enzymes involved in the metabolic clearance of a new chemical entity, a process which reaches its zenith for the P450s, due to the wealth of specific substrates, inhibitors, and recombinant enzymes that exist. The increasing availability of crystal structures for human P450s is also propelling efforts to understand and predict P450–ligand interactions *in silico*. However, impediments to the full implementation of such P450 modeling approaches include the relative dearth of structures with isoform-specific ligands bound and the demonstrated elasticity of mammalian P450 active sites, and research to address these issues will likely be priority items for the future. Much larger knowledge gaps exist for some of the other drug-metabolizing enzymes, notably the reductases, CESs, and glucuronyltransferases, where few isoform-specific substrates and inhibitors are available and recombinant human enzymes are only widely available for the human UGTs. In the case of the reductases, a systematic understanding of the basic enzymology of xenobiotic reduction is still in its infancy. These are important considerations because non-P450 clearance pathways are increasingly emphasized in drug development in order to avoid or minimize drug–drug and drug–gene interactions. Even with a more complete toolbox for the non-P450 enzymes, a much better appreciation of individual tissue isoform concentrations (as opposed to mRNA) will be needed to progress towards realistic scaling of *in vitro* data to the *in vivo* situation. While incomplete, experience and advances within the P450 field can serve as a useful template for developing experimental strategies to integrate better non-P450 enzymology into drug development.

## Biographies

**Rheem A Totah** obtained a PhD in Medicinal Chemistry in 2002 from the University of Kansas. Later, she spent 18 months as an Elmer M and Joy B Plein Fellow for Excellence in Pharmacy Education at the University of Washington. Currently Dr Totah is an Acting Assistant Professor in the Medicinal Chemistry Department at the University of Washington. Dr Totah's research interests are focused on studying the mechanism and structure–activity relationship of cytochrome P450 enzymes especially those expressed mainly in extrahepatic tissues.

**Allan E Rettie** obtained a PhD in Pharmaceutical Sciences following studies at the Wolfson Unit at the University of Newcastle-upon-Tyne, England under the direction of Prof Sir Michael Rawlins. After postdoctoral research training with Drs Mont Juchau and William Trager at the University of Washington, Seattle, Dr Rettie joined the faculty of the School of Pharmacy at the same institution, where he is now Professor and Chair of Medicinal Chemistry. Dr Rettie's research interests revolve around structure–function relationships for the cytochrome P450 enzymes, particularly those in the CYP2 and CYP4 families, and the pharmacogenomics of oral anticoagulants.

## 5.08 Mechanisms of Toxicification and Detoxification which Challenge Drug Candidates and Drugs

### 5.08.1 Introduction

#### 5.08.1.1 Scope of Drug Metabolism toward Xenobiotic Detoxification

Over the course of evolution organisms were exposed to environmental compounds of negligible nutritive value. These have variably been called 'foreign compounds' or 'xenobiotics.' Also the term 'drug' is used for them in contrast to the narrower term 'therapeutic drug' to specifically designate those xenobiotics that are intended for clinical use. Organisms that developed systems enabling them to get rid of these xenobiotics before they could accumulate to toxic levels had an evolutionary advantage. Such systems therefore had an obvious scope toward detoxification.<sup>1</sup>

The major excretory systems of mammals – the renal and the biliary excretion system – require a minimal hydrophilicity of chemical compounds to be excretable. This generated the necessity for lipophilic xenobiotics to be

converted to hydrophilic metabolites in order to become excretable.<sup>1–3</sup> This necessity represented one driving force for the metabolism of xenobiotics to develop during evolution.

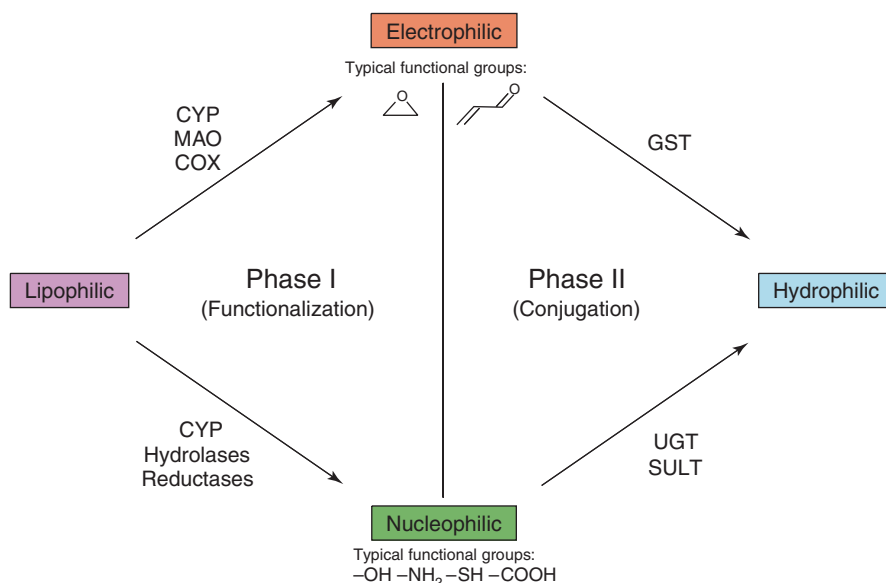

A further need was the ability to detoxify ‘future unknowns.’ Therefore, the enzymes exclusively or predominantly catalyzing the metabolism of xenobiotics usually: (1) have a very broad substrate specificity; and (2) exist in large families or superfamilies of enzymes each one of them possessing a broad but distinct substrate specificity, which in part overlaps with the specificities of the other isoenzymes.<sup>1</sup> The catalytically active site of a typical drug-metabolizing enzyme must be able to accommodate a large number of substrates such that the fit of an individual substrate to the active site cannot be very tight. An important consequence of this is that the geometry of the substrate/catalytic site is not optimized for maximal speed of the reaction but rather for substantial flexibility. Therefore, drug-metabolizing enzymes are relatively slow enzymes.<sup>1</sup> Glutathione *S*-transferases are among the fastest of them (approximately  $10^4$  mole substrate turned over per minute per mole of enzyme). Even this is very slow compared with fast enzymes such as carboanhydrase (turnover number about  $4 \times 10^7 \text{ min}^{-1}$ ).

#### 5.08.1.2 Toxicification versus Detoxification

The key point is that a given species was not able to ‘predict’ what kind of xenobiotics it would be exposed in future since the organisms and their constituents in its environment obviously also underwent evolutionary changes. Thus, excretory systems of low specificity and hence high flexibility provided an evolutionary advantage. However, there was a price to pay for this flexibility. The low substrate specificity of the enzymes catalyzing the reactions allowing for a vast array of ‘unforeseen’ lipophilic xenobiotics to ultimately be converted to metabolites sufficiently hydrophilic for excretion quite frequently led to toxic intermediary metabolites.<sup>1</sup> Therefore, drug metabolism leads to both detoxification and toxification. Indeed, practically all drug-metabolizing enzymes that have been investigated so far play dual roles: detoxification and toxification. However, for individual structural elements of a given drug it becomes increasingly possible to predict whether a given enzyme will lead to toxification or to detoxification, an important basis for extrapolations from an experimentally used animal species to human when the enzyme in question is expressed to vastly different levels between these species, as is frequently the case.<sup>1</sup>

#### 5.08.2 The Phase Concept of Drug Metabolism and Its Importance for Toxicification versus Detoxification

The phase concept of drug metabolism is described elsewhere in this book (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions; 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). With respect to toxification versus detoxification it is important that depending on their chemical nature the functional groups introduced in the phase I of drug metabolism can be classified as electrophilic or nucleophilic (**Figure 1**). Functional groups with an electrophilic carbon are, for example, epoxides or  $\alpha,\beta$ -unsaturated carbonyl groups. Nucleophilic substituents are, for example, hydroxyl, amino, sulfhydryl, or carboxylic groups. Owing to their ability to react with electron-rich substituents in important intracellular steering molecules such as proteins and nucleic acids, electrophilic metabolites can – depending on their individual chemical reactivity – be highly cytotoxic and/or mutagenic. Nucleophilic metabolites, however, usually do not covalently modify endogenous macromolecules and are therefore generally less toxic. On the other hand, they are often determinants of receptor interactions and thus of the biological activity of a xenobiotic compound. Therefore, acutely toxic effects of xenobiotics or their metabolites caused by receptor activation at the wrong time or wrong intensity can depend on specific nucleophilic groups in the compound.<sup>1</sup> Electrophilic substrates (e.g., epoxides,  $\alpha,\beta$ -unsaturated carbonyls) are conjugated by the glutathione *S*-transferases. Nucleophilic substrates (i.e., those with hydroxyl-, sulfhydryl-, amino- or carboxyl groups) are conjugated by UDP-glucuronosyltransferases (UGTs), sulfotransferases (SULTs), acetyltransferases (ATs), and methyltransferases (MTs). Conjugation reactions usually terminate the potential of electrophiles to react with proteins and DNA, or the ability of nucleophiles to interact with a receptor. Conjugation to both types of substituents usually increases the water solubility of the respective compound greatly.<sup>1–3</sup> Therefore, conjugation reactions usually are the major detoxification step in drug metabolism. However, there are exceptions that are important for predictions of toxification versus detoxification: glutathione conjugation strongly increases the electrophilic reactivity of vicinal dihaloalkanes and enzymatic sulfate ester formation with hydroxymethylated aromatic compounds and with aromatic hydroxylamines (metabolites of aromatic amines) leads to markedly and strongly mutagenic species, respectively.<sup>1</sup>

**Figure 1** The phases of drug metabolism. Metabolism of lipophilic foreign compounds typically proceeds in sequential steps. In phase I, the compounds are functionalized via introduction or liberation of nucleophilic or electrophilic anchor groups by oxidoreductases or hydrolases, which allow conjugation with strongly polar endogenous building blocks, such as glucuronic acid or glutathione, in phase II of drug metabolism. The resulting metabolites are usually readily water soluble and therefore easily excretable in the urine or bile. The conjugation usually terminates the biological activity of compounds, such as the genotoxic effects of certain electrophiles or the pharmacological effects of therapeutic drugs. (Reproduced from Oesch, F.; Arand, M. *Xenobiotic Metabolism*. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.)

### 5.08.3 Toxicologically Relevant Properties of Individual Drug-Metabolizing Enzymes

#### 5.08.3.1 Phase I Enzymes

##### 5.08.3.1.1 Oxidoreductases

##### 5.08.3.1.1.1 Cytochromes P450 (CYP; E.C. 1.14.14.1)

5.08.3.1.1.1.1 Multiplicity of CYPs<sup>2,4–8</sup> The nomenclature of the multiple CYPs is described elsewhere in this book (see 5.05 Principles of Drug Metabolism 1: Redox Reactions). When attempting to extrapolate toxicological results obtained in an experimental animal species to human it is often helpful to discriminate whether orthologous CYPs exist in the test species and in man since in many cases, apart from the conservation of a high percentage of the overall primary structure, much of the individual function including substrate specificity is conserved among species in orthologous enzymes. It is possible to define orthologous enzymes in different organisms if there is higher sequence similarity between these forms from different species than there is between the closely related isoenzymes of the same subfamily within the same species. Such orthologous CYPs from different species receive the same designation. This is the case for the individual isoenzymes of CYP family 1. If the assignment of orthologous CYPs is not possible the CYPs within the subfamily are numbered consecutively (many CYPs from families 2, 3, and 4).<sup>1</sup>

5.08.3.1.1.1.2 Enzymatic mechanism of the reactions catalyzed by CYP and toxicological consequences The CYP-catalyzed oxygenation proceeds by a number of sequential steps forming the CYP reaction cycle (Figure 2; see 5.05 Principles of Drug Metabolism 1: Redox Reactions).<sup>2,5,6</sup> The prosthetic heme of CYP has its central iron in the ferric state [ $\text{Fe}^{3+}$ ] and, in most CYPs, is predominantly low spin in its  $d^5$ -orbitals. Binding of a substrate in the catalytic pocket of CYP in most cases leads to the conversion of the iron from the low- to the high-spin configuration, which favors the reduction of the ferric [ $\text{Fe}^{3+}$ ] to the ferrous [ $\text{Fe}^{2+}$ ] iron of CYP by the NADPH-CYP-reductase by a one-electron transfer. In this state, the iron can bind molecular oxygen to form a  $\text{Fe}^{2+}\text{-O}_2$  complex. The generation of the ultimately activated form of oxygen is now initiated by a further reduction, again by a one-electron transfer. This is

**Figure 2** Cytochrome P450 (CYP)-catalyzed reactions: (1) a substrate molecule (depicted example: chrysene) binds in the active site of CYP thereby facilitating the conversion of the heme iron from the low-spin to the high-spin configuration; (2) the ferric  $\text{Fe}^{3+}$  of CYP is reduced to the ferrous  $\text{Fe}^{2+}$  by NADPH-CYP-reductase by a one-electron transfer; (3) the iron binds molecular oxygen; (4) a second one-electron reduction either by NADPH-CYP-reductase or by cytochrome  $b_5$  leads to the highly activated  $[\text{Fe}^{2+}-\text{O}_2^-]$ ; (5) heterolytic scission of the  $\text{O}-\text{O}$  bond and binding of two protons lead to the release of water; and (6) the reactive  $(\text{FeO})^{3+}$  intermediate oxygenates the substrate, which is then released. (Reproduced from Oesch, F.; Arand, M. Xenobiotic Metabolism. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.)

catalyzed by the NADPH-CYP-reductase or sometimes (depending on the individual CYP and on the substrate) by cytochrome  $b_5$  (activated by the NADH-dependent cytochrome  $b_5$  reductase).<sup>1,2,5,6</sup> It is of importance toxicologically that the complex is now in a highly activated form (mesomerically between  $\text{Fe}^{2+}-\text{O}_2^-$  and  $\text{Fe}^{3+}-\text{O}_2^{2-}$ ) that can release active oxygen species, for instance, hydrogen peroxide<sup>9,10</sup> and thereby start cytotoxic processes such as lipid peroxidation. Although the analysis of the unstable intermediates is difficult the available evidence indicates that heterolytic scission of the O–O bond and binding of two protons leads to the formation of a water molecule and a  $(\text{FeO})^{3+}$  intermediate with a high oxygen transfer and high oxidation potential, which now oxygenates or oxidizes the substrate in many cases leading to toxic metabolites.<sup>1,2,5,6</sup>

It is of toxicological importance that:

- Many, but not all, CYP bind and activate oxygen only after substrate binding. This partially protects from the potentially destructive generation of reactive oxygen species by CYP;
- Because of their intrinsic ability to activate oxygen, CYP can per se lead to reactions toxic for the organism, especially in the presence of competitive inhibitors that are not (or poor) substrates binding to the active site without themselves being oxidized thereby activating oxygen for a long time.<sup>1</sup>

5.08.3.1.1.3 Individual CYPs that are important for xenobiotic toxicification and detoxification CYP-mediated drug metabolism in mammalian species is mainly due to CYPs of families 1–3<sup>11</sup> (Table 1). The CYP1 family<sup>8,12–14</sup> has only three isoenzymes CYP1A1, CYP1A2, and CYP1B1. In all mammalian species investigated these isoenzymes are orthologous, that is, the % amino acid sequence identity of the individual isoenzymes between mammalian species is higher than between these isoenzymes within a given species. This allows for some toxicologically important extrapolations between mammalian species although the respective functions of the individual isoenzymes are, of course, not strictly identical in different species.<sup>1</sup>

CYP1A1<sup>8,12,14</sup> metabolizes planar and highly lipophilic compounds such as polycyclic aromatic hydrocarbons (PAH), including many carcinogenic environmental chemicals. CYP1A1 metabolizes these by hydroxylation to phenols, which are conjugated and excreted (detoxification). At the same time CYP1A1 metabolizes them to electrophilically reactive epoxides.<sup>1</sup> In a multistep reaction the very highly reactive dihydrodiol bay region epoxides are formed, which are responsible for much of the genotoxic (DNA damaging, mutagenic) and carcinogenic activity of PAHs.<sup>15,16</sup> Figure 3 shows the steps leading from benzo[*a*]pyrene to the ultimate carcinogenic metabolite benzo[*a*]pyrene-7,8-dihydrodiol-9,10-epoxide. Both CYP-mediated reactions of this pathway can be catalyzed by CYP1A1. Many PAHs greatly enhance their own metabolism by CYP1A1. The mechanism underlying this induction of the members of the CYP1 family is a transcriptional activation mediated by the aryl hydrocarbon receptor (Ah receptor), which itself is activated by binding of these inducers.<sup>1,8,14,17,18</sup> Just as many xenobiotic metabolizing enzymes have endogenous functions as well, the Ah receptor is also activated in the absence of xenobiotic ligands.<sup>19</sup> Constitutively, i.e., in the absence of exogenous inducers, CYP1A1 expression is virtually absent in human liver but is present in several other tissues such as lung, lymphocytes, and placenta.

CYP1A2, in contrast, is almost exclusively expressed in the liver in humans. It is also inducible by many planar PAHs, markedly but to a much more modest extent than CYP1A1. On average, about 10% of the total liver CYP is CYP1A2, but the level of expression differs considerably among individuals. Many important procarcinogens are metabolically toxified by CYP1A2. This includes the human carcinogenic aromatic amines as well as heterocyclic amines such as the protein pyrolysis products 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ) and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP); these occur in human food after cooking and are mutagenic and carcinogenic, at least in rodents. Also, the reactive epoxide derived from the mycotoxin aflatoxin B<sub>1</sub>, which is strongly hepatocarcinogenic for man, is metabolically produced by CYP1A2. In many cases the substrate specificities of CYP1A1 and CYP1A2 overlap: polycyclic aromatic hydrocarbons are preferentially metabolized by CYP1A1 but also by CYP1A2; and aromatic amines are preferentially metabolized by CYP1A2 but also by CYP1A1.<sup>1</sup>

CYP1B1 has been discovered more recently. In several respects it is similar to members of the CYP1A family:

1. It metabolizes some polycyclic aromatic hydrocarbons albeit with a preference for the second step in the toxicification to the ultimate carcinogens dihydrodiol bay region epoxides, i.e., the pre-bay dihydrodiols, themselves metabolites of angular PAHs, are good substrates for CYP1B1.
2. It is inducible by many planar PAHs.

CYP1B1 is the most important enzyme for the toxicification to fjord-region dihydrodiol epoxides, the PAH metabolites with the highest carcinogenic potency known to date.

**Table 1** Toxicologically important human drug-metabolizing cytochromes P450 (CYP)

| <i>Iso-enzyme (selection)</i> | <i>Organ<sup>a</sup></i>                   | <i>Toxicologically relevant substrates (selection)</i>   | <i>Relation to animal CYPs</i>   |
|-------------------------------|--|--|--|
| CYP1A1                        | Multiple, constitutively very low in liver | Polycyclic aromatic hydrocarbons (PAH)   | Orthologous forms with similar biochemical characteristics in different vertebrates  |
| CYP1A2                        | Liver                                      | Aromatic amines, PAH, aflatoxin B <sub>1</sub> , phenacetin, acetaminophen, caffeine, warfarin, imipramine | Orthologous forms with similar biochemical characteristics in different vertebrates  |
| CYP2A6                        | Liver                                      | 6-Aminochrysene, aflatoxin B <sub>1</sub> , nitrosamines, coumarin   | No clear relationship to a specific animal CYP   |
| CYP2B6                        | Liver                                      | Cyclophosphamide, nicotine   | In contrast to the rat CYP2B1 that is strongly inducible by, e.g., phenobarbital and thereby becoming a major hepatic CYP in this species, CYP2B6 has been found only in rather small amounts in human liver and does not seem to play an important role in the metabolism of most drugs |
| CYP2C8                        | Liver                                      | Taxol, retinoids   | No clear relationship to a specific animal CYP   |
| CYP2C9                        | Liver, kidney                              | Diclofenac, ibuprofen, phenytoin, tolbutamide  | No clear relationship to a specific animal CYP   |
| CYP2C19                       | Liver                                      | (S)-Mephenytoin, omeprazole  | No clear relationship to a specific animal CYP   |
| CYP2D6                        | Liver                                      | Debrisoquin, propranolol, dextromethorphan   | No clear relationship to a specific animal CYP   |
| CYP2E1                        | Liver, gastrointestinal tract              | Ethanol, benzene, dimethylnitrosamine, chlorzoxazone   | Orthologous enzymes in different species. Only one enzyme in the subfamily in humans and in many animal species  |
| CYP3A4                        | Liver, small intestine                     | Aflatoxin B <sub>1</sub> , acetaminophen, benzphetamine, nifedipine, steroid hormones, erythromycin        | Several very closely related isoenzymes in man (CYP3A3, CYP3A5, and CYP3A7) make it impossible to assign orthologous forms in other species; otherwise, the biochemical characteristics resemble those of animal CYP3A isoenzymes  |

Reproduced from Oesch, F.; Arand, M. *Xenobiotic Metabolism*. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.

<sup>a</sup> Primarily identified in the indicated organ, but possibly also expressed in other locations.

In the CYP2 family the isoenzymes of major toxicological interest in human are CYP2A6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, and CYP2E1. The expression of CYP2A6<sup>20</sup> in human liver is modest (less than 5% of total CYP). This CYP can toxify the important human hepatocarcinogen aflatoxin B<sub>1</sub> (with high affinity but low capacity), as well as some tobacco-specific nitrosamines and some carcinogenic aromatic amines such as 6-aminochrysene. Coumarin can serve as an *in vivo* probe substrate. Its 7-hydroxylation is selectively catalyzed by CYP2A6.<sup>20</sup>

CYP2B family members<sup>11,21</sup> are important in many experimental animal species such as the rat and rabbit. However, the only human CYP2B member known, CYP2B6, is expressed at a very low level in the liver and appears to be of limited importance in drug metabolism. One important substrate is the cytostatic drug cyclophosphamide, which is toxified by the human CYP2B6.<sup>22</sup> Inactivation of CYP2B by cAMP-mediated phosphorylation substantially changes the metabolism of cyclophosphamide and its consequent toxicity.<sup>23</sup>

Conversely, the CYP2C family members<sup>24</sup> are highly important in human drug metabolism and apparently much more so than in rodents. They metabolize a large number of drugs (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions)

**Figure 3** Toxicologically important pathways of benzo[a]pyrene (BP) metabolism. BP is metabolized to many primary, secondary, and tertiary metabolites. Depicted is the toxicification to the ultimate carcinogen BP-7,8-dihydrodiol-9,10-epoxide. First CYP-mediated oxidation leads to the 7,8-epoxide, which is then hydrolyzed by microsomal epoxide hydrolase to the 7,8-dihydrodiol. Now conjugation to glucuronic acid or sulfate, dehydrogenation to the catechol, and isomerization to the phenol (not shown) compete with the final toxicification to the 7,8-dihydrodiol-9,10-epoxide catalyzed by CYP or prostaglandin synthase (COX). The diol epoxide is a highly mutagenic compound that is not a substrate for epoxide hydrolase. Conjugation to glutathione leads to detoxification, but is not fast enough to abolish the genotoxicity. (Reproduced from Oesch, F.; Arand, M. *Xenobiotic Metabolism*. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.)

CYP2D6<sup>25,26</sup> is especially important in humans because of its highly relevant polymorphism, which is due to: (1) inactive and less active alleles resulting in poor metabolizers; and (2) gene amplification of active alleles resulting in ultrarapid metabolizers. CYP2D6 metabolizes many drugs that have a basic nitrogen atom at a distance of 5–7 Å from an easily oxidizable atom. Lack of CYP2D6 activity can lead to accumulation of highly toxic levels of these drugs. About 7% of the Caucasian population have a defective CYP2D6 gene and must be aware of potentially toxic effects caused by standard doses of drugs that are predominantly metabolized by CYP2D6 and have a narrow therapeutic window. There are correlations between CYP2D6 genotype and the incidence of certain forms of the parkinsonian syndrome, which can result from drug-induced toxicity to dopaminergic neurons in the central nervous system.

CYP2E1<sup>27,28</sup> metabolizes a wide array of substrates all of which have a relatively small molecular size. This includes therapeutic drugs such as acetaminophen, environmental carcinogens such as benzene, and several alkylnitrosamines, as well as the compound from which the letter of the family (E) is derived: ethanol. In the presence of inducer, most notably relatively high concentrations of substrate, the half-life of CYP2E1 is increased leading to an accumulation of enzyme protein. In several cases a concomitant stimulation of the transcription occurs. In some cases a stimulation of translation has also been reported. The heme iron of CYP2E1 is predominantly in a high spin state even in the absence of substrate, which is relatively unusual for CYPs. The consequence is that oxygen can bind to CYP2E1 also in the absence of substrate, which leads to the production of activated oxygen that is not used for substrate oxygenation. Thus, induced levels of liver CYP2E1 may lead to hepatotoxicity. Ethanol-induced liver injury may in considerable part be due to oxidative damage caused by increased levels of CYP2E1 as a consequence of the induction by ethanol. Conversely, phosphorylation of CYP2E1 mediated by cAMP and hence by drugs that lead to an increase in cAMP leads to CYP2E1 inactivation.<sup>29</sup>

The CYP3 family<sup>6,30</sup> is the most important CYP family for the metabolism of therapeutic drugs. The most important member of the family is CYP3A4. It is usually the most abundant CYP in human liver (about 30% of the total CYPs). CYP3A4 has extraordinarily broad substrate specificity. This includes a great number of therapeutic drugs (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions), but also several carcinogens such as the important human hepatocarcinogen aflatoxin B<sub>1</sub> (with high capacity but low affinity) as well as the metabolically formed key intermediary PAH-derived dihydrodiols, which it toxifies to the ultimate carcinogens the dihydrodiolepoxides. CYP3A4 is induced by rifampicin, dexamethasone, pregnenolone carbonitrile, and phenobarbital. The strong induction by rifampicin led to one of the most spectacular cases of drug interactions. The contraceptive steroids were metabolically inactivated as a consequence of CYP3A4 induction by the coincident treatment with rifampicin in tuberculosis patients to such an extent that a great number of unwanted pregnancies resulted.

#### 5.08.3.1.1.2 Flavin-containing monooxygenases (FMOs; E.C. 1.14.13.8)

The flavin-containing monooxygenases (FMOs)<sup>31</sup> possess a broad substrate specificity; however, this is limited to the oxygenation of soft nucleophiles such as the heteroatoms nitrogen and sulfur. **Table 2** shows the substrates of pig liver FMO-1, which has been especially well investigated in this respect. *N*-oxide and *S*-oxide formation represent the major FMO-mediated reactions. In contrast to most CYP isoenzymes, the FMOs bind and activate molecular oxygen before the substrate binds. First the prosthetic group of FMO, the flavin adenine dinucleotide (FAD), is reduced by NADPH to form FADH<sub>2</sub>. Then O<sub>2</sub> is incorporated into the FAD, resulting in the formation of the hydroperoxide FADH-4 $\alpha$ -OOH. This reactive form is capable to transfer one oxygen atom to the substrate. The toxicologically important question is how does the organism protect itself from the activated oxygen that forms on FMO before the oxygen-accepting substrate is present in the enzyme? The protective mechanism is twofold. First, the oxygen transfer potential of FMO is much lower than that of CYP, restricting exogenous acceptor substrates as well as potential endogenous targets for oxygen transfer-mediated toxicity to soft nucleophiles, usually molecules containing sulfur or nitrogen. Second, charged molecules that carry a single charged group are usually poor FMO substrates, if the charged group is not itself the acceptor site for the oxygen. This substrate specificity protects many important endogenous soft nucleophiles such as glutathione, amino acids, or polyamines from metabolism by FMO.<sup>1</sup>

FMO genetic deficiency leads to the 'fish odor' syndrome, which is caused by the inability to metabolize trimethylamine to its *N*-oxide, a reaction that is carried out exclusively by FMOs. As a result the unmetabolized amine, which is highly volatile and smells like rotten fish, is exhaled and excreted, which often results in severe social problems.<sup>1</sup>

#### 5.08.3.1.1.3 Monoamine oxidases (MAOs; E.C. 1.4.3.4)

Monoamine oxidases (MAOs) are described elsewhere in this book (*see* 5.05 Principles of Drug Metabolism 1: Redox Reactions). The major function of MAOs consists of the inactivation by oxidative deamination of monoamine

**Table 2** Substrate specificity of pig liver flavin-containing monooxygenase (FMO)

##### Organic nitrogen compounds

Secondary and tertiary cyclic and acyclic amines  
*N*-Alkyl- and *N,N*-dialkyl arylamines  
 Hydrazines

##### Organic sulfur-containing compounds

Mercaptopurines, -pyrimidines, and -imidazoles  
 Cyclic and acyclic sulfides and disulfides  
 Thioamides, thiocarbamides, dithiocarbamides, dithioacids

##### Other organic substrates

Boronic acid  
 Phosphines  
 Selenides  
 Selenocarbamides

##### Inorganic compounds

Sulfur, sulfides, thiocyanates  
 Iodine, iodides, hypoiodites

Reproduced from Oesch, F.; Arand, M. Xenobiotic Metabolism. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.

neurotransmitters such as serotonin and dopamine. MAO also metabolizes many xenobiotic primary, secondary, or tertiary amines thereby generating an amine (or ammonia), an aldehyde, and hydrogen peroxide:

The hydrogen peroxide formed can reach toxicologically relevant levels.

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is an interesting example of metabolism-related selective toxicity. It is toxified via the intermediate 1-methyl-4-phenyl-2,3-dihydropyridinium salt (MPDP<sup>+</sup>) to the 1-methyl-4-phenyl pyridinium salt (MPP<sup>+</sup>). MPP<sup>+</sup> is taken up by a high-affinity reuptake system specifically localized in the nigrostriatal dopaminergic neurons and blocks their mitochondrial energy metabolism. This leads to death of these neurons, which causes Parkinson's disease. Within the neurons only MAO can metabolize MPTP, while in other tissues CYP- and FMO-catalyzed detoxification reactions compete with MAO for the substrate. This combination of selective uptake into cells possessing a selective pattern of drug-metabolizing enzymes causes the selective neurotoxicity. MPTP is an experimental chemical. Related compounds such as beta-carboline or tetrahydroisoquinoline are present at low concentrations in food. Whether they behave in a similar way to MPTP and therefore are neurotoxicologically important by contributing to the etiology of idiopathic Parkinson's disease is unclear.<sup>1</sup>

#### 5.08.3.1.1.4 Cyclooxygenases (COX; E.C. 1.14.99.1)

The most important function of cyclooxygenases (also called prostaglandin synthases) is endogenous in that they metabolize arachidonic acid to prostaglandins (Figure 4). First, the incorporation of two molecules of oxygen into arachidonic acid generates a cyclic peroxide (endoperoxide) and a hydroperoxide substituent. The resulting intermediate is prostaglandin-G<sub>2</sub>. Then, the hydroperoxide substituent is reduced to a hydroxyl group. The resulting compound is prostaglandin-H<sub>2</sub>. Many sufficiently lipophilic drugs that have a low redox potential act as an oxygen acceptor or electron donor in this second reaction and several of them are toxified in this way. This includes many

**Figure 4** Cyclooxygenase-mediated cooxidation. In the first step of prostaglandin-H<sub>2</sub> synthesis, two molecules of O<sub>2</sub> are incorporated into arachidonic acid, forming the cyclic peroxide (endoperoxide) prostaglandin-G<sub>2</sub>, which in addition contains a hydroperoxide substituent. This hydroperoxide substituent is then converted to a hydroxy group, resulting in prostaglandin-H<sub>2</sub>. During this reaction, the oxygen can be transferred to an exogenous acceptor substrate, which includes many toxification reactions. (Reproduced from Oesch, F.; Arand, M. Xenobiotic Metabolism. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.)

phenolic compounds and aromatic amines. Thus, many drugs are substrates for COX. The ease with which a compound may be co-oxidized by COX can be estimated from the influence of its substituents at the aromatic ring on its redox potential, e.g., electron-withdrawing substituents on the aromatic ring of *N*-methyl aniline derivatives and *N*-acetylation of aromatic amines reduce the rate of COX-mediated metabolism.

Some substrates are toxicified to radicals during this COX-mediated co-oxidation. The unpaired electron radicals can react with other molecules to yield new radicals thereby, for example, initiating lipid peroxidation or can damage cellular proteins or DNA by covalent modifications. In addition prostaglandin-G<sub>2</sub> can form a peroxy radical over a number of intermediate steps, which can lead to the formation of highly genotoxic epoxides derived from several compounds including environmental carcinogenic polycyclic aromatic hydrocarbons and the important human hepatocarcinogen aflatoxin B<sub>1</sub>.

Two COX isoenzymes are known, COX-1 and COX-2. COX-1 is constitutively expressed and COX-2 is an inducible enzyme, which is increased during inflammation. Many extrahepatic tissues are rich in COX but low in CYP. This makes COX important for the carcinogenic effect of aromatic amines in several extrahepatic organs such as lung, gastrointestinal tract, kidney, urinary bladder, and brain.<sup>1</sup>

#### 5.08.3.1.1.5 Dehydrogenases and reductases

Alcohol dehydrogenase (E.C. 1.1.1) (ADH)<sup>32</sup> toxicifies ethanol to acetaldehyde, which is then (predominantly) detoxified by an aldehyde dehydrogenase (E.C. 1.2.1) to acetic acid. The second step, the aldehyde dehydrogenase-mediated oxidation to acetic acid, is inhibited by disulfiram (Antabus), which is used in the treatment of alcohol addiction. After alcohol consumption disulfiram leads to the accumulation of the toxic acetaldehyde. The resulting toxicity provokes headache and nausea, which is intended to keep the alcoholic from further alcohol consumption. Many other aldehydes, such as the  $\alpha,\beta$ -unsaturated aldehydes (lipid peroxidation products), are also markedly toxic. Thus, aldehyde dehydrogenase predominantly leads to detoxification. However, as is the case with all adequately investigated drug-metabolizing enzymes, aldehyde dehydrogenase plays a dual role with respect to toxicification/detoxification, the nature of which depends on the substrate in question. Methanol is metabolized via formaldehyde to formic acid. Although formaldehyde is also considerably toxic, the decisive toxic metabolite is formic acid, leading to edema of the retina, blindness, and death. Remarkably, ethanol is an effective antidote, since it has a much higher affinity for the ADH compared with methanol. A relatively high concentration of ethanol inhibits the dehydrogenation of methanol allowing for the excretion of unmetabolized methanol thereby preventing the toxicification to formic acid.<sup>1</sup>

ADH is a member of the family of medium-chain alcohol dehydrogenases.<sup>32</sup> The major function of most short-chain alcohol dehydrogenases<sup>32</sup> in mammals is steroid metabolism. Nevertheless, many of them play important roles in drug toxicification and detoxification. The  $3\alpha$ -hydroxysteroid dehydrogenase ( $3\alpha$ -HSD) of rat and man oxidizes vicinal dihydrodiols of polycyclic aromatic hydrocarbons to catechols and these to quinones.<sup>33</sup> Hence,  $3\alpha$ -HSD is also called dihydrodiol dehydrogenase. This reaction sequesters the pre-bay dihydrodiols of polycyclic aromatic hydrocarbons away from their critical toxicification pathway to the ultimate carcinogenic dihydrodiol bay-region epoxides to produce instead the much less toxic catechols<sup>33</sup> (Figure 3). In addition, it inactivates the highly mutagenic and carcinogenic bay region diol epoxides.<sup>34</sup> Both of these reactions are protective, but the formation of catechols, which are further oxidized to quinones, is on the other hand also a potential toxicification, since quinones frequently undergo redox cycling producing toxic reactive oxygen species. Thus, as usual for drug-metabolizing enzymes, with respect to toxicification/detoxification the dihydrodiol dehydrogenase plays a dual role, the nature of which depends on the substrate. Toxicification by dihydrodiol dehydrogenase occurs by catechol formation from naphthalene 1,2-dihydrodiol leading to naphthalene-induced cataract formation. In rabbit liver, at least eight enzymes possess dihydrodiol dehydrogenase activity. In rat liver only the  $3\alpha$ -HSD possesses dihydrodiol dehydrogenase activity.<sup>35</sup> This is an interesting example of enzymes of endogenous function in some but not all species having acquired the ability to toxicify/detoxify xenobiotics.

The  $11\beta$ -hydroxysteroid dehydrogenase ( $11\beta$ -HSD) can also metabolize drugs, acting as a carbonyl reductase.<sup>36</sup> The toxicification of 4-(methylnitrosamino)-1-(3-pyridyl)-butan-1-one (NNK), a tobacco-specific nitrosamine, to the ultimate mutagenic metabolite can be prevented by  $11\beta$ -HSD-catalyzed reduction of the keto function followed by conjugation to glucuronic acid.<sup>36</sup>

Similarly, the dimeric flavoprotein NAD(P)H quinone oxidoreductase (NQOR; E.C. 1.6.99.2) (also called DT-diaphorase) protects against the toxicity of quinones by their reduction to catechols followed by their conjugation and excretion. Two NQORs are known. NQOR-1 is induced by 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD; also called 'dioxin'). The NQOR works by an interesting 'ordered ping-pong' mechanism. First, an enzyme-cofactor complex is formed, leading to the reduction of the prosthetic group. NADH and NADPH can serve as reducing cofactors. After dissociation of the enzyme-cofactor complex the substrate binds, is reduced, and the product is released. Therefore,

the enzymatic reaction can be inhibited by high concentrations of the substrate or the cofactor. Coumarin derivatives, such as warfarin, are naturally occurring inhibitors.

There are important species differences in the relevance of NQOR for drug metabolism and protection against their toxicities. In the rat NQOR is by far the most important enzyme for the reduction of many quinones. In man, however, a less specific carbonyl reductase is quantitatively of much higher importance.<sup>37</sup> This represents an important difference for extrapolations between these species.

NQOR acts on its substrate by a two-electron transfer mechanism. It thereby circumvents the formation of the highly reactive semiquinone radicals from quinones. In this respect NQOR is protective against drug toxicity. On the other hand, NQOR reduces aromatic nitro compounds to aromatic hydroxyl amines, precursors of highly genotoxic reactive esters. Again, with respect to toxicification/detoxification NQOR plays a dual role, the nature of which depends on the substrate and can easily be predicted, which is helpful for extrapolations between species.<sup>1</sup>

#### 5.08.3.1.2 Hydrolases

##### 5.08.3.1.2.1 Carboxylic ester hydrolases (E.C. 3.1.1) and amidases (E.C. 3.5.1–3.5.4)

Esterase and amidase reactions are catalyzed by the same enzymes, despite the assignment of different enzyme class numbers for the two different activities. The esterases are grouped according to their interaction with the toxicologically important organophosphates into A-, B-, and C-esterases. Organophosphates are substrates of and are therefore detoxified by A-esterases whereas organophosphates are strong inhibitors of B-esterases, which is the basis of their (intended selective insecticidal as well as unintended overdose mammalian) toxicity. C-esterases do not interact with organophosphates.

Although esters derived from aromatic compounds are preferred substrates of A-esterases (also called aryl esterases), the toxicologically most important substrates are the organophosphates. The selective toxicity toward insects is due to the lack of organophosphate detoxifying A-esterases in nonvertebrates, while mammals are largely protected by their high A-esterase activities.

The prominent member of the B-esterases is the acetyl choline esterase responsible for the inactivation of the neurotransmitter acetyl choline. Organophosphates are mechanism-based inhibitors of B-esterases. Their toxic effects are produced by an accumulation of acetyl choline and therefore by an exaggerated cholinergic activity. The inhibitory effect of the organophosphates is due to the fact that the enzyme phosphoserine ester formed between B-esterases and organophosphates hydrolyzes very slowly, if at all, and thus there is virtually no regeneration of the enzyme. The inhibition of another B-esterase, the neuropathy target esterase (NTE) localized in the central nervous system, leads to neurotoxicity called organophosphorus-induced delayed polyneuropathy (OPIDP). The neurotoxicity observed in some gulf war veterans is suspected to have been caused by a combination of the acetylcholine esterase inhibitor pyridostigmine (used as an antidote against anticholinergic chemical weapons) with organophosphate insecticides. The ‘unspecific carboxyl esterase’ predominantly expressed in the liver is also a B-esterase. It metabolizes many xenobiotic esters and amides, including several antiarrhythmic and anesthetic drugs. The ‘unspecific carboxylesterase’ is polymorphic in humans. Individuals lacking this esterase activity are prone to overdose toxicity of those drugs that are preferentially hydrolyzed by this enzyme. In individuals deficient in the unspecific carboxylesterase the neuromuscular-blocking agent suxamethonium leads to overdose toxicity (diaphragm muscle relaxation, cessation of breathing, and death) if the usual artificial respiration is not used or the dose is not adjusted.

C-esterases preferentially hydrolyze acetyl esters. Therefore, they are also called acetyl esterases. Typical substrates are 4-nitrophenyl acetate, propyl chloroacetate, and fluorescein diacetate.<sup>1,3</sup>

##### 5.08.3.1.2.2 Epoxide hydrolases (E.C. 3.3.2.3)

Epoxide hydrolases (EHs)<sup>38</sup> catalyze the hydrolytic cleavage of oxirane rings. Because of the higher electron attracting force of the oxygen atom compared with the two carbon atoms of oxirane rings, epoxides possess two electrophilic carbon atoms, the electrophilic reactivity of which is enhanced by the tension of the three-membered oxirane ring. Depending on the influences of the rest of the molecule this can make epoxides highly cytotoxic, genotoxic, and carcinogenic. Therefore, the EH-catalyzed hydrolytic opening of oxirane rings is normally a detoxification reaction. Some important, and predictable, exceptions are discussed below.

Several mammalian EHs are specialized for endogenous substrates, while two mammalian EHs preferentially metabolize xenobiotic epoxides.<sup>38</sup> These are the microsomal epoxide hydrolase (mEH)<sup>39,40</sup> and the soluble epoxide hydrolase (sEH).<sup>41,42</sup> The two enzymes are  $\alpha/\beta$  hydrolase fold proteins, thus, in spite of a very low similarity of their amino acid sequences (<15%), they share a common three-dimensional structure<sup>43,44</sup> that displays a catalytic triad in its catalytic center: an aspartate as the catalytic nucleophile and a histidine/glutamate pair (mEH) or a histidine/aspartate pair (sEH) as the water-activating charge relay system.<sup>45</sup> The oxirane ring of the substrate is attacked by the

aspartate to form an enzyme–substrate ester that is hydrolyzed by a water molecule activated by proton abstraction through the histidine/acidic amino acid pair. This releases the product, a vicinal (*trans*-, if applicable) diol, and restores free enzyme. While the second step of detoxification (hydrolysis of the enzyme–substrate ester to give the diol product) is slow, it is of prime importance that the first step (covalent binding of the epoxide to the enzyme) is very fast. This leads to a practically instantaneous removal of the toxic epoxide from the system as long as the enzyme is present in excess (i.e., as long as the slow regeneration of the free enzyme is unnecessary for the removal of further epoxide).<sup>46</sup> mEH, which is a major constituent of the endoplasmic reticulum, is present in large amounts. This generates for epoxides that are mEH substrates a practical threshold concentration below which genotoxic damage is negligible,<sup>47</sup> an unusual and remarkable situation for genotoxic carcinogens.

mEH<sup>38</sup> is highly expressed in the liver and several steroidogenic organs and at more moderate levels in many tissues of man and other mammals. mEH is induced by phenobarbital, *trans*-stilbene oxide, Aroclor 1254, and by several other xenobiotics including many antioxidants such as ethoxyquin. mEH metabolizes many structurally diverse epoxides. Structural requirements for a mEH substrate are sufficient lipophilicity and lack of *trans*-substitution at the oxirane ring.<sup>39</sup> mEH substrates include epoxides metabolically formed from drugs, such as carbamazepine and phenytoin, from occupational compounds such as styrene, and from environmental compounds such as polycyclic aromatic hydrocarbons.<sup>38</sup> With respect to toxification/detoxification it is important to note that epoxide hydrolysis – normally a detoxification reaction – can be involved in overall toxification pathways in some predictable cases. The mEH-catalyzed hydrolysis of pre-bay epoxides metabolically formed from angular PAHs (e.g., the benzo[*a*]pyrene-7,8-epoxide) prevents its isomerization to the corresponding phenols, products of comparatively low toxicity that are easily conjugated and then excreted. Instead, the pre-bay dihydrodiol (e.g., the benzo[*a*]pyrene-7,8-dihydrodiol) is formed, which can be further metabolized by a variety of enzymes to the highly electrophilically reactive, mutagenic and carcinogenic dihydrodiol bay region epoxides (e.g., benzo[*a*]pyrene-7,8-dihydrodiol-9,10-epoxide), which are not (or very poor) substrates of EHs (see Figure 3). Thus, depending on which CYPs are predominantly present (and consequently which metabolic pathways of the large PAHs are predominantly operative) higher amounts of mEH can substantially increase the mutagenicity of angular PAHs such as benzo[*a*]pyrene, i.e., mEHs can paradoxically but predictably contribute to toxification.<sup>15,16</sup>

sEH<sup>42</sup> is predominantly expressed in liver, kidney, heart, brain, and in low amounts in several other organs. It has an unusual and toxicologically important dual localization in the cytosol and in the matrix of peroxisomes, the latter performing several metabolic functions including long chain fatty acid degradation. Several peroxisomal enzymes produce hydrogen peroxide. The fact that sEH is present in peroxisomes and is induced by peroxisome proliferators (which induce peroxisomal beta-oxidation and thereby hydrogen peroxide generation), suggests a protective role of sEH against hydrogen peroxide-induced oxidative damage. Fatty acid epoxides, products of lipid peroxidation, are in fact good substrates of sEH. Some fatty acid epoxides derived from arachidonic acid or linolenic acid are involved in signal transduction. Thus, sEH is likely to have an important regulatory function and sEH inducers or inhibitors are likely to render sEH an important toxification enzyme by disturbance of such regulatory functions. In addition, the sEH catalyzed metabolism of leukotoxin leads to the considerably more toxic 9,10-dihydroxyoctadec-12-enoic acid. This toxification suggests a central role of sEH in the pathogenesis of multiple organ failure, in particular the adult respiratory distress syndrome (ARDS), which develops as a consequence of a leukotoxin overproduction by leukocytes.<sup>42</sup>

The substrate specificity of sEH is complementary to that of mEH. It metabolizes many *trans*-substituted epoxides, such as *trans*-stilbene oxide and *trans*-ethyl styrene oxide, which are not hydrolyzed by mEH. Conversely, in contrast to mEH, sEH does not hydrolyze or poorly hydrolyzes epoxides derived from most polycyclic aromatic hydrocarbons.<sup>38</sup>

For extrapolations of metabolism-related toxicities between species it is important to note that sEH expression displays enormous interspecies differences. The rat has a particularly low level of sEH in the liver (only 0.01% of the total soluble hepatic protein). In contrast, the enzyme is highly abundant in mouse liver (0.3% of the soluble hepatic protein), and is about three times more active than rat sEH. In humans, sEH represents about 0.1% of the soluble liver proteins and possesses a specific activity similar to that of the rat.<sup>38</sup>

#### 5.08.3.1.2.3 Other hydrolases

Glycosidases and sulfatases are further hydrolases of importance for drug metabolism. They primarily metabolize endogenous substrates including glycosaminoglycans and steroids, but they also accept some xenobiotic substrates; this is particularly true for the beta-glucuronidases. The gut flora can deconjugate compounds that are excreted via the bile as glucuronides or sulfates. The deconjugation products are often reabsorbed from the gut leading to enterohepatic circulation. Frequently, the toxicity and mutagenicity of natural products is masked by sugar moieties in glycosides and deglycosylation leads to their toxic effects. Thus, glycosidases are toxifying in many cases. The procarcinogenic

glycoside cycasin of the cycad plant, for example, needs glycosidase-mediated toxicification. After oral treatment with cycasin, rats with a normal gut flora develop tumors in the liver, kidney, and intestine as a consequence of the bacterial glycosidase-mediated liberation of the genotoxic aglycon methyl azoxymethanol. However, germ-free rats do not suffer from any long-term effects of cycasin.<sup>1</sup>

### 5.08.3.2 Phase II Enzymes: Transferases

#### 5.08.3.2.1 Glutathione S-transferases (E.C. 2.5.1.18)

Glutathione (GSH) and glutathione *S*-transferases (GSTs)<sup>48</sup> represent the prime defense system against electrophile-mediated drug toxicity in mammals. However, as is the case with all adequately investigated drug-metabolizing enzymes, GSTs in some predictable cases act as toxifying enzymes and glutathione is itself mutagenic when activated by rat kidney homogenates (S9).<sup>49</sup> The 'normal' detoxifying role of GSTs is due to the fact that they detoxify lipophilic and structurally very diverse electrophiles by conjugating them with the endogenous hydrophilic nucleophile glutathione. This neutralizes the electrophilic reactivity and renders the compound easily excretable.<sup>1</sup>

The structure and catalytic mechanism of GST are described elsewhere in this book (5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). Almost all GSTs are soluble, dimeric drug-metabolizing enzymes. Subunit dimerization is necessary for their catalytic activity. The substrate specificity is dictated by the subunit and the substrate specificity of the dimer is purely additive of the specificities of the two individual subunits. In addition, there are at least two membrane-bound glutathione-dependent enzymes, one of which is called the microsomal GST, also a drug-metabolizing enzyme.

Glutathione conjugates are released from the cells by an active transport system that belongs to the multidrug resistance (MDR) protein complex. Since the GSTs are often strongly product-inhibited this active removal of the products is important for the efficiency of GST-mediated detoxification.<sup>50</sup>

Glutathione conjugates, predominantly formed in the liver, are usually further processed in the kidney. The glutamate moiety is cleaved off by the  $\gamma$ -glutamyltranspeptidase. Then glycine is released by aminopeptidase M. The resulting cysteinyl conjugate is usually *N*-acetylated to form a mercapturic acid. In competition with the *N*-acetyltransferase, beta-lyase can convert some cysteinyl conjugates to the sulfhydryl metabolite. This reaction can lead to highly toxic metabolites and hence represents a toxicification. In these cases the GST-mediated reaction has ultimately led to a highly toxic metabolite.<sup>1</sup>

The superfamily of cytosolic GSTs (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions) composed of families (also called classes): the  $\alpha$  (alpha),  $\mu$  (mu),  $\pi$  (pi),  $\theta$  (theta),  $\sigma$  (sigma), and  $\kappa$  (kappa) families (Table 3). The cytosolic GSTs are homodimers or heterodimers of subunits belonging to the same family. The recommendation for a nomenclature system proposes to use 'GST' for the enzyme, preceded by a lower case letter for the species (h for human, r for rat, etc.) followed by a capital letter for the family (A for  $\alpha$ , M for  $\mu$ , P for  $\pi$ , T for  $\theta$ , K for  $\kappa$ , S for  $\sigma$ ) followed by arabic numbers for the subunits (i.e., mGSTA1-1 is the homodimer of the mouse  $\alpha$  family subunit 1). For extrapolations of metabolism-controlled toxicities between species it is important to note that, in contrast to the system used for the CYPs, the use of the same number of GST subunits of different animal species does not (necessarily) indicate that they are orthologous; they are usually used in sequence of their discovery.<sup>1</sup>

A number of reactions are catalyzed by GSTs:

- Nucleophilic substitution of electron-withdrawing substituents by GSH such as the formation of *S*-(2,4-dinitrophenyl)glutathione from the broad-spectrum substrate 1-chloro-2,4-dinitrobenzene (CDNB), which is conjugated by almost all GSTs (the exception being the  $\theta$  family).
- Nucleophilic addition of GSH to epoxides by opening of the oxirane ring and to  $\alpha,\beta$ -unsaturated carbonyl compounds by Michael addition, both detoxification reactions. Many epoxides are good substrates for several GSTs. GSTP1 from most species has been shown to possess significant activity to detoxify the ultimate carcinogen benzo[*a*]pyrene-7,8-diol-9,10-epoxide (Figure 3). Also aflatoxin-8,9-epoxide is detoxified by GST. The glutathione conjugate of the endogenous epoxide leukotriene A<sub>4</sub> is leukotriene C<sub>4</sub> formed by GST and further metabolized to leukotriene D<sub>4</sub> both of them being active components of the slow reacting substance of anaphylaxis (SRS-A), which plays an important role in the genesis of anaphylaxis and bronchial asthma. rGSTA4-4 (in older literature 'rat GST 8-8' or 'Y<sub>k</sub>-Y<sub>k</sub>') has a particularly high Michael addition rate with the toxic lipid peroxidation product 4-hydroxynon-2-enal, implying an important role for GST in the protection against oxidative stress.

**Table 3** Rat cytosolic glutathione S-transferases and typical substrates

| <i>Glutathione S-transferases</i> | <i>Selective substrate</i>                                      |
|-----------------------------------|---|
| <b>Alpha family</b>               |   |
| GSTA1-1                           | $\Delta 5$ -Androstene-3,17-dione                               |
| GSTA2-2                           | $\Delta 5$ -Androstene-3,17-dione                               |
| GSTA3-3                           |   |
| GSTA4-4                           | 4-Hydroxynon-2-enal   |
| GSTA5-5                           | Aflatoxin B <sub>1</sub> <i>exo</i> -8,9-epoxide                |
| <b>Mu family</b>                  |   |
| GSTM1-1                           | 1,2-Dichloro-4-nitrobenzene                                     |
| GSTM2-2                           | <i>trans</i> -Stilbene oxide                                    |
| GSTM3-3                           | 1,2-Dichloro-4-nitrobenzene                                     |
| GSTM4-4                           |   |
| GSTM5-5                           |   |
| GSTM6-6                           |   |
| <b>Pi family</b>                  |   |
| GSTP1-1                           | (+)- <i>anti</i> -Benzo[ <i>a</i> ]pyrene-7,8-diol-9,10-epoxide |
| <b>Theta family</b>               |   |
| GSTT1-1                           | 1,2-Epoxy-3-(4-nitrophenoxy)propane                             |
| GSTT2-2                           | Menaphthyl sulfate  |
| <b>Sigma family</b>               |   |
| GSTS1-1                           | Prostaglandin H (isomerization)                                 |
| <b>Kappa family</b>               |   |
| GSTK1-1                           | Ethacrynic acid   |

Reproduced from Oesch, F.; Arand, M. Xenobiotic Metabolism. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.

This list includes only homodimers. In general, the properties of heterodimers are additive with respect to their subunits, probably because the substrate binding site (H-site) is formed by a single subunit. A broad-spectrum substrate for all GST except GSTTs is 1-chloro-2,4-dinitrobenzene (CDNB). .

- Reduction of organic hydroperoxides, converting them to the corresponding alcohols. GSTs are unable to reduce hydrogen peroxide (in contrast to glutathione peroxidase, which reduces hydrogen peroxide and organic hydroperoxides).
- Isomerizations, e.g. formation of  $\Delta 4$ -androstenedione from  $\Delta 5$ -androstenedione.<sup>1</sup>

In most cases GST-mediated reactions are detoxifications. However, there are at least two pathways by which GST toxifies halogenated hydrocarbons. Vicinal dihaloalkanes (e.g., 1,2-dibromoethane) can be conjugated to GSH, preferentially by GSTT1. The conjugate can undergo an intramolecular nucleophilic substitution reaction releasing the second halogen atom as an anion and forming a highly reactive episulfonium (thiiranium) ion, the thio-analogue of an epoxide with an electrophilic reactivity enhanced by the positive charge of the sulfur atom. This GST-catalyzed reaction, therefore, is a toxification yielding highly cytotoxic and genotoxic metabolites.

The second GST-mediated toxification pathway is particularly relevant for the organic solvent perchloroethylene. A highly cytotoxic and carcinogenic thioketene is formed by the following sequence: formation of the glutathione conjugate, degradation to the cysteinyl conjugate, which is then metabolized by the beta-lyase to the highly toxic thioketene.<sup>50</sup>

#### 5.08.3.2.1.1 Polymorphisms of GSTs

A homozygous null allele, i.e., the absence of a functional gene, of hGSTM1 and hGSTT1 occurs in about 50% and 15% of the Caucasian population, respectively. Lack of a functional hGSTM1 is associated with an increased risk for bladder (possibly also lung) cancer, and lack of a functionally active hGSTT1 is associated with a myelodysplastic syndrome.<sup>51</sup>

#### 5.08.3.2.2 UDP-glucuronosyltransferases (E.C. 2.4.1.17)

Conjugation with glucuronic acid is the most abundant phase-II reaction (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). UDP-glucuronosyltransferases (UGTs)<sup>52</sup> catalyze the formation of beta-D-glucuronides from a large variety of xenobiotics by their reaction with UDP-glucuronic acid (UDPGA). Hydroxyl-, thiol-, amino-, hydroxylamino- and carboxyl-substituents serve as the anchor to which glucuronic acid can be conjugated (also C-glucuronides can be formed if the hydrogen of the respective C–H bond is sufficiently mobile such as a carbon atom between two carbonyl functions). The xenobiotic substituents engaged in the glucuronic acid conjugation are nucleophilic. Accordingly, the majority of the UGT substrates are not genotoxic. The anchor groups listed above are often determinants or co-determinants of the biological activity of drugs and toxins, since they are frequently involved in the interaction with receptors or enzymes. Therefore, conjugation of these frequently terminates therapeutic or also toxic activity. Additionally, in most cases, glucuronic acid conjugation substantially increases the hydrophilicity of a drug enhancing its excretion. Hence, UGTs are predominantly detoxifying enzymes.<sup>1</sup>

In a few cases, however, UGTs enhance the toxicity of their substrates. This is the case with some nonsteroidal anti-inflammatory drugs (NSAIDs). The resulting ester glucuronides can undergo acyl migration, i.e., the intramolecular transesterification from the C1 hydroxy group of the glucuronic acid to the C2 hydroxy group and further to the C3 and C4 hydroxy groups. This can lead to the formation of a free aldehyde group at C1, which can react with primary amino groups in proteins generating Schiff's bases. Amadori rearrangement can then lead to a stable protein adduct, which may give rise to allergic reactions, a well-known drug toxicity of some NSAIDs. Glucuronic acid conjugation can also result in enhanced genotoxicity. Aromatic amines, including important human carcinogens, are metabolized by CYPs (preferentially CYP1A2) to aromatic hydroxylamines. Glucuronidation of these leads to the formation of a (moderately good) leaving group, which after being cleaved off leaves behind a strongly electrophilic and genotoxic aryl nitrenium ion. Mildly acidic conditions, which are usually present in the urine, but not neutral pH, suffice to produce this situation. The hydroxylamines are converted into glucuronides as transport forms, which survive their journey in the blood from the liver where they are produced to the bladder where they dissociate and lead to bladder cancer (alternative conjugation reactions, sulfation and acetylation, of aromatic hydroxylamines form better leaving groups, which already dissociate at neutral pH).<sup>1,53</sup>

The families and subfamilies of UGTs<sup>52</sup> are described elsewhere in this book (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). The most important family toxicologically is UGT1.<sup>54</sup> A single gene codes for at least 10 different proteins of this family. Differential splicing results in mRNAs that differ in the sequence of their first exon and are identical in the sequences of exons 2–5. The N-terminal portions of the resulting proteins, which correspond to the variable exon 1, contain the substrate binding sites. Therefore, the corresponding UGTs differ in their substrate specificities. These range from the endogenous bilirubin to pharmacologically active drugs such as morphine, to carcinogen precursors, such as benzo[*a*]pyrene-7,8-dihydrodiol. Therefore, a defect in this gene can have dramatic consequences. Heritable human diseases that have been attributed to such defects are the Crigler–Najjar syndrome and the Gilbert syndrome. The hyperbilirubinemia that results from the reduced or lost capacity to detoxify bilirubin can lead to an early death (Crigler–Najjar type 1). An experimental model for this disease is the Gunn rat. Owing to a mutation in exon 2 it lacks all UGT1 proteins. Rats are less sensitive than humans to the toxic action of bilirubin. Gunn rats can survive the lack of these UGTs, which makes them useful as a tool for studying the toxicological consequences of this defect.<sup>1</sup>

#### 5.08.3.2.3 Sulfotransferases (E.C. 2.8.2)

Sulfotransferases (SULTs)<sup>55</sup> catalyze the transfer of a sulfonyl group from 3'-phosphoadenosine-5'-phosphosulfate (PAPS) to nucleophilic substituents of their substrates, analogous to the UGTs. Accordingly, SULTs are often detoxifying enzymes for the same reasons discussed above for the UGTs. On the other hand, sulfoconjugation is in a predictable fashion also an important toxication mechanism for several types of precarcinogens.<sup>55,56</sup> Aromatic hydroxylamines, metabolically produced from aromatic amines by CYP, are metabolized by SULT to aromatic *N*-O-sulfate esters, which heterolytically decompose to the sulfate anion and to the genotoxic nitrenium ions. Sulfation of benzylic alcohols leads to the formation of reactive carbenium ions after cleaving off the sulfate group. Thus, mice with

an inherited deficiency in the synthesis of the cofactor required for SULT activity, PAPS, are less prone to develop liver cancer when treated with the hepatocarcinogen 1'-hydroxysafrol.<sup>1</sup>

SULTs have a substrate spectrum similar to that of the UGTs, except they do not conjugate carboxylic acids. Generally, SULTs have a lower  $K_m$  than UGTs. Hence, an important detoxification function of SULT is the efficient conjugation of low amounts of xenobiotics. They have a high affinity but only limited capacity for their substrates. The concentrations of the respective cosubstrates are in line with this: the PAPS concentration in the human liver is about 50  $\mu$ M and UDPGA is present at an approximately 10-fold higher concentration. Thus, in general, drugs are preferentially sulfated at low concentrations and preferentially glucuronidated at high concentrations. When interpreting results from toxicity testing it is important to note that if for a given drug one of these pathways represents a detoxification and the other a toxification, low environmental or moderate therapeutic doses can lead to the opposite effect to the high concentrations used in toxicity tests.<sup>1</sup>

The SULT families<sup>55</sup> are described elsewhere in this book (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions).

#### 5.08.3.2.4 Acetyltransferases (included in E.C. 2.3.1)

Two acetyltransferases (ATs) have major implications in drug metabolism: *N*-acetyltransferases 1 and 2 (NAT-1 and NAT-2)<sup>57</sup> (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). Both enzymes catalyze the acetyl transfer from acetyl-CoA to amines or hydroxylamines.

Since, in contrast to most phase II reactions of drug metabolism, the metabolites of NAT reactions (typically amides) are usually less hydrophilic than their parent compounds (typically amines), the function of NAT appears to be primarily the inactivation of biologically active, potentially toxic compounds, rather than a conversion to more hydrophilic metabolites.<sup>1</sup> The role of NATs in the detoxification of the procarcinogenic aryl amines is ambivalent but dependent on the nature of the substrate: *N*-acetylation of the aromatic amine is a detoxification reaction, since it competes with the formation of the hydroxylamine, i.e., with the initiation of the toxification pathway. However, if *N*-oxidation takes place first, the resulting hydroxylamine is also a substrate for NAT leading to the *N*-*O*-acetate ester (an acetoxamino-group) from which acetate is easily cleaved off, which results in the generation of a reactive nitrenium ion. Thus, the balance between toxification and detoxification is in part determined by the velocity of the oxidative pathway relative to the acetylation pathway, which in turn is in part dependent on the substrate in question. In man, this leads to a high interindividual variability in risk since the expression of CYP1A2, the major contributor to the hydroxylation of aromatic amines, differs greatly among individuals, and NAT-2, which is often quantitatively very important in the acetylation of aryl amines and aryl hydroxylamines, is polymorphic. Slow acetylators are very slow in the acetylation of aromatic amines and their metabolites. The acetylator phenotype appears to be decisive for the organ selectivity of the tumor formation. Rapid acetylators are less susceptible to bladder cancer development caused by (occupational or therapeutic) aromatic amines since rapid acetylation effectively competes against the first step (hydroxylamine formation) in the major toxification pathway. Conversely, rapid acetylators have a higher risk of developing colorectal cancer. The causative agents for these colorectal cancers may be heterocyclic aryl amines arising from amino acids during high-temperature food preparation, such as PhIP. These are poor substrates for both NATs, hence oxidative formation of the corresponding hydroxylamines is favored. This makes NATs into predominately toxifying enzymes in this case. Hence, rapid acetylators are at greater risk for developing colorectal cancer from the food-derived heterocyclic amines in the gut.<sup>58</sup>

The NAT-2 polymorphism also has consequences for drug toxicities. Isoniazide, for example, has a very prolonged half-life in slow acetylators, which can lead to accumulation and toxicity. The acetylator phenotype can be assayed with caffeine as an *in vivo* probe.<sup>59</sup> One strong cup of coffee is sufficient for this purpose. A ratio between the metabolites 5-acetylamino-6-amino-3-methyl uracil (AAMU) and 1-methylxanthine (1X) greater than two indicates a rapid acetylator.

#### 5.08.3.2.5 Methyltransferases (E.C. 2.1.1)

Methyltransferases are important in drug metabolism related control of toxicities in only a few cases. Beta-lyase products of the glutathione conjugation pathway can be detoxified by methylation of the free SH group competing against the formation of highly reactive and highly toxic thioketenes derived from perchloroethylene (*see* Section 5.08.3.2.1). Some catechol-moieties-containing drugs can be *O*-methylated by the catechol *O*-methyltransferase preventing the formation of toxic quinones. The enzymes catalyzing these reactions are mainly specialized to endogenous substrates. The cosubstrate for these reactions is usually the *S*-adenosyl methionine.<sup>1</sup>

## 5.08.4 Factors Influencing Drug Metabolism and Consequent Drug Toxicities

### 5.08.4.1 Modulation of Expression and Activity of Drug-Metabolizing Enzymes and Consequences for Drug Toxicities

Drug-metabolizing enzymes may be modulated by:

- increase of the amount of enzyme protein ('induction' in the broad sense of the term, usually but not always due to transcriptional activation);
- decrease of the amount of enzyme protein ('repression' in the broad sense of the term, sometimes but not always due to transcriptional repression);
- increase of the enzyme's specific activity, i.e., higher activity of the same amount of enzyme protein (activation); and
- decrease of the enzyme's specific activity (inhibition).

Induction by substrate is a strategy to economically meet the demands of drug metabolism without excessive waste of resources. In the strict sense induction is defined as an enhanced rate of transcription. In drug metabolism the term is used to describe an increased amount of enzyme protein regardless of the underlying mechanism. An enhanced stability of the protein and/or mRNA are included in this loose definition. Information on *in vitro* induction assays can be found elsewhere in this book (see 5.10 *In Vitro* Studies of Drug Metabolism).

The substrate-induced induction of drug-metabolizing enzymes leads to pharmacokinetic tolerance, an important mechanism of drug interactions and consequent toxicities. As an example treatment with narrow-therapeutic-window anticoagulants (e.g., warfarin), which are substrates of phenobarbital-inducible CYP2Bs, CYP2Cs, and/or CYP3As, simultaneously with inducers of these CYPs, such as the hypnotic drug phenobarbital, lead to a strong increase in the metabolism of these anticoagulants reducing their plasma concentrations. In order to maintain an effective therapy this necessitates a corresponding increase in the dose of the anticoagulant. When the concomitant treatment with the inducer is discontinued this can result in drastic drug toxicity. The decrease in the activity of the induced enzymes leads to accumulation of the anticoagulant, which may result in massive internal bleeding, and eventually death.<sup>1</sup>

Repression of drug-metabolizing enzyme expression in some instances occurs when induction of one set of drug-metabolizing enzymes goes at the expense of the expression of another set of drug-metabolizing enzymes. Some peroxisome proliferators that induce CYP4A, UGT1A1, and sEH decrease the expression of several other CYPs and also that of some GSTs. Cytokines such as interleukin 1 $\beta$ , interleukin 6, and interferon  $\gamma$  repress the expression of several CYPs. Therefore, inflammatory processes may substantially alter the rate of drug metabolism and the metabolite pattern.<sup>60</sup>

Activation of drug-metabolizing enzymes has been reported in relatively few cases. Alpha-naphthoflavone has complex effects including activation of some CYPs. Clotrimazole and isoquinoline enhance the *in vitro* activity of mEH toward styrene oxide considerably (fivefold). Diethyl ketone and structurally related solvents lead to a strong increase of UGT2B3 activity toward 2-aminophenol, resulting in a marked change in the substrate preferences.<sup>1</sup>

Inhibition of enzyme activities can occur as a result of interaction of the inhibitor with the enzyme resulting in isoenzyme-specific inhibition, or by cofactor depletion, the latter affecting all enzymes that depend on the respective cofactor. CYP1A2 significantly contributes to the metabolic inactivation of caffeine. Drugs/drug candidates that at the intended therapeutic concentrations inhibit CYP1A2 (e.g., fluvoxamine, furaflyline) can strongly reduce the caffeine tolerance of individuals with an initially high CYP1A2 activity. This can lead to intoxication by regular coffee intake. Naringenin and related flavone glucosides are effective inhibitors of CYP3A4 at dosages that can be reached by drinking a glass of grapefruit juice. This may reduce the susceptibility to chemical carcinogens that are activated by CYP3A4, but increase unwanted drug effects of CYP3A4 substrates. Since 3A4 is the CYP that metabolizes the greatest number of therapeutic drugs, CYP3A4 inhibition is of great practical importance for drug toxicity.<sup>1</sup>

### 5.08.4.2 Significance of Interindividual Differences for Drug Metabolism-Associated Toxicities

Genetic polymorphisms are a major cause of interindividual differences in drug metabolism (Table 4)<sup>61–67</sup> (see 5.10 *In Vitro* Studies of Drug Metabolism). Several of them have an important impact on drug metabolism and must be taken into consideration in drug therapy and to avoid drug toxicities. Also, the susceptibility toward chemical carcinogenesis is profoundly influenced by polymorphisms of drug-metabolizing enzymes. The consequences of individual polymorphisms are discussed above where the individual drug-metabolizing enzymes are described (Sections 5.08.3.1 and 5.08.3.2).

**Table 4** Polymorphic drug-metabolizing enzymes

| <i>Established</i> | <i>Suspected</i> |
|--------------------|------------------|
| CYP1A1             | FMO              |
| CYP2A6             | UGT2B7           |
| <b>CYP2C9</b>      | SULT1A3          |
| CYP2C18            |                  |
| <b>CYP2C19</b>     |                  |

Reproduced from Oesch, F.; Arand, M. Xenobiotic Metabolism. In *Toxicology*; Marquardt, H., Schäfer, S. G., McClellan, R., Welsch, F., Eds.; Academic Press: New York, 1999, pp 83–109, with permission from Elsevier.  
Bold print: especially important.

During ontogenetic development individual drug-metabolizing enzymes develop differently with pronounced consequences for drug toxicities. Human CYPs are already active in the fetus at about the fourth month of gestation, but appear in rodents only 2–3 days before birth. Also, sulfation and acetylation develop early in humans while the glucuronidation of bilirubin is still underdeveloped in the neonate This causes severe problems in neonatal erythroblastosis leading to a toxic accumulation of bilirubin resulting in jaundice. In some CYP families the expression of individual enzymes changes from fetus to adult. Thus, in humans the fetal CYP3A is CYP3A7, which disappears during development and is replaced by the adult CYP3A4.

Sex differences in the expression of drug-metabolizing enzymes are frequent in several experimental animal species, especially the rat, but are usually not pronounced in humans. In the rat there are marked sex-specific differences in the CYP2A, CYP2C, and CYP3A subfamilies. In humans, some drugs that are preferentially metabolized by CYP3A4 are cleared at rates that differ by twofold between the genders. Women have a lower alcohol clearance than men and therefore are more susceptible to alcohol intoxication.<sup>1</sup>

5.08.4.3    **Species Differences**

During its evolution, every animal species was under an individual selection pressure with regard to drug metabolism, in major part dictated by its preferred diet. Thus, some major species differences in drug metabolism<sup>68,69</sup> may tentatively be rationalized by species-specific requirements. Cats are exclusively carnivores. They almost completely lack the ability to glucuronidate xenobiotics, presumably because they do not have a need to render the easily glucuronidatable plant flavonoids or alkaloids excretable. For less obvious reasons, pigs are slow in drug sulfation and dogs are poor acetylators. The rat has extremely low levels of sEH in the liver.

It is important to choose the appropriate animal species for the analysis of the metabolism of a drug, in order to make predictions for metabolism-dependent toxicities in man. An impressive example of wrong predictions concerning toxification versus detoxification was the use of cynomolgus monkeys as an animal species closely related to man in the assessment of the carcinogenicity of heterocyclic amines present in cooked meat. Cynomolgus monkeys do not possess the heterocyclic amine toxifying CYP1A2. Thus, the study gave false-negative results. In contrast, these heterocyclic amines were potent carcinogens in the marmoset, a primate with a significant level of CYP1A2.

Toxicologically important species differences also occur in the regulation of enzyme expression. Peroxisome proliferators lead to an increase in the number and size of peroxisomes. Peroxisomal beta-oxidation, which produces hydrogen peroxide, is induced together with several drug-metabolizing enzymes by peroxisome proliferators. Treatment of rodents with peroxisome proliferators led to hepatocellular carcinomas. Peroxisome proliferation, the putative reason for the increased liver cancer incidence, did not occur to a significant extent in humans. Therefore, the peroxisome-proliferating hypolipidemic fibrates, which induce liver cancer in rodents, are rightfully still used in human therapy.

Since drug metabolism takes place predominantly in the liver, primary hepatocytes from experimental animal species and from man are often good predictors of drug metabolism-dependent drug toxicities and hence also of the best choice of an animal model for metabolism-dependent drug toxicities.<sup>70,71</sup> An example is the stomach parietal cell proton pump inhibitor pantoprazole that caused death in dogs by formation of the toxic benzimidazole, which was formed by dog but not by human hepatocytes.<sup>68</sup> An additional excellent model is that of 'humanized' mice in which genes coding for individual xenobiotic metabolizing enzymes have been knocked out and replaced by related human genes.<sup>72</sup>

#### 5.08.4.4 Consequences of Stereoselectivity in Drug Metabolism for Metabolic Toxicification

Enzymes are chiral and interact with their substrates stereoselectively and enantioselectively. Enantioselective toxicification has been shown for nitrogen mustard-derived cytostatic drugs, such as cyclophosphamide and ifosfamide. Also, metabolic toxicification of procarcinogens often proceeds with high stereoselectivity. A striking example is the toxicification pathway of benzo[*a*]pyrene, which ultimately leads to the potent genotoxic metabolite 7,8-dihydrodiol-9,10-epoxide (see Figure 3). Four chiral centers are present in this reactive metabolite (carbon atoms 7, 8, 9, and 10). The conformation at position 7 relative to position 8 is usually *trans* and that at position 9 relative to position 10 must be *cis*. This reduces the number of possible diastereomers from 16 to 4. Of these, the (+)-*anti* enantiomer (absolute configuration R,S,S,R) is the most abundant dihydrodiol epoxide formed during the mammalian metabolism of benzo[*a*]pyrene. Unfortunately, in addition it has the highest tumorigenic potential of the 7,8-dihydrodiol-9,10-epoxides derived from benzo[*a*]pyrene.<sup>73</sup>

#### 5.08.5 Conclusion

Over the course of evolution organisms were faced with the problem of how to counteract internal accumulation of xenobiotics to toxic levels. These xenobiotics were ever changing in their chemical structures since all other organisms also underwent evolution. Hence, those organisms that developed xenobiotic metabolizing systems that could deal with compounds of highly differing structures were in an advantageous situation for better survival. The problem was solved by (1) developing enzymes catalyzing reactions that work on many different structural elements; and (2) development of many enzymes and isoenzymes with broad and overlapping substrate specificities. For the former, the price that has to be paid is that these reactions because of their lack of specificity convert some substrates into harmless metabolites and others into highly toxic metabolites. Drug metabolism studies have made and will continue to make great progress in elucidating the molecular details of these reactions, which enables us to recognize which combination of structural elements of chemical compounds will be converted by which enzyme to highly toxic or harmless metabolites. This will help us to understand and predict species differences in drug metabolism, to define the risk for humans, and to recognize whether for a given chemical compound more susceptible developmental stages, physiological/pathophysiological conditions or, due to genetic polymorphisms in defined drug-metabolizing enzymes, more susceptible entire populations exist. All this will bring us a great step closer to the development of safer chemicals and drugs and to the safer use of them.

## Biographies

**Barbara Oesch-Bartlomowicz** passed her Medical State Examination at the Pommeranian Medical Academy, Szczecin, Poland in 1978, and was awarded her License to Practice Medicine in 1979. In 1981 she was a Visiting Scientist at the Institute for Biocatalysis, Academy of Sciences, Berlin-Buch, Germany. She was awarded her MD degree in 1983 by the Pommeranian Medical Academy, Szczecin, Poland where she obtained her License in 1984 as a specialist in Pharmacology and Toxicology and as a specialist in Dermatology. In 1987 she was a Visiting Scientist at the Institute of Toxicology, University of Mainz, Germany. Between 1988 and 1989 she was a Scholar of the European Science Foundation. In 1989 she became a Research Associate at the Institute of Toxicology, University of Mainz, Germany, becoming a University Assistant in 1994. In 1999 she was nominated Professor of Pharmacology and Toxicology. In 1996 she was a visiting scientist at the Department of Environmental Toxicology, University of California, Davis, USA. Professor Oesch-Bartlomowicz is currently University Docent, Institute of Toxicology, University of Mainz.

**Franz Oesch** obtained a PhD from the University of Fribourg, Switzerland in 1969. In 1973 he became Privatdozent at the University of Basel, Switzerland. Between 1974 and 1981 he was Professor (C3) of Pharmacology and Toxicology and Head of Section for Molecular Pharmacology at the University of Mainz, Germany. From 1981 on he was Professor

(C4) of Pharmacology and Toxicology initially (1981–1983) as Chairman of the Department of Molecular Pharmacology, then (from 1983 on) as Director of the Institute of Toxicology, University of Mainz.

Professor Oesch has been awarded the following prizes:

Professor Max Cloetta Prize 1977; American Society of Pharmacology and Experimental Therapeutics Award for the best publication of 1980 in Drug Metabolism and Disposition; Robert Koch Prize 1982; GUM Prize of the Environmental Mutagen Society 1985; Prize of the Rheinisch-Westfälische Academy of Sciences 1989; German Cancer Prize 1990; Hoechst-Marion-Roussel-Price 1998; and Prize for Scientific Innovation of the State Rheinland-Pfalz 1999. Other honors include: Most Quoted Scientists: belonging to the top 0.1% (Current Contents No. 41, October 12, 1981); Keynote Lecture, International ISSX Meeting, Amsterdam, 1991; Otto Warburg Memorial Lecture, Berlin, 1992; Election to the Academia Europea, 1992; Keynote Review, International EAPCCT Congress, Zürich, 1998; Keynote Lecture, European Workshop on Drug Metabolism, Copenhagen, 1998; The Gerhard Zbinden Memorial Lecture Award, EUROTOX, London, 2000; and Werner Heisenberg-Medaille, 2000.

### 5.09.1 Principles of the Immune System

The immune system is the organ that fights infection by pathogenic organisms such as bacteria, viruses, protozoa, or even worms. It also protects against toxins, for instance those from bacteria. The defense system of invertebrates against pathogens is simple, relying mostly on macrophages and bactericidal substances. In vertebrates, however, highly specialized cells have evolved, capable of producing cells with receptors of high binding specificity against literally billions of molecules, be they peptides, lipids, sugars, metal salts, or other chemical classes. The vertebrate immune system is a unique organ in that it is composed of a multitude of cells, molecules, and organized tissue structures, found distributed over the entire body as its field of action ([Table 1](#)). Immune cells are mobile and capable of communicating directly with each other by cell surface structures, or over considerable distances via lymphokines and chemokines. Close cell–cell contact is often necessary to orchestrate an effective immune response. Lymphoid organs are found at many sites in the body and can provide the relevant spatial structures for this contact. The number of lymphocytes (T and B cells) in the human body is approx.  $10^{12}$ , i.e., about the same as the number of cells of the brain or the liver.

Several features of the immune system must be considered when looking at the possible impact of chemical substances on the immune system: (1) the continuous differentiation and de novo generation of immune cells, (2) the capacity of the specific immune system to distinguish between structures of the own body and foreign structures (called ‘self’ and ‘nonself’) and between harmless and harmful molecules, (3) the high mobility of immune cells, (4) the sequestration of certain cell types within the body, (5) immunologic memory, and (6) communication with the environment via specialized signal transduction and cell surface receptors ([Table 2](#)).

All cells of the immune system, lymphoid and myeloid, are generated throughout life from the common hematopoietic stem cell, and have individual lifespans ranging from a few days (e.g., granulocytes) to many years. For instance, memory T and B cells can live several years.<sup>1–3</sup> Differentiating immune cells pass many checkpoints, which

are either intrinsically programmed or triggered exogenously, e.g., by antigen. Most checkpoints are at the same time ‘points of no return,’ and there appears to be very limited transdifferentiation. Immunotoxic substances can interfere with cell differentiation, cell homeostasis, or immune functions of cells. Various differentiation stages and cell lineages can become targets of chemical substances, e.g., by affecting intrinsic cell programming or interfering with the quality of the necessary exogenous stimuli such as antigen presentation (Figure 1). Thus, it is important to think of the immune system as a continuously dynamic spatial and temporal organ in order to understand any toxic interference by chemicals and to evaluate risks.

The immune system can be divided into the nonadaptive (or innate) part and the adaptive immune system. The adaptive immune system has ‘memory,’ i.e., it can react faster and better on a renewed contact with the chemical, even after years of not having had any exposure. The cells of the innate immune system use surface receptors to recognize bacterial structures, and initiate defense reactions against them directly. Moreover, the innate defense reaction may include recruitment and instruction of cells of the adaptive immune response, for instance via secretion of cytokines or chemokines. Adaptive immune responses by T cells and B cells can in principle respond to any given structure, i.e., any protein (T cells and B cells), lipid (some specialized T cells, B cells), sugar chain, or chemical substance (B cells only), and mount a humoral or cellular response. Antibody producing B cells, cytokine producing helper T cells, and killer T cells capable of directly killing infected cells recognize pathogenic insult in a uniquely specific way, by virtue of their receptors. These receptors are generated by a genetic process involving stochastic rearrangement of gene segments to finally give rise to coding genes for the millions of different B cell or T cell receptors. B cell receptors in soluble form are also known as antibodies. Every single B cell or T cell has a receptor specificity different from any other B cell or T cell. Because the process of genetic rearrangement is stochastic it will also generate receptors with undesired specificities, i.e., with specificities against molecules of one’s own body. Destruction of self – autoimmunity – can be the consequence. The status of not mounting an immune response against self antigens is called tolerance. Not being tolerant against self would pose a strong risk for the body, thus many mechanisms exist to ensure tolerance. The most prominent mechanism is the elimination of autoreactive T cells, which react with good affinity against self proteins; this happens directly after T cells are generated in the thymus.<sup>4</sup> The process has its limits where self proteins are not present in the thymus to begin with,<sup>5</sup> or where self proteins are modified outside of the thymus, e.g., by xenobiotic substances, and thus ‘look’ foreign. The latter phenomenon is important in immunotoxic effects of many chemical molecules, as will be discussed in detail below.

The immune system also must ignore or not recognize, let alone fight, harmless structures such as food constituents, inhaled pollen, proteins from animal hair, or many xenobiotic chemicals of the environment whether inhaled, ingested, or

**Figure 1** Schematic sequence of immune cell differentiation using T cells as example. Starting with the hematopoietic stem cell in the bone marrow, cells proliferate and differentiate in a well-defined sequence. Transcription factor cascades and regulated expression of surface receptors (to make use of external factors such as interleukin-7 (IL7) produced by the stroma of the bone marrow or the thymus) ensure that the differentiation steps are followed through in a tightly controlled fashion. For T and B cells, selection processes at defined differentiation stages serve to eliminate autoreactive cells (indicated by **X X**). The dotted arrows indicate that from the stem cells other lineages derive as well; eventually T and B cells, granulocytes, macrophages, erythrocytes, platelets, etc. are produced. The late phases of T and B cell differentiation are antigen driven, i.e., the signal to move on into effector cells is antigen contact. For T cells this contact is provided through binding of the T cell receptor with antigenic peptides in association with surface major histocompatibility complex (MHC) molecules on specialized antigen-presenting cells. B cells can be activated by soluble antigen. Black flashes: possibilities for chemicals to act adversely on general immune cell functions. Grey flash: possibility for chemicals to interfere with the specific immune response to antigen (see text).

contacted on the skin. Similar to the tolerance against self, the body is under normal circumstances tolerant against such molecules.<sup>6,7</sup> If this is not the case, we speak of allergy. Allergies and xenobiotic induced autoimmunity are called adverse immune reactions. Adverse immune reactions are common, range from mild to severe, and may even cause death.<sup>8</sup>

### 5.09.2 The Two Basic Immunotoxic Action of Chemicals: Unwanted Activation and Unwanted Shutdown

The World Health Organization has estimated that at least 100 000 different chemicals are on the market, most of them with unknown immunotoxic potential. The complex nature of the immune system as sketched above allows for two very different mechanisms how low-molecular-weight chemicals such as drugs, food additives, metal salts, naturally occurring chemicals, or any of the many chemicals used in industry, agriculture, or household products can become immunotoxic (**Figure 2**). Chemicals or their metabolites can exert toxic effects on the immune system as the target organ. Any cell type can be affected, granulocytes, stem cells, natural killer cells, lymphocytes, etc. From the point of view of an immunologist, this type of immunotoxicity is nonspecific because it is not mediated by the specific antigen receptors on B or T lymphocytes. This type of immunotoxic effect will not lead to memory to the chemical in an immunological sense. Immunotoxic effects of this type usually cause immunosuppression, whose severeness may vary considerably, depending on the cell(s) affected. However, also examples of unspecific immunostimulation are known, for instance silicosis.<sup>9,10</sup>

Secondly, chemicals or their metabolites can act by the immune system. This means they interfere with the response mediated by the specific antigen receptors of B and/or T cells. Chemicals may be recognized as antigen and elicit immune responses, or they may directly or indirectly change self antigens and thus break tolerance. It is generally accepted by now that T cells are the major players in xenobiotic-induced autoimmunity and allergy. Chemicals acting by the immune system lead to sensitization and a memory response. Memory lymphocytes can expand and mediate a stronger immune response on second contact with the chemical, even if it occurs long after the first contact. Adverse immune reactions of this type may lead to allergy or autoimmunity.

#### 5.09.2.1 Immunological Tolerance

As pointed out above, tolerance is a necessary feature of the immune system and usually exists toward self proteins and against harmless antigens, such as food. Immune tolerance is an active process at both the B cell and

**Figure 2** The two principal ways in which chemicals can change normal immune response. (a) They can lead to general dysfunction of the immune system, by destroying cells or disturbing their function. Immunosuppression might lead to more infections, or more severe illness. This type of adverse immune reaction is nonspecific in an immunological sense, i.e., it is not antigen-related. Typical example for this type is the immunotoxicity of dioxins. (b) If chemicals change antigen presentation, the resulting response is antigen-specific, will involve T cells and B cells, will and lead to memory and amplified secondary immune responses. These adverse immune reactions lead to immune responses against self (autoimmunity) or against normally harmless substances (allergy). A typical example is the allergic potential of penicillin. Black line: course of a normal immune response; dotted line: course of an immunotoxic reaction.

T cell level. Potentially harmful autoreactive B cells or T cells are eliminated in the bone marrow or the thymus. In this process, termed negative selection or central tolerance, future T cells die by apoptosis in the thymus, if their T cell receptor can bind with high affinity to self peptides presented on major histocompatibility complex (MHC) molecules.<sup>4</sup> B cells get negatively selected against in the bone marrow.<sup>11</sup> Outside of thymus and bone marrow, i.e., in the periphery (bloodstream, tissues, lymphoid organs), other mechanisms exist.<sup>12,13</sup> T cells need two signals to become activated: one is the antigen contact, the other is provided by surface molecules of the antigen-presenting cell. In general this second signal is not present on cells of uninjured and uninflamed tissue. Moreover, T cells do not enter healthy tissues, so self proteins are sequestered and do not come in contact with potential autoreactive T cells. Some self antigens, which need extra protection, are physically sequestered and not accessible to T cells at all, e.g., proteins in the chamber of the eye, or the brain. A second important mechanisms ensuring tolerance is the existence of regulatory T cells, which have received particular attention in recent years.<sup>14,15</sup> Regulatory T cells, also known as CD4<sup>+</sup> CD25<sup>+</sup> T cells because they express these two surface molecules, suppress the proliferative response and the production of inflammatory cytokines. Dendritic cells also play a pivotal role in balancing peripheral immune responses and maintaining tolerance. The means how such tolerogenic dendritic cells work are not entirely clear but include inducing T cells to no longer proliferate or produce cytokines (so called anergic T cells), as well as regulatory T cells, and suppressive cytokine secretion. Understanding tolerance mechanisms and manipulating tolerance is currently a highly dynamic research area.

### 5.09.2.2 Antigen Presentation

In general, T cells only respond to peptide antigens. The peptides of 8–10 or 13–17 amino acids length must be placed in the groove of MHC molecules, which are membrane proteins present on all nucleated cells of the body (MHC class I) or upregulated on lymphoid cells (MHC class II). MHC class II can be significantly induced by  $\gamma$ -interferon.<sup>16</sup> The T cell receptor never binds to ('recognizes') the antigenic peptide alone, but to the peptide–MHC complex. Antigen recognition is the immunologists' expression for an affinity achieved through noncovalent interactions between the T cell receptor and the peptide–MHC proteins, such as hydrophobic, electrophilic or van der Waals forces. If the affinity passes a given threshold, a signal is relayed into the T cell interior,<sup>17,18</sup> triggering the cellular response, i.e., the antigen is 'recognized.'

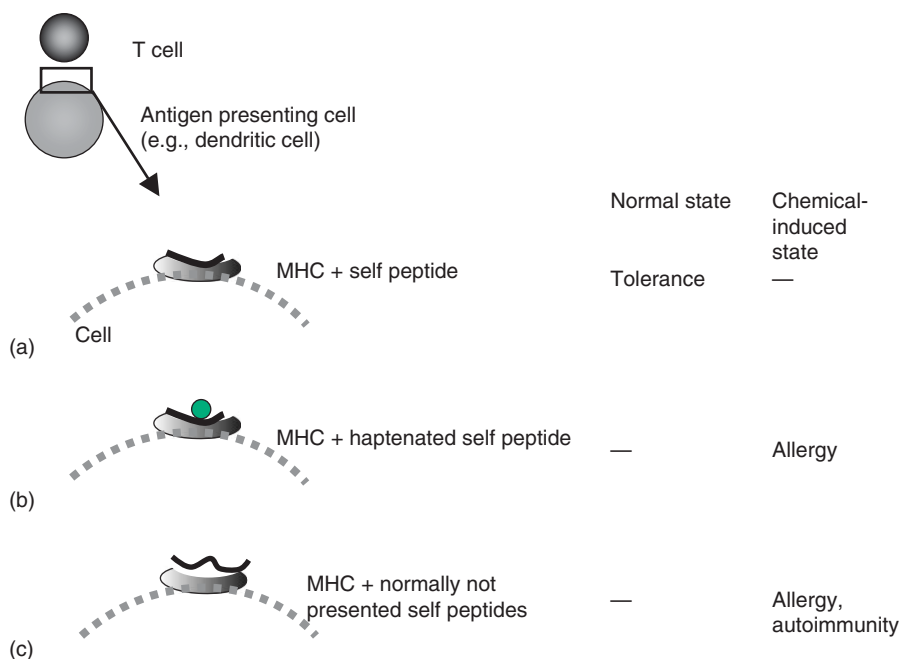

Antigen presentation on MHC molecules is an immunologic feature, which involves enzymatic digestion of proteins, and several metabolic processes. Briefly, protein antigens are degraded in the cell into peptides, transported onto MHC molecules, which are then brought to the cell surface for possible recognition by T cells.<sup>19</sup> Intracellular self proteins or proteins from pathogens living in the cytoplasm (e.g., viruses) are degraded by proteasomes and transported into the

endoplasmatic reticulum for loading onto MHC class I molecules.<sup>20</sup> In contrast, extracellular proteins are taken up by phagosomes, degraded, and loaded onto MHC class II molecules in the lysosomal compartments.<sup>21</sup> Accordingly, xenobiotic substances can have several routes of attack.

### 5.09.3 Unwanted Activation: Breaking Tolerance by Low-Molecular-Weight Chemicals

#### 5.09.3.1 The Hapten Concept

Low-molecular-weight chemicals (commonly with a molecular mass of less than 1000 Da) are not recognizable by T cells. However, if they are reactive and capable of binding to proteins they may become part of presented peptides (**Figure 3**) as so-called haptens. In particular electrophilic properties of a chemical will enable it to react with nucleophilic groups of proteins such as the thiol group in cysteins (–SH), amino group of lysine (–NH<sub>2</sub>) or the hydroxy (–OH) group of tyrosine.<sup>22</sup> Known reactive chemicals are isocyanates, quinones, aldehydes, epoxides, beta lactams, and certain nitroaromatics. If a chemical is very reactive, the immune reactions will take place at the site of first contact, e.g., the skin or the lung. Formation of novel antigens recognizable by T cells ('neoantigens') has been shown using the classical hapten trinitrophenol,<sup>23</sup> the sensitizing compound of poison ivy, 3-pentadecyl-catechol (urushiol),<sup>24</sup> or penicillin.<sup>25</sup> Penicillin-induced allergies have been intensively studied. There are immediate type and delayed type forms of penicillin allergy, clinically evident by, e.g., exanthema, urticaria, or specific immunoglobulin E (IgE) formation.<sup>26</sup> The contact sites of T cells with the protein penicilloyl adduct have been mapped. **Table 3** lists examples of known chemicals that form protein adducts (hapten–carrier conjugates in immunological terms) and can lead to adverse immune reactions. Frequently, protein reactive haptens lead to sensitization after dermal contact or inhalation.

**Figure 3** Possible outcomes of the formation of protein adducts with low-molecular-weight compounds. T cells recognize peptides lying in a groove of the cell surface molecule MHC. T cells with receptors that would recognize self peptides are eliminated in the thymus. (a) Those which escape the thymus elimination processes are kept in an inactive state in the healthy situation. (b) Low-molecular-weight chemicals which can bind to presented peptides, covalently or not, change the form of the peptide, which no longer 'looks' like a self antigen. T cells can react. Binding to the peptide can occur inside or outside of the cells, depending on the chemical. (c) Low-molecular-weight chemicals can change either the protein degradation or the loading of peptides in the cell and lead to a changed pattern of presentation and presentation of normally not presented peptides. Thus, even if presented peptides are 'self,' T cells will exist with receptors specific for them, as the selection processes in the thymus will have used the normal set of self peptides, not the cryptic ones. Note that binding of the T cell receptor to the peptide inside the MHC groove is necessary but not sufficient for T cell activation. A second signal, i.e., yet another contact of surface molecules by T cells and antigen-presenting cell, must be provided. This is discussed in the context of the danger hypothesis in the text.

Metals and their salts can also interact with proteins, either by their oxidizing properties, or as haptens, as they can form highly stable coordination bonds with certain amino acids in peptides.<sup>27,28</sup> Nickel salts are a well-known example of this type.

### 5.09.3.2 The Prohaptens Concept

Many low-molecular-weight chemicals are not protein reactive themselves. However, they can become subject to cell metabolism by the xenobiotic metabolizing enzymes (cytochrome P450, glutathione *S*-transferases, *N*-acetyltransferases, quinone reductases, etc.). Haptenic reactive intermediates can form and cause adverse immune reactions (Table 4). The chemicals are often called prohaptens and the process bioactivation. While the liver is the major detoxifying organ and expresses the necessary enzymes for bioactivation, the extrahepatic metabolism appears to be more important for the conversion of low-molecular-weight chemicals into haptens of immunotoxic potential. Extrahepatic metabolism is found in macrophages,<sup>29</sup> white blood mononuclear cell, or the skin.<sup>30</sup> Dermal Langerhans cells, or at least Langerhans-like cell lines, can metabolize xenobiotics as shown for dimethyl-benzanthracene and urushiol.<sup>31</sup> Surprisingly, keratinocytes also have bioactivating capacity.<sup>32</sup> For many enzymes of the xenobiotic

**Table 3** Examples of some chemicals known to cause adverse immune reactions

| <i>Compound</i>          | <i>Adverse immune reaction</i>                                      | <i>Hapten-carrier conjugate shown</i> | <i>Specific T cells demonstrated</i> |

| Sulfamethoxazole           | Nitrososulfamethoxazole         | Skin reactions                             |
| Tienilic acid              | Tiophene sulfoxide              | Autoimmune hepatitis                       |
| Urushiol                   | 3-Pentadecyl- <i>o</i> -quinone | Contact dermatitis                         |

<sup>a</sup> Clinically observable in humans.

metabolizing system, isoforms with differing activity are known. Genetic polymorphisms of these enzymes may influence the generation of reactive metabolites among humans and hence, may be connected with differing susceptibilities to drug-induced adverse immune reaction. For the enzyme *N*-acetyltransferase clear associations with the slow acetylator genotype and procainamide have been shown.<sup>33</sup> Of patients developing severe erythema multiforme variants following sulfonamide treatment the slow acetylator phenotype is more common than in controls.<sup>34</sup> Other substrates (e.g., dihydrazalazine, dapsone, sulfasalazine, isoniazid) of *N*-acetyltransferase, which also cause drug-induced adverse immune reactions, have not been tested for associations. Detecting an association of an autoimmune or allergic disease with genetic polymorphism of xenobiotic-metabolizing enzymes indirectly points to a substrate of those enzymes as etiological agents. For psoriasis a protective action associated with the rarer variant alleles of *CYP1A1* was shown, although a possible chemical involved remains enigmatic.<sup>35</sup>

### 5.09.3.3 The Danger Hypothesis: Low-Molecular-Weight Chemicals as Adjuvants

T cells get activated only if they receive two signals, one via antigen recognition by the T cell receptor, the other from an independent receptor–ligand cell surface interaction, also called the costimulatory signal. Additionally, cytokines produced from cells of the innate immune system appear to be necessary.<sup>16,36</sup> The theory of a danger signal<sup>37</sup> claims that T cells will react only if antigen is presented in the context of danger. Known endogenous danger signals are uric acid, heat shock proteins, nucleotides, reactive oxygen intermediates, extracellular matrix breakdown products, and cytokines like the interferons (IFNs).<sup>37–43</sup> The danger signal can upregulate costimulatory signals on the antigen-presenting cells, notably the dendritic cells, thus providing the second signal necessary for the T cell to react.<sup>40</sup> In adverse immune reactions the danger signal might come either from the chemical or from an independent source, for instance provided by an unrelated ongoing infection, where viral or bacterial products alert the dendritic cells. In agreement with this, drug hypersensitivity reactions are more common in patients with certain concomitant viral infections.<sup>44</sup> Alternatively, the chemical can provide the danger signal itself, either through causing cell damage, or by direct upregulation of costimulatory molecules or cytokines.<sup>45</sup> For instance, 2,4,6-trinitrochlorobenzene (TNCB), 2,4-dinitrofluorobenzene (DNFB), 2,4-dinitrochlorobenzene (DNCB), and nickel sulfate induce IL1 $\beta$  in Langerhans cells,<sup>46–48</sup> or mercuric chloride aids in secretion of IL1 by macrophages.<sup>49,50</sup> Haptens, such as DNCB, TNCB, DNFB, NiCl<sub>2</sub>, MnCl<sub>2</sub>, CoCl<sub>2</sub>, SnCl<sub>2</sub>, and CdSO<sub>4</sub>, have been shown to change the expression of the costimulatory molecule CD86 by dendritic cells. In most cases the mechanism of induction of the costimulatory signal is not known. As diverse as the haptens are the patterns of their effects.

One additional level of complexity must be considered. As described above, haptens can provide both signal 1 and signal 2 to T cells, although not all of them are bifunctional in this way. Moreover, haptens can contribute to the pattern of cytokines which are secreted by dendritic cells when they mature.<sup>51–54</sup> As a consequence, T cells differentiate either into T helper 1 or T helper 2 cells, which differ in their cytokine secretion patterns. Thus, the chemicals contribute to what type of an adverse immune response (type 1 or type 2) is triggered.

### 5.09.3.4 Direct Presentation via Cluster of Differentiations 1 (CD1) Molecules

For decades, the paradigm that T cells recognize only peptide antigens has held. Recently, it was discovered that T cells exist that recognize lipid moieties; recognition is not on MHC molecules, but on evolutionarily related cell surface proteins, the CD1 molecules.<sup>55</sup> Lipids from intracellular pathogens or self lipids can be presented.<sup>56</sup> The CD1 system also allows for polycyclic compounds to be presented, although alkyl chains are preferred.<sup>57</sup> Sulfisomidine, sulfadiazin, sulfasalazine, and celecoxib induce strong hypersensitivity reactions, and are possibly presented by CD1 molecules.<sup>58</sup> Thus, drugs may not only alter peptides and be recognized after covalent binding as haptens, they may simply be presented themselves in a noncovalent way. Apparently, noncovalent binding and associated presentation can also occur via the MHC system.<sup>59</sup> No drug metabolism is required in this case, and the binding is labile. Nonetheless, the immunological consequences may be as dangerous as those of covalent binding.<sup>60</sup> Well-studied examples are sulfamethoxazole, lidocaine, and carbamazepine.<sup>61–63</sup>

## 5.09.4 Unwanted Shutdown

### 5.09.4.1 Basic Considerations on Immunosuppression

Proliferation and de novo protein synthesis are necessary for an immune response. Chemicals and drugs can interfere with these physiological functions independent of any activation of antigen-specific cells (as described in the previous sections). Immunotoxic reactions of this type lead either to immunosuppression or to immunostimulation.

Immunosuppression by chemicals can be caused by (1) killing of cells of the immune system, (2) changes in cell differentiation leading to fewer or incapacitated immune cells, and (3) changes in typical cell function such as cytokine secretion or expression of costimulatory molecules. For many drugs and chemicals the exact mechanism by which they change immune functions has not been assessed. Rather, the literature brims over with publications titled “Effects of  $x$  on parameter(s)  $y$ .” Although often not satisfying for lack of knowledge on the relevant mechanisms, at least these studies show the broad scope of interference. In some cases the unknown mechanism will turn out to be adverse immune reactions as described above, but often action is nonspecific in the immunological sense. Interference may, however, be highly specific in terms of protein chemistry, e.g., interaction with intracellular enzymes, signaling molecules, transcription factors, or other proteins. The action of dioxins, furans, glucocorticoids are very good examples of this (*see* Section 5.09.4.2.1).

Immunosuppression is an operational term describing an immune system operating with less efficiency than normal. Immune responses may start later, or they might be weaker. Immunosuppression might be general, or restricted to certain pathogens. Whether their immunosuppression is caused intentionally by pharmacotherapy, or unintentionally by environmental chemicals, immunosuppressed individuals are more susceptible to infections and the development of spontaneous cancers. Epidemiologically, immunosuppression can be measured by comparing the average healthy population with a particular subgroup, e.g., workers exposed to a toxic substance. However, no easily accessible and universally accepted markers for immunosuppression have been identified *in vivo*, and the considerable functional reserve of the immune system must be exceeded before immunosuppression becomes clinically relevant.<sup>64,65</sup> Loss of immune cells (unless very large scale as in acquired immunodeficiency syndrome (AIDS)), or a shift in proportion of cells in the blood or in lymphoid organs is of limited diagnostic value in humans. Standard immunotoxicity tests to detect immunosuppression or potentiation have been developed and validated.<sup>66,67</sup> It is worthwhile to keep in mind, however, that both acute clinical illness and small shifts in the susceptibility to normal infections are of medical and economic relevance.

In the following an attempt will be made to look at some examples of actions on the immune system where interference with cellular functions are known in more detail.

## 5.09.4.2 Signal Transduction and Immunotoxicity

### 5.09.4.2.1 Single-pathway multieffect chemicals

Perhaps the most important, certainly among the best-studied immunosuppressive environmental chemicals, are the polycyclic halogenated aromatic hydrocarbons (PHAHs), in particular the prototypical substance 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD).<sup>68</sup> Other substances with known immunosuppressive effects are pesticides, organotin compounds, lead, cadmium, and mercury molecules.<sup>69,70</sup> Immunosuppressive PHAHs are polychlorinated biphenyls, dioxins, furans, and others. PHAHs are usually found in mixtures in the environment, and their relative and additive risks can be calculated using the toxic equivalence factor,<sup>71</sup> which describes toxicity in relation to TCDD.

The immune system is a highly sensitive target of TCDD, and thymus atrophy and immunosuppression are hallmarks of even low doses of dioxin exposure in all laboratory species.<sup>68</sup> A dose of only 10 ng TCDD kg<sup>-1</sup> body weight suffices to induce thymus atrophy in mice.<sup>72,73</sup> The common mechanism of action underlying PHAH toxicity is the activation of an endogenous transcription factor, the arylhydrocarbon receptor (AHR). The exact biochemistry of activation of the AHR has been elucidated in detail. Briefly, lipophilic PHAHs diffuse into the cells, bind with high affinity to the AHR, which then translocates to the nucleus, heterodimerizes with its partner molecule, the arylhydrocarbon receptor nuclear translocator (ARNT), binds to short promoter sequences, and induces gene transcription.<sup>74</sup> Many genes can be targeted by the activated AHR, depending on cell type and cell stage.<sup>75–77</sup> With respect to the immune system, TCDD can cause apoptosis, inhibit cell proliferation of T cell precursors, downregulate IgM production by B cells, upregulate costimulatory molecules on antigen-presenting cells, induce cytokine production, etc.<sup>78,79</sup> While dioxins are immunosuppressive, they also have other effects, such as teratogenicity, tumor promotion, dermatological problems, changes in lipid metabolism, or oxidative stress. The pleiotropic action of the toxic substance (here PHAHs) is not based on a multitude of interactions with various cell proteins, but due to the characteristics of the targeted tissue.

TCDD action differs depending on cell type and cell stage. In immune cells, many TCDD-inducible genes have now been identified using various methods.<sup>75,80</sup> Genes responsive to TCDD include for instance cytokine genes (IL1 $\beta$ , IL2, tumor necrosis factor alpha (TNF- $\alpha$ )), apoptosis genes (FasL, TRAIL), differentiation markers (Notch-1, CD44, CD69), costimulatory signals (CD40, CD80), depending on the cell type and cell differentiation stage. Gene expression profiling of isolated cell types (hepatocytes, thymocytes) has been performed with TCDD-treated cells versus controls. The results of these experiments illustrate several important points: many more genes are modulated after exposure than was

originally thought; signaling can be direct or indirect (via AHR-triggered secondary or tertiary events); and exposure regimen is relevant. Moreover, interaction of TCDD with the AHR to achieve transcriptional gene activation is controlled at many levels, e.g., species specificities, cell stage specificities, abundance of the AHR in the cytoplasm, or competition for additional DNA-binding factors. The detailed analysis of TCDD-induced (immuno)toxicity has thus led many scientists to acknowledge a single-pathway–multieffects concept, i.e., the realization that despite a single underlying biochemical pathway, the outcome on the cellular, organ, or systemic level can be very diverse. This has to be considered in any risk assessment, predictive assays using model cell types, or interpretation of molecular and cellular events by TCDD, or any other substance suspected to be immunotoxic.

#### 5.09.4.2.2 Multi-pathway multieffect chemicals

Cells follow their intrinsic programs, but more often they communicate intensely with their environment and adapt to it. Physiological functions such as protein expression or proliferation can be triggered and controlled by chemical or physical exogenous signals, which are relayed into the cells by a limited number of signal transduction pathways. Major pathways are direct ligand activation of latent transcription factors, G protein-coupled receptors, the mitogen activated protein (MAP) kinases, and the Janus kinase (JAK)–STAT pathway.

Tests for immunotoxicity can use typical responses as readouts such as induction or inhibition of lymphocyte proliferation. Indirectly such effects then point to an interference of the chemical in question with one of the signal transduction pathways. Many chemicals have been tested for their ability to inhibit proliferation. However, only for a few chemicals have the underlying mechanisms been addressed. Knowledge of the pathways is necessary for a more rational risk assessment, or for any need to manipulate the effects, e.g., in drug usage. As activated immune cells (in particular T cells and B cells) proliferate extensively, these cells are particularly sensitive to any chemicals that interfere with proliferation.

Two examples shall serve to detail how low-molecular-weight chemicals can interact with signaling pathways, and eventually lead to a shutdown or decrease of immune capacity.

##### 5.09.4.2.2.1 Arsenite

Various forms of inorganic arsenic have been used in agriculture and forestry as components of pesticides and insecticides. Arsenic has become an environmental pollutant of great concern. Worldwide millions of people are exposed to doses believed to be immunosuppressive.<sup>81</sup> Chronic exposure to arsenic is associated with the suppression of hematopoiesis, damage to humoral and cell-mediated immunity,<sup>81,82</sup> and suppression of cytokine production.<sup>83</sup> For arsenic it could be shown that the JAK–STAT pathway is directly inhibited, abolishing STAT activity-dependent expression of suppressors of cytokine signaling (SOCS), and eventually affecting IL6 expression.<sup>84</sup> The JAK–STAT signaling pathway mediates the immune response of various cytokines and growth factors, and thus participates in inflammation. In contrast to TCDD, arsenic is not a single-pathway molecule as, e.g., interaction with the signaling pathway of c-Jun–N-terminal kinase was shown as a causal factor of arsenite mediated apoptosis in tumor cells.<sup>85</sup> Upstream events of c-Jun kinase inhibition were studied in T lymphocytes and membrane structures identified as the first signal affected by arsenite, probably needing interaction between arsenite and protein sulfhydryl groups.<sup>86</sup>

##### 5.09.4.2.2.2 Organotin compounds

Organotin compounds are chemicals with at least one covalent Sn–C bond. They are widely used as polyvinyl chloride (PVC) stabilizers, biocides, or antifouling paints and have given rise to ubiquitous environmental contamination.<sup>87</sup> They are known to be immunotoxic, to induce thymus atrophy in experimental animals, and to decrease proliferation of human lymphocytes.<sup>88</sup> Apoptosis by organotin compounds is apparently mediated by caspase activation triggered via the mitochondrial pathway and the death receptor pathway. Like the pleiotropic effects of PHAHs the effects of organotin differ depending on the cell type and on the exposure regimen.<sup>89,90</sup> In natural killer cells, for instance, the MAP kinases p38 and p44/42 are activated by the organotin tributyltin.<sup>91</sup> Consideration of the dose effect is highlighted in organotins, as different doses have strikingly different outcomes, ranging from necrosis and apoptosis to subtle changes in cytokine secretion by T helper cells.<sup>92</sup>

##### 5.09.4.2.3 Immunosuppressive drugs

Immunosuppressive drugs are of enormous clinical relevance. Their mechanisms of action are known in better detail than for environmental chemicals. The search for new and better immunosuppressive drugs continues and will draw on

information about the immune system on one hand, and on the action of chemicals on immune cells and intracellular signaling on the other hand.

In general, the action of immunosuppressive drugs is due to a direct interaction of the drug with immunocompetent cells,<sup>93</sup> in particular with signal transduction. Cyclosporine A and FK506 (tacrolimus) bind to cyclophilin or FKBP12, respectively, and inhibit calcineurin.<sup>94–96</sup> As a consequence the signaling pathway normally triggered by T cell receptor/antigen activation gets blocked and cytokines are not produced as necessary.<sup>97</sup> Another macrolide, rapamycin, also binds to FKBP12, but instead of targeting calcineurin, the complex binds to ‘target of rapamycin’ (TOR), a serine-threonine kinase with important functions in cell growth and proliferation. TOR inhibition by rapamycin prevents phosphorylation of proteins important for translation.<sup>98</sup> The rapamycin-FKBP12 complex blocks signaling pathways of nuclear factor kappa B (NFκB) as well, and it inhibits cyclin C kinases.<sup>99</sup> The action of rapamycin extends to suppression of actin synthesis by activated T cells, with consequences for cell motility and the formation of the immunological synapse.<sup>100</sup> Other macrolides can block actin polymerization as well.<sup>101</sup>

Another class of immunosuppressants, the glucocorticoids, induce genes directly via the glucocorticoid receptor (a transcription factor) and the respective promoter elements, the glucocorticoid receptor elements (GREs), of the targeted genes. Also, glucocorticoids weaken the activation of T cells by interfering with the immunological synapse.<sup>102</sup> In the thymus, where development of T cells takes place, this leads to a change of the affinity sensitivity window within which T cells are activated or deleted when their T cell receptor binds to antigen. While thymocytes get killed in the thymus upon glucocorticoid treatment, in the periphery the same treatment changes the sensitivity of T cells toward antigen activation. The immunosuppressive action of glucocorticoids thus is not only restricted to gene modulation, but targets the very beginning of T cell activation, namely the integration and relay of the signals from the immunological synapse. The action on the immunological synapse can affect both sides, the T cells and the antigen-presenting cell. However, makrolides and glucocorticoides appear to have contrasting impacts in this regard.<sup>93</sup>

Histone deacetylase inhibitors (HDACIs) are a new emerging class of immunosuppressive drugs with great potential. They are also of interest in cancer treatment. Histone deacetylase inhibitors induce hyperacetylation of core histones modulating chromatin structure and affect gene expression. Treatment with HDACIs eventually can also cause apoptosis. As expected, the mechanisms of HDACI are pleiotropic because of their capacity to modulate gene expression. Downregulation of IL2, changes in CD154 expression after antigen contact, and other changes contribute to their immune cell specific action.<sup>103</sup> In [Table 5](#) some more examples of immunosuppressive drugs are listed. It must be emphasized that a common pattern of effects does not equate to a common molecular mechanism.

### 5.09.5 Toxicogenomics

All immune responses in all immune cells pass at some point through the executive step of up- or downregulation of genes. De novo synthesis of cytokine genes, surface molecules, cytoskeleton structures, and so on, are part of the response against antigens, and require controlled gene expression. Thus, the effects of chemicals on the immune response will become evident to some extent by changes in transcription in the individual participating immune cells. This is the basis of toxicogenomics, which has an increasing impact on drug discovery, safety evaluation, elucidation of pathways of toxicity, and risk assessment. The method of gene expression profiles is as follows: short or long DNA sequences of between several hundred genes (usual for complementary DNA (cDNA) microarrays) or several tens of thousands of genes (Affymetrix microarrays covering almost all genes in a genome) are spotted onto a tiny membrane, silicone chip, or glass chip. The RNA of the cells or an organ to be analyzed is isolated and hybridized to the genes on the chip. Either radioactive-based or fluorescent-based methods allow the detection of the formed cDNA hybrids (presence, absence, and relative abundance). Sophisticated computer-assisted evaluation then allows the experimenter to get lists of differentially expressed genes, cluster them into functional groups, and eventually pinpoint detailed expression patterns, and even signaling networks. Gene expression profiles become more and more important in the assessment of risk for new chemicals. Chemicals are usually screened in a tiered approach.<sup>66,67</sup> Tier I screening assays are more coarse and look at general pathology. Tier II assays look closer at immune responses. Smaller-scale microarray chips can be used to screen for immunotoxic effects such as cytokine modulation. The question of which part of immunotoxic risk testing (tier I or tier II) gene expression profiling would be best integrated into is still open. ‘Immunotox chips’ on which genes for cytokines, chemokines, adhesion molecules, or costimulatory molecules are spotted are already on the market. Global gene expression profiles in addition help in hypothesis generation when the molecular immunotoxic action of a chemical is unknown. New genes regulated under the influence of the chemical can be identified, and further analyzed by classical molecular and cellular approaches.

**Table 5** Examples of immunosuppressive drugs<sup>a</sup>

|                                     |   |
|-------------------------------------|---|
| <i>Glucocorticoids</i>              |   |
|                                     | Dexamethasone   |
|                                     | Methylprednisolone  |
| <i>Macrolides (from soil fungi)</i> |   |
|                                     | Everolimus (derivative of rapamycin)  |
|                                     | FK506 (tacrolimus)  |
|                                     | Pimecrolimus  |
|                                     | Rapamycin (sirolimus)   |
| <i>Histone deacetylases</i>         |   |
|                                     | Apicidin [cyclo( <i>N</i> - <i>O</i> -methyl-L-tryptophanyl-L-isoleucinyl-D-pipecolinyl-L-2-amino-8-oxodecanoyl)] |
|                                     | FR23522 (from <i>Acremonium</i> sp.)  |
|                                     | FR901228  |
|                                     | Oxamflatin  |
|                                     | Phenylbutyrate  |
|                                     | Pyroxamide  |
|                                     | Sodium butyrate   |
|                                     | Suberoylanilide hydroxamic acid   |
|                                     | Trapoxin  |
|                                     | Trichostatin A  |
| <i>Other</i>                        |   |
|                                     | Cerivastatin (3-hydroxy-3-methylglutaryl coenzyme reductase inhibitor)  |
|                                     | Cyclosporin A   |
|                                     | Leflunomide   |
|                                     | Prodigiosin 25 C (from <i>Serratia marcescens</i> )   |
|                                     | Microcolin A (lipopeptide from <i>Lyngbya majuscula</i> )   |
|                                     | 2,2'-[3-Methoxy-1'-amyl-5'-methyl-4-(1-pyrryl)]dipyrrylmethene (from <i>Micrococcus</i> sp.)                      |

<sup>a</sup> Mechanisms of action vary. Note that not all mentioned substances are in clinical use; for some, only animal data are available.

**Figure 4** Summary of possible immunotoxic effects of low-molecular-weight chemicals. For details see text.

As the immunotoxic effects are unknown for the vast majority of the chemicals on the market, let alone their mixtures, it is urgent to take toxicology (i.e., immunotoxicology) from a predominantly observational science at the level of disease-specific models to a predominantly predictive science focused upon a broad inclusion of target-specific, mechanism-based, biological observations. At the same time, toxicogenomics might provide routes to valid and robust biomarkers of exposure.

## 5.09.6 Conclusions

The immune system is an organ composed of a large number of very different cell types with very different functions. Cell–cell interactions, mobility, responsiveness to external stimuli, memory, and continuous cell renewal are typical characteristics. Low-molecular-weight chemicals can biochemically interact with proteins produced by immune cells. Covalent or noncovalent binding with proteins can lead to adverse immune reactions affecting the specific, anamnestic responses of B or T cells and lead, depending on the circumstances, to allergy or autoimmunity. On the other hand, low-molecular-weight chemicals can interact with typical immune cell-signaling pathways, resulting in enhanced or repressed immune responses (Figure 4). The underlying mechanisms of both unwanted activation of the adaptive immune response and unwanted shutdown of the immune system in a general way are as diverse as the chemicals and the responsive cells and their targeted proteins. However, increasing knowledge of single substances and their mechanisms of inference leads to the detection of common patterns of reactions. Immunotoxicology and immunopharmacology are on the way from being a descriptive science to a mechanism- and chemical structure-based predictive science.

## Biography

**Charlotte Esser** studied biology at the universities of Cologne and T  bingen, and at Duke University, North Carolina. She received her PhD in immunology at the University of Cologne, Germany, in 1990. Her research focus at the Institute for Environmental Medical Research has been the immunotoxicology of xenobiotic substances and their interference with signal transduction pathways and T cell differentiation programs. Other topics of her research interest include protective strategies against UVB-induced immunosuppression, and genetic susceptibility loci to autoimmune diseases. She is Professor of Immunology at the University of D  sseldorf.

## 5.10 In Vitro Studies of Drug Metabolism

### 5.10.1 Introduction

During the screening and development of a new chemical entity (NCE) many studies are set up in order to better understand its pharmacokinetic and metabolic characteristics.<sup>1</sup> This knowledge increases during the lifetime of a drug.

At the registration level however, safety and efficacy are the prime concerns of any medical authority and studying metabolism can bring key elements to better understand these issues.

For metabolism studies, two important questions have to be answered: how does the metabolism in animals used for the toxicological/pharmacological evaluations compare and is it as representative as possible of the human metabolism? Is there any risk of drug interactions in the clinic? These two aspects should be the leitmotiv of any screening and development program in metabolism. In this chapter, we discuss how early in vitro metabolism studies can bring important decisional elements always keeping in mind the safety and efficacy profile of the NCE of interest.

Metabolism (*see* 5.07 Principles of Drug Metabolism 3: Enzymes and Tissues) has been defined as the chemistry of enzymatic and nonenzymatic processes. It covers the identification of the metabolites during early in vitro research programs and in classical in vivo metabolism studies in animals used in the safety program and in humans. It also implies to determine the major characteristics of the enzymes (mainly cytochrome P450 (CYP)) involved in these metabolic reactions. These data will allow one to predict, understand and control potential interactions with co-administered drugs in the clinic, and are of help in explaining metabolic related variability in the activity of a drug.

### 5.10.2 In Vitro Tools

In vitro tools (Table 1) can be divided into four groups: organs, cells (primary cultures and cell lines), subcellular fractions (S9, cytosol, and microsomes), and isolated enzymes (purified and recombinant enzymes).

#### 5.10.2.1 Organ-Derived Tools

The perfused organ represents the in vitro tool closest to the in vivo situation. The technical difficulties of maintaining the viability of the organs, even with complex perfusion media, together with ethical difficulties (availability of organs), have limited these methods mainly to mechanistic studies in animals.

As an alternative, liver slices, which retain the organ architecture, have been developed with more or less success depending on the incubation conditions. Organ slices contain the complete metabolism machinery with all phase I and phase II drug metabolizing enzymes so that a drug can undergo all possible metabolic reactions. They also contain the different cell subtypes that contribute to the global environment, i.e., interaction between Kupfer or biliary cells with hepatocytes leading to complex regulations in response to drug exposure. Once the problems of oxygen supply and nutrients diffusion up to the inner part of the slices are overcome, the well-preserved cell–cell communications make liver slices a unique model for the differentiated phenotype of hepatocytes, and thus can be applied to metabolism or toxicological studies.

To obtain reproducible, reliable, and predictive results in drug metabolic profiling, preparation of liver slices requires high-precision tissue slicers (e.g., Krumdieck or Brendel-Vitron) producing uniform and thin (less than 250  $\mu\text{m}$  thickness) slices.<sup>2</sup>

However, liver slices are not very often used in drug metabolism studies and even less often in the earliest stage of drug development because of major drawbacks such as the labor-intensive nature of the preparation, which requires

**Table 1** In vitro tools<sup>a</sup> for drug metabolism studies and their applications

<sup>a</sup> ++, model used in first intention; +, model used in second intention; + / –, model only used to address a specific question; –, not applicable.

fresh material. Also, there is no possible automation of the incubation process, no optimal cryopreservation conditions, a short storage time of the preparation (at 4 °C only), a short viability period (5 days), and the problem of damaged cells on the outer edge of the slice with impaired biotransformation.<sup>2</sup>

### 5.10.2.2 Primary Cultures and Cell Lines

#### 5.10.2.2.1 Hepatocytes

Primary hepatocytes are isolated from the whole liver (for animals<sup>3</sup>) or from liver biopsies (for humans<sup>4</sup>) by collagenase perfusion techniques adapted for human or animal species.<sup>2</sup> After isolation, the cells can be stored at 4 °C for up to 48 h in a solution (University of Wisconsin solution) without relevant loss of viability.<sup>5</sup>

Once isolated, Hepatocytes can also be kept in suspension, in which case they remain viable only for a few hours or can be maintained in monolayer cell culture for at least 4 weeks.<sup>2</sup> Details about the procedures to obtain and use this model have been reviewed by Gebhardt *et al.*<sup>6</sup>

Cell culture conditions have been optimized to overcome the dedifferentiation process leading to a decrease in enzymatic activity with time (especially for CYP2E1 and 3A4 enzymes<sup>7</sup>) enabling therefore long-term cultures of hepatocyte.<sup>8–10</sup> These culture conditions include the use of specific media (culture media, serum, additional components such as hormones and inducers), different matrix compositions (simple matrices such as rat tail collagen, or complex matrices such as fibronectins or, preferably, Matrigel) or cocultures with epithelial cells derived from primitive biliary cells.<sup>10</sup>

The collagen sandwich model<sup>11,12</sup> has been considered by some authors as the most reliable for studying drug biotransformation, induction, and also transporter-mediated biliary excretion,<sup>2</sup> since it gets closer to reality in terms of cell polarity and of structural and functional normal bile canalicular network or cellular integrity.

Cryopreserved hepatocytes have been shown to retain the activity of most of phase I and phase II enzymes.<sup>2</sup> Fairly successful predictions of in vivo hepatic clearance with cryopreserved hepatocytes in suspension and good correlation when compared to fresh cell cultures have been obtained,<sup>13–15</sup> making them suitable for early metabolism studies.

Moreover these cryopreserved hepatocytes can overcome the problems of interindividual variability and limited time of use after preparation that are encountered with fresh human hepatocytes, since several batches can be pooled (as with liver microsomes).

#### 5.10.2.2.2 Combined culture systems

To study enterohepatic metabolism, a new coculture system combining hepatocytes and intestinal bacteria has been developed. A two-chamber system under aerobic and anaerobic conditions allows analysis of the sequential metabolism of chemicals by liver and microflora in vitro. This model may help to obtain data on hepatic and microbial metabolism during the early phase of drug development.<sup>6</sup>

A new coculture system has also been developed to obtain a full picture of the role of presystemic compartment (including absorption and metabolism) and consists in combining Caco-2 cells and hepatocytes into two linked chambers.

#### 5.10.2.2.3 Hepatoma cell lines

The poor availability of human hepatocytes and their relatively short lifespan in standard cultures have encouraged scientists to develop hepatocyte cell lines. However, even though several sources of cell lines exist, they are still less popular than other in vitro models. This is mainly due to their dedifferentiated cellular characteristics and incomplete expression of the major families of metabolic enzymes.<sup>2</sup>

HepG2 has been the most frequently used and is the best-characterized human hepatoma cell line. It displays different patterns of metabolizing enzyme expressions according to the source and culture conditions limiting its interest as a real alternative for hepatocytes.<sup>16</sup>

Other cell lines such as HLE,<sup>17</sup> THLE,<sup>18</sup> BC2,<sup>19</sup> or Fa2N-4<sup>20</sup> express different metabolizing enzymes but not the full enzymatic profile.

HepaRG, a new hepatoma cell line, developed by Guillouzo's group,<sup>21</sup> has shown high degrees of similarity with fresh hepatocytes in term of morphology, express specific hepatic functions, in particular genotypic profiles for metabolizing enzymes (phase I and II), and transporters, and also in nuclear receptors (AhR, PXR, CAR, PPAR-alpha).<sup>22,23</sup> HepaRG represents a real and reliable alternative to human hepatocytes for drug metabolism and toxicity studies.<sup>22</sup>

In contrast with fresh or cryopreserved hepatocytes, these cell lines can be transfected with vectors that can mediate DNA or RNA constructs to either express, activate, or knockout a specific gene (BC2 cell line). Small

interfering RNA (siRNA) technology allows a specific gene to be quenched quite easily and sometimes permanently. The knockout of genes encoding for an enzyme, a transporter, or a nuclear receptor in these cell lines would be of great interest for enzyme or transporter phenotyping or induction mechanisms.

In addition to HepaRG, new avenues of research have been opened, in particular with human medullar cells that might be transformed into human hepatocytes under certain culture conditions.<sup>24,25</sup> Further studies should however be performed to confirm the full similarity of these cells both in terms of metabolic capacity and inducibility.

### 5.10.2.3 Subcellular Fractions

Subcellular fractions are obtained by successive centrifugations of tissue homogenates. While the S9 fraction is obtained after the first centrifugation step at about 9000 g, the microsomal fraction requires an ultracentrifugation at 100 000 g to separate the cytosolic soluble fraction from the microsomes.

These systems offer many advantages. They are commercially available from individual livers (inter-individual variation can be studied) or a pool of livers (representative of the average enzyme activities of the population). They can be stored and remain stable at  $-80^{\circ}\text{C}$  for many years and can be thawed easily. They are very easy to handle for several types of incubations and they are suitable for full automation. All of these advantages make them very useful for metabolism studies in the earliest stage of drug development including the screening program.

Subcellular fractions can be obtained from any tissue (liver, intestine, kidney, brain, etc.) with slight differences in the preparation procedure. We will focus on the liver subcellular fractions.

#### 5.10.2.3.1 Human liver S9 fraction

The liver S9 fractions contain both microsomal and cytosolic fractions. They regroup therefore the same metabolic enzyme profile (phase I and phase II enzymes including their cofactors) as hepatocytes with the exception of the membrane barrier and its transporters. Hence, S9 fractions offer a more complete representation of the metabolic profile compared with microsomes and cytosolic fractions.<sup>2</sup> They are therefore of great potential interest for in vitro studies in drug metabolism and drug interaction. However, their low enzyme activities compared to microsomes limit their use for drug metabolism studies.

#### 5.10.2.3.2 Human liver cytosolic fraction

The liver cytosolic fraction contains the soluble phase I enzymes such as esterases, amidases, or epoxide hydrolases and the soluble phase II enzymes such as most of the sulfotransferases (ST), glutathione *S*-transferases (GST), and *N*-acetyltransferases (NAT). For the catalytic activity of the phase II enzymes, some exogenous cofactors such as adenosine 3'-phosphate-5'-phosphosulfate (PAPS) for sulfotransferase activity<sup>2</sup> can be added especially in concentrated (ultrafiltration) cytosolic fractions.

Although this cytosolic fraction cannot be used as a complete metabolic system, it can help to address some issues in metabolic profiling for drugs that are metabolized by soluble enzymes. Coincubation with microsomes is also possible to obtain a more complete system.

#### 5.10.2.3.3 Human liver microsomes

Liver microsomes are by far the most widely used in vitro model, providing an affordable way to give a good indication of the CYP and UDP-glucuronyltransferases (UGT) involved in the metabolism of a drug.<sup>2</sup>

Liver microsomes, as vesicles of the hepatocyte endoplasmic reticulum, contain membrane phase I enzymes namely CYPs, flavine-containing monooxygenases (FMO), esterases, amidases, and epoxide hydrolases, and also the phase II enzymes such as UGTs. For the catalytic activity of both phase I and II enzymes, addition of exogenous cofactors such as NADPH for CYPs and FMO, and UDPGA/alamethicin for UGTs is necessary.

Liver microsomes are the model of choice (with human hepatocytes) for drug metabolism studies (metabolic profile and prediction of hepatic clearance) and drug interaction studies (phenotyping and inhibitory potential studies).

### 5.10.2.4 Isolated Enzymes

Microsomes containing specific individual human CYPs and UGTs have become extremely important methodological options for in vitro drug metabolism studies, in particular to investigate the contribution of enzymes involved in the biotransformation of an NCE.<sup>2,26</sup>

A variety of recombinant expression systems has been developed including insect, bacterial, yeast, and mammalian models. They have been reviewed in detail by Friedberg *et al.*<sup>27</sup>

The obvious advantage is that the activity of one specific human CYP or UGT can be studied in isolation. However, one has to keep in mind that such isolated systems have de facto no interaction with the other enzymes and factors present in intact cells. The lipids, the apoprotein nature, and the level of CYP coenzymes can all be different depending on the cell type, leading to potential over- or underestimation of the metabolic reactions.<sup>28</sup>

### 5.10.3 Rate of Metabolism

Besides the identifications of metabolites, which represented the major part of metabolism work in the past, determination of the rate of in vitro metabolism across species, organs, or enzymes has become more and more important in recent years.

#### 5.10.3.1 Michaelis–Menten Kinetics

The standard approach assumes that the drug obeys to Michaelis–Menten kinetics (Table 2):

$$v = \frac{V_{\max} \times S}{K_m + S} \quad [1]$$

where  $V_{\max}$  is the maximum rate of the reaction, and  $K_m$  is the Michaelis–Menten constant (concentration of the substrate  $S$  at which  $v$  is half maximal). The intrinsic clearance ( $CL_{\text{int}}$ ) can be obtained from

$$CL_{\text{int}} = \frac{V_{\max}}{K_m + S} \quad [2]$$

When the substrate concentration is lower than the  $K_m$  (negligible as compared to the  $K_m$ ), eqn [2] can be simplified as follow:

$$CL_{\text{int}} = \frac{V_{\max}}{K_m} \quad [3]$$

$CL_{\text{int}}$  then represents the slope of the initial linear part of the reaction velocity versus substrate concentration curve.

Proper determination of the enzyme kinetics ( $K_m$ ,  $V_{\max}$ ,  $CL_{\text{int}}$ ) of a compound requires to measure the rates of metabolite formation at several substrate concentrations and that the data fit to the simple Michaelis–Menten equation in case of a monophasic reaction (substrate metabolized by one enzyme) or to eqns [4] or [5] in case of multiphasic reactions.<sup>26</sup>

$$v = \frac{V_{\max(1)} \times S}{K_{m(1)} + S} + \frac{V_{\max(2)} \times S}{K_{m(2)} + S} \quad [4]$$

$$v = \frac{V_{\max(1)} \times S}{K_{m(1)} + S} + CL_{\text{int}(2)} \times S \quad [5]$$

**Table 2** In vitro enzyme kinetics

| Type of inhibition | Apparent $K_m$                                       | Apparent $V_{\max}$  | Michaelis–Menten equation   | $AUC_i/AUC^a$<br>prediction  |
|--------------------|--|--|---|--|
| No inhibition      | $= K_m$  | $= V_{\max}$   | $v = \frac{V_{\max} \times S}{K_m + S}$   |  |
| Competitive        | $= K_m \times (1 + I/K_{ic})$                        | $= V_{\max}$   | $v = \frac{V_{\max} \times S}{K_m \times (1 + I/K_{ic}) + S}$                       | $1 + I/K_{ic}$   |
| Uncompetitive      | $= \frac{K_m}{(1 + I/K_i)}$                          | $= \frac{V_{\max}}{(1 + I/K_i)}$   | $v = \frac{V_{\max} \times S}{K_m + S \times (1 + I/K_i)}$                          | $1 + \left(\frac{I}{K_i}\right) \times \left(\frac{S}{S + K_m}\right)$ |
| Mixed              | $= \frac{K_m \times (1 + I/K_{ic})}{(1 + I/K_{iu})}$ | $= \frac{V_{\max}}{(1 + I/K_{iu})}$  | $v = \frac{V_{\max} \times S}{K_m \times (1 + I/K_{ic}) + S \times (1 + I/K_{iu})}$ | $1 + I/K_{ic}$   |
| Noncompetitive     | $= K_m$  | $= \frac{V_{\max}}{(1 + I/K_i)}$   | $v = \frac{V_{\max} \times S}{K_m \times (1 + I/K_i) + S \times (1 + I/K_i)}$       | $1 + I/K_{ic}$   |
| Mechanism-based    | $= K_m$  | $= V_{\max} \times \frac{k_{\text{degrad}}}{\left(k_{\text{degrad}} + \frac{I \times k_{\text{inact}}}{K_i + I}\right)}$ | $\lambda = \frac{k_{\text{inact}} \times I}{K_i + I}$                               | $1 + \frac{V_{\max}}{V_{\max}(\text{inactivated})}$                    |

<sup>a</sup> In vitro to in vivo extrapolation.

This implies that the metabolites are available as authentic standards or that the radiolabeled drug has been synthesized. In early stages of drug development, such conditions are not fulfilled and an alternative approach must be considered.

A particularly adapted method for screening programs consists in measuring the intrinsic clearance of a drug using a substrate depletion approach called in vitro  $t_{1/2}$  approach described by Obach *et al.*<sup>29,30</sup> and using eqn [6]. A first-order depletion rate constant for a substrate is measured in an incubation at a single low concentration.

$$CL_{int} = \frac{\ln 2}{t_{1/2} \times [M]} \quad [6]$$

where  $[M]$  represents the concentration of microsomal protein.

This approach implies that the drug concentration used is below the  $K_m$  ( $10^{-7}$  M is a good compromise for screening purposes) and that the enzymes remain fully active throughout the incubation period. Any autoinactivation or product inhibition can lead to an underestimation of  $CL_{int}$  using this approach (see below).<sup>26</sup>

However, many of the enzymes implicated in the metabolism of xenobiotics are highly saturable so that the single substrate concentrations may not be low enough<sup>31</sup> to properly estimate the  $CL_{int}$ . To overcome this problem, two substrate depletion approaches have been developed.

The first method, proposed by Obach *et al.*,<sup>32</sup> consists in monitoring substrate concentration loss (in vitro  $t_{1/2}$  approach) at multiple substrate concentrations. The substrate depletion rate constant is plotted against the substrate concentrations and fitted to:

$$k_{dep} = k_{dep(S=0)} \times \left(1 - \frac{S}{S + K_m}\right) \quad [7]$$

The inflection point of the curve corresponds to the  $K_m$  and the maximum depletion rate constant is represented by  $k_{dep(S=0)}$ . This approach gives a better understanding of the enzyme kinetics of a compound ( $K_m$  available) than using the simple in vitro  $t_{1/2}$  approach.

The second method, developed in our laboratory,<sup>31,33</sup> and named substrate disappearance kinetic (SDK) method, provides apparent  $K_m$  and  $V_{max}$  for the overall metabolism of a drug, based on computer fitting of two in vitro disappearance curves using the following Michaelis–Menten integrated equation:

$$-\frac{dS}{dt} = \frac{t_{prot} \times V_{max} e^{-k_d \times t} \times S}{K_m + S} \quad [8]$$

Here  $t_{prot}$  represents the concentration of microsomal protein and  $k_d$  the enzyme activity degradation constant ( $\text{min}^{-1}$ ). This model offers the advantage to use only two substrate concentrations (surrounding the  $K_m$ ) and integrates the loss of enzyme activity with time (denaturation of the enzyme) conversely to the previous approach. This is particularly important for long incubation periods (low clearance drugs). This approach is particularly adapted for studies in early drug development.

### 5.10.3.2 Non-Michaelis–Menten Kinetics

The observation of atypical enzyme kinetics, particularly involving CYP, has become relatively common. Since predictions of in vivo clearances are based on kinetic parameters observed during in vitro experiments, misidentification of the drug kinetic profile can lead to inaccurate predictions of intrinsic clearance.<sup>34</sup>

The atypical kinetic profiles include autoactivation (sigmoidal kinetics or homotropic cooperativity), substrate inhibition, heteroactivation (heterotropic cooperativity), partial inhibition, and substrate-dependent inhibition (see Hutzler and Tracy<sup>35</sup> for a review of enzymes exhibiting atypical kinetics).

Among these atypical kinetic profiles, autoactivation kinetics have been more and more observed over the past few years, particularly for CYP3A and 2C9. In this case, the  $v$  versus  $S$  plot yields a sigmoidal curve, attributed to more than one substrate molecule simultaneously binding to the enzyme and stimulating the activity. To prevent the underestimation of the  $CL_{int}$  in case of autoactivation, Houston *et al.*<sup>36</sup> suggested the use of the  $CL_{max}$ , describing the steepest part of the  $v$  versus  $S$  curve and being visualized as the maximum point on a plot of  $v/S$  versus  $S$ . However this type of model<sup>36,37</sup> remains by far too complex to be integrated in early drug discovery.

### 5.10.3.3 Metabolic Stability

The prediction of in vivo hepatic metabolic clearance of a drug from its apparent intrinsic clearance requires theoretically to include the unbound fraction of the drug in plasma ( $f_{up}$ ). Interestingly, several authors reported an underestimation of the predicted in vivo clearance by taking into account the  $f_{up}$  alone.<sup>29,38,39</sup> A better correlation was observed between the actual and predicted clearance values when the free fraction in plasma was ignored in the equations describing hepatic extraction or when the nonspecific binding to microsomes ( $f_{umic}$ ) and plasma ( $f_{up}$ ) were both taken into account. Obach *et al.*<sup>29,38</sup> recommended to use both unbound fractions for the prediction of the in vivo hepatic clearance.

However, there are exceptions to this rule suggesting that other factors may influence the availability of the drug at the active site of the enzyme. This might be due to the use of isolated parameters ( $f_{up}$ ,  $f_{umic}$ ,  $CL_{int}$ ), measured separately, without taking into account the various competitions occurring at the cellular level. In early metabolism programs, with the event of 96-well plate technologies and complete automation, all these individual parameters can be measured today on series of compounds.

In theory, a drug must first dissociate from the nonspecific binding sites before it can bind to, and be metabolized by enzymes.<sup>29</sup> The availability of a drug at the enzymatic site is therefore dependent on both the specific and nonspecific binding to proteins as well as on the affinity toward metabolizing enzymes.

Coincubation models, including the interaction between plasma, nonspecific proteins present in the classical in vitro metabolism models, and metabolizing enzymes have therefore been developed. Isolated hepatocytes suspended in serum have been found to give more accurate predictions of hepatic clearances.<sup>40</sup>

### 5.10.3.4 Organ and Species Differences

Early discovery programs have mainly been based on in vitro hepatic tools using microsomes as the simplest and fastest in vitro model to generate the first metabolism data. Now that metabolic stability screens have been performed successfully with microsomes for a number of years, we observe more and more non-CYP reactions, particularly soluble enzymes metabolizing the drugs. Microsomal information is therefore very often completed with hepatocyte experiments, but these enzymes are also present in other tissues such as the gut or the lung and can be of major importance in the bioavailability of the drug.

Even drugs stable on hepatic tools (CYP- and non-CYP-dependent reactions) can be oxidatively metabolized in other tissues such as the gut. This is probably not related to catalytic differences between hepatic and intestinal enzymes but is more related to the protein binding properties of the drug of interest. For a highly protein-bound drug, the free fraction available to the enzyme is low in the liver but much higher in the intestine, because the drug is assumed to be free in the intestine. Intestinal extraction can therefore be as important or even greater than the hepatic extraction. Midazolam, as a highly protein-bound and pure CYP3A4 substrate, is a good example of the importance of intestinal (0.4–0.6) versus liver extraction (0.3–0.5).<sup>26</sup>

With regard to animal species, the rat is probably the most frequently used comparative species in early programs, which are completed later with dog and monkey data. However, one very often sees, with hepatic tools, major differences in rate between rat (rapid) and human (slow). The validity of the metabolic bioavailability predicted in humans is then questioned. One has to remember that these results only suggest that the compound is stable in the liver. However, because in many cases the liver is not the only metabolic organ, these results will have to be completed with extrahepatic in vitro tools. A typical example is, with the advent of combinatorial chemistry and the frequent use of amide bonds, the differences in hydrolytic activities between rodent species and larger species including humans, as well as some tissue differences (plasma, liver, and gut).

An interesting rodent species to be added in early programs is the mouse. This is documented as regards to the enzymatic content of the intestine. The importance of CYP3A isoenzymes in the mouse intestine appears to mirror that in humans, whilst in rat this family of enzymes is negligible and the CYP2C family is of prime importance.<sup>41</sup> This correlation between human and mouse can also be observed for the liver with common pathways and similar rates on chemical series conversely to the rat.

### 5.10.4 Metabolic Profiling

Today drug research programs, including early screening studies on large series of compounds and more informative studies on selected candidates, allow a rapid understanding of the in vivo fate of a drug candidate. These studies are able to define systematically, at early stages, the metabolic stability, drug permeability, and drug solubility of the drugs

tested, with the aim of selecting rapidly lead candidates.<sup>42</sup> These programs are then completed with in vivo studies in animals. But most of this early information is oriented toward predicting differences in rate of metabolism (clearances) with the ultimate goal of predicting the in vivo pharmacokinetic behavior of a drug. In comparing species only on the basis of their metabolic stability, one tends to forget sometimes the vast difference that can exist in the nature and amount of metabolite formed. Some phenomenon observed in animal species can be of little relevance to man as regards safety and efficacy profile of the NCE tested.

#### 5.10.4.1 Biological Importance of Metabolites

In the actual research and development programs, knowledge on metabolites has been described as important in order to assist in the selection of the appropriate compound for development.<sup>43</sup> Moreover, the chemical nature of the metabolites is essential because they have to be evaluated for their biological activity. This includes the evaluation of their activity in pharmacology, safety in toxicology and both safety and efficacy aspects in clinical programs.

Before discussing how the in vitro tools can give, as early as possible, an insight into both the safety and efficacy aspects of an NCE, it is worth trying to understand what the future requirements will be at the registration stage.

For the pharmacological/clinical aspects, some authors have proposed that the metabolites participating to the overall pharmacological activity (at least 25% of the total activity) and which are major in human,<sup>44</sup> will have to be monitored in future animal and clinical studies.

Although it is difficult to give an absolute number as a definition for a major metabolite, because it can be very much drug-specific, a number of proposals has been made which can be grouped in two categories:

1. For drug interaction purposes, some authors have proposed to initiate CYP phenotyping only for major reactions namely if a sum total of 25–30% of compound clearance appears to be related to the formation of primary oxidative metabolites.<sup>45,46</sup>
2. For safety testing of metabolites, the recent draft guidelines<sup>47</sup> have focused on circulating metabolites representing more than 10% of the administered dose or circulating drug related material, whichever is the less. The guidance describes a unique metabolite as one produced only in humans or formed to a much greater extent in humans compared to animal species used in toxicology programs.

In any case, identification of major active metabolites is essential for the interpretation of the clinical response.<sup>43</sup> The same applies for the safety profile of an NCE in animals in support of human safety: one has to compare exposures to individual metabolites or global routes of metabolism obtained in humans to those obtained in mutagenicity tests and animal species of the toxicological safety program. Some authors have highlighted the potential safety concerns of metabolites specific to humans as well as the presence of structural alerts.<sup>48</sup>

The question remaining to be answered is what can be defined as an adequate coverage and safety ratio. An optimal '25 times rule' difference in exposure between animals and humans has been discussed for either the parent drug or metabolites.<sup>44</sup> In a number of cases the net exposure, defined as the sum of the exposure to the drug and its metabolites, will have to be used. In practice, for minor metabolites which can be of importance in the safety aspects, it is not always easy to compare chemical entity per chemical entity throughout the species because of possible major differences in rate (formation and elimination), e.g., between rodents and humans. The combination of both chemical entities and common metabolic routes, using urinary and fecal metabolites, is then more appropriate. Safety aspects mainly focus on phase I pathways even though conjugation reactions can be of importance when dealing with mutagenicity and carcinogenicity mechanisms.

When looking at the degree of precision required in the assessment of safety and efficacy profiles of the drug and its metabolites before the clinical programs, one can easily see the enormous expectations put on in vitro tools in early research programs. They are frequently seen as decision-making tools, and it tends to be forgotten, as for other fields such as pharmacology or in vitro toxicology, that they are only models able to bring new building blocks to our understanding of particular series or processes. A combination of in vitro approaches together with tools integrating this information into a more physiological context has in recent years been a major step to increase our knowledge in early screening phases and to better challenge and combine our in vitro results. In any case, the actual recommendations are that attempts should be made as early as possible in the drug development process to identify differences in drug metabolism between animals used in nonclinical safety assessments compared to humans.

### 5.10.4.2 Identification of Metabolites

For biotransformation investigations of in vitro and in vivo studies in development programs, radioactively labeled drugs provide one of the most important tools to completely track the metabolites in complex biological matrices, such as blood, urine, feces, and bile, and in in vitro samples. The most frequently used approach is to administer the drug containing a radioactive isotope such as  $^{14}\text{C}$  or  $^3\text{H}$ . In combination with separation methods, e.g., liquid chromatography (LC), radioactive labeling allows the highly selective, sensitive, and quantitative detection of unknown metabolites. Coupled with mass spectrometric and/or other spectroscopic data it allows to completely elucidate biotransformation pathways for an administered drug. Major progress in the on-line radio detection such as LC-accurate radioisotope counting (LC-ARC) and LC topcount have brought the detection level from 200–500 disintegration per minute (dpm) down to 5–20 dpm.<sup>42</sup> These techniques are nowadays essential for the quantification of circulating metabolites. The use of radioisotopes is however not a good alternative in early research programs.

Identification of the metabolites produced in in vitro experiments is generally not performed in a screening approach. At this stage it is a difficult and time-consuming exercise. It can be done and is very useful on a few selected compounds most of the time at a somewhat later stage. This identification is performed using mass spectrometry (MS), which is an extremely powerful technique in the detection and identification of unknown chemical entities. However one has to remember that MS remains (in the absence of synthesized reference metabolites), a qualitative technique. Non or poorly ionizable compounds will also be difficult to detect using LC/MS/MS. Overall, the metabolic pathways obtained from microsomal incubations give a good picture of the primary reactions occurring in the drug, or in other words major metabolic reactions but not necessarily the major metabolites. One of the reasons can be the absence of secondary and tertiary phase I metabolites that are simply not formed in sufficient amount in the in vitro conditions. In vitro profiles can also in many instances give a reasonable qualitative picture of the circulating metabolites of major importance in the biological profiles of the drug. With hepatocytes and the presence of phase I soluble enzymes and phase II conjugation enzymes, we can complete the picture (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). Some in vitro/in vivo differences can also occur with regard to glucuronides predicted to be a major pathway in human hepatocytes but finally representing a minor metabolite in vivo. This can be the case for certain conjugation reactions of acids.

One of the pitfalls of early identification of metabolites is that most experiments are done on what we can call an a posteriori metabolite identification. The MS expert is searching for possible metabolites either on the basis of the chemical structure of the drug or making hypotheses on the sites of attack based on his knowledge of the metabolic reactions. This latter stage can be improved with the use of databases predicting potential pathway but the risk of missing an important metabolite or pathway exists (*see* 5.33 Comprehensive Expert Systems to Predict Drug Metabolism).

One interesting alternative could come from the treatment of data. One illustration can be derived from the metabolomic field (*see* 5.43 Metabonomics) where powerful statistical tools such as principal component analysis are used to follow the changes in urinary and plasma patterns of endogenous markers after treatment with a drug in comparison with a control. An automated treatment can enable to separate drug related from endogenous material in in vitro incubations as well as in vivo samples helping in the early identification of metabolites. This can be achieved with a reduced number of samples as compared with a classical metabolomic approach requiring statistical power. This approach has the advantage of being an a priori technique of metabolite identification. It gives information on the number of metabolites having an MS response (molecular ion) in the sample. Even if this technique is not quantitative in the absence of reference products, it allows one to monitor the change in concentration of these metabolites with the dose, comparing species, and can be applied to both in vitro and in vivo samples. Knowing the number of metabolites present in the sample allows a further identification to be performed to define the exact structure of these metabolite(s) using further LC/MS/MS techniques and LC-(NMR) nuclear magnetic resonance to position the chemical modification.<sup>42</sup>

### 5.10.4.3 Link between Metabolism and Safety

#### 5.10.4.3.1 Activity of metabolites

Historically, the selection of the large toxicological species using the in vitro interspecies comparison study performed with liver microsomes or hepatocytes was the major link between metabolism studies and safety (*see* 5.39 Computational Models to Predict Toxicity). Today, with the early identification of human metabolites, the question of their potential positive (pharmacological) or negative (toxicological) activity can be asked (*see* 5.08 Mechanisms of Toxification and Detoxification which Challenge Drug Candidates and Drugs).

Even though toxicity of a metabolite is difficult to identify in research programs, it can be defined as either an extension of target pharmacology or mediated via other receptors. In this case the on-line combination of mass spectrometric characterization and biological screening based on ligand–receptor or antigen–antibody interactions can be attractive for some applications. An example of such an approach is on-line affinity capillary electrophoresis–MS. The receptor is present in the electrophoresis buffer and the metabolite mixture is injected as the sample. Metabolites showing strong binding to the receptor are retained and thus separated from compounds that do not interact. On-line MS detection allows direct characterization of the interesting ligands.<sup>42</sup>

#### 5.10.4.3.2 Metabolites in genotoxicity tests

Genotoxicity is typically not an extension of the pharmacology and has to be studied separately. It represents today the earliest link with safety done during the early genotoxicity screens such as Ames II and in vitro micronucleus tests. When positive, many discussions on possible work around based on the nature of metabolites and/or degradation products as well as alternative compounds within a series are held within the research teams. With regard to genotoxicity screens, the presence of major human metabolites or a different metabolic pathway in comparison to those formed in the test is the prime information necessary.

The metabolic profile in the media used in these in vitro tests is essential for the understanding of the toxicological profile of the drug. This evaluation has therefore to be done in the strict conditions of the mutagenic test because of the hydrolytic enzymes present in certain media as well as in the light of the high concentrations used and the resulting frequent saturation of certain metabolic pathways. Because the activation media are most often from rat origin it would also be useful, when possible, to perform these tests in parallel with human activation in vitro media (S9 or microsomes).

#### 5.10.4.3.3 Structural alerts and reactive metabolites

It is well known that reactive structures or substructures as well as reactive metabolites formed after activation of chemicals by metabolic enzymes can potentially covalently bind to cellular proteins. This binding leads to modified proteins and can trigger various organ toxicities. A comprehensive listing of compounds, the proposed metabolic activation process as well as the type of toxicity observed is given by Evans *et al.*<sup>49</sup> As a logical consequence of metabolic activation, the liver, as the main metabolizing organ, is the main target organ of these reactive metabolites.

Capturing reactive xenobiotic metabolites using glutathione (GSH) or potassium cyanide are well-described techniques. These tests are performed in the presence of liver microsomes or hepatocytes and in the case of GSH the loss of the gamma-glutamyl moiety in MS analysis<sup>36</sup> can point toward a potential GSH adduct which however needs to be identified. A highly efficient screening method has been developed mixing natural GSH and GSH labeled with two <sup>13</sup>C and one <sup>15</sup>N (+ 3 in mass) in equal molar ratios. With this technique a unique MS signature is obtained with the presence of an isotopic doublet in MS.<sup>50</sup> There is no consensus with regard to the minimum amount of adduct acceptable in terms of safety. The threshold amount proposed is 50 pmol<sup>−1</sup>mg of proteins.<sup>50</sup>

Identifying potential structural alerts can be done with the appropriate databases containing more and more the potential structural alerts.

### 5.10.5 Drug Interactions

#### 5.10.5.1 Importance of In Vitro Tools in Drug Interaction Studies

Drug interactions can be defined as the modification of the safety and efficacy profile of a medication following the coadministration of drugs, environmental pollutants, ingredients or additives present in the diet (*see* 5.35 Modeling and Simulation of Pharmacokinetic Aspects of Cytochrome P450-Based Metabolic Drug–Drug Interactions).

Drug interactions are usually defined as being either of pharmacodynamic or of pharmacokinetic origin. These two aspects are closely linked and need to be studied together to evaluate both safety and efficacy in the clinic. Only the latter category, defined also as metabolism-based interactions (i.e., the alteration of the metabolic clearance of a drug by another coadministered drug) will be further detailed in this chapter.

With the increasing prevalence of polypharmacy,<sup>51,52</sup> these drug interactions have become more frequent,<sup>51,53,54</sup> and can lead to serious side effects, e.g., Cerivastatin<sup>55</sup> and increased morbidity and mortality.<sup>54</sup>

It is well recognized that testing in the clinic all the possible combinations between an NCE and the potential interacting compounds on the market is impossible for obvious cost and time reasons, but also because it is nonrelevant. In vitro studies have therefore become essential to explore the molecular mechanisms involved in these drug interaction processes with the aim of first selecting a compound with a safe or a controlled drug interaction profile but also in order to help in the future design and optimization of drug interaction clinical studies.

In 2003, the Pharmaceutical Research and Manufactures of America (PhRMA) Drug Metabolism and Clinical Pharmacology Technical working Groups have defined a minimal in vitro and in vivo pharmacokinetic drug interaction package for registration purposes.<sup>46</sup> In October 2004, a preliminary concept paper of the US Food and Drug Administration (FDA) has focused more on study design, data analysis, as well as implications on dosing and labeling.<sup>45</sup>

CYP are involved in the metabolism of more than 90% of currently available drugs<sup>56</sup> and are recognized by regulatory authorities as an important cause of drug interactions.<sup>57,58</sup> Therefore, the guidelines focus essentially on those enzymes that can be inhibited, activated, or induced by concomitant drug treatments. These changes in enzyme activities may significantly increase or decrease the exposure of the body to the drug or metabolites at potentially toxic levels. The approaches described can however be adapted to other enzymes.

This chapter suggests the following general topics to be investigated during the drug development program:

- Drug metabolism enzyme identification
- Evaluation of CYP inhibition
- Evaluation of CYP induction.

A pragmatic approach is recommended to define the drug interaction strategy which will, at the registration level, be able to justify the selection of the interacting compounds used during the clinical trials, limit the number of clinical studies to be undertaken, and, finally, in the labeling, position the compound as regards future comedications as well as suggest dosage adjustments if required.<sup>46</sup>

#### 5.10.5.2 Reaction Phenotyping

Reaction phenotyping consists in identifying the enzyme(s) involved in a metabolic reaction. Before initiating these phenotyping studies, one should ideally first determine the in vitro metabolic profile of a drug in humans (identity of the metabolites formed and their quantitative importance) and estimate the relative contribution of each enzyme to the total clearance.<sup>45</sup>

There is no rationale for performing CYP reaction phenotyping with an NCE if CYP-mediated reactions play only a minor role in the overall clearance, i.e., less than 25% as recommended recently.<sup>45</sup>

One has to keep in mind that in screening programs the use of in vitro tools most of the time only allows the assessment of the primary reactions of a drug but not necessarily the major in vivo pathways. The in vitro model selected at this stage will only be fully validated once the metabolic profile in humans is known. It is recommended that the metabolism of an NCE is examined in an, as complete as possible, in vitro system.<sup>46</sup> Freshly isolated hepatocytes are theoretically the best choice for conducting such experiments even though microsomes are preferred for technical reasons (characterization, availability, presence of membranes, etc.)

The enzymes involved in the drug clearance can be identified using four well-defined approaches:

1. Specific chemical inhibitors for each CYP (or other enzymes).
2. Specific antibodies for each CYP.
3. Individual human recombinant CYPs.
4. A bank of human liver microsomes characterized for CYP activities prepared from individual donor livers<sup>45</sup> (correlation studies).

At least two of these methods should be performed to identify the specific enzyme(s) responsible for drug metabolism.

The specific inhibition experiments should preferably be conducted in pools of human liver microsomes (except for correlation studies) to represent the average population. The in vitro incubations should be performed under linear rate conditions (linearity of metabolite production rates with respect to time and enzyme concentrations) and whenever possible, with pharmacologically relevant concentrations of drugs.<sup>1,46</sup> It is also recommended that each metabolite produced by individual CYP selected for identification be mentioned. By consensus, the pharmaceutical companies<sup>46</sup> have classified the CYPs as major (1A2, 2C9, 2C19, 2D6, and 3A4), of emerging importance (2C8, 2B6, and 3A5), and minor in drug metabolism (1A1, 1B1, 2A6, 2E1, 4A11, etc.).

No explicit recommendations are given for the number of CYPs to investigate so far in the current guidance<sup>57</sup> or the new draft paper.<sup>45</sup> However, the major CYPs can represent the minimum package to be investigated in screening programs completed, in later programs, and for registration purposes, with the other CYPs.

**Table 3** Method for identification of pathways involved in the oxidative biotransformation of a drug

| <i>In vitro system</i>  | <i>Condition</i>  | <i>Tests<sup>a</sup></i>                                |
|-------------------------|---|---|
| Microsomes              | + / – NADPH   | CYP, flavine monooxygenases (FMO) versus other oxidases |
| Microsomes, hepatocytes | + / – 1-aminobenzotriazole + clotrimazole, 1-benzylimidazole, SKF-525A or anti-NADPH-CYP reductase antibodies (+ cofactor required) | Broad-specificity CYP-inactivator                       |
| Microsomes              | 45 °C pretreatment  | Inactivates FMO   |
| S9                      | + / – pargyline   | Broad monoamine oxidase (MAO) inactivator               |
| S9                      | + / – menadione, allopurinol  | Mo-CO (oxidase) inhibitors                              |

<sup>a</sup> See <sup>45,46</sup>.

The FDA guidelines<sup>45</sup> encourage the identification of non-CYP enzymes such as glucuronyltransferases, sulfotransferases, and *N*-acetyltransferases, although there are only few documented cases of clinically significant drug interactions related to these classes of enzymes. These enzymes can be of importance in certain chemical series if they are involved in primary reactions and before initiating the phenotyping experiments, it is important to define the role of CYP and non-CYP enzymes in the metabolic clearance of the drug (Table 3). Taking a close look at the chemical structures will allow the selection of a more appropriate in vitro model and limit the number of systematic experiments at early stages.

Most of the early investigations are performed by monitoring the substrate only usually using a LC/MS/MS method; alternatively LC coupled with UV or fluorescence can be used but these methods give too low a sensitivity to monitor low drug concentration incubations. This is why the characterization of the enzyme kinetics, for each major pathway, is performed in later stages of the drug development plan in order to fine-tune the predictions of drug interactions generated in early stages.

#### 5.10.5.2.1 Use of specific inhibitors

For phenotyping studies, the use of specific CYP inhibitors requires well-defined conditions to ensure a reliable result.<sup>59</sup> The substrate concentration should be lower than or equal to the  $K_m$  and the inhibitor concentration should ensure selectivity and adequate potency. A range of inhibitor concentrations may be used to aid the interpretation.<sup>28</sup> It is necessary that their conditions of use have been validated earlier in order to ensure a reliable answer. For example, some specific inhibitors have a very low metabolic stability (such as coumarin, a potential CYP2A6 inhibitor) and they do not show any inhibitory potential in typical incubation conditions because they are completely metabolized.

The contribution of a specific CYP can be given directly by the percentage of inhibition of the NCEs metabolism. The most common CYP specific inhibitors are given in Table 4.

In early screening, only the major CYPs (1A2, 2C9, 2C19, 2D6, and 3A4) are studied, with CYP3A4 and 2D6 frequently selected first, since they represent the CYP isozymes very often involved in the metabolism of the currently marketed drugs.<sup>60,61</sup> At a somewhat later stage, a larger panel of CYPs will be investigated and the effect of the CYP specific inhibitors can be studied on each metabolic reaction.

#### 5.10.5.2.2 Use of specific antibodies

The problem of some of the specific inhibitors lies in their poor specificity and potency although they are preferred to antibodies in drug-interaction studies. However, the use of inhibiting antibodies has been recently promoted<sup>62,63</sup> in the quantitative assessment of a particular CYP in the metabolic pathway of a drug, in particular when several CYPs are involved.<sup>64</sup> Much improvement has been made in their selectivity, with reduced cross reactivity between homologous CYPs (e.g., 1A2 and 1A1).

It remains however difficult for some CYP antibodies to attain complete inhibition of the activity of the enzyme (at most 80%) even with large amounts of antibodies. Another drawback is their limited commercial availability, and antibodies raised against non-CYP enzymes are even less accessible. Finally, the use of inhibiting antibodies requires further optimization (titration curve) and they are not suitable for early screening programs.

**Table 4** Most common specific CYP inhibitors used for phenotyping studies (see <sup>45,66</sup>)

| <i>Enzyme</i> | <i>Specific CYP inhibitors</i>                         | <i>Range of <math>K_i</math> from the literature (<math>\mu M</math>)</i> |
|---------------|--|---|
| CYP1A1        | Alpha-naphthoflavone                                   | 0.01–10   |
| CYP1A2        | Furafylline <sup>a</sup>                               | 0.6–4.7   |
| CYP2A6        | Tranlycypromine  | 0.02–0.2  |
| CYP2A6        | Methoxsalen  | 0.01–0.2  |
| CYP2A6        | Pilocarpine  | 1–4   |
| CYP2B6        | 8-Methoxypsoralene (8-MOP) <sup>a</sup>                |   |
| CYP2B6        | ThioTEPA <sup>a</sup> (triethylenethiophosphoramidate) | 4.8   |
| CYP2C8        | Quercetine <sup>b</sup> /Retinol                       | 1.1/7   |
| CYP2C9        | Diclofenac/Sulfaphenazole                              | 20/0.3–0.5  |
| CYP2C19       | N3-benzyl nirvanol                                     | 0.25–0.41   |
| CYP2D6        | Quinidine  | <0.1–0.5  |
| CYP2E1        | Diethyldithiocarbamate (DDC) <sup>a</sup>              | 13–24   |
| CYP2E1        | Disulfiram   | 50  |
| CYP3A4        | Ketoconazole   | 0.015–0.15  |
| CYP3A4        | Itraconazole   | 0.27–2.3  |
| All CYP       | Clotrimazole   | 0.1–12  |
| FMO           | Methimazole  | 5700–8600   |

<sup>a</sup> Mechanism based inhibitor necessitating a preincubation period before adding substrate.

<sup>b</sup> CYP2C8 and 1A2 inhibitor.

#### 5.10.5.2.3 Use of recombinant enzymes

The use of cDNA-expressed enzymes is now preferred to estimate the contribution of each CYP in the clearance of the NCE.<sup>45</sup> The great advantage of these recombinant human CYPs is that they contain one isolated enzyme ruling out the problem of selectivity of the chemical inhibitors or CYP inhibiting antibodies.

The experiments can be conducted in microplates (96 to 1536 wells)<sup>65</sup> and are suitable for a complete automation making them fully adapted to screening programs. However, because the turnover number of each recombinant is not representative of those found in human liver microsomes, their incubation with the NCE cannot alone directly give the relative contribution of the CYPs in the overall metabolism of the drug. Without scaling factors, it only gives the ability of a particular enzyme to metabolize an NCE.

The microsomal environment, i.e., lipids, apoproteins, level of both cytochrome b5 and NADPH cytochrome CYP reductase, is different in the cDNA-expressed CYP system from the one in human liver microsomes. These differences can affect the turnover number ( $V_{\max}$ ) for a given enzyme, although the affinity ( $K_m$ ) of CYP is quite comparable between recombinant enzymes and human liver microsomes (Table 5). A thorough literature search performed with the aid of a drug interaction database (Aurquest database<sup>66</sup>) can illustrate this aspect (Table 5).

This link between the recombinant CYP and human liver microsomes can be obtained using a relative activity factor (RAF) for each CYP.<sup>62</sup> This RAF is a sort of extrapolation factor from a simple system expressing only one enzyme to the human microsomes containing a mixture of enzymes. These RAF can be calculated using the maximal velocity of the reaction ( $V_{\max}$ ) or better, by estimating of intrinsic clearance  $CL_{\text{int}}$ <sup>67,68</sup> in both systems using specific probe substrates of each CYP.

**Table 5** Comparison of the metabolic affinities ( $K_m$ ) for CYP-dependent reactions obtained in human liver microsomes and recombinant system (obtained from Aurquest database<sup>66</sup>). Results are expressed as median values (Min, Max)<sup>a</sup>

| <i>CYP</i> | <i>Substrate</i>              | <i>Reaction</i>           | $K_m$ HLM ( $\mu M$ ) | $K_m$ Recombinant ( $\mu M$ ) |
|------------|-------------------------------|---------------------------|-----------------------|-------------------------------|
| 1A2        | Phenacetin <sup>b</sup>       | <i>O</i> -Deethylation    | 45.3 (2.7–7691)       | 29.9 (9.19–107)               |

| 2C8        | Taxol <sup>b</sup>            | 6-Hydroxylation           | 15 (3.37–26)          | 6 (2.85–29.1)                 |
| 2C9        | S-Warfarin <sup>b</sup>       | 7-Hydroxylation           | 4.73 (3.79–27)        | 5.8 (0.78–30)                 |
| 2C9        | Diclofenac <sup>b</sup>       | 4'-Hydroxylation          | 12 (1.5–31)           | 4.8 (0.9–15.5)                |
| 2C9        | Tolbutamide <sup>b</sup>      | 4-Methylhydroxylation     | 125 (18–2580)         | 132 (43–523)                  |
| 2D6        | (+/-)-Bufuralol <sup>b</sup>  | 1'-Hydroxylation          | 9.3 (3–250)           | 10 (1.5–54.5)                 |
| 2D6        | Dextromethorphan <sup>b</sup> | <i>O</i> -Demethylation   | 5.5 (1.5–282)         | 2.3 (0.3–8.5)                 |
| 2E1        | Chlorzoxazone <sup>b</sup>    | 6-Hydroxylation           | 70 (15.8–238)         | 132 (6–660)                   |
| 3A4        | Alprazolam                    | 4-Hydroxylation           | 530 (234–764)         | 531 (238–743)                 |
| 3A4        | Alprazolam                    | $\alpha$ -Hydroxylation   | 409 (256–575)         | 178 (90–328)                  |
| 3A4        | Dextromethorphan <sup>b</sup> | <i>N</i> -Demethylation   | 286 (217–700)         | 232 (18–660)                  |
| 3A4        | Midazolam <sup>b</sup>        | 1'-Hydroxylation          | 5.6 (1.37–14)         | 2.35 (0.8–5)                  |
| 3A4        | Nifedipine                    | Oxidation                 | 20 (13–30)            | 8.75 (2.35–20.9)              |
| 3A4        | Quinidine                     | 3-Hydroxylation           | 17.6 (4–85.5)         | 2.25 (1–88)                   |
| 3A4        | Testosterone <sup>b</sup>     | 6- $\beta$ -Hydroxylation | 63 (33.48–120)        | 60 (33–108)                   |

<sup>a</sup>Biphasic kinetics explain the wide range of  $K_m$  obtained in HLM (high and low affinity enzymes). Recombinant CYP, containing only one enzyme, cannot display the lowest affinity enzymatic system (lower range of  $K_m$ ).

<sup>b</sup>Preferred chemical substrates for in vitro experiments.<sup>47</sup>

HLM, human liver microsomes; Recomb., recombinant CYPs.

Individual CYP  $CL_{int}$  values for a new compound, obtained separately with the expressed systems, can then be multiplied by the corresponding RAF factors allowing to assess the  $CL_{int}$  of the corresponding CYP in human microsomes. This approach is integrating the relative abundance of each hepatic isoform<sup>62</sup> and allows the estimation of the relative contribution of an individual CYPs to the metabolism of an NCE.

This method is of course applicable for all types of enzymes once a recombinant form of the enzyme and a specific substrate are available, such as is the case for some UGTs.<sup>69</sup> However, this approach can be time consuming for screening programs on large series of compounds.

An approach derived from the model proposed by Crespi *et al.*<sup>70</sup> is in use in our laboratories. Using their relative activity factor, each major CYP (1A2, 2C9, 2C19, 2D6, and 3A4) is mixed with relative proportions allowing to mimic the metabolic capacity found in a pool of human liver microsomes. Another mix is prepared by omitting the CYP of interest. The velocity of the overall reaction or intrinsic clearance of the NCEs is then measured using a mix of all the major CYPs, the same mix missing one of the CYPs and the CYP alone. The comparison of the intrinsic clearances then allows the estimation of the relative contribution of the CYPs of interest. This experimental approach, limited in this example to the five major human CYPs, can be extended to other enzymes reconstituting and standardizing in a way human microsomes. This approach is particularly adapted when evaluating large series of compounds.

Although the RAF approach is now commonly used either indirectly in screening programs or directly in development programs, there are still uncertainties about this method since controversial results showed that this relative activity approach may or may not depend on the index reaction used to create the RAFs for each CYP isoform and the expression system employed.<sup>62,68,71</sup> A closely related method named relative substrate activity factor (RSF) is based on the ratio of activities of the recombinant CYP toward the NCE and the CYP specific substrates. The RSF and RAF approaches are similar and they suffer from the same limits.<sup>72</sup> An alternative approach (relative abundance) is based on the immunoquantification of CYPs, but is very dependent on the source of recombinant enzymes and very time-consuming.<sup>62,72,73</sup>

Despite these limits, regulatory agencies recommend the use of recombinant human CYPs as they consider that they can provide the relative contribution of each pathway if more than one CYP is involved.<sup>45</sup>

However, at early stages, the emphasis is more on identifying the drugs metabolized by a single enzyme. A contribution of more than 70% to the metabolic clearance can be given as a general rule at this stage. Other clearances (biliary and renal) can decrease the risk of drug interaction due to coadministered drugs.

In later programs, the impact of substrate concentrations toward the relative contribution of enzymes will have to be defined with proper enzyme kinetics ( $K_m$ ,  $V_{max}$  of each enzyme). When a NCE is metabolized by multiple enzymes, the effect of multienzyme inhibitors should also be considered in later stages.

#### 5.10.5.2.4 Correlation studies

The different rates for each primary pathway of an NCE are correlated with reference activities of each individual CYP in the same bank of liver microsomes. This bank of individual human liver microsomes should be constituted of at least 10 donors with a wide range of enzyme activities for each CYP and no cross-correlations between each individual enzyme.

This approach, more than the others, is not sufficient in itself due to its lack of accuracy. Only the major enzymes involved in a metabolic reaction can be characterized and no quantitative contribution can be deduced. The lack of power of this method means that it is definitively not suitable for early screening programs.

#### 5.10.5.3 Inhibition

Assessment of the inhibition potential of a drug and the evaluation of its impact on plasma concentrations of coadministered drugs has been a major part of the early in vitro metabolism programs in the past decade. Fortunately, even though the potential consequences of inhibition on safety and efficacy are major, the basic understanding of the mechanisms involved as well as the in vitro tests available to address these issues are well known by metabolism scientists.

As a logical consequence regulatory agencies have required in vitro studies to be undertaken to determine the inhibitory potential as well as the mechanism of inhibition of an NCE toward CYPs.

These studies contain three major steps:

1. Kinetic experiments, determining  $IC_{50}$ s or  $K_i$ s of NCE toward CYPs.
2. Type of inhibition (time-dependent experiments assessing a mechanism based inhibition).
3. Prediction of the risk of interaction (extrapolation to the in vivo situations).

The new FDA draft guidelines recommend to select specific substrates with preferentially a simple metabolic scheme (ideally no sequential metabolism), allowing to set up sensitive, rapid and simple assays with reasonable incubation times.<sup>47</sup> A list of CYP probe substrates proposed by this draft guidance is given in Table 5. The probe substrates listed covers the major CYPs as well as those of emerging importance. There is no specific recommendation on investigating non-CYPs.

Similarly to phenotyping studies, initial rate conditions need to be respected. No more than 10% substrate or inhibitor depletion should occur.<sup>45</sup> This is somewhat difficult to maintain for the substrate in order to obtain a reasonable detection of the CYP specific metabolite. Solvents should be used at low concentrations ( $\leq 1\%$ , v/v and preferably  $< 0.1\%$ ) because of their potential inhibiting or activating effects.<sup>1,26</sup> No particular recommendations are made for the human model to be used. Determinations of inhibition potentials, in development programs, are based on monitoring the changes in the metabolism of specific CYP substrates in human liver microsomes or recombinant CYPs in the presence of an adapted range of concentrations of the NCEs of interest.<sup>52</sup>

Enzyme inhibition can be divided into reversible and irreversible processes (discussed below).

#### 5.10.5.3.1 Reversible inhibition

Reversible inhibition can be classified further as competitive, uncompetitive, mixed, or noncompetitive (Table 2).

For competitive inhibition, the binding of the inhibitor prevents binding of the substrate to the active site of the enzyme; for noncompetitive inhibition, the inhibitor binds to another site of the enzyme and the inhibitor has no effect on binding of substrate, but the enzyme-substrate-inhibitor complex is nonproductive. In the case of uncompetitive inhibition, the inhibitor does not bind the free enzyme but binds to the enzyme-substrate complex and again, the enzyme-substrate-inhibitor complex is nonproductive.<sup>74</sup> Finally in the case of mixed (competitive–noncompetitive) inhibition, the inhibitor binds to the active site as well as to another site on the enzyme, or the inhibitor binds to the active site but does not block the binding of the substrate.

The kinetics and the affinity with which an inhibitor binds to an enzyme are described by the inhibition constant  $K_i$ .

Transformations of the Michaelis–Menten equation (Table 2) are not only used for calculating  $K_i$  values but also for graphical depiction of the type of inhibition.<sup>28</sup> These equations allow to predict the risk of drug interaction as a change in substrate exposure (AUC) in presence of an inhibitor ( $AUC_i/AUC$ ) (Table 2).

##### 5.10.5.3.1.1 $K_i$ Determination

An accurate appreciation of the inhibitory potential and the type of inhibition are given by the determination of the inhibition constant  $K_i$ . The standard approach consists in incubating varying concentrations of substrate (around the  $K_m$ ) and inhibitor (around the  $K_i$ ) with fixed amounts of enzyme for a constant period of time after having checked the linearity of the kinetics.<sup>45</sup>

An alternative technique, derived from the SDK method (see Section 5.10.3.1) requires only two-substrate and two-inhibitor concentrations.<sup>33</sup> However, even if this approach is more rapid than the regular Michaelis–Menten one, both experiments are too time-consuming to be included in early stages of drug development and will only be conducted if necessary and for a limited number of CYPs. Determination of  $K_i$  is too labor-intensive, so only the  $IC_{50}$  is measured in early stages. This constant represents the concentration of inhibitor required to reach 50% inhibition under given experimental conditions.<sup>28</sup>

##### 5.10.5.3.1.2 $IC_{50}$ determination

To determine  $IC_{50}$ , only one concentration of the probe substrate, equal to or below the  $K_m$  of the index reaction, is incubated with several inhibitor concentrations.

In screening programs, a simplified method using cDNA expressed systems and non-CYP selective fluorogenic probes (Table 6), able to be conducted in 96 and even 1536 well microplates, has been developed.<sup>65</sup> It offers the great advantage of being suitable for a full automation.<sup>75,76</sup> Because cDNA-expressed systems contain only one enzyme, there is no need to use a selective probe substrate for each CYP as would be the case with human liver microsomes.<sup>18</sup> The method is based on the use of low or nonfluorescent CYP substrates producing highly fluorescent metabolites able to be read using a fluorescence plate reader, which does away with the need laborious and time-consuming LC methods.<sup>76</sup>

At this early stage of development, the inhibitory potential of the NCE is studied toward the major CYPs only (i.e., 1A2, 2C9, 2C19, 2D6, and 3A4).<sup>1</sup> To avoid solubility problems, the NCEs are usually solubilized in DMSO (0.5% maximum final concentration) and incubated at relatively low concentrations (maximum 25  $\mu M$ ). A positive control (known CYP specific inhibitor) can be added to validate the assay. If several concentrations of NCE are incubated, an  $IC_{50}$  can be calculated. Due to the low inhibitor concentrations incubated, only  $IC_{50}$  below 25  $\mu M$  can be assessed, enabling to screen potent ( $IC_{50} < 1 \mu M$ ), marginal ( $1 \mu M < IC_{50} < 10 \mu M$ ), or weak ( $IC_{50} > 10 \mu M$ ) inhibitors.<sup>46</sup>

However, this method is limited by the quality of expression of these isolated systems in the microsomal environment or the turnover number of these enzymes.

**Table 6** List of the fluorimetric probe substrates (and their respective CYP-dependent index reaction) commonly used for screening the inhibitory potential of NCEs

| <i>Substrate</i>   | <i>CYP</i>   | <i>Metabolite</i>   |
|--|--------------|---|
| Resorufin benzyl ether (BzRes)   | 1A1/1B1/3A4  | Resorufin   |
| 3-Cyano-7-ethoxycoumarin (CEC)   | 1A2/2C19     | 3-Cyano-7-hydroxycoumarin (CHC)   |
| Coumarin   | 2A6          | 7-Hydroxycoumarin (7-HC)  |
| 7-Ethoxy-4-trifluoromethylcoumarin (EFC)   | 2B6          | 7-Hydroxy-4-trifluoromethylcoumarin (7-HFC)                               |
| Dibenzylfluorescein (DBF)  | 2C8/2C9/2C19 | Fluorescein   |
| 7-Methoxy-4-trifluoromethylcoumarin (7-MFC)  | 2C9/2E1      | 7-Hydroxy-4-trifluoromethylcoumarin (7-HFC)                               |
| 3- <i>O</i> -Methylfluorescein (OMF)   | 2C19         | Fluorescein   |
| 7-Methoxy-4-(aminomethyl) coumarin (MAMC)  | 2D6          | 7-Hydroxy-4-(aminomethyl) coumarin (HAMC)                                 |
| 3-[2-( <i>N,N</i> -Diethyl- <i>N</i> -methyl-ammonium)ethyl]-7-methoxy-4-methylcoumarin (AMMC) | 2D6          | 3-[2-( <i>N,N</i> -diethyl-amino)ethyl]-7-hydroxy-4-methylcoumarin (AHMC) |
| Benzylxyquinoline (BQ)   | 3A4          | Quinolinol  |
| 7-Benzylxy-4-trifluoromethylcoumarin (BFC)   | 3A4/3A5      | 7-Hydroxy-4-trifluoromethylcoumarin (7-HFC)                               |
| Dibenzylfluorescein (DBF)  | 3A4          | Fluorescein   |

When several CYPs are involved in the metabolism of a compound, the use of cDNA-expressed systems may not always properly estimate the inhibitory effects of a given drug. Contradictory results on the correlation level of inhibitory potential using different fluoroprobes have been shown in the literature.<sup>65,76</sup>

In any case it remains a very useful tool for preliminary screening stages, completed later on selected compounds with conventional probes in models showing a full metabolic competence.<sup>99</sup> When working on small series of compounds, human liver microsomes are the preferred test system to determine the inhibitory potential,<sup>46,65</sup> because CYP kinetic measurements are not confounded with other metabolic processes or cellular uptake, as can be the case in hepatocytes.

The major issue in using human liver microsomes is the selection of highly specific CYP probes or index reaction (Table 5). The kinetic parameters should be assessed and the conditions of incubation should be validated by testing and comparing the inhibitory potential of known inhibitors with literature values.

In the past, the index reactions were monitored using several analytical techniques namely, LC coupled with UV, fluorescence, radiochemical, or MS/MS detections. Today a single LC/MS/MS technique can follow most of the CYP substrates and their respective metabolites within the same run, supplanting the standard use of radiolabeled substrates.<sup>42</sup> A method is in use in our laboratory enabling us to follow 11 metabolic reactions, each specific for one human CYP<sup>42</sup> in a single incubate.

IC<sub>50</sub> or *K<sub>i</sub>* generated in vitro can be corrected for nonspecific microsomal binding (not including plasma binding) in order to avoid an underestimation of the drug interaction risk or even false negatives. Tran *et al.*<sup>77</sup> have shown that the inhibition of several CYP3A4 inhibitors on diazepam metabolism decreased when microsomal proteins increased. This highlights the interest of correcting inhibition constants for microsomal binding.

These IC<sub>50</sub> determinations are sufficient in early stages to extrapolate a preliminary risk of drug interaction using a pragmatic safety approach. They do not, however, allow one to distinguish the type of inhibition that is normally required to select the right model for drug interaction predictions (Table 2).

#### 5.10.5.3.1.3 In vivo risk prediction

It can be assumed, as a simplification, that the vast majority of inhibitors involved in drug interactions are competitive inhibitors. In this case when the substrate concentration is equal to the *K<sub>m</sub>*, the *K<sub>i</sub>* is theoretically equal to IC<sub>50</sub>/2.

**Figure 1** Influence of the inhibition index ( $I/K_i$ ) of a drug on the drug interaction risk (based on CYP 3A4 substrates). AUC ratio:  $AUC_i/AUC$  represents the predicted ratio of the exposure to the drug undergoing the drug interaction in presence of the interacting compound ( $AUC_i$ ) and the exposure to the drug without the interacting compound ( $AUC$ ).  $I/K_i$  represents the inhibition index where  $I$  is the concentration of the inhibitor at the active site of the enzyme and  $K_i$  the constant of inhibition. \*, with respect to the safety margins.

As shown in [Table 2](#), the prediction of the risk of drug interaction is based on the inhibition index  $I/K_i$  ([Figure 1](#)) resulting from equation

$$AUC_i/AUC = 1 + I/K_i \quad [9]$$

$I$  is the concentration of inhibitor at the active site of the enzyme which is an unknown parameter somewhat difficult to figure out.

Mean steady-state  $C_{\max}$  ( $C_{\max}(ss)$ ) values for total drug following administration of the highest proposed clinical dose have been recommended as surrogate estimates of the inhibitor concentration for in vitro–in vivo scaling.<sup>45,46</sup> As reviewed by Venkatakrishnan *et al.*<sup>26</sup> if some reasonably accurate projections of the magnitude of clinical interactions have been obtained using  $C_{\max}(ss)$  as an inhibitor concentration, underestimated predictions have been observed,<sup>78</sup> which implies the risk of developing a potential inhibitory drug.

In early screening programs the emphasis is on safety and the objective is to predict the highest possible risk as regards to drug interactions. This safety approach consists in using the maximum concentration reaching the liver ( $C_{in}$ ) as the concentration at the site of the enzyme using the following equation:

$$C_{in} = \frac{k_a \times F_{abs} \times D_a}{Q} \quad [10]$$

where  $C_{in}$  represents the concentration of the inhibitor entering the liver after its oral administration at the dose  $D_a$ ;  $F_{abs}$  is the fraction absorbed,  $k_a$  the absorption rate constant, and  $Q$  the hepatic blood flow. This equation assumes that the NCE follows a first-order absorption kinetics.

Some authors recommend to use the  $C_{in}$  corrected by the unbound fraction in plasma ( $f_{up}$ ).<sup>79</sup> However, in respect to a safety approach, it is deemed better to use the total fraction to obtain the maximal inhibitor concentration at the active site of the enzyme (overestimation).

The therapeutic dose in humans can be estimated by allometry from the pharmacological dose in the rat making the assumption of linear kinetics.

The default value for the absorption rate constant<sup>79</sup> is  $0.1 \text{ min}^{-1}$ . In order to maximize the  $C_{in}$ , the NCE is assumed to be completely absorbed by the gastrointestinal tract ( $F_{abs} = 1$ ).

At steady state, Ito *et al.*<sup>79</sup> considered the inhibitor concentration at the active site of the enzyme as the sum of  $C_{in}$  and  $C_{\max}$  weighed by the plasma unbound fraction ( $f_{up}$ ). Successful predictions of clinical drug interactions have been obtained using this approach. It is however only applicable at clinical stages. A combined use of  $C_{\max}(ss)$  and  $C_{in} + C_{\max}$  can avoid a number of false negatives.<sup>78</sup> When using such a safety approach one has to accept the risk of false positives.

In addition, some compounds have been found to accumulate extensively in the hepatocytes (e.g., itraconazole, ketoconazole, diltiazem, verapamil<sup>80</sup>) so that even the  $C_{in}$  might underestimate the intrahepatic inhibitor concentrations. An alternative proposed by Yamano *et al.*<sup>80</sup> and Ito *et al.*<sup>79</sup> would be to measure this partition using hepatocytes in suspension. Such experiments are only adaptable to small series of compounds.

When using hepatocytes to measure apparent  $IC_{50}$ , this uptake is taken into account, even though it is only adaptable to small series of compounds.

When the intrahepatic enzyme-available inhibitor concentration has been estimated, the inhibition index  $I/K_i$  (with  $K_i = IC_{50}/2$ ) and the ratio  $AUC_i/AUC$  can be calculated. The new FDA draft guidance<sup>45</sup> classifies a drug as a strong ( $AUC_i/AUC$  is  $\geq 5$ ) or moderate inhibitor  $2 \leq AUC_i/AUC < 5$ .

An  $AUC_i/AUC$  ratio of 2 or higher can be used as a trigger to plan further in vitro and in vivo drug interaction studies with different probe substrates and concomitant treatments.

#### 5.10.5.3.2 Irreversible inhibition

In irreversible inactivation, the inhibitor first acts on the target enzyme before inhibition occurs. In many cases, this involves conversion of the inhibitor into a chemically reactive intermediate that forms a covalent bond with the enzyme, inactivating it permanently. For CYP enzymes, irreversible inhibition can be noncovalent occurring through metabolite–intermediate complexes tightly bound to the iron of the heme prosthetic group (quasi-irreversible inhibition). Irreversible inactivation, whether it occurs through formation of covalent bonds or iron complexes, is the underlying mechanism of some high-magnitude drug interactions,<sup>16</sup> e.g., CYP2D6 inactivation by paroxetine,<sup>81</sup> CYP3A4 inactivation by diltiazem,<sup>82</sup> erythromycin, or troleandomycin,<sup>26,74,83</sup> CYP2C9 inactivation by tienilic acid,<sup>84</sup> etc.

It is crucial to distinguish time-dependent inhibition due to the reversible inhibitory effect of a metabolite formed during the incubation from the irreversible inactivation of the enzyme by a reactive intermediate formed from the drug itself (mechanism-based inhibition). The risk is an underestimation of drug interaction potential. This has been demonstrated by Mayhew *et al.*<sup>85</sup> with diltiazem, clarithromycin, and fluoxetine significantly increasing the exposure to CYP3A4 substrates, for which a simple competitive model failed to predict drug interactions.<sup>85</sup>

In vitro, a mechanism-based inhibition is characterized by: the irreversibility of the reaction, an NADPH-, time-, and concentration-dependent enzyme inactivation, substrate protection,<sup>86</sup> loss of the CYP content, and the incapability of superoxide dismutase, catalase or exogenous nucleophiles such as glutathione to reverse the inactivation.

The consequences of a mechanism-based inhibition are not only an alteration of the kinetic behavior of the drug involved by a decrease in its first pass clearance but also possible potent drug interactions. In this respect, this kind of inhibition has to be evaluated as early as possible, as recommended by the new FDA draft guidelines<sup>45</sup> even if the full set of experiments required to assess the mechanism involved can be quite time-consuming.

However, a simple approach can be used as a preliminary step. This consists in experiments in which the metabolism-dependent inhibitor is preincubated (usually for 15–60 min (30 min being recommended by FDA draft guidance<sup>45</sup>)), allowing the metabolite(s) to be formed. The probe substrate is then added assessing the inhibition potential of both inhibitor and its metabolites in comparison to the substrate only in control samples. In order to minimize reversible inhibition due to metabolites, a dilution of the preincubate has been proposed (minimum  $10 \times$  dilution) to discriminate between reversible and mechanism-based inhibition. This technique should, however, be handled with care for specific substrates with low turnovers.

To appreciate the potency of mechanism-based inhibition and predict the risk of drug interaction, the inactivation kinetic constant  $k_{inact}$  and inhibition constant  $K_i$  should be measured in vitro. The impact of a mechanism-based inhibition can now be better appreciated with the use of adapted models for the prediction of drug interaction.<sup>85</sup> In addition to  $K_i$  and  $k_{inact}$ , this model requires the rate of de novo biosynthesis of enzyme ( $k_{degrad}$ ) estimated at  $0.000825 \text{ min}^{-1}$  by Mayhew *et al.*<sup>85</sup>; this probably constitutes the major limit of this model.

All this information is required to optimize the design of future clinical drug interaction studies. For example, in case of a mechanism-based inhibition, it may be important to administer the inhibitor prior to (e.g., 1 h) the administration of the substrate to maximize the effect.<sup>45</sup> It is interesting to notice that in case of mechanism-based inhibitions, a time-dependent deviation of the first order kinetics can lead to false predictions of intrinsic clearances using the in vitro half-life approach.<sup>26</sup>

In conclusion, even though in vitro based drug interaction predictions have been very successful in early metabolism programs, one has to keep in mind some of the pitfalls of this approach. It includes the percentage of solvent used, microsomal protein binding, substrate depletion, mechanism-based inhibition, probe selectivity, substrate substitution (particularly for CYP3A4), and uptake in the hepatocytes. The in vitro incubation conditions including buffers, ionic strength, pH; and addition of cytosol and/or albumin can also influence the metabolic properties of in vitro microsomal systems, thereby having implications on the predictions of the magnitude of drug interaction.<sup>26</sup>

#### 5.10.5.4 Induction

Induction has been defined as an increased level of enzyme gene expression (*see* 5.08 Mechanisms of Toxication and Detoxification which Challenge Drug Candidates and Drugs), and hence an increase in enzyme activity, resulting from exposure to a xenobiotic or endogenous components.<sup>87</sup>

The consequences are modifications in exposure to the drug (decrease) and its metabolites (increase) leading to potential changes of the efficacy profile of the drug (duration and intensity of action) or to its safety profile (reduced therapeutic margin). This is the case of the well-known interaction between oral contraceptives and rifampicin where the bioavailability of the former decreased by 42% due to induction of CYP3A4 by rifampicin, resulting in the loss of contraceptive efficacy.<sup>87</sup> If both parent drug and major metabolites have the same pharmacological activity, then the pharmacological effect of the induction is reduced although the pharmacokinetics of both parent drug and metabolites have changed. This has been observed for the induction of alprenolol by pentobarbital.<sup>88</sup>

In addition, the induction may enhance the formation of reactive metabolites resulting in potential adverse reactions. The timescale of an induction and an inhibition is somewhat different. Induction processes, at the level of an organism, are not as immediate as inhibition mechanisms. They involve fewer isozymes, affecting only the inducible ones (principally CYP1A1–1A2, CYP2C9, CYP2E1, and CYP3A4).

The prime concern is the induction potential of an NCE able to affect the metabolism of coadministered compounds. On the other hand known inducers can also affect the metabolism of an NCE. For the latter case the information on the identity of the enzymes involved in the metabolism of an NCE is crucial to evaluate potential impacts.

Evaluation of the induction potential of a drug has been a weak point in early screening programs, carried out only for specific projects in which induction was known to represent a potential issue.

Strategies for evaluating the induction potential of drug candidates have often been, and still are, based on ex vivo animal liver analyses obtained from toxicological studies.<sup>31</sup> However, with regard to the number of animals, amount of compound, and time required, they have proven to be inadequate for early screening. In addition, scaling results from animals to humans is unreliable due to interspecies differences<sup>89</sup> in metabolizing enzymes and their regulation factors (such as nuclear receptor CAR, PXR, or AhR).<sup>87</sup>

#### 5.10.5.4.1 Primary cultures of human hepatocytes

Primary cultures of human hepatocytes have been considered by most academic, industrial and regulatory scientists to be the current 'gold standard' for preclinical induction studies.<sup>8,87</sup>

Culture conditions have been optimized to increase the culture period duration, the parallel decrease in enzymatic activity over time being less an issue for induction than metabolic profiling purposes.<sup>8–10</sup> Hepatocytes can be cultured on collagen-coated 96-well plates, more adapted for screening purposes.

Nevertheless, no real standardized conditions exist between laboratories thus making some comparison quite difficult. A preliminary concept paper by the FDA is under discussion to propose some guidelines that could allow a homogenization of the techniques.<sup>45</sup>

Practically, the study design recommended consist in a 1 or 2 day culture period of fresh or cryopreserved hepatocytes (time of attachment) after which the cells are treated with the test compounds for an additional 2–4 day induction period. Finally, gene or protein expression or CYP specific activities are measured.<sup>8,45,87</sup> Usually, only CYP1A2 and 3A4, as the most frequently induced enzymes, are studied in screening programs. However, because CYP expression can be regulated by multiple pathways and that one activator of a nuclear receptor can cause the induction of several CYPs it is worth completing the panel of enzymes at latter stages of development.

Three concentrations of NCE should be tested and should span the expected human plasma drug concentrations at the therapeutic dose, with at least one concentration that is an order of magnitude greater than the average concentration.<sup>45</sup> It is clear that the highest concentration tested should be compatible with the solubility of the compound and should not cause cellular toxicity.

A known potent inducer (positive control causing more than twofold increase in enzyme activity) (Table 7), should be included in the test together with a negative control (solvent treated hepatocytes).<sup>45</sup> Once the CYP specific activities are measured, the final results may be expressed as induction potential ( $x$ -fold induction over control), EC<sub>50</sub> (effective concentration for 50% maximal induction), or potency index (the ratio of induction response of the test compound compared to a reference inducer).<sup>28,46</sup> It is highly recommended to compare the results with a positive control given the high variability in induction response.<sup>87</sup> For example, in similar culture conditions, rifampicin can produce a 5- to 50-fold increase in the 6 $\beta$ -hydroxy-testosterone CYP3A4-dependent activity.<sup>90,91</sup>

A drug that produces a greater than twofold increase in activity or more than 40% of the positive control can be considered as an enzyme inducer and will have to be evaluated in vivo.<sup>46</sup>

Even if long-term cultures permit re-use of the same preparation for several additional induction studies following a washout period, the major issue of the fresh human hepatocytes still remains their availability. To avoid high variability in induction response it is recommended to use preparations from at least three individual donors<sup>20,46</sup> which further

**Table 7** Typical chemical inducers for in vitro experiments<sup>45</sup>

| <i>CYP</i> | <i>Inducer</i>       | <i>Inducer concentration (μM)</i> | <i>Induction</i> |
|------------|----------------------|-----------------------------------|------------------|
| 1A2        | Omeprazole           | 25–100                            | 14–24            |
|            | β-Naphthoflavone     | 33–50                             | 4–23             |
|            | 3-Methylcholanthrene | 1.2                               | 6–26             |
| 2A6        | Dexamethasone        | 50                                | 9.4              |
| 2B6        | Phenobarbital        | 500–1000                          | 5–10             |
| 2C8        | Rifampicin           | 10                                | 2–4              |
| 2C9        | Rifampicin           | 10                                | 3.7              |
| 2C19       | Rifampicin           | 10                                | 20               |
| 3A4        | Rifampicin           | 10–50                             | 4–31             |

complicates the issue of availability. This is why cryopreserved human hepatocytes have been proposed as an acceptable alternative for induction studies.<sup>46</sup> Some batches of these cryopreserved human hepatocytes commercially available are capable of attaching in culture and have shown to be as inducible as fresh hepatocytes in certain culture conditions.<sup>15</sup>

Other model such as the collagen sandwich model<sup>92</sup> has been considered by some authors as the most suitable for induction studies since it gets closer to reality in terms of cell polarity, structural and functional normal bile canalicular network, and cellular integrity. This model is however less suitable for early screening studies.

In addition to the more classical measurements of enzyme activity, other techniques allow the level of induction to be assessed. The increase in expression level of an enzyme can be evaluated by western blotting using enzyme selective antibodies, but this is not suitable for screening purposes.

Messenger RNA (mRNA), coding for metabolizing inducible enzymes, can be quantified by real-time techniques reverse-transcriptase polymerase chain reaction (RT-PCR) using either the Taq-Man or SIBERGREEN technologies.<sup>11,93</sup> Care must be taken in the interpretation of the results since an increase in the gene expression is not always mirrored by an increase in the protein activity (false positive); vice versa, a false negative can occur if the inducer affects a non-transcriptional mechanism such as activation of translation (e.g., isoniazid toward CYP2E1<sup>94</sup>) or protein stabilization (e.g., acetone toward rat hepatic *N*-nitrosodimethylamine demethylase<sup>95</sup>). However some rather good correlations have been obtained between real-time RT-PCR and enzyme activity results.<sup>96</sup>

DNA microarrays and more targeted low-density DNA microarrays dedicated to drug metabolizing enzymes and transporters are also useful tools for studying changes of CYP gene expression in response to drug treatment.<sup>97</sup> Such a low-density human hepatochip is in use in our laboratory allowing us to screen 151 genes (additionally including nuclear receptors, kinases, growth factors, etc.) after treatment of human fresh and cryopreserved hepatocytes (10<sup>6</sup> cells) with potential inducing drugs.<sup>97</sup> The possibility of analyzing the level of all of these genes in one shot makes these techniques nicely adapted to early research programs.

#### 5.10.5.4.2 Genetically engineered tools

In order to overcome the problem of availability of hepatocytes and/or to make induction studies more adapted to screening programs, genetically engineered tools have become available. Even if they still necessitate further validation, they represent promising alternatives or preliminary techniques to evaluate the induction potential of an NCE in the earliest stage of drug development. These tools regroup new cell lines expressing a wider range of enzymes and transporters as well as reporter gene technologies and DNA constructs.

##### 5.10.5.4.2.1 Hepatoma cell lines

Hepatoma cell lines have been proposed for studying CYP induction in vitro. Among the numerous cell lines developed, HepG2 is the most popular for use in induction studies. However, because of the discrepancy between this cell line and hepatocytes (see Section 5.10.2.2) care should be taken in the interpretation of induction results. The HepaRG line exhibits higher degrees of similarities with fresh hepatocytes and should represent a better alternative for in vitro induction studies.

In addition to HepaRG, new avenues of research have been opened, with in particular, human mesenchymal stem cells or peripheral blood monocytes that might be transformed into human hepatocytes in certain culture conditions (see Section 5.10.2.2).<sup>24,25</sup>

#### 5.10.5.4.2.2 Reporter gene and other DNA constructs

Nuclear receptors constitute a large family of ligand-dependent DNA transcription factors. This family includes receptors such as AhR, PXR, CAR, and VDR which regulate xenobiotic metabolism through CYP.

Nuclear receptor activation assays, utilizing cell culture with transient transfection of reporter gene under the control of various nuclear receptors and subsequent assays of luciferase or  $\mu$ -galactosidase activities are an alternative to assess the induction potential of a drug.<sup>98</sup>

These constructs have shown to be valuable tools for the assessment of CYP3A4 induction for example using PXR activation assays, with a good correlation with human hepatocytes in screening series (internal data). There are however false positives such as troleandomycin, tamoxifen, or ritonavir, which markedly activated human PXR in reporter gene assay whereas in primary cultures of human hepatocytes, pretreatment with these compounds did not significantly increase CYP3A4-dependent metabolic activity.<sup>98</sup>

For the other receptors, the correlation with in vivo CYP induction requires additional validation.<sup>46</sup> They can however be very useful for comparing activation profiles within series of compounds. The selected compounds can then be tested as regards to their induction profile with human hepatocytes. One also has to keep in mind that they do not address post-transcriptional mechanisms of induction.<sup>87</sup>

### 5.10.6 Discussion and Conclusion

Progress in optimizing the way to carry out in vitro metabolic studies in R&D has been constant over the last decade. In a way, xenobiotic metabolism represents a quite unique domain within R&D. It is effectively one of the sole disciplines present at every major step in R&D, and provides pivotal information to pharmacologists, chemists, toxicologists, and clinical scientists. It has therefore evolved toward the use of a large range of metabolic tools, allowing the rapid understanding of a drug's fate.

This nonexhaustive panel of in vitro tools has been very much used by pharmaceutical companies to better select drug candidates in high-throughput screening (HTS) programs. However, go/no-go decisions on simple parameters are somewhere an idealistic search for the (perfect) drug. The actual strategies have moved toward better evaluation, anticipation, and control of the potential safety and efficacy issues that one can, and probably will, encounter at a certain degree when administering a xenobiotic to a living organism.

These safety and efficacy aspects have been discussed in this chapter, trying to show how in vitro metabolism tools can better address, at very early stages, the nature and the importance of metabolites formed throughout species as well as the drug interactions risks.

These two issues have been recognized by regulatory authorities as major and the studies to be undertaken have been defined quite precisely for development programs and registration purposes in recent draft guidelines on safety testing of metabolites and predictions of drug interactions. These new requirements will have to be discussed and integrated by research teams. But one has to keep in mind that getting a similar level of understanding in research projects on series of drugs will only be possible if one can further adapt the tools using new technologies and apply different and more global interpretation strategies.

Screening programs have in a way broken down the important mechanisms involved in drug disposition (absorption, metabolism, etc.), trying to avoid their potential negative consequences in humans (variability, drug interactions, etc.). Today a large number of individual key parameters (solubility, permeability, rates of metabolism, inhibition and induction characteristics, etc.) or even surrogate markers (log  $P$ , parallel artificial membrane permeability assay (PAMPA), etc.) of these parameters exist to screen series of compounds.

Despite the large number of tests used routinely, a number of weak points remain to be addressed. Because these programs have been successful in selecting more stable compounds as regards CYP oxidative pathways, the role of non-CYPs has become more apparent and represents one important aspect to be developed by metabolism scientists.

Nonspecific binding to microsomes will have to be further integrated on a systematic basis in these early programs. The incubation of microsomes, in the presence of plasma or otherwise, should enable these binding issues to be simply addressed in routine tests.

The impact of gastrointestinal tract enzymes (endogenous enzymes from small intestine but also exogenous microflora enzymes from colon) on drug metabolism as well as on the risk of drug interaction is another aspect that has been neglected in early evaluations. In this respect, there are no real validated human tools as regards in vivo

extrapolations. The CYP activity profile of human gut microsomes, in the presence of protease inhibitors, is variable with the time of storage with sometimes a dramatic loss in certain activities, hence a limited predictivity.

On the other hand the in vivo relevance of well-known human liver tools such as microsomes and hepatocytes is regularly questioned. The former, even though they are used as pools of several livers, are frequently not representative of the average population because these pools are difficult to constitute. An alternative, discussed in this chapter, would be to reconstruct human microsomes using expressed enzymes. This is a way to standardize microsomes, better representing the average population for all major and minor enzymes, or if needed any other type of subpopulation, i.e., integrating the polymorphic aspects of these enzymes. Hepatocytes, mainly because of their poor availability, are not really adapted to large screening programs. Cell lines as well as stem cells or medullar cells are probably going to resolve these aspects in the near future.

The domain having recently progressed the most in metabolism screening is probably the evaluation of the induction potential. Nuclear receptor activation assays, even though the exact correlation with the in vivo induction profile still has to be fully validated, are useful for evaluating the induction potential within series of compounds. Human hepatocytes, as a reference model for induction studies, can be used on smaller series of compounds at a somewhat later stage.

As regards the nature of metabolites, the identification of major metabolic pathways in drug discovery programs has always represented a significant analytical challenge. It seems that with the new technological advances, this information, very frequently asked for by chemists, pharmacologists, and toxicologists in research groups, will be available on small series of compounds. It will contribute to more precisely determine their positive (efficacy) and negative (safety) importance in nonclinical and clinical programs.

However, the future challenge is more in combining this early information, and thus reconstructing partially or totally these mechanisms at the level of the cell, the organ, or the organism.

At the cellular level coculture or coinubation systems (hepatocytes and plasma or microsomes and plasma) better integrate the different equilibrium occurring in and between the cells. Measuring individual parameters such as protein binding on one side and clearance of the drug on the other side and mathematically combining them to predict the bioavailability has proven to fail in a number of cases.

At the organ or the organism level, the use of physiologically-based pharmacokinetics (PBPK) models is a way to extrapolate in vitro data in order to get in vivo time concentration profiles. This approach allows one to challenge the multiple assumptions made when measuring in vitro parameters and extrapolating them to the entire organism (*see* 5.37 Physiologically-Based Models to Predict Human Pharmacokinetic Parameters).

On the other hand, the enormous amount of absorption, distribution, metabolism, and excretion (ADME) data generated over the last decade in HTS programs has been used to develop in silico prediction packages. Even though these in silico approaches need further refinements and validations, they will be of great value when linked to PBPK models and will probably in the future replace entire parts of HTS programs.

For drug interaction predictions, based on the inhibition and induction potential as well as knowledge of the enzyme(s) involved in the drug's metabolism, one can get a clear picture of the potential risks of coadministered drugs in the clinic, using drug interaction databases such as AurQuest,<sup>66</sup> DIDB,<sup>99</sup> drug interaction,<sup>100</sup> or Gentest websites.<sup>101</sup> Even though interlaboratory differences in kinetic parameters ( $K_m$ ,  $V_{max}$ ,  $CL_{int}$ ,  $K_i$ , and  $IC_{50}$ ) can be quite large in the literature, it is a useful source of in vitro data, especially with packages such as AurQuest integrating the calculation of drug interaction risks.

In conclusion, in vitro metabolism tools have been recognized by the recent guidelines on drug interactions as valid decision-making tools able to avoid unnecessary in vivo studies. In parallel, more information on the identity and the concentration of metabolites will potentially be available helping for a better interpretation of drug safety and efficacy programs. After almost a decade of selection of drug candidates on simple ADME parameters, the need for more global tools allowing to better combine this early information has emerged. New approaches, such as physiological models, integrating in vitro parameters, and emerging molecular modeling tools will, without doubt, be key elements in the future selection processes of drug candidates. They represent also valuable tools to optimize future clinical studies (*see* 5.34 Molecular Modeling and Quantitative Structure–Activity Relationship of Substrates and Inhibitors of Drug Metabolism Enzymes).

## Biographies

**Yannick Parmentier** studied Pharmacy in Lille (Faculté des Sciences Pharmaceutiques et Biologiques – France) and molecular and cellular pharmacology in ‘Ecole Normale Supérieure’ of Paris VI.

He spent 1 year in the Institut de Recherches Servier at Croissy (France) to study the involvement of PPAR $\gamma$  nuclear receptors in the cellular differentiation of adipocytes.

In 1998, he worked 18 months in the Metabolism Department at Servier Research and Development (England) as research officer. He was in charge of the validation of the cytochrome P450 co-expressed functionally in *E. coli* with human NADPH-P450 reductase and engineered by Dundee University (Scotland).

He took on a position as Study Director in the Metabolism Department at Servier (France) in 1999 before being appointed as Section leader in the DMPK predevelopment Division in 2005 in charge of the supervision of all ADME predevelopment selection programs as well as the development of new in vitro models.

**Marie-Jeanne Bossant** studied Analytical Chemistry, Metabolism and Pharmacokinetics in Paris (Faculté des Sciences Pharmaceutiques Paris XI – France) and obtained his PhD on PAF-Acether: characterization and quantitation (collaboration between Paris XI and INSERM U200, Clamart – France – J Benveniste)

She spent 2 years as a postdoctoral fellow at the NIH (NIAAA Bethesda – USA – Norman Salem Jr – 1989–91) period during which, she was involved on metabolism of lipids in alcoholic patients, before taking up a position as Study Director in the Metabolism Department at Servier (France) in 1991.

She has since been involved in medical writing for registration purposes, design of metabolism databases and is currently following the predevelopment of New Chemical Entities for both their Pharmacokinetic and Metabolic properties.

**Marc Bertrand** studied Biology and Physiology in Clermont Ferrand (University of Clermont Ferrand – France) and then Biochemistry in Lyon (University Claude Bernard – Lyon – France) and obtained his PhD in 1987 at INSERM U171 (Lyon – Pr J-F Pujol) on central catecholaminergic systems developing an in vitro brain slice model.

He took up a position as Study Director in the Metabolism Department at Servier (Orléans – France) in June 1987, an important part of his role being to develop and implement in vitro models.

In 1991, he was appointed Head of the Metabolism Department (Orléans – France) managing both in vitro experiments such as interspecies comparisons, drug–drug interaction and in vitro based pharmacokinetic parameter predictions as well as in vivo animal and human metabolism studies for registration purposes.

From 1998 onward he took over the Drug Discovery Support Department, responsible for the generation and integration of biopharmaceutical parameters (physicochemical, metabolism, pharmacokinetics, and safety fields) within research programs as well as the development of new approaches in early discovery support (new in vitro based models, transcriptomics and in silico molecular modeling prediction tools).

**Bernard Walther** studied Pharmacology in Nancy (Faculté des Sciences Pharmaceutiques et Biologiques – France) and obtained his PhD at the Centre du Médicament (Nancy – Pr G Siest) on cytochrome P450: characterization and role in the brain.

He spent 3 years as a postdoctoral fellow at the School of Pharmacy, University of Lausanne (Switzerland – Pr B Testa – 1986–88) period during which, he was involved on QSAR and CNS uptake projects. He was also supervising a PhD on the hepatic and cerebral hydrolysis of nicotinic acid esters and the relation between structure and metabolism, before taking up a position as Study Director in the Metabolism Department at Servier (France) in 1988.

In 1991, he was appointed as General Manager of the Pharmacokinetic and Metabolism laboratory at Servier Research and Development (England).

From 1995 onward he took over the Pharmacokinetic and Metabolism Centre as Director of the Pharmacokinetics Centre at Technologie Servier in France (Orléans), involved in drug screening and development and more recently dedicated to early discovery and predevelopment programs as well as the implementation of new technologies.

## 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption

### 5.11.1 Introduction

A recent analysis of the success rates from first-in-human studies to registration during a 10 year period (1991–2000) for the 10 big pharma companies in Europe and the USA indicates an average success rate for all therapeutic classes in drug development of around 11%.<sup>1</sup> A closer examination identifies the major underlying causes of attrition as problems related to clinical safety, efficacy, formulation, pharmacokinetics/bioavailability, toxicology, cost of goods, and commercial reasons, and it also reveals how these underlying causes have developed from 1991 to 2000. Only in the case of pharmacokinetic/bioavailability issues can a positive development be observed, although these issues may also be incorporated within the categories of toxicology, clinical safety, and efficacy.<sup>1</sup> In 1991, pharmacokinetic/bioavailability issues were the most significant cause of attrition, accounting for about 40% of all attrition.<sup>2</sup> A decade later, the percentage of clinical drug failures that could be related to pharmacokinetic/bioavailability issues had been reduced to about 10%.<sup>1</sup> This development occurred in parallel with the development and implementation of cell culture-based in vitro routine tools for the prediction of ADMET properties in drug discovery, and, in particular, absorption and metabolism models. It is likely that these models have assisted in providing better grounds for making pharmacokinetics-related decisions for the selection of lead compounds in drug discovery.

What factors spurred the development of predictive cell culture models for the assessment of permeability and absorption in the ADMET area? Apart from the awareness that inferior pharmacokinetic properties, including inadequate drug absorption, were major reasons for the failure of candidate drugs in the clinical phase,<sup>3</sup> it was realized that drug absorption across biological barriers is a fairly complex process involving several pathways and that, because of this, it cannot easily be delineated in experimental animals.<sup>4</sup> Another, more concrete, reason was that the increasing output of compounds from combinatorial chemistry could not be accommodated by the conventional absorption

assessment, which was based on low-throughput animal experiments. This was probably the most important reason for implementing cell culture-based ADMET models, including permeability models such as the Caco-2 model, in drug discovery settings.

About 15 years have passed since Caco-2 cells grown on permeable supports were introduced as an experimental tool for mechanistic studies of intestinal drug transport.<sup>5–8</sup> At that time it was also suggested that the Caco-2 model might be suitable for screening intestinal drug permeability and predicting the oral absorption potential of new drug compounds.<sup>9</sup> After some initial skepticism, Caco-2 cells were gradually accepted as a versatile *in vitro* tool for predictive and mechanistic studies of intestinal drug absorption. A period of critical evaluation followed, and nowadays the majority of researchers using Caco-2 cells and other similar models are aware not only of their advantages but also of their limitations.<sup>4,10</sup>

In this article, we review cell culture-based methods for the prediction of drug permeability, transport mechanisms, and oral absorption. First, we review the discrete barriers to drug absorption provided by the intestine, and discuss whether they need to be considered in *in vitro* permeability and transport models. Then we review the various drug transport routes across the intestinal epithelium, and discuss their relative importance. A number of cell culture models used for the *in vitro* prediction of intestinal permeability, transport, and absorption are discussed, as is the general methodology used in these studies and the limitations of this methodology. Many of the examples are taken from studies conducted in Caco-2 cells, simply because of the dominant position occupied by this cell line in drug permeability and transport studies for the prediction of oral absorption. However, the discussion is of a principal nature, and is, therefore, also applicable to emerging alternatives to Caco-2 cells.

### 5.11.2 The Role of Permeability, Transport, and Absorption Prediction in Drug Discovery

Ideally, assessment of drug permeability and transport should be used at all stages of drug discovery. In the early stages, when *in silico* screening of virtual or real combinatorial libraries is required, global rules or filters based on simple molecular properties, such as the ‘rule of five’<sup>11</sup> and the polar surface area (PSA),<sup>12–14</sup> are the best choice of screening technique since they are cheap and rapid, and provide immediate feedback to the discovery scientists.<sup>15,16</sup> In contrast, during later stages of drug discovery when the number of compounds under investigation has been reduced, and the iterative process of lead optimization is taking place, the use of experimental permeability assessments should be increased in order to obtain more reliable predictions of the drug permeability after oral administration. Consequently, for maximum impact, drug permeability and transport assessment (and pharmaceutical profiling in general) should be performed simultaneously with the determination and optimization of pharmacological properties.<sup>15–19</sup>

### 5.11.3 Intestinal Drug Absorption – Solubility and Permeability Issues

In the intestine, a single layer of epithelial cells covers the interior of the intestinal wall and forms the rate-limiting barrier to the absorption of a dissolved drug. Although many other factors, and in particular the drug solubility in the intestinal fluids, may limit the bioavailability of a drug (Figure 1), the intestinal epithelial cell layer has proved to be the rate-limiting step to the absorption of many registered oral drug molecules (i.e., drugs for which solubility problems tend to have been sorted out during drug development). It is for this reason that it is possible to predict human intestinal absorption of druglike molecules from drug permeability studies in *in vitro* models consisting of a single layer of epithelial cells, such as Caco-2 cells. Whether drug permeation or drug solubility should be the assay of choice in pharmaceutical profiling should, ideally, be dependent on an educated guess of which of these two absorption barriers will be the rate-limiting step for the set of compounds of interest.<sup>20</sup> Simple rule-based systems based on molecular properties such as lipophilicity are generally used to this end. The physicochemical properties that influence the pharmacokinetic properties of drugs are discussed elsewhere in this volume (e.g., *see* 5.18 Lipophilicity, Polarity, and Hydrophobicity).

In many drug discovery programs, very lipophilic compounds are obtained in the effort to generate high-affinity ligands.<sup>11</sup> Such compounds often have severe solubility problems, and their absorption may therefore be solubility limited.<sup>15,20,21</sup> Because of this, in some drug discovery settings, such compounds are initially screened for solubility rather than for permeability. However, very lipophilic compounds may also distribute strongly to the lipophilic cell membranes, which may result in significantly reduced permeation.<sup>22–24</sup> Thus, for such drugs too, it will eventually be important to study drug permeability in *in vitro* models such as Caco-2. Methods for studies of drug solubility and dissolution are treated elsewhere in this volume (*see* 5.17 Dissolution and Solubility), and the specific problems associated with permeability studies of lipophilic compounds discussed elsewhere.<sup>25</sup>

**Figure 1** The sequential events during the transfer of a drug molecule from a solid dosage form in the gastrointestinal tract to the systemic circulation. The dissolution and permeability across the epithelium are the two most important determinants for the absorption process. Enzymatic and chemical degradation as well as complexation in the GI tract, active secretion, and enzymatic degradation in the intestinal epithelium, and enzymatic degradation in, and biliary excretion from, the liver may decrease the fraction of the drug entering the systemic circulation.

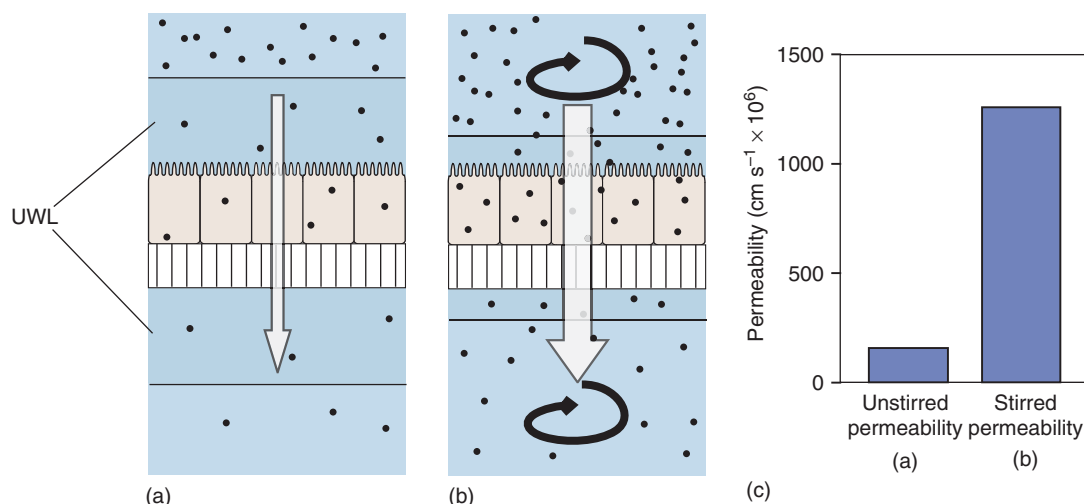

The relative importance of drug solubility and permeability for ensuring appropriate absorption will be dependent on the assumed dose of the druglike compound. For traditional drugs given in relatively high doses, the demands for good solubility and permeability are high. For high-affinity drugs, which can be administered in lower doses, the demands are less strict. Unfortunately, in early drug discovery the minimal dose that needs to be absorbed after oral administration *in vivo* is rarely known.

#### 5.11.4 Physiological and In Vitro Barriers to Intestinal Drug Absorption

Knowledge of the physiological barriers to intestinal drug absorption is vital if one is to appreciate the opportunities and limitations that the cell culture models of the intestinal epithelium represent. The intestinal mucosa can be considered to act as a system of sequential barriers to drug absorption, the outermost barrier being the unstirred water layer (UWL) and the mucus layer.

*In vivo*, the luminal fluids in the intestine are considered to be well stirred.<sup>26,27</sup> As a result of efficient mixing, even rapidly absorbed drugs are available at the same concentration as in the bulk fluid of the intestinal lumen at the luminal surface of the mucus layer covering the intestinal epithelium. *In vitro* screening models such as Caco-2, the situation is different. Without stirring, the UWL adjacent to the apical epithelial surface facing the luminal buffer compartment is rapidly depleted of high-permeability drugs, as they are quickly absorbed across the cell monolayer (Figure 2).<sup>9,28,29</sup> As a result, the drug permeability becomes limited by the (artificially thick) UWL (where the drug concentration is lower than in the bulk), rather than by the epithelial cell monolayer. Importantly, the drugs that are limited by the UWL are the ones with high-transcellular-permeability coefficients, and, therefore, in some screening settings, stirring is not considered to be necessary when the aim is binning into well and poorly absorbed compounds. This may be acceptable when it is sufficient to obtain qualitative rather than quantitative results.

However, when more accurate quantitative results are required, for example for ranking compounds, controlled stirring is mandatory.<sup>30</sup> When extrapolations of Caco-2 permeability data are desired to obtain a value for the permeation of, for example, the blood–brain barrier, a well-stirred system is necessary for the predictions to be of use.<sup>18,31,32</sup> This becomes clear if we consider that the UWL in the brain capillaries cannot, in the unstirred situation, be larger than the diameter of these capillaries (3  $\mu\text{m}$ ), and is probably much smaller because of the blood flow and cellular

**Figure 2** The effect of stirring in in vitro permeability measurements. In an unstirred system (a), drugs with high cellular permeability will be limited by their diffusion through the unstirred water layer (UWL). Under stirring conditions (b), the thickness of the UWL is reduced, and the bulk concentration will be available for diffusion through the cell monolayer. The permeability of verapamil, an example of a high-permeability drug, was measured at low and high stirring rates (c). Data redrawn from Avdeef, A.; Artursson, P.; Neuhoﬀ, S.; Lazorova, L.; Gråsjö, J.; Tavelin, S. *Eur. J. Pharm. Sci.* **2005**, *24*, 333–349, with permission from Elsevier.

contents.<sup>32</sup> Another consequence of disregarding stirring is that computational models built from drug transport experiments performed under inadequate stirring conditions will be overly affected by the barrier of the UWL.

The next barrier that a permeating drug molecule encounters during its approach to the intestinal wall is the mucus layer. In general, the hydrogel-like structure of the mucus does not restrict the diffusion of normal-sized drugs.<sup>33</sup> However, the mucus is thought to present a barrier to the absorption of highly lipophilic drugs and some peptides because of the restrictions to diffusion in this matrix.<sup>34</sup> Probably, such interactions are saturable under in vivo conditions, and therefore of little significance. This conclusion is supported by the fact that the permeability of lipophilic drugs in general is high and the reduction in drug permeability caused by interactions with the mucus layer will in most cases not influence the absorbed fraction of the drug. Thus, in permeability screening of average-sized oral drugs,<sup>35</sup> the barrier of the mucus layer does not have to be considered. Cell culture models of the intestinal epithelial goblet cells that produce a mucus layer are available,<sup>36,37</sup> but their application is normally limited to specific investigations on the effects of molecular structures that are larger than those of normal drugs, such as macromolecules,<sup>38–41</sup> and nanoparticles.<sup>42</sup> Attempts to produce co-cultures of Caco-2 and HT29 goblet cells have been made, but no real advantages over standard Caco-2 cell cultures have been revealed.<sup>43–45</sup>

Independently of the bulk pH of the luminal fluids of the human intestine, which ranges between 5.5 and 7.5,<sup>46</sup> the mucus layer buffers an acid microclimate that keeps the pH adjacent to the apical surface of the enterocytes at the villus tips relatively constant. The acid microclimate is maintained by sodium–proton exchangers in combination with several HCO<sub>3</sub><sup>-</sup>-ion exchangers (e.g., the Cl<sup>-</sup>/HCO<sub>3</sub><sup>-</sup>-exchanger) and other transporters.<sup>47</sup> The expression and activity of the transporters along the GI tract and along the crypt–villus axis will also influence the buffer capacity.<sup>48</sup> The pH adjacent to the human jejunal surface was determined to be 5.9,<sup>49</sup> and the surface pH of the normal human rectal mucosa was between 6.2 and 6.8.<sup>50</sup> The acid microclimate can easily be mimicked during permeability experiments across cell monolayers such as Caco-2, and will influence both the outcome and interpretation of such experiments.<sup>25</sup>

The absorptive epithelium lining the GI tract follows the folds and villi that increase the anatomical surface area of the mucosa several-fold in the small intestine.<sup>52</sup> The villi are interspaced with crypts in which the regeneration of intestinal cells occurs. In between the crypts and the tips of the villi are the more basal parts of the villi (Figure 3a). The properties that are relevant for drug absorption differ along the crypt–villus axis.

Owing to its enlarged surface area, the small intestine is considered to be the major site for passive transcellular drug absorption. The anatomical surface area of the intestinal epithelium is, however, not necessarily analogous to an effective absorptive surface area (Figure 3b).<sup>53</sup> For example, it has been calculated that the most rapidly absorbed compound known to date, glucose, has an absorptive surface area that covers only a small part of the total anatomical surface area of the small intestine (i.e., the villus tips).<sup>27,54</sup> By contrast, a low-permeability drug does not distribute rapidly into the cell membrane of the villus cells and therefore resides longer in the intestinal fluids.

**Figure 3** The crypt–villus axis and the properties of its various parts. (a) Schematic representation of the crypt–villus axis, divided into upper villus, basal villus, and crypt. (b) The effective intestinal surface area that the drug encounters will be determined by the epithelial permeability to the drug. Compounds with lower permeability coefficients (open circles) will have time to diffuse further down the crypt–villus axis, and can therefore be absorbed across a larger surface area (dashed line) than can the high-permeability compounds (solid circles) that are rapidly absorbed at the villus tips and therefore utilize a smaller absorptive surface area (solid line). The average size of the paracellular pores varies along the crypt–villus axis, with the pores becoming more narrow as the cells mature and move toward the villus tips.<sup>51</sup>

During this time the drug will diffuse down the length of the crypt–villus axis to be absorbed eventually over a larger absorptive surface area. Thus, the contribution of the absorptive surface area to the drug transport of the intestinal mucosa will be dependent on the permeability to the drug. The variability in absorptive surface area is an unknown parameter, and, thus, not considered in intestinal perfusion studies in animals or humans, where the absorptive surface area is treated as a constant and considered to be equal to a smooth tube of the intestinal inner diameter.<sup>55,56</sup>

The intestinal epithelium does not only restrict access, thereby protecting the body from harmful agents, but also allows selective absorption of nutrients and secretion of waste products and xenobiotics. The intestinal epithelium consists of several types of cells including the absorptive enterocytes and mucus-secreting goblet cells, of which the enterocytes are the most abundant.<sup>52</sup> At the villus tips, where the absorption of most orally administered drugs occurs, the epithelium is dominated by well-differentiated enterocytes. Caco-2 cells are unusually well differentiated, and therefore express many of the functions found in the mature small intestinal villus enterocytes, despite the fact that they originate from a human colorectal carcinoma.<sup>57,58</sup> In fact, so far all attempts to isolate and grow or immortalize normal intestinal epithelial cells have resulted in less differentiated phenotypes than that of Caco-2 cells.<sup>59,60</sup>

**Figure 4** Transport routes across the intestinal epithelium that are relevant for the absorption of druglike compounds: 1, passive transcellular; 2, passive paracellular transport; 3, active efflux; 4, active uptake. Passive permeability can occur in both absorptive (a) and secretory (b) directions, depending on local drug concentrations. Likewise, because the membrane proteins responsible for efflux and uptake can be situated either in the apical or in the basolateral membrane, active transport can occur in both absorptive and secretory directions.

The barrier properties of the differentiated enterocyte at the villus tips is best described by an examination of the several parallel drug transport mechanisms across these cells (**Figure 4**). These mechanisms and their impact on drug absorption are discussed in the next section.

### 5.11.5 Transport Mechanisms Across the Intestinal Epithelial Barrier

There are two general pathways by which a drug molecule can cross the intestinal epithelium: the transcellular pathway, which requires that the drug can cross the lipophilic cell membranes, and the paracellular pathway, in which diffusion occurs through the water-filled pores of the tight junctions between the cells. Both passive and active transport may contribute to the permeability of drugs via the transcellular pathway (and also via the paracellular pathway). The passive and active transcellular pathways are inherently different, and therefore the molecular properties that influence drug transport by these routes are also different. The four principal drug transport pathways are presented in **Figure 4**. Note that all of the transport processes may occur in both directions, depending on local drug concentrations (in the case of passive transport) and the location and directionality of the involved transporter (in the case of active transport). The various transport mechanisms across the intestinal epithelium are discussed below.

#### 5.11.5.1 Passive Transcellular Transport

The passive transcellular pathway is still by far the most important absorption pathway for drugs. Drug transport via the passive transcellular route requires that the solute permeates the apical cell membrane. The composition of the phospholipids and proteins of the cell membranes varies from cell type to cell type, and may, theoretically, give rise to different permeability properties depending on the cell type. In addition, monolayer-forming cells such as the intestinal enterocytes have a polarized cell membrane with distinct differences in membrane composition in the apical and the basolateral membrane.<sup>61</sup> It is generally believed that the apical membrane has a lower permeability than the basolateral membrane, and therefore the former is considered to be the rate-limiting barrier to passive transcellular drug transport.<sup>62</sup>

Early models of the transcellular pathway regarded the cell membrane as a homogeneous barrier, and thereby considered drug permeability to be a process of partitioning into the lipid bilayer followed by diffusion across the membrane.<sup>63</sup> This ‘solubility–diffusion’ model was later extended with the so-called pH-partitioning theory, which states that only the uncharged form of an electrolytic molecule will partition into the cell membrane.<sup>64</sup> One consequence of the assumption, that drug partitioning into the membrane is a one-step process, is that the cell membrane is considered to be an isotropic system. This assumption explains why drug partitioning in simple isotropic solvent systems, such as octanol–water, has been extensively used to predict passive membrane permeability (e.g., see 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery; 5.28 In Silico Models to Predict Oral Absorption).<sup>65,66</sup> However, the protein-containing lipid bilayer that constitutes the cell membrane is an anisotropic system.<sup>67</sup> Multiple-step permeability models have therefore been proposed to account for the anisotropic nature of the cell membrane.<sup>68</sup> Molecular dynamics simulations have shown that a drug molecule

entering the cell membrane will experience different diffusion rates in different parts of the membrane,<sup>69–71</sup> and, perhaps more importantly, different inter-molecular forces will affect the permeating substance depending on the local environment in the lipid bilayer.<sup>67,69–74</sup>

Independently of whether the solubility–diffusion model or a more complex description of the cell membrane is used, passive transcellular drug permeability can usually be relatively well described using rather simple molecular properties such as size, charge, polarity, and hydrogen bonding (*see* 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery; 5.28 In Silico Models to Predict Oral Absorption).<sup>15,17</sup> Many experimental and theoretical predictive models of intestinal drug permeability have therefore been based on descriptors relating to these basic molecular properties (*see* 5.28 In Silico Models to Predict Oral Absorption).<sup>15,17</sup> Importantly, these models assume that the passive transcellular route dominates the drug permeation. However, when other transport routes, such as the paracellular or active transcellular routes, are involved to a significant extent, they will introduce a bias that reduces the predictivity of such models. Likewise, significant intestinal metabolism will be a complicating factor.

### 5.11.5.2 Paracellular Transport

Drugs of low to moderate molecular weight (MW) can permeate the intestinal epithelium through the water-filled pores between the cells. This process is known as paracellular transport, and is generally considered to be a passive process, even if this pathway appears to be selective for cationic rather than anionic and neutral drugs.<sup>62,75,76</sup> The paracellular pathway has also been shown to be saturable<sup>77–79</sup> by at least two independent mechanisms, one of which involves an intracellular process.<sup>79</sup> These examples illustrate the complexity and dynamics of the regulation of this pathway, which had previously been considered to be invariable.

The paracellular route is guarded by extracellular tight junction proteins that create narrow water-filled pores between the cells. The narrow pores of the tight junction complex, which form a seal at the most apical part of the intercellular space, constitute the rate-limiting step of the paracellular pathway. This route is, therefore, mainly accessible to smaller molecules, and is of significance only if these small drugs are too hydrophilic to distribute into the cell membranes at appreciable rates. If one considers the large difference in surface area between the membrane surface of intestinal epithelial cells and that of the intercellular spaces between the cells, it may be surprising to find that the paracellular route is of any importance at all. The issue remains controversial, and different opinions are held about its significance, ranging from it being a route that significantly contributes to drug absorption to it being of negligible importance.<sup>75,80,81</sup>

Drugs believed to be significantly absorbed by the paracellular route include the beta receptor antagonist atenolol (MW: 266),<sup>82</sup> the H<sub>2</sub> receptor antagonists cimetidine (MW: 252), ranitidine (MW: 314), and famotidine (MW: 337),<sup>78,79</sup> and the loop diuretic furosemide (MW: 331).<sup>83</sup> These drugs are all of moderate MW (around 250–340), and are relatively hydrophilic. Paracellularly absorbed drugs are usually incompletely absorbed since the absorption only occurs during the passage through the small intestine where the pores are sufficiently large to allow the passage of small solutes. In addition, the paracellular pores cover only 0.01–0.1% of the total surface area of the intestine,<sup>84,85</sup> and the size-restricting gate function of the paracellular pathway significantly limits the permeability.<sup>86</sup> The paracellular permeability is dynamically regulated, and varies both along the path of the intestine and along the crypt–villus axis.<sup>51,87–89</sup> Quite specific ways of bringing about pharmacological regulation of the paracellular pathway have been proposed, with the intention of enhancing the absorption of polar drugs, but fear of inducing nonspecific simultaneous absorption of toxic compounds from the gut has reduced interest in pursuing this approach.<sup>77,90–94</sup>

The paracellular pathway of the small intestine appears to be a dual-pore system, with larger pores further down the crypt–villus axis.<sup>51,95</sup> Given this, it can be hypothesized that a hydrophilic drug that is partitioning slowly into the intestinal cell membrane will have time to diffuse further down the crypt–villus axis (**Figure 3b**) and eventually be absorbed via paracellular pores that are significantly larger than those available at the villus tips. Thus, such compounds may exhibit higher *in vivo* absorption than expected from their passive transcellular permeability.

### 5.11.5.3 Active Transport

Global gene expression studies on intestinal tissues show that more than 100 transport proteins and ion channels are expressed at the mRNA level in the gut.<sup>96,97</sup> While most of these transporters are highly specialized and mediate facilitated transport of essential nutrients, an increasing number have been found to have more general transport functions. These transporters, which have broader substrate specificity, are often referred to as polyspecific transport proteins, and have the capacity to transport drug molecules. Comparison with Caco-2 cells has revealed that, although

**Figure 5** Comparison of the number of compounds reported to have affinity for the major drug transporters (OCT, organic cation transporter; OAT, organic anion transporter; PEPT, peptide transporter of the intestine; other transporters defined in the text). The data were extracted from the publicly available transporter database from Tokyo University.<sup>99</sup> Note that the numbers reflect the extent to which the transporters have been studied and not their relative importance as drug transporters. In total, 994 compounds were listed in the database in May 2005.

the majority of the transporter genes had detectable expression, the expression levels generally differed from those in human intestinal tissue. However, the relevance of the reported mRNA expression levels will remain uncertain until more data on protein expression and function has become available. In at least one case, a clear correlation between transporter mRNA expression, protein expression, and protein function was observed in Caco-2 cells.<sup>98</sup> Importantly, for the majority of drugs, it is still not known which transporters of all those possible are of significance for their intestinal absorption.

An examination of a database containing data assembled from the literature on substrates/inhibitors for various transporters indicates how the research community has scored their relevance for drug transport (Figure 5).<sup>99</sup> Clearly, the extensively studied efflux protein P-glycoprotein (P-gp) has the highest number of substrates/inhibitors, followed by other efflux transporters of the ATP-binding cassette (ABC) transporter family, various transporters for organic anions, cations, and the oligopeptide transporter PEPT1.<sup>99</sup> This rating can probably be explained by the role of ABC transporters in drug resistance,<sup>100,101</sup> brain uptake,<sup>102,103</sup> and drug–drug interactions,<sup>104–106</sup> and by the importance of ABC transporters and organic anion and cation transporters for drug transport and elimination in the liver, kidney, and, perhaps, the intestine,<sup>107</sup> and by the exploitation of PEPT1 as a (pro)drug target for enhanced absorption.<sup>108</sup>

Examples of successful exploitation of PEPT1, which is responsible for the uptake of dietary small peptides from the intestine, include the modification of the antiviral drug acyclovir to the PEPT1 substrate valacyclovir, which increased the bioavailability from 22% to 77%.<sup>109</sup> A potential drawback with the exploitation of drug transporters for increased drug absorption could be the occurrence of complex drug–drug interactions. For instance, the bioavailability of cefixime, which is another substrate for PEPT1, was increased by the calcium channel blocker nifedipine,<sup>110</sup> an effect attributed to calcium ion effects on proton-dependent transporters such as sodium–proton exchangers that maintain the apical acid microclimate necessary for PEPT1 function.<sup>111,112</sup> Further, successful improvement of drug uptake with the aid of a transporter such as PEPT1 will not necessarily result in increased absorption since the compound may be trapped and degraded inside the cell.<sup>108,113</sup>

In contrast to transport proteins that mediate uptake into the cells, other transport proteins expel their substrates out of the cells. These so-called efflux proteins belong to the ATP-binding cassette (ABC) super-family of membrane transporters. The ABC gene family has about 50 members, and includes the multidrug resistance 1 (MDR1, ABCB1) gene product P-gp and the multidrug resistance associated protein family (MRP, ABCC).<sup>114,115</sup> Fairly recently the homodimeric breast cancer resistance protein (BCRP, ABCG2) has been identified as a potential contributor to actively limiting the oral bioavailability of some drugs.<sup>116,117</sup> The function of the efflux proteins in the intestine may be to prevent the uptake of toxic substances, and also to eliminate such substances from the blood.<sup>106,118,119</sup>

While the significance of drug efflux proteins such as P-gp and BCRP are undisputed in barriers such as the endothelial blood–brain barrier,<sup>120</sup> which is exposed to comparably low and often nonsaturating concentrations of efflux substrates, their role in limiting drug absorption in the small intestine, which is exposed to much higher, often

saturating drug concentrations, is disputed.<sup>121–123</sup> In one case, a polymorphism in P-gp was suggested to influence intestinal absorption of digoxin,<sup>124</sup> but the relevance of this finding has been questioned.<sup>125</sup> In particular, the effects of concomitantly administered drugs on the P-gp substrate digoxin has been studied.<sup>105,106,126–128</sup> Interestingly, the serum levels of orally administered digoxin have been shown to increase in a stepwise manner with the number of P-gp inhibitors co-administered to patients, suggesting that several weaker P-gp inhibitors may have additive effects in the clinical setting.<sup>104</sup> Thus, an emerging concern is that drug–drug interactions may be more pronounced in the clinical setting, where co-administration of several P-gp-interacting drugs is a reality.

#### 5.11.5.4 Complexity of Drug Transport

Absorption processes involving transport proteins are generally saturable. Because of this, drugs that are substrates for an active transport protein can display a nonlinear dose–response relationship. In addition, many of these proteins transport nutrients, and therefore their capacity is likely to be influenced by food intake.<sup>129</sup> These factors may complicate the oral delivery of drugs that are absorbed by active mechanisms.<sup>130</sup>

A further complication arises because one drug may be a substrate for several transporters. For instance, the drug may be taken up into the cell by one transporter and effluxed by another.<sup>131–133</sup> Moreover, an interplay between drug transport and drug metabolism may occur.<sup>134–138</sup> Last, but not least, active transport components often occur in parallel with passive diffusion processes, the latter being the most significant process. For instance, the pharmacokinetics of the partly actively transported drug levodopa was dramatically improved by maximizing the passive diffusion of the drug across the intestinal wall.<sup>139,140</sup> Thus, in summary, an intricate picture has emerged where several transport processes may act in parallel or in series with each other in the transfer of a drug across the intestinal epithelium. It is very difficult to clarify such multifaceted processes in the complex intestinal tissue. They are more easily studied in the simple cell culture models of epithelial cells, where each transport process can be examined in isolation. Thus, it is possible to extract information about specific transport processes in Caco-2 cells and alternative epithelial cell cultures that would be difficult to obtain in more complex systems, such as models based on whole tissues from experimental animals.

#### 5.11.6 Permeability Assay

Transport studies in Caco-2 cells and in other monolayer-forming cells are generally performed using an experimental setup in which the cells are grown on a porous filter insert, although some variants of the setup have been suggested. For instance, continuous-dissolution–Caco-2 permeability systems<sup>141–143</sup> and an automated continuous-perfusion system have been suggested.<sup>144</sup> In the standard setup, the porous support covers the bottom of a plastic cell culture insert, which forms a small compartment to which the cell culture medium is added. The insert is placed in a slightly larger cell culture well, to form a second compartment that is filled with cell culture medium. The medium is then changed to a buffer suitable for transport experiments, and the drug is added to one of the compartments, called the donor compartment. The amount of transported drug is determined from samples withdrawn from the other compartment, called the acceptor compartment. Detailed descriptions of the cell culture procedures for Caco-2 cells (and other cell lines) and more general descriptions of how to perform drug transport experiments in these cell cultures are available in handbooks on cell culture methodologies.<sup>145–148</sup>

This experimental setup has several unique features that are attractive for permeability assessment. If the filter is sufficiently porous, it will not form a rate-limiting barrier to drug permeation. This means that true intrinsic cellular permeability coefficients can be obtained.<sup>149</sup> If the system is well stirred, so that stagnant water layers are avoided,<sup>150</sup> the measured passive transcellular permeability coefficients are in quantitative agreement with those measured in the perfused human jejunum.<sup>151</sup> In addition, since the apical and basolateral surface areas are approximately equal, the passive transcellular permeability will be equal in the absorptive and secretory directions.<sup>152</sup> Similarly, the paracellular surface areas are comparable, and, hence, paracellular surface markers such as mannitol generally have the same permeability in both directions.

Thus, in principle, it can be revealed that an active transport process is involved if a clear difference is observed between the permeabilities in the two opposing directions. Therefore, a common choice in the screening of intestinal permeability is to measure the permeability in both directions across the cell monolayers, and determine the efflux or uptake ratio. The efflux ratio is calculated as the ratio of the secretory permeability to the absorptive permeability ( $P_{app, B \rightarrow A}/P_{app, A \rightarrow B}$ ), and the uptake ratio as the inverse of the efflux ratio. An efflux or uptake ratio significantly larger or smaller than unity is generally taken to be an indication of an active transport process.<sup>153,154</sup>

A complicating issue in the assessment of permeability is that many investigators prefer to perform permeability studies using a slightly acid pH on the apical side of the monolayer. There are two explanations for this: first, this mimics

the acid microclimate on the apical side of the enterocytes in the small intestine, and, second, independent studies have suggested that slightly better correlations were obtained with *in vivo* data under these conditions.<sup>96,155,156</sup> However, since most drugs have protonizable functionalities, the asymmetrical pH condition will result in a different concentration of the uncharged drug species on each side of the monolayer.<sup>25</sup> In turn, this will result in passive asymmetric transport, that is, the absorptive permeability will be different from the secretory permeability without any transporter being involved.<sup>157</sup> Another complication is that access to the transporter may differ between the apical and basolateral sides.<sup>158,159</sup>

The use of an effective inhibitor of the transporter may be an alternative to studies of asymmetrical transport. In this setup, the drug permeability in the absorptive direction is studied in the absence and presence of the inhibitor, and, if the resulting permeability ratio ( $P_{app, -inhibitor}/P_{app, +inhibitor}$ ) is significantly different from 1, an active transport mechanism may be involved. Indeed, when such an inhibition ratio was used *in vitro* to predict the effect of P-gp on plasma drug levels in mice, a better *in vivo* prediction was obtained than for efflux ratios obtained from measurements of asymmetrical transport.<sup>160</sup>

#### 5.11.6.1 Quality of Data and Data Sets

It is not possible to obtain good predictions of human intestinal permeability and absorption from cell culture models if the data generated are of a poor quality. Nevertheless, higher-throughput permeability data, often based on just one or a few samples per compound, are produced in many screening settings. If appropriately applied, though, such data are still useful for binary classification of groups of compounds or even whole chemical libraries in earlier stages of drug discovery. However, more recently, the value of such data sets has been questioned due to the improvements seen in *in silico* predictions of drug permeability.

Caco-2 data sets can also serve as reference data sets for the evaluation of computational permeability filters. Permeability data from Caco-2 cells have been successfully used to evaluate computational screening filters that extracted compound sets enriched in high-permeability compounds from chemical libraries.<sup>161</sup>

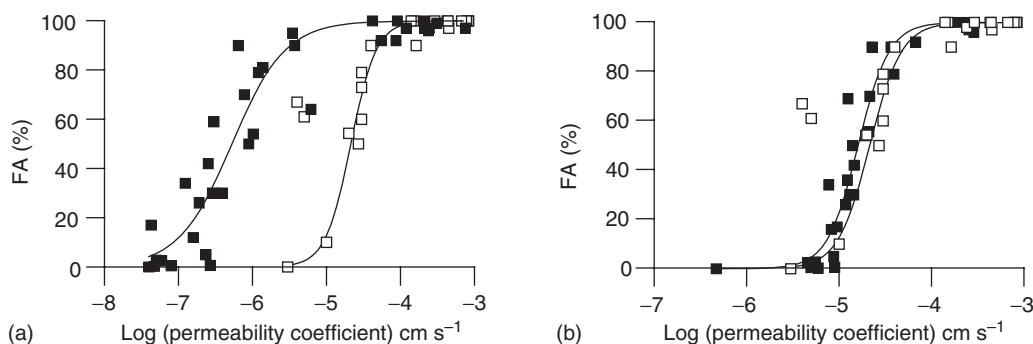

One result of the fact that the permeability data generated in drug discovery are often obtained from rapid, more or less binary screening assays is that the data are of insufficient quality to allow development of the good predictive relationships needed in later drug discovery phases. Unfortunately, the literature contains very few reliable data sets of sufficient size even though increased information sharing is predicted to be beneficial for academia, government, and industry alike.<sup>162</sup> This deficiency of high-quality published data sets has resulted in repetitive and sometimes uncritical use of poor data in predictions and computer modeling of drug absorption. Thus, in the absence of large data sets of high quality, relatively small data sets comprising reliable and reproducible experimental data have been used.<sup>30,163</sup>

One bias that is evident in *in vitro* models (and, indeed, in *in silico* models) intended to predict drug absorption is that the data sets are generally over-represented by completely absorbed compounds.<sup>164</sup> This is probably a consequence of the data sets being based on orally administered marketed drugs, most of which have favorable oral absorption properties. Despite their bias, models based on such skewed data sets can often distinguish between high-(>80% absorbed) and low-permeability compounds, and rapidly give useful information about the expected average permeability of compound libraries. However, compounds with moderate absorption properties may also be of interest in the early phases of drug discovery, and it is therefore advantageous to include such compounds in the evaluation of permeability models.<sup>164</sup> The need to include a significant number of incompletely absorbed compounds in the data set is emphasized during lead optimization, when ranking compounds according to their permeability or their predicted absorption properties is desirable. The fact that the data sets are generally based on passively transported compounds and that no consideration is given to the potential influence of active transport processes is indicative of another weakness. Although this approach gives better models of passive permeability, these models only generate selective information about the passive route, and their performance in the screening of data sets that include actively transported compounds should be evaluated.

#### 5.11.6.2 Prediction of In Vivo Drug Permeability and Absorption Using Caco-2 Cells and Alternative Models

Initially, the good relationship between the passive drug transport across Caco-2 cells and the fraction absorbed after oral administration to humans<sup>9</sup> may be surprising, given that oral drug absorption is influenced by many factors besides drug permeability, such as drug solubility, dissolution, active transport, and, in some cases, presystemic metabolism.<sup>165</sup> The first study conducted with Caco-2 cells was performed under highly controlled conditions on registered drugs that were known to be free from solubility problems and which were mostly transported by passive transport.<sup>9</sup> Furthermore, their metabolism could be accounted for. Later investigations have revealed that results of a similar standard can be obtained when the same parameters are strictly controlled in expanded data sets (Figure 6a, solid symbols).<sup>30</sup>

**Figure 6** Comparison of permeability coefficients obtained from human jejunal perfusion experiments (open symbols)<sup>166,167</sup> and in Caco-2 cells (a, solid symbols)<sup>30,168</sup> and 2/4/A1 cells (b, solid symbols).<sup>168</sup> The 2/4/A1 cell line gives permeability coefficients that overlap the human jejunal permeability coefficients. FA is the fraction of a dose that is absorbed after oral administration. (Reproduced from Artursson, P.; Tavelin, S. Caco-2 and Emerging Alternatives for Prediction of Intestinal Drug Transport: A General Overview. In *Drug Bioavailability – Estimation of Solubility, Permeability, Absorption and Bioavailability*; Artursson, P., Ed.; Wiley-VCH: Weinheim, Germany, 2003, pp 72–89, with permission from Wiley-VCH.)

However, early on, many drug discovery scientists were disappointed when their experimental in-house compounds gave rise to relationships between FA and permeability with a much larger scatter than reported in the original publication. With hindsight, these results are not surprising considering the fact that the majority of the discovery compounds had neither been characterized nor optimized with regard to the chemical stability, metabolism, solubility, or (if available in crystalline form) dissolution rate. Another factor contributing to this scatter is related to the experimental design. For small data sets, Caco-2 permeability measurements are generally performed manually, with full attention being given to, for example, issues related to mass balance and the contribution from active transport. In contrast, permeability measurements for large data sets are normally established in automated systems, with little consideration being given to mass balance and active transport. Despite these simplifications, there are several reports that have indicated the usefulness of permeability data obtained in automated systems in predictions of oral absorption<sup>161,169–172</sup> and drug efflux.<sup>173</sup> The implementation of Caco-2 cells in the 96-well format was reported fairly recently.<sup>174</sup> Unfortunately, miniaturization to plate formats below 96-well plates has been technically difficult to achieve, because of the small surface area of the cell monolayers in such formats.<sup>19</sup> Also, discovery scientists have experienced larger problems with the mass balance in this format, in that larger fractions of lipophilic compounds are sometimes lost during transport experiments. In addition to automating the experimental runs, another way to increase the efficiency of permeability screening is to use cassette dosing (*n*-in-one). Independent investigations have shown that the dosing of several compounds to each cell monolayer gives fairly good permeability data, but concerns have been expressed about the impact of potential drug–drug interactions (e.g., on transporter inhibition), and, in one case, interactions between acidic compounds were observed.<sup>175–177</sup> Analytical methods for cassette dosing of sets of reference compounds sets have been developed.<sup>178–180</sup> An extreme but useful variant of cassette dosing is to study partly purified extracts from, for example, plants or food supplements in the cell monolayers.<sup>181</sup>

One example of the wide-spread acceptance of absorption prediction from in vitro permeability measurements in Caco-2 cells and similar cell lines is that the US Food and Drug Administration (FDA) has approved drug permeability measurements in these cell lines as substitutes for in vivo investigations in bioequivalence studies of well-absorbed drugs.<sup>182,183</sup> Thus, according to the FDA-implemented biopharmaceutics classification system (BCS), it is possible to waive FDA bioequivalence studies for high-solubility and high-permeability drugs (see 5.42 The Biopharmaceutics Classification System). Ways of expanding the BCS by allowing a broader definition of high-solubility/high-permeability drugs or of other classes of drugs have been discussed.<sup>184–186</sup> The need to consider the dose in the biopharmaceutical classification has also been investigated, and was found to be particularly important for solubility-limited drugs.<sup>187</sup> The classification of druglike compounds according to the BCS is increasingly applied in drug discovery, and modifications to the scheme have been suggested with this in mind.<sup>163,188</sup>

It is noteworthy that the Caco-2-based relationship in Figure 6a was established using a structurally diverse data set and that analogous series of compounds often give better relationships. Consequently, Caco-2 cells have often been used to rank series and libraries of analogous compounds. When such data sets are used, permeability measurements from Caco-2 cells and other cell monolayers provide the opportunity to establish structure–permeability relationships for quite different analogous series of drugs. Several examples of the latter have been published. For example, these

include series of conventional drugs,<sup>5,189,190</sup> peptides, and peptide mimetics<sup>74,191–193</sup> as well as newer types of druglike compounds.<sup>194–197</sup> Although most of these structure–permeability relationships have been established for passive membrane permeability, there are also many examples of structure–transport relationships for series of drugs that are absorbed by means of an active transport mechanism.<sup>198,199</sup>

### 5.11.6.3 Alternatives to Caco-2 Cells

Over the years, several alternatives to Caco-2 cells have been suggested for the assessment of drug permeability. In fact, MDCK cells, which are epithelial cells derived from dog kidney, were the first cells grown as monolayers on a permeable support,<sup>200</sup> and were proposed as a cellular drug transport barrier as early as 1989.<sup>201</sup> However, while MDCK cells were exploited as host cells for transfected transport proteins,<sup>202</sup> it was not until later that their performance was compared with that of Caco-2 cells with regard to predictions of oral drug absorption in humans.<sup>203</sup> The results revealed that the two cell lines were comparable for the investigated data set, and the Papp values from the two models correlated relatively well ( $r^2 = 0.79$ ).<sup>204</sup> Other alternative cell lines include the Caco-2 clone TC7, a cell line which, in contrast to parenteral Caco-2 cells, also expresses some drug-metabolizing enzymes.<sup>205,206</sup> Drug permeabilities determined in Caco-2TC7 cells result in fairly good correlations with the absorbed drug fraction after oral administration to humans, as do other monolayer-forming intestinal epithelial cell lines, such as the mucus-producing cell clone HT29-MTX.<sup>207</sup>

In contrast to high-permeability drugs, which partition into the cell membranes at comparable, rapid speeds in vitro and in vivo, compounds of intermediate or low permeability have a lower permeability in the Caco-2 model than in the human small intestine in vivo.<sup>151,208,209</sup> As can be seen in [Figure 6a](#), this difference increases with a decrease in the compound permeability. One reason for this difference is that the paracellular route is tighter in Caco-2 cells than that in the small intestine in vivo. While the average pore radius of the tight junctions in the human small intestine is around 8–13 Å,<sup>210</sup> the corresponding radius in Caco-2 cells is about 4 Å.<sup>168</sup> When the paracellular pathway is narrower, the intrinsic permeability will be lower than in the in vivo situation. The contribution of the paracellular pathway to the overall transport of one lipophilic high-permeability drug (alfentanil) and one hydrophilic low-permeability drug (cimetidine) was investigated in Caco-2 cells.<sup>81,211</sup>

A more leaky cell culture model established from the rat fetal intestine, 2/4/A1, was suggested as a solution to this problem.<sup>208,212</sup> This cell line, which has a paracellular permeability comparable to that of the human small intestinal epithelium in vivo (pore radius 9 Å), gives a better quantitative relationship than Caco-2 cells with human permeability data generated in the Loc-I-Gut perfusion technique ([Figure 6b](#)).<sup>164,168,208</sup> Interestingly, the 2/4/A1 cell line does not seem to functionally express important drug transporters,<sup>213</sup> which makes it an interesting alternative in studies of passive permeability. Another advantage of the 2/4/A1 cell line is that relatively large amounts of low-permeability drugs are transported, thereby eliminating the need for expensive analytical equipment such as liquid chromatography with tandem mass spectrometry.

In summary, passive permeability measurements conducted not only in Caco-2 cells but also in other monolayer-forming epithelial cell lines seem to predict oral drug absorption of registered drugs. The question then arises if even simpler models, such as monolayers of the less differentiated and therefore less complex 2/4/A1 cells, or even artificial membranes consisting of phospholipids (parallel artificial membrane permeability assay, PAMPA<sup>214</sup>), or of organic solvents such as hexadecane membrane (HDM<sup>215</sup>), can rank compounds with regard to permeability or oral drug absorption equally well as the more complex cell culture models. A recent study investigated how the more leaky small intestinal-like 2/4/A1 cells compared with Caco-2 cells, which have tighter tight junctions and express many functional transport proteins, and with HDM, which lack tight junctions completely and have no transport proteins.<sup>164</sup> The completely absorbed compounds in this study (fraction absorbed > 80%), were well predicted by all three models. This was most likely because all of these compounds utilized the transcellular route, which was available in all models. However, when incompletely absorbed compounds were also included in the data set (fraction absorbed = 30–80%), the two cell culture models, which in addition to the transcellular route also have a paracellular route, performed much better. For instance, the Spearman rank order correlation ( $r_s$ ) with fraction absorbed was around 0.75 for the cell cultures and 0.47 for the artificial membranes when a data set of compounds evenly distributed with regard to intestinal absorption (FA = 0–100%) was used.<sup>164</sup> Thus, cellular permeability models that take the paracellular route into consideration seem to perform better than those that do not.

In the study comparing Caco-2, 2/4/A1, and HDM permeability data, the significance of active transport in permeability screening was challenged, since half of the compound data set of 30 compounds was reported to be at least partly actively transported.<sup>164</sup> Neither 2/4/A1 cells nor the artificial membranes exhibit significant transport activities, and, with the possible exception for some ABC transporters,<sup>117</sup> the transporter expression in Caco-2 cells does not

correspond quantitatively to that found in the human intestine.<sup>96</sup> Thus, it was expected that compounds that were transported actively to a significant extent would be outliers. However, the influence of active transport was not clear-cut. For instance, only three actively transported compounds, digoxin, a substrate for MDR1, GlySar, a substrate for PEPT1, and methotrexate, a substrate for the reduced folate transporter, were clear outliers in the correlation based on 2/4/A1 cell permeabilities while all other actively transported compounds were predicted equally well as the passively transported compounds. When the three outliers were removed, the rank order correlation with the fraction absorbed increased to 0.95. While these results bring hope for the prediction of oral absorption from permeability data, they require an explanation. The most likely reason is that active transport is insignificant in comparison to the strongly dominant passive component and that passive permeability dominates even more at the early phase of absorption, when the oral dosage form has been dissolved and a very high concentration of the drug is presented to the intestinal wall.<sup>139,140</sup> Despite these results, which were obtained with registered oral drug products, it is clear that in many cases the impact of active drug transport is more pronounced for many current discovery compounds, which often have higher receptor affinities and, hence, are intended for administration at lower, non-saturating doses. In vitro tools for studies of active drug transport will therefore most likely become a more important tool in ADMET research.

#### 5.11.6.4 Prediction of Active Drug Transport

The functional expression of many relevant drug transporters in Caco-2 cells may complicate the interpretation of the results. For instance, when druglike compounds are screened in Caco-2 cells, they are usually used at low, micromolar range, concentrations. At such low concentrations, many active drug transport processes might not be saturated. The results from Caco-2 cells may, for example, then suggest that, at micromolar range concentrations, efflux systems significantly limit the permeability of the drug at the same time that simple calculations may show that the drug when administered to humans will be presented to the epithelium of the upper small intestine at a much higher concentration (millimolar range) than that used in the screening.<sup>15,216</sup> Since the transport mechanism may be saturated at higher concentrations, the drug efflux may sometimes be considered as an in vitro artifact that will not be relevant in the in vivo situation, at least for compounds that are administered at higher doses or that have high protein binding.

Another complicating factor in performing in vitro prediction of the active transport in vivo is that there is no quantitative relationship between active drug transport in the cell culture models and in vivo.<sup>151,217</sup> The explanation for this may be that the level at which the transporter is expressed in Caco-2 cells is not comparable to that in vivo.<sup>117,218</sup> In addition, studies of active transport are further complicated by the absence of specific substrates. For example, most substrates for the drug efflux transporters can be transported by several transport proteins.<sup>219</sup> A look into the listed substrates/inhibitors in the transporter database provided by the University of Tokyo reveals that a large fraction of the listed compounds interact with several transporters; for example, taurocholic acid was reported to interact with 14 different transporters.<sup>99</sup> Whether the compounds listed as interacting with a single transporter are indeed specific for that particular transporter remains to be shown, since most compounds have only been studied with a single or a few transporters.

In the absence of specific substrates, epithelial cell culture models, such as LLC-PK1 (a monolayer-forming epithelial cell line originating from the pig kidney) and MDCK, which have a low background expression of endogenous transporters and which can sort many transfected transporters to the correct membrane, have been stably transfected to express high levels of a specific transporter, as discussed in numerous references.<sup>220–224</sup> These models have become increasingly popular for the characterization of active transport mechanisms, since, in theory, the requirement for specific substrates should be lower in these models. Unfortunately, epithelial cell lines such as MDCK and LLC-PK1 also in fact do express functional endogenous transporters at levels that can complicate the interpretation of the results.<sup>223,225–227</sup> A comparative study of the performance of Caco-2 cells and P-gp-transfected cell lines for evaluating the in vivo function of P-gp showed that all cell models performed well, although with slightly better results being achieved with the transfected cell lines.<sup>228</sup> Similarly as for passive permeability screening<sup>174</sup> the implementation of Caco-2 cells in the 96-well plate format has been reported for P-gp interaction studies.<sup>19</sup>

A further simplification in the prediction of active transport is to use adherent or suspension cell lines that are either transiently or stably transfected with the transporter of choice. A commonly used adherent cell line that is easily transfected with various transporter genes is HEK293. This cell line is derived from human embryonic kidney, and has been extensively used in the characterization of various uptake carriers.<sup>229–231</sup> One example of a commonly used suspension cell line is CHO (derived from Chinese hamster ovaries), which has been used to study the uptake characteristics for a variety of transporters.<sup>232–234</sup> Surprisingly, the endogenous 'background' expression of transporters in the various expression systems is generally unknown. An exception is the Saos-2 cell line (derived from a human osteosarcoma), which was shown to lack significant expression of at least a few important ABC drug transporters, and

was therefore used as a relatively clean expression system for BCRP,<sup>235</sup> an ABC transporter of increasing significance.<sup>119,236</sup> Importantly, suspension cell lines, as well as adherent cell lines such as HEK293, cannot be used as models for drug transport across epithelial barriers, since they do not form monolayers. Rather, they have found their application in the characterization of active drug uptake into or efflux out of cells by means of the expressed transporter.

Other assays for transporter interaction, such as ATP consumption by transporters of the ABC transporter family, have been used to assess active drug transport.<sup>237,238</sup> In the case of P-gp, two studies compared the performance of assays based on active transport across cell monolayers, interaction studies using a fluorescent substrate (rhodamine 123 or calcein) and ATP consumption.<sup>153,154</sup> In the first study, about half of the investigated compounds exhibited concordance between the assays. The compounds that differed between the assays were divided into those that were and those that were not actively effluxed across MDCK cell monolayers expressing P-gp. In general, compounds that had lower permeabilities were actively effluxed, while those having higher permeabilities were not. In contrast, the calcein and ATPase assays revealed P-gp interactions for the more highly permeable compounds, while these assays were less responsive to compounds exhibiting lower permeabilities.<sup>153</sup> On the basis of these findings, the authors recommended that the efflux assay across MDCK-MDR1 cells should be used as the primary screen (despite its lower throughput), since P-gp-mediated efflux is more relevant for in vivo drug disposition when the passive permeability is low, and this assay was the only one responding properly to such compounds. It was also suggested that an efflux ratio as low as 1.5 should be taken as an indication of P-gp involvement. The second study focused on interaction assays using rhodamin 123 and calcein as fluorescent probes, and drug efflux studies across P-gp-expressing LLC-PK1 cells were only performed on a subset of the compounds.<sup>154</sup> The authors concluded that the more indirect fluorescence-based interaction assays should be used as the primary screen, and that these assays should be followed by an ATPase assay, but with the reservation that the results from the primary screens should be followed up by efflux studies across cell monolayers at later stages of the drug development. As in the first study, an efflux ratio of 1.5 was taken as an indication of a significant active efflux. The authors also used cell systems expressing P-gp homologs from different species, and observed clear differences in P-gp interactions between the species.

One problem that has emerged with the transgenic expression systems is that the active transport of some drugs can be mediated by two (or more) transporters simultaneously or in series.<sup>239</sup> This problem becomes particularly evident when polar compounds that are substrates for efflux transporters are to be studied, and may explain some of the unexpected findings in the comparative studies discussed above. Since the substrate-binding sites of important efflux proteins such as P-gp are suggested to be located in the inner leaflet of the plasma membrane or directly adjacent to the cytosolic compartment, more polar drugs may need an uptake transporter to gain access to the transporter. In this context, it was reported that the active transport of pravastatin, a substrate for both the basally located organic anion transporting polypeptide 2 (OATP2) and the apically located drug efflux transporter MRP2 in the liver, could only be studied in MDCK cells double transfected with these two transporters while no significant efflux of the drug was observed in MDCK cells expressing MRP2 only,<sup>240</sup> since the substrate was not able to reach the transporter-binding site. Another recent example is the compound CCK-8, which was found to be transported by both OATP8 and MRP2 across double-transfected MDCK cells.<sup>241</sup> Thus, transgenic cell lines overexpressing a single transporter may be inadequate when more complex drug transport mechanisms are to be clarified. Unfortunately, it is difficult to generate multiple-transfected cell lines that retain the required differentiated properties. It will also be very demanding to maintain a whole panel of double-transfected MDCK cells and the necessary control cell lines, including mock-transfected cells and single-transfected cells, although such efforts are underway in some laboratories. Caco-2 cells may, therefore, remain a viable alternative in the future in some of these situations, provided that sufficiently specific substrates or inhibitors can be identified.

### 5.11.7 Conclusions

We can conclude that technologies are now available for the study of drug permeability and transport in vitro with good precision. However, sound predictions of drug absorption rely on additional data, such as information on the drug solubility in the intestinal fluids and in the acid microclimate adjacent to the intestinal epithelium. Furthermore, better knowledge of the expression and function of the increasing number of drug-transporting proteins is required. Only through the combination of physicochemical and biological data will new and improved predictions of oral absorption, and even bioavailability eventually, be obtained.

Caco-2 cells remain a versatile and general model for the screening of drug permeability and for the prediction of oral absorption, provided that the absorption is not solubility limited. The comparable performance of similar cell culture models in the prediction of drug absorption suggests that fine tuning of permeability protocols may not be

critical for all applications. Techniques have been developed to account for in vitro artifacts in the cell culture monolayers, as have ways to minimize and compensate for the variability in the permeability assays. Further optimization of the active transport studies is needed; for instance, with regard to the use of transport ratios or inhibitors in primary screening of active transport.

The rich selection of functional transporters in Caco-2 cells sometimes makes it difficult to study passive permeability or specific active transport processes in isolation. New, alternative cell models that exhibit fewer drug transport pathways may be preferable in situations where specific drug transport mechanisms are to be studied. Thus, one current trend is to develop alternative models to Caco-2 cells by adopting a reductionist approach, either by isolating the study of specific transporters to various transgenic cell lines or by isolating the study of passive transport using cell lines in which transporters are not functionally expressed.

Successful evaluation of cellular models for studies of passive permeability and active transport is dependent on data sets of high quality, obtained with compounds that represent the appropriate part of the chemical space. Unfortunately, such data sets are rare. It is the conviction of the authors that technology development would be driven to the benefit of all if such data sets were to be constructed through cooperation between academia, government, and the drug industry.

## Biographies

**Per Artursson** studied pharmacy at Uppsala University, Sweden, where he also obtained his thesis in 1985. He spent 1 year as a postdoctoral fellow at the Medical Products Agency, Uppsala (1986), and 1 year as a visiting scientist at Advanced Drug Delivery Research, Ciba-Geigy, UK (1987), before taking up a position as Assistant Professor in Pharmaceutics at Uppsala University. In 1992 he was appointed to his present post as Professor of Dosage Form Design at the Department of Pharmacy, Uppsala University. In 1996 he spent a sabbatical at GeneMedicine, the Woodlands, TX. Dr Artursson's research interests range from drug and gene delivery and targeting to drug absorption. He is on the editorial boards for the leading scientific journals in the pharmaceutical sciences, was Editor-in-Chief for the *European Journal of Pharmaceutical Sciences* (1998–2001), and has received several awards for his research. He is one of the worlds most cited scientists in *Pharmacology and Toxicology* (ISI, 2004). In 2004, he founded a new unit at his department, dedicated to pharmaceutical screening and informatics.

**Sibylle Neuhoff** graduated from the Johan Wolfgang Goethe University, Frankfurt am Main, Germany, with a BSc in food chemistry in 1992, and gained her MSc in chemistry in 1996. Between 2002 and 2005 she studied for her PhD at the Department of Pharmacy, Uppsala University, Sweden, with Professor Per Artursson as her supervisor, and partly at AstraZeneca R&D, Sweden, with Associate Professor Anna-Lena Ungell as her supervisor (2002–05). Her PhD thesis was entitled “Refined in vitro Models for Prediction of Intestinal Drug Transport”.

**Pär Matsson** graduated from Uppsala University, Sweden, with an MSc in pharmacy. He started his PhD studies at the Department of Pharmacy, Uppsala University, with Professor Per Artursson as his supervisor in 2002.

**Staffan Tavelin** graduated from Uppsala University, Sweden, with an MSc in pharmacy in 1996. Between 1996 and 2003 he studied for his PhD at the Department of Pharmacy, Uppsala University, with Professor Per Artursson as his supervisor. His thesis was entitled “New Approaches to Studies of Paracellular Drug Transport in Intestinal Epithelial Cell Monolayers”. He currently holds a position as a lecturer in pharmaceutics at Umeå University, Sweden.

### 5.12.1 Introduction to Nonoral Routes for Drug Absorption

In recent years, pharmacotherapy has been used to search for novel routes of drug absorption as an alternative to the oral route or the invasive injection pathway. The main reason for this interest is the increasing number of therapeutic substances, in particular peptides and proteins, that can not be administered orally. Pharmacotherapeutic innovations in drug administration have been boosted by the development of controlled release preparations (CR).

The development of products for alternative administration routes continues to be based on strategic considerations that can be summarized as the three Cs of alternative drug delivery: clinic, compliance, and commercial. These highlight the need for assessing the bioavailability and safety of the product linked to a specific route, as well as the acceptability by the patient and the marketability of the product. Thus, these elements play a pivotal role in the introduction of products for alternative nonoral administration routes.

The evolution of drug release control has led to a great number of modified release preparations. Research in this area has resulted in new materials, structures, mechanisms, instruments, and techniques. Controlled release refers to the study of principles and devices for the control of drug availability in time and space. Initially, most CR products were given by mouth or by injection to obtain a systemic effect, whereas other routes were mainly explored for the treatment of local diseases. More recently, advances in the field of drug release science and technology have made it possible to attain a systemic effect by nonenteral and nonparenteral administration, such as buccal, nasal, pulmonary, vaginal, or transdermal. For example, the introduction and application of the bioadhesion concept developed in parallel with these alternative routes. The goal of controlled drug delivery based on bioadhesion is to localize the formulation in an accessible body area in order to enhance drug absorption in a site-specific way. The use of bioadhesion has been proposed for novel buccal, transmucosal, and vaginal drug delivery systems,<sup>1</sup> as localization of the drug formulation might enhance absorption of the released drug. Good mucoadhesion at the gel carrier/mucosa interface is obtained in the presence of molecular adhesion promoters, i.e., polymeric structures, which are free to diffuse across the interface in the mucus.<sup>2</sup>

The most extensively explored alternative absorption route for systemic effects has been the skin, which successfully fulfils the criteria of the three Cs of alternative drug delivery. In general, when a new route is proposed, the greatest concern is the safety of the application. Using the skin as a delivery site is relatively safe since the structure of

skin makes it less vulnerable to applied foreign substances. In contrast, the mucosal epithelia typical of the other routes of administration exist for specific physiological functions and not as a transport pathway for substances of varying aggressiveness. Thus, safety in the case of mucosal involvement is very important and explains why one of the oldest alternative mucosal routes was the buccal route. In fact, as the first part of the GI tract, the mucosa of the mouth has a structure adapted for dealing with aggressive substances from food or the environment. Similarly, rectal administration has been used for a long time and was successful in some countries, although its use is limited by poor patient compliance and low therapeutic value. The safety aspects related to the use of the highly permeable nasal, pulmonary, and vaginal routes have only recently been tackled; the acquisition of a sufficient amount of knowledge as to the effect of the exposure to foreign substances at this level has opened up the possibility of using these routes for systemic effect. A few examples of marketed products for administration by nonoral routes are shown in [Table 1](#).

An aspect that is common to all the alternative routes is the need to enhance the permeability of the tissue to compensate for the limited surface area involved. The use of penetration enhancers, i.e., substances that reorganize the epidermis or epithelial structures or open up the intercellular tight junctions, is very important in this area, but it adds further safety concerns and requires careful evaluation of both immediate and long-term effects on tissue integrity and functionality.

Finally, the studies of different routes of drug administration initiated the science of drug delivery, i.e., methods and techniques for efficiently administering a drug to a specific site. The strategies adopted for drug delivery to the nose, lungs, or mouth are the heritage of different technologies developed for CR preparations. At present, mucosal drug delivery only involves products employed for immediate release and prompt effect, whereas the conjugation of CR and drug delivery is classically obtained with the transdermal systems. Alternative drug delivery has evolved from the science of drug release control, since the products or systems developed are mainly designed for targeting a specific site of drug absorption. Alternative drug delivery routes that incorporate controlled or prolonged release are currently the subject of a great deal of research. Quality, efficacy, and safety issues must be considered very carefully when exploiting these ways of systemic application.

## 5.12.2 Mucosal Routes for Drug Absorption

### 5.12.2.1 Buccal Route

Buccal administration is intended for delivering drugs within/through the buccal mucosa in order to achieve a local or systemic effect. This route is particularly attractive since substances absorbed through the buccal mucosa bypass gastrointestinal enzymatic degradation and the hepatic first-pass effect. The mouth has a relatively large area for drug application and good accessibility compared to the nose, rectum, and vagina.<sup>3</sup> In addition, the mucosa is resistant to damage or irritation because of the rapid cell turnover<sup>4</sup> and frequent exposure to food. The buccal mucosa consists of a surface layer of stratified squamous epithelium linked to the underlying connective tissue (lamina propria and submucosa) by a basal lamina. In the connective tissue a network of blood capillaries is present where drugs that have permeated through the epithelium can enter the systemic circulation. The surface layers of the epithelium (approximately the uppermost 25–30%) are reported to be the main barrier to the penetration of substances.<sup>5,6</sup> Cell layers of the buccal mucosa contain membrane-coating granules (MCGs), which are spherical or oval organelles, 100–300 nm in diameter. MCGs appear to fuse with cell membranes and extrude their content, mainly lipids, into the intercellular space. By means of confocal laser scanning microscopy, the region corresponding to MCG in porcine buccal epithelium was visualized as the rate-limiting layer for diffusion of hydrophilic fluorescein isothiocyanate.<sup>7</sup> The intercellular lipids extruded by MCG (150–200 µm deep) represent the permeability barrier for hydrophilic compounds. A recent paper proposed a bilayer diffusion model to quantitatively describe the relative contributions of epithelium and connective tissue to the permeation barrier for 2',3'-dideoxycytidine.<sup>8</sup> It was shown that the basal lamina layer within the buccal epithelium acted as an important barrier to drug permeation.

The drug transport pathways across buccal mucosa can be both transcellular and paracellular, but for many hydrophilic drugs the permeation is mainly due to passive diffusion via the paracellular route. Most transbuccal permeation studies have been conducted *in vitro*<sup>9</sup> using various diffusion cells (flow-through cells, vertical Franz cell, horizontal cells, Ussing chamber). A schematic representation of a common vertical Franz diffusion cell is reproduced in [Figure 1](#).

Porcine buccal mucosa is the most common model barrier for *in vitro* experiments. The anatomy and metabolism of this nonkeratinized epithelium are similar to that of human buccal mucosa. In general, full-thickness buccal mucosa is used in permeation studies. Technically, pig buccal tissue (check) is obtained from a slaughterhouse and transported to

**Table 1** Some examples of marketed products formulated for administration by nonoral routes

| <i>Proprietary name</i>                            | <i>Approved name</i>              | <i>Uses</i>   | <i>Route and dose</i>  |
|--|-----------------------------------|---|--|
| <b>Buccal</b>                                      |                                   |   |  |
| Nitrolingual Pumpspray (First Horizon Pharm., USA) | Nitroglycerin                     | Treatment of angina pectoris  | Metered dose spray to apply onto or under the tongue; 400 µg of nitroglycerin per spray  |
| Striant (Columbia Laboratories, USA)               | Testosterone                      | Hormone replacement therapy in males  | Buccal system; mucoadhesive tablet for the gum tissue; 30 mg of testosterone   |
| <b>Nasal</b>                                       |                                   |   |  |
| Miacalcin (Novartis Pharm., USA)                   | Calcitonin-salmon                 | Treatment of postmenopausal osteoporosis  | Spray pump; nasal solution; 200 IU of calcitonin per actuation   |
| DDAVP (Aventis, USA)                               | Desmopressin acetate              | Management of primary nocturnal enuresis and central cranial diabetes insipidus               | Spray pump; nasal solution; 10 µg of desmopressin acetate per actuation  |
| Synarel (Searle, USA)                              | Nafarenil acetate                 | Treatment of central precocious puberty   | Spray pump; nasal solution; 200 µg of nafarenil per actuation  |
| <b>Pulmonary</b>                                   |                                   |   |  |
| Intal Inhaler (Monarch, USA)                       | Cromolyn sodium                   | Prophylactic agent in the management of patients with bronchial asthma                        | Metered dose inhaler; delivered dose: 800 µg of cromolyn sodium  |
| Atrovent (Boehringer Ingelheim, USA)               | Ipratropium bromide               | Bronchodilator for maintenance treatment of bronchospasm associated with COPD                 | Metered dose inhaler; delivered dose: 18 µg of ipratropium bromide   |
| Serevent Discus (GlaxoSmithKline, USA)             | Salmeterol xinafoate              | Maintenance treatment of asthma and prevention of bronchospasm                                | Dry powder inhaler; delivered dose: 47 µg of salmeterol xinafoate  |
| Clenil jet (Chiesi Farmaceutici, Italy)            | Beclomethasone dipropionate       | Control of asthmatic disease development and of bronchostenotic conditions                    | Metered dose inhaler; CFCs free; delivered dose: 50 µg of beclomethasone dipropionate  |
| Exubera (Aventis/Pfizer, USA)                      | Insulin human Phase III completed | For the treatment of type 1 and type 2 diabetes   | Dry powder inhaler; metered dose: 1–3 mg of insulin  |
| <b>Vaginal</b>                                     |                                   |   |  |
| Nuvaring (Organon, USA)                            | Etonogestrel/ethinyl estradiol    | Prevention of pregnancy   | Nonbiodegradable, flexible vaginal ring releasing 0.120 mg day <sup>-1</sup> of etonogestrel and 0.015 mg day <sup>-1</sup> of ethinyl estradiol |
| Prochieve (Columbia Laboratories, USA)             | Progesterone                      | Treatment of secondary amenorrhea and in assisted reproductive technology for infertile women | Bioadhesive vaginal gel; once daily application of 1.125 g of 4% w/w gel delivering 45 mg of progesterone  |
| Cervidil (Forest, USA)                             | Dinoprostone                      | Cervical ripening in patients at or near term for the induction of labor                      | Thin polymeric slab for vaginal insertion, releasing 0.3 mg h <sup>-1</sup> of dinoprostone  |

Table 1 Continued

| <i>Proprietary name</i>        | <i>Approved name</i>             | <i>Uses</i>   | <i>Route and dose</i>  |
|--------------------------------|----------------------------------|---|--|
| <b>Transdermal</b>             |                                  |   |  |
| Duragesic (Janssen, USA)       | Fentanyl                         | Treatment of chronic pain that requires continuous opioid administration  | Transdermal system releasing $25 \mu\text{g h}^{-1}$ of fentanyl per $10 \text{ cm}^2$                             |
| Ortho evra (Ortho-McNeil, USA) | Norelgestromin/ethinyl estradiol | Prevention of pregnancy   | Transdermal system releasing $150 \mu\text{g day}^{-1}$ of norelgestromin and $20 \mu\text{g}$ of ethinylestradiol |
| Oxytrol (Watson, USA)          | Oxybutynin                       | Treatment of overactive bladder with symptoms of urinary incontinence     | Transdermal system ( $39 \text{ cm}^2$ ) releasing $3.9 \text{ mg day}^{-1}$                                       |
| Climara (Berlex, USA)          | Estradiol                        | Relief of moderate to severe vasomotor symptoms associated with menopause | Transdermal system ( $25 \text{ cm}^2$ ) releasing $0.1 \text{ mg day}^{-1}$ of estradiol                          |

**Figure 1** Schematic representation of an assembled vertical Franz diffusion cell: D, donor compartment; M, membrane; SP, sampling port; R, receptor compartment; MB, magnetic bar; WJ, water jacket.

the laboratory in cold Krebs buffer (pH 7.4). The buccal mucosa, along with a part of the submucosa, is carefully separated from fat and muscles using a scalpel. Then, by means of an electro-dermatome, the epithelium (including mucus layer and basal lamina) is isolated from the underlying tissue. The average thickness of samples is about  $500 \mu\text{m}$ . Because of the time-dependent viability, the buccal epithelium must be used within 2 h of removal. The mucosa is mounted, for example, on an Ussing chamber with the mucosal side facing the donor compartment. Donor and acceptor compartments are filled with Krebs buffer (pH 7.4). Carbogen gas (95%  $\text{O}_2$ , 5%  $\text{CO}_2$ ) is circulated through both compartments in order to maintain tissue viability and provide adequate mixing. Electrophysiological parameters are determined for assessing the integrity and viability of the biological sample. After a 1-h equilibration period at  $34 \pm 0.5^\circ\text{C}$ , the receptor is replaced with fresh Krebs buffer and the donor side is filled with the donor solution. A saturated solution of drug is used as donor to measure the permeability coefficient. Diffusion experiments are conducted for 3 h. In the case of determination of the drug concentration profile within the buccal epithelium, the thin-slicing technique has been applied after the transport experiments.<sup>10</sup> Buccal mucosa specimens were also snap-frozen in liquid nitrogen and stored at  $-85^\circ\text{C}$  for periods of up to 6 months. Frozen specimens were then used for permeability studies: it was observed that the permeability characteristics of the mucosa were not adversely affected by freezing and storage.<sup>11</sup>

Data analysis for permeability coefficient determination through the mucosa is usually performed in the steady-state transport period of time.<sup>8</sup> For one-dimensional diffusion, the permeability of a diffusant through a solid membrane can be calculated as:

$$P_c = \frac{J_{ss}}{\Delta C} \quad [1]$$

where  $P_c$  is the permeability coefficient of the diffusant ( $\text{cm s}^{-1}$ ),  $\Delta C$  is the concentration difference between the two surfaces of the membrane, and  $J_{ss}$  is the flux at steady state ( $\text{mg s}^{-1} \text{cm}^{-2}$ ).

The steady-state flux is given by the following equation:

$$J_{ss} = \frac{\Delta M}{\Delta t \cdot A} \quad [2]$$

where  $\Delta M$  is the amount of diffusant transported through the membrane during the interval time  $\Delta t$  at steady state, and  $A$  is the diffusion area.

Buccal drug absorption studies were performed in vitro and in vivo with porcine buccal mucosa.<sup>12</sup> The distribution of fluorescein isothiocyanate (FITC)-labeled dextrans in the epithelium using confocal laser scanning microscopy allowed the permeation pathways to be visualized. At molecular weights lower than 20 kDa the passage of hydrophilic FITC-dextrans was impeded. The paracellular route was found to be the main pathway for these molecules. An in vivo delivery device, consisting of an application chamber containing a solution of FITC-labeled dextran 4400 (FD4) or buserelin, was attached to the buccal mucosa for 4 h with an adhesive. Steady-state plasma levels were rapidly achieved. Coadministration of 10 mM sodium glycodeoxycholate, an absorption enhancer, increased the absolute bioavailability of FD4.

In a more recent study,<sup>13</sup> the in vitro permeability of porcine buccal mucosa showed consistently lower values with different markers (arecoline,  $17\beta$ -estradiol, water, and vasopressin) compared to porcine mouth floor mucosa. Porcine mouth floor mucosa was a good model of human buccal mucosa using a continuous flow-through perfusion system (20 °C, 24 h).

To enable in vitro studies of irritation, oral pathologies, and basic oral cavity phenomena, EpiOral and EpiGingival tissue models are available, consisting of normal, human-derived epithelial cells (MatTek corporation, Ashland, MA, USA). The cells have been cultured to form multilayered, highly differentiated models of the human buccal and gingival phenotypes.

The delivery of thiocolchicoside, a muscle-relaxant, through oral mucosa was studied by investigating its in vitro permeation through porcine oral mucosa and in vivo buccal transport in humans.<sup>10</sup> A bioadhesive disk and a fast dissolving disk for buccal and sublingual administration, respectively, were tested. The in vitro permeation of thiocolchicoside through porcine buccal mucosa from these dosage forms was compared with the in vivo drug absorption in humans. The buccal absorption test was performed on healthy volunteers in accordance with Rathbone.<sup>14</sup> Before each administration, the volunteers washed their mouths with 100 mL of distilled water. The dosage form (4 mg of thiocolchicoside) was then placed under the tongue (fast dissolving disk) or in contact with the gingival mucosa (bioadhesive disk) and kept in place avoiding swallowing during a fixed period of time. The residue of the dosage form was then expelled and the mouth was rinsed with water. The residue of dosage form and the washing solutions were combined and analyzed for the residual drug content. The fast dissolving form (sublingual) resulted in a quick uptake of 0.5 mg of thiocolchicoside within 15 min, whereas with the bioadhesive buccal form the same dose could be absorbed over an extended period of time. Despite the variability of the in vivo results, an interesting correlation between in vitro (porcine) and in vivo (human) data for both dosage forms was found.

Buccal delivery systems include mouthwashes, sprays, chewing gums, bioadhesive tablets, gels, and patches. Transbuccal delivery devices can be easily applied and removed. However, drug therapy within the oral cavity is subjected to a rapid elimination of drug due to the flushing action of saliva, and may require repeated and frequent doses. This aspect can affect the inter-patient variability and is likely strongly dependent on the system technology used for keeping the drug product in contact with the absorbing mucosa. In fact, significant absorption is obtained by a prolonged exposure of the drug to the mucosal surface. Lectins or bioadhesive substances have been proposed to prolong the system residence time and improve drug absorption through the oral mucosa.<sup>15</sup> A sublingual tablet for rapid drug absorption based on mixtures of carrier particles partially covered by fine drug particles was studied for fentanyl citrate buccal delivery.<sup>16</sup> Plasma concentrations of fentanyl were obtained within 10 min, with no second peak. The bioadhesive component prevented the fentanyl from being swallowed, without hindering its release and absorption. Chimera agglomerates, a formulation in powder form based on primary particles that are agglomerated in soft and porous clusters, represent a new dosage form for buccal insufflation.<sup>17</sup> These free-flowing powders can be used for

generating a mouth aerosol or for direct introduction into the gingival space in order to achieve bioadhesion and prompt or delayed dissolution. The appropriate choice of drug product formulation and mode of application can improve the reproducibility of the administration and of the response. However, it must be remembered that the doses that can be applied remain in the order of a few tenths of milligrams and the lipid solubility of the drug improves the reliability of the administration. This last aspect was supported by the good absorption of fentanyl compared to the more hydrophilic morphine.<sup>18</sup>

Buccal immunization with films loaded with plasmid DNA (CMV-beta-gal) or beta-galactosidase protein has also been studied.<sup>19</sup> Bilayer films were developed using different polymers as the mucoadhesive layer and a pharmaceutical wax as the impermeable backing layer. These films were applied to the buccal pouch of rabbits and the immune response to beta-gal was determined. All rabbits were immunized with plasmid DNA administered via the buccal route, whereas none was by subcutaneous injection of the antigen protein. Different mucoadhesive films based on chitosan hydrochloride and polyacrylic acid sodium salt showed the possibility of achieving buccal absorption of problematic drugs such as acyclovir.<sup>20</sup>

Finally, another approach in buccal delivery was based on a bioadhesive device as a method for controlling delivery of cyanocobalamin to the gastrointestinal tract in male beagle dogs.<sup>21</sup> The novelty was in the use of bioadhesive controlled delivery in the mouth for improving gastrointestinal absorption of this actively transported drug. Significantly higher bioavailability was observed with the buccal bioadhesive device than with the oral immediate release capsule.

### 5.12.2.2 Nasal Route

Nasal administration is an alternative to injection for low-dose drugs when rapid onset of action is required.<sup>22</sup> This route is also useful for peptide substances, as demonstrated by the marketed products calcitonin, buserelin, desmopressin, and nafarelin. As for all inhalation products, nasal products are characterized by two features that are relevant to drug bioavailability: the formulation itself and the delivery device. In the pharmaceutical development, the nasal formulation has to be adapted to the delivery device, in order to provide complete deposition of the dose on the nasal mucosa. Nasal deposition is relevant for avoiding drug swallowing, which for certain drugs can be detrimental to the bioavailability due to instability in the GI tract. However, with nasal administration, due to the structure of the nasal cavity, swallowing of the drug product is minimal compared with the pulmonary delivery.

Nasal absorption can be investigated by *in vitro* studies on: (1) primary cell cultures of human nasal epithelium; (2) human nasal cell lines<sup>23</sup>; (3) excised nasal epithelium from different animals (rabbit, pig, cow, sheep); or (4) *in vivo* studies with animal models. The degree of epithelial perturbation in the *in vitro* models is higher than *in vivo*, where the tissue benefits from the protective mucus and mucociliary clearance. On the other hand, the mucus that normally lines the nasal mucosa and protects the epithelium can also affect the absorption of drugs. A comprehensive review of the cell models for nasal absorption, metabolism, and toxicity is available in the literature.<sup>24</sup>

Studies with primary cell cultures of human nasal epithelium allow for the exploration of drug permeation, metabolism, and toxicity while bypassing potential problems arising from interspecies diversity. Nasal cell specimens can be obtained from the vestibular area, atrium, or turbinates. The area of the nasal cavity should be selected depending on the zone where the formulation is expected to deposit. In many cases, the selection falls on the middle and inferior turbinate, which is covered by a pseudostratified columnar epithelium consisting of basal cells, goblet cells, and columnar cells. This respiratory area is lined with a moist mucous membrane that contains tall column-shaped cells. On the surface of these cells fine hair-like projections, known as cilia, collect and move debris toward the oropharynx. Using human nasal epithelial tissues obtained during elective surgery, the absorption enhancement of methionine enkephalin in the presence of protease inhibitors and absorption enhancers was investigated.<sup>25</sup> The nasal epithelium was dissociated with pronase, filtered, and preplated in a 95% O<sub>2</sub> and 5% CO<sub>2</sub> environment in order to reduce fibroblast contamination. Epithelial cells were then seeded at a density of  $5 \times 10^5$  cells cm<sup>-2</sup>, on a different support depending on the study. For transport studies, cells were cultured on collagen CD-24 inserts. A procedure for collecting cells with the brushing technique without using anesthesia has been described.<sup>26</sup> Cells were collected by means of plastic strips equipped with a sticky albumin surface. Independently of the method used, permeation studies are performed on viable cells grown to confluence. Cytotoxicity studies are therefore required, especially when the permeation pathway involves active transport or other viable cell functions.

Primary cell cultures of human nasal epithelium present several drawbacks, which could be overcome by culturing nasal cell lines that show extended life span, easier proliferation, and good homogeneity. Human nasal septum tumor cells (RPMI 2650) are an example of nasal cell lines having metabolic activity close to that of human nasal tissue. However, since they are poorly differentiated, not polarized, and unable to form a monolayer, RPMI cells are considered unsuitable for transport studies.<sup>27</sup> Alternatively, human lung adenocarcinoma cell lines (Calu-3) have been used to

simulate nasal epithelium in drug permeation studies, owing to their similarity with the serous cells of the upper airway. Moreover, they are able to grow in a confluent polarized monolayer with tight junctions. Calu-3 cell lines were used to investigate the bioadhesive properties of formulations and the bovine serum albumin transport in vitro.<sup>28</sup>

Nasal mucosa excised from different animal species (rabbit, sheep, cow, and pig) is mounted as a barrier on diffusion cells in order to predict the intranasal transport. The method used to obtain the nasal mucosa specimens depends on the animal. In general, the nasal mucosa has to be dissected immediately after the animal's death. With rabbits, for example, the nasal bone is incised with a knife along the welding line from the frontal bone to the nose tip. After the opening of the nasal cavity, the nasal septum is separated by cutting it from its connections with the maxillary region, and extracted. The mucosa layers are then carefully detached from the septum cartilage by means of a pair of tweezers. The specimens removed (surface area 0.7–1 cm<sup>2</sup>; thickness 100 µm) are rinsed with a saline solution and immediately inserted between the donor and the receptor compartments of a vertical or horizontal diffusion cell, with the mucosal surface facing the donor. In order to preserve the viability of the mucosa during the experiment, a gas mixture O<sub>2</sub>–CO<sub>2</sub> (95:5) or oxygen alone can be bubbled through. Before starting the permeation experiment, the mucosa mounted on the cell is allowed to equilibrate at 37 °C and the integrity is assessed. The formulation to be tested is then introduced into the donor compartment and aliquots are sampled from the receiving medium. Usually, the diffusion cells have a receptor volume ranging between 1 and 12 mL; small cells are required when drug quantification is a critical issue. Compartments can be equipped with ports for the introduction of electrodes for continuous electrophysiological measurements. In the determination of permeability coefficients, good stirring of the solutions contained in both compartments is required to ensure sink conditions.

Permeation studies performed under the above conditions provide information on transport rates, quantity of permeated drug, metabolism, and effect of absorption enhancers. The cumulative amount of drug permeated per unit area ( $Q_n$ ) is calculated by the following equation:

$$Q_n = \frac{V_R \times C_n + \sum_{i=0}^{n-1} V_P \times C_i}{A} \quad [3]$$

where  $C_n$  is the drug concentration in the receiving compartment at time  $n$ ,  $V_R$  is the volume of the receiving compartment,  $V_P$  is the sampling volume,  $C_i$  is the drug concentration at time  $i$ , and  $A$  is the permeation area.

Permeation data are generally plotted as quantity of drug permeated per unit of area versus time in order to verify the steady-state flux. Figure 2 illustrates the results of a transport experiment through nasal mucosa analyzed in order to calculate the permeation parameters. The experiment compared the transport of desmopressin from powder and liquid formulations.

The permeability coefficient ( $P_e$ ) across the mucosa has been calculated from the slope of the linear part of the curve relative to the desmopressin solution, according to eqn [1];  $P_e$  is related to the diffusion coefficient  $D$  (cm<sup>2</sup> s<sup>-1</sup>) and mucosa-medium partition coefficient  $K$  by the following equation:

$$P_e = \frac{D \times K}{h} \quad [4]$$

where  $h$  is the mucosa thickness (cm).

**Figure 2** Desmopressin permeation through rabbit nasal mucosa from a solution (▲) and a nasal powder formulation (◆). Regression line of the solution steady-state permeation profile:  $y = 0.0173x + 0.2559$  ( $R^2 = 0.9919$ ). Permeation parameters according to eqn [1]:  $J_{SS} = 0.0173 \mu\text{g min}^{-1} \text{cm}^{-2}$ ;  $\Delta = 100 \mu\text{g mL}^{-1}$ ;  $P_e = 2.88 \times 10^{-6} \text{cm}^2 \text{s}^{-1}$  (s.d.  $8.84 \times 10^{-7}$ ).

An *in vitro* model for permeation studies using porcine nasal mucosa has been described.<sup>29</sup> Three different nasal mucosal tissues were evaluated: full thickness septum mucosa, dermatomed septum mucosa, and nasal cavity mucosa. The dermatome was used for the removal of the underlying connective tissue, in order to achieve a more homogeneous thickness of septum mucosa. This study demonstrated that the drug permeability depended not only on the thickness of the mucosa, but also on the presence of connective tissue.

Permeation across porcine nasal mucosa of drugs with different physicochemical properties (insulin, lidocaine, nicotine, propranolol, sumatriptan) has also been measured.<sup>30</sup> Permeability coefficients determined with the Ussing chamber were correlated with the literature data on the fraction absorbed after nasal administration in humans. A weak correlation was found between excised porcine mucosa and nasal absorption in humans: among the different drugs, the closest correlation was found for drugs transported by passive diffusion.

An original *ex vivo* model not performed with classical diffusion cells has been reported in the literature.<sup>31</sup> Nasal turbinate mucosa of sheep was detached from the underlying bone and mounted at the bottom of a cylindrical support connected to the drive shaft of the basket dissolution apparatus (USP Apparatus 1). A metoclopramide formulation was introduced in the cylinder closed at the bottom by the mucosa. The system was rotated at 50 r.p.m. in the dissolution vessel keeping the mucosa just in contact with the surface of the receiving medium. The transport-enhancing properties of chitosan were evidenced. During the permeation test, transmission electron microscopy analysis was also performed in order to study the morphological changes of the epithelial cells. It was observed that chitosan/alginate microspheres were able to open the cell tight junctions.

Hussain<sup>32</sup> described three variants of a frequently used rat model for studying nasal drug absorption, from which he predicted the absorption profile after nasal administration in other species. They were an *in situ* method, an *in vivo in situ* method, and an *in vivo* method. In the *in situ* method, the rat is anesthetized and the trachea is cannulated. A tube inserted through the esophagus to the posterior part of the nasal cavity serves to circulate the perfusion solution into the nasal cavity. The absorption rate is determined by analyzing the remaining amount of drug in the perfusing solution. The *in vivo in situ* method is a variant of the previous *in situ* recirculation method to keep the solution in the nasal cavity. A small volume of drug is administered into the nasal cavity for absorption and hydrolysis studies. In the *in vivo* method, the drug is directly deposited on the nasal mucosa of the rat and blood samples are withdrawn at predetermined time points. Owing to the use of a close and confined system, the authors claimed to have reproducible and reliable data.

Nasal mucociliary clearance has implications in nasal drug absorption.<sup>33</sup> Drugs are rapidly cleared from the nose after intranasal administration, and several approaches have been proposed to prolong the residence time of formulations in the nasal cavity. It has already been emphasized that increasing the contact time between the formulation and the nasal mucosa can improve the absorption of drugs. Bioadhesive drug delivery systems can help to counteract clearance of the formulation. Intranasal *in vivo* administration of apomorphine powder in rabbits was performed in order to determine the effect of bioadhesion on drug absorption.<sup>34</sup> A sustained plasma level of apomorphine using a carboxymethylcellulose formulation was obtained, reaching a relative bioavailability equivalent to subcutaneous injection. The nasal formulations were insufflated with an air-filled syringe expelling the drug through a plastic tip inserted into the rabbit's nostril. Sometimes this procedure requires superficial local anesthesia of the external nostrils to prevent the animal sneezing.

Interspecies differences between rat, rabbit, and man have been described for the nasal administration of peptide and protein drugs with cyclodextrins as absorption enhancers.<sup>35</sup> In fact, the nasal absorption of drugs, in particular of polar compounds (buserelin, leuprolide, ACTH analog, LHRH analogs, calcitonin, glucagon, insulin) can be improved by combining drugs with the absorption enhancer to promote the permeation. The physical state of the formulation could also have an important effect on the absorption rate, as demonstrated by administration of a desmopressin solution and desmopressin nasal powder in a rabbit mucosa model (see [Figure 2](#)). The nasal absorption of insulin after its administration in the form of insulin/chitosan nanoparticles, insulin/chitosan solution, and insulin/chitosan powder formulations was evaluated in anesthetised rats and in conscious sheep.<sup>36</sup> In the sheep model, chitosan nasal powder was the most effective chitosan-based formulation for insulin absorption, with a bioavailability of 17%.

Finally, nasally administered drugs could reach the central nervous system directly from the nasal cavity, thus bypassing the blood–brain barrier. Studies in animal models and in man have shown this possibility with uptake of drugs into the cerebrospinal fluid and the brain tissue olfactory bulb depending on their molecular weight and lipophilicity.<sup>37</sup>

### 5.12.2.3 Pulmonary Route

The inhalation route has been developed primarily for the treatment of respiratory disorders that today affect two hundred million people worldwide. Pulmonary drug administration allows locally acting drugs to be administered

directly to their site of action such as asthma and chronic obstructive pulmonary disease (COPD) treatments. More recently, pulmonary drug delivery has gained interest for the administration of systemic drugs, due to the large absorptive surface of the lung, the high permeability, and the fact that it bypasses the liver.

The respiratory tract is divided into the conducting and the respiratory zones.<sup>38</sup> An epithelial lining fluid, acting as a trap for inhaled particles, covers the conducting airways. The airways are lined by the secreting goblet cells (except in the bronchioles) and ciliated cells moving the mucus back to the pharynx. The respiratory zone comprising the alveolar region is lined with continuous sheets of epithelial cells, which differentiate in type and functions throughout the tracheobronchial tree. In the alveoli, type I cells cover almost 97% of the exposed surface area; the remaining surface area is made up of type II pneumocytes secreting surfactant. Type I pneumocytes are large (approx. 200  $\mu\text{m}$ ) and thin (less than 0.2  $\mu\text{m}$ ) cells, so their barrier to drug transport is at least one order of magnitude lower than typical mucosal or epithelial membranes. This allows the inhaled drug dose to be absorbed quickly into the blood circulation.

Passive transport and carrier-mediated active transport are the two major mechanisms of absorption. In the case of passive transport, drugs cross the cell membrane by travelling through small pores (bulk flow) or are absorbed by pinocytosis. Recently, it has been suggested that even caveolae (omega-shaped invaginations of the plasma membrane of type I cells) play a role in drug absorption.<sup>39</sup> The alveoli contain freely roaming macrophages that act as scavengers for inhaled particles, engulfing them and moving out of the respiratory tract with their payload.

Drugs can be easily absorbed from the alveolar site, provided that particles or droplets survive transit and clearance mechanisms. It is known that lung uptake of a formulated drug is affected in rate and extent by formulation pH, ionic strength, partition coefficient, and solubility. Macromolecules are absorbed in the lung to a degree that is inversely proportional to their molecular weight.<sup>40</sup>

All the phenomena affecting drug absorption in the GI tract (dissolution, permeation, stability) are also relevant for the pulmonary route, but an additional aspect has to be considered, i.e., the need for lung deposition. The pulmonary route is accessible for drugs only if they are inhaled as aerosols, i.e., airborne suspensions of fine particles, and deposited on the epithelium. It is essential to consider that the formulation and the device together constitute the inhalation product. The two components determine the performance of the administration, and a change in formulation or device will affect the bioavailability of the drug. Available devices for producing such fine aerosols are metered dose inhalers (MDIs), dry powder inhalers (DPIs), nebulizers and metered dose nebulizers (MDNs), or soft mist inhalers. The popular MDIs consist of a pressurized canister containing a mixture of micronized drug suspended or dissolved in a propellant and are devices that require coordination between dose delivery and patient inhalation during administration. DPIs were designed to deliver the drug with the minimum patient coordination. Nebulizers are predominantly employed for antibiotic therapy or in emergency situations. Metered dose nebulizers, the last generation devices, generate a slow-moving aerosol as a bolus dose to be subsequently inhaled.

Drug deposition and absorption from the lung can be assessed using *in vitro* and *in vivo* methods. Considering that a drug for pulmonary absorption requires entry into the lung by inhalation, the aerodynamic behavior of particles is decisive for the biopharmaceutical quality of the preparation. Inhaled asthma drugs act locally on receptors in the airway walls, while inhaled drugs intended for systemic delivery must be deposited in the alveolar regions to be absorbed optimally. Thus, the deposition in the lungs has a predictive role for the absorption of drugs and is the limiting step for the product's efficacy. Deposition is dependent on aerosol behavior. Particle size parameters of an inhaler, i.e., mass median aerodynamic diameter (MMAD), geometric standard deviation, and the fine particle dose (or fraction) have to be assessed. The fine particle dose has particular relevance, since it expresses the respirable mass of drug contained in an aerosol. Inertial separation methods are prescribed in order to measure the fine dose of a therapeutic aerosol. Aerosol particles are separated according to their aerodynamic diameter, which describes the particle tendency to fly along an air stream. European guidelines consider those particles with an aerodynamic diameter less than 5  $\mu\text{m}$  to be respirable. **Figure 3** shows the Andersen cascade impactor (US and European Pharmacopoeia 5) for determination of aerodynamic particle size distribution and lung deposition prediction.

Methods used in the early stages of formulation involve the sizing of the aerosol particles using laser diffraction and particle time-of-flight methods. The first technique determines the volume diameter and the second the aerodynamic size directly. Some authors have compared results from impactors with laser scattering methods for simplifying the determination of the aerodynamic diameter.<sup>41</sup> Even though these tools are routine in the early development of a pulmonary formulation, further experiments must prove an effective correlation between *in vivo* and *in vitro* data.<sup>42</sup> Particle size data are essential in the quality control of the pharmaceutical product and for bioavailability expectations. The relationship between particle size data and lung deposition data is complex. The fine particle fraction or dose has been found to overestimate whole lung deposition.<sup>43</sup>

*In vivo* lung deposition is quantified by external imaging radiographic techniques employing a radiolabeled drug molecule (typically  $\gamma$ -emitting 6 h half-life nucleotide  $^{99\text{m}}\text{Tc}$ ) that is inhaled. Besides the commonly used gamma

**Figure 3** Aerodynamic assessment of aerosol. Andersen Cascade Impactor: seven stages impactor able to separate the aerosol particles sizes in relation to the deposition at different levels of the human respiratory tract.

scintigraphy, other techniques include single photon emission computed tomography (SPECT), positron emission tomography (PET), and magnetic resonance imaging (MRI), the latter not employing radioactive substances.<sup>44</sup> Gamma scintigraphy has been used despite some concerns due to the fact that about 30% of photons detected are wrongly positioned.<sup>45</sup> In comparison with conventional  $\gamma$ -scintigraphy, SPECT has the advantage of constructing a three-dimensional image of the lung. PET does not need to chemically modify the structure of the drug to link the radioactive moiety. Results from imaging techniques are suitable for comparing efficiency of delivery and bioequivalence of pulmonary formulations. However, owing to the practical problems associated with the use of SPECT and PET, traditional planar gamma scintigraphy remains a standard.

For studying pulmonary drug absorption, *in vitro* models are used mainly as a formulation-screening tool, whereas *in vivo* analysis monitors the drug in plasma and tissues after inhalation. Cell lines and primary cultures of airways and alveolar epithelia from animals and humans have been developed and studied for pulmonary drug transport as a predictive tool to estimate the *in vivo* absorption.<sup>46, 47</sup> Examples of airway epithelial cell lines are the bronchial HBE4/E6/E7, 16HBE14o-, used for assessing  $\beta_2$ -adrenergic drug permeation, and the Calu-3 cells,<sup>48</sup> extensively investigated because of their ability to form tight junctions. Human cell line A549 is derived from type II cells that rapidly differentiate into monolayer morphologically and functionally similar to those of type I pneumocytes.<sup>49</sup> This cell line exhibits the *in vivo* enzyme activities, but it does not form tight junctions and lacks some clearance mechanisms typical of the alveolar epithelium. Monitoring the protein expression and permeability of Calu-3 cell lines grown in different conditions and placed in a liquid impinger has provided an estimation of the effect of particle impact. This interesting experimental set up combines an *in vitro* model with aerosol deposition.<sup>50</sup>

Isolated perfused organs from rats, guinea pigs, and rabbits have also been used to study deposition and transport phenomena within the lung.<sup>51</sup> The advantages range from the absence of interactions with other organs to the integrity of the anatomical structure and cellular organization. The role of respiration, i.e., the dynamic change in the lung tissue on drug transport across the air-blood barrier, has been investigated in a bullfrog model, in order to establish the quantitative relationship between the effect of respiration and the physicochemical properties of drugs.<sup>52</sup> It was suggested that respiration not only increases the surface area of lung membrane for permeation, but also dramatically affects the permeability of the lung membrane. Furthermore, the enhancement in permeation rate produced by respiration was observed to be in a linear correlation with the hydrophilicity of the substance.

Lung slices and homogenates have also been used for studying the drug transport. They are easier to prepare, but also undergo variations in enzyme activity and oxygen uptake.

Pharmacokinetic (PK) studies by body fluid analysis establish the amount absorbed of the inhaled drug, which depends on deposition and residence time.<sup>53,54</sup> This approach is direct for the systemic acting drugs, but is less stringent for locally acting substances. The different target, local or systemic, obliges to manipulate the drug particles formulation in order to modulate the pulmonary deposition. For example, drugs exhibiting a fast dissolution profile will be rapidly absorbed from the lung. For drugs acting locally, an increase in pulmonary selectivity has been reached by

creating surface-modified microparticles. For high-molecular-weight drugs, such as peptides and proteins, an increase in the lung bioavailability could be obtained, since modifying the formulations can modulate the pulmonary targeting. For example, with insulin, large porous microparticles<sup>55</sup> and drug release control<sup>56</sup> led to an increased bioavailability in animals.

Pharmacokinetic methods for the clinical evaluation of pulmonary formulations must be considered as being highly drug specific, and provide no information about the regional deposition of the active ingredient. The assessment is obtained by comparing the plasma concentration-time profiles of the drug after inhalation ( $AUC_{inh}$ ) and intravenous administration ( $AUC_{iv}$ ). A problem relevant to the use of the PK approach in drug absorption studies is that a systemic drug level does not only result from lung exposure. In the case of corticosteroids delivered with MDI devices, drug passage and absorption in the GI tract is also possible, thus the  $AUC_{inh}$  will also account for this fraction of drug absorbed orally. In the case of terbutaline sulfate pulmonary bioavailability, in order to avoid concomitant oral absorption, the technique of charcoal blocking has been proposed<sup>57</sup>; this consists of mouth rinsing and swallowing a charcoal slurry immediately after inhalation to adsorb the drug that has entered the GI tract. The pulmonary bioavailability<sup>54</sup> can then be obtained by comparing AUCs:

$$F_{inh} = \frac{AUC_{inh,char}}{AUC_{iv}} \quad [5]$$

Pulmonary availability of aerosol generated by a device (fine particle fraction) differs from one formulation to another, ranging from 10% for the older MDIs up to 40% for newer MDIs and DPIs. The pharmacokinetic approach has been used to highlight the differences in the bioavailability among different formulations, different devices, and even different patients. Then, not only the formulation differences contribute to the variability but also the respiratory effort linked to obstructive diseases, particularly where patient-driven devices are used, can add important variability to lung deposition.<sup>58</sup>

Pharmacodynamic (PD) data are considered to be the most reliable for proving the efficacy and safety of formulations for inhalation. Very recently, many PD studies have been carried out for bronchodilators and inhaled corticosteroids and several protocols have been developed for this use. For systemically acting drugs, PD analysis is conducted by monitoring changes in biochemical parameters, for example, the serum glucose and C-peptide in the case of inhaled insulin.

Correlations between clinical evidence and in vitro results have been reviewed by Newman<sup>43</sup> in a very comprehensive contribution for identifying the role of each method in inhalation drug absorption. No method for assessing inhaled drug delivery is perfect, and data from several sources are welcomed. Gamma scintigraphy is used to quantify lung deposition, but PK methods do not require the drug formulation to be manipulated during the radiolabeling process. Respirability experiments are valuable for quality assessment purposes, although their importance also extends to bioavailability.

#### 5.12.2.4 Vaginal Route

The relatively large surface area of the vagina wall and the dense network of blood vessels make this organ suitable for systemic treatments. Vaginal administration of drugs circumvents hepatic first-pass metabolism but, in particular, opens up the possibility for prolonged drug delivery. In hormone therapies for contraception and postmenopause, the vaginal route offers greater efficacy with lower side effects than oral administration. From a histological point of view, the vaginal mucosa is formed by a lamina propria, consisting of collagen and elastin with an extensive vascular network, and a nonsecretory squamous epithelium (200–300  $\mu$ m thick). In designing drug delivery systems for vaginal administration, the different physiological conditions occurring during the menstrual cycle or at different ages, along with the enzymatic activity of the vaginal microflora, should be taken into account. In particular, the pH and composition of vaginal fluid change from low pH values (3.5–4.5) during the ovulation phase to a higher pH during menstruation.<sup>59</sup> As for other mucosal routes, drug absorption may occur through the transcellular, paracellular, or receptor-mediated pathways.<sup>60</sup>

In vitro studies performed on human vaginal mucosa mounted on continuous flow-through diffusion cells allowed for the determination of the permeability of a series of molecules, in comparison with other tissues, such as buccal, small intestinal, and colonic mucosa. The vaginal mucosa specimens, obtained from postmenopausal patients after hysterectomies, had the connective and adipose tissue trimmed. They were either immediately used or snap-frozen in liquid nitrogen and stored at  $-85^{\circ}\text{C}$  for several months, without affecting their permeability.<sup>11</sup> Vaginal mucosa was shown to be more permeable than intestinal mucosa to various molecules and to a greater extent to lipophilic hormones

such as  $17\beta$ -estradiol.<sup>61,62</sup> In comparison with human buccal mucosa, a similar transport was shown in the case of vasopressin.<sup>63</sup> Recent studies on the dependence of the permeability of vaginal mucosa on temperature suggested that the main barrier to drug diffusion was lipoidal in nature and mainly linked to the presence of inter- and intracellular granules containing lipid lamellae.<sup>64</sup> Average thickness, surface keratinization, lipid composition, and the presence of intra- and intercellular MCGs make the vaginal mucosa similar to buccal mucosa.<sup>65</sup> From the histological and structural point of view, porcine vaginal mucosa is more representative of human mucosa than other animal models.<sup>66</sup> Sheep,<sup>67</sup> rabbit,<sup>68</sup> and cow vaginal mucosa<sup>69</sup> has also been employed as permeation barriers.

The use of cultures of vaginal epithelial cells has also been proposed for permeability studies. Human vaginal epithelial cells were obtained from healthy tissue specimens and grown in well plates for 2–3 weeks in an appropriate medium. At confluence, cells were trypsinized and seeded on collagen-coated membranes in a Transwell system. The flux of tritiated water through these vaginal epithelial cell layers was found to be three times higher than that measured for the intact mucosa.<sup>70</sup> Similar reconstructed tissues have been used for the in vitro study of mucosal irritation.<sup>71</sup> Highly differentiated multilayer vaginal tissue models are commercially available (EpiVaginal by MatTek, Ashland, MA, USA; Reconstituted Human Vaginal Epithelium by SkinEthic, Nice, France).

Traditional pharmaceutical forms for vaginal delivery include creams, ointments, gels, pessaries, tablets, and vaginal rings. In the case of semisolid formulations and conventional tablets, short residence time at the administration site and product leakage have been evidenced.<sup>60</sup> To circumvent these problems, attention has been devoted to the development of mucoadhesive formulations based on derivatives of cellulose and chitosan or on acrylic acid- based polymers. The goal was to prolong the residence time in order to enhance absorption.<sup>72</sup> In vitro tests for mucoadhesion properties of drug delivery systems have been proposed, determining the tensile strength of system/mucosa detachment.<sup>69,73</sup>

For the in vivo evaluation of vaginal formulations, several animal models have been exploited. Mice, rats, and rabbits are the most commonly used species. Rhesus monkeys were employed for the development of a novel vaccine against HIV infection through vaginal administration.<sup>74</sup> In a recent study, the aminopeptidase activity of vaginal homogenates from rabbit, rat, guinea pig, and sheep have been compared with the activity of the same enzymes in human vaginal tissue. This could allow for the identification of the best animal model for vaginal administration of proteins and peptides. Rabbit and rat vaginal mucosa displayed aminopeptidase activity similar to human tissue.<sup>75</sup>

Nowadays, vaginal drug delivery is applied for local therapies with antibacterial, antifungal, antiviral, or labor-inducing drugs and for systemic treatments with hormones for contraception and postmenopausal therapies. However, the characteristics of the site and the improvements made in delivery systems indicate that vaginal administration shows promise in the delivery of peptides, proteins, and vaccines.<sup>60,76</sup>

### 5.12.2.5 Rectal Route

Rectal route for drug administration has been proposed to complement the classical GI way for systemic delivery of drugs either in cases of peculiar patient conditions, such as nausea, vomiting or convulsions, or, more importantly, for treating children.<sup>77</sup> From an anatomical point of view, the rectal mucosa differs slightly from other mucosal epithelia of the GI tract. However, the dense vascular network of the rectum potentially allows the systemic distribution of absorbed drugs while bypassing the first pass metabolism. In fact, even though the superior rectal vein drains into the portal vein, the inferior and middle rectal veins drain to inferior vena cava. However, the unpredictability of the exposition to the appropriate veins as well as others physiological parameters, such as pH, volume, and viscosity of the rectal fluid, are responsible for important interpatient variability in serum levels of rectally administered drugs.<sup>78</sup> Among the drugs administered via the rectal route anticonvulsants, analgesics, antiemetics, antipyretics, antibacterial agents, migraine medications, diuretics, and vaccines have been reported.<sup>79–81</sup>

The establishment of an in vitro system based on cell culture for the evaluation of rectal drug transport has been proposed.<sup>82</sup> However, no model system has been realized yet. In order to assess rectal formulations, in vivo experiments using rats<sup>83</sup> or rabbits<sup>84</sup> as animal models are usually performed.

In summary, despite the advantages of this administration route in pediatrics, until now the erratic drug absorption and low patient compliance have downgraded this delivery approach to line extension products.

## 5.12.3 Dermal and Transdermal Route for Drug Absorption

### 5.12.3.1 Biological Background

The skin has traditionally been used for the topical application of creams, pastes, or gels for local effect, although since the 1980s it has also been used for drug administration for systemic effect, using transdermal patches. The skin is the

**Figure 4** Microscopic image of a human skin section.

largest organ of the body, with an average weight of 7 kg in adults. With a surface area of approximately 2 m<sup>2</sup>, the skin offers a unique and easily accessible body surface across which drugs can be delivered. Transdermal administration is noninvasive, and allows for the attainment of constant plasma levels over extended periods of time. Additionally, the incidence of side effects after transdermal administration may be lower than after oral administration, such as in the case of estradiol.<sup>85</sup> Transdermal patches are discreet to wear and were preferred for nicotine replacement therapy over other administration devices (nasal sprays and pulmonary inhalers) that, although equivalent in efficacy, were considered embarrassing to use.<sup>86</sup>

The skin is a multilayered organ delimiting the body. **Figure 4** shows a section of human skin (haematoxylin-eosin stain). The main layers of the skin are the stratum corneum (10–15 µm thick), the viable epidermis (100–150 µm), and the dermis (1000 µm).

The structure of the stratum corneum can be described as a brick&mortar wall,<sup>87</sup> in which bricks represent the corneocytes and mortar the extracellular matrix. The particular composition and structure of the stratum corneum controls the diffusion and penetration of molecules in and across the skin. Cellular elements, the corneocytes, are embedded in an intercellular matrix organized as lamellar lipid layers.<sup>88</sup> The stratum corneum lamellar structure has been extensively investigated using different techniques, such as freeze- fracture electron microscopy followed by osmium or ruthenium tetroxide fixation<sup>89,90</sup> or wide and small angle x-ray diffraction.<sup>91</sup> Other techniques used to investigate stratum corneum structure and modifications are infrared spectroscopy, differential scanning calorimetry (DSC), and laser scanning confocal microscopy (LSCM).<sup>92</sup>

The stratum corneum lipids are mainly composed of ceramides, cholesterol, and free fatty acids. There are at least seven classes of ceramides, each containing various species, which have the same head group and different chain lengths. Ceramides play an important role in maintaining and structuring the water permeability barrier of the skin.

### 5.12.3.2 Structure–Permeation Relations

Drug absorption across the skin is considered as being composed of partition and diffusion processes, the limiting step being, in most cases, the stratum corneum. The active molecule included in the dosage form is released to the skin surface and then diffuses through the cells of the stratum corneum, eventually reaching the dermis, where blood capillaries are located. Two permeation routes across the skin are possible (**Figure 5**): annexial (i.e., through the annexes of the skin, namely pilosebaceous units and sweat glands) and transepidermal (i.e., across the stratum corneum). The latter involves diffusion through the intercellular lipid matrix and can be divided into polar and lipid routes. The annexial route is predominant for hydrophilic drugs, since skin pores have a hydrophilic character. However, since skin annexes constitute only 1% of the total surface area, the annexial route contributes to a limited extent to the total transport. The annexial route may be relevant in specific conditions, such as in the case of application of electric current (iontophoresis). Beside the use of confocal microscopy, an original approach for studying the relevance of the annexial route of skin penetration is the use of a skin sandwich.<sup>93</sup>

**Figure 5** Permeation routes across the skin.

Owing to the excellent barrier properties of the skin, only molecules possessing the appropriate physicochemical properties can be used for this administration route.<sup>94</sup> In particular, water and lipid solubility should be such that the drug can cross the lipophilic barrier of the stratum corneum. On the other hand, the permeant should not be too lipophilic, otherwise the subsequent partitioning in the hydrophilic living epidermis would be hindered.

The molecular size and weight is another limiting parameter, the upper limit being around 500 Da in conditions of passive diffusion.<sup>95</sup> It is interesting to point out that the limit of molecular weight for penetration across the skin is identical to the limit set out by Lipinski for oral drug absorption.<sup>96</sup> It is well accepted that, without penetration enhancement, only relatively small and lipophilic molecules can cross the skin in therapeutically active amounts. Several attempts have been made to predict the permeability of a molecule across the skin from its physicochemical properties, the first being that of Potts and Guy,<sup>97</sup> who predicted the value of permeability coefficient ( $P_e$ ) of a permeant on the basis of octanol/water partition coefficient ( $P$ ) and molecular weight (MW):

$$\log P_e = -6.36(\pm 0.28) + 0.72(\pm 0.13)\log P - 0.0059(\pm 0.0014)MW$$

$$n = 93, r^2 = 0.67, q^2 = 0.65, s = 0.74, \text{ and } F = 92 \quad [6]$$

More recently, solute hydrogen bond basicity and volume have been taken into consideration since they can influence permeability coefficient.<sup>98</sup> In a recent review, Geinoz and co-workers emphasized the limitations of such structure–permeation relationships, stressing that their applicability is restricted by the limited range of polarity and size of the permeants on which they are based.<sup>99</sup>

The possible approaches to increasing passive skin penetration, such as the use of penetration enhancers or supersaturated solutions, have recently been reviewed by Moser and colleagues.<sup>100</sup> Other alternatives are the use of physical techniques, such as iontophoresis, electroporation or sonophoresis,<sup>94</sup> or minimally invasive techniques such as microneedles.<sup>101</sup> In particular, iontophoresis consists of the application of a small electric current density ( $<0.5 \text{ mA cm}^{-2}$ ) to the skin in order to facilitate the transdermal passage mainly of ionized molecules. The technique has been shown to promote the transdermal penetration of peptides and proteins, such as calcitonin in vivo in rabbits.<sup>102</sup>

### 5.12.3.3 In Vitro Models

In vitro permeation across the skin is usually studied using diffusion cells. Either horizontal or vertical diffusion cells can be used, the constituting material usually being glass.<sup>103</sup> The receptor compartment is maintained at approximately 37 °C, in such a way that the temperature of the skin surface is at its physiological value of 32 °C. Care should be taken to avoid the formation of air bubbles in the receptor compartment (which can reduce the area of contact) and to guarantee homogeneous mixing. The choice of the receptor medium, which should mimic body fluids, is conditioned by the solubility of the permeant. Isotonic pH 7.4-buffered saline can contain solubilizing additives, such as bovine serum albumin or cyclodextrins, which increase the solubility of the permeant without altering the permeability of the skin, and guarantee sink conditions to be respected. As an alternative, for low solubility permeants, flow-through diffusion cells can be used, although in this case the dilution of the receptor solution may limit the analytical sensitivity. Other special types of diffusion cells exist, most of them designed for use in specific cases, such as when iontophoresis is applied. One of them is the dual chamber diffusion cell, which allows the two electrodes to be placed on the same site of the skin – in exactly the same way as electrodes are placed in vivo.<sup>104</sup>

The analyte permeated across the skin is then quantified in the samples taken from the receptor compartment, using a validated analytical method. The use of radioactive tracers is in some respects quite convenient, for the rapidity of analysis, but does not allow for evaluating skin metabolism, as do chromatographic methods, since it is not specific.

High-performance liquid chromatography (HPLC) represents the method of choice in most cases. Microdialysis, a typical *in vivo* technique, has been proposed as an *in vitro* tool for assessing drug penetration through the skin, with the advantage of measuring local drug concentration at the skin level the probe was inserted.<sup>105</sup> Running a permeation experiment on static diffusion cells is time-consuming, and needs the presence of an operator to withdraw samples of receptor solution at each sampling interval. Automatic diffusion cell systems are available on the market containing up to 12 diffusion cells that can run simultaneously, while samples are collected automatically into HPLC or liquid scintillation vials. The Microette Plus Diffusion Cell Test System (Hanson Research, Chatsworth, CA, USA) has been validated for drug release from semisolid formulations across a synthetic membrane.<sup>106</sup> The use of a synthetic membrane as a barrier for separating the donor and receptor solutions has the advantage of easy availability and reproducibility. There are no membranes able to simulate the complex structure of the skin. Synthetic membranes can be useful for quality control purposes in topical formulations, but for skin permeation studies a biological barrier has to be used. The most obvious skin model used in *in vitro* penetration experiments is excised human skin. Cadaver skin or skin coming from surgery can be used as full thickness, i.e., with all layers present. However, drug absorption to the systemic circulation takes place at the level of the upper dermis, and so the use of full thickness skin can create an artificial barrier to drug penetration that is not present *in vivo*. For this reason, sections of the skin can be used to better mimic the *in vivo* situation. The use of a dermatome allows for the preparation of a sample with a predetermined and constant thickness. As an alternative, the full thickness skin can be heat-separated into epidermis and dermis. Although skin heating (at approximately 60 °C for 1 min) can produce a modification of viability,<sup>107</sup> this technique is widely used, and preferred over chemical separation.<sup>108</sup> Artusi and co-workers<sup>109</sup> used both full thickness and heat-separated epidermis for studying skin permeation of thiocolchicoside, and found that with epidermis the lag time was 4 h, compared to 12 h for full thickness skin. Another alternative is the use of isolated stratum corneum, which can be separated from epidermis through the enzymatic action of trypsin. The rationale behind the use of isolated stratum corneum is that, with polar drugs, it represents the rate limiting step to drug transport. Sekkat and co-workers<sup>110</sup> demonstrated that lidocaine permeation across pig ear skin increased when the stratum corneum was progressively removed.

Although the use of fresh skin has the basic advantage of preserving the metabolic activity of the skin, it is seldom available. Frozen skin (at –20 °C) is more commonly used, although freezing can alter its metabolic activity.<sup>107</sup> There are several reports concerning the differences between fresh and frozen skin, most of them suggesting that freezing increases the permeability of the skin. However, for some molecules, such as 8-methoxypsoralen, fresh skin is more permeable than frozen skin, owing to alterations in the molecular arrangement of the skin components during freezing.<sup>111</sup>

Animal skin is often used as an alternative to human skin.<sup>112</sup> The use of hairless or bare species is preferred over hairy ones, because it has been shown that the presence of hair follicles produces shunts available for permeation that produce an increase in permeability. Additionally, shaving can damage the stratum corneum, leading to an increase in skin permeability. Mouse, rat, pig, and guinea pig are the most common species used, although their permeability is usually higher than that of human skin.<sup>100</sup> Pig skin has been shown to be most similar to human skin in terms of both biochemical composition of the stratum corneum lipids and of permeability.<sup>113</sup>

Perfused skin models use excised regions of the skin, complete with their associated microvasculature. They have the advantage of maintaining the viability of the skin, since the tissue is continuously perfused. Rabbit ear and pig skin flaps have been used for this purpose.<sup>114,115</sup>

Skin equivalents have recently been developed as alternatives to the use of excised skin. All of them are obtained from keratinocytes cultured *in vitro* on a substrate of collagen or fibroblast containing collagen gel. The use of air interface technique allows for epidermis differentiation, mimicking the natural differentiation of the skin *in vivo*. This procedure allows for the formation of a stratum corneum, if an appropriate medium is used, having a composition very close to human skin. Among commercially available products are EpiSkin developed by Imedex and Oreal and EpiDerm developed at MatTek. These skin equivalents can be successfully used for *in vitro* skin irritation and metabolism studies, since they are a living substrate. However, the permeability of skin equivalents is typically much higher than that of excised human skin. Wagner and coworkers examined the permeability to flufenamic acid of EpiDerm, isolated stratum corneum, epidermis, and full thickness human skin. The permeability obtained with the skin equivalent was 5 times higher than with isolated stratum corneum and epidermis and 30 times higher than with full thickness skin.<sup>116</sup>

The flux of a drug across a membrane ( $J$ ) can be described in terms of Fick's law of diffusion<sup>117</sup>:

$$J = -D \frac{dc}{dx} \quad [7]$$

where  $D$  is the diffusion coefficient and  $dc/dx$  represents the concentration gradient across the barrier.

In the simplest case of an infinite donor solution at a constant concentration, the cumulative drug permeated is plotted versus time, and the steady-state permeation rate is calculated from the slope of the linear portion of the curve. However, in the case of skin penetration, the attainment of steady-state conditions may take too long to be reliably measured in a diffusion cell experiment. A better approach is to fit the entire curve to the appropriate solution of Fick's law of diffusion<sup>118</sup>:

$$Q = (K H) C_{\text{veh}} \left[ \frac{D}{H^2} t - \frac{1}{6} - \frac{2}{p^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \exp\left(\frac{-D n^2 p^2 t}{H^2}\right) \right] \quad [8]$$

where  $Q$  is the cumulative amount of drug permeated per unit area at time  $t$ ,  $C_{\text{veh}}$  is the concentration of the drug in the donor vehicle,  $K$  is the stratum corneum/vehicle partition coefficient,  $D$  is the diffusion coefficient, and  $H$  is the diffusion path length.

The permeability coefficient ( $P_e$ ) can be calculated as:

$$P_e = K * H * \frac{D}{H^2} \quad [9]$$

and steady-state flux ( $J_{\text{ss}}$ ) as:

$$J_{\text{ss}} = P_e * C_{\text{veh}} \quad [10]$$

This method can be used to gain indications as to the mechanism of action of different enhancers. Harrison and co-workers<sup>119</sup> used this method to compare the relative effect of Azone and Transcutol on 4-cyanophenol permeation and found that Azone reduces the diffusional resistance while Transcutol increases the solubility of the permeant in the stratum corneum.

Skin stripping is a technique that can be used either in vitro or in vivo. The rationale behind its use is the consideration that this layer is often the rate-limiting barrier for percutaneous penetration. It is reasonable then to expect that the concentration of a topically applied drug in the stratum corneum will be related to its concentration in deeper skin layers and in some cases also to the total amount absorbed.<sup>120</sup> Tape stripping consists of the progressive removal of stratum corneum by serial application of adhesive tape and subsequent determination of the amount of drug in each tape strip.<sup>100</sup> If the amount of stratum corneum removed by each tape strip is known, it is possible to calculate the stratum corneum thickness and to determine the permeation parameters of the permeants, using an appropriate solution of Fick's law of diffusion, which predicts the concentration of the drug as a function of position and time within the stratum corneum ( $C(x)$ )<sup>121</sup>:

$$C(x) = P C_{\text{veh}} \left[ 1 - \frac{x}{H} - \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{1}{n} \sin \frac{n \pi x}{H} \exp\left(\frac{-D n^2 \pi^2 t}{H^2}\right) \right] \quad [11]$$

where  $C_{\text{veh}}$  is the concentration of the drug in the donor vehicle,  $D$  is the diffusion coefficient in the stratum corneum,  $P$  is the stratum corneum/vehicle partition coefficient, and  $H$  is the diffusional path length.

Attenuated total reflectance Fourier transform infrared spectrometry (ATR/FTIR) has been used as an alternative to the conventional diffusion cell to determine drug or solvent permeation across the stratum corneum.<sup>119</sup> The stratum corneum is placed on the ZnSe crystal of the ATR/FTIR spectrometer face-up and is covered with the drug donor solution. The diffusion of the permeant is monitored by the appearance and increase in the drug-specific infrared (IR) absorbance as a function of time. By appropriate calibration, the absorbance can be transformed into concentration. Pirot and coworkers<sup>121</sup> validated the ATR/FTIR method, using liquid scintillation counting as analytical reference method and 4-cyanophenol as a model permeant: they found a direct correlation between the amount of permeant determined by ATR/FTIR and liquid scintillation counting. Unfortunately, this technique is limited to IR-active permeants, showing absorption bands in the regions of the spectrum free of skin-related bands.

Finally, autoradiography and laser scanning confocal microscopy (LSCM) are used mostly to visualize and to quantify penetration through and distribution within the skin. Applications of LSCM in transdermal drug delivery, recently reviewed by Alvarez-Roman *et al.*,<sup>122</sup> include the determination of the distribution of fluoropores in hair follicles and the study of enzyme activity and localization in the skin.

## 5.12.4 Conclusions

Nonoral routes are considered novel routes for drug administration. The increased frequency in their application for systemic drug absorption is due to the increased understanding of the transport mechanisms across tissues as well as the development of new materials and devices. The introduction in therapy of new products for alternative routes of administration is mainly presented as line extension. Nevertheless, it is useful as a series of additional in vivo studies, particularly where the anatomic district involved in the administration has never been exposed to the drug formulation before. However, while showing the advantages of new ways of administering a drug, safe use of the drug product originally formulated for other routes requires not only in vitro demonstration, but also in particular additional clinical data. The potential benefits in terms of patient acceptance, therapy outcome, and pharmaco-economic value ensure that the pharmaceutical development of drug products for alternative routes of administration continues to move forward.

## Biographies

**Paolo Colombo**, born in 1944 in Italy, was graduated in Pharmacy in 1968 at the University of Pavia, Italy. In 1986 he became Full Professor of Pharmaceutical Technology at the University of Parma, Italy, where he is now active. He is presently the Head of the Department of Pharmacy.

Paolo Colombo was acknowledged with the award for scientific production by University of Pavia in 1973, the Colorcon Award in 1991 and the AFI-Pharma Works 1992 Award. He was called as AAPS Fellow in 1996 and awarded with the 1999 Jorge Heller Journal of Controlled Release/CRS Outstanding Paper Award. From April 18 to July 30, 2001 he has been Associated Professor at the Faculty of Pharmacy of the University of Paris Sud. In 2003 the Academy of Pharmacy of France nominated Prof Colombo as foreign correspondent member. In 2004 he received the Maurice-Marie Janot Award as highly recognized drug research scientist. Professor Paolo Colombo has over 180 original papers and 30 patents on drugs and drug delivery systems.

His research interests are devoted to oral matrices delivery, inhalatory nasal and pulmonary powders and transdermal delivery. Many patents filed became products registered in various countries. One is the Geomatrix technology consisting in a hydrophilic matrix, partially coated with impermeable films that allows the modulation of drug delivery kinetics. Several products based on this technology are registered. The first one was Dilacor XR, containing diltiazem. Another marketed product is the new physical form of the antiulcer drug sucralfate. This new form named sucralfate gel, resulted much more active than the regular sucralfate powder, allowing the reduction of the therapy schedule of sucralfate from 4 to 2 g day<sup>-1</sup>.

**Stefano Cagnani** received his PharmD from University of Parma in 1998 and the PhD degree in Biopharmaceutics and Pharmacokinetics from the same University in 2004. His interests are focused on the pulmonary field with particular attention to the delivery of peptides and proteins. He is co-inventor of a formulation for the pulmonary administration of insulin.

**Fabio Sonvico** was born in Italy in 1974 and he graduated in Pharmaceutical Chemistry and Technology in 1999 at the University of Pavia (Italy) after spending a research stage at the laboratories of the Bayer Italia in Milan. He obtained a co-tutorial PhD at the Université de Paris Sud and the University of Parma. The subject of the research was 'Folate-targeted metallic nanoparticles for the treatment of solid tumors.' Since 2004, he is funded from the National Institute for the Physics of the Matter (INFN) on a research project dealing with the development of biopolymeric nanosystems suitable for the controlled delivery of drugs.

**Patrizia Santi** received her Pharm D and subsequently PhD in Pharmaceutical Chemistry and Technology from the University of Parma (Italy), where, in 1991, she became Assistant Professor. From 1998 to 2002 she was Associate

Professor in the same University (Faculty of Pharmacy) where she is Full Professor of Pharmaceutical Technology since 2002. She has published 58 papers and she is co-inventor of nine patents. Her main research interests are transdermal drug delivery and iontophoresis.

**Paola Russo** was born in Italy in 1977. She graduated in Pharmaceutical Chemistry and Technology in 2001 at the University of Naples (Italy), where she also obtained her PhD. The subject of the research was 'Microparticulates for drug administration.' In 2004 she was granted of a fellowship from 'Consorzio SPINNER' working on a research project dealing with nasal drug delivery at the Pharmaceutical Department, University of Parma. Today, she has a research assistant position at the university of Salerno (Italy).

**Gaia Colombo** was born in Italy in 1976. In 2001 she graduated in Pharmaceutical Chemistry and Technology at the University of Parma (Italy), after an 8-month research stage at the faculty of Pharmacy, University of Paris XI (France). From 2002 to 2004 she was granted of a PhD scholarship from the University of Parma and spent an 18-month appointment at Massachusetts Institute of Technology (Cambridge, MA, USA) within Prof Robert Langer's research team, where she worked on new systems for prolonged local anesthesia. Since January 2004, she has a permanent research assistant position at the University of Ferrara (Italy), where she is involved in several projects about nasal, buccal, and oral drug delivery.

## 5.13 In Vitro Models for Examining and Predicting Brain Uptake of Drugs

## 5.13.1 Introduction

### 5.13.1.1 Central Nervous System Barriers

The neurons of the brain communicate with each other using chemical and electrical signals that depend on fine control of the local ionic microenvironment; moreover such communication requires greater protection from circulating toxins than found in most other tissues of the body.<sup>1–3</sup> Barriers at three interfaces separate the blood from the brain interstitial fluid (ISF, also called extracellular fluid, ECF) (**Figure 1**): the blood–brain barrier (BBB), formed by the endothelial cells lining the microvessels (**Figure 2**); the blood–CSF barrier, formed by the choroid plexus epithelium, which also secretes cerebrospinal fluid (CSF); and the arachnoid epithelium, which forms part of the meningeal covering.<sup>4</sup> At each of these layers, tight junctions between cells form the ‘physical’ barrier, specific transport proteins/transcytosis mechanisms mediate uptake and efflux (‘transport’ barrier), and enzymes add a ‘metabolic’ barrier. Together these mechanisms regulate molecular traffic between blood and brain, both inward and outward. The BBB, with the largest surface area and shortest diffusion distances to neurons, is the most important interface in regulating drug permeability to the brain and is the focus of this chapter; however, for some drugs and pathological conditions, the other two barriers may also be relevant.

### 5.13.1.2 Cellular Anatomy of the Blood–Brain Barrier In Vivo

A number of cell types are closely associated with the brain endothelium (**Figure 2**). These include pericytes, astrocytic glial cells, microglia, and several cells that may be present in the perivascular space, including derivatives from the meninges, and in certain pathological conditions such as inflammation, invading cells from the blood.<sup>3</sup> Neurons occasionally send processes toward the endothelium, but are generally separated from direct contact by the astrocytes. In arterioles, smooth muscle cells controlling microvessel diameter are present between the astrocytic sheath and the endothelium. There is growing evidence for a ‘modular’ organization by which clusters of neurons are surrounded by the processes of specific astrocytes, which in turn contact individual segments of the vascular bed; the resulting ‘neurovascular unit’ may be a mechanism by which groups of neurons regulate their own blood flow.<sup>5</sup> At the capillary level, a finer degree of modular organization may be present, with neurons signaling via individual astrocytes to short segments of the capillary endothelium, possibly regulating local metabolic interaction.<sup>6,7</sup> However, most studies of drug permeation in vivo using animal models examine the blood–brain interface without approaching the level of individual microvessels. Hence the BBB activity observed will reflect the average function over the region assayed, often confined to cortical regions of the cerebral hemispheres. Microdissection of brain regions and autoradiographic techniques can be used where regional distribution is likely to be important.

### 5.13.1.3 Routes Across the Blood–Brain Barrier

For drug discovery programs involving compounds designed to target or avoid the central nervous system (CNS), several potential routes for permeation across the BBB are relevant.<sup>1,8,9</sup> The brain endothelial tight junctions severely restrict the penetration of hydrophilic solutes via the intercellular cleft (paracellular pathway), forcing molecular traffic between blood and brain to take a largely transcellular route (**Figure 3**).<sup>2,3</sup> Gaseous molecules such as O<sub>2</sub> and CO<sub>2</sub>, and small lipophilic agents, including many CNS drugs, can diffuse passively through the lumen-facing (apical) and brain-facing (basal, abluminal) endothelial cell membranes<sup>10</sup>; hence, compounds of greater lipophilicity generally show higher permeability (**Figure 4**). The endothelial membranes contain a number of specific transport (carrier) proteins that can shuttle necessary nutrients into the brain (uptake carriers, e.g., for glucose and amino acids)<sup>2,3,11</sup> or efflux waste products and exogenous compounds of potential toxicity (efflux carriers, e.g., P-glycoprotein, P-gp).<sup>9,12–15</sup> Molecules too large for carrier-mediated entry, such as peptides and proteins, may be able to cross the endothelium to a limited degree via a

**Figure 1** Location of barrier sites in the CNS. Barriers are present at three main sites: (1) the brain endothelium forming the blood–brain barrier (BBB), (2) the arachnoid epithelium forming the middle layer of the meninges, and (3) the choroid plexus epithelium which secretes cerebrospinal fluid (CSF). In each site, the physical barrier is caused by tight junctions that reduce the permeability of the paracellular (intercellular cleft) pathway. In circumventricular organs (CVO), containing neurons specialized for neurosecretion and/or chemosensitivity, the endothelium is leaky. This allows tissue–blood exchange, but as these sites are separated from the rest of the brain by an external glial barrier, and from CSF by a barrier at the ependyma, CVOs do not form a leak across the BBB. (Reproduced with permission from Abbott, N. J. *Drug Disc. Today: Technol.* **2004**, 1, 407–416 (with permission from Elsevier), based on Figure 1.1 in Segal, M. B.; Zlokovic, B. V. *The Blood–Brain Barrier, Amino Acids and Peptides*; Kluwer: Dordrecht, 1990, with kind permission of Springer Science and Business Media.)

vesicular route, either by specific receptor-mediated transcytosis (RMT) or following nonspecific adsorption of cationic molecules to the membrane surface (adsorptive-mediated transcytosis or AMT).<sup>9,16</sup> The endothelial cells express a number of surface and intracellular enzymes (e.g., peptidases, monoamine oxidase, cytochrome P450 enzymes) that form a metabolic barrier.<sup>3</sup> Several aspects of the barrier phenotype have been shown to be induced by cell types associated with the endothelial cells in vivo (Figure 2) especially astrocytic glia, but including neurons, pericytes, and perivascular macrophages<sup>17</sup>; this complexity has implications for development of in vitro models of the BBB (see below).

**Figure 2** Cell types at the BBB, shown (a) in three dimensions, and (b) in transverse section. The endothelial layer coupled by tight junctions forms the barrier; perivascular astrocytes and pericytes have associated roles, including induction of BBB phenotype in the endothelium. Other associated cell types such as neurons and microglia are not shown. A, astrocyte; BM, basement membrane; E, endothelial cell; P, pericyte; TJ, tight junction. (Reproduced with permission from Abbott, N. J. *et al. Progr. Appl. Microcirc.* **1990**, 16, 1–19.)

**Figure 3** Potential routes for transport across the brain endothelium forming the BBB. (a) Leucocytes may cross the BBB adjacent to, or by modifying, the tight junctions. (b) Solutes may passively diffuse through the cell membrane and cross the endothelium. Greater lipid solubility favors this process. (c) Active efflux carriers may intercept some of these passively penetrating solutes and pump them out of the endothelial cell. (d) Carrier-mediated influx, which may be passive or secondarily active, can transport many essential polar molecules, such as glucose, amino acids and nucleosides, into the CNS. (e) Receptor-mediated transcytosis (RMT) can transport macromolecules such as peptides and proteins across the cerebral endothelium. (f) Adsorptive-mediated transcytosis (AMT) appears to be induced nonspecifically by negatively charged macromolecules and can also result in transport across the BBB. (g) Tight junction (TJ) modulation may occur, which 'relaxes' the junctions and wholly or partially opens the paracellular aqueous diffusional pathway. (Modified with permission from Begley, D. J.; Brightman, M. W. In *Progress in Drug Research*; Prokai, L., Prokai-Tatrai, K., Eds.; Birkhäuser: Basle, Switzerland, 2003; Vol. 61 © Birkhäuser Verlag, Switzerland.)

**Figure 4** BBB permeability versus lipophilicity. Relation between measured BBB capillary permeability  $\times$  surface area (BBB PS) and the octanol/water partition coefficient for reference tracers (squares), drugs (circles), and nutrients (triangles). BBB PS data are all from in situ brain perfusion in the rat in the absence of plasma protein binding. Each point represents the mean of  $n = 3$ –8 perfusions. In *Methods in Molecular Medicine 89: The Blood–Brain Barrier: Biology and Research Protocols*; Nag, S., Ed.; Humana: Totowa, NJ, 2003, pp 193–208.)

#### 5.13.1.4 Drug Concentration in Brain Interstitial Fluid

The concentration of compounds in the brain under steady-state conditions will depend on a number of factors<sup>18</sup>: the plasma concentration versus time curve (pharmacokinetics in blood), the degree of plasma protein binding (since the effective concentration determining BBB permeation is the free concentration in blood), the permeability across the BBB (whether by passive diffusion or some mediated mechanism), metabolic modification by barrier enzymes, and the ‘sink effect’ of the continual secretion and drainage of CSF and ISF, giving turnover of both fluids.<sup>4</sup> Methods are available for determining all of these, but for most compounds complete information is lacking; instead, a mixture of technologies can be used to estimate the likely behavior of compounds at the chief barrier layer, the BBB, on the understanding that this is generally the most critical step in determining CNS penetration and concentration (Table 1).<sup>18</sup>

#### 5.13.1.5 Need for In Vitro Models

The earliest studies of the blood–brain interface were made more than 100 years ago, and involved in vivo preparations.<sup>19</sup> Injection of dyes and other chemical substances intravascularly in animal models, followed by assessment of their degree of penetration into the brain and CSF gave evidence for the barrier layers indicated above (see Section 5.13.1.1), and demonstrated some general principles of BBB penetration. Thus BBB penetration was observed for certain lipophilic uncharged compounds, while larger, more hydrophilic and charged compounds showed lower permeability, and specific carrier-mediated transport mechanisms for nutrients and waste products were demonstrated. In vivo preparations preserve the normal relations of brain cellular and fluid compartments, as well as cerebral blood flow, and allow investigation of drug pharmacokinetics (see 5.02 Clinical Pharmacokinetic Criteria for Drug Research). However, the complexity of the cell types and processes occurring at the BBB mean that it is often difficult in vivo to separate the mechanisms that lead to the observed drug distribution. Cell-based in vitro methods were introduced in the 1970s, and have allowed rigorous investigation not only of the events occurring at the brain endothelial cell membranes, but also of the intracellular signal transduction pathways that regulate BBB function. Certain of the in vitro models introduced allow relatively rapid measurement of BBB permeability, and of drug–transporter interaction, hence have applications in drug screening. Information gained from both in vivo and in vitro studies is now being used to construct and validate in silico tools (see 5.31 In Silico Models to Predict Brain Uptake),

**Table 1** Comparison of technologies for studying BBB permeability and transport

| <i>Technology</i> | <i>In vivo: log BB</i>  | <i>In vivo: log PS</i>  | <i>In vivo, knockout (k-o) animals</i>  | <i>In vitro cell-based assays</i>  | <i>Non-cell-based assays</i>  | <i>In silico modeling</i>   |
|-------------------|---|---|---|--|---|---|
| Summary, species  | Brain:plasma ratio, ideally from AUC<br>Rat, mouse  | Permeability $\times$ surface area, from unidirectional uptake coefficient<br>$K_{in}$ Rat, mouse   | Influence of P-gp – mdr1a/1b –/– or triple k-o together with MRP1 –/– (mouse)<br>Effect of BCRP/ABCG2 and other efflux transporters using inhibitors      | Choice of primary culture (1°), 1° + astrocyte influence, or cell line model<br>Study of permeability, transport. Most useful: bovine, porcine, rat, mouse, human  | Use of immobilized artificial membrane (IAM = HPLC technology) or membrane filter systems (PAMPA) mimicking aspects of BBB membranes  | Based on correlations between compound permeation and physicochemical descriptors<br>(see 5.31 In Silico Models to Predict Brain Uptake)  |
| Pros              | Reflects real behavior of compounds in blood: brain distribution                                    | Accurate measure of BBB permeability step, better basis for predictive modeling of this interface<br>Reliable ‘gold standard’ reference for other methods | Relatively clear-cut ‘classification’ system to distinguish efflux transporter substrates   | Medium throughput; can select model according to information required (permeability, mechanism of transport)   | PAMPA: Medium to high throughput (UV analysis)<br>Moderately good predictor for passive permeation  | Several models available, similar levels of predictive power for passively permeating compounds<br>Some quite high throughput   |
| Cons              | Influenced by factors apart from BBB permeability, especially nonspecific binding<br>Low throughput | Labor intensive Low throughput<br>May need ‘capillary depletion’ technique to confirm compound reaches parenchyma   | A ‘classification’ rather than ranking system – not well suited for deriving structure–activity relationships information or generating predictive models | No industry standard model. Primary cultures labour intensive<br>Cell line models generally too leaky for permeability assays<br>Very lipophilic compounds may stick to membranes<br>Need to minimize unstirred water layers | Less suitable for compounds not detectable by UV – then need to use LC/MS/MS <sup>a</sup><br>Very lipophilic compounds may stick to membranes<br>Need to correct for unstirred water layers | Few models can yet offer prediction for carrier-mediated transport. For predicting passive permeability, accuracy depends on training set used, and chemical space of test compound set |

<sup>a</sup>LC/MS/MS, liquid chromatography followed by tandem mass spectrometry and identification of product ions.

with the aim of conducting as much drug screening as possible without the need to use biological preparations. However, the complexities of the living system mean that prediction is likely to remain an inexact science for the foreseeable future, so that cell-based models will continue to play an important role.

#### 5.13.1.6 Cell-Based In Vitro Models

A number of approaches have been tried to create in vitro models that can act as simpler systems for examining BBB function. Inevitably these will not reproduce all aspects of the in vivo BBB, but the aim is to develop models that will show features relevant to the specific application. Thus isolated brain capillaries may be useful for investigations of brain endothelial metabolism and transporters,<sup>20–23</sup> and brain slices make possible examination of the neurovascular unit.<sup>6</sup> However, by far the most useful models for understanding BBB mechanisms at the cellular and molecular level have been cell culture models, either using brain capillaries as a starting material to obtain endothelial cell cultures, or using cell lines that when cultured show some features of the in vivo barrier. Before these can be used as reliable models of the BBB, they need careful characterization, with comparison of their properties with those of the in vivo BBB. In the field of drug delivery to the brain, this characterization will include examination of the extent to which the in vitro model reproduces the tightness and transport properties of the in vivo BBB.

Section 5.13.2 below summarizes key technologies that help establish and predict BBB permeation using in vivo and in vitro models.

### 5.13.2 Key Technologies

#### 5.13.2.1 Range of Technologies

This chapter focuses on in vitro techniques, while other technologies relevant to the BBB are covered in detail elsewhere in this volume (see 5.31 In Silico Models to Predict Brain Uptake). For completeness, methods that give valuable data for reference or comparison with the in vitro models<sup>1,24,25</sup> are summarized here. Table 1 lists the six technologies that have contributed most to understanding compound behavior at the BBB over the last 5–10 years.

Designing drugs to treat brain disorders needs to take into account the properties of the BBB outlined above. Improved understanding has come from techniques for measuring BBB permeability in vivo, and for establishing the properties of both passive and mediated transport routes across the barrier. In vivo techniques still provide some of the most reliable reference information for testing and validating other models, but in vitro technologies are increasingly useful, especially to provide mechanistic information. For passively permeating compounds, non-cell-based assays may be valuable, and methods combining in vitro and physicochemical information may even be able to predict penetration for compounds using mediated transport systems. In silico (computer-based) modeling and BBB permeability prediction have been limited by the quality and quantity of the data (training set) used to construct the models, but more practical methods are becoming available. Although there is as yet no agreement on ‘industry standard’ models, the ability to choose from a range of technologies to generate a BBB ‘permeability profile’ for a drug provides valuable internal checks and prediction covering an expanding chemical space.

#### 5.13.2.2 In Vivo and In Situ Methods

Of several methods for assessing BBB permeability in vivo,<sup>24</sup> two are widely used: determinations of brain:plasma ratio (log BB); and measurement of the permeability  $\times$  surface area product (PS or log PS), from which permeability  $P_e$  can be derived provided vessel surface area ( $S$ ) can be estimated.

##### 5.13.2.2.1 Extent of brain penetration: brain:plasma ratio, log BB

Most pharmaceutical companies generate log BB data in animals (often rat) as part of standard pharmacokinetic profiling of compounds.<sup>18,26</sup> Single time-point log BB determinations are of limited value as they depend critically on the time chosen and the relation between the concentration in plasma and brain at this time point. The ratio of the areas under the curve (AUC) for brain and plasma concentrations is more useful. However, these measurements are generally made over several hours, with a number of animals required per data point, so are costly and labor intensive. Moreover, a number of factors, including metabolism and binding, affect the brain distribution, so that log BB is not a pure measure of BBB permeability.

#### 5.13.2.2.2 Rate of brain penetration: unidirectional influx coefficient ( $K_{in}$ ) and permeability–surface area product (PS)

Determining the unidirectional influx coefficient ( $K_{in}$ ) using the in situ saline-based perfusion method (for rat, mouse, typically over 1–10 min, plotting the volume of distribution against time, from which slope =  $K_{in}$ ) more accurately reflects the BBB permeation step, effectively isolating this ‘kinetic’ element of drug penetration.<sup>24,26</sup> The saline composition of the perfusate can be controlled, and plasma protein included if needed to test the effect of protein binding. If perfusate flow is also measured,  $K_{in}$  can be converted to PS (see above). These are absolute values that can be compared across preparations and tissues, and used to follow changes under altered conditions (e.g., in pathology). Because of the accurate quantitation, the  $K_{in}$  (or PS) measurement acts as a valuable ‘gold standard’ reference for other methods.<sup>27</sup>

#### 5.13.2.2.3 Microdialysis: free drug concentration in brain

For drugs acting on the chief CNS target sites (membrane receptors, transporters), the critical concentration is the free concentration in brain ISF. Brain:plasma ratio measured especially at longer times and for more lipophilic agents will be affected by drug distribution into brain lipids and nonspecific binding. Measuring free concentration with a microdialysis probe is possible but technically difficult, and there is a particular problem of recovery of more lipophilic agents.<sup>28,29</sup> Measurement of CSF:plasma ratio has been used as a ‘surrogate’ measure of ISF concentration, especially in steady state.<sup>30</sup> However, depending on the balance between uptake and clearance mechanisms influencing drug concentration in ISF and CSF, including the ‘sink effect’ of CSF and ISF turnover and drainage, the CSF:ISF ratio may be greater or less than 1.0.<sup>31</sup>

#### 5.13.2.2.4 Knockout and gene-deficient animals

Although there is a general relation between BBB permeability and lipophilicity (Figure 4), such plots show a number of outliers. Those considerably above the line generally prove to be substrates for uptake carriers at the BBB, while many below the line prove to be substrates for efflux transporters, such as P-gp. This was most strikingly demonstrated in P-gp knockout mice (initially *mdr1a*, later double-knockout *mdr1a/1b*  $-/-$ ), when log BB increased up to 90-fold for certain compounds, identifying them as P-gp substrates.<sup>32</sup> A high proportion of established CNS-active drugs are proving to be substrates for P-gp<sup>33</sup> yet these are efficacious drugs; there are indications that if passive BBB permeability, and potency on the target site, are high enough, these factors can outweigh the effect of P-gp-mediated efflux at the BBB. Nevertheless, transport by P-gp needs to be taken into account in designing and optimizing new CNS drugs, since it will affect the free drug concentration in brain ISF concentration resulting from any particular plasma concentration versus time curve. Following the identification of further efflux transporters at the BBB (breast cancer resistance protein BCRP1/ABCG2; major vault protein MVP; the Ral-interacting protein RLIP-76),<sup>34–36</sup> knockout and gene-deficient animals will be valuable in assessing their role.

### 5.13.2.3 In Vitro Cell-Based Methods

All the animal-based studies discussed above are labor intensive and low throughput. Given the need for higher-throughput methods to deal with the increasing numbers of compounds generated by combinatorial chemistry, there has been great interest in in vitro methods.<sup>37</sup> Cell-based model systems and the techniques for their examination are the most widely applied and are discussed in more detail in Sections 5.13.3 and 5.13.4 below.

#### 5.13.2.4 Non-Cell-Based Permeability Assays

In the 1980s, efforts were made to generate high-performance liquid chromatography (HPLC) columns, ‘immobilized artificial membranes’ (IAMs), that mimicked the properties of biological membranes to use as a permeability screen. Some were moderately successful, capable of ranking compounds according to BBB permeability,<sup>38</sup> but they have not proved suitable for medium- to high-throughput operation. A more promising technology is the parallel artificial membrane permeability assay (PAMPA) (see 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery), first developed as a surrogate for gastrointestinal absorption. PAMPA is suitable for passively permeating compounds, showing moderately good correlation with data from the human colonic epithelial cell line (Caco-2) and in vivo studies. By modifying the lipid composition of the artificial membranes, the system appears capable of predicting CNS permeability with reasonable accuracy.<sup>39</sup>

### 5.13.2.5 High-Throughput Assays

None of the *in vitro* tools for studying the BBB has so far led to high-throughput assays. At best, cell culture preparations have allowed medium-throughput studies of BBB features of interest, for example interaction of modulators and inhibitors with transporters expressed, such as the efflux transporter P-gp.<sup>40,41</sup>

### 5.13.3 Theoretical Basis: Permeability and Transport Measurements in Blood–Brain Barrier Models

The theory behind flux measurements in *in vitro* BBB models is the same as that for measurements of this kind in other cell and monolayer systems, such as Caco-2 and Madin–Darby canine kidney cell line (MDCK) epithelial cells (*see* 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption), and the same basic equations apply.<sup>42,43</sup> The mathematical treatments frequently used for BBB models are described in this section.

#### 5.13.3.1 Measurement of Cell Monolayer Permeability

Cell monolayers for BBB permeability measurement, as for epithelial models, are generated by growing the cells on permeable filters, mounted in a device that separates the apical (luminal) compartment and the basal (abluminal) compartment (e.g., Ussing chamber, Transwell system). Drug is added to one compartment (the donor) and the amount appearing in the other compartment (receiver), is determined over time. Permeability across the monolayers can be assessed using the equations governing chemical flux, based on Fick's first law:

$$J = P_c(C_1 - C_2) \quad [1]$$

where  $J$  is flux ( $\text{mol s}^{-1} \text{cm}^{-2}$  membrane),  $P_c$  is the permeability coefficient ( $\text{cm s}^{-1}$ ), and  $C_1 - C_2$  ( $\text{mol mL}^{-1}$ ) is the concentration difference between compartments 1 (donor) and 2 (receiver). If the experimental conditions mean that the concentration in the receiver compartment is negligible compared with that in the donor compartment, then this can be simplified to:

$$J = P_c C_1 \quad [2]$$

and hence  $P_c = J/C_1$

In the pharmaceutical science field, it is often sufficient to gain a measure of permeability ranking within a compound series, hence the measure frequently used is apparent permeability ( $P_{\text{app}}$ ) ( $\text{cm s}^{-1}$ ):

$$P_{\text{app}} = (dQ/dt) * (1/c_0 S) \quad [3]$$

where  $dQ/dt$  ( $\text{mol s}^{-1}$ ) is the increase in the amount of drug in the receiver chamber per time interval,  $S$  ( $\text{cm}^2$ ) is the growth area of the cell culture filter insert, and  $c_0$  ( $\text{mol mL}^{-1}$ ) is the initial drug concentration in the donor chamber.  $P_{\text{app}}$  is an empirical value, since there is generally no attempt to correct for the series barrier of the filter on which the cells are grown. However, if the filter is sufficiently porous, and the cell layer sufficiently tight (so that leakage through the tight junctions, the paracellular pathway, is small), and unstirred water layers are minimized by stirring or shaking, then useful ranking of drug permeabilities can be obtained. Refinement of the method to check for mass balance and allow for cell retention of the drug can be used where this is a problem, e.g., for very lipophilic drugs.<sup>44</sup>

An alternative approach is to make use of the clearance principle (widely used in physiology) to give a concentration-independent transport parameter. Here the 'cleared volume' is a calculated virtual volume equivalent to the smallest volume of donor solution necessary to deliver the amount of drug appearing in the receiver solution, i.e., the volume of donor solution from which that drug has been 'cleared.' It is calculated as described by Siflinger-Birboim *et al.*<sup>45</sup> by dividing the amount of compound in the receiver compartment by the drug concentration in the donor compartment. The normal direction for study is from luminal to abluminal compartment, but for studies of efflux transport, the opposite direction can be used.

For the most reliable analysis, filters with cells grown on, as well as blank filters, coated with any cell growth matrix but without cells, are studied. At time zero, an aliquot of the test compound in buffered saline is added to the donor compartment, and at set times (typically 10, 15, 20, 30, and 45 min), aliquots are removed from the receiver compartment, and the amount of compound determined. After removal of the aliquots, fresh buffer is added to the receiver solution to maintain equal volumes in both chambers, the dilution being taken into account in data analysis.

Alternatively, the filter insert is moved to a fresh receiver well at each time point, to minimize possible back-flux from the receiver compartment, and aliquots of each receiver well, and of the initial donor solution, are analyzed.<sup>46</sup>

The total volume cleared ( $V_{CL}$ ) at each time point is calculated by summing the cleared volumes up to the given time point:

$$V_{CL} = A/C_d \quad [4]$$

where  $A$  is the amount of test compound on the receiver side, and  $C_d$  is the concentration of test compound on the donor side at each time point. If permeability is constant during the experiment, then the total cleared volume will increase linearly with time, and the slope of the line (cleared volume divided by time) calculated by linear regression analysis will give the  $P_e S_t$  (or total clearance), where  $P_e S$  is the permeability  $\times$  surface area product in  $\text{mL s}^{-1}$ . The slope of the clearance curve for control (blank) filters is denoted  $P_e S_f$ . Hence the  $P_e S$  value for the endothelial or epithelial cell monolayer ( $P_e S_e$ ) can be calculated from

$$1/P_e S_e = (1/P_e S_t) - (1/P_e S_f) \quad [5]$$

$P_e S_e$  is then divided by the surface area of the filter  $S$  to give the monolayer permeability coefficient  $P_e$  ( $\text{cm s}^{-1}$ ). The advantage of this parameter is that it represents the measured permeability of the test molecule through that cell system, and can be compared with measurements made across other biological interfaces (e.g., gastrointestinal tract, skin) and by in vivo or in situ techniques. Since the permeability coefficient is proportional to the mobility of the drug in the monolayer or membrane system, divided by the path length (often the cell or membrane thickness),<sup>47</sup> absolute values of  $P_e$  made in different tissues and membrane systems will generally differ. However, these differences can give valuable information about the nature of the barrier layers.

### 5.13.3.2 Measurement of Uptake Transport by Cells

Studies of brain endothelial cell uptake of a test substance typically involve incubation of the cells in a tracer molecule of interest, stopping the uptake process at set time points (e.g., by washing with cold buffer solution, or using a stopping solution containing specific inhibitors to block transport), lysing the cells and analyzing the contents for presence of the tracer (e.g., by radioactive counting, quantification of fluorescence, HPLC or liquid chromatography-mass spectrometry (LC/MS)), as well as total protein content. The volume of distribution of the test substance,  $V_d$  ( $\mu\text{L mg}^{-1}$  protein), is determined from the ratio of counts (or amount) per milligram protein to counts (or amount) per microliter incubation medium. Where uptake is mediated by transporters, kinetic parameters of transport can be estimated using nonlinear regression analysis of the concentration ( $C$ ) dependence of the influx,  $J_{in}$  ( $\text{nmol min}^{-1} \text{mg}^{-1}$  protein) based on conventional Michaelis–Menten kinetics,<sup>48</sup> e.g.,

$$J_{in} = (V_{max}C)/(K_m + C) + K_D C \quad [6]$$

where  $K_m$  is the half-saturation concentration,  $V_{max}$  is the maximum transport capacity ( $\text{nmol min}^{-1} \text{mg}^{-1}$  protein), and  $K_D$  the constant of passive diffusion ( $\mu\text{L min}^{-1} \text{mg}^{-1}$  protein).

## 5.13.4 Cell-Based In Vitro Tools for Studying Blood–Brain Barrier Function

### 5.13.4.1 Range of In Vitro Tools

A variety of in vitro tools have been developed to study the behavior of compounds at the BBB, and to predict their BBB permeability. The earliest studies compared in vivo permeation with compound behavior in brain slices, the latter designed to bypass the BBB. Later it became possible to study isolated brain microvessels, to examine brain capillary endothelium directly. Both these techniques have recently returned to the experimental repertoire, thanks to improvements in imaging technology. However, the introduction of brain endothelial cell culture was the most significant advance in the 1970s. This led to the isolation of cell membrane and organelle fractions, to examine function in more detail at the molecular level. Where drug distribution has proved to be largely dependent on physical chemistry, particularly the nature of the lipid bilayer cell membranes, attempts have been made to mimic these in non-cell-based in vitro systems. All these tools continue to be used, often in combination to obtain the most reliable information, and to make allowance for the artifacts associated with each method.

#### 5.13.4.2 Brain Slices

In the early 1960s, the location of the BBB was still not established with certainty; one view was that the apparent restriction on compound entry to the brain was due to a limited extracellular space.<sup>19</sup> Brain slices were used to establish that the brain contained appreciable extracellular fluid, so that restriction on uptake *in vivo* must be due to a barrier at the capillary level.<sup>49</sup> In the 1970s brain slices were used to make significant advances in understanding of brain biochemistry and neurochemistry, for example for glucose transport.<sup>50,51</sup> However, they were not suitable for kinetic studies, since diffusion in the extracellular space rather than the transporter itself often proved the rate-limiting step, and cell swelling caused changes in the fluid compartments.<sup>51</sup>

More recently, improvements in techniques for isolation and maintenance of brain slices with well-preserved extracellular space,<sup>52</sup> together with new imaging techniques (such as 2-photon confocal microscopy) allowing examination of structures within the slice, have allowed studies of cell–cell interaction within the neurovascular unit, including influences of astrocytes on blood vessels.<sup>6</sup> However, as the vessels within the slice are unperfused, these preparations are not suitable for examining BBB permeability and transport. For studies of gene and protein expression, the powerful technique of laser capture microdissection (LCM) can be used not only to sample from individual blood vessels in defined regions of brain slices, but also to separate relatively cleanly the endothelial and perivascular cells.<sup>53</sup> This tool has significant applications in determining changes in phenotype of blood vessels in pathological human brain material (resectioned, biopsy, or post-mortem), to guide drug delivery strategies.

#### 5.13.4.3 Isolated Cerebral Microvessels

In 1975 Goldstein *et al.*<sup>21</sup> reported isolation of metabolically active capillaries from rat brain, and this preparation was used for a number of studies on transport and metabolism, e.g., for hexoses<sup>20</sup> and small ions.<sup>22</sup> Since Na<sup>+</sup>-dependent glutamate uptake by the BBB could not be detected *in vivo*, but was observed in isolated brain microvessels, where the bathing medium mainly has access to the outer vessel surface, an abluminal location for this transport was proposed.<sup>54</sup> The vessels were less suitable for studies of processes with high energy demand such as transcytosis, possibly because of the damage caused in vessel isolation and the resultant impairment in ATP production. Recent improvements in technique have led to more physiological preparations of isolated brain microvessels preserving normal polarized (apical-basal) function, and modern confocal imaging techniques using fluorescent substrates have allowed good resolution of real-time transport activity at the single vessel level.<sup>55</sup> The technique has been valuable in identifying location and specificity of transporters present at the BBB, and for examining drug interaction with these transporters,<sup>56,57</sup> but is not suitable for screening large numbers of compounds to establish whether they are substrates for these transporters.

#### 5.13.4.4 Cell Culture Preparations

Brain microvessels can be readily isolated from brain; when seeded in culture medium, endothelial cells grow out to form monolayers suitable for experimental examination.<sup>58</sup> So far no single *in vitro* BBB model has been adopted as ‘industry standard’; rather the choice depends on the application, convenience, and resource available.

##### 5.13.4.4.1 Primary endothelial cultures

Primary endothelial cultures maintain a number of features of the *in vivo* BBB phenotype, though with some downregulation or altered expression: tight junctions, transporters, enzymes, and receptors are preserved to differing extents.<sup>59,60</sup> Coculture with astrocytic glial cells (or astrocytoma cells) generally leads to some upregulation of BBB phenotype, including tightness,<sup>61,62</sup> making monolayers suitable for permeability screening.<sup>63</sup>

##### 5.13.4.4.2 Immortalized brain endothelial cell lines

These have proved useful for examining mechanisms of transport and cell–cell interaction, but generally make leakier monolayers than primary cells.<sup>64,65</sup> Some conditionally immortalized cells appear to express transporters at higher levels than in primary cultures.<sup>66</sup> Growing endothelial cells in porous tubes with luminal flow (dynamic *in vitro* BBB model) may help differentiation of a BBB phenotype.<sup>67,68</sup> Some of the models are suitable for examining permeability under conditions mimicking pathology, such as ischemia and hypoxia,<sup>69,70</sup> and infection.<sup>71</sup> Further detail is given in [Section 5.13.5](#) below.

#### 5.13.4.5 Membrane Vesicles

In vitro models based on whole living cells are often too complex to permit detailed examination of the interactions of compounds including drugs with individual receptors or transporters, so a number of techniques have been developed for isolating cell membranes, both the plasmalemma and membranes from organelles, and maintaining them for the few hours needed for experimental study.<sup>72,73</sup> By using marker enzymes or antibodies against specific membrane antigens it is possible to distinguish the membranes coming from apical and basolateral plasmalemma, and from different organelles. For study of ATP-dependent processes, 'inside-out' vesicles can be used, e.g., for examination of P-gp or breast cancer resistance protein (BCRP1 = ABCG2). These vesicles can be used to screen for compound interaction with transporters, but not in high-throughput mode for identifying transporter substrates.

### 5.13.5 Cell Culture Models of the Brain Endothelium

#### 5.13.5.1 History of Brain Endothelial Cell Culture

The first successful isolation of viable brain microvessels<sup>74</sup> was soon followed by the observation that if the microvessel fragments were seeded in dishes in culture medium, cells would grow out, proliferate, and become confluent.<sup>75</sup> Several culture models have since been developed and characterized.<sup>58,76</sup>

#### 5.13.5.2 Primary Cultures

All the methods for generating primary cultures of microvessel endothelial cells from brain tissue aim to maximize the yield and purity of the cells obtained, and to minimize or eliminate fast-growing contaminating cells, chiefly pericytes, fibroblasts, and smooth muscle cells. This can be achieved by various combinations of enzymatic digestion, filtration, centrifugation, differential adhesion on different matrices, and techniques to kill contaminants.<sup>76</sup> The last were initially based on use of complement with antibodies against antigens expressed on contaminating cells, such as the surface glycoprotein thymus protein-1 (Thy-1 or CD90) expressed on pericytes and fibroblasts. More recently, methods based on growth in medium containing a cytotoxic P-gp substrate such as puromycin have been introduced; the principle is that brain endothelial cells (expressing P-gp) will survive, while contaminating cells lacking this transporter will not.<sup>77</sup> It may be necessary to allow presence of some contaminants in the early growth phase of the culture, as they appear to produce important growth factors for the endothelium, but to remove contaminants later to encourage endothelial differentiation and formation of uniform monolayers. The nature of the extracellular matrix on which the cells are grown can influence differentiation.<sup>78</sup>

It is important to characterize the culture produced to demonstrate that important features of the in vivo BBB relevant to the study planned are expressed. A number of suitable biomarkers are available, to assess endothelial phenotype (e.g., von Willebrand factor, platelet endothelial adhesion molecule PECAM-1, alkaline phosphatase),<sup>79–82</sup> presence of tight junction proteins (e.g., occludin, claudins, zonula occludens protein-1 (ZO-1)) and apical–basal transport polarity (e.g., apical transferrin receptor, basolateral Na<sup>+</sup>, K<sup>+</sup>-ATPase).<sup>83</sup> The best established primary cultures of brain microvessel endothelial cells have been generated and characterized from bovine,<sup>61</sup> porcine,<sup>59</sup> rat,<sup>76,77</sup> mouse,<sup>81</sup> and human brain,<sup>84</sup> and methods have also been reported for ovine, goat, and monkey brain.

#### 5.13.5.3 Immortalized Brain Endothelial Cell Lines

There are several drawbacks to primary cultures, the most important being their limited lifespan, and hence the need to obtain fresh brains as a source material on a regular basis. Other problems are lack of consistency resulting from variability in state and viability of the starting material, the need to cull large numbers of animals when working with small (e.g., rodent) brains, difficulty in removing contaminating cells, and batch-to-batch variation in cell growth. This last is often difficult to explain, but may relate to minor differences in cell isolation and growth conditions. As a result of these problems, a great deal of effort has been put into developing immortalized brain endothelial cell lines, by transfection of pure brain endothelial cells. The technology has been particularly applied to rat and mouse brain,<sup>85</sup> as these animals are widely used as in vivo models (for physiological, pharmacological, and pharmaceutical applications), so that a great deal of reference information is available for them, and useful probes (e.g., antibodies, oligonucleotides) have been developed. A drawback is that immortalized cell lines generally form leakier monolayers than primary cultures, although a recently reported mouse cell line (cEND) may be an encouraging exception.<sup>82</sup>

#### 5.13.5.4 Methods to Upregulate Blood–Brain Barrier Features in Cell Culture Models

Many BBB features present *in vivo*, and still detectable in freshly isolated brain capillaries, are found to disappear or decline in expression over hours to days in culture.<sup>86</sup> These include presence and correct localization of tight junctional and associated proteins, certain enzymes such as alkaline phosphatase and gamma-glutamyl transpeptidase,<sup>83</sup> and presence and polarized membrane localization of efflux proteins such as P-gp. By contrast, certain proteins expressed in non-brain endothelium but apparently downregulated in BBB endothelium (MRP1, multidrug resistance associated protein-1,<sup>87</sup> aquaporin1 water channel<sup>88</sup>), begin to reappear in culture. Some of the phenotypic features of the BBB phenotype can be reinduced by coculture of the brain endothelium with astrocytes or astrocytic cell lines (e.g., C6 glioma),<sup>89</sup> suggesting that *in vivo* the perivascular astrocyte endfeet play an important role in inducing (sculpting) and maintaining the BBB phenotype.<sup>79</sup> Recent studies indicate that other cells associated with brain microvessels may also take part in induction, and that it is a two-way or even multiway process between the cell types involved.<sup>90</sup>

A number of candidate molecules for inducing agents have been identified, including basic fibroblast growth factor (bFGF), glial cell-derived neurotrophic factor (GDNF), and transforming growth factor beta (TGF- $\beta$ ),<sup>17,79</sup> but so far it has not been possible to mimic all aspects of the differentiated BBB phenotype by adding any one of them to the medium. It is useful to distinguish between ‘permissive’ influences that prime the endothelium (intraluminal flow,<sup>67</sup> corticosteroids,<sup>59</sup> elevation of intracellular cyclic AMP<sup>86</sup>), and release of specific ‘inductive’ influences from associated cell types that trigger the full differentiation.<sup>90,91</sup> Generally the combination of permissive and inductive influence leads to the highest expression of BBB features.<sup>17,79</sup>

This knowledge has led to development of a number of coculture models that generate a more differentiated BBB. The key features that are relevant to pharmaceutical studies are the tightness of the endothelial monolayer, and the presence and polarized location of the appropriate transporters.<sup>83</sup> For a number of years, the tightest *in vitro* models were obtained from primary bovine brain endothelial cells cocultured above primary rat astrocytes.<sup>46</sup> More recently it has been possible to generate tight porcine brain endothelial cell monolayers by exposure to hydrocortisone.<sup>59</sup> Both models have proved valuable in pharmaceutical applications. It has recently become possible to make tight rat<sup>77</sup> and mouse<sup>81</sup> primary coculture models, and although these are not so suitable for medium-throughput drug permeability screening, they will be valuable where correlation with animal studies is needed (e.g., drug pharmacokinetics in rat, studies in transgenic mice). Certain of the cell line models also retain responsiveness to glial factors and hydrocortisone,<sup>82,85</sup> suggesting that generating cell line models as tight as the best primary models may be possible in the future.

#### 5.13.5.5 Models for Studying Specific Transport by Brain Endothelial Cells

Since production of the earliest primary cultures of brain endothelial cells, and then cell line models, these preparations have proved valuable for studying the mechanisms for specific transport, their kinetics, and mode of operation. Cell lines often express a reduced phenotype compared to primary culture (e.g., in range of transporters expressed), but this can be turned to advantage for examining the mechanisms that are expressed.<sup>92</sup> Where the main question concerns the mechanism and kinetics of transport, monolayer tightness is unimportant.<sup>48</sup> For transporters with polarized (apical–basal) expression, full polarization is likely to require the presence of effective tight junctions, which not only restrict paracellular permeability (‘gate’ function) but also limit lateral diffusion of membrane proteins such as transporters within the membrane and hence segregate apical and basolateral transporters (‘fence’ function).<sup>92,93</sup>

#### 5.13.5.6 Models for Studying Permeability and Transport Across the Blood–Brain Barrier

Effective tight junctions are an important element of a fully differentiated BBB. This is largely because the physical barrier to hydrophilic molecules thus provided is one of the defining roles of the BBB. As mentioned above, polarization of transporters to apical and basolateral membrane domains also requires effective tight junctions. Hence the two features for pharmaceutical applications, tightness and polarized expression of transporters, depend on the tight junctions. This readily explains why the two models most commonly used in pharmaceutical assays are the bovine brain endothelial model (with or without astrocytes)<sup>37,46,61</sup> and the porcine model (with or without hydrocortisone).<sup>59</sup> Furthermore, scientific study of the mechanisms underlying polarized transendothelial transport, whether mediated by membrane carrier proteins or by vesicles (RMT or AMT), requires tight junctions restricting enough to allow resolution of the transport without excessive shunting (short-circuiting flux) via the junctions.<sup>94</sup>

The tightness of an endothelial or epithelial layer can be assessed by two measures of paracellular permeability, the transendothelial (or epithelial) electrical resistance (TEER,  $\text{ohm cm}^2$ ) and the transmonolayer permeability to a

hydrophilic tracer molecule with negligible cell uptake or binding. Suitable permeability markers of a size similar to small drug molecules (typically 100–400 Da mol. wt.) are sucrose and mannitol (used as radiolabeled probes) or fluorescent indicators such as fluorescein and Lucifer yellow.<sup>76</sup> As electrical resistance is the reciprocal of conductance, related to the permeability of small ions, TEER is inversely proportional to the permeability or conductance of  $\text{Na}^+$  and  $\text{Cl}^-$  through the tight junctions, these being the major charge carriers in extracellular fluids.<sup>92</sup>

A plot of TEER versus small solute permeability through an epithelial or endothelial monolayer will give an asymptotic curve reflecting this relationship.<sup>95</sup> Net solute flux increases as the sum of fluxes across individual junctional clefts, while TEER is most affected by areas with the lowest resistance, which shunt current flow. Hence a small flaw in a monolayer can cause a large drop in TEER with little drop in sucrose or fluorescein permeability. Monolayers with TEER greater than  $\sim 100\text{--}200\text{ ohm cm}^2$  give the expected relation between TEER and solute permeability,<sup>37,76,95</sup> so TEER assessment is a useful way of checking the uniformity and tightness of a monolayer before starting a drug permeability assay. The ability of a monolayer to rank drug permeabilities (its dynamic range) will depend partly on its tightness, as this will determine the degree of paracellular leak of the drug, and hence the dynamic range of the model.

### 5.13.5.7 Models Incorporating Intraluminal Flow

As discussed above, when endothelial cells are exposed to fluid flow exerting a shear stress across their apical surface, and inducing factors from astrocytes on their abluminal surface, this should provide an optimal combination of conditions encouraging BBB differentiation. Indeed, in the three-dimensional ‘dynamic’ in vitro BBB model (DIV-BBB) in which endothelial cells are seeded inside porous tubes with astrocytes on the outside, and medium flow is maintained via the lumen, TEER of up to  $2000\text{ ohm cm}^2$  has been reported.<sup>67,68</sup> A number of transporters and receptors characteristic of the BBB are also upregulated in the cells. Although less easy to use for kinetic studies than flat monolayer cultures, as the control and sampling of apical and basolateral fluid is less direct, the model has been used to test drug permeability. Recent miniaturization of the system and connection to a control module will make it possible to run several sets in parallel for statistical treatments.

### 5.13.6 In Vitro Surrogate Blood–Brain Barrier Models

In spite of the documented value of cultured brain endothelial cells as BBB models, they have not been universally popular with pharmaceutical companies. This is largely due to the labor-intensive nature of their preparation, and the fact that the expertise needed to prepare reproducible cultures is greater than for commonly used epithelial models such as Caco-2 and MDCK. These are widely used as assay systems to predict gastrointestinal permeability of a compound or drug (*see* 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption).

Since the earliest studies of BBB and blood–CSF barrier permeability *in vivo*, it has been clear that for many drug compounds, there is an approximate relation between permeability and lipid solubility, indicating a major role for lipid membranes of the barrier layers in determining drug delivery to the brain. As Caco-2 and MDCK cells are already used to give information about permeability across barrier layers, albeit for the gastrointestinal tract, many companies have applied these models as ‘BBB surrogates’ to estimate entry to brain. For compounds penetrating the brain by passive partition into brain endothelial membranes involving no interaction with transporters, this can give a reasonable prediction.<sup>96,97</sup> However, careful comparison using groups of druglike molecules shows that the correspondence is not exact,<sup>63,98</sup> indicating that for decisions affecting CNS-targeted drugs, a real BBB-based model gives better prediction (Figure 5).<sup>63,99</sup> Certainly the profile of transporter expression in the gastrointestinal tract and the BBB is different, and since a high percentage of current drugs appear to be substrates for efflux transporters, the expression profile and transporter density in the barrier layer (gastrointestinal tract or BBB) is likely to have major impact on drug penetration across the barrier.

It has recently become clear that the nature of the lipid membranes is different in the gastrointestinal tract and BBB.<sup>39,100</sup> This has implications for passive permeability and permeability ranking of drugs between the two systems. In addition, as more becomes known about the ways in which the membrane lipids influence the activity and transit time of substrates for uptake and efflux transporters,<sup>101</sup> it is likely that we will become aware of differences in drug delivery across the gut wall and across the BBB that can be attributed to the differences in lipid composition.

For studies where it is desirable to use human-derived cells, the ECV304/C6 coculture model is of interest.<sup>58</sup> The ECV304 cell line is apparently a clonal derivative of T24 human bladder carcinoma cells, and expresses a mixed endothelial–epithelial phenotype. It is widely used as a model of endothelial cell function, for example expressing a number of antigens recognized by anti-endothelial antibodies. When cocultured with C6 glioma cells

**Figure 5** Ability of an in vitro brain endothelial model to predict BBB permeability in vivo. In vitro BBB permeability (bovine brain endothelium cocultured above astrocytes) as a function of (a) brain uptake index (BUI),  $r^2 = 0.86$ , and (b) in vivo BBB permeability from in situ brain perfusion ( $r^2 = 0.92$ ). All parameters were normalized for molecular weight (MW). There was less good correlation for the plot of BUI versus permeability across Caco-2 monolayers,  $r^2 = 0.46$  (not shown). (Reproduced with permission from Lundquist, S.; Renftel, M.; Brillault, J.; Fenart, L.; Cecchetti, R.; Denouck, M.-P. *Pharm. Res.* **2002**, *19*, 976–981.)

it shows upregulation of some BBB features, in particular tight junctional organization, generating TEER of typically  $100\text{--}300 \text{ ohm cm}^{-2}$ .<sup>102</sup> It has been used to screen BBB permeability of flavonoid compounds,<sup>103</sup> and performed well in the recent study sponsored by the European Centre for the Validation of Alternative Methods (ECVAM) comparing cell culture models as drug screening tools.<sup>96</sup> Although it appears to express P-gp, it does so at lower levels than the BBB in vivo, so should be used with caution.

### 5.13.7 Cell Lines Transfected to Express Transporters

Rather than try to create in vitro models that expresses all relevant BBB features, an alternative approach is to develop assays for particular features that can be used as parallel screening tools. If each has advantages of reproducibility and potential for automation, this may prove a better strategy overall. Thus cell lines expressing the major drug efflux transporters present at the BBB including P-gp, multidrug resistance associated proteins (MRPs), and organic anion and cation transporters are currently used.<sup>104,105</sup> There have so far been few studies assessing the reliability of this kind of approach; one problem is that it is difficult to allocate ‘weighting factors’ that reflect the relative importance of particular transporters in the in vivo BBB, since this information is itself lacking.

### 5.13.8 Comparison of In Vitro Tools: Cell-Based versus Non-Cell-Based

Non-cell-based tools for permeability measurement that have been used to mimic the BBB include IAM columns and PAMPA (see 5.19 Artificial Membrane Technologies to Assess Transfer and Permeation of Drugs in Drug Discovery). PAMPA using filters coated with brain lipids in solvent can give permeability results well correlated with those determined in in vivo models<sup>39</sup>; interestingly the correlation was less good using a filter coating appropriate for mimicking gastrointestinal membranes, confirming the differences in the cell membranes of these two barrier layers. So far no direct comparisons have been made between the performance of PAMPA and cell-based in vitro BBB models, although it would be predicted that PAMPA would do well with passively distributed compounds, less well with those subject to specific carrier-mediated transport. Interestingly, it has been possible using high-speed magnetic stirring to minimize unstirred water layers in the PAMPA system, something not so easy to do with the more vulnerable membranes of living cell cultures.

### 5.13.9 Relevance to Predictability in Humans

The best test of the validity of any in vitro or in silico model is to establish how well it can predict and rank order the permeability of drugs determined in an in vivo or in situ model (for methods, see Section 5.13.2.2 above; also 5.31 In Silico Models to Predict Brain Uptake). Surprisingly few studies have attempted such a comparison. One difficulty is that the bulk of the data from in vivo BBB models come from brain:blood ratio measurements, where other factors apart from BBB permeability influence the ratio. The  $P_{app}$  data from in vitro cell culture models are derived from a kinetic measure, the rate of solute flux. Some comparisons have used the kinetic brain uptake index (BUI) data,<sup>46</sup> but this has poor resolution for the more lipid soluble compounds. Small sets of compounds have been compared across the bovine brain endothelial/rat astrocyte coculture model, and in in situ brain perfusion ( $K_{in}$  or  $PS$ ), with good correlations, indeed better than for Caco-2 cells.<sup>63</sup>

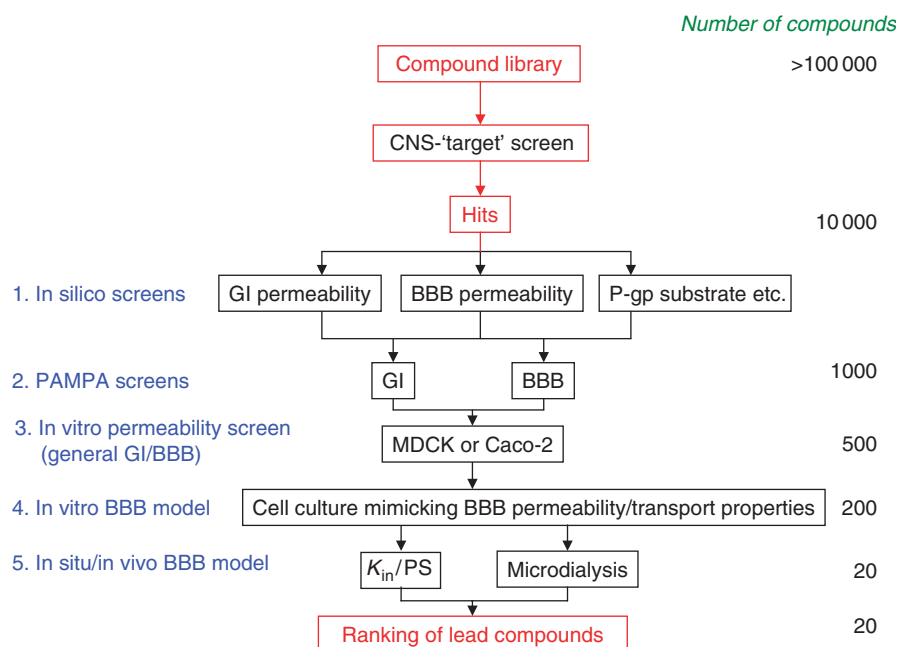

The recent ECVAM study compared the efficacy of a number of in vitro BBB models, and their ability to predict the rank order of permeabilities of a drug series determined in an in vivo preparation.<sup>60,96</sup> The best-performing models were Caco-2 cells and bovine brain endothelial cells cocultured with rat astrocytes; however, even for these models the correlation with the in vivo data was poor. MDCK cells expressing the human P-gp (MDCK-MDR1) gave the best separation of passively permeating and effluxed compounds. The conclusion was that further development and optimization of models was required, and testing with larger data sets, covering a greater 'drug-like' chemical space. The final test of predictability, the degree to which the model is able to predict drug permeability at the human BBB, must await improved noninvasive methods for determining human BBB permeability.

### 5.13.10 Conclusions and Strategy

The properties of the brain endothelium forming the BBB are important considerations when designing drugs to target or avoid the brain. Molecular traffic across the BBB is regulated by a combination of physical, transport, and metabolic barrier properties. Tight junctions restrict the paracellular pathway, and endothelial membrane lipids and other components determine the passive pathway across the cells. Specific uptake transport proteins and vesicular transcytotic mechanisms mediate the transcellular entry of necessary nutrients unable to use the lipid pathway, while efflux transporters help exclude potentially toxic (including lipophilic) agents, and contribute to clearance of waste products from the brain.

Given the complexity of BBB function, it is not surprising that in vivo models still provide some of the most reliable measurements of BBB drug permeation, as is necessary for the derivation and validation of predictive tools. Measurements of brain:plasma ratio, as routinely made by pharmaceutical companies, do not necessarily give a clear picture, either of the BBB entry step, or of the free drug concentration in brain ISF. Measurement of  $K_{in}$  or  $PS$  focuses on the kinetic (BBB entry) step and may be more useful in generating data for predictive modeling. Brain microdialysis is technically demanding and difficult to use with very lipophilic agents, but may be necessary for establishing the ISF concentration of 'anomalous' compounds that do not behave as predicted from simpler approaches. Knockout and gene-deficient mouse models allow testing of the role of specific transporters in regulating BBB permeation, under close to physiological conditions, but results may be affected by compensatory upregulation of other transporters.

Several practical in vitro models of the brain endothelium have been developed, which have helped to give valuable mechanistic insights (especially into transporter function). Unlike Caco-2 and MDCK cells, which are frequently used for predicting gastrointestinal absorption, no simple cell-line assay is available for BBB prediction, mainly because they are generally too leaky for permeability studies. However, the best primary cultures do give medium throughput and

**Figure 6** Suggested strategy for prediction of new drug permeability across the BBB. Flow chart showing suggested sequence of screens to handle 'hits' from high-throughout CNS-target screen, to facilitate ranking of lead compounds for optimal BBB penetration.

are used by companies with large CNS programmes. Higher-throughout methods ('surrogate BBB' cell-based; non-cell-based PAMPA; in silico modeling) can help in prediction, but a combination of techniques is still required to cover the range of drug entry and efflux mechanisms present at the BBB.

In summary, companies needing to predict BBB permeation data for novel compounds should consider a serial and parallel screening process that incorporates the best of current knowledge and understanding, selecting from 'hits' (observed activity in suitable target assay) to 'leads' (lead compounds with most potential for development as drugs) (Figure 6).

1. An initial high-throughput in silico screen of hits, using a number of computational tools, to predict passive gastrointestinal and BBB permeability, interaction with the main BBB efflux transporters, and chemical fit with known substrates for uptake transporters.
2. Selection of the most promising agents to test in a non-cell-based medium-throughput permeability screen (e.g., PAMPA), using artificial lipid membranes that mimic as closely as possible those of the gastrointestinal tract and BBB.
3. Use of data from MDCK (preferably expressing MDR1) or Caco-2 cells where available as check on PAMPA permeability data. Medium throughput.
4. Testing of permeability in validated in vitro BBB model (warranted for CNS drug program). Medium–low throughput.
5. In situ/in vivo screen (warranted for selected members of classes of new compounds, or for ranking lead compounds), preferably  $K_{in}$  (PS) from brain perfusion, or brain microdialysis; note problems in interpretation of log BB data (above). Low throughput.

Several pharmaceutical companies use in vitro tools together with information from in vivo and in situ studies to optimize the rate and extent of brain penetration of drugs. Increasing passive permeability, and reducing efflux transport and brain tissue binding are valuable strategies to increase drug concentration at CNS target sites.<sup>26</sup> Where microdialysis is judged too labor-intensive, equilibrium dialysis of drug concentration in brain homogenate can give an approximate measure of free drug concentration in brain,<sup>106</sup> usefully complementing the measures of BBB permeability.

There are still many challenges. These include the need for a simple, cost-effective industry-standard in vitro BBB model; difficulty in assessing the effects of all influx and efflux transporters and enzymes present at the BBB, since it is

likely that more remain to be discovered; problems predicting drug concentration in brain ISF beyond the BBB; difficulty extrapolating from animal models to human, with growing evidence for species differences in BBB transport proteins, especially for efflux; and the need to mimic pathological effects on the BBB in model and predictive systems for greater relevance to clinical situations.

## Biography

**N Joan Abbott**, PhD, is professor of neuroscience at King's College London, and a member of the Wolfson Centre for age-related disease which specializes in neuroscience. With Dr David J Begley she co-directs the Blood–Brain Barrier (BBB) Research Group. She has worked on the BBB for more than three decades, recently focusing on in vitro models for study of the cell physiology, pharmacology, and toxicology of the brain endothelium. A particular interest is in the development, optimization, and characterization of in vitro BBB models suitable for studying drug delivery to the central nervous system, with emphasis on the nature of their lipid membranes, and specific transport functions.

## 5.14 In Vitro Models for Plasma Binding and Tissue Storage

## 5.14.1 Plasma Protein Binding

### 5.14.1.1 Overview

The role of plasma protein binding (PPB) in the discovery process and the impact this key parameter has on the discovery and clinical process is now becoming fully realized. The pharmacokinetic and pharmacodynamic properties of drugs are greatly influenced by the reversible binding to plasma proteins with the unbound fraction of the drug being responsible for the biological activity. Methods are now available for the rapid determination of free levels in plasma using a multitude of techniques from the traditional dialysis methods to the more recent surface plasmon resonance methodologies.

### 5.14.1.2 Biological Aspects

Human plasma is known to contain over 60 different proteins, the major component being albumin, which comprises approximately 60% of the total plasma protein.<sup>1</sup> The next most abundant and well-characterized protein is  $\alpha_1$ -acid glycoprotein. Human serum albumin has a molecular weight of 66 kDa and contains 585 amino acid residues. At least 18 different mutations of human serum albumin have been identified and are primarily due to a single amino acid mutation, accounting for distinct protein–ligand binding.<sup>2</sup> The concentration of albumin in a normal healthy adult male is typically  $43 \text{ g L}^{-1}$ , with a range of  $35\text{--}53 \text{ g L}^{-1}$ . Females have approximately a 9% lower concentration ( $38 \text{ g L}^{-1}$ )<sup>1,3</sup> and this is argued to account for the gender difference in binding of chlorodiazepoxide and warfarin.

In diseased patients the albumin concentration can be significantly different. For patients with nephrotic syndrome, burns, or cirrhosis, the albumin concentration can be less than  $10 \text{ g L}^{-1}$ , i.e., 20–30% of the normal concentration.<sup>4</sup> In contrast, the normal plasma concentration (human) of  $\alpha_1$ -acid glycoprotein is  $0.4\text{--}1.0 \text{ g L}^{-1}$  ( $10\text{--}30 \mu\text{M}$ ) (MW = 44 kDa), and in patients with inflammatory diseases, it can be elevated by up to 4–5-fold.<sup>4</sup> Taking into account the significant variation in protein content and concentration in human plasma (and other species) it is useful to determine PPB using large plasma pools containing a statistically reasonable number of donors.<sup>2</sup>

Plasma contains many other globulins (the name of a family of proteins precipitated from plasma or serum by addition of ammonium sulfate). These can be separated into many subgroups, the main ones being alpha-, beta-, and gamma-globulins which differ with respect to the associated lipid or carbohydrate. Immunoglobulins (antibodies) are in the a and b fractions, lipoproteins are in the c and d fractions. Other substances in the globulin fractions include macroglobulin, plasminogen, prothrombin, euglobulin, antihemomorphic globulin, fibrinogen, and cryoglobulin. The lipoproteins in plasma, of which  $\alpha_1$ -acid glycoprotein is one, can be further classified into very high-density (VHDL), high-density (HDL), low-density (LDL), and very low-density (VLDL). The higher the density the lower the lipid content. Lipoproteins are macromolecular complexes displaying characteristic sizes, densities, and compositions. All lipoproteins contain protein components, called apoproteins, and polar lipids (phospholipids) in a surface film surrounding a neutral core (free and esterified cholesterol, triglycerides). The plasma lipoproteins vary in composition with respect to the lipid component, because their principal physiological function is to transport lipids in a water-soluble form, but also vary with respect to the polypeptide chain composition. Lipoprotein plasma concentration may vary 5–10-fold. Gamma-globulins generally only marginally account for the plasma binding of drugs.<sup>5</sup> Often it is only when a drug is present at very high concentrations that binding to components other than albumin or  $\alpha_1$ -acid glycoprotein occurs.<sup>6</sup> Considerable intersubject variability in the PPB of some compounds (4–5-fold variation in  $f_{u,p}$  is not uncommon) and in the concentration of proteins exists even within healthy human volunteers.<sup>3</sup> Genetically determined variations in amino acid sequences of human serum albumin can also contribute to variability in binding, and cause higher variability in patients with highly bound drugs. The binding affinities of warfarin, salicylate, and diazepam to five known variants of human serum albumin have been studied.<sup>7</sup> The association constants for all three drugs to albumin decreased by a factor of 4–10-fold for the mutations relative to each other.

### 5.14.1.3 Effect of Plasma Protein Binding on Drug Disposition

The extent of plasma protein binding is extremely important in its influence on many pharmacokinetic parameters. The relationship between the in vitro intrinsic clearance,  $CL_{\text{int}}$  and the in vivo clearance,  $CL$ , may be understood by the use of the well-stirred model, which is given in its most simple form by eqn [1]:<sup>8</sup>

$$CL = \frac{(Q_H \times f_{u,b} \times CL_{\text{int}})}{(f_{u,b} \times CL_{\text{int}} + Q_H)} \quad [1]$$

where  $Q_H$  is the hepatic blood flow, with units of  $\text{mL min}^{-1} \text{ kg}^{-1}$ , and  $f_{u,b}$  the fraction of compound unbound in blood as defined in Section 5.14.2.1.

For drugs with low hepatic clearance, compared to liver blood flow, the in vivo clearance can be approximated by<sup>9</sup>:

$$CL \cong f_{u,p} \times CL_{int} \quad [2]$$

where  $CL_{int}$  is the intrinsic clearance of the drug and  $f_{u,p}$  is the fraction of compound unbound in plasma. Under these conditions clearance is directly proportional to  $f_{u,p}$ . An example of this behavior is given by the clearance of warfarin in male Sprague–Dawley rats which is proportional to the free fraction of the drug within each individual rat,<sup>10,11</sup> as shown in Figure 1a. For drugs with high hepatic clearance, the clearance is largely controlled by the liver blood flow,  $Q_H$ , and is independent of the extent of plasma binding<sup>9</sup>:

$$CL \cong Q_H \quad [3]$$

This type of behavior is illustrated by propranolol where the clearance in humans does not depend on the human free fraction of drug in plasma<sup>12</sup> (Figure 1b).

The degree of plasma protein binding cannot only influence metabolic clearance, but also renal clearance.<sup>13</sup> The renal clearance ( $CL_R$ ) of a drug consists of four different processes; glomerular filtration ( $CL_f$ ), active secretion ( $CL_{rs}$ ),

**Figure 1** (a) Clearance of warfarin in male Sprague–Dawley rats showing dependence of the clearance on the plasma free fraction. (Reproduced with permission from Yacobi, A.; Levy, G. *J. Pharm. Sci.* **1974**, 63, 805–806). (b) Clearance of propranolol in humans showing the lack of relationship between clearance and the plasma free fraction. (Reproduced with permission from Evans, G. H.; Nies, A. S.; Shand, D. G. *J. Pharmacol. Exp. Ther.* **1973**, 186, 114–122.)

**Figure 2** Human renal clearance data for ceftriaxone showing the dependence on free fraction.

passive reabsorption ( $F_r$ ), and renal metabolism ( $CL_{rm}$ ).<sup>14</sup> The glomerular clearance is related to  $f_{u,p}$  by:

$$CL_f = f_{u,p} \times GFR \quad [4]$$

where GFR is the rate at which plasma water is filtered through the glomerulus, which is approximately 125 mL min<sup>-1</sup> in a 70-kg human.

Figure 2 demonstrates how the human renal clearance of ceftriaxone is proportional to the plasma free fraction as shown by eqn [4], with higher plasma free fraction in individual patients leading to higher renal clearance of the drug.<sup>13</sup>

#### 5.14.1.4 Influence of Blood:Plasma Ratio on Pharmacokinetic Parameters

Clearance and volume of distribution measurements depend on the reference body fluid, such as blood or plasma, in which drug concentrations are measured.<sup>15,16</sup> Blood clearance,  $CL_b$ , is the actual volume of blood cleared of a drug per unit time from either the entire blood pool in the body (systemic blood clearance) or from the blood passing through the eliminating organs (organ blood clearance). The systemic blood clearance is the sum of all the organ blood clearances.

Plasma clearance,  $CL_p$ , does not represent the actual volume of plasma cleared of drug, rather it is the apparent volume of plasma cleared per unit time, reflecting the ratio between the rate of drug elimination from the entire body (or the organs) and the drug concentration in plasma. Plasma clearance and volume of distribution are more often measured, because sample preparation and analysis are easier in plasma than in blood.

The relationship between blood clearance and plasma clearance is given by eqn [5], and between blood volume of distribution ( $V_{ss,b}$ ) and plasma volume of distribution ( $V_{ss,p}$ ) by eqn [6]:

$$CL_p = CL_b \times \left( \frac{C_b}{C_p} \right) \quad [5]$$

where  $C_b/C_p$  is the experimentally accessible blood:plasma ratio. Hence there can be substantial differences between blood and plasma clearances. If  $C_b/C_p > 1$ , plasma clearance is greater than blood clearance; if  $C_b/C_p < 1$  then plasma clearance is lower than blood clearance. It is important therefore to ensure that it is known whether plasma or blood clearance is being considered. Likewise, differing blood:plasma ratios can lead to differences in the steady-state volume of distribution in blood and plasma.

$$V_{ss,p} = V_{ss,b} \times \left( \frac{C_b}{C_p} \right) \quad [6]$$

**Table 1** Drug to plasma ratios and pharmacokinetic parameters for marketed drugs in human patients

| <i>Drug</i>   | $C_b/C_p$ | $CL_p$<br>( $mL \cdot min^{-1} kg^{-1}$ ) | $V_{ss,p}$<br>( $L \cdot kg^{-1}$ ) | $CL_b$<br>( $mL \cdot min^{-1} kg^{-1}$ ) | $V_{ss,b}$<br>( $L \cdot kg^{-1}$ ) |

Data from Goodman, A. G.; Gilman, A. G. In *The Pharmacological Basis of Therapeutics*, 10th ed.; Harman, J. G., Limbird, L. E., Gilman, A. G., Eds.; McGraw-Hill: New York, 2001, pp 1924–2023.

If two drugs have equivalent properties except differences in  $C_b/C_p$ , clearance and volumes of distribution of the drugs will be different depending on the reference fluid (blood or plasma); however, there will be no differences between blood and plasma half-lives. The lower limit for a blood to plasma ratio is 0.5, which corresponds to a compound that has no affinity for the blood and is present totally in the plasma compartment. Blood:plasma ratios > 50 are possible. A list of drugs with a range of blood to plasma ratios and the corresponding blood and plasma pharmacokinetic parameters in human patients is given in [Table 1](#).

#### 5.14.1.5 Drug–Drug Interactions

The obvious question arises as to whether highly plasma bound drugs can displace each other from plasma proteins. The potential does exist, but as most drugs have therapeutic concentrations far below the plasma concentration of albumin and often below that of  $\alpha_1$ -acid glycoprotein, proteins are rarely at the point of saturation and so competition for binding sites is much diminished.<sup>9</sup>

Although the literature is replete with examples of drug–drug interactions suggested to be due to PPB interactions, many of these have now been attributed to other mechanisms.<sup>18</sup> The drug–drug interactions are often due to cytochrome P450 inhibition, or to coadministered drugs acting as competitive substrates, although a few may still be attributable to pure displacement. [Table 2](#) lists some drugs for which other mechanisms are in fact responsible for drug–drug interactions, rather than the original suggestion of PPB displacement.

The fact that high drug concentrations are required in order to induce significant displacement interactions is illustrated by studies on the effect of salicylic acid on the PPB of ibuprofen<sup>19,41</sup> which show that very high concentrations of salicylic acid (1500  $\mu$ M) have only a moderate effect on the free concentration of ibuprofen. The possibility of significant albumin displacement interaction in vivo is therefore only a reality when one of the interacting drugs has a very low potency (or short half-life) and consequently is dosed in such a way that very high plasma concentrations are achieved. Since plasma concentrations of  $\alpha_1$ -acid glycoprotein are about 40-fold lower than that of albumin, displacement interactions at this protein could be possible at more typical therapeutic drug concentrations.

### 5.14.2 Experimental Aspects

#### 5.14.2.1 Scales of Measurement of Plasma Protein Binding

The term protein binding normally refers to the reversible association of a drug with the proteins of the plasma compartment of blood, and this binding is due to electrostatic and hydrophobic forces between drug and protein.<sup>3</sup> Drug that is bound reversibly will be in equilibrium with the free (unbound) drug, with the amount bound being dependent on both the affinity of the drug for the various proteins and the binding capacity of each protein.

Upon entering plasma, most drugs bind rapidly to the plasma constituents, which principally include albumin and  $\alpha_1$ -acid glycoprotein.<sup>20,21</sup> Measurement of the extent of this binding requires either a physical separation of free from

**Table 2** Drug–drug interactions originally suggested being attributable to plasma protein displacement, and the actual mechanism responsible

| <i>Drug</i>  | <i>Displacing drug</i> | <i>Mechanism responsible</i>  |
|--------------|------------------------|-------------------------------|
| Methotrexate | Salicylate             | Inhibition of renal clearance |
| Phenytoin    | Valproate              | Inhibition of metabolism      |

bound drug, or a technique that can distinguish some property of bound from unbound drug. Equation [7] defines the free fraction of a drug in plasma:

$$f_{u,p} = [\text{free drug in plasma}]/[\text{total drug in plasma}] \quad [7]$$

The fraction of drug bound  $f_{b,p}$  is given by:

$$f_{b,p} = 1 - f_{u,p} \quad [8]$$

While plasma binding refers to the binding of a drug to the plasma compartment of blood, studies can also be carried out on binding to serum or to whole blood. The major difference between plasma and serum is the removal of fibrinogen from plasma, and since most drugs do not bind to fibrinogen, no differences in binding to plasma or serum are expected.<sup>22</sup> Plasma is the fluid that remains after blood cells have been removed by centrifugation, and is usually obtained using an anticoagulant so that all clotting factors (e.g., fibrinogen) are retained. Serum is the fluid that remains after clotting factors have been removed by first allowing clotting to take place. Proteins not involved in clotting, e.g., albumin, are still present in serum. In whole blood, drugs can bind to plasma proteins and to blood cells, and hence there can be significant differences between blood binding and plasma binding.<sup>20</sup> The whole blood free fraction of a compound,  $f_{u,b}$ , is related to the plasma free fraction by eqn [9]. Here  $C_b/C_p$  is the experimentally accessible blood to plasma ratio of the drug, i.e., the ratio of total concentration of drug in whole blood to the total concentration of drug present in the plasma compartment of the blood.

$$f_{u,b} = \frac{f_{u,p}}{C_b/C_p} \quad [9]$$

Highly detailed studies of PPB allow derivation of several binding constants from the experimental data. Two different formulations may be used for this purpose, one being stoichiometric and the other being site-oriented.<sup>23–25</sup> However, most plasma binding data are simply quoted on a percentage scale as given by:

$$\%PPB = 100f_{u,p} \quad [10]$$

Because the percentage scale is bounded by 0 and 100, a pseudo-binding constant ( $K^{B/F}$ ) for PPB is frequently used, and this is defined by<sup>26,27</sup>:

$$K^{B/F} = \frac{(1 - f_{u,p})}{f_{u,p}} = \frac{\%bound}{\%free} \quad [11]$$

More detailed quantitative binding information can be obtained by carrying out a Scatchard analysis.<sup>28,29</sup> In this analysis, B/F is plotted against B for a compound, covering a range of compound concentrations at a chosen protein or

plasma concentration. For binding of compound to a single site on the protein, this plot is linear; the slope is related to the equilibrium-binding constant of the compound and protein,  $K$ , and the intercept being equal to the concentration of the binding protein. For a situation where binding to a number of different sites on protein, or sites on a multitude of proteins, occurs over the compound concentration range studied, curved Scatchard plots are observed, and nonlinear regression curve fitting then allows the binding constants to each site to be determined.

### 5.14.2.2 Experimental Methods for Plasma Protein Binding Measurement

There are many experimental methods that have been used to determine the extent of plasma protein binding and these techniques are summarized in more detail in the following section.

#### 5.14.2.2.1 Equilibrium dialysis

Equilibrium dialysis is still regarded as the ‘gold standard’ method by most researchers. In this technique two cells are separated by a semipermeable membrane which precludes high molecular weight compounds and plasma proteins from crossing from one cell to the other, but does allow transfer of low molecular weight compounds to occur.<sup>30,31</sup> In one cell, an appropriate volume of plasma is placed. In the other cell, an equivalent volume of an appropriate aqueous buffer solution is placed. The compound is spiked into either dialysis cell, more often the plasma containing cell.

The cells are then equilibrated at the desired temperature (often 37 °C) for the chosen dialysis time. The plasma dialysis cell contains compound which is bound to plasma proteins and compound which is unbound (free) the latter being able to cross the semipermeable membrane into the buffer side, and vice versa. If the dialysis time is sufficiently long then an equilibrium is reached, where the free concentration of compound is the same in both the plasma and buffer dialysis cells. An aliquot from the buffer cell is analyzed, which gives a measure of the free concentration of compound. An aliquot from the plasma cell is also analyzed and this gives a measure of the total concentration of compound (bound and free). The extent of plasma protein binding as measured by  $f_{u,p}$  is then given by:

$$f_{u,p} = \frac{C_{\text{buffer}}}{C_{\text{plasma}}} \quad [12]$$

where  $C_{\text{buffer}}$  is the concentration of compound in the buffer dialysis cell and  $C_{\text{plasma}}$  the total concentration of compound in the plasma cell. A variant of equilibrium dialysis is dynamic dialysis.<sup>32,33</sup>

#### 5.14.2.2.2 Fluid shifts during equilibrium dialysis

Osmotic volume shifts across the dialysis membrane can occur during equilibrium dialysis experiments.<sup>34,35</sup> These result in a dilution of the plasma with the buffer, leading to an overestimate of the free fraction,  $f_{u,p}$ . A correction can be made for the observed average volume shift for a given equilibrium dialysis apparatus and equilibration time as given by:

$$f_{u,p} = 1 - \frac{(C_{\text{plasma}} - C_{\text{buffer}})(V_{\text{final}}^{\text{plasma}}/V_{\text{initial}}^{\text{plasma}})}{(C_{\text{plasma}} - C_{\text{buffer}})(V_{\text{final}}^{\text{plasma}}/V_{\text{initial}}^{\text{plasma}}) + C_{\text{buffer}}} \quad [13]$$

where  $C_{\text{plasma}}$  and  $C_{\text{buffer}}$  refer to the observed concentrations in the plasma and buffer cells at equilibrium,  $V_{\text{final}}^{\text{plasma}}$  is the volume of the plasma at equilibrium (accounting for the fluid shift) and  $V_{\text{initial}}^{\text{plasma}}$  the volume of the plasma at the start of the experiment.

#### 5.14.2.2.3 The Donnan effect in equilibrium dialysis

One aspect of equilibrium dialysis that is sometimes raised as an issue is the so-called Donnan effect.<sup>36–38</sup> This results in an unequal distribution of ionic species in the dialysis cells during an equilibrium dialysis experiment, which causes a difference between the observed binding compared to the situation where no Donnan effect occurred. This arises because the plasma protein molecules themselves often possess a net charge, but they cannot diffuse between the two cells, owing to the presence of a semipermeable membrane. Small ionic species present in the buffer and plasma are free to diffuse across the membrane. Owing to the conditions of the balanced chemical potential of ionic species on both sides of the dialysis membrane and electroneutrality, the charge on the protein molecules on one side of the membrane is compensated for in part by a reduced concentration of small (diffusible) ions on that side of like charge, and in part by an increased concentration of small ions of the opposite charge. However, the Donnan effect can be almost completely suppressed if a sufficiently high concentration of electrolyte is used, i.e., a large buffer concentration is used (ionic strength >0.10 M), as in many equilibrium dialysis experiments.<sup>36</sup>

#### 5.14.2.2.4 Ultrafiltration

Determination of the extent of plasma protein binding by ultrafiltration involves separation of the unbound drug present in an equilibrated solution of drug and plasma proteins by filtering it through a semipermeable membrane (no protein can pass through the membrane).<sup>1,39</sup> The separation is assisted either by application of a vacuum, positive pressure from compressed nitrogen, or by centrifugation. Ultrafiltration has the advantage of a fast equilibration time, typically 30 min at 37 °C. Equilibrium dialysis is rate limited by the time it takes the unbound compound to pass through the semipermeable membrane and reach equilibrium between the two dialysis cells; this often takes several hours. One issue with ultrafiltration is that significant nonspecific binding to the membrane can occur and this needs to be characterized. In addition, the plasma protein concentration increases during the filtration step, which can potentially cause a change in the binding of the drug and introduce a bias in the measured binding; however, only a small volume is filtered (typically 5–10% of the initial volume) so the disturbance of the equilibrium is minimal and the error introduced is quite small. It is also possible for the pore size of the membrane to be decreased by accumulation of protein at the membrane surface.

#### 5.14.2.2.5 Ultracentrifugation

The ultracentrifugation method achieves separation of free and protein bound drugs by centrifugation ( $10^5 g$  or higher) of a mixture of drug and plasma in a tube with no membrane.<sup>1,40–42</sup> Ultracentrifugation is an alternative to both equilibrium dialysis and ultrafiltration as it removes the problems associated with membrane effects (e.g., nonspecific binding) and osmotic volume shifts. However, ultracentrifugation takes 12–16 h and causes errors in the estimation of the free drug concentration by some physical phenomena such as sedimentation, back diffusion, and viscosity, and additionally requires expensive centrifugation equipment.<sup>42</sup>

#### 5.14.2.2.6 Alternative methods for the determination of plasma protein binding

A number of alternative methods have been employed for the determination of plasma binding and to describe these all in any detail is beyond the scope of this chapter. However, the authors point the reader to key references for a number of other methods: chromatographic methods,<sup>43–45,65</sup> fluorescence spectroscopy,<sup>46,47</sup> ultraviolet spectroscopy,<sup>46</sup> derivative spectroscopy,<sup>48–50</sup> circular dichroism,<sup>51</sup> nuclear magnetic resonance spectroscopy,<sup>52,53</sup> surface plasmon resonance,<sup>54–58</sup> capillary electrophoresis,<sup>59–63</sup> microdialysis,<sup>64,65</sup> and high-throughput equilibrium dialysis methods.<sup>66,67</sup>

### 5.14.3 Tissue Binding

#### 5.14.3.1 Overview

Although not studied as extensively as plasma binding, tissue binding can have as profound an effect upon the pharmacokinetics of a compound as can the plasma binding.<sup>68–70</sup> The binding of drugs to plasma and tissue constituents affects both the pharmacokinetics and pharmacodynamics of the compound. The pharmacokinetic parameters, steady-state volume of distribution, clearance, and half-life, all depend upon the free fraction in plasma that is in turn dependent upon the relative affinity between plasma and tissue constituents.

The methods for the determination of tissue binding can generally be divided into two rather distinct areas of *in vivo* methods, and *in vitro* methods each of which possess their own advantages and disadvantages based around the complexity of the experiment and the ability to monitor biologically relevant processes.

#### 5.14.3.2 In Vitro Methods for the Determination of Fraction Unbound in Tissue

##### 5.14.3.2.1 Binding to tissue homogenates

The binding to tissue homogenates can be determined by many of the methods described for protein binding. Generally, equilibrium dialysis is the preferred method but wide use has also been made of the ultrafiltration and ultracentrifugation methods. One clear disadvantage of the use of tissue homogenates is the complete disruption of the cellular integrity of the tissue homogenate. However, the tissue-to-plasma equilibrium constant,  $K_p$ , obtained from this method is not distorted by uptake into the tissue. Homogenization may release tissue constituents that the drug would otherwise not be exposed to and this may also distort the observed  $K_p$  value. Because of the fact that tissue homogenate is difficult to handle due to the formation of a paste like heterogeneous suspension, experiments are generally carried out in diluted homogenate. This then leads to the question as to whether the binding is linear with tissue concentration.<sup>71</sup> It was noted that for warfarin, phenytoin, and quinidine a linear relationship exists between B/F and the percent muscle in the homogenate, but for propranolol and imipramine, linear extrapolation from lower percent muscle in homogenate to higher levels would be incorrect and lead to an over estimate of the B/F term.

### 5.14.3.2.2 Binding to tissue slices

Determination of binding to tissue slices is a frequently used method and has the advantage of retaining the cellular integrity, a fact that is often a deciding factor for the use of tissue slices over tissue homogenates. Because of the intact nature of the tissue it is possible to observe accumulation of compound due to uptake processes although the accumulation rates may vary significantly from that observed in vivo. The use of tissue slices can also be extended to tissue pieces as it often difficult to generate tissue slices with certain tissue such as muscle and lung.

Tissue pieces have been used to predict total water and extracellular space using the marker compounds  $^{14}\text{C}$ -urea and  $^3\text{H}$ -inulin.<sup>72</sup> In this case the  $K_p$  values for  $^{14}\text{C}$ -urea were greater than the total tissue water due to tissue swelling. The tissue swelling was driven by osmotic pressure to equilibrate the protein-containing tissue with the protein-free media. The apparent  $K_p$  value for  $^{14}\text{C}$ -urea was corrected for the  $^{14}\text{C}$ -urea in the absorbed media and the corrected  $K_p$  values were then considerable closer to the in vivo situation when the correction was made (Table 3).

The extent to which albumin diffusion from tissue into the surrounding medium during in vitro incubations has also been shown to have a significant affect on the  $K_p$  values obtained from tissue pieces.<sup>73</sup> In this study 12 different tissues were obtained from rats after an intravenous dose of  $^{125}\text{I}$ -human albumin and tissue pieces incubated to determine the efflux of albumin over a 2 h and 4 h period. The authors derived a mathematical model eqn [14] and a correction factor eqn [15], with readily measurable or derived terms, to modify the apparent  $K_{pu}$  taking into account diffusion of albumin from the tissue:

$$\frac{K_{puapp}}{K_{pu}} = \frac{1 - (1 - f_r)f_p \left( \frac{1 - f_{u,p}}{f_{u,p}} \right)}{1 + f_p \left( \frac{1 - f_{u,p}}{f_{u,p}} \right) + \left( \frac{1}{\theta_E} - 1 \right) / f_{ul}} \quad [14]$$

$$1 + \theta_E \frac{V_T}{V_M} f_p \left( \frac{1 - f_{u,p}}{f_{u,p}} \right) (1 - f_r)$$

where  $\theta_E = V_E/V_T$  ( $V_E$  and  $V_T$  are the extracellular and total tissue volumes respectively),  $V_M$  the volume of the media;  $f_p$  is the ratio of the plasma binding concentrations in the extracellular space to that in plasma<sup>74</sup>;  $f_{u,p}$  the unbound fraction of compound in plasma;  $f_r$ , the fraction of extracellular binding protein remaining in tissue at the end of the incubation;  $f_{ul}$ , the unbound intracellular fraction of the compound.

**Table 3** Tissue swelling, tissue water content,  $^{14}\text{C}$ -urea partition coefficients with and without swelling

| Tissue        | % Swelling (sd) | Fraction water content (sd) | $^{14}\text{C}$ -Urea ( $K_p$ ) | $^{14}\text{C}$ -Urea ( $K_{pcorr}$ ) | $^{14}\text{C}$ -Urea ( $K_p$ in vivo) |

Reproduced from Ballard, P.; Leahy, D. E.; Rowland, M. *Pharm. Res.* **2000**, *17*, 660–663, with kind permission of Springer Science and Business Media.

A correction factor (CF) of the apparent tissue-to-medium partition coefficient to give the true  $K_{pu}$  when no albumin has diffused out of the tissue is given by:

$$CF = \frac{K_{pu}}{K_{puapp}} = \left(1 + \theta_E \left(\frac{V_t}{V_M}\right) \cdot \left(\frac{1 - f_{u,p}}{f_{u,p}}\right) f_p (1 - f_t)\right) + \frac{\theta_E (1 - f_t) (1 - f_{u,p}/f_{u,p}) f_p}{K_{puapp}} \quad [15]$$

From the models the authors concluded that albumin diffusion would have a minimal effect on the measured  $K_p$  unless the compound is highly plasma bound, in which case the measured  $K_p$  would be significantly underestimated.

The ability to determine in vivo tissue-to-unbound plasma distribution coefficients  $K_{pu}$  from in vitro data was examined for a series of 5-*n*-alkyl-5-ethyl barbituric acids.<sup>75</sup> Unbound tissue-to-unbound-plasma distribution coefficients were determined in 15 rat tissue/organs for a homologous series of nine barbiturates. The steady-state in vivo  $K_{pu}$  values were estimated from tissue and plasma concentrations following constant rate intravenous infusions for the homologous series. Correction of the in vitro tissue-to-unbound-plasma distribution coefficients for tissue swelling and barbiturate in the vasculature showed a good prediction of the in vivo values over a wide range of lipophilicity. However, it was noted that for the most lipophilic barbiturates the in vitro  $K_{pu}$  under predicted those that were observed in vivo. This under-prediction may have been associated with the combination of binding to albumin and partitioning into lipids that had diffused from the tissue into the medium or insufficient equilibration time.

#### 5.14.3.3 In Vivo Methods for the Determination of Fraction Unbound in Tissue

In vivo methods generally involve the inference of tissue binding from the plasma or blood concentration time course or from the determination of tissue to plasma or blood concentration ratio. For example tissue to blood partition coefficients for lidocaine were calculated following constant rate infusion of the drug to marmoset monkeys.<sup>76</sup> Also tissue to plasma partition coefficients were obtained for digoxin in rats.<sup>116</sup> However, the tissue to plasma partition coefficients for adriamycin were calculated from the terminal elimination phase following an intravenous bolus dose of the drug. In general there is no consensus as to which method is the most appropriate for the determination of tissue to plasma partition coefficients. The volume of distribution can be expressed as:

$$V_{ss} = V_p + V_t \cdot \frac{f_{u,p}}{f_{u,t}} \quad [16]$$

This can be rearranged to give:

$$f_{u,t} = \frac{V_t \cdot f_{u,p}}{V_{ss} - V_p} \quad [17]$$

where  $f_{u,t}$  is the fraction unbound in tissue,  $f_{u,p}$  the fraction unbound in plasma,  $V_p$  the plasma volume,  $V_t$  the volume of other tissue in the body, and  $V_{ss}$  the apparent volume of distribution at steady state. Using this approach the steady-state volume of distribution is determined in the normal manner and plasma binding can be determined in vitro by any of the methods outlined earlier in the chapter. The  $f_{u,t}$  determined in this way represents the average fraction unbound in all tissue. From these measurements it is not possible to draw any conclusions about the disposition of the drug in any particular tissue or organ. This methodology was used to estimate the  $f_{u,t}$  values of phenytoin<sup>77</sup> in healthy volunteers. For compounds, which are highly bound to plasma proteins, it was pointed out that the use of eqn [17] may be misleading<sup>116</sup> as this does not take into account the fact that plasma proteins are distributed throughout the extracellular fluids.

#### 5.14.3.4 Tissue-to-Plasma Concentration Ratios In Vivo

The second approach to the determination the tissue binding is to determine tissue-to-plasma or tissue-to-blood partition ratio, which is defined below:

$$\frac{C_{TSS}}{C_{PSS}} = K_p \frac{f_{u,p}}{f_{u,t}} \quad [18]$$

where  $C_{TSS}$  is the concentration in the tissue of interest at steady state and  $C_{PSS}$  the steady-state plasma concentration. The ratio of the concentration in tissue at steady state to that in plasma at steady state is the tissue to plasma partition coefficient denoted by  $K_p$ . The assumption in the derivation of eqn [18] is that at steady state the free concentration between tissue and plasma are equal. In order to fully characterize  $K_p$ , knowledge of whether the compound is eliminated from the organ of interest is required.<sup>76</sup> For eliminating organs such as the liver and lung

calculation of  $K_p$  is only possible if the extraction ratio for that organ is known and in this case the apparent  $K_{p(\text{app})}$  can be corrected using:

$$K_{p(\text{app})} = K_p(1 - E) \quad [19]$$

It is worth noting that to unambiguously assign  $K_p$  to a given organ or tissue it should be nonelimination and steady state should be achieved by constant rate infusion. For eliminating organs and when using bolus dosing regimen  $K_p$  depends on the assumptions that the perfusion rate limits the distribution of the drug into the tissue and the tissue is viewed as well stirred. In this case the emergent blood is in equilibrium with the tissue.<sup>76</sup> If this is not the case then the relationship for  $K_p$  given in eqn [19] is not valid.

#### 5.14.3.5 Binding to Adipose Tissue

Binding and disposition studies of drugs into adipose tissue have received considerably fewer investigations than into other tissue. However, adipose tissue must be considered an important storage tissue as it contains a high proportion of stored lipid in the form of triglycerides and the tissue mass of adipose in human is large.

Since many compounds that accumulate into adipose tissue have long half-lives, steady-state distribution measurements in adipose tissue are not practicable. This led to the introduction of the adipose storage index (ASI),<sup>78–80</sup> which is defined as:

$$\text{ASI} = \frac{C_{\text{admax}}}{D_{\text{admax}}} \quad [20]$$

where  $C_{\text{admax}}$  is the maximum concentration in adipose tissue after a single dose and  $D_{\text{admax}}$  the hypothetical (average) concentration of evenly distributed drug at  $t = t_{\text{max}}$ . This can be calculated from the mass balance of the kinetic distribution experiment, or if elimination is slow, the value can be approximated to  $t = 0$ . This has been suggested to be superior to the frequently used adipose/plasma concentration ratio.

A number of studies have been aimed at understanding the properties that control disposition into adipose tissue. It has been noted that there was a surprising lack of correlation between adipose tissue build up and lipophilicity in vivo. It was suggested the distribution is the binding competition between adipose tissue, lean tissue and plasma proteins. The binding to adipose tissue is driven mainly by  $\log P$  (octanol/water partition coefficient) whereas blood and lean tissue binding is determined by  $\log P$  and the drug's molecular structure.

### 5.14.4 Incubational Binding

#### 5.14.4.1 Overview

The kinetics of in vitro metabolism are most frequently studied using liver microsomes or hepatocytes as the incubation medium, and from such kinetic experiments the in vitro intrinsic clearance of the compound under study may be derived. The intrinsic clearance data is then often used in the important field of in vitro–in vivo correlations for the purpose of predicting the in vivo clearance of the compound in animals or humans.<sup>81–83</sup> Nonspecific binding of compounds to the microsomes or hepatocytes in the incubation medium will cause a reduction of free drug available to interact with the drug metabolising enzymes, and hence a decrease in the observed intrinsic clearance. The scaling methods used in in vitro–in vivo correlation require the use of unbound intrinsic clearance ( $\text{CL}_{\text{int,u}}$ ) rather than the observed intrinsic clearance ( $\text{CL}_{\text{int}}$ ), and the two properties are related by<sup>81</sup>:

$$\text{CL}_{\text{int,u}} = \frac{V_{\text{max}}}{K_{\text{M,U}}} = \frac{V_{\text{max}}}{K_{\text{M}}f_{\text{u,inc}}} = \frac{\text{CL}_{\text{int}}}{f_{\text{u,inc}}} \quad [21]$$

where  $V_{\text{max}}$  is the maximum velocity,  $K_{\text{M,U}}$  the Michaelis constant based on free substrate concentrations,  $K_{\text{M}}$  the observed Michaelis constant determined from plots of reaction rate against total substrate concentration, and  $f_{\text{u,inc}}$  the free fraction of compound in the incubation medium.<sup>84</sup> The most widely used model for relating the observed  $\text{CL}_{\text{int}}$  to in vivo clearance is the well-stirred model<sup>84,85</sup>:

$$\text{CL} = \frac{(Q_H \cdot A \cdot B \cdot f_{\text{u,p}} \cdot \text{CL}_{\text{int}} / f_{\text{u,inc}})}{(Q_H + (A \cdot B \cdot f_{\text{u,p}} \cdot \text{CL}_{\text{int}} / f_{\text{u,inc}}))} \quad [22]$$

where  $A$  is a constant representing the amount of microsomes or hepatocytes per gram of liver,  $B$  a constant describing the grams of liver per kilogram of body weight,  $Q_H$  represents liver blood flow, and  $f_{u,p}$  the free fraction of the compound in plasma. Equation [22] indicates that knowledge of the extent of binding of drugs to in vitro incubations is required in order to make best use of in vitro–in vivo scaling methods, and this has been confirmed in studies of the prediction of human clearance of diverse sets of marketed drugs from in vitro data.<sup>86,87</sup>

#### 5.14.4.2 Microsome Binding

##### 5.14.4.2.1 Experimental methods

The binding of drugs to liver microsomes can in principle be determined using a variety of the techniques described for the measurement of plasma binding. However, the literature of microsome binding data is very much dominated by the equilibrium dialysis technique, with the larger compilations of data all using this method.<sup>86,88–91</sup>

##### 5.14.4.2.2 Use of microsome binding to determine unbound intrinsic clearance

An important consequence of in vitro microsomal binding is that it causes the observed intrinsic clearance to be dependent on the concentration of microsomes, such that  $CL_{int}$  decreases with increasing microsomal concentration, whereas  $CL_{int,u}$  should be independent of microsomal protein concentration. This has been clearly demonstrated in several studies.<sup>90,92,93</sup> In terms of the components of  $CL_{int}$  (eqn [21]), it is the observed  $K_M$  that is dependent on microsome concentration while  $V_{max}$  is not.<sup>92,93</sup> The concentration dependence can be strong, and some compounds can have very different values of  $CL_{int}$  at different microsomal protein concentrations. For example, the lipophilic base amiodarone has been shown to have  $CL_{int} = 115, 28, \text{ and } 3 \mu\text{L min}^{-1} \text{mg}^{-1}$  protein at microsomal protein concentrations of 0.25, 1, and 4  $\text{mg mL}^{-1}$ , respectively.<sup>90</sup> The use of such data for making in vivo clearance predictions using eqn [22], but with ignorance of the  $f_{u,inc}$  terms, would lead to three very different clearance predictions that are clearly erroneous. However, there are many examples of this mistreatment of data in the literature. Once data like that of amiodarone above have been corrected for the extent of microsomal binding, the unbound intrinsic clearance should be constant within experimental error,<sup>90</sup> yielding data that lead to better predictions of in vivo clearance.<sup>86,87</sup>

In addition to the important use of microsomal binding data for the correction of observed intrinsic clearance, the data also has a role in the correction of cytochrome P450 inhibition constants determined in microsomal systems. It has been shown that correction of the observed inhibition constants should lead to better predictions of in vivo drug interactions from in vitro data.<sup>94,95</sup>

#### 5.14.4.3 Dependence of Binding on Drug and Microsome Concentration

The extent of microsomal binding will clearly increase with increasing microsomal protein concentration, and several studies have demonstrated this.<sup>88,90–92</sup> However, it is also possible that  $f_{u,inc}$  of a compound will depend on compound concentration and that the binding is saturable. This area has not been widely studied experimentally, but it has been shown that the microsomal binding of amitriptyline, imipramine, propranolol, phenytoin, and tolbutamide is independent of compound concentration over the range of concentration studied (up to 100  $\mu\text{M}$ ),<sup>88,91,92</sup> and weak concentration dependence has been demonstrated for nortriptyline and warfarin.<sup>88,89</sup> Microsomal binding is therefore not strongly dependent on compound concentration, and saturation does not occur at the low concentrations relevant to in vitro metabolic assays. It is therefore clear that microsomal binding, at concentrations relevant to in vitro metabolic assays, is not characterized by saturable binding to specific binding sites, but is instead controlled by rather nonspecific binding to various protein and lipid components of the microsomes. A model involving specific and saturable binding sites has been reported<sup>89</sup> for describing the concentration dependence of microsomal binding, but appears to be unnecessarily complex since a more simple phase equilibrium model has been successfully used to describe the binding of 12 diverse drugs as a function of microsomal concentration.<sup>90</sup> This binding model (eqn [23]) can generate an estimate of the extent of microsomal binding ( $f_{u_2}$ ) at given microsomal concentration ( $C_2$ ) from the observed extent of binding ( $f_{u_1}$ ) at a different microsomal concentration ( $C_1$ ):

$$f_{u_2} = \frac{1}{\frac{C_2}{C_1} \left( \frac{1-f_{u_1}}{f_{u_1}} \right) + 1} \quad [23]$$

Microsome binding could in principle show a dependence on the animal species from which the microsomes are derived. However, it has been shown that propranolol, imipramine, and warfarin have no species dependence in their binding to rat, dog, monkey, and human microsomes,<sup>84</sup> and another study on a set of eight drugs demonstrates no species dependence in binding to rat, dog, and human microsomes.<sup>91</sup> Species dependence in general is therefore likely to be weak or nonexistent, which is consistent with the finding that binding to other types of tissue such as muscle is independent of species for a wide variety of drugs.<sup>93</sup>

#### 5.14.4.4 Relationship of Microsome Binding with Physicochemical Properties

The extent of nonspecific binding of drugs to liver microsomes is expected to be dominated by lipophilicity since microsomes contain about 60% phospholipid by mass.<sup>97</sup> A relationship of binding with lipophilicity was first shown in a semiquantitative way with a small set of acidic and basic drugs,<sup>89</sup> and this study also highlighted enhanced binding of the basic drugs compared with acidic drugs. This emerging trend was made clearer in later study which demonstrated a quantitative relationship of microsomal binding with lipophilicity using a diverse set of 37 acidic, basic, and neutral drugs.<sup>90</sup> It was found that when octanol/water  $\log D_{7.4}$  was used as the index of lipophilicity, a broad trend of increasing binding with increasing lipophilicity was apparent, but with enhanced binding of basic compounds compared with neutral or acidic compounds of the same  $\log D_{7.4}$ . This was argued as being consistent with the enhanced affinity of basic compounds for phospholipid membranes compared with octanol, as previously demonstrated by liposome binding studies.<sup>98,99</sup> The phospholipid studies demonstrate that the affinity of compounds for model membranes at pH 7.4 is better modeled by  $\log P$  than  $\log D_{7.4}$  for bases, but by  $\log D_{7.4}$  rather than  $\log P$  for acids. The difference in behavior of the two classes is due to the ability of the ionized form of bases to bind to the membrane with similar affinity to the unionized form, whereas the ionized form of acids have much lower membrane affinity than the neutral form. To account for the different behavior of acids and bases in microsome binding, a combined lipophilicity descriptor,  $\log(P/D)$  was used. This descriptor is equal to the  $\log P$  of the molecule if it is a base (basic  $pK_a > 7.4$ ) and equal to the  $\log D_{7.4}$  of the molecule if it is an acid (acidic  $pK_a < 7.4$ ). For neutral molecules  $\log P$  and  $\log D_{7.4}$  are equivalent, and that value is used. It was found that the extent of binding to rat liver microsomes with  $1 \text{ mg mL}^{-1}$  microsomal protein concentration, expressed as  $\log((1-f_u)/f_u)$ , is highly correlated with the combined lipophilicity descriptor as shown in Figure 3.<sup>90</sup>

The least squares fit to the data in Figure 3, eqn [24], allows a prediction of  $f_{u,inc}$  from readily available lipophilicity and ionization data, and was proposed as a useful method for estimating  $CL_{int,u}$  from observed intrinsic clearance data,

**Figure 3** Plot of extent of microsomal binding against the combined lipophilicity descriptor  $\log(P/D)$ . (Reproduced with permission from Austin, R. P.; Barton, P.; Cockcroft, S. L.; Wenlock, M. C.; Riley, R. J. *Drug Metab. Dispos.* **2002**, *30*, 1497–1503.)

which would be helpful in the prediction of in vivo clearance from in vitro data<sup>90</sup>:

$$\begin{aligned}\log((1 - f_u)/f_u) &= 0.53 \log(P/D) - 1.42 \\ n = 37 \quad r^2 &= 0.82 \quad s = 0.41 \quad F = 160.0\end{aligned}\quad [24]$$

### 5.14.5 Hepatocyte Binding

#### 5.14.5.1 Experimental Methods

Most hepatocyte binding studies have used rapid centrifugation methods to separate drug in solution from that bound to or contained within the hepatocytes.<sup>100–102</sup> These methods generally involve centrifugation of a hepatocyte suspension through a layer of oil which allows a very rapid separation of the hepatocytes and bound compound from aqueous solution. These methods are rapid enough to allow measurement of the kinetics of uptake of compounds into hepatocytes, which has been the focus of many of the reports. A recent study has used an alternative method of using metabolic inhibitors along with the equilibrium dialysis technique.<sup>103</sup> The inhibitors effectively remove all metabolic turnover of the compounds, which then enables hepatocyte binding to be determined using the relatively slow equilibrium dialysis technique.

#### 5.14.5.2 Mechanism of Drug Binding to Hepatocytes

The term binding to hepatocytes refers to the net effect of a number of different processes. There will be passive processes such as binding to the cell wall and other phospholipids. Another process is accumulation of basic compounds within regions of the hepatocyte where the pH is lower than the extracellular pH.<sup>104,105</sup> An active process for some compounds will be carrier mediated transport into hepatocytes.<sup>101,102</sup> All of these processes will affect the free concentration of compound that accesses the drug metabolizing enzymes, and hence will influence the observed intrinsic clearance in an in vitro assay.

Studies on some lipophilic pesticides have shown that the binding of these compounds to rat hepatocytes is a passive process with a well-defined equilibrium position that is reached rapidly.<sup>106</sup> The extent of hepatocyte binding was found to increase with increasing lipophilicity, although the extent of binding solely to hepatocytes was unclear due to the presence of bovine serum albumin in the buffer. In another study, the binding of parathion to rat hepatocytes has also been shown to be rapid and reversible, and to reach a defined equilibrium position.<sup>107</sup> Most other investigations relating to hepatocyte binding have focused on kinetic studies of uptake and metabolism of compounds by hepatocytes where active uptake processes were expected to be present, for example with drugs known to have extensive biliary clearance.<sup>101,108–111</sup> In these studies, the active and passive components of hepatocyte uptake were deconvoluted from the results of kinetic measurements as a function of compound concentration, and a variety of inhibitors of uptake transporters were shown to decrease the rate of uptake of those compounds with an active component.

#### 5.14.5.3 Use of Hepatocyte Binding to Determine Unbound Intrinsic Clearance

Hepatocytes have historically been less widely utilized than liver microsomes for in vitro drug metabolism studies. However, the current easier availability of hepatocytes, for example with cryopreserved hepatocytes, is leading to their increased use. One study analyzed the influence of binding of a set of nine compounds to rat hepatocytes and found an improvement in the clearance prediction of all compounds when the  $f_{u,inc}$  correction was applied.<sup>100</sup> The accuracy of the clearance prediction for some of the compounds was still quite poor, but the  $f_{u,inc}$  correction did always move the clearance prediction closer to the correct value. Another study involved the prediction of human clearance of a large set of marketed drugs from human hepatocyte intrinsic clearance.<sup>87</sup> The extent of incubational binding was estimated from the lipophilicity of the compounds using a quantitative structure–activity relationship (QSAR) model, and incorporation of the predicted  $f_{u,inc}$  values significantly improved the correlation of observed versus predicted human clearance.

#### 5.14.5.4 Relationship of Hepatocyte Binding with Physicochemical Properties

Since an active transport component of hepatocyte binding exists for some compounds, and given that basic compounds can accumulate within certain regions of hepatocytes due to pH differences, it is likely that the dependence of hepatocyte binding on physicochemical properties will be more complex than for microsomal binding. One study reported hepatocyte binding data on a set of 17 drugs that had a diverse range of lipophilicity and ionization class.<sup>103</sup> It was found that the extent of binding of these compounds was related to lipophilicity. The correlation of binding with lipophilicity was best when  $\log D$  was used for acidic and neutral compounds and  $\log P$  was used for bases,

in a similar way to the microsomal binding studies described previous. Despite the potential complexities of the hepatocyte binding process, this simple physicochemical model was able to predict  $f_{u,inc}$  with significantly less than twofold error for 16 of the 17 drugs. The method therefore has promise as facile way of obtaining an initial estimate of  $f_{u,inc}$  when performing in vitro–in vivo correlation using intrinsic clearance data from hepatocytes, as has been demonstrated with the human clearance prediction of a diverse set of marketed drugs.<sup>87</sup>

## 5.14.6 Influence of Plasma Binding and Tissue Binding on Volume of Distribution

### 5.14.6.1 Overview

Volume of distribution ( $V_{ss}$ ) is a critical pharmacokinetic parameter that is an important component of drug in vivo half-life. The ability to generate reliable predictions of human  $V_{ss}$  from preclinical data will frequently be a key component of the success of a drug research project. Volume of distribution can be viewed as a property that arises from the relative affinity of a compound for plasma versus tissue. Consequently, most methods for understanding and predicting  $V_{ss}$  do so with considerations of absolute tissue affinity and/or plasma affinity, or interspecies differences in these affinities. Such methods include those based on the Oie–Tozer equation, and those that make use of tissue plasma partition coefficients. Another frequently used method for  $V_{ss}$  prediction is allometry, which does not directly consider relative affinities for tissue and plasma and instead, in its simplest form, assumes a relationship between  $V_{ss}$  in various species and the body weights of the animals.

### 5.14.6.2 Allometry

It is well known that there can be large interspecies variation in volume of distribution ( $V_{ss}$ ), and a recent study on a set of 103 drugs showed that  $V_{ss}$  data from rat, dog, and monkey all show a similarly poor correlation with human  $V_{ss}$ .<sup>112</sup> Allometry has been a widely used method for the prediction of human  $V_{ss}$ ,<sup>113,114</sup> and the largest reported study describes its application to this 103 drug data set resulting in rather modest levels of predictivity.<sup>112</sup> Since it has been shown that interspecies differences in plasma affinity are much greater than for tissue affinity,<sup>96</sup> it should be expected that observed interspecies differences in  $V_{ss}$  will be strongly influenced by the interspecies differences in plasma affinity. It is significant therefore that for a data set of 14 drugs it has been shown that allometry using unbound volume of distribution ( $V_{ss}/f_{u,p}$ ), which takes into account the interspecies differences in plasma binding, greatly outperforms simple allometry.<sup>115</sup> If, for certain compounds, interspecies differences in plasma affinity happen to be related to animal size, and hence are allometrically related, then simple allometry will as a consequence be able to model interspecies differences in  $V_{ss}$  in terms of interspecies differences in plasma affinity. In cases such as this, simple allometry would be expected give better results. However, a more reliable way of incorporating interspecies differences in plasma affinity into allometry is to work with unbound volume of distribution, and as more examples of this methodology are reported it is expected that more accurate predictions of  $V_{ss}$  will generally be found than with the use of simple allometry.<sup>112</sup>

### 5.14.6.3 Methods Based on the Oie–Tozer Equation

Many nonallometric methods for predicting  $V_{ss}$  and for understanding the influence of plasma binding on  $V_{ss}$  have been based on the Oie–Tozer equation<sup>116</sup>:

$$V_{ss} = V_p(1 + R_{E/I}) + f_{u,p}V_p(V_E/V_p - R_{E/I}) + \frac{f_{u,p}}{f_{u,t}}V_R \quad [25]$$

The parameters  $V_p$ ,  $V_E$ , and  $R_{E/I}$  are constants describing the plasma and extracellular fluid volumes ( $L\ kg^{-1}$ ) and the ratio of extravascular to intravascular albumin respectively.  $V_R$  is the physical volume into which the drug distributes minus the extravascular space (often referred to as  $V_t$ ), and  $f_{u,t}$  the fraction unbound in tissues. This equation is often used in a simplified format eqn [16].<sup>116</sup> These equations clearly show how  $V_{ss}$  is largely controlled the relative affinity of a compound for plasma and tissue. The way these equations have been used involves rearranging them such that  $V_t/f_{u,t}$  or  $V_R/f_{u,t}$  can be evaluated in terms of measurements of  $V_{ss}$  and  $f_{u,p}$  in a given animal species, and estimates of the other parameters from physiological data. It is then possible to obtain estimates of  $V_t/f_{u,t}$  in several animal species. Several studies have shown that for a variety of drugs, there is often a significant interspecies variation in  $V_{ss}$ , while the variation in  $V_t/f_{u,t}$  is much smaller.<sup>117,118</sup> It then follows that if  $V_t/f_{u,t}$  has little dependence on species,

the value of  $V_t/f_{u,t}$  in humans can be assumed to be the same as that in an animal species, which can then be substituted into eqns [25] or [16] along with a measured value of human  $f_{u,p}$  in order to obtain a prediction of human  $V_{ss}$ . This approach has been applied to a range of drugs resulting in predictions of human  $V_{ss}$  of very useful accuracy.<sup>115,117–119</sup> An advantage of this method of  $V_{ss}$  prediction compared with allometry is it is able to produce good predictions from *in vivo* data in a single animal species such as rat,<sup>119</sup> allowing generation of human  $V_{ss}$  predictions earlier in the drug discovery process and with less use of *in vivo* experiments.

A further simplification of the methods based on the Oie–Tozer equation is to assume in eqn [16] that  $V_p$  is small compared with  $f_{u,p}V_t/f_{u,t}$ , which is a reasonable approximation for drugs with  $V_{ss} > 0.3 \text{ L kg}^{-1}$ . Equation [16] then simplifies to:

$$\frac{V_{ss}}{f_{u,p}} = \frac{V_t}{f_{u,t}} \quad [26]$$

As described earlier,  $V_t/f_{u,t}$  tends to be species independent, hence  $V_{ss}/f_{u,p}$ , known as the unbound volume of distribution, should also be approximately independent of species. This approach leads to the very simple equation below for prediction of human  $V_{ss}$ :

$$V_{ss,\text{human}} = V_{ss,\text{animal}} \frac{f_{u,p,\text{human}}}{f_{u,p,\text{animal}}} \quad [27]$$

All that is needed for human  $V_{ss}$  prediction using eqn [28] is a measurement of  $V_{ss}$  in a single animal species and the extent of plasma binding in animal plasma and human plasma. This method has been shown to give very good predictivity for a set of 14 drugs using data from dog as the animal species.<sup>115</sup>

Equation [25] has been combined with an empirical QSAR approach in order to predict human  $V_{ss}$  without the use of any *in vivo* data.<sup>120,121</sup> In these studies, eqn [25] was rearranged to give  $f_{u,t}$  in terms of a training set of human  $V_{ss}$  and  $f_{u,p}$  data from firstly 64, and later 120 neutral and basic drugs. Regression analysis was then used to model  $\log f_{u,t}$  in terms of  $\log D_{7.4}$  and the fraction ionized at pH 7.4 (from  $\text{pK}_a$ ) and fraction unbound at pH 7.4 (from PPB) of the drugs. It was found that  $\log f_{u,t}$  has a good relationship with the physicochemical properties, and the equation derived from the later study of 120 drugs is<sup>121</sup>:

$$\log f_{u,t} = 0.23(\pm 0.04)\log D - 0.93(\pm 0.08)f_{i,7.4} + 0.89(\pm 0.10)\log f_u$$

$$n = 120; \quad r^2 = 0.87; \quad q^2 = 0.85; \quad \text{rmse} = 0.37; \quad F = 250.9 \quad [28]$$

Equation [28] was then used to predict  $f_{u,t}$  for a separate test set of 18 drugs. These predicted values of  $f_{u,t}$  were then substituted into eqn [25] along with measured values of  $f_{u,p}$  in order to generate predictions of human  $V_{ss}$ . This method produced fairly good predictions of human  $V_{ss}$  with 10 out of 18 compounds in the separate test set having a predicted  $V_{ss}$  within a factor of 2 of the experimental value. Recently QSAR methods have been published to predict  $V_{ss}$  purely from molecular structure.<sup>127,128</sup>

#### 5.14.6.4 Methods Based on Tissue Plasma Partition Coefficients

In the field of physiologically based pharmacokinetic modeling,  $V_{ss}$  is related to the volumes of the tissues into which a drug distributes multiplied by the corresponding tissue-to-plasma partition coefficients, in addition to the plasma volume.<sup>122</sup> This relationship is expressed quantitatively by<sup>123</sup>:

$$V_{ss} = \sum V_t P_{t,p} + V_e E:P + V_p \quad [29]$$

where  $V_t$  and  $V_e$  are the volumes ( $\text{L kg}^{-1}$ ) of tissue and erythrocytes respectively,  $E:P$  is the erythrocyte to plasma concentration ratio, and  $P_{t,p}$  the tissue-to-plasma partition coefficient. The sum is taken over all tissue types (muscle, liver, lung, etc.). The widespread use of equations such as eqn [29] has largely been prevented by the difficulties in the measurement of the tissue-to-plasma partition coefficients and the lack of availability of human tissue.<sup>122</sup> A useful simplification of eqn [29] arises from the fact that the tissue plasma partition coefficients from different tissues are highly correlated with one another. Linear regression has been used on a set of 65 drugs to derive empirical relationships between muscle-to-plasma partition coefficients and tissue-to-plasma coefficients of other tissues.<sup>124</sup> These relationships can be used to estimate the tissue-to-plasma partition coefficients of a compound from a measurement of only the muscle-to-plasma partition coefficient. Further developments that should facilitate more widespread use of eqn [29] involve prediction of tissue-to-plasma partition coefficients from readily available

physicochemical properties. A QSAR approach has been applied to the prediction of tissue-to-plasma partition coefficients of a set of nine homologous barbituric acids<sup>125</sup> and to a set of ten lipophilic basic and neutral drugs.<sup>126</sup> Good relationships were found between the tissue-to-plasma partition coefficients and lipophilicity in both reports, but a limitation of this approach is that the derived equations are likely to only apply with useful accuracy to chemical structures that are similar to those used for building the QSAR models. A more recent tissue composition based mechanistic method<sup>124</sup> for predicting tissue-to-plasma partition coefficients from knowledge of solvent partition coefficients,  $pK_a$ , and  $f_{u,p}$  is likely to be more widely applicable than the QSAR equations. The method was validated on a set of 65 drugs, where it was found that 70% of the predicted tissue-to-plasma partition coefficients were within a factor of 2 of the experimental value.<sup>124</sup> This method was later applied to the prediction of tissue-to-plasma partition coefficients of another set of 123 drugs followed by substitution of the predicted values in eqn [29] in order to predict human and rat  $V_{ss}$ .<sup>123</sup> It was found that 80% of the predicted  $V_{ss}$  values were within a factor of 2 of the experimental value, indicating good predictive power of a method that only uses in vitro data.

### 5.14.7 Outlook

Due to the high attrition rate in late stage development, the pharmacokinetic and pharmacodynamic profiles of new compounds are obtained at an earlier stage than ever before. In order to fully understand these data, plasma protein binding and tissue studies are in greater demand than ever before. Understanding of the properties controlling plasma and tissue binding is increasing dramatically. Studies are now being undertaken on the crystallization of albumin and  $\alpha_1$ -acid glycoprotein with ligands of interest in order to further elucidate the mechanism of binding to these proteins and their ligands.

## Biographies

**Patrick Barton** received his first degree in Applied Chemistry from the University of Huddersfield in 1989 followed by a PhD in the field of Physical Organic Chemistry from the same institution in 1993, under the supervision of Prof M I Page investigating the reaction catalyzed by Porcine Liver Esterase. He is now Team Leader of Physical Organic Chemistry at AstraZeneca R&D Charnwood. His interests are in physical property measurements, the influence of physical properties on drug metabolism and pharmacokinetics and QSAR methodologies.

**Rupert P Austin** received his first degree in Chemistry from University College London in 1990 followed by a PhD in the field of Physical Organic Chemistry from the same institution in 1993, studying under Prof J H Ridd. He joined what is now AstraZeneca in 1993 working in the Physical Organic Chemistry group. His interests include QSAR, the binding of molecules and to biological matrices such as plasma, phospholipids, and proteins and the structure activity relationships of these processes, and laboratory automation.

**Roger E Fessey** received his first degree in Chemistry from the University of Liverpool in 1993 followed by a PhD in the field of Physical Organic Chemistry from the same institution in 1997, under the supervision of Prof D Bethell. He joined what is now AstraZeneca in 1998 working in the Physical Organic Chemistry group. His interests include structure–activity relationships, QSAR, and binding of molecules to phospholipids and plasma proteins.

### 5.15.1 The Automated Absorption, Distribution, Metabolism, and Excretion (ADME) Screening Era

The high costs involved in the discovery and development of a new drug and the high attrition rate of drug candidates in development have shifted the current drug discovery and development paradigm towards the parallel assessment of efficacy and comprehensive ADME (absorption, distribution, metabolism, and excretion) properties of drug candidates.<sup>1-5</sup>

**Figure 1** New strategy for drug discovery and development where direct interactions between discovery and development are greatly enhanced and the optimization of efficacy and druggability will be performed in parallel. The new strategy will require a comprehensive suite of predictive in silico and automated in vitro ADMET profiling tools in the early discovery phase.

Multiple predictive filters of ADME properties (such as in silico, high-throughput in vitro and in vivo pharmacology assays in animals, etc.) are established in the various stages of drug discovery and development process to flag the potential ADME issues of new chemical entities (NCEs) in man.<sup>6–10</sup> Of these, high-throughput (HT) in vitro ADME assays offer the first experimental tools to rank and prioritize NCEs in the early discovery phase in a faster and cost-effective fashion.

Such a new trend to evaluate therapeutic and drug-like features of NCEs together has led to a number of changes in the modern drug discovery and development process. First, a new mentality to break down the wall between drug discovery and development has appreciably encouraged the interdisciplinary and translational interactions to drive the projects effectively toward the same goal, the clinical launch of the medicine. As a result, industry tends to migrate from sequentially assessing efficacy and druggability to a parallel process in the new drug discovery and development strategy as shown in [Figure 1](#). Hits, leads, and NCEs are being assessed at different milestones. The ‘go’ and ‘no-go’ decisions to advance drug candidates to the next stage should rely not only on a particular parameter (e.g., efficacy) but also on the drug’s overall performance and their potential to become a commercial drug. In addition, industry has committed to investment in developing and implementing cascaded HT, miniaturized, cost-effective automated in vitro ADME profiling assays with good predictivity for in vivo druggability, for usage at various stages in the drug discovery and development process. This offers a solution in early discovery to modernize those in vitro ADME assays that were usually costly, labor-intensive, low throughput, and required a large amount of materials and were therefore available only in the late development stages. Finally, the follow-up ‘pharmacoinformatic’ studies are critical to establish reliable and predictive models to translate the in vitro ADME profiling data into useful druggability information for an NCE. It is essential to gradually build up the predictive in silico models for future ADME profiling. All of these can be implemented in the optimization cycle of chemical synthesis and thus can directly improve and accelerate the selection of early hits, leads, and NCEs in the early stages of discovery.

#### 5.15.1.1 Is Automation Absolutely Necessary for High-Throughput In Vitro Absorption, Distribution, Metabolism, and Excretion Assays?

In the past decades, many novel in vitro ADME assays have been established to predict the potential pharmacokinetic (PK) and other toxicological or pharmacological behaviors of new drug candidates in animals and man. From proof of concept, in vitro assays were found to be quite useful to assess the respective in vivo activities. However, they used to be available only in the development phase due to limited capacity. In early ADME, those in vitro ADME assays are modernized in the early discovery phase by utilizing state-of-the-art automation and streamlined bioanalysis technologies that are widely applied in high-throughput screening (HTS) for a drug’s efficacy. A number of review articles have summarized the latest developments in the automated ADME profiling field.<sup>11–15</sup> [Table 1](#) outlines the major differences between conventional in vitro ADME assays currently operating in development laboratories and those for HT ADME assays in the discovery phase.

Currently, HT ADME assays are an integral part of the early drug discovery process ranging from hit/lead nomination to lead optimization. Sometimes in vitro follow-up assays are required for the declaration of NCEs. Therefore, cascaded in vitro ADME assays are required with a greatly enhanced capacity (thousands to tens of thousands) to support such activities. In addition, the data must be available for periods lasting hours to days to cope with the designated decision tree used for each chemistry cycle in the lead optimization phase. Furthermore, a streamlined and efficient logistic

**Table 1** Comparison of assay requirements for HT in vitro ADME assays with those for conventional in vitro ADME assays offered in development

|                      | <i>Conventional in vitro ADME assays</i> | <i>HT in vitro ADME assays</i>   |
|----------------------|--|----------------------------------|
| Capacity (yearly)    | 10s to 100s                              | 1000s to 10 000s                 |
| Turn-around time     | Days/weeks to months                     | Hours to days                    |
| Sample amounts       | 1 to 100s $\mu$ mol                      | 0.1 to 10s nmol                  |
| Cell culture/prep    | Manual, individual labs                  | Automated (QC on wells)          |
| Assay platform       | Manual in vials/test tubes               | Automated in 96/384-plate format |
| Bioanalytical format | Manual/semiautomated                     | HT program, automatic            |
| Cost per sample      | \$100s to \$1000s                        | \$10s to \$100s                  |
| Data tracking/mining | Not available mostly                     | Database/LIMS                    |

**Figure 2** Number of publications on automated ADME assays (data source: SciFinder, using a combination of keywords ‘automation’ and ‘absorption, distribution, metabolism, excretion’).

process is a prerequisite for handling high demands with the limited sample amount available in the early phase. In practice, this cannot be achieved by simply multiplying the capacity of the conventional in vitro ADME assays by the additional number of full-time employees (FTEs) required. Most organizations consequently seek solutions via automation and streamlined bioanalysis. [Figure 2](#) demonstrates that the number of publications on ADME automation has risen steeply recently.

#### 5.15.1.2 Automation Strategy

Implementation of efficient and user-friendly automated in vitro ADME assays is not a trivial matter, as the automation platforms required are more complex and thus far less standardized than those used in HTS systems. For instance, most of the in vitro permeability assays (using either an artificial membrane or a cell monolayer) utilize a sandwich-type of device comprising 96-well donor and receiver plates to mimic the in vivo permeation of test compounds across the gastrointestinal walls in animals or man. Another example is the automated HT-equilibrium solubility assay involving very complicated sample preparation steps that are difficult to automate. Complicating matters even further, the development of in vitro ADME assays has not reached a static stage and the constantly improved/revised assay protocols for the designated parameters (e.g., solubility, permeability, clearance, etc.) add additional challenges or variability to the design of the automated ADME assay platform.

#### 5.15.1.2.1 Shared assay workstations

Sometimes, an automated assay workstation system can be integrated such that it can run a number of in vitro ADME assays sequentially. This is feasible and cost effective for small organizations or even business units (or satellite sites) of large organizations that have limited capacity and usage requirements for each of the in vitro ADME assays. This shared workstation solution is ideal to cope with a number of in vitro assays utilizing similar biological and analytical approaches by sharing the same labware, device(s), and readout equipment. For example, the determination of lipophilicity ( $\log P$ )<sup>35</sup> via the microtiter-plate format<sup>16</sup> can be carried out on the same automated workstation that is used for the measurement of parallel artificial membrane permeability assay (PAMPA).<sup>17,18</sup>

#### 5.15.1.2.2 Individual workstation dedicated to a specific assay

The latest trend in industry is to centralize the in vitro ADME screening assays in one or two hub laboratories within an organization. It offers a number of advantages such as: (1) reduced cost by consolidating the requests; (2) more easily managed internal logistics; and (3) efficiently maintained global assay standard and quality control (QC) within an organization. Therefore, the automation of a dedicated assay in a user-friendly, efficient, and reliable format will allow each hub laboratory to capture requests from the satellite sites without additional manpower. With the increased responsibility to support projects at multiple sites, the hub laboratories must acquire a favorable service contract with the major automation vendors to ensure the shortest downtime of the automated system (e.g., within 24–48 h). Contingency plans should always be available between the major hub laboratories to support each other under those conditions.

#### 5.15.1.2.3 'Fully-automated' versus 'semi-automated' systems

The dedicated automated ADME systems can be integrated in distinct formats. Not every step needs to be automated and a balance between the complexity for automation/cost and the gain needs to be carefully evaluated. For example, it might not be necessary to automate loading of a high-performance liquid chromatography (HPLC) autosampler if it takes only a few minutes per day for an operator to do it manually. On the other hand, steps such as plate sealing might be worth automating if they allow for an unattended overnight run. In another example, the cell permeability assay can be assimilated either as 'pseudo-full automation' or as 'full automation.' Both approaches were attempted in our laboratories. Pseudo-full automation can separate the entire assay process into 3–4 segments such as: (1) sample preparation (from solid powders or DMSO stock solution); (2) cell culturing (of cell monolayers on 96-transwell plates in 21 days); (3) permeability assay (assemble donor/receiver and perform incubation); and (4) bioanalysis (quantification of samples in liquid chromatography/mass spectrometry (LC/MS)). Individual workstations are integrated for each of the four dedicated tasks in an automated fashion with minimal personal involvement for sample/plate transfers between workstations (e.g., once a day). Alternatively, in the 'full automation' mode, those four self-automated workstations can be further integrated by a Thermo-CRS or Mitsubishi mobile robot so that no personal intervention is required.

Apparently both approaches have advantages and limitations. 'Full automation' has complex integration and interfacing among individual workstations, generally involving multiple vendors. In addition, the individual workstations may often be idle as required by the scheduling of shared components (e.g., CRS robot) and therefore the entire system is not effectively utilized. Despite there being no need for personnel to transfer plates between workstations, the system may still require qualified workers for maintenance and daily operation. In the worst-case scenario, the technical failure of one individual workstation may interrupt the operation of the entire automated system. The challenges for integration and maintenance have been significantly reduced in pseudo-full automation and all four workstations can be operational in parallel without interference. However, the limitation is a required level of assay monitoring between workstations. As most of the repetitive and tedious components of the assay are performed on the individual automated workstations and the manual interventions between workstations are limited, we found this to be the most efficient and effective solution for our laboratory.

#### 5.15.1.2.4 Large-scale fully integrated automation systems versus automated workstations

The challenges in dealing with complicated interfacing among individual workstations are being tackled by automation- or profiling-specialized vendors such as Thermo Electron Corp. (Thermo), The Automation Partnership, and Cypotex. This type of undertaking requires the corporations to have integration teams with a good understanding of the business needs and future trends for in vitro ADME screening. In addition, they often have strong business units in automation and bioanalytical equipment, as well as a software programming team. They intend to generalize the majority of user requirements to create a universal automation platform for multiple in vitro ADME screening assays in a streamlined format. Apparently, they will help users to address the interfacing between workstations, the compatibility between

assays sharing the same workstations, and compound tracking and data processing/interpretation issues that are commonly encountered by scientists of in vitro ADME laboratories. This full integration is a new approach and its fate lies in the future successful resolution of the technical roadblocks such as: (1) the flexibility of a universal giant to address the specific requirements in assay protocols by an individual user; (2) the applicability or adaptability of the generic system to assays that are extremely challenging to automate (e.g., HT thermodynamic solubility); and (3) its financial advantage (capital investment, operating and personnel costs) over the individual automated workstations.

### 5.15.2 Automation of In Vitro Absorption, Distribution, Metabolism, and Excretion Assays in Users' Laboratories

At present, there appears to be a consensus in the early ADME field that automation is a must to enhance the throughput and productivity of in vitro ADME assays in early drug discovery. However, adoption of an appropriate implementation strategy is essential for a successful integration, timely launch, and smooth subsequent operation of the in vitro ADME screening assays.

#### 5.15.2.1 Off-the-Shelf Workstation

Nowadays, fewer people utilize a sewing machine to make their own clothes. Construction of a customized house can be a similar luxury to meet specific cultural, architectural, or other personal preference, not necessarily for the economic benefit. Off-the-shelf products are generally welcome as long as they have the important features required by a majority of users. This is particularly crucial for HT ADME assays as they can alleviate scientists from automation, integration, interfacing, and programing problems. For a successful and well-received system, the cost of the investment by the vendors can be shared by users, which may lead to some financial benefits over an individual integration. Another advantage lies in the existence of tangible products with confirmed specifications, which translates to minimal risk in delayed implementation and in failure of deliverables. [Table 2](#) summarizes the off-shelf automated ADME products on the market.

Factors to be considered prior to purchase of an off-the-shelf automated system include:

- quality of deliverables (whether they meet the specific requirements of a user's organization);
- designed throughput (maximal and sustainable);
- user-friendliness of the system (automation, analysis, data processing, and quality of life for operators);
- reliability and technical support (in particular for the centralized laboratories);
- stability of the products and the vendors (to avoid discontinued products);
- cost effectiveness (both the upfront investment and the subsequent operational cost including personnel expenses);
- possibility to be upgraded in the future (to a higher or more advanced version); and
- compatibility to the infrastructure within a user's organization (e.g., information technology (IT), assay format, etc.).

Commonly, evaluations are carried out prior to purchase of an off-the-shelf product. Typically, the users have a set of reference compounds with known data serving as a 'gold standard' for the assessment. Sometimes inconsistent and unsatisfactory results are found after installation compared to those from evaluation, possibly because of overly optimistic data derived from evaluating well-behaved commercial drugs. In reality, the current drug discovery compounds are more challenging due to their properties being poorer than those of commercial drugs.<sup>19</sup> Therefore, it is essential to create the test set by combining commercial drugs and internal discovery compounds. Ideally, side-by-side comparisons should be made if there are multiple products available.

#### 5.15.2.2 The Customized Workstation in Users' Laboratories

##### 5.15.2.2.1 Automation planning and strategy

One of the largest advantages of integrating your own automation system is the high degree of flexibility, wherein the users can design a completely customized system based on specific requirements. It also allows users to combine favorite components and other special devices. Nonetheless, designing a customized system is a large project entailing significant commitments. Several key elements should be considered before an automation project is initiated: (1) necessity for customization (review existing off-shelf product availability); (2) urgency (generally 3–12 months are

**Table 2** Summary of off-the-shelf automated ADME products

| <i>Assays</i>                | <i>Vendor/website</i>   | <i>Main features</i>   |
|------------------------------|---|--|
| Solubility                   | pION ( <a href="http://www.pion-inc.com">www.pion-inc.com</a> )                         | Start with DMSO solution on Beckman Tecan 8-probe liquid handlers, pH monitored, plate filtration<br>Readout: UV (with HPLC & MS interface)  |

required to complete customized automation from scratch); (3) availability of a validated protocol for a manual assay that can feasibly be automated; and (4) availability of an internal team with all related knowledge and expertise needed (e.g., ADME assay, automation, bioanalysis, programming, etc.); and (5) the budget.

In summary, the users must have a clear idea of the scope of the project, with clearly defined but realistic time-lines and anticipated deliverables. In the cases where the assay to be automated has only partially been validated and the additional development is still underway, the proposed automation solution has to be flexible enough to cover most of the possible scopes of the project. Once the project is initiated, a project leader should be nominated to oversee it during its entire course and coordinate all activities. A detailed business plan and strategic vision should include an assessment of the anticipated demand for compound profiling, the allowable operating costs, the anticipated turnaround time, and the number of staff required.

#### 5.15.2.2.2 Preparation of user requirement specifications (URS)

Typical issues involved in customized automation are: (1) missed completion time-lines; (2) substantially deteriorated assay quality in automated format; (3) overspending; (4) incompatibility or failed interfacing between components from different vendors; and (5) bespoke systems that are so inflexible that no new features can be accommodated. In these circumstances, most of the disputes between frustrated users and vendors result from the lack of a clearly defined user requirement specification (URS) document. Therefore, users are highly recommended to prepare a URS document to clearly describe their specifications (e.g., deliverables) and required time-line. This is an extremely useful exercise that allows the end users to compose different aspects of the assay and foresee the scope of the entire project. It is critical to include all possible changes of the protocol or future development of the assay so that contingency plans can be arranged upfront by the vendors. Normally, the selected vendors will convert this URS into a technical requirement. These documents serve as a vital guidance for the integration and implementation of the automated system. It is also important to establish guidelines for the project to accommodate changes in scope and modifications of requirements. The project team needs to balance delivering a quality system with schedule and budget.

#### 5.15.2.2.3 Selection of proper components and vendors

Unlike the large-scale automated system or off-the-shelf integrated system described earlier (*see Sections 5.15.1.2.3 or 5.15.2.1*), most users also have the option to select individual components for the assembly. The challenge is that the users have to be very familiar with the latest technologies on the market for the critical components of the integration. A common and also efficient practice is to interview prospective vendors after they have looked over the URS. In general, users should break down the integrated system into several functional units requiring different types of vendors (e.g., special cell culturing facilities, liquid handlers, bioanalytical equipment, or mobile robots to incorporate all selected components together). Clearly, this is a time-consuming process, as, usually, there are a number of well-established suppliers in each of those fields. Here are some tips for the selection process:

1. Include someone in the team who is knowledgeable in those products and also familiar with the integration process of automated ADME systems. The involvement of an automation and/or IT specialist is very beneficial for any project involving intermediate to advanced complexity, as they can provide technical advice on instruments and can comment on design preferences thus aiding in selection.
2. Distribute the URS to all potential vendors with a given deadline (typically 2–4 weeks) for response, provided that a nondisclosure agreement is signed ahead of time by the vendors. For large projects a RFP (request for proposal) can take up to 8 weeks. Establishing clear rules during the RFP is important in these cases. Usually vendors are expected to give their presentation in person.
3. In addition to the features, specifications, and cost analysis provided by a vendor, take into consideration the instrument reliability, data quality, and customer service reputation as well as the stability of the vendor. For a large organization where the particular integration will be implemented in parallel in multiple sites, the above assessment has to be done on a global basis. Generally, there are minimal risks when choosing the most popular models from vendors with an excellent global sales and support network. Some users tend to retain no more than two brands of equipment for ease of training and maintenance within the laboratory.
4. Identify the crucial steps or specifications of your ADME assays for the evaluation. For instance, the expected percent coefficient of variation (CV%) for dilution curves (e.g., for  $IC_{50}$  determination of cytochrome P450 (CYP) inhibition and preparation of calibration curve for thermodynamic solubility, etc.) will guide the assessment for precision and accuracy of the respective liquid handling steps. Keep in mind that some of the specifications provided by vendors are reached under optimized conditions using ideal samples. It is essential to confirm the

performance of the products and the quality of the deliverables from daily samples (which normally are much more challenging than those used by vendors) under routine conditions. It is useful to prepare a set of validation samples, which can be tested in the demo experiments by each vendor. Sometimes vendors are willing to ship their demo equipment to users' laboratories to conduct such testing.

5. The evaluation criteria should be quite similar to those used for 'off-the-shelf' systems (*see* Section 5.15.2.1) except that interfacing and compatibility of each component of an integrated system become the user's responsibilities. In general, major vendors have experience of interfacing with peripheral equipment from divergent suppliers. It is wise and efficient to encourage direct communications between vendors of the different functions.
6. The users should be prepared to receive an alternative or revised proposal that may utilize a different technical approach than that originally described in the URS, normally due to the vendor's technical or budgetary limitations. Users should be flexible for noncritical items but should demand that key requirements are met to avoid sacrificing quality or capacity.
7. It is important to confirm if the proposed automated solution is feasible for the labware used in the assays. For example, we found the medium exchange protocol for 21-day cell culturing on the 96-well filter plates from some suppliers was perfectly fine in the manual operation. In the automated procedure, however, the robot failed to consistently remove the lid of the filter plates because of surface tension when taking the plate out of the cell-culturing incubator. In addition, the exchange of the fed media was incomplete because the robotic liquid handler could not remove all remaining fed media from the basolateral well of the plates. Although the suppliers for the filter plates eventually resolved these issues after 6–12 months, clearly this hurdle kept users from offering the designated capacity within the desired timeframe.
8. For a large and complex project, execution of the vendor selection process should be completed with a formal selection process where vendors are narrowed to 1–2 candidates. Once a vendor is selected, all vendors may be notified in writing of the outcome. The letters should be brief and courteous, to clearly communicate the outcome of the selection process and to strengthen the relationship between the vendor and the customer for future projects.

#### 5.15.2.2.4 Keeping integration on track with system factory acceptance test and site acceptance test

The completion of integration projects can be delayed in many cases for various reasons. The project manager from the user side should closely monitor the project with predefined milestones. Typically, the time-line, any necessary URS revisions, including special requirements, and the criteria for site acceptance test (SAT) should be clearly defined in the quote and agreed among all parties. In addition, good communication is a must to avoid last minute changes or misunderstandings.

For a large automation project, it is important to consider a factory acceptance test (FAT) in addition to a SAT. The FAT requires the customer to be at the vendor's site while the test is run. A proper FAT will reduce the risk of the system arriving at the customer site unfit for its designated purpose. It is always cheaper, easier, and faster for a vendor to fix problems at the vendor site than at the customer site. A system shipped unfit for its defined purpose can lead to delays due to the 'out of sight, out of mind' mentality that ensues as the vendor moves on to the next project. The testing protocols used for the FAT and SAT should be outlined in detail and agreed upon by both parties. These documents should be signed prior to the start of testing and once the testing has been completed.

### 5.15.3 Early Absorption, Distribution, Metabolism, and Excretion Analytics

Bioanalytics is an important factor in early ADME screening as it is often the bottleneck in assay automation. In practice, almost all automated in vitro ADME assays were designed and integrated based on selection of the assay readout. In vitro assays used to assess ADME properties of drug candidates utilize a broad range of detection methods (Table 3). Direct optical detection without any chromatographic step has the advantage of speed and is relatively easy to incorporate in a robotic workstation. It also allows the user to follow reaction kinetics if valuable to an assay, for example, time-dependent CYP inhibition. One disadvantage of this approach is that the detection is not compound specific; therefore, one needs to have tight requirements for compound purity (>95%).

Solubility and permeability measurements are the two prominent assays for which insufficient compound purity can cause the most severe problems in bioanalysis. In these cases, more compound-specific detection methods like HPLC/UV or LC/MS tolerate a lower compound purity but are more difficult to automate and generally more labor

**Table 3** Assay technology and detection methods for in vitro ADME assays

| <i>Molecular property</i> | <i>Assay technology</i>                              | <i>Detection mode</i>                 |
|---------------------------|--|---------------------------------------|
| Kinetic solubility        | Nephelometric titration<br>semi-shake flask          | Light scattering,<br>HPLC/UV/MS       |
| Equilibrium solubility    | Shake flask  | UV, LC/UV, LC/MS, LC/CLND             |
|                           | Potentiometric titration                             | pH electrode                          |
| Ionization                | Rapid mixing + UV titration                          | UV/DAD                                |
|                           | Titration  | pH electrode                          |
|                           | Ionization-related mobility                          | CE/HPLC                               |
| Permeability              | PAMPA  | UV plate reader, HPLC/UV, LC/MS (/MS) |
|                           | Caco-2 monolayers/P-gp-transferred MDCK cells        | LC/MS/MS, LC/MS/MS                    |
| Protein binding           | Dialysis/centrifugation                              | LC/MS/MS                              |
| Metabolic clearance       | Liver microsomes/S9/hepatocytes                      | LC/MS/MS, LC/MS/MS                    |
| CYP inhibition            | Recombinantly expressed CYP + fluorogenic substrates | Fluorescence                          |
|                           | Human liver microsomes + prototypical substrates     | LC/MS/MS                              |

intensive. While the data acquisition itself can be automated and multiparallel systems are used to increase throughput, data analysis remains labor intensive. Detection based on mass spectrometry has the advantage of a higher sensitivity, which can be particularly useful for the analysis of compounds with low solubility. However, it requires a higher capital investment.

### 5.15.3.1 Kinetic Solubility

Kinetic solubility is one of the approaches to estimating aqueous solubility of NCEs rapidly. It is mainly achieved by directly introducing a dimethyl sulfoxide (DMSO) solution of the test compound into the designated media, followed by an immediate readout using optical detection techniques such as turbidimetry,<sup>20,21</sup> nephelometry,<sup>22,23</sup> laser flow cytometry,<sup>24</sup> or direct-UV (using a UV plate reader).<sup>25</sup> In general, multiple samples are prepared with increasing concentrations of the test compound so that one can define the solubility by monitoring the concentration at which particles fall out of the solution. The advantage is that this is a fast and relatively universal detection mode. Sensitivity varies with particle size. Solubility limited by lipophilicity is usually more difficult to detect than solubility limited by other factors such as crystal packing, which usually produces a stronger signal.<sup>26</sup> In addition to the errors caused by the insufficient incubation time and coexistence of DMSO in kinetic solubility determinations, the readout is also interfered by impurities of low solubility, which can lead to a substantially underestimated solubility value of the parent compound.

The above kinetic solubility samples can also be quantified using the direct-UV tactic at a specific wavelength. It offers a fast analytical approach but requires high compound purity and a filtration procedure to remove precipitates from solutions. An alternative method based on full spectra analysis enhances sensitivity, while comparison of the shape of the reference with the analyte spectra can flag the presence of an impurity interfering with the measurement. However, this is successful only if the UV spectrum of the impurity is different from the parent compound, which may not be the case, especially if the impurity is a synthesis by-product that shares the same scaffold as the parent compound. From a process viewpoint, flagging mechanisms imply that the sample needs to be reprocessed using a different readout. The additional steps for this type of follow-up analysis, however, can add complexity to the automation process. It is also worth mentioning that the use of different detection systems for the same assay may affect assay robustness.

### 5.15.3.2 Equilibrium Solubility

There are essentially two techniques to measure equilibrium solubility. The 'classical' approach is based on the shake flask followed by separation of the solute from the precipitate and quantification of the amount of compound in filtrate.

Whereas various approaches are being used to quantify the compound concentration, the most common approach in the development laboratories is to use generic HPLC/UV. While the data capture itself is relatively easy, automated data analysis is challenging for different reasons: (1) automatic peak integration requires a good signal/noise ratio (S/N); (2) some compounds give more than one peak (diastereoisomers, some enantiomers); (3) retention time can shift with concentration; and (4) when impurities are more soluble than the parent compound, correct peak identification is not always straightforward (on-line qualitative MS can then help to identify which is the compound of interest). Currently, a number of vendors such as Agilent, Waters, and Nanostream have developed customized application software to automate the time-consuming data processing steps and to derive ADME data, such as equilibrium solubility, in a HT fashion. One of the key features of this type of software is its ability to review and process the HPLC data interactively and tackle only the problematic data that are flagged by the predefined criteria. It should be mentioned that some laboratories may utilize the direct-UV approach to quantify the equilibrium solubility samples to enhance the throughput but the assay using this approach will face the same analytical challenges as mentioned in [Section 5.15.3.1](#).

The other accepted method to measure solubility is potentiometric titration, popularized by pION Inc.<sup>27</sup> In this case, there is no need to separate the filtrate from the precipitate as the pH electrode measures proton exchange of the fraction of compound that is in solution. However, this method is time consuming and not very amenable to HT as each sample requires a specific experimental design and data analysis requires a skilled operator and would be difficult to automate.

### 5.15.3.3 Ionization

Measurement of ionization constants via potentiometric titration is usually a lengthy process. In order to record the pH changes accurately (with a glass electrode) caused by introducing a known volume of titrants to the well-mixed solution of a drug candidate, one needs to wait until the equilibrium is reached after each titrant addition. This approach, albeit reliable, can only analyze 5–10 compounds daily and requires materials in the milligram scale; therefore, it is commonly utilized in the late discovery and early development stages. In addition, solubility is often an issue, as potentiometry requires concentrations in the 0.1–1 mM range in aqueous media. Cosolvents are usually used to circumvent solubility, but several titrations are required to back extrapolate to aqueous media. One additional problem with potentiometric titration is the increasing number of NCEs in early discovery that are delivered as salts with protogenic counter-ions, like acetate or fumarate.

Capillary electrophoresis (CE) can be utilized to monitor the migration or mobility of the compounds under electric potential. As mobility is highly dependent on the ionization process,  $pK_a$  data of NCEs can be assessed accordingly.<sup>21,28,29</sup> This tactic demonstrates the advantages of dealing with the common issues in early discovery such as interference of impurities and a limited amount of sample materials. However, the inability to handle poorly soluble compounds that are frequently analyzed in the early phase becomes the major hurdle for its applications in early discovery. A new approach utilizing an HPLC method may help accurately measure  $pK_a$  for sparingly soluble compounds.<sup>30</sup>

Another method based on a continuously flowing pH gradient and a UV-DAD, (diode array detector) was developed a few years ago and allows for a much higher throughput.<sup>31</sup> The method establishes a stable time-dependent pH gradient by rapidly mixing acidic and basic buffers, during which drug candidates predissolved in organic solvent are introduced at different pH conditions. The assay works effectively with poorly soluble NCEs by using cosolvent in the media. The  $pK_a$  data measured on this 'rapid-mixing' approach correlate very well with those from the potentiometric titration method. The method has shown a number of key advantages in measuring  $pK_a$  in early discovery as being high throughput, automatic, robust, and, most importantly, quite predictive to the reliable potentiometric titration method used in later stages. The limitation is that only ionizations that induce a change in the UV spectra can be detected. In other words, not only will a UV chromophore be required but also it may have to locate close enough to the ionization center within a NCE. According to our experience, this fast method allows full characterization of ionizable groups for ca. 70% of the possible  $pK_a$  data and usually gives high-quality data, that is, close to what is obtained by potentiometric titration. Nonetheless, this tactic can be nicely combined with the potentiometric approach. It should be mentioned that neither this 'rapid mixing' nor the potentiometric titration approach is compound specific, so compound purity >95% is required to get accurate data.

### 5.15.3.4 In Vitro Permeability Assays

A variety of approaches were developed to predict permeability of NCEs in early drug discovery.<sup>5,32,33</sup> The PAMPA<sup>17,18,36–39</sup> using a chemical membrane (e.g., dodecane or hexadecane) immobilized on a 96-well filter plate offers an avenue to quickly estimate permeability for NCEs with passive diffusion mechanisms and small molecular

weights (e.g., <500). For the Madin–Darby canine kidney (MDCK) cell model that originates from dog kidney, the expression of transporters is quite different from that of human intestine.<sup>32,40</sup> As a result, the MDCK monolayer is commonly used for permeability evaluation of NCEs transported by passive diffusion mechanisms,<sup>41</sup> as does the PAMPA model. The latest development has extended the permeability studies using a P-glycoprotein (P-gp)-transferred MDCK model to estimate the contributions of efflux transporters.<sup>42</sup> The human colon adenocarcinoma (Caco-2) cell permeability model, exhibiting morphological (e.g., tight junction and brush-border) as well as functional (e.g., multiple transport mechanisms) similarities to human intestinal enterocytes, has been widely received in drug discovery and development.<sup>41,43,44</sup> Caco-2 cells extensively express a variety of transport systems beyond P-gp normally found in small intestinal enterocytes, which made it possible to investigate the interplay among different transport systems and differentiate the relative contributions from passive and active transport mechanisms to the overall permeability across the human gastrointestinal (GI) tract.<sup>45</sup> Despite the extensive insights offered by the Caco-2 model over other in vitro permeability models, its lengthy and complicated cell culturing has led to high cost for assay maintenance and daily operation. It is preferable to use PAMPA as a fast and HT prescreening tool for permeability ranking and apply Caco-2 assays only to the challenging compounds that failed in the PAMPA assay.

The permeability assays are carried out similarly for the above in vitro models. In Caco-2 or P-gp transferred MDCK models the bidirectional mode (apical to basolateral chambers and basolateral to apical compartments) is utilized to estimate the permeability in both directions and to differentiate the contribution of the active transporters in the permeation process of NCEs. For PAMPA, permeability can be assessed by either direction due to the lack of active transporters. Analytically, while the cellular permeability assays are commonly quantified by LC/MS/MS, PAMPA is analyzed by UV plate reader, HPLC, and/or LC/MS. Therefore, the same arguments used in Section 5.15.3.2 still apply here. For all permeability measurements, it is important to avoid precipitation in the donor compartment or it will lead to underestimated permeability values. In order to maximize the S/N ratio when UV is used as a detection method, one needs to optimize the loading concentration based on solubility of the compound. This extra step makes the compound management more complicated but increases the fraction of compounds that can be quantified using the UV method. A fraction of compounds cannot be measured in this way because they lack a UV chromophore or because their solubility prevents the use of a concentration suitable for UV detection. LC/MS can then be used as a complementary method. The use of formulation<sup>46</sup> or a cosolvent<sup>47</sup> can be used to prevent compound precipitation. The alternative is to work at a lower loading concentration also using LC/MS as a complementary method. The main issue with this strategy is that accurate UV measurements impose requirements on high compound purity (e.g., >95%) and a tight correlation between the two detection modes used. Data given in Figure 3 show the assay reproducibility using UV or MS

**Figure 3** Measurements of effective permeability using UV and LC/MS detection. Filled triangles: both runs were analyzed by a UV plate reader; filled squares: both runs were measured by the LC/MS approach; open circles: one of the two determinations was quantified by LC/MS and the other by a UV plate reader.

detection. The two detection methods correlate fairly tightly for highly permeable compounds ( $-3.1$  to  $-4.5$  in [Figure 3](#)), but the situation becomes more complex when permeability of test compounds decreases where permeable impurities can interfere with the optical detection.

#### 5.15.3.5 Metabolic Clearance

Metabolic clearance, particularly hepatic, is recognized as one of the main determinants of the concentration in blood as well as the volume of the distribution of NCEs, and therefore is used to help predict bioavailability and toxicokinetics.<sup>48,49</sup> A metabolically unstable NCE, albeit orally absorbed, might never reach the required therapeutic concentration. Alternatively, a certain degree of instability might be desirable in cases where a metabolite is more active than its parent (i.e., a prodrug).

Currently, *in vitro* approaches that are utilized to monitor the metabolic clearance as well as to predict the human clearance of drug candidates include the use of recombinant CYP enzymes, liver microsomes, S9 fraction (the 9000 g supernatant of a liver homogenate), isolated hepatocytes, and liver slices.<sup>50–52</sup> While liver microsomes and S9 remain most commonly used to measure clearance in early discovery, utilization of hepatocytes has been drastically increased due to the latest breakthrough in cryogenic technology in handling them.

Analytically, a generic LC/MS/MS approach is usually used to probe the disappearance of the test compounds and report the half-life and intrinsic clearance values. This is a very compound-specific detection method, which allows for a quick LC step. Small compound impurities are usually not an issue unless they inhibit CYP enzymes that are involved in the metabolism of the parent compound.

#### 5.15.3.6 Cytochrome P450 Inhibition

Currently, two approaches are commonly utilized to monitor the metabolism-related drug–drug interactions through cytochrome CYP inhibition: LC/MS and fluorogenic methods.<sup>53–55</sup> The former uses clinically relevant substrates such as midazolam or testosterone (e.g., for CYP3A4) and human liver microsomes (HLM), allowing concurrent metabolic events as well as interplay among multiple CYP isozymes in HLM to be monitored. The latest study using the above substrate/enzyme/detection combination approach has demonstrated a good correlation to the *in vivo* drug–drug interaction issues.<sup>56</sup> In addition, this approach complies with the US Food and Drug Administration (FDA) requirement and is therefore considered a ‘gold standard’ *in vitro* assay. Despite the wide acceptance in the development phase, its application in early discovery, however, was somewhat hindered by the limited capacity of LC/MS quantification. In this case, the obtained metabolites are separated and analyzed by LC/MS (occasionally by LC/UV), which imposes major limitations to the throughput and cost effectiveness.

The fluorogenic approach, using a fluorescence plate reader, quantifies the fluorescent metabolites from a known substrate, generally used in combination with recombinant CYP enzymes, and monitors the fluorescent signal reduction as a result of the inhibition of CYP enzymes caused by the coexistence of drug candidate(s). The fluorogenic approach does not require metabolite separation by LC, substantially improving the throughput, turn-around time, and cost effectiveness. The downside of this approach, however, is its limited sensitivity and assay robustness for each enzyme/substrate pair when the DMSO concentration reaches a specific level (e.g.,  $>0.1\%$ ).<sup>57,58</sup> It should be mentioned that although the DMSO-induced analytical issues also occur with the LC/MS/HLM approach, their impact on the fluorescent methodology is significantly greater due to the limited dynamic range of the detection in the fluorogenic method. It should be noted that, unlike the prototypical substrates that are commercial drugs used in the LC/MS/HLM assay, the fluorescent substrates are not mimicking clinically relevant drugs, but rather are derived from known fluorescent compounds, such as coumarin or fluorescein. In general, those fluorogenic substrates are smaller molecules serving only as analytical markers. Therefore, their physiological relevance and predication to the *in vivo* drug–drug interactions are yet to be established. Colored, impure, unstable compounds and auto-fluorescent compounds (and/or metabolites) will interfere with the assay detection and need to be flagged. In some organizations, the fluorescent assay is used as a first filter followed by a confirmation using the LC/MS assay. The fluorescent assay is also practical to study time-dependent inhibition as kinetics are easily followed using the optical readout, provided that automation-compatible temperature control and/or reaction mixing can be properly addressed.

#### 5.15.3.7 Impact of Dimethyl Sulfoxide on Early Absorption, Distribution, Metabolism, and Excretion Analytics

In order to make compound logistics efficient and keep compound consumption to a minimum, scientists usually prefer to handle solutions rather than dry powders. The most common compound format for *in vitro* ADME studies is to start

**Table 4** Factors affecting ADME automation and analysis

| <i>Factors</i>               | <i>Impacts</i>                                      | <i>Potential assays/process</i>  | <i>Suggestions</i>   |
|------------------------------|---|--|--|
| DMSO (other solvents)        | Precision/accuracy                                  | Liquid handling for dilution process, kinetic solubility, CYP inhibition | Evaluation of solvent class specification  |
| DMSO                         | Fluorescence or LC/MS readout                       | CYP inhibition (inhibit enzyme & increase assay variability)             | Minimize DMSO concentration if possible<br><br>Try other solvents (e.g. acetonitrile (ACN), etc.)  |
| Purity or chemical stability | Almost all readouts by plate readers                | Solubility, PAMPA, CYP inhibition  | Utilize LC or other online purification<br><br>Verify purity prior to profiling assays   |
| Solubility in DMSO           | Accuracy for all assays                             | All  | Ensure compounds fully dissolved in DMSO<br>Include sonication for prep. if needed<br>Monitor precipitation by light scattering<br>Quantify the concentration of DMSO solution if needed |
| Solubility in assay media    | Accuracy for all assays                             | All  | Set up solubility surrogate in ADME assays<br>Properly define assay dynamic range<br><br>Perform assay in validated formulations   |
| Colored samples              | Accuracy for those using a laser or UV plate reader | Kinetic solubility or PAMPA  | Utilize LC/MS for colored samples  |

with a 10 mM DMSO solution. Most compounds are fully dissolved at that concentration and this 10 mM concentration in the DMSO stock solution is high enough to get to a reasonably low amount of solvent at the final compound concentration in most assays. It is advisable to check whether the compound is truly in solution at the beginning of the process. Nephelometry easily detects the presence of microcrystals that are not visible to the eye. DMSO solutions are hygroscopic and as much as 10% of water can be taken up, thus diluting the sample and changing the physical properties of the solution. As many of the ADME assay endpoints (e.g., solubility and  $IC_{50}$  for CYP inhibition, etc.) are back-calculated from 10 mM DMSO stock, it is preferable to confirm the true concentration of 10 mM stock in DMSO. In addition, all DMSO stocks should be properly sealed to avoid adsorption of water moisture. It has also been shown that freeze/thaw cycling can cause significant issues in solubility and stability of the compounds in solution. To minimize the possible stability issues, the DMSO stocks should be used as quickly as possible subsequent to preparation and stored at room temperature only. [Table 4](#) summarizes all factors that affect ADME automation and analysis, as discussed throughout the chapter.

Keeping the solvent concentration low enough is critical for some assays like CYP inhibition or metabolic clearance because even 1% of DMSO can significantly inhibit the enzyme activities (unpublished data). In the kinetic solubility assay, solubility of test compounds was drastically enhanced by a few orders of magnitude when the DMSO concentration increased from 0.5 to 8% (unpublished data). DMSO can also directly interfere with detection methods where its signals overlap or suppress those from test compounds. For example, one tends to be careful to use UV detection at wavelengths above 260 nm to avoid high background contributions from DMSO. The presence of DMSO also prevents the use of direct flow injection in MS analyzers.

#### 5.15.3.8 Laboratory Information Management System within Absorption, Distribution, Metabolism, and Excretion Laboratories

The most critical part of any automation system is the management of the sample and dataflow and the synchronization between the two. A proper laboratory information management system (LIMS) is designed to bring scientists the right

information at the right time, keep track of samples and plates, monitor assay QC, and secure data storage. As all of these are used daily, the system stability is critical. LIMS can be fully developed in-house or partially with external vendors. In the latter case, the integration with the in-house IT infrastructure and the corporate databases needs to be carefully planned. LIMS is at the interface between laboratory-automated workstations and corporate databases where the final results are stored and made available to the scientific community. It is important to balance the system capabilities versus complexity so that the LIMS to be established will be relatively simple to use. Manual data input must be kept to a minimum in order to minimize risk of human errors as well as to improve the employee's quality of life. Typically, sample vials or plates are registered using bar code readers and the information flow between the different modules does not require manual editing. While LIMS has proven effective in assuring data integrity and increasing productivity in the cascaded automated ADME assays in particular for the hub laboratories within large organizations, their flexibility in comparison to the standalone instruments needs further improvement. In general, process changes and assay modifications require planning and need to be validated and integrated into the LIMS before productive implementation. A well-designed LIMS should include mechanisms allowing scientists to introduce small changes on their own at least in the pilot study, without relying on the input of IT engineers, who should be responsible for more profound changes and system maintenance.

### 5.15.4 Outlook for Absorption, Distribution, Metabolism, and Excretion Automation

In the next decade, the demands for automated in vitro ADME assays will continue to grow in major pharmaceutical and biotech companies. More ADME assessments will be shifted from development to the early discovery phase. Additional in vitro ADME profiling assays will be developed to predict the in vivo behaviors of NCEs. The high-quality in vivo and in vitro ADME profiling data derived from drug-like libraries<sup>34</sup> allow for the development of robust predictive in silico models.<sup>59–61</sup> These require industry to reshape and enhance the ADME profiling strategy by consolidating and streamlining the existing automated assays to one or two major sites within an organization to improve efficiency and return on investment (ROI) in both assay development and automation aspects. Increasing efforts are dedicated to the quality and robustness of the automated in vitro ADME assays to warrant the integrity and predictivity (to the next tier of ADME assays) of the data derived.

As automation technologies approach maturity, the challenges to integrate and operate automated in vitro ADME assays will shift away from the liquid handling aspect to the streamlined logistics, high-end quantification, management of the mass data derived and the interface among the above components. Despite the attractive concept and substantial improvements made over the past years, large-scale automated ADME systems will be accepted only after they can demonstrate the flexibility to address the individual assay requirements, the realistic operational scheme for multiple assays, the user-friendly interface between different functional modules, and the capability to accommodate the addition of new assays in the future. Nonetheless, the individually integrated automated in vitro ADME assays, either the off-the-shelf systems or custom-built units, will still play critical roles due to the divergent user groups and assay requirements.

## Biographies

**Jianling Wang** is a Sr Research Investigator in Novartis institutes for Biomedical Research at Cambridge, MA. He obtained his PhD in biophysical chemistry in US. He extended his career as a postdoctoral fellow at AT&T Bell laboratories and joined Novartis (formerly Ciba-Geigy) in 1995. Recently, he has devoted to the novel techniques in HT ADME profiling tools that can significantly improve the existing drug discovery and development process. Currently, he is heading the early ADME program in Novartis at Cambridge and responsible for the development and/or implementation of a number of automated ADME assays such as HT-equilibrium solubility, artificial and Caco-2 permeability,  $pK_a$ , log P/D, chemical and metabolic stability, CYP-450 inhibition, and rate of dissolution in Cambridge, in support of the drug discovery research throughout the company.

**Bernard Faller** graduated as a biochemist from the University of Strasbourg, France where he went on to obtain a PhD in 1991. His initial interest was in inhibitors of neutrophil elastase for the treatment of respiratory diseases. In 1991 he moved to Ciba-Geigy as a postdoctoral fellow and focused on enzyme kinetics of aromatase inhibitors. In 1995 he became head of laboratory at Ciba-Geigy (and then Novartis) responsible for physicochemical characterization of iron-chelating agents. He then focused on biochemical characterization of fatty-acid binding proteins and in 1999 moved to central technologies and established the foundations of the Novartis early ADME profiling platform, which investigates molecular properties governing drug disposition. In 2001, he became technology program head for physicochemical profiling in the Preclinical Compound Profiling Unit. Today, he leads the Profiling Group Basel within Discovery Technologies Department of Novartis Institutes for BioMedical Research.

## 5.16.1 Terminology, pH Scale and $pK_a$ Definitions

This section introduces the terminology of pH and ionization, as well as equations for calculating the pH of solutions of weak acids and bases, and for plotting distribution of species profiles. It also introduces ampholytes and zwitterions, and the concept of protonation microconstants.

### 5.16.1.1 Solution Equilibria

This chapter is concerned only with acid–base ionizations of organic molecules involving the gain or loss of hydrogen ions; this is the main class of ionization that can occur in solution. The terminology for ionization processes developed over more than 100 years of solution chemistry, with the result that many different words and phrases have been used to describe the same things. Thus, hydrogen ions are written as  $H^+$ , but they are also referred to as protons. The acquisition of a hydrogen ion by a molecule is called protonation; the loss of a hydrogen ion is called deprotonation. Molecules that can gain or lose one proton may be called monobasic, though the word monoprotic is clearer; those that can gain or lose two are called diprotic, and so on. Molecules that can be protonated to create positively charged cations are called bases, and the protonated cations are called conjugate acids; molecules that can be deprotonated to create negatively charged anions are called acids, and the deprotonated anions are called conjugate bases. Some molecules can both gain and lose protons, existing as cations, anions, and unionized molecules, depending on pH. These are called either ampholytes or zwitterions; there is a tendency to use these terms interchangeably, but they represent distinctly different chemical forms, as explained later. The different forms of the molecule (unionized, ionized) are called species. Aside from mentioning these terms in this section, the remainder of the chapter will use a standardized set of terms that may be convenient for medicinal chemists, who are not on the whole concerned with the theories of solution chemistry but with the practical use of the numbers.

Ionizable drugs and drug-like molecules transform between their unionized and ionized states at pH values between 1 and 13. They are called weak acids and bases. The strength of the acid or base is denoted by its ionization constant,  $K_a$ . Besides ionization constant, this term has been called several other names in the literature, such as protonation constant, equilibrium constant, and dissociation constant. There is a related term, stability constant, which is equivalent to  $1/K_a$ .  $K_a$  is usually expressed logarithmically as a  $pK_a$  value, meaning  $-\log_{10} K_a$ ; where possible, the term  $pK_a$  will be used throughout this chapter.

### 5.16.1.2 Definition of pH

Because  $pK_a$  values are numbers on the pH scale, it is important to understand the concept of pH. The term pH is used to express the acidity of aqueous solutions, and was first introduced by Sørensen in 1909. In two important papers published simultaneously in German and French,<sup>1</sup> he compared the usefulness of the degree of acidity with that of the total acidity, proposed the hydrogen ion exponent, set up standard methods for the determination of hydrogen ion concentrations by both electrometric and calorimetric means, with a description of suitable buffers and indicators, and discussed in detail the application of pH measurements to enzymatic studies.

Sørensen introduced a potential of hydrogen  $P_H = -\log C_{H^+}$ , which was subsequently modified to pH. Modern usage recognizes the following terms that are used in the so-called operational scale,

$$pH = p a_H = -\log a_H = -\log_{10} [H^+] \gamma_+ \quad [1]$$

as well as a concentration pH, which is valid in solutions of constant ionic strength,

$$pC_{H^+} = -\log [H^+] = p[H^+] \quad [2]$$

In the above expressions,  $a_H$  represents the activity of the hydrogen ion,  $\gamma_+$  represents the activity coefficient, and  $C_{H^+}$  represents the concentration of hydrogen ions.

### 5.16.1.3 Concentration and Activity

Concentration expresses the amount of solute as a proportion of the amount of solvent or of solution, in units such as or moles per kilogram, moles per liter, grams per liter, etc. It is conventionally denoted by the use of square brackets in

equilibrium expressions, so  $[S]$  means the concentration of  $S$ . The concept of activity was developed to relate concentration to thermodynamic activity as measured by solubility, vapor pressure, or electrochemical potential. For rough calculations, or in very dilute solutions that approach zero ionic strength, activity is more or less equal to concentration, but at higher concentrations activity ( $a$ ) is shown as

$$a_S = [S]\gamma_S \quad [3]$$

where  $S$  denotes solute and  $\gamma_S$  is the activity coefficient of the solute. When considering molecules that ionize in solution, it would be easy to regard the ions as mere points of charge. However, this is not realistic, and the activity of ions is affected by a number of factors. One factor is temperature, and another is the dielectric of the solvent medium. Another significant factor is that hydrated ions occupy a volume of the solution in proportion to their size, and exclude other ions from this solution space. This competition for space inhibits the dissociation at high ionic strength. Ions self-associate to form ion pairs, so as the concentration of the solute increases, the activity of ions increases somewhat less. The equations to derive activity coefficients are complicated. However, two special cases are often used to avoid this complication. Results may be reported at zero ionic strength, where the activity coefficient is unity, though this introduces some practical difficulties. More usually, if the solute under study is dilute but the total ionic strength is high because an inert electrolyte has been added, then the activity coefficient of the solute ions will have a constant value at constant ionic strength.

Although the relationship between concentration and activity has been properly considered in fundamental work to establish the composition of primary buffer solutions, it is too complicated to apply in everyday measurement situations. For this reason, pH is measured and reported in units of activity. Values for  $p[H]$  can be obtained by measuring pH in solutions that have been adjusted to a constant ionic strength by adding a solution of an inert electrolyte; under these conditions, pH is proportional to  $p[H]$ . A constant ionic strength background of 0.15 M KCl is commonly used in the measurement of  $pK_a$  values. The ionic strength of this solution is close to that of human blood; KCl is used in preference to NaCl because high concentrations of sodium ions interfere with the response of the glass electrode used to measure pH.

#### 5.16.1.4 pH of Water

Liquid water is composed of molecules of  $H_2O$ . Interactions between the molecules lead to complex metastable structures within liquid water, and a solvated ionized molecule ( $H_9O_4^+$ ), as well as structures with additional solvation shells have been proposed.<sup>2</sup> It is too complicated to include these hydration structures in written acid–base reactions. The ionization of water can be expressed in terms of the hydrated hydrogen ion  $H_3O^+$ ,

or more simply using the proton  $H^+$  itself (even though  $H^+$  ions do not exist as free species in solution). Thus, the ionization of water can be written as

In terms of ionic activities an equation can be written containing the equilibrium constant  $K^o$ :

$$a_H a_{OH} = K^o a_{H_2O} \quad [6]$$

The activities of  $H^+$  and  $OH^-$  are proportional to their concentrations, but by convention the activity of  $H_2O$  is proportional to the mole fraction of water in the solution. Thus,  $a_{H_2O}$  is close to 1.000 in dilute solutions, and may be included in the equilibrium constant  $K_w^o$ :

$$a_H a_{OH} = [H^+]\gamma_+[OH^-]\gamma_- = K_w^o \quad [7]$$

If the activity coefficients are also included in the constant, the ionic product of water  $K_W$  can be derived:

$$[H^+][OH^-] = K_W \quad [8]$$

Values for  $K_w$  have been calculated from conductance data measured in water at varying temperatures and pressures,<sup>3</sup> and a value of  $10^{-13.997}$  (25 °C, 1 bar, zero ionic strength) is generally accepted.<sup>4</sup> The corresponding value of  $pK_w$  ( $-\log_{10} K_w$ ) is 13.997 (i.e. close to 14.0 under standard conditions). The concentration of  $H^+$  and  $OH^-$  must be equal when water dissociates. Therefore, if  $[H^+] = [OH^-]$ , and  $[H^+][OH^-] = 10^{-14}$  then  $[H^+]$  in pure water has a value of  $10^{-7}$ , and the pH ( $-\log_{10} 10^{-7}$ ) of pure water is 7.0 at 25 °C. In fact, the pH of water at 25 °C is usually about 5.5, because water in equilibrium with air becomes saturated with carbon dioxide, thus forming a dilute solution of carbonic acid.

Note that pH varies with temperature, especially for solutions at high pH. This is because temperature affects the activity coefficients involved in the calculation of  $K_w^0$  (eqn [7]). The values of  $pK_w$  vary from 14.96 at 0 °C to 13.26 at 50 °C.<sup>5</sup> Note also that the value of  $K_w$  varies as a function of ionic strength. The values of the  $pK_w$  of water at 25 °C vary between 13.997 at 0 mol L<sup>-1</sup> to 14.18 at 3.0 mol L<sup>-1</sup>.<sup>6,7</sup>

### 5.16.1.5 pH of Strong Acids and Bases

Acids are molecules that are not ionized at low pH, but which become negatively charged ions at higher pH because they lose one or more hydrogen ions to the solution. Bases are not ionized at high pH, but become positively charged ions at lower pH because they gain one or more hydrogen ions from the solution. HCl and KOH are examples of a strong acid and base, respectively, meaning that they are fully ionized in aqueous solution; their unionized forms would only exist in solution outside the range of the aqueous pH scale. These definitions are in accordance with Brønsted's concept that an acid is a species having a tendency to lose a proton.

The pH values of solutions of strong acids and bases in water can be easily calculated. In a solution of HCl of concentration  $C$  mol L<sup>-1</sup>, the following equations may be defined:

$$[Cl^-] = C \text{ (because dissociation is complete)} \quad [9]$$

$$[H^+][OH^-] = K_w = 10^{-14} \text{ (ionic product)} \quad [10]$$

$$[H^+] = [OH^-] + [Cl^-] \text{ (charge balance)} \quad [11]$$

Substituting for  $[Cl^-]$  from eqn [9] and  $[OH^-]$  from eqn [10] in eqn [11] gives the following equation, which has terms in units of  $[H^+]$  alone:

$$[H^+] = \frac{K_w}{[H^+]} + C \quad [12]$$

which reduces to a quadratic equation of the form

$$[H^+]^2 - C[H^+] - K_w = 0 \quad [13]$$

which could be solved for an explicit value of  $[H^+]$ .

However, consider a solution of  $10^{-1}$  M HCl in water. The concentration of hydrogen ions supplied by the dissociation of the HCl is  $10^{-1}$ , and the term  $K_w/[H^+]$  in eqn [12] is  $10^{-13}$ , which is very small compared with  $10^{-1}$  and can be neglected. Equation [12] therefore reduces to

$$[H^+] = C = 10^{-1} \quad [14]$$

which rearranges to

$$\text{pH} = -\log_{10}[H^+] = 1.00 \quad [15]$$

A similar series of equations can be defined for a strong base, such as a solution of KOH of  $C$  mol L<sup>-1</sup>:

$$[K^+] = C \text{ (because dissociation is complete)} \quad [16]$$

$$[H^+][OH^-] = K_w = 10^{-14} \text{ (ionic product)} \quad [17]$$

$$[H^+] + [K^+] = [OH^-] \text{ (charge balance)} \quad [18]$$

Substituting for  $[K^+]$  from eqn [16] and  $[OH^-]$  from eqn [17] in eqn [18] gives the following equation that has terms in units of  $[H^+]$  alone:

$$[H^+] + C = \frac{K_w}{[H^+]} \quad [19]$$

which reduces to a quadratic equation of the form

$$[H^+]^2 + C[H^+] - K_w = 0 \quad [20]$$

which can be solved for an explicit value of  $[H^+]$ .

However, in basic solutions the pH is higher than 7, and therefore  $[H^+]$  is less than  $10^{-7}$ . If  $C$  is much larger than  $10^{-7}$  then  $[H^+]^2$  is negligible compared with  $C$ , and eqn [19] could be simplified to

$$C[H^+] - K_w = 0 \quad [21]$$

which rearranges to

$$p[H] = pK_w + \log C = 14.00 + \log C \quad [22]$$

In a solution of  $10^{-1}$  M KOH in water,  $\log C = -1$ , therefore  $pH = 13$ .

Solutions of HCl and KOH supply points at the extremes of the pH scale. On this logarithmic scale, a 0.1 M solution of HCl would have a pH of 1, and a solution of 0.1 M KOH would have a pH of 13. While solutions exist whose pH values are outside the range 1 to 13, they are not normally encountered in the human body, and these values represent the limits of the pH scale for most aspects of medicinal chemistry.

#### 5.16.1.6 Weak Acids, Weak Bases, and Ionization Constants ( $pK_a$ )

Ionizable drugs are called weak acids and bases because their unionized forms exists in solution over at least a part of the pH range from about 1 to 13. A convenient nomenclature uses AH (and  $AH_2$ ,  $AH_3$ , etc.) to represent weak acids, B to represent weak bases, and XH to represent ampholytes and zwitterions.

Consider a monoprotic (i.e., singly ionizing) acid AH that dissociates according to

The term  $K_a$  is the ionization constant such that at equilibrium,

$$K_a = \frac{[A^-][H^+]}{[AH]} \quad [24]$$

The ionization of a monoprotic base B may be represented in a similar way:

and

$$K_a = \frac{[B][H^+]}{[BH^+]} \quad [26]$$

From the above equations, when  $[A^-] = [AH]$  or  $[B] = [BH^+]$ , then  $[H^+] = K_a$ . Therefore, for monoprotic compounds the  $pK_a$  ( $= -\log_{10} K_a$ ) is the pH at which equal concentrations of neutral and ionized forms of the sample are present in the solution.

Equations [24] and [26] can be written in the following form, which is frequently cited as the Henderson-Hasselbalch equation:

$$pH = pK_a - \log \frac{[AH]}{[A]} \quad [27]$$

In a series of acids with increasing  $pK_a$  values, those with higher  $pK_a$  values are said to be weaker, while acids with lower  $pK_a$  values are stronger. In contrast, bases with higher  $pK_a$  values are stronger, while bases with lower  $pK_a$  values are weaker.

As with pH values,  $pK_a$  values vary with temperature and ionic strength, so it is helpful if these conditions are cited along with the  $pK_a$  value. Conditions of 25 °C and 0.15 M ionic strength are widely used for drugs. It is also important to know whether the  $pK_a$  refers to an acidic or basic group.

#### 5.16.1.7 Distribution of Species

The  $pK_a$  and the type of compound (acid or base) provide a snapshot of the acid-base behavior of a molecule, and may be visualized graphically. For example, ibuprofen is a carboxylic acid with a  $pK_a$  of 4.35. The relative concentration of unionized and ionized species as a function of pH may be plotted as a distribution of species graph (Figure 1). The graph consists of two lines plotted on the same axes. While these graphs conventionally plot the relative concentrations as percentages, they are based on the following equations. At any pH, the fraction of compound in the form  $A^-$  is expressed as

$$[A^-] = \frac{K_a}{[H^+] + K_a} \quad [28]$$

and the fraction in the form AH is expressed as

$$[AH] = \frac{[H^+]}{[H^+] + K_a} \quad [29]$$

Figure 2 shows the distribution of species graph for carvedilol, a base with a  $pK_a$  of 7.97. The fraction in the form B is expressed as

$$[B] = \frac{K_a}{[H^+] + K_a} \quad [30]$$

and the fraction in the form  $BH^+$  is expressed as

$$[BH^+] = \frac{[H^+]}{[H^+] + K_a} \quad [31]$$

#### 5.16.1.8 Ionization Equations for Samples with up to Six $pK_a$ Values

Table 1 shows a general scheme for describing the ionization of compounds with up to six  $pK_a$  values, together with equations for plotting the distribution of species. The equations in the table, as well as those used to draw the graphs and profiles of lipophilicity and solubility appearing in this chapter, are derived from principles of mass balance and

**Figure 1** Distribution of species of ibuprofen, an acid with  $pK_a = 4.35$ . A total of 18% of ibuprofen is in unionized form at pH 5, which is the pH in the duodenum and jejunum in the fed state.

**Figure 2** Distribution of species of carvedilol, a base with  $pK_a = 7.97$ . A total of 6.3% of carvedilol is in unionized form at pH 6.8, which is the pH in the duodenum and jejunum in the fasted state.

charge balance. Each class of molecule (monoprotic acid, diprotic acid, etc.) has its own set of equations for each type of graph. The general principles of mass balance and charge balance are explained in Butler's book on ionic equilibrium,<sup>8</sup> which guides readers in the derivation of new equations. Another source is Albert and Serjeant's book on the determination of ionization constants.<sup>9</sup> Unfortunately, the latter book is out of print, but as it provides an excellent introduction to the subject, it is worth trying to obtain a copy.

#### 5.16.1.9 Ampholytes and Zwitterions

Ampholytes and zwitterions are molecules with at least two  $pK_a$  values, at least one of which is acidic and at least one is basic. Figures 3 and 4 show the distribution of species graph for clioquinol (an ampholyte) and ampicillin (a zwitterion). Both molecules have two  $pK_a$  values. In clioquinol, the base  $pK_a$  is lower than the acid  $pK_a$ , so at pH values between the  $pK_a$  values, the molecule is neutral. However, the acid  $pK_a$  for ampicillin is lower than the base  $pK_a$ , and the molecule is charged across the entire pH scale. Ampholytes are most lipophilic and least soluble in their neutral form. However, zwitterions are always charged; they are rarely lipophilic, and they are often soluble in water at any pH. The following equations are used for the ionization and distribution of species of diprotic ampholytes and zwitterions. Because there are two ionizations, the ionization constants must be labeled  $K_{a1}$  and  $K_{a2}$ .

$$K_{a1} = \frac{[XH][H^+]}{[XH_2^+]} \quad [33]$$

and

$$K_{a2} = \frac{[X^-][H^+]}{[XH]} \quad [35]$$

The distribution of species equations for diprotic ampholytes and zwitterions are

$$[X^-] = \frac{K_{a1}K_{a2}}{[H^+]^2 + K_{a1}[H^+] + K_{a1}K_{a2}} \quad [36]$$

**Table 1** General ionization scheme

| Equation                    | $pK_a$ order | Ionization constant                 | Plot versus pH for distribution of species graph for species [X], [XH], etc.  |              |          |                   |         |          |

**Figure 3** Distribution of species of clioquinol, an ampholyte with base  $pK_a = 2.96$  and acid  $pK_a = 7.60$ . Clioquinol is unionized at intestinal pH.

**Figure 4** Distribution of species of ampicillin, a zwitterion with base  $pK_a = 7.14$  and acid  $pK_a = 2.55$ . Ampicillin is ionized across the entire pH range.

$$[\text{XH}] = \frac{K_{a1}[\text{H}^+]}{[\text{H}^+]^2 + K_{a1}[\text{H}^+] + K_{a1}K_{a2}} \quad [37]$$

$$[\text{XH}_2^+] = \frac{[\text{H}^+]^2}{[\text{H}^+]^2 + K_{a1}[\text{H}^+] + K_{a1}K_{a2}} \quad [38]$$

Selected ampholytes and zwitterions are listed in [Table 2](#). Diprotic molecules with one acidic and one basic  $pK_a$  that are far apart behave unequivocally as ampholytes or zwitterions. However, those whose  $pK_a$  values are separated by less than about three units may exhibit both zwitterionic and ampholytic properties. Note that the species  $\text{XH}$  in the equations above represents a composite of the neutral species  $\text{XH}^0$  and the charged species  $\text{XH}^\pm$ , which can both exist at the same time. To properly describe the ionization of diprotic ampholytes and zwitterions with close  $pK_a$  values, a more detailed picture of the ionization equilibria is required. This must include microconstants, which are the  $pK_a$  values for the ionization of the microspecies (note the lower-case  $k$  in  $pK_a$ ). This is illustrated in [Figure 5](#) for the ionization of a diprotic ampholyte or zwitterion. (Molecules with three or more  $pK_a$  values including at least one acidic  $pK_a$  that is lower than a basic  $pK_a$  may also be evaluated in terms of microconstants. Examples include tetracycline (discussed in [Section 5.16.2.2.2](#)) and cetirizine (discussed in [Section 5.16.3.4](#)).

**Table 2**  $pK_a$  values of ampholytes and zwitterions. A or B written after each  $pK_a$  denotes whether the ionizable group is acidic or basic. The term  $A - B$  is the difference between the nearest acidic and basic  $pK_a$  values. Compounds for which  $A - B$  is less than 3 are shown in bold, as they are expected to exhibit both ampholytic or zwitterionic properties, depending on the solution conditions

#### 5.16.1.10 The Curious Behavior of Zwitterions

The ratio  $K_z$  between the concentrations of  $XH^0$  and  $XH^\pm$  changes with the solution conditions. Figure 6 shows that the concentration of charged species of labetalol ( $pK_a = 9.36$  (base), 7.41 (acid)) diminishes with increasing solvent content of aqueous solution.<sup>10</sup> This is because the base  $pK_a$  is lowered in the presence of solvent and the acid  $pK_a$  is raised. Together these changes make the molecule more ampholytic with increasing solvent. This observation could explain the relatively high bioavailability of some zwitterions, as the dielectric constant in water–solvent mixtures is much closer to the value at water–membrane interfaces (about 32) than to the value in water (about 78).

**Figure 5** Ionization of microspecies for ampholytes and zwitterions. If the acid  $pK_a$  is much lower than the base  $pK_a$ , the zwitterionic microspecies Z will predominate. If the base  $pK_a$  is much lower than the acid  $pK_a$ , the ampholytic microspecies A will predominate. If the  $pK_a$  values are close together, A and Z will coexist. The macro-species XH is a mixture of the Z and A microspecies.

**Figure 6** Zwitterion and neutral distribution of species for labetalol. The zwitterionic species predominates in water. In the presence of methanol, the acid  $pK_a$  rises and the base  $pK_a$  falls, causing labetalol to convert to the ampholytic species with increasing concentration of methanol.

Some properties of zwitterions are normally measured in terms of the composite species XH. However, the form  $XH^0$  is much more lipophilic than  $XH^\pm$ . A value of  $\log P(XH)$  for labetalol has been measured at 1.48, from which a  $\log P(XH^0)$  of 2.70 has been calculated using equations derived from microconstants.<sup>10</sup>

Ciprofloxacin is a zwitterion with an acidic  $pK_a$  of 6.16 and a basic  $pK_a$  of 8.62.<sup>11</sup> Considering only its charge, the zwitterionic species  $XH^\pm$  might be expected to be more soluble than  $XH_2^+$  or  $X^-$ . However, ciprofloxacin can precipitate from solutions whose pH lies between its  $pK_a$  values. This clearly occurs in pH-metric titrations to measure solubility of ciprofloxacin, whose solubility–pH profile is shown in [Figure 15](#). Presumably it is the ampholyte form  $XH^0$  that precipitates, suggesting that once a precipitate has formed a few crystals, the precipitated state is energetically more favored than the dissolved zwitterionic state.

### 5.16.2 Ionizable Groups

This section reviews the most common ionizable groups, and the structural factors that influence  $pK_a$  values.

### 5.16.2.1 The Number of Ionizable Drugs

To evaluate their ionization properties, compounds can be divided into several classes. Some compounds are neutral (nonionizable); they will not be discussed in this chapter. Most ionizable compounds are acids or bases with one, two or more ionizable groups. Another class includes ampholytes and zwitterions, which are molecules with at least one acidic and one basic group. Finally, compounds such as quaternary ammonium salts contain species that are always charged; they rarely make successful drugs, so will not be discussed in this chapter. A study published in 1988 suggested that 75% of drugs at the time were bases, 20% were acids, and only 5% were nonionizable.<sup>12</sup> A search of the World Drug Index for 1999 suggested that 63% of the 51 600 listed drugs were ionizable, of which 67% were bases, 15% were acids, and 18% were ampholytes.<sup>10</sup> While it is difficult to ascertain the reliability of either set of figures, it is clear that most drug molecules are ionizable, and that most ionizable drugs are bases.

### 5.16.2.2 The Most Common Ionizable Groups

Ionization in drugs occurs at well-recognized ionizable groups. **Figures 7–13** give the structures of molecules containing the most common ionizable groups that are found in drugs. Some structures are simple organic molecules; others are drugs.

#### 5.16.2.2.1 Carboxylic acids

The carboxylic acid group is the most common type of acidic group found in drugs. Their  $pK_a$  values typically occur between 3 and 5 for monobasic acids, unless other structural features have a significant effect on the ionization. Of the monobasic carboxylic acids in **Figure 7**, two have  $pK_a$  values outside this range. The  $pK_a$  of trifluoroacetic acid is very low because the  $CF_3$  group is strongly electron-withdrawing; this property tends to lower the  $pK_a$  values of both acidic and basic groups. Other properties that modify  $pK_a$  values by electrostatic and inductive effects are listed in **Table 3**. The  $pK_a$  of flumequine is higher than typical carboxylic acids (6.27) because the proton is stabilized by hydrogen bonding to the adjacent  $=O$  group, and is held on the molecule until relatively high pH. Carboxylic acids are larger than hydroxyl or primary amino groups, and are therefore more susceptible to steric interactions of this type.

The  $pK_a$  values of some dicarboxylic acids are shown in **Figure 7**. For diprotic acids, it is the first  $pK_a$  (that which describes the transition between the neutral molecule and the species with a charge of  $-1$ ) that has the major influence on  $pK_a$ -dependent properties of pharmacokinetic interest such as lipophilicity and solubility.

Molecules with two identical ionizable groups tend to have two well-separated  $pK_a$  values. This can be illustrated by the ionization of fumaric acid, a dibasic carboxylic acid:

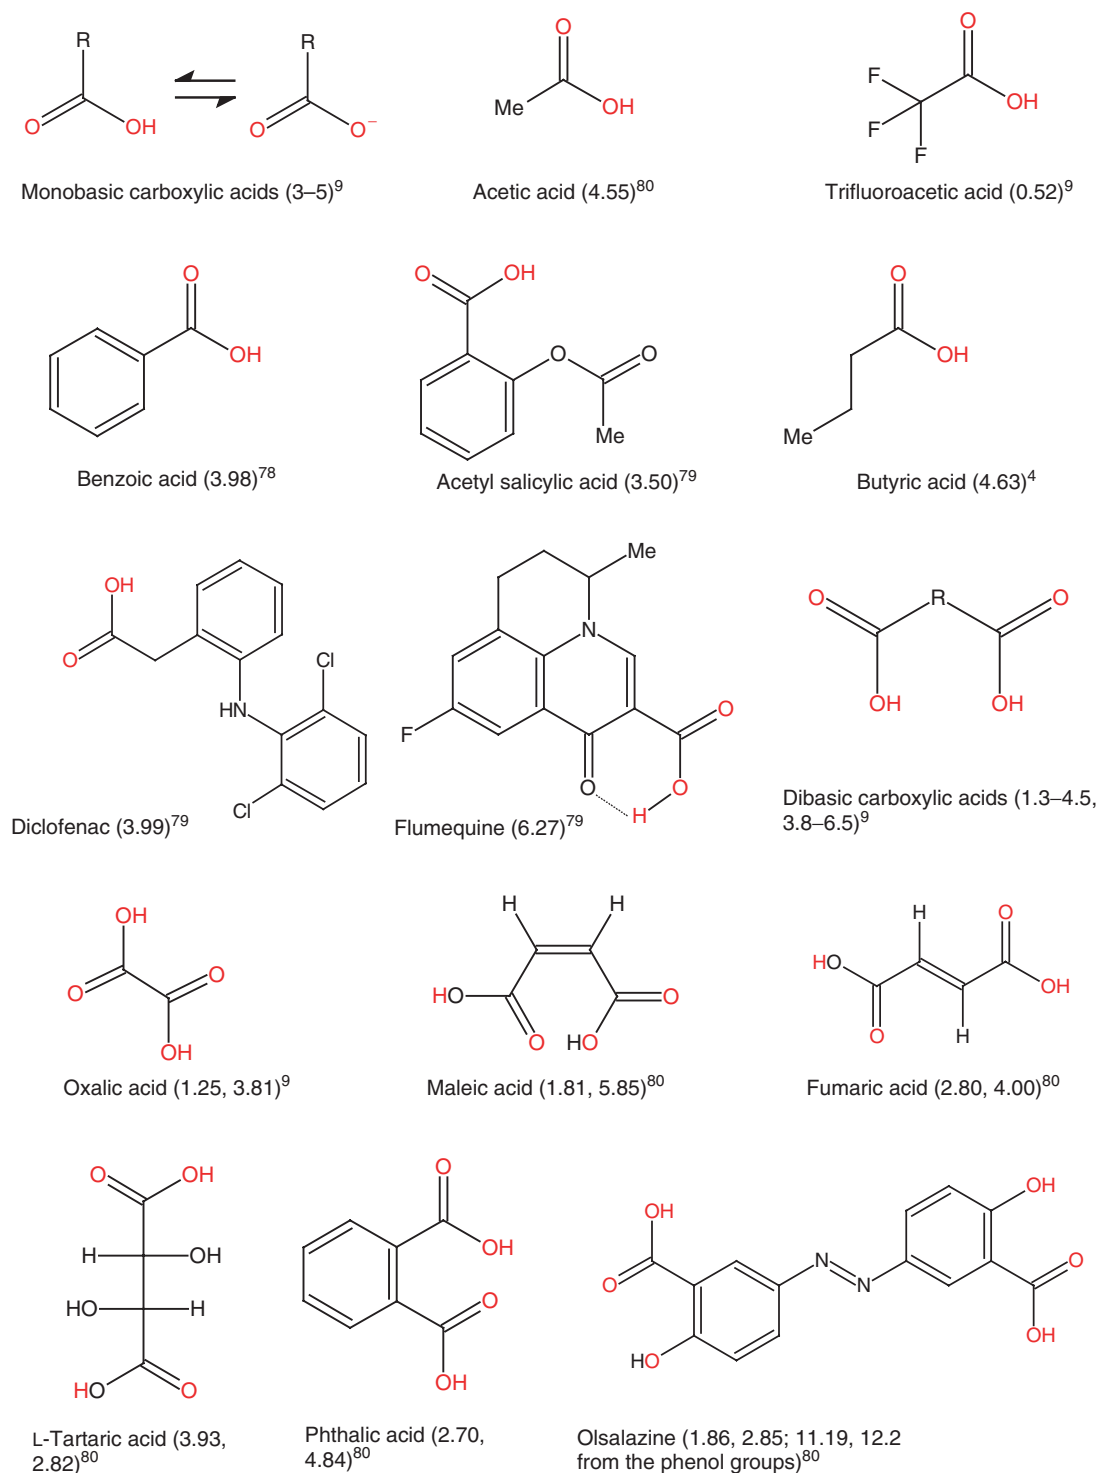

In the first stage of ionization, the equilibrium shown in eqn [39] can lose a proton from two positions, but it can add a proton from only one position. In the second stage of ionization shown in eqn [40], it can lose a proton from only one position but it can add to two positions. Thus equilibrium [39] is therefore statistically favored over equilibrium [40], with the result that the  $pK_a$  is lower for this ionization. The  $pK_a$  difference is further enhanced by electrostatic effects, because the negatively charged species in eqn [39] tends to repel the negatively charged hydroxide ions that are required to raise the pH for the second ionization.

The  $pK_a$  values of maleic acid (*cis*-isomer) are more widely spaced than those of fumaric acid (*trans*-isomer) because the proton involved in the higher  $pK_a$  is stabilized by hydrogen bonding; for steric reasons, this cannot occur in fumaric acid, whose  $pK_a$  values are therefore much closer together.

The carboxylate  $pK_a$  values of olsalazine are lower than expected, while the phenol  $pK_a$  values are higher. This may be because after the loss of the protons, stable hydrogen-bonded structures form between the phenol  $-OH$  groups and the carboxylate  $=O$ , which also serve to make it more difficult to remove the protons from the phenols.

Sometimes, large symmetrical molecules with identical ionizable groups that are well separated lose two protons simultaneously. The author has observed several instances of this behavior, but unfortunately not for any whose structures are in the public domain. However, this behavior has been reported for a dye, *meso*-tetra (3-hydroxyphenyl)porphine (see **Figure 13**), which appears to lose two protons at a common  $pK_a$ .<sup>13</sup>

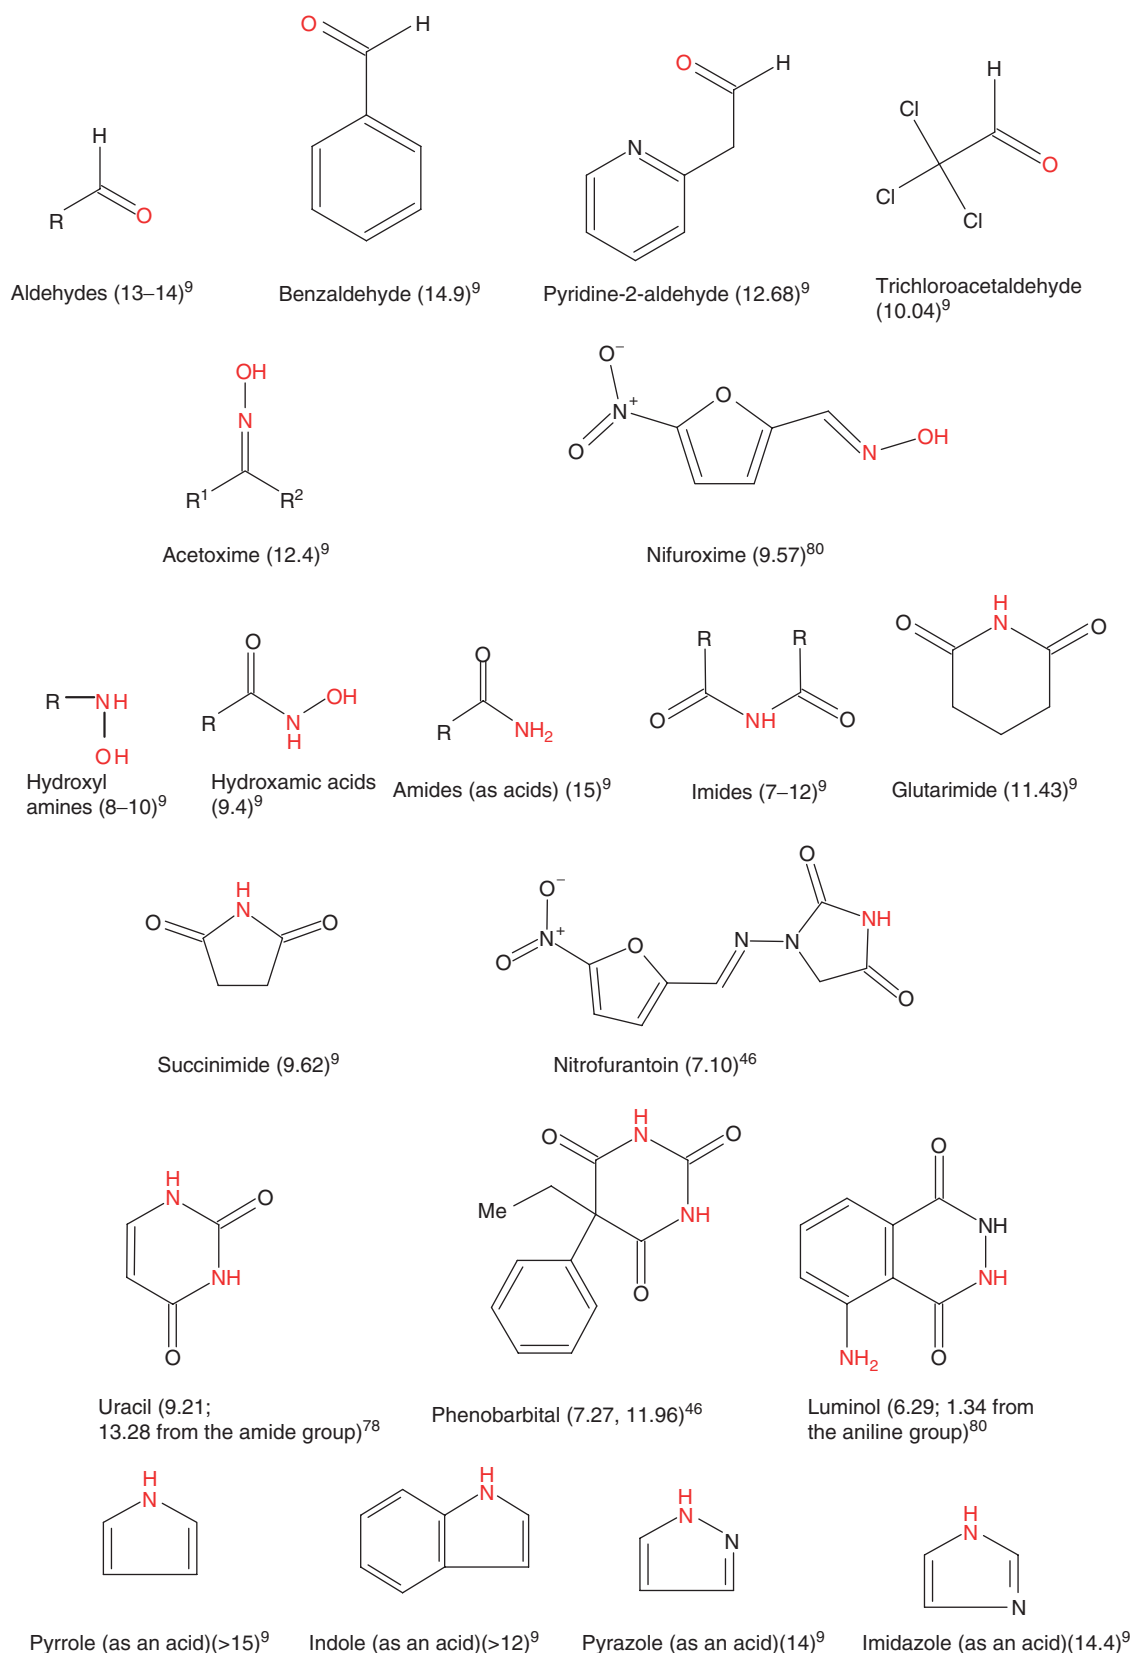

**Figure 7** Structures of ionizable molecules: carboxylic acids. Here and in **Figures 8–13**, red atoms denote acidic groups, and blue atoms indicate basic groups ( $pK_a$  values are given in parentheses).

**Figure 8** Structures of ionizable molecules: phenols, alcohols, and enols.

**Figure 9** Structures of ionizable molecules: other acidic groups.

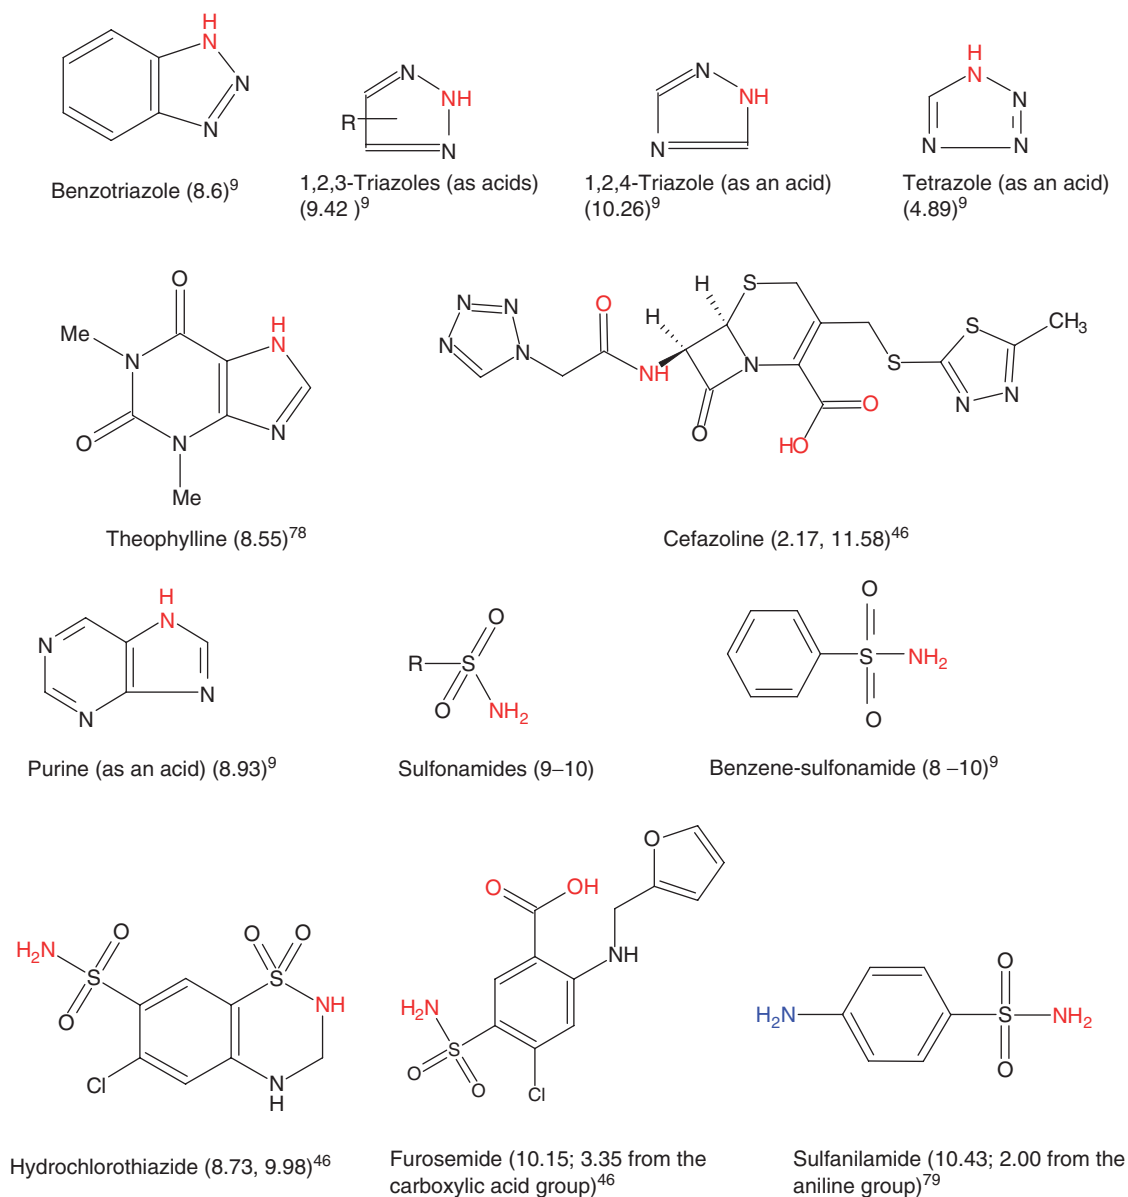

Figure 9 Continued

#### 5.16.2.2.2 Phenols, alcohols, and other molecules with –OH groups

The –OH group that occurs in phenols and alcohols is the other common acidic ionizable group found in drugs. While the  $pK_a$  of phenol itself is 9.74, the  $pK_a$  values of substituted and heterocyclic phenols are typically between 7 and 10.5 (see Figure 8). In contrast to phenols, the  $pK_a$  values of aliphatic alcohols are greater than 13 unless lowered by the effect of substituents. The  $pK_a$  of phenol is so much lower than that of alcohols because of the electron-withdrawing effect of the benzene ring coupled with the negative mesomeric effect in the anion. The phenol anion exists in equilibrium between two forms, as shown in Figure 8. The  $pK_a$  of 4-nitrophenol (6.9) is much lower than that of phenol because of the combined electron-withdrawing and mesomeric effects of the nitro group in the *para* position. A similar lowering of  $pK_a$  occurs in 4-nitrocatechol. The  $pK_a$  of 4-chlorophenol (9.24) is closer to that of phenol than the  $pK_a$  of 3-chlorophenol (8.81), because in 4-chlorophenol a positive mesomeric effect via the *para* substitution opposes the electron-withdrawing tendency of the Cl atom.

Hexachlorophene has two phenol groups, both with unusual  $pK_a$  values. With six Cl substituents, the molecule is strongly electron-withdrawing, leading to the very low  $pK_a$  (3.9) for the transition between neutral and ionized. Once the

**Figure 9** Continued

first proton has been lost, however, it is likely that the second phenol forms a stable hydrogen bond with the first phenol in its ionized keto form, and the molecule loses the second proton only at very high pH, as denoted by the  $pK_a$  of 11.4.

While aliphatic alcohol  $pK_a$  values are very high, the  $pK_a$  values of  $-OH$  groups can be lower as a result of substitution. The  $-OH$  groups that result from keto–enol tautomerism usually have quite low  $pK_a$  values, as seen in warfarin (4.9), piroxicam (5.3), and ascorbic acid (4.0).

Tetracycline has three  $pK_a$  values, and it is known that two are acidic and one is basic. While the basic amine is easily identified, the acidic  $pK_a$  values are difficult to assign by casual inspection of the structure. Stevens *et al.* in 1956 measured  $pK_a$  values of tetracycline, substituted tetracyclines, and substructures of tetracycline, and deduced that the  $pK_a$  values could be assigned as shown in [Figure 8](#), where A and C are acidic functions, and B is a base.<sup>14</sup> Nuclear magnetic resonance (NMR) spectroscopy has since been used to determine a protonation scheme for tetracycline, showing the possibility of eight microspecies, and determining microconstants for each equilibrium.<sup>15</sup>

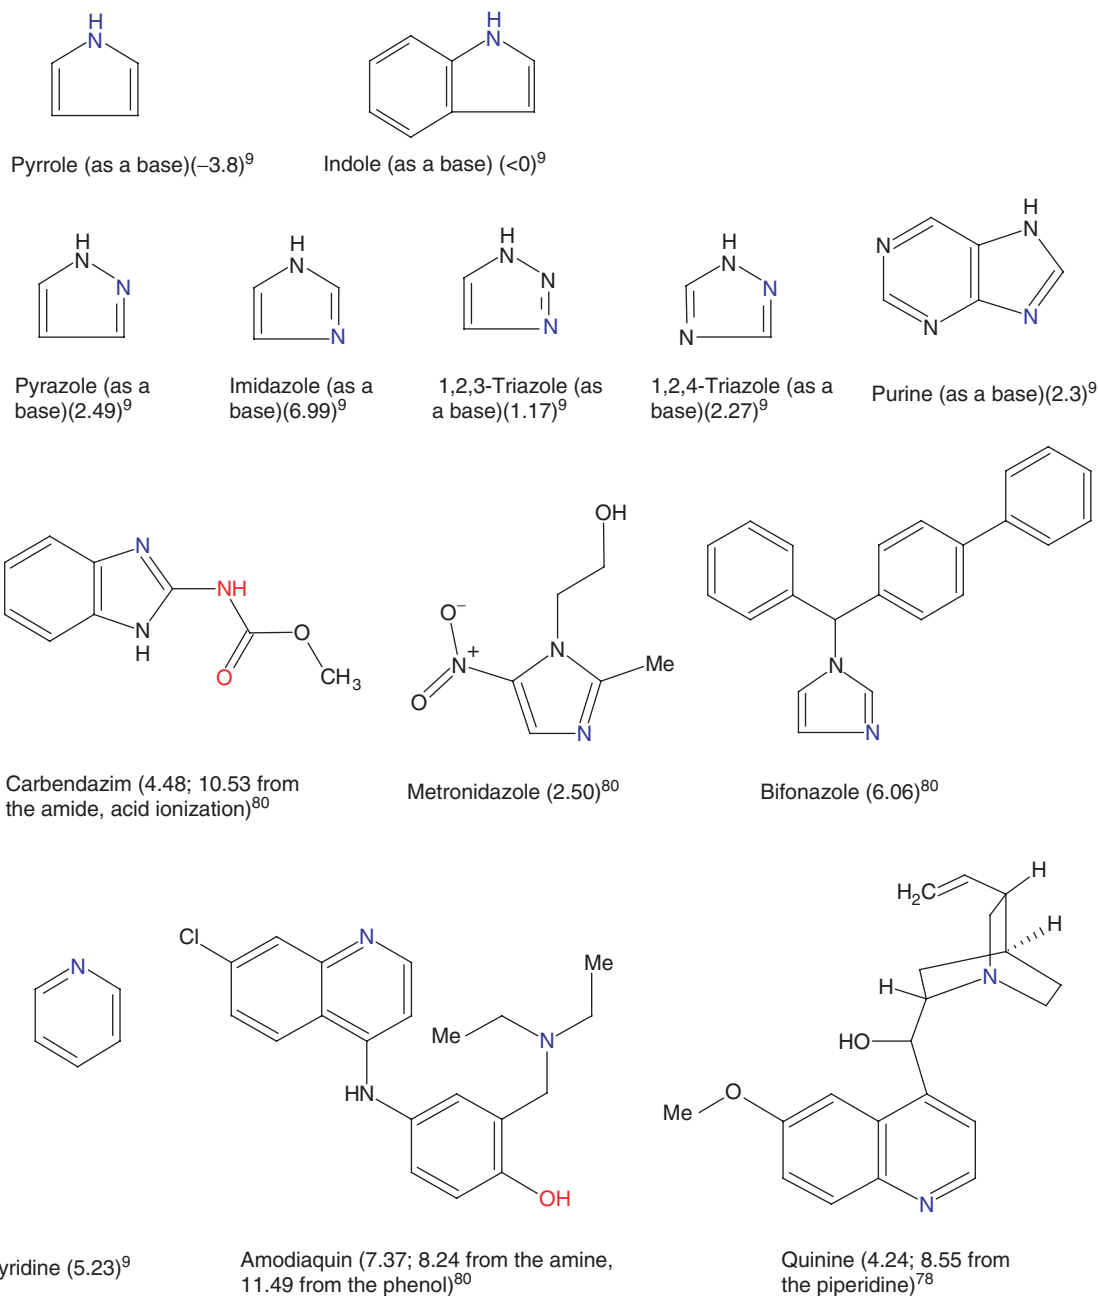

Figure 10 Continued

**Figure 11** Structures of ionizable molecules: aromatic and heteroaromatic bases.

#### 5.16.2.2.3 Other acidic ionizable groups

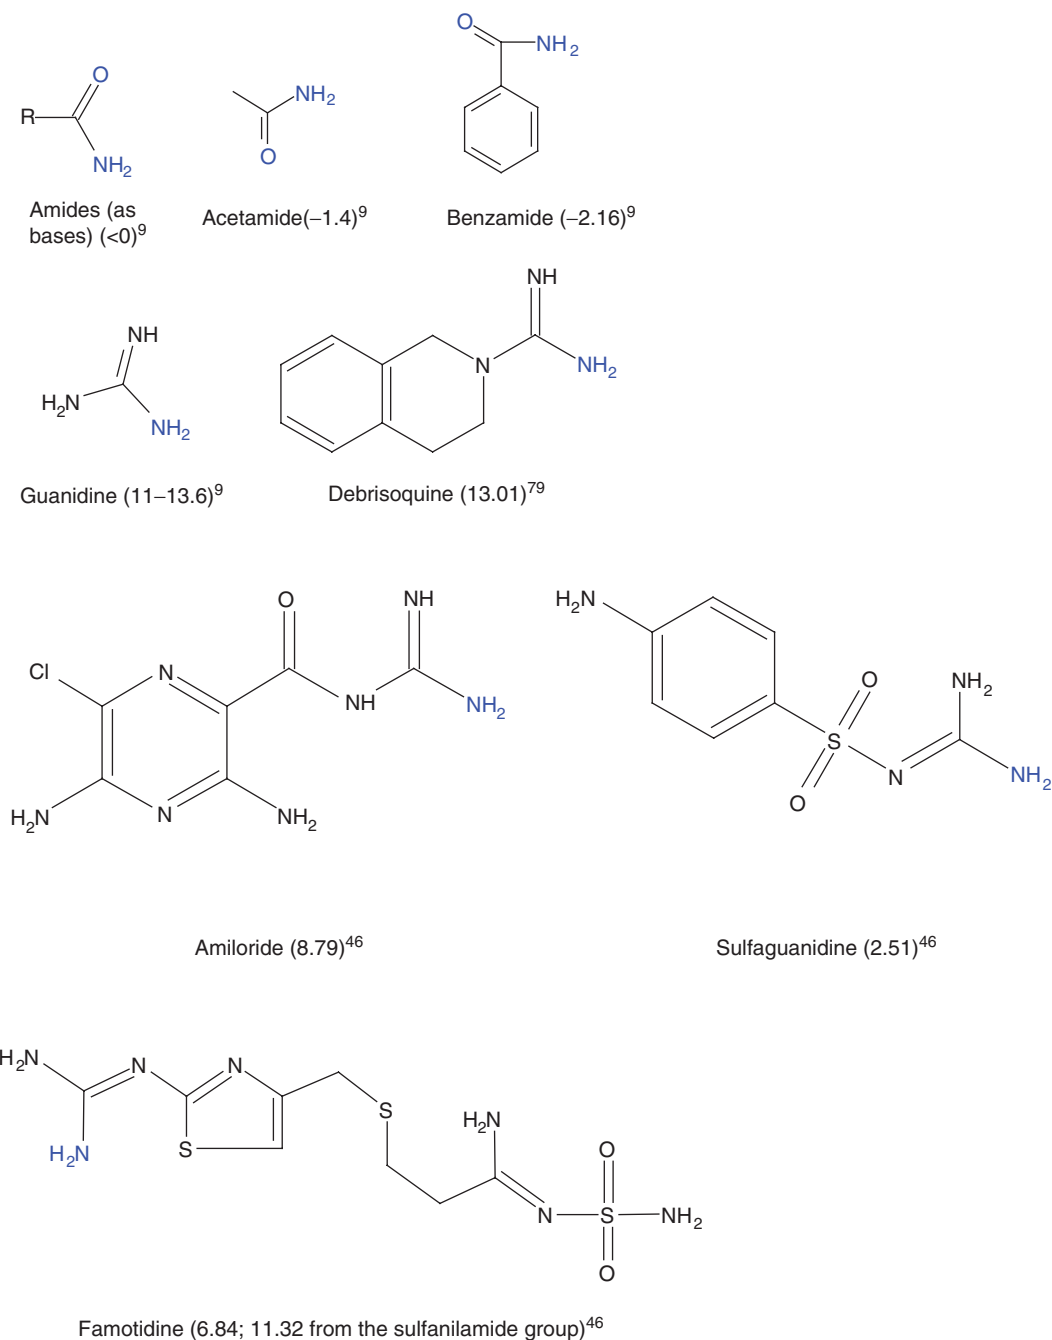

The structures shown in [Figure 9](#) illustrate aldehydes and other acidic ionizable groups, including molecules in which the dissociable proton is attached to nitrogen, sulfur, and phosphorus-containing groups. The pK<sub>a</sub> values of aldehydes are generally above 13, but substitution of electron-withdrawing groups can lower them, as shown by the pK<sub>a</sub> of trichloroacetaldehyde (10.1). There are many acidic drugs in which the dissociable proton is attached to a nitrogen atom, including oximes, hydroxylamines, sulfonamides, and rings containing N atoms. Some acidic nitrogen-containing groups can also be bases at different parts of the pH scale. For example, purine is an acid with a pK<sub>a</sub> of 9 and a base with a pK<sub>a</sub> of 2.3; and triazole is an acid with a pK<sub>a</sub> of 10.3 and base with a pK<sub>a</sub> of 2.3. Phenylbutazone is a carbon acid. Its pK<sub>a</sub> of 4.2 corresponds with the loss of a proton from the carbon atom between the two =O groups.

Papaverine (6.45)<sup>46</sup>Clioquinol (2.81; 7.49 from the phenol)<sup>80</sup>Pyrimidine (1.23)<sup>9</sup>1,3-Diaminobenzene (5.11, 2.5)<sup>9</sup>Aniline (4.87)<sup>9</sup>Procaine (2.29; 9.04 from the amine)<sup>78</sup>Tetracaine (2.39; 8.49 from the amine group)<sup>78</sup>Benzidine (4.65, 3.43)<sup>9</sup>Benzocaine (2.39)<sup>78</sup>**Figure 11** Continued

#### 5.16.2.2.4 Aliphatic bases

This class includes aliphatic amines or saturated nitrogen-containing rings such as piperazine, pyrrolidine, or morpholine (see [Figure 10](#)). Most aliphatic bases are quite strong, typically with  $pK_a$  values of 9 and above. When incorporated into drugs, steps to reduce the  $pK_a$  values using electron-withdrawing substituents may be required, otherwise the molecules will be fully ionized at the pH of body tissues, and thus will be poorly permeable by passive diffusion.<sup>16</sup>

**Figure 12** Structures of ionizable molecules: amides and guanidines.

#### 5.16.2.2.5 Aromatic and heteroaromatic bases

The  $pK_a$  values of aromatic nitrogen bases are generally much lower than those of aliphatic bases (see [Figure 11](#)). When incorporated in drugs, they are often unionized at body pH, causing molecules to be poorly water-soluble. Aniline ( $4.87$ ) is a much weaker base than its saturated analog cyclohexylamine ( $10.64$ ) because of resonance in the neutral molecule that is not possible in the ion, as shown in [Figure 11](#). Additional base weakening occurs in aniline because of the electron-withdrawing effect of the benzene ring, which adds to the effect of the resonance. The  $pK_a$  values of anilines that are substituted in the *ortho* position are generally higher than expected because their bulk twists the amino group out of the plane of the benzene ring, thus interfering with the resonance. *Meta*-substituted anilines show similar

R = alkyl.

inductive effects to those seen with carboxylic acids, which are reinforced by mesomeric effects in *para*-substituted anilines. The effects of substituents in pyridines is similar to the effect in anilines. In contrast to aniline, resonance in the cationic species occurs in the five-membered imidazole ring (6.95), which is a much stronger base than pyrrole (<0).

#### 5.16.2.2.6 Amides and guanidines

Amides commonly occur in drugs, and have both basic and acidic possibilities (see Figure 12). However, their basic  $pK_a$  values are very low, and their acidic  $pK_a$  values are very high, and, unless affected by substitution, they are always unionized at physiological pH. Guanidine is a strong base with a  $pK_a > 13$ , and is therefore always ionized at physiological pH. Guanidine groups are sometimes attached to molecules to improve their solubility. As explained below, their  $pK_a$  values can change significantly in response to substitution.

#### 5.16.2.3 Structural Factors that Modify $pK_a$ Values

The  $pK_a$  values of ionizable groups are influenced by other structural factors in the molecule, as illustrated in Table 3. They comprise inductive, electrostatic, and electron delocalization (mesomeric) effects, together with contributions from hydrogen bonding, conformational differences, and steric factors.

Electrical work is required to remove a proton from an acidic center and transfer it to a solvent molecule, or to remove a proton from a solvent molecule and transfer it to a basic center. The amount of work is influenced by the locations and distributions of dipoles and electrical charges. The inductive effects of charge are transmitted through bonds in the molecule, while the electrostatic effects of charge operate across the low dielectric cavity provided by the solute or through the solvent. Inductive effects would be expected to remain more or less constant in *cis*- and *trans*-isomers, with the major difference in  $pK_a$  values arising from differences in electrostatic field effects, but because inductive and electrostatic effects operate in similar directions, it is difficult to consider them separately.

If a substituent withdraws electrons, and therefore reduces the electron density in other parts of the molecule, it has a negative inductive effect. For example, the electrons forming the C–F bonds in trifluoroacetic acid are displaced toward the F atoms, making the C atom more electron-deficient than an ordinary methyl group. In turn, the carbonyl oxygen atoms are more electron-deficient, making it easier for a proton to be removed from the unionized acid. The consequence is that the  $pK_a$  of trifluoroacetic acid is significantly lower (0.32) than the  $pK_a$  of acetic acid (4.54). Electron-withdrawing groups make acids stronger and bases weaker.

If a substituent donates electrons, it increases the energy density at the ionizable group, making it harder for the group to become deprotonated. For example, the  $-C(CH_3)_3$  group donates electrons, raising the  $pK_a$  of isobutyl acetic acid to 4.83. Electron-donating groups make acids weaker and bases stronger.

Mesomeric effects result from  $\pi$ -electron delocalization, and contribute significantly to changes in the strength of acids and bases caused by remote substituents, especially via double bonds in conjugation with the ionizable center, including *ortho* or *para* (but not *meta*) substituents in aromatic or heteroaromatic systems. Large free energy differences can result from charge delocalization, so that acids or bases may become much stronger or weaker than would otherwise be expected. Mesomeric effects may enhance or oppose inductive effects. Charge delocalization leads to the high basic  $pK_a$  of guanidine (> 13), though  $pK_a$  values of substituted guanidines can be appreciably lower because of the electron-withdrawing effects of substituents (8.79 for amiloride, 2.51 for sulfaguanidine).

### 5.16.3 Ionization and Drugs

Over 700 publications since the first edition of *Comprehensive Medicinal Chemistry* in 1989 have mentioned  $pK_a$ , ionization constants, or related properties in connection with drugs. This section reviews a selection of these publications to cover the most popular topics, including drug–receptor binding, ionization and absorption, macromolecules and NMR. It also cites publications with compilations of  $pK_a$  values.

#### 5.16.3.1 Drug–Receptor Binding

The comparison between the ionization state and the binding properties on brain membrane receptors of myo-inositol 1,4,5-trisphosphate (see [Figure 13](#)) has been studied by pH-metric titration, leading to the conclusion that the biologically active species may be either the monoprotonated or the fully deprotonated trisphosphate.<sup>17</sup>

It has been shown that the binding of sulpiride (see [Figure 13](#)) to  $D_2$  dopamine receptors in the bovine brain is highly pH-dependent.<sup>18</sup> It is thought that the negatively charged sulpiride ion binds with an ionized residue at the active site. Similar behavior has been observed for other substituted benzamide drugs.<sup>19</sup>

In a study of the design, synthesis, and biological activity of a series of high-affinity basic ligands for the cholecystokinin-B receptor, the compounds (which incorporated a piperidin-2-yl or a homopiperidin-2-yl group attached to C-5 of a benzodiazepine core structure) had significantly higher  $pK_a$  values than previously reported antagonists based on 5-amino-1,4-benzodiazepines (e.g., 9.48 versus 7.1). In view of their high  $pK_a$  values, significant concentrations of ionized species would exist at lower pH, and it is thought that they bind to the CCK-B receptor in their protonated form.<sup>20</sup>

The binding of lidocaine (a base with  $pK_a = 7.95$  – see [Figure 10](#)) and homologs to specific sites associated with the sodium channel were investigated. The lidocaine homologs differed in the length of the link between the arylamide and amine domains of the molecule and in the number of carbons attached to the terminal amine. Drug affinity was measured with a radio-ligand binding assay, and freshly isolated cardiac myocytes. Optimal binding was obtained when the link between the arylamide and amine domains was two carbons in length. The affinity of the drug for the receptor was optimal with four or more amino-terminal carbons; the precise arrangement of the carbons was not important. Each of the amino-terminal carbons independently contributed 1.26 kJ of free energy of binding, suggesting that the carbons dissolve in a hydrophobic pocket.<sup>21</sup>

To determine the binding site of quinine (a base with two  $pK_a$  values, 8.55 and 4.24, see [Figure 11](#)), the effect of quinine and a permanently charged quaternary derivative of quinine were investigated at various external and internal pH values of mammalian cells. Raising the external pH increases the concentration of the uncharged form and increases the block rate and potency, while increasing the internal pH reduced the cationic form in the cytoplasm. The uncharged drug crosses the membrane and binds to the receptor, probably in its ionized form. The results indicate that the binding site for quinine is intracellular, possibly within the pore.<sup>22</sup>

#### 5.16.3.2 Drug Binding with Membranes, Membrane Analogs, and Proteins

Changes in the fluorescence properties of quinine after association with neutral and negatively charged small unilamellar lipid vesicles at pH 7 and 37 °C were used to obtain binding isotherms over a range of phospholipid compositions at different ionic strengths. All the findings suggested that the association of quinine to liposomes is controlled primarily through electrostatic attractions, and, to a lesser extent, by hydrophobic forces. Electrostatic and hydrophobic interactions play a crucial role in both the drug–membrane affinity and the location of the drug.<sup>23</sup>

The distribution of four ionizable molecules (amlodipine, 5-phenylvaleric acid, 4-phenylbutylamine, and 5-hydroxyquinoline – see [Figure 13](#)) between small unilamellar vesicles of dimyristoylphosphatidylcholine and aqueous buffers was studied as a function of pH using an ultrafiltration method. The results show that the charged forms of the molecules are able to interact with the phospholipid bilayer.<sup>24</sup>

The liposomal membrane/water partition coefficients of eight ionizable drugs (5-phenylvaleric acid and propranolol (see [Figure 13](#)), ibuprofen (see [Figure 1](#)), diclofenac (see [Figure 7](#)), warfarin (see [Figure 8](#)), lidocaine (see [Figure 10](#)), and tetracaine and procaine (see [Figure 11](#))) were determined using a pH-metric technique, and it was shown that the liposomal membrane/water partition coefficients as derived from the pH-metric technique are consistent with those obtained from alternative methods such as ultrafiltration and dialysis. It was found that in the liposome system, partitioning of the ionized species is significant and is influenced by electrostatic interaction with the membranes.<sup>25</sup>

To gain insight into the molecular mechanisms governing drug binding to albumin, an ultracentrifugation method was used to measure the drug fraction bound to bovine serum albumin for a series of 14 structurally diverse drugs.

Values for  $\log D$  at pH 7.4 were obtained from  $pK_a$  and  $\log P$  values. The study shows good correlation between binding and  $\log D_{\text{oct}}(7.4)$  for neutral compounds and bases, but not for acids, for which bovine serum albumin binding is stronger, probably because of supplementary electrostatic interactions.<sup>26</sup>

### 5.16.3.3 Ionization and Absorption

According to the classic pH partition theory, only the uncharged species of ionizable drugs will partition into biological phases.<sup>27</sup> Thus molecules are more permeable by passive diffusion through lipid membranes when unionized, while ionized molecules remain in aqueous phases such as blood and are more readily excreted via the kidneys. The fraction of drug absorbed may be higher than expected from pH partition theory when biological phenomena relating to membranes are taken into account. Thus, the pH microclimate at the surface of the membrane may allow a molecule to become more (or less) ionized close to the membrane surface, with consequences for its lipophilicity. Drugs may bind to the membrane surface, or their transport may be retarded by an unstirred aqueous diffusion layer adjacent to the membrane surface.<sup>28</sup> After these phenomena are taken into account, pH partition theory adequately explains drug transport through membranes by passive diffusion, though the existence of other transport mechanisms (e.g., paracellular transport or active transport) must be noted.

The high- and low-permeability drugs alfentanil and cimetidine were investigated in three models expressing different drug permeability mechanisms: hexadecane membranes (HDMs), Caco-2, and 2/4/A1 cell monolayers. For both drugs, sigmoidal relationships between membrane permeability and pH were observed in all models. The ionized species of cimetidine was found to permeate through the cell membranes, but not through the HDMs. The results showed that the paracellular route has a significant role in the permeability of small basic hydrophilic drugs, such as cimetidine, in leaky small intestinal-like epithelia such as 2/4/A1. By contrast, in tighter epithelia such as Caco-2 and in artificial membranes such as HDM, the permeability of the ionized forms of the drugs and the paracellular permeability were lower or insignificant, respectively.<sup>29</sup>

Synthetic chemists often seek to modify the properties of molecules by modifying ionizable groups, for example to reduce their lipophilicity or to provide specific drug–receptor interactions. An example is a study to enhance the oral absorption of selective serotonin 5HT<sub>1D</sub> receptor agonists.<sup>16</sup> A lead compound with good efficacy and minimal side effects was identified; however, its bioavailability was low because of deficient oral absorption. The lead compound contained a basic piperidine group with a  $pK_a$  of 9.7, so it existed only in ionized form at the pH encountered in the small intestine, leading to poor absorption by passive diffusion. A series of fluorine-substituted analog structures was synthesized. The electron-withdrawing properties of fluorine lowered the  $pK_a$  values of the analogs to between 8.2 and 8.7, leading to increased oral absorption in rats. The authors do not comment on the mechanism of absorption. However, it can be deduced from the distribution of species that a base with a  $pK_a$  of 9.7 is only 0.2% unionized at pH 7, suggesting that passive transport of the unionized species would not be an effective mechanism for oral absorption. On the other hand, a base with a  $pK_a$  of 8.2 is 6% unionized at pH 7, and should be much better transported.

The gastrointestinal absorption of 3-amino-1-methyl-5H-pyrido[4,3-*b*]indole (Trp-P-2), a mutagen/carcinogen, was investigated in rats. Trp-P-2, a weak base with a  $pK_a$  of 8.2, was poorly lipophilic below pH 5, and therefore the gastric absorption was negligible at pH 1.1 and 3.0. On the other hand, this compound was rapidly absorbed from the small intestine even at pH 4.0, and the absorption was even faster at higher pH values, where the unionized fraction increases.<sup>30</sup>

Many basic drugs are absorbed in the intestine, where the pH may vary between 5 and 8 depending on which part of the intestine is considered, and whether the patient is in the fed or fasted state (food raises the pH of the stomach, but reduces the pH of the intestine). Itraconazole (marketed as Sporanox; see [Figure 13](#)) is an antifungal drug that may be taken orally. Patients are advised to take itraconazole with meals, when the pH of the intestine contents may go down to 5 or below. The wall of the intestine is shielded from the intestine contents by a layer of mucus. The pH at the wall itself is around 6, and not greatly affected by the pH of the intestine contents.<sup>31</sup> While  $pK_a$  and  $\log P$  values have not been reported in the literature, itraconazole is a base, and at high pH it is not ionized and is almost insoluble. It ionizes at low pH, and would be rather more soluble at pH 5 than at pH 6. At pH 5 some compound can dissolve in the intestine contents. This enables it to approach the wall, where it will be transformed into the neutral form that is more easily absorbed.

Sildenafil is a vasodilator, and is marketed under the name Viagra (see [Figure 13](#)). This molecule is an ampholyte, with an acidic  $pK_a$  of 9.12 and a basic  $pK_a$  of 6.78.<sup>32</sup> While sildenafil is charged at low and high pH, it is neutral at mid-range pH, and therefore exists in its most lipophilic form ( $\log P = 3.18$ ) at intestinal pH; this enhances its absorbance in the gastrointestinal tract.

#### 5.16.3.4 Ionization and Macromolecules; the Use of Nuclear Magnetic Resonance Spectroscopy

Macromolecules such as DNA, RNA, proteins, and receptors are so large and contain so many ionizable groups that it is not possible to measure the  $pK_a$  values of these groups by the methods generally used for small-molecule drugs. The technique of NMR spectroscopy, coupled with pH-metric titration<sup>33</sup> or buffers, is commonly used to study individual ionizable groups attached to macromolecules.

To understand why the RNA–RNA duplexes in general have a higher thermodynamic stability over the corresponding DNA–DNA duplexes, the  $pK_a$  values of nucleosides modeling as donors as well as acceptors of base pairs in duplexes have been measured by  $^1\text{H}$ -NMR (at 500 MHz) with 20–33 different pH measurements for each compound. The study showed that monomeric DNA nucleobases are more basic than those of the corresponding RNA. The  $pK_a$  values of the monomeric nucleotide blocks, and differences between  $pK_a$  values of the donor as well as acceptor, can be used to understand the relative base-pairing strength in the oligomeric duplexes in the RNA and DNA series.<sup>34</sup>

To investigate the formation of aggregates in the peptide fragment of the non-amyloid-beta component,  $pK_a$  values were determined by pH titration experiments in NMR spectroscopy, indicating that the protonation of the carboxyl group of the N-terminal glutamic acid triggers the aggregation.<sup>35</sup>

The catalytic activity of serine proteases is due to a serine–histidine–aspartate triad of amino acids. The  $pK_a$  values for the histidine residue have been determined by NMR for several cases in which there is a negative charge installed at the serine residue to mimic the oxyanionic intermediate and the related transition state for the catalytic pathway. In every case studied, there was an elevation of the  $pK_a$  at the histidine residue when the negative charge is installed at the serine position.<sup>36</sup>

One benefit of  $pK_a$  measurement by NMR is the ability to assign  $pK_a$  values unambiguously to particular ionizable groups; this can be difficult for molecules with two or more  $pK_a$  values whose values are close together. An example is a study of the zwitterionic antihistamine cetirizine and its parent drug hydroxyzine (see [Figure 13](#)). The two basic  $pK_a$  values were attributed by NMR spectroscopy, and the most common conformations for each electrical species were determined by molecular dynamics simulations and confirmed by NMR measurements. For cetirizine, the results demonstrate that the zwitterion, which is the predominant species at physiological pH, exists as folded conformers able to partly mask polar groups. Extended and folded conformers of similar energy were also found for neutral hydroxyzine, whose monocationic species displayed folded conformers stabilized by intramolecular hydrogen bonds. These findings could explain the favorable pharmacokinetic properties of the drug.<sup>37</sup>

While NMR provides an unambiguous assignment of  $pK_a$  values, the technique is complicated and expensive. It is often possible to assign them by deduction from other experimental techniques such as pH-metric and pH/ultraviolet (UV) spectroscopy. These techniques were combined to elucidate the microconstants of cetirizine by a two step divide and conquer approach, in which values were determined for 12  $pK$  microconstants and four tautomerization constants.<sup>38</sup> Other examples of deductive assignment are given in [Section 5.16.5.1](#) (pH-metric assignment) and [Section 5.16.5.3](#) (UV assignment). NMR, as well as Raman spectroscopy has been used to measure very low  $pK_a$  values (down to  $-7$ ) for very weak bases and strong acids. Experiments are typically done in strong sulfuric acid solutions [9].

#### 5.16.3.5 Other Connections between $pK_a$ and Drugs

Ionization is important in the chemical analysis of drugs by high-performance liquid chromatography, because ionized and unionized forms of molecule behave quite differently in chromatographic systems.<sup>39,40</sup>

As well as its influence on gastrointestinal absorption, ionization is important in the transport and disposition of drugs in other organs and biological fluids. For example, it is noted that in the treatment of diseases of the prostate, the tissues are best penetrated by antimicrobial drugs with a high lipid solubility and high  $pK_a$ .<sup>41</sup> Irritation caused by 12 basic drugs with  $pK_a$  values between 1.4 and 11.2 applied to the skin increased significantly with increasing  $pK_a$ , the drugs which are ionized at skin pH causing the greatest irritation.<sup>42</sup> In forensic investigations of drugs of abuse, secretion into saliva is suggested to be by passive diffusion and to depend on lipid solubility,  $pK_a$ , plasma protein binding, and the pH of saliva.<sup>43</sup> Amphetamine (see [Figure 13](#)) and related compounds are bases, with  $pK_a$  values around 9.9, so they are ionized at physiological pH. However, their relatively low molecular weights allow amphetamine-type stimulants to diffuse easily across cell membranes and lipid layers and to those tissues or biological substrates with a more acidic pH than blood, facilitating their detection in alternative matrices at relatively high concentrations.<sup>44</sup>

### 5.16.3.6 Published Values for $pK_a$ Values of Drugs

Wherever possible, original literature references have been provided for  $pK_a$  values cited in this chapter. While most publications report on just one or two measurements, lists and compilations have also been published. In 1978, Newton and Kluza published a compilation of  $pK_a$  values from the literature with references for about 400 drugs.<sup>45</sup> In his 2003 book, Avdeef<sup>31</sup> showed a compilation of about 250 measured  $pK_a$  values with references, including some values measured by the author. Box *et al.* measured  $pK_a$  values of 71 drugs in 2003.<sup>46</sup>

## 5.16.4 The Effect of Ionization on Other Physicochemical Properties

This section discusses the effect of ionization on the lipophilicity and solubility of drugs, and provides equations for calculating the shapes of lipophilicity and solubility profiles.

### 5.16.4.1 Ionization and Lipophilicity

Molecules are most lipophilic when they are unionized, and their lipophilicity decreases rapidly when they are ionized. This has an important implication for the absorption and transport of drugs as a result of their permeability by passive diffusion through membranes and lipid bilayers. Figure 14 shows the lipophilicity (expressed as octanol/water partition) of three ionizable drugs as a function of pH. Significant variations in lipophilicity occur over the physiological pH range. The pH of blood and at the blood–brain barrier is 7.4. The pH in the stomach can vary between 1 and 7, but is usually between 1.4 and 2.1. In the gastrointestinal tract, where many drugs are absorbed, there is a pH gradient in the small intestine, with values gradually rising from about 5 to 7.4 between the duodenum and ileum. Also, the pH changes slightly according to the fed and fasted state, and the type of food ingested.<sup>47</sup> These factors can influence the conversion of drugs into their unionized form, and underline the importance of obtaining  $\log D$  values at the appropriate pH.

**Figure 14** Lipophilicity profiles for ibuprofen (acid, see Figure 1), carvedilol (base, see Figure 2) and labetalol (ampholyte/zwitterion, see Figure 6).  $\log D$  denotes the ratio between the concentration of sample in all forms dissolved in solvent and the concentration in water. The lines are drawn using eqns [41]–[43], which are based on the partition coefficient of the unionized species ( $P$ ) and  $pK_a$ . Dashed lines indicate the pH range where the molecule may partition in its ionized form as an ion pair with a counter-ion (depends on conditions).

<sup>a</sup>The  $pK_a$  values of labetalol are close together, and it exhibits both ampholyte and zwitterionic properties, depending on solution conditions. This graph represents the partition of the composite species  $XH$ . It has been shown that  $\log P$  for the neutral species  $XH^0 = 2.70$ .<sup>10</sup>

Lipophilicity profiles complement the aqueous distribution of species graph, and are useful for assessing the lipophilicity at a given pH. Bases with low  $pK_a$  values and acids with high  $pK_a$  values are most lipophilic at gastrointestinal pH values. However, provided at least some of the unionized species is available at a given pH, the molecule will be able to partition from an aqueous solution into a lipid phase (e.g., from the intestine into the gut wall). As the unionized molecules partition, and thus have been removed from the aqueous phase, the aqueous acid–base equilibrium redistributes, and more unionized species will be produced in solution.

The following equations were used to obtain  $\log D$  values in [Figure 14](#):

- lipophilicity–pH profile of a monoprotic acid,

$$\log D_{AH} = \log_{10} \left( P \frac{[H^+]}{[H^+] + K_{a1}} \right) \quad [41]$$

- lipophilicity–pH profile of a monoprotic base,

$$\log D_B = \log_{10} \left( P \frac{K_{a1}}{[H^+] + K_{a1}} \right) \quad [42]$$

- lipophilicity–pH profile of an ampholyte,

$$\log D_{XH} = \log_{10} \left( P \frac{K_{a1}[H^+]}{[H^+]^2 + K_{a1}[H^+] + K_{a1}K_{a2}} \right) \quad [43]$$

In these equations,  $P$  represents the octanol/water partition coefficient of the unionized species, and  $D$  represents the ratio of the concentrations of all species (unionized plus ionized) partitioned between octanol and water at a given pH.  $K_{a1}$  and  $K_{a2}$  are taken from [Table 1](#). To draw these graphs, it is assumed that only the unionized species partitions into the lipid phase. These equations represent the three most common classes of ionizable compound.

[Table 1](#) illustrates a general ionization scheme for compounds with one to six  $pK_a$  values. As explained in the table, the charge on X can vary, depending on the class of compound. The form of the equations is quite general. Explicit equations are provided for  $[X]$ ,  $[XH]$ ,  $[XH_2]$ , and  $[XH_3]$ ; equations for  $[XH_4]$  and higher can easily be deduced.

To calculate  $\log D$  (the lipophilicity at a given pH) for a lipophilicity–pH profile for a compound with up to six  $pK_a$  values, identify the unionized species (X, XH,  $XH_2$  etc.), obtain the  $\log P$  value (partition coefficient of unionized species), and calculate  $P$ , then calculate  $\log(P \times [X])$ , etc., at each pH. For examples:

$$\log D = \log (P \times [XH]) \text{ (for a monoprotic acid)} \quad [44]$$

$$\log D = \log (P \times [X]) \text{ (for a monoprotic base)} \quad [45]$$

The equations in [Table 1](#) can only be used to plot the lipophilicity of the unionized species. Avdeef has published general equations for the lipophilicity–pH profiles of all classes of ionizable molecules, covering both the partition of unionized and ionized species.<sup>48</sup>

$pK_a$  values are used in the pH-metric method for measuring  $\log P$  of ionizable compounds. In this method, the shape of a titration curve of a sample titrated in a water–octanol mixture is compared with a curve based on calculated pH values; the  $pK_a$  is required to calculate the pH values used in the calculated titration curve.<sup>49</sup>

### 5.16.4.2 Ionization and Solubility

Ionizable molecules are least soluble when unionized, and their solubility increases rapidly when they are ionized. Drugs are permeable by passive diffusion when they are unionized, but they may be so poorly soluble at the pH where they are unionized that they cannot get into solution in order to be permeable. Poor solubility is a major problem in drug discovery. The solubility–pH profiles in [Figure 15](#) show how solubility increases when molecules are ionized. These profiles are calculated from the equations below. Superimposed on these profiles are lines suggesting the solubility of the drug in salt form. The positions of these lines vary according to the counter-ion. Some salts are so soluble that the entire substance remains in solution at all pH values where the substance is ionized. The solubility for different types of molecule is calculated as follows:

- solubility–pH profile of monoprotic acid,

$$\log S_{\text{pH}} = \log_{10} \left( S_0 \frac{[\text{H}^+] + K_{\text{a1}}}{[\text{H}^+]} \right) \quad [46]$$

- solubility–pH profile of monoprotic base,

$$\log S_{\text{pH}} = \log_{10} \left( S_0 \frac{[\text{H}^+] + K_{\text{a1}}}{K_{\text{a1}}} \right) \quad [47]$$

- solubility–pH profile of ampholyte,

$$\log S_{\text{pH}} = \log_{10} \left( S_0 \frac{[\text{H}^+]^2 + K_{\text{a1}}[\text{H}^+] + K_{\text{a1}}K_{\text{a2}}}{K_{\text{a1}}[\text{H}^+]} \right) \quad [48]$$

In these equations,  $S_0$  refers to the intrinsic solubility of the sample, which is the concentration of the free acid or base form of an ionizable compound at a pH where it is fully unionized in a saturated solution when excess solid is present, and the solution and the solid are at equilibrium;  $S_{\text{pH}}$  refers to the concentration of the substance in solution in

**Figure 15** Solubility–pH profiles of ketoprofen (acid), pindolol (base), and ciprofloxacin (zwitterion).  $\log S$  denotes the concentration of sample species that could dissolve at any pH. The lines are drawn using eqns [37]–[39], which are based on intrinsic solubility ( $S_0$ ) and  $\text{p}K_{\text{a}}$ . The solubility would only follow the dashed lines if (1) a sufficient weight of the sample was available, and (2) if salts of the sample were soluble. See discussion of ciprofloxacin in [Section 5.16.1.10](#).

equilibrium with excess solid at a given pH;  $K_{a1}$  and  $K_{a2}$  are taken from Table 1. In the graphs,  $S_0$  and  $S_{pH}$  are expressed in moles per liter.

The equations in Table 1 can be used to calculate  $\log S_{pH}$  (the solubility at a given pH) for compounds with up to six  $pK_a$  values. First, identify the unionized species (X, XH, XH<sub>2</sub>, etc.), then obtain the  $\log S_0$  value (intrinsic solubility of unionized species), and calculate  $S_0$ , then follow the examples below:

$$\log S_{pH} = \log \frac{S_0}{[XH]} \quad (\text{for a monoprotic acid}) \quad [49]$$

$$\log S_{pH} = \log \frac{S_0}{[X]} \quad (\text{for a monoprotic base}) \quad [50]$$

Streng *et al.* have published equations for solubility–pH profiles of acids, bases, and ampholytes, including the effect of salts.<sup>50,51</sup> Ozturk *et al.* have published equations showing the dependence of the dissolution rate on  $pK_a$  and intrinsic solubility.<sup>52</sup>

$pK_a$  values are used in pH-metric methods for measuring solubility of ionizable compounds. A method has been described in which the shape of a titration curve of a sample that precipitated during the titration is compared with a curve based on calculated pH values; the  $pK_a$  is required to calculate the pH values.<sup>53</sup> Another method calculates the solubility during a process of chasing equilibrium for compounds that form supersaturated solutions; this calculation also requires the  $pK_a$  value.<sup>54</sup>

### 5.16.5 Measuring $pK_a$ Values

To measure  $pK_a$  values it is necessary to expose the compound to an environment of changing pH, and monitor a property that changes as a function of the ionization state of the molecule. Several considerations affect the choice of method. If the sample is poorly water-soluble in its unionized form, it must either be measured in very dilute solution, or in water–solvent mixtures. If only a very small quantity of sample is available (e.g. less than 1 mg), the only practical methods involve UV spectroscopy. If high throughput measurement is required, not all methods are suitable.

#### 5.16.5.1 The Effect of Co-Solvents on $pK_a$

Methods of  $pK_a$  of measurement were developed using water-soluble samples. However, many drugs are poorly soluble in water alone, and require the presence of a water-miscible co-solvent to keep them in aqueous solution. The solvent affects the  $pK_a$  in two ways. It causes the pH scale to shift, and it causes the  $pK_a$  to shift. The consequence is that apparent  $pK_a$  values measured in the presence of solvent are different from aqueous values.

For the sake of improving throughput, it is tempting to ignore this effect, and to work always in water–solvent mixtures and report the apparent  $pK_a$  values, which may be considered ‘good enough’ for use during early stage discovery. As seen in Figure 16, however, the shifts can be quite high. An error in  $pK_a$  of 0.5 unit, when applied in a calculation of  $\log D$  from a  $\log P$  would cause an error in  $\log D$  estimation of about 0.5  $\log D$  units. It causes a similar error in pH-metric measurement of solubility. When  $pK_a$  values are close to the physiological pH in the region where the drug is absorbed, errors  $pK_a$  in could have a significant effect on predictions of drug behavior.

The technique of extrapolating a series of  $p_s K_a$  (apparent  $pK_a$ ) values obtained in several ratios of water/solvent to obtain an aqueous value is well established, but three or more experiments at different water/solvent ratios are required. The Yasuda–Shedlovsky plot of ( $p_s K_a + \log[H_2O]$ ) versus  $1/\epsilon$  (where  $\epsilon$  is the dielectric constant of the water–solvent mixture) is widely used for methanol and 1,4-dioxane.<sup>55,56</sup> A linear plot of  $p_s K_a$  versus the water/solvent ratio is preferred for dimethyl sulfoxide (DMSO), whose dielectric constant is similar to that of water. A method of calculating aqueous  $pK_a$  values for various classes of organic acids and bases from single apparent  $pK_a$  values obtained in water–solvent mixtures has been reported,<sup>57</sup> and looks promising as a way of speeding  $pK_a$  measurement.

The most widely used solvent for  $pK_a$  measurements is methanol. However, not all drugs dissolve in water–methanol mixtures. Other solvents have been used, notably 1,4-dioxane and DMSO, though the latter solvent has high UV absorbance at low wavelengths, and absorbs water at room temperature, causing  $pK_a$  measurement difficulties. Quite often, only small sample quantities are available and there is no time to do experiments to choose the best solvent. In this case it is desirable to use a water–solvent mixture in which the largest number of compounds will dissolve. Some mixtures of solvents with low UV absorbance have been described for  $pK_a$  measurement. A 1:1:1 mixture

**Figure 16** Apparent  $pK_a$  values of labetalol in increasing concentrations of methanol. The acid  $pK_a$  increases from 7.39 in water to 7.9 at 40% methanol.

of methanol, acetonitrile, and diethyleneglycol monoethyl ether, mixed 15% or 20% with an aqueous buffer has been used in the pH-gradient method<sup>81</sup>; to correct apparent  $pK_a$  values to their aqueous values, 0.3 was subtracted from acid values, and 0.2 was added to bases. A 1:1:1 mixture of methanol, 1,4-dioxane, and acetonitrile (called MDM) has been used in titrations at various water/solvent ratios, with  $pK_a$  values calculated by extrapolation. These mixtures contain both polar and nonpolar solvents, offering a good opportunity to solubilize the maximum number of drug molecules.

Figure 16 shows  $p_s K_a$  values versus the water/methanol ratio extrapolated to the aqueous  $pK_a$  for labetalol (see Figure 6). Note how the three  $p_s K_a$  values for each ionization extrapolate to the aqueous  $pK_a$  value. Note also the slopes of the two lines. The  $p_s K_a$  values of acids increase with increasing solvent, and the  $p_s K_a$  values of bases decrease, in both cases because the molecules form charged species with increasing difficulty under lower dielectric conditions. These slopes may be used to assign  $pK_a$  values to the corresponding acid and base ionizable groups.

#### 5.16.5.2 pH-Metric Titration

The pH-metric method can be used to measure all  $pK_a$  values between 2 and 12, with or without a UV chromophore, provided the sample can be dissolved in water or water/co-solvent over the pH range of interest.

Albert and Serjeant<sup>9</sup> described a simple pH-metric method for measuring  $pK_a$  values, illustrated here for a sample of 30.9 mg of boric acid in 47.5 mL of water at 20 °C. Ten aliquots of NaOH titrant are added, and the pH measured after each addition. The results are calculated as shown in Table 4. They illustrated similar methods in which corrections were made for concentration of hydrogen ions and hydroxyl ions that are present in increasing quantity as the pH deviates from 7. These simple methods are suitable for high weights (> 30 mg) of water-soluble samples with a single  $pK_a$  in the mid-pH region (4–10), and they can be carried out with the simplest of apparatus and calculations. However, these calculations involve approximations, and for smaller weights, overlapping  $pK_a$  values (i.e., values separated by less than 3 units) and values outside the range 4–10, methods using charge and mass balance without approximations are required. These involve the use of automatic titration apparatus and computer programs, which must be able to deal with changes in ionic strength and their effect on ionic activity, the effect of carbon dioxide on the titration curve, and the volume changes in solutions as titrants are added. Figure 17 shows some of the graphs that can be obtained using Sirius RefinementPro 2 software during the pH-metric measurement of  $pK_a$  of labetalol.

In an automated pH-metric titration for measuring  $pK_a$ , the pH of a solution of the drug is adjusted by adding acid or base until the sample is fully ionized, and then titrated with base or acid until the sample is fully unionized. The pH of the sample solution is monitored with a glass pH electrode, and the  $pK_a$  is calculated from the change in shape of the titration curve.<sup>55</sup> A sample concentration of at least about  $5 \times 10^{-4}$  M is required in order for any significant change in shape to be detectable between pH 3 and 11, and a higher concentration is required outside this range.<sup>58</sup> Although pH-metric  $pK_a$  titration in volumes as low as 100  $\mu$ L has been reported using pH micro-electrodes,<sup>59</sup> the physical size of glass pH electrodes and stirrers generally dictates that the smallest practical volume of sample solution

**Table 4** Method published by Albert and Serjeant<sup>9</sup> to measure the  $pK_a$  of boric acid. The sample is 30.9 mg of boric acid in 47.5 mL of water at 20 °C

is about 5 mL. This requires at least 1 mg of sample for a compound with a molecular weight of 400 to achieve a concentration of  $5 \times 10^{-4}$  M. A typical titration between pH 3 and 11 requires about 45 measured pH values. The need to wait for equilibrium after each pH measurement means that automated titrations typically take 20–40 min to perform.

The  $pK_a$  result is calculated by comparing the experimental titration curve (consisting of measured pH versus the volume of titrant added) with a theoretical curve made up from calculated pH values. Each calculated pH requires a  $pK_a$  value for the sample. The pH values are calculated and recalculated iteratively using different  $pK_a$  values until the experimental and theoretical curves reach the closest agreement. The  $pK_a$  value giving best agreement is taken to be the true measured value.

The calculation of pH values of aqueous solutions of weak acids and bases is based on mass balance and charge balance. Consider a monoprotic acid AH of concentration  $C_{AH}$  moles per liter, which dissociates according to

Based on the  $pK_a$  of AH, we can write

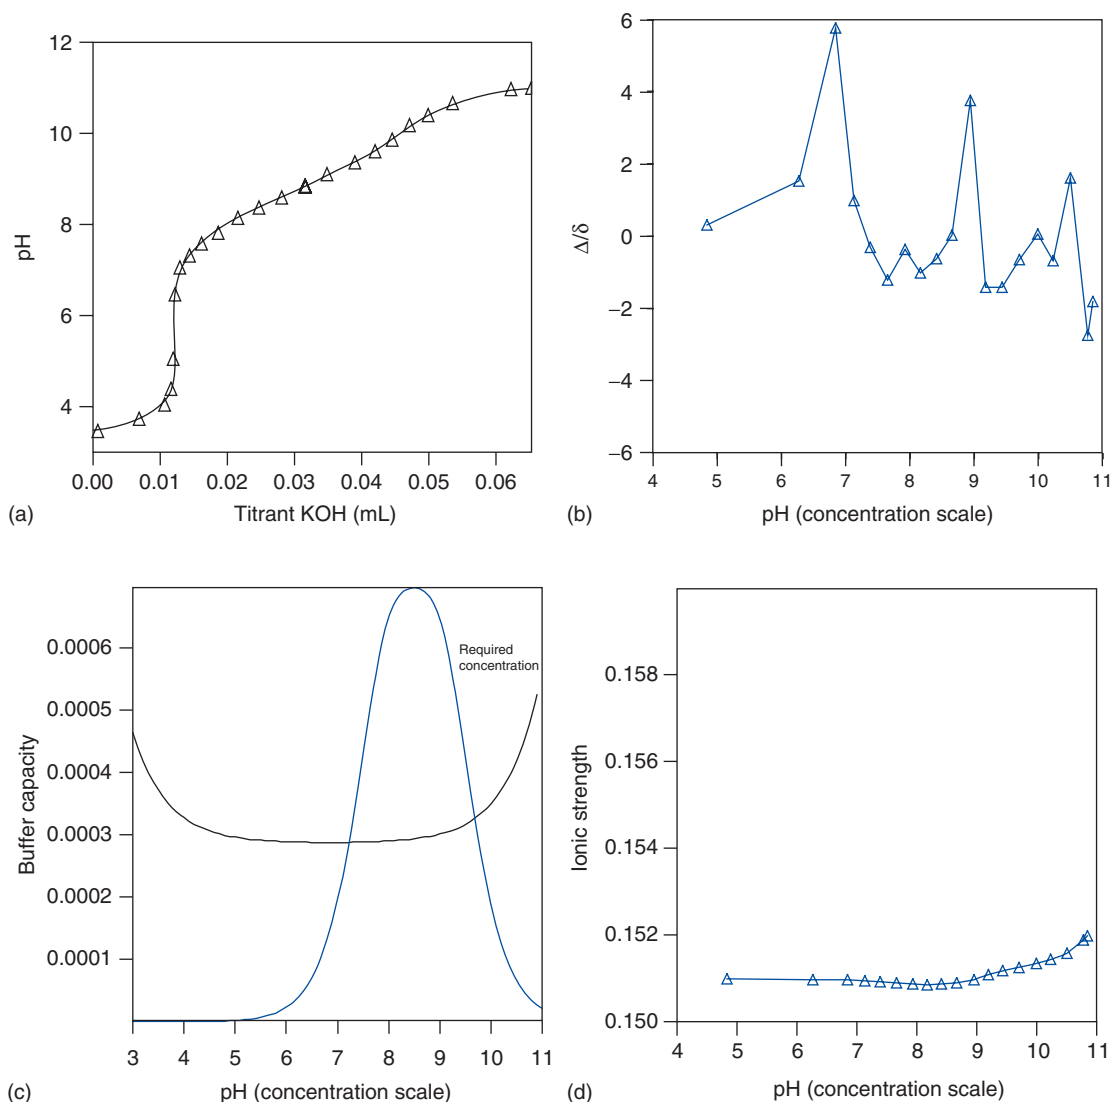

$$[H^+][A^-] = K_a[AH] \quad [52]$$

The other equations required to calculate the pH of the solution are

$$[H^+][OH^-] = K_w = 10^{-14} \text{ (ionic product)} \quad [53]$$

$$C_{AH} = [A^-] + [AH] \text{ (mass balance)} \quad [54]$$

$$[H^+] = [A^-] + [OH^-] \text{ (charge balance)} \quad [55]$$

**Figure 17** Selection of graphs obtained during the pH-metric measurement of  $p_sK_a$  of labetalol. The sample weight was 2.77 mg. The sample was dissolved in 10 mL of an acidified water–methanol mixture (49% methanol, 0.15 M KCl, 25 °C). The titrant was 0.5 M KOH. (a) The titration curve. (b) The residuals at each pH, representing the unexplained pH after comparing the measured and calculated pH for each point. (c) The buffer capacity of the water–solvent background, and the contribution from the buffer capacity of the sample. When the sample peak is higher than the background signal, there is sufficient signal for a good-quality pH-metric measurement. (d) The total ionic strength of the solution at each pH during the titration

Combining these equations, substituting  $C_A$  for  $[A^-]$ , and rearranging leads to a cubic polynomial equation:

$$[H^+]^3 + [H^+]^2(C_A + K_a) - [H^+](C_{AH}K_a + K_w) - K_wK_a = 0 \quad [56]$$

Values for  $C_A$  and  $C_{AH}$  change with each point in the titration curve in response to the increase in solution volume caused by the addition of titrants. Note that the comparable equations will be different for di- or triprotic substances, and different again for bases and ampholytes. This class of equation can be solved explicitly for  $[H^+]$  and thus for pH, but it is not easy to do so by simple algebraic techniques. A number of methods have been proposed in which results can be obtained graphically. The Newton–Raphson method is widely used. The pH-metric method may be used for samples with one, two, three, or more  $pK_a$  values, as well as for samples with titratable counter-ions. In these cases, the equations used to calculate the pH of each point must take account of each  $pK_a$  of the substance and the counter-ion.

### 5.16.5.3 Hybrid pH-Metric/Ultraviolet Method

Significantly smaller sample concentrations ( $10^{-5}$  M or below) are required for  $pK_a$  measurement by the hybrid pH-metric/UV method, in which multiwavelength UV absorbance of the sample solution is monitored throughout the titration. Samples must have a chromophore, and the absorbance must change as a function of ionization. Recent advances in this method have enabled  $pK_a$  measurement in volumes less than 8 mL by the use of a fiber-optic dip probe in a titration cell, and has been automated on the Sirius GLpKa with D-PAS attachment. During measurement, samples are acid–base titrated across a pH range that includes the  $pK_a$  values, and multiwavelength UV spectra are measured at each pH. The  $pK_a$  values are calculated using a technique based on target factor analysis (TFA).<sup>60</sup> The apparatus has been used for the determination of  $pK_a$  values of samples with multiple ionization centers,<sup>61</sup> and the determination of protonation microconstants of zwitterionic molecules.<sup>38,62</sup> Titrations in unbuffered solutions take up to 30 min because of the need to wait for electrode stability, but they can be done in less than 4 min in the presence of linear buffer solutions, taking advantage of the fast electrode equilibration time in buffered solutions. The ability to work at lower concentrations increases the scope for measuring  $pK_a$  values of poorly soluble samples by the Yasuda–Shedlovsky technique, but throughput will be lower if this technique is used.

Figure 18 shows some of the graphs that can be obtained using Sirius RefinementPro 2 software during the pH/UV measurement of  $pK_a$  of labetalol. The structure of labetalol contains two ionizable groups: a phenol and an amine. The phenol is part of a strong UV-absorbing chromophore, while the base is distant from the chromophore, and will exert only a small influence on the UV absorbance. From the graphs, it is clear that the absorbance change associated with the equilibrium  $X^- + H^+ \rightleftharpoons XH$  is much smaller than the change associated with  $XH + H^+ \rightleftharpoons XH_2^+$ . This provides another way to assign the  $pK_a$  values, as it can be deduced that  $X^- + H^+ \rightleftharpoons XH$  refers to the ionization of the amine and  $XH + H^+ \rightleftharpoons XH_2^+$  refers to the ionization of the phenol.

### 5.16.5.4 pH Gradient Titration

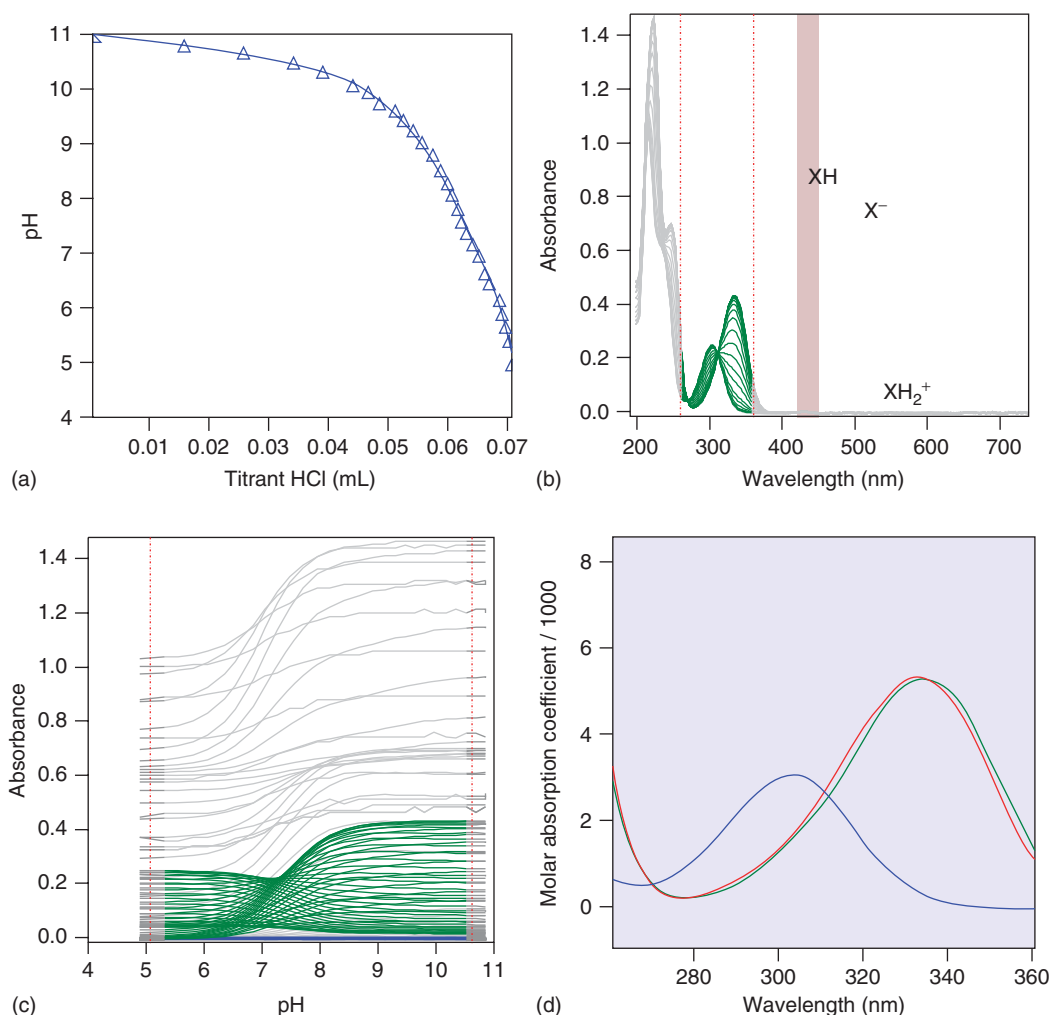

A technique called pH gradient titration can be used for the rapid measurement of  $pK_a$ . In this technique, samples are injected into a flowing pH gradient, which is created by mixing an acidified and a basified linear buffer together using syringe pumps running at inversely varying speeds. During the gradient the pH varies linearly, and the pH at any given time may be predicted from the time elapsed since the start of gradient generation. This eliminates the need for pH measurement, which is one of the rate-limiting steps in conventional titration. The gradient and sample pass through a diode array UV spectrophotometer, and  $pK_a$  values are determined from changes in absorption as a function of pH. The linear buffer is created by mixing several weak acids and bases in varying concentrations such that the titration curve is linear in terms of pH, and the ionic strength approximates to 0.15 M at any pH. The buffer components were chosen because of their low UV absorbance, and have a total of nine  $pK_a$  values spaced approximately equally over the 2–12 pH range. Experimental data consist of measured absorbance, wavelength, and pH (which is calculated from the time elapsed from the start of gradient generation). The  $pK_a$  values are obtained by differentiation or by TFA using methods described elsewhere.<sup>63</sup> A validation study has been published showing good correlation between  $pK_a$  values measured by this method and previously measured values for 71 pharmaceutical drugs with published structures.<sup>46</sup> The pH gradient technique is offered on the Sirius ProfilerSGA instrument, which accepts samples in 10 mM stock solutions in 96-well plates. Typical assay cycle is 4 min per sample, including a gradient time of 90 s, leading to a throughput of over 200 samples per day.

### 5.16.5.5 Capillary Electrophoresis

Measurement of the  $pK_a$  by UV absorption after separation by capillary electrophoresis has been described for acids<sup>64</sup> and bases.<sup>65</sup> The principle of  $pK_a$  determination by capillary electrophoresis is the measurement of the ionic effective mobility of the solute as a function of pH. Equations that relate effective electrophoretic mobility to  $pK_a$  for monoprotic and diprotic acids and bases have been published.<sup>66</sup> The measurement of  $pK_a$  by capillary electrophoresis requires small sample quantities, and the rate of throughput using single-channel instruments is currently about 20–35 samples per day.<sup>67</sup> A method using an array of 96 capillaries has been described for measuring  $pK_a$  values of samples supplied in solutions in 96-well plates.<sup>82</sup> A rate-limiting step in the capillary electrophoresis method is the need to make separate experimental runs at different buffered pH values to determine the relative concentration of ionized species at each pH; this limitation does not apply to titration methods, which are inherently faster than methods using buffers.

### 5.16.5.6 Other Methods

Albert and Serjeant<sup>9</sup> described a general method for measuring  $pK_a$  by conductivity. This was a widely used method up to about 1932, before pH-metric methods took over. The conductometric method is extremely temperature-sensitive,

**Figure 18** Selection of graphs obtained during the pH/UV measurement of  $pK_a$  of labetalol. The sample weight was 0.6 mg. The sample was dissolved in 20 mL of basified 0.15 M KCl solution in water containing 0.0001 M  $K_2HPO_4$  buffer (25 °C). The titrant was 0.5 M HCl. (a) The titration curve. (b) the absorbance versus the wavelength. Each line represents a different pH. Only the absorbance between 260 nm and 360 nm are used in the calculation. (c) The absorbance versus the pH. The  $pK_a$  values of labetalol occur in those pH regions where the lines are crossing. TFA deconvolutes the data to find the exact  $pK_a$  values. (d) The absorption of each species of labetalol ( $XH_2^+$ ,  $XH$ ,  $X^-$ ).

and cannot be used to measure overlapping  $pK_a$  values. A possible advantage for samples without a chromophore is that it can be used in very dilute solutions, down to  $2.8 \times 10^{-5}$  M. In recent years, conductometry has been used to measure the  $pK_a$  of lidocaine,<sup>68</sup> though the result obtained was 0.7 unit lower than the generally accepted pH-metric value.

Albert and Serjeant<sup>9</sup> also described a method for determining the  $pK_a$  from solubility measurements. As mentioned above, solubility is  $pK_a$ -dependent, so if the solubility is measured at several pH values on a curve, such as is shown in Figure 15, the  $pK_a$  could be deduced. Peck and Benet<sup>69</sup> described a general method for estimating  $pK_a$  values for monoprotic, diprotic, and amphoteric substances, given a set of solubility and pH measurements. Hansen and Hafliger<sup>70</sup> derived the  $pK_a$  of a sample that decomposed rapidly by hydrolysis from its initial dissolution rates as a function of pH in a rotating-disk apparatus. The result agreed well with a pH/UV result, but decomposition made the latter method difficult.

A hybrid pH/fluorometry method has been used to measure  $pK_a$  values of porphyrins<sup>13</sup> and ciprofloxacin.<sup>71</sup> The methodology and calculations required are similar to those used in pH/UV methods. Fluorescence methods have the advantage of using very dilute drug solutions, and may be applicable in cases where UV methods are restricted.

A flow injection method has been reported in which  $pK_a$  values are measured by UV absorbance after injection into a flowing phosphoric acid buffer.<sup>72</sup> No mention of throughput was made.

### 5.16.6 Calculating $pK_a$ Values from Chemical Structures

The acidic and basic groups in organic molecules are easily recognized, and the structural factors that modify  $pK_a$  values are well known (see Table 3). Experienced chemists can estimate the  $pK_a$  values of molecules by inspecting their structures. Over the years, these rules have consolidated into a series of methods for predicting  $pK_a$  values, often with high accuracy, especially for molecules that are structurally similar to other molecules with measured  $pK_a$  values; they are summarized in Perrin's 1981 book.<sup>73</sup> This section cites examples from the book, and briefly reviews the currently available prediction software. More information is provided in 5.25 In Silico Prediction of Solubility, on  $pK_a$  prediction for.

#### 5.16.6.1 Hammett and Taft Equations

Values can be predicted using linear free energy relationships, from the class of compound, and also by analogy and extrapolation. The change in free energy ( $\Delta G$ ) that is produced by adding a substituent leads to a corresponding change in  $pK_a$ , and the effects are additive, more or less. This observation forms the basis of the Hammett and Taft equations that are the most widely used methods of prediction. As seen in Figures 7–13,  $pK_a$  values change according to the class of compound. An example is the  $pK_a$  values of primary, secondary, and tertiary aliphatic amines, whose values fall into the ranges  $10.6 \pm 0.2$ ,  $11.1 \pm 0.1$ , and  $10.5 \pm 0.2$ , respectively. Values like these can be used to provide the starting  $pK_a$  of the parent compound.

Hammett<sup>74</sup> demonstrated that the effects on of *meta*- and *para*-substituted benzoic acids were linear and additive. This led to the Hammett equation

$$pK_a = pK_a^0 - \rho(\Sigma\sigma) \quad [57]$$

where  $\rho$  is a constant for the particular equilibrium (i.e., an acid or base functional group),  $\sigma$  is a constant that is characteristic of a particular substituent, and  $pK_a^0$  is the  $pK_a$  of the unsubstituted acid or base.

In the original formula, two constants needed to be assigned to each substituent,  $\sigma_{\text{meta}}$  for *meta*-substitutions and  $\sigma_{\text{para}}$  for *para*-substitutions. This was extended to aliphatic systems by Taft,<sup>75</sup> who introduced the term  $\sigma^*$ .

Hammett and Taft  $\sigma$  and  $\sigma^*$  values for large numbers of substituents have been published, as have equations for different classes of compound. The best predictions of  $pK_a$  use the least number of substituent sigma constants and the least number of approximations. Ideally they should be based on a model compound as similar in structure as possible to the sample.

The method may be illustrated by the following examples:

- Calculation of the  $pK_a$  of 3-acetylpyridine (see Figure 13). First, find a Hammett or Taft equation for the  $pK_a$  of a substituted pyridine, such as the following:<sup>76</sup>

$$pK_a = 5.25 - 5.90 \sum \sigma^* \quad [58]$$

- Next, find a  $\sigma_{\text{meta}}$  value for the  $-\text{COCH}_3$  substituent. According to Perrin,  $\sigma_{\text{meta}}$  for  $-\text{COCH}_3$  is 0.36. Therefore,

$$pK_a = 5.25 - (5.90 \times 0.36) = 3.13 \quad [59]$$

- Calculate the  $pK_a$  of 4-chloro-3,5-dimethylphenol (see Figure 13). The following Hammett equation has been published for phenol<sup>77</sup>:

$$pK_a^0 = 9.92 - 2.23 \sum (\sigma^*) \quad [60]$$

- $\sigma_{\text{meta}}$  for  $-\text{CH}_3$  is  $-0.06$ , and  $\sigma_{\text{para}}$  for  $-\text{Cl}$  is  $0.24$ . Therefore,

$$pK_a = 9.92 - [2.23 \times (0.24 - 0.06 - 0.06)] = 9.65 \quad [61]$$

A problem associated with  $pK_a$  prediction based on the use of Hammett and Taft equations is the difficulty of finding values for the substituent constants and for the acid/base functional group under consideration. While they may be obtained from books and publications, they are more easily handled by databases; and the calculation of  $pK_a$  values is more easily handled by software.

### 5.16.6.2 Software for Predicting $pK_a$ Values

Several vendors, including Compudrug (Pallas), Simulations Plus, ACD, and Pharma Algorithms supply software for the calculation of  $pK_a$  values. Software predicts values very well for simple molecules, but for more complex or novel structures, the prediction may be suspect. Many software developers are keen to improve their predictions by taking advantage of published, measured  $pK_a$  values for new compounds, and it seems likely that predictions will improve considerably during the coming years (see 5.25 In Silico Prediction of Ionization).

## Biography

**John E A Comer**, after studying chemistry at the universities of Warwick and Newcastle upon Tyne, joined the analytical instrument industry, working for several years in technical and marketing roles with Orion Research Inc., before co-founding Sirius Analytical Instruments in 1990. Sirius Analytical Instruments develops and manufactures instruments for the measurement of drug  $pK_a$ , lipophilicity, and solubility, and provides analytical services. Currently the technical director, Comer leads a team of chemists and software engineers who are researching into novel aspects of the measurement of physicochemical properties of drugs and other small organic molecules. Achievements include the development and introduction of automated instrumentation for the measurement of  $pK_a$  by pH-metric and pH/ultraviolet techniques, together with several publications in the field of  $pK_a$  measurement. Current research is concerned with the behavior of ionizable drugs, looking at parallel artificial membrane permeability assay and its correlation with  $\log P$  and  $\log D$ ; solubility measurement by a novel, pH-metric approach; miniaturization of measurement apparatus; ultraviolet methods for  $pK_a$ ; solubilization of drugs for analysis; and  $\log P$  measurement using small sample quantities.

### 5.17.1 Introduction

This chapter critically reviews the experimental strategies and theoretical basis of the pH-dependent measurement of solubility and dissolution of multiprotic ionizable drugs. Property assessment of ionizable molecules is more complicated than that of neutral molecules, and in this review, focus is primarily placed on the former class of molecules. Well-tested methods, suitable for application in discovery as well as preformulation, and appropriate for the analysis of solubility and dissolution of problematic molecules, are discussed. Medicinal chemists confronted by low-solubility compounds may find several of the discussed topics helpful. If the complexity of some parts of the presentation are of limited direct interest, the medicinal chemist will at least have some basis for asking critical questions of their physical chemistry counterparts.

Several carefully selected molecules that illustrate important concepts are considered in detail, with some literature data illustrated, using improved computational tools. Considered elsewhere are extensive compilations of experimental results.<sup>1</sup> Several excellent publications serve as important background material for the present review, stressing solubility,<sup>2</sup> salt formation,<sup>3</sup> and dissolution,<sup>4</sup> and covering the solubility analysis of complicated systems.<sup>5</sup>

The solubility treatment here should be of practical interest to discovery-support physical chemists intent on making fast, quality measurements of physical properties of test compounds in lead finding and optimization, and on effectively communicating these measured results to medicinal chemists, so that rational structural modifications leading to improved properties can be made.<sup>6–10</sup> Moreover, this treatment should be particularly useful to downstream preformulation scientists, sometimes charged with the daunting task of formulating poorly soluble molecules into drug products.<sup>3,5</sup>

The dissolution coverage is primarily focused on the disk intrinsic dissolution rate (DIDR) and powder sample dissolution rate measurement used in early preformulation, rather than late-stage highly regulated development and quality control applications, which have been covered very well in the recent literature.<sup>11–17</sup> The close relationship between solubility and dissolution is stressed throughout this review. The case study molecules have been selected in many instances to link applications in solubility to those in dissolution.

#### 5.17.1.1 Solubility

The measurement of the solubility of multiprotic drugs can be very challenging.<sup>18</sup> Speciation characteristics (usually pH-dependent), such as multiple (often overlapping) ionization,<sup>19</sup> complexation,<sup>20</sup> aggregation,<sup>21</sup> micelle formation,<sup>22,23</sup> and common-ion effects (see Section 5.17.6.5.2)<sup>24,25</sup> can hamper the interpretation of the measurements. Potential experimental artifacts, such as adsorption to microporous filters, plastic (or glass) surfaces, ‘promiscuous inhibitor’ molecules forming very small (0.1–0.2  $\mu\text{m}$ ) particles that can pass through filters,<sup>26</sup> and a multitude of other confounding effects may escalate the interlaboratory variability of the measured values. Different polymorphic forms of a compound may produce subtle differences in solubility and dissolution behavior.<sup>27,28</sup> Unanticipated polymorphs isolated during the scale-up of synthesis can mislead interpretations of measurements.

Two types of solubility assays are considered in detail, based on using (1) just a pH electrode as a concentration sensor (the dissolution titration template (DTT) method),<sup>29–31</sup> and (2) ultraviolet (UV) microtitre plate technology.<sup>8,9,19</sup> In the potentiometric method, it is not necessary to separate the solid from the solution in order to deduce solubility. In the UV-metric methods, however, the solid usually needs to be separated from the solution, either by microfiltration or centrifugation, before concentrations are determined. The small-volume dissolution apparatus (see Sections 5.17.6.3 and 5.17.7.2), which is used also for solubility measurement, however, has a special algorithm to allow the direct concentration determination in a turbid solution. As special case studies, the apparent aggregation

reactions of piroxicam, indomethacin, 2-naphthoic acid, and phenazopyridine are illustrated using the ‘shift in the apparent  $pK_a$ ’ method.<sup>1</sup>

The early results of the DDT solubility–pH method have been successfully compared with those obtained by traditional shake-flask methods,<sup>30,35,36</sup> and an optimistic assessment has been suggested.<sup>37</sup> In the US Food and Drug Administration’s biopharmaceutics classification system (BCS; *see* 5.42 The Biopharmaceutics Classification System), the new acid–base titration method is deemed suitable for the determination of solubility.<sup>38</sup>

### 5.17.1.2 Dissolution

The theory of dissolution kinetics of multiprotic ionizable molecules, based on the convective diffusion with simultaneous chemical reaction (CDR) model, explored extensively in the pioneering contributions of Higuchi *et al.*,<sup>40</sup> Mooney and co-workers,<sup>41–44</sup> McNamara and co-workers,<sup>45–47</sup> and Southard *et al.*,<sup>48</sup> and a number of others, is still evolving, and according to McNamara *et al.*:<sup>4</sup>

Today, the opportunity is still available, for those inclined to numerical analysis, to derive a robust numerical dissolution model capable of including contributions due to diffusion, convection, and reaction which can encompass the entire pH scale.

Our further analysis of the CDR model<sup>39</sup> has uncovered some limitations to the assumptions made in earlier treatments. With the new computational treatment, only briefly described in this article (*see* Section 5.17.5), we explore the insights gained from the improved model.

For example, in the new treatment, the electrostatic fields created in the aqueous boundary layer (ABL) (surrounding the dissolving solid) by the convection and diffusion of ions with different mobilities are explicitly considered, using the Vinograd–McBain<sup>49</sup> formalism. This is an important generalization of the earlier CDR treatments.

Concentration–time profiles as a function of pH, buffers, salt, and aggregation are considered. Concentration–position profiles of all species in the ABL, including solid species, are also considered under the above conditions. An intriguing ‘fog of solid’ in the ABL can be predicted under certain circumstances. The dissolution flux profiles of indomethacin, reported earlier,<sup>41,42</sup> are re-evaluated, taking into account suspected anionic aggregates formed during dissolution of this molecule.

The dissolution kinetics equations for two variants in the CDR model, (1) rotating disk<sup>50</sup> and (2) spherical particles,<sup>51,52</sup> are discussed. The new small-volume (2–20 mL) dip probe UV detection apparatus, developed for polymorph screening, stability assessment, and solubility determination, is applied to phenazopyridine hydrochloride dissolution as a case study.

### 5.17.1.3 The Relation between Solubility and Dissolution

Solubility and dissolution are closely linked. The thin ABL adjacent to the surface of the dissolving solid particles, separating the solid–liquid interface from the bulk medium, is the rate-limiting barrier in dissolution. When the solid is introduced to the dissolution medium, almost instantaneously (assuming ‘wettability’ is not an issue, a topic beyond the scope of the present coverage), the concentration of the drug at the solid–liquid interface becomes equal to its solubility under the conditions of the bulk medium. After a further short delay (typically < 1 s), the steady state (when the dissolution rate is constant in time) is established. At that time, the sink condition is still in effect (since the amount of drug dissolved in the bulk medium is vanishingly low), and the linear concentration gradient which initially drives the dissolution process (Fick’s law of diffusion) is equal to the solubility divided by the thickness of the ABL. As more compound dissolves (> 10% of the solubility value), the process becomes more complicated to analyze (due to nonsink conditions), but the concentration of the drug at the solid–liquid interface still remains equal to the solubility. Dissolution will continue until the concentration of the drug in the bulk medium becomes equal to the solubility, or until all of the solid dissolves. In such a view, solubility drives dissolution.

### 5.17.1.4 Why Should Medicinal Chemists Care about Dissolution?

In discovery, compounds are usually stored in dimethyl sulfoxide (DMSO), and when compounds are initially isolated as a solid, their form is often amorphous. Early evaluation of the physical properties are made. But after a period of storage (e.g., 6 months or more), some amorphous compounds may undergo partial transformation into a crystalline form. Properties evaluated at that time can be very different from those observed earlier. To anticipate or check for such

polymorphic changes, dissolution measurements of minute quantities of the powdered sample may be made, and compound-sparing small-volume dissolution screening for polymorphic changes can be practical.

As medicinal chemists scale up the synthesis of a particularly promising compound, it is not uncommon that the isolated solid is morphologically transformed in new batches from its earlier states, as a result of altered procedures. Dissolution measurements on small quantities of the compound can reveal such polymorphic changes. If the particle size distribution is not known, such measurements are only approximate, but still may be useful for comparative assessments.

In the earliest stages of development, where drug delivery issues are first explored and syntheses of promising compounds are scaled up further, there is often a shortage of the candidate material to use for some of the desirable testing. The traditional US Pharmacopeia (USP)-type dissolution methods<sup>11–17</sup> are based on 500 or 900 mL assay volumes. There simply is not enough of the active pharmaceutical ingredient (API) then, and API-sparing methods need to be considered. Excipient-sparing methods are also needed, especially when expensive media, such as simulated intestinal fluid (SIF) or human intestinal fluid, are used. However, at formulation-oriented conferences (e.g., the long-standing June Land-of-Lakes Conference), presentations on ‘API-sparing’ topics still describe the use of 900 mL vessels. The apparent reluctance among some of the practitioners to use smaller volumes stems from concerns that the familiar (USP) ‘hydrodynamic conditions’ may not be valid in small-volume settings, when employed volumes are as low as 2 mL. Were small-volume dissolution apparatus used, SIF media would be cost-effective to use in early development.

The powder sample dissolution rates measured in 2 mL volumes will very likely be different from those done in 900 mL apparatus. This may be a source of confusion in discovery projects. The discussion of scalability of measurement (e.g., 2–900 mL), done under non-USP conditions, both its limitations and its advantages, could be of use to medicinal chemists, before their compounds transfer into development. The present theoretical discussion of dissolution simulation can help to address such issues. The small-volume, small-sample consumption methods described here could allow critical tests to be performed at more upstream positions than conventional methods would allow.

Since the dip-probe UV method (*see* Section 5.17.6.2) does not depend on the separation of solid from the suspension, in situ measurement of concentration is possible. This enables the method to be applied to the assessment of the in situ stability of very small quantities of the API in various test media.

## 5.17.2 Theoretical Solubility

The idealized (Henderson–Hasselbalch type) relationships<sup>1,2,19</sup> between solubility and pH can be easily derived for any given equilibrium model, although this may not be a familiar process to many practicing pharmaceutical scientists. The model refers to a set of equilibrium equations and the associated equilibrium constants.

### 5.17.2.1 Monoprotic Weak Acid, HA

In a saturated solution, the two relevant equilibrium equations for the case of a monoprotic weak acid, HA, are the ionization reaction (defined by  $pK_a$ ) and the solubility reaction (defined by  $S_0$ , the intrinsic solubility – the solubility of the uncharged molecular species, [HA]). The solubility,  $S$ , at a particular pH is defined as the mass balance sum of the concentrations of all of the species dissolved in the aqueous phase:

$$S = [A^-] + [HA] \quad [1]$$

where the square brackets denote the concentration of species. It is useful to convert eqn [1] into an expression containing only constants and  $[H^+]$  (as the only variable), by substituting the ionization and solubility equations into it<sup>1,2,19</sup>:

$$S = S_0(10^{-pK_a+pH} + 1) \quad [2]$$

with the limiting linear solutions,

$$\log S = \log S_0 \quad \text{for } pH \ll pK_a \quad [3a]$$

$$\log S = \log S_0 - pK_a + pH \quad \text{for } pH \gg pK_a \quad [3b]$$

**Figure 1** Log solubility–pH profiles for monoprotic acids (thin solid, long-dash, and short-dash curves), diprotic acid (dash-dot curve), a base (dash-dot-dot curve), and ampholyte (thick solid curve). For monoprotic acids, the tangent horizontal line segment denotes the intrinsic solubility, and the slope of +1 segment denotes the increase in the apparent solubility due to the formation of the anionic species. For diprotic acids, the ascending segment has a slope of +2. For monoprotic bases, the ascending portion of the curve has a slope of –1. An ampholyte has both acidic and basic behavior to the ascending portions of the curves. Salt precipitation is not indicated in these curves.

**Figure 1** shows a plot of  $\log S$  versus pH for several monoprotic acids (benzoic acid, 2-naphthoic acid, and indomethacin). Note that in eqn [3b],  $\log S$  is defined by a straight line as a function of pH, exhibiting a slope of 1. At the bend in the curves in **Figure 1**, the pH equals the  $pK_a$ .

#### 5.17.2.2 Diprotic Weak Acid, $H_2A$

The solubility for a diprotic weak acid is defined by (cf., eqn [1])

$$S = [A^{2-}] + [HA^-] + [H_2A] \quad [4]$$

The conversions of all variables into expressions containing only constants and  $[H^+]$  produces<sup>1,19</sup>

$$S = S_0(10^{-pK_{a1}-pK_{a2}+2pH} + 10^{-pK_{a1}+pH} + 1) \quad [5]$$

where  $S_0 = [H_2A]$ , and  $pK_{a1} < pK_{a2}$  are the two ionizations constants. The dash-dot curve in **Figure 1** shows the plot of  $\log S$  versus pH for the diprotic molecule hydrochlorothiazide, which has overlapping  $pK_a$ s (**Table 1**). For  $pH \ll pK_{a1}$ , the function reduces to a horizontal line, with  $\log S = \log S_0$ . For pH values between  $pK_{a1}$  and  $pK_{a2}$ ,  $\log S$  is straight line as a function of pH, exhibiting a slope of 1 (provided the  $pK_a$  constants are not overlapping). For  $pH \gg pK_{a2}$ ,  $\log S$  is a straight line as a function of pH, exhibiting a slope of 2, as is evident above pH 10 in **Figure 1**.

#### 5.17.2.3 Monoprotic Weak Base, B

For a monoprotic weak base,

$$S = [BH^+] + [B] \quad [6a]$$

$$= S_0(10^{pH+pK_a} + 1) \quad [6b]$$

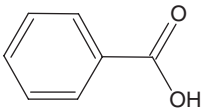

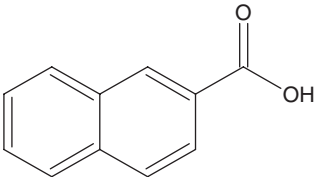

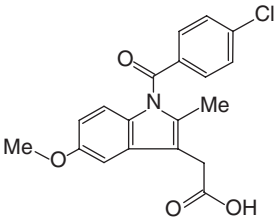

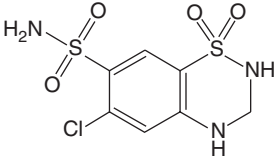

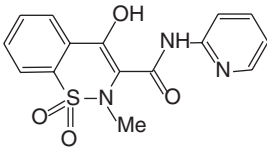

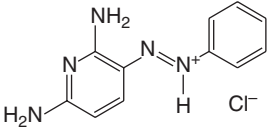

where  $S_0 = [B]$ . The limiting linear solutions are

$$\log S = \log S_0 \quad \text{for } pH \gg pK_a \quad [7a]$$

$$\log S = \log S_0 + pK_a - pH \quad \text{for } pH \ll pK_a \quad [7b]$$

The dash-dot-dot curve in **Figure 1** shows the plot of  $\log S$  versus pH for the weak base phenazopyridine. Note the sign reversal between eqns [7b] and [3b]. This shows up as the mirror relationship between this base curve and those of the acids.

**Table 1** Equilibrium constants for selected compounds<sup>a</sup>

| Compound  | MW    | $pK_a$            | $-\log S_0^b$     | $S_0$ ( $\mu\text{g mL}^{-1}$ ) | $-\log K_{sp}^c$  |
|---|-------|-------------------|-------------------|---------------------------------|-------------------|
| <br><b>Benzoic acid</b>                    | 122.1 | 3.98              | 1.59              | 3100                            |                   |
|   |       | 4.03 <sup>d</sup> | 1.67 <sup>d</sup> | 2600                            |                   |

|   |       | 4.31 <sup>i</sup> | 3.76 <sup>i</sup> | 30                              |                   |
|   |       | 4.02 <sup>d</sup> | 3.89 <sup>d</sup> | 22                              |                   |
|   |       | 4.30 <sup>e</sup> | 3.38 <sup>e</sup> | 72                              |                   |
| <br><b>Indomethacin</b>                    | 357.8 | 4.42              | 5.06              | 3                               |                   |
|   |       | 4.17 <sup>d</sup> | 5.58 <sup>d</sup> | 1                               |                   |
| <br><b>Hydrochlorothiazide</b>            | 297.7 | 9.95              | 8.76              | 2.63                            | 700               |
| <br><b>Piroxicam</b>                     | 331.4 | 5.07              | 2.3               | 5.48                            | 1                 |
|   |       | 5.34 <sup>f</sup> | 2.3               | 4.18 <sup>g</sup>               | 22                |
| <br><b>Phenazopyridine hydrochloride</b> | 249.7 | 5.15              | 4.24              | 14                              |                   |
|   |       | 5.20 <sup>h</sup> | 3.83 <sup>h</sup> | 37                              | 3.53 <sup>h</sup> |

<sup>a</sup> 25 °C, 0.15 M (KCl) ionic strength, solubility determined by the DTT method,<sup>31</sup> unless otherwise noted.<sup>b</sup> Intrinsic solubility, based on molar units.<sup>c</sup>  $K_{sp} = [\text{BH}^+][\text{Cl}^-]$ , the solubility product.<sup>d</sup> 25 °C, 0.5 M (KCl).<sup>42</sup><sup>e</sup> 25 °C, 0.1 M (KCl).<sup>46</sup><sup>f</sup> 37 °C, 0.15 M (KCl) (pION, unpublished work).<sup>g</sup> Re-analysis of 37 °C data of Jinno *et al.*<sup>58</sup><sup>h</sup> 37 °C, no ionic strength adjuster added.<sup>53</sup><sup>i</sup> 25 °C, 0.01 M ionic strength, determined by the UV method (pION, unpublished work).

Also shown in [Figure 1](#) is the case of the ampholyte piroxicam (thick line). An ampholyte is a molecule containing both acid and base functionality (*see* 5.16 Ionization Constants and Ionization Profiles). The curve shows features of both an acid ( $\text{pH} > 5$ ) and a base ( $\text{pH} < 3$ ).

#### 5.17.2.4 Gibbs $\text{pK}_a$ (Weak Base Example)

Although [Figure 1](#) properly conveys the shapes of solubility–pH curves in saturated solutions of uncharged ionizable species, the effect of salt precipitation is not shown. It has been observed, for example, that in 0.15 M NaCl solutions, when the solubility exceeds its lowest (intrinsic) value by about four orders of magnitude for a weak acid and about three orders of magnitude for a weak base, the sodium and chloride salts of the charged drugs, respectively, will likely precipitate, and under the right circumstances, co-precipitate with the free acid or free base.<sup>30</sup> This has been called the ‘sdiff 3–4’ effect.<sup>1,19</sup> Salt formation stunts further increases in equilibrium solubility, which is not represented in [Figure 1](#).

Consider the case of a very concentrated solution of the weak base hypothetically titrated with HCl from high pH (well above its  $\text{pK}_a$ ) down in pH to the point where the solubility product is exceeded. At the start, the saturated solution contains only the free base precipitate. As the pH is decreased below the  $\text{pK}_a$ , the solubility increases, as more of the free base ionizes, and a portion of the solid B dissolves, as indicated by the dash-dot-dot curve in [Figure 1](#). When the concentration of  $\text{BH}^+$  times the concentration of  $\text{Cl}^-$  reaches the solubility product value, at the critical pH, solid  $\text{BH}^+\text{Cl}^-$  starts to precipitate, but at the same time there may be remaining free base, B, precipitate. The simultaneous presence of the two solids invokes the Gibbs phase rule constraint, forcing the pH and the solubility to be precisely constant. (As shown by Gibbs, the thermodynamic phase rule describes the possible degrees of freedom in a closed system at equilibrium, which puts a limit on the number of independent reactants that describe the system uniquely, for a given number of separate phases in the system.) As long as B(s) still remains, the HCl titrant, in effect, is diverted entirely into the solid state, to transform the remaining B(s) into  $\text{BH}^+\text{Cl}^-$ (s). This process produces a ‘perfect’ pH buffer.<sup>29</sup> This special pH point has been called the Gibbs  $\text{pK}_a$ , indicated as  $\text{pK}_a^{\text{Gibbs}}$ .<sup>1,29</sup> The equilibrium equation associated with this phenomenon is

where the constant,  $K_a^{\text{Gibbs}} = [\text{H}^+] = K_s/[\text{Cl}^-]$ . This is a conditional constant, inversely depending on the value of the background  $[\text{Cl}^-]$ , as is illustrated in [Figure 2](#), for the profile of phenazopyridine hydrochloride at two different levels of added KCl, using the 37 °C data of Serajuddin and Jarowski<sup>53</sup> in the simulation (see [Table 1](#)). The decrease in the solubility at low pH is an example of the common-ion (chloride) effect.<sup>24,25</sup> The chloride contributed by the HCl, needed to lower the pH, drives down the solubility of the charged form of the drug.

**Figure 2** Log solubility–pH profiles of phenazopyridine,<sup>53</sup> indicating the formation of chloride salt precipitates. The solid curve is the predicted profile in the background of 0.15 M KCl, whereas the dash-dot curve is the predicted profile in the presence of no added KCl. In both cases, the simulation considered a titration of the drug suspension solution using concentrated HCl, from high pH to low pH. The ‘common-ion’ effect refers to the decrease in solubility of the salt below pH2, due to the increased presence of chloride ions entering the solution from the HCl titrant used to lower the pH. The point where both the solid free base and the chloride salt of the conjugate acid coprecipitate is referred to as the Gibbs  $\text{pK}_a$ .

Since solubility is constant (the Gibbs phase rule constraint) during the two-solid interconversion process, one may set eqn [6b] equal to eqn [2], noting that for a weak base,  $10^{-pK_a+pH} \ll 1$  and  $10^{+pK_a-pH} \gg 1$ , to get (in logarithmic form) the conditional expression<sup>1</sup>

$$\log S_i - \log S_0 = pK_a - pK_a^{\text{Gibbs}} \quad [9]$$

where  $S_i$  is the solubility of the ionized form of the drug.

### 5.17.3 Solubility Measurement

#### 5.17.3.1 Shake-Flask Method

The traditional solubility measurement<sup>2</sup> under equilibrium conditions is largely a manual, time-intensive process, taking many hours, sometimes as long as several days, at a given pH. It is often a simple procedure. The drug is added to a standard buffer solution until saturation occurs, indicated by undissolved excess drug. The saturated solution is shaken at constant temperature as equilibration between the two phases establishes. After centrifugation and/or microfiltration, the concentration of the substance in the supernatant solution is then determined. If a solubility–pH profile is required, then the measurement needs to be performed in parallel in several different pH buffers. The whole process can easily take a week to complete.

Many of the measurements by the shake-flask method use a pH 6.5 or 7.4 buffer solution (often 50 mM phosphate) as the medium. Alternatively, a biomimetic SIF medium can be used, which consists of phospholipids, bile salts, and other ingredients, in addition to buffer.<sup>12,13</sup> Many low-solubility drugs show elevated solubility in a SIF medium. Due to the complexity and relatively high cost of the SIF medium, it is used less often than simple buffers.

It is critical that the pH at the end of each assay be carefully measured, when working with ionizable drugs. Surprisingly, this is not always done.

#### 5.17.3.2 Potentiometric Method

In acid–base dissolution titrations of ionizable compounds, the titrant perturbs the saturated system at equilibrium and causes a portion of the suspended solid to dissolve (taking the system out of equilibrium), a process which can be very slow, depending on a number of factors related to dissolution kinetics (see Section 5.17.5). In order to collect pH data suitable for the reliable determination of solubility constants, it is necessary to allow the titrated system to return to an equilibrium state following each titrant addition.

The DTT method consists of an unusual data collection regime, based on the use of precalculated titration curves serving as templates.<sup>29–31</sup> The instrument takes as input parameters the  $pK_a$  and the octanol/water partition coefficient ( $\log P_{ow}$ ) of the sample. The latter parameter is used to estimate the intrinsic solubility,  $S_0$ , according to the simple linear expression  $\log S_0 = 1.17 - 1.38 \log P_{ow}$ .<sup>54</sup> Using the  $pK_a$  and the estimated  $S_0$ , the instrument calculates the entire titration curve before starting the assay. The curve serves as a template that the instrument uses as a guide on how to collect individual pH measurements in the course of the titration.

Enough sample is weighed to cause precipitation during some portion of the titration. The pH where precipitation takes place is estimated from the template simulation, and the data collection strategy is set accordingly.<sup>31</sup> Titrations of weak acids begin at low pH, and those of weak bases begin at high pH. KOH (or HCl) titrant is dispensed accurately and slowly into the slurry, to drive the pH of the solution in the direction of dissolution, eventually well past the point of complete dissolution.

As titrant is added, careful measurements of pH are made. The instrument dramatically slows down the rate of data taking as the point of complete dissolution approaches in the titration. It uses the Noyes–Whitney dissolution rate expression,<sup>2</sup> with the necessary reactant concentrations calculated on the basis of the template model, to estimate how long to wait for equilibrium to be reached following the addition of titrant. Consequently, some data are collected at moderate speeds and some at very slow speeds. Only after the precipitate completely dissolves (assessment based on the template prediction), does the instrument collect the remainder of the data rapidly, as would an ordinary titrator. Typically, 4–10 h is required for the entire equilibrium solubility data taking (20–50 pH points). The more insoluble the compound is anticipated to be (based on the template), the longer the recommended assay time.

#### 5.17.3.3 High-Throughput Microtitre Plate Methods

##### 5.17.3.3.1 Turbidimetric assays ('kinetic' solubility)

The turbidity method described by Lipinski *et al.*,<sup>6</sup> which assesses 'kinetic' solubility, although not thermodynamically rigorous, is an attempt to rank molecules according to expected solubilities. Versions of the method are used by several

pharmaceutical companies, with custom-built equipment. Nephelometers using 96-well microtitre plates have been adapted into these systems.<sup>7</sup> Often, single-pH (6.5 or 7.4) 50 mM buffer solutions are used. Note that phosphate at such high concentration can form complicated-stoichiometry salts with positively charged drugs.<sup>35</sup> Buffers such as MES and HEPES are less problematic.<sup>1</sup> Being a result of a 'kinetic' method, the measured solubility can depend dramatically on the timings used in the assay. In this regard, standard methodology is not well defined. For binning purposes, the turbidity analysis is fine. However, the turbidity-based measurements may not be of sufficient quality for medicinal chemistry structure–activity relation (SAR) applications.

#### 5.17.3.3.2 High-performance liquid chromatography (HPLC) based assays

Several pharmaceutical companies have taken the classical saturation shake-flask method and transferred it to 96-well plate technology and a robotic liquid dispensing system. Analyses are performed with reverse-phase HPLC, often using fast generic gradient methods. In some laboratories, the DMSO is first eliminated by a freeze–drying procedure, before the aqueous buffers are added. Data handling is often the rate-limiting step in the customized operations.<sup>7–9</sup> Such methods can be very reliable,<sup>35</sup> but the lack of method standardization is potentially problematic.

#### 5.17.3.3.3 Direct ultraviolet assay

A highly-automated direct-UV 96-well microtitre plate equilibrium solubility method has been described recently.<sup>19</sup> Samples are typically introduced as 10 mM DMSO solutions in a 96-well microtitre plate. The robotic liquid-handling system (e.g., the Beckman FX series) draws a 3–10  $\mu\text{L}$  aliquot of the DMSO stock solution and mixes it into an aqueous universal buffer solution, so that the final (maximum) sample concentration is 50–150  $\mu\text{M}$  and the DMSO concentration is 0.5–1.0% (v/v). The solutions are stirred magnetically, then filtered, and assayed by direct UV spectrophotometry. The direct UV measurement eliminates the need for method development, and easily lends itself to more complete automation and, hence, higher throughput. The buffers used in the assay are automatically prepared by the robotic system. The quality controls of the buffers and the pH electrode are performed by alkalimetric titration, incorporating the Avdeef and Bucher<sup>55</sup> procedure. This method has been applied to determine solubilities as low as  $2 \text{ ng mL}^{-1}$ .<sup>73</sup>

### 5.17.4 Common Complications in Solubility Measurement of Low-Solubility Compounds

#### 5.17.4.1 Aggregation Reactions in Solubility Measurement

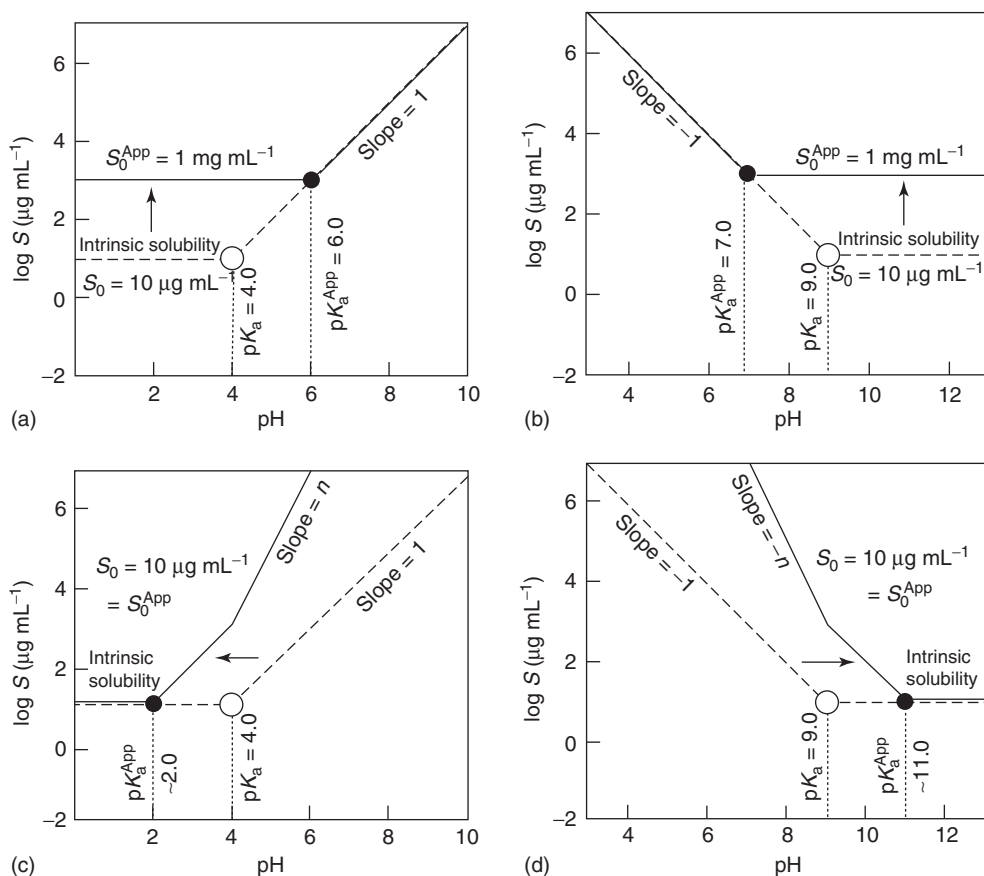

When a compound forms a dimer or a higher-order oligomer in aqueous solution, the characteristic log  $S$ –pH profile (e.g., see [Figure 1](#)) often indicates the observed  $\text{p}K_{\text{a}}$  (pH at the bend in the log  $S$ –pH profile in [Figure 1](#)), to be different from the true  $\text{p}K_{\text{a}}$ , as measured in dilute solutions. Besides aggregation, other anomalies can cause the  $\text{p}K_{\text{a}}$  to appear shifted, including compound adhesion to the filter material, DMSO binding, and excipient effects. This shift-in-the- $\text{p}K_{\text{a}}$  effect has been discussed previously, although its use appears not to be widespread.<sup>1</sup>

If an uncharged molecule undergoes some speciation anomaly (aggregation, DMSO binding, filter retention, etc.), weak acids will indicate an apparent  $\text{p}K_{\text{a}}$  higher than the true  $\text{p}K_{\text{a}}$ , as indicated schematically in [Figure 3a](#), and weak bases will indicate an apparent  $\text{p}K_{\text{a}}$  lower than the true  $\text{p}K_{\text{a}}$ , as indicated schematically in [Figure 3b](#). If the observed shifts are opposite to those stated above, then the charged (rather than the neutral) species is involved in the anomaly ([Figures 3c](#) and [3d](#)). Anomalies involving charged species also reveal themselves by nonunit slopes in the diagonal portions of the log  $S$ –pH curves (see below). Although the precise mechanism of the anomaly may not be apparent, the shift combined with the apparent solubility will often reveal the intrinsic (unshifted) solubility,  $S_0$ . [Figure 3](#) illustrates these four cases schematically as 'stick' diagrams.

In this section we will present several examples of putative aggregation reactions, involving 2-naphthoic acid, indomethacin, phenazopyridine, and piroxicam. The medicinal chemist may wish to skip the mathematical treatment below, but an appreciation of the characteristic shapes of log  $S$ –pH profiles under conditions of 'anomaly' would be beneficial.

##### 5.17.4.1.1 Indomethacin and 2-naphthoic acid anion aggregation

Roseman and Yalkowsky<sup>22</sup> described the solubility–pH behavior of prostaglandin  $\text{F}_{2\alpha}$ , and noted that anionic aggregates appeared to form, as in [Figure 3c](#). No further characterization of the aggregation behavior was reported. There are numerous other literature examples of the phenomenon, which is often not fully assessed.

**Figure 3** Stylized schematic log solubility–pH profiles, showing just the straight line segments, and not the curved regions linking them (as in [Figure 1](#)). (a) The solid segments are observed in the case of a weak acid, where neutral aggregates form. The dashed segments refer to the underlying curve that would have been observed had there been no aggregation. The difference between the apparent  $pK_a$  (solid circle) and the true  $pK_a$  (open circle), when subtracted from the apparent intrinsic log solubility (low pH horizontal region), reveals the hidden intrinsic log solubility. (c) The solid segments are observed in the case of a weak acid where anionic aggregates form. The expected slope in the right-most portion of the ascending solid plot is equal to the order of aggregation,  $n$ , if just a single aggregate stoichiometry exists. (b, d) The parallel cases to parts a and c, but concerning weak-base behavior (see the text).

Let us hypothesize that the oligomeric species  $A_n^{n-}$  forms. The required equilibrium equations and the associated concentration quotients to completely define the mass balance problem are

The expanded form of eqn [1] becomes

$$S = [A^-] + [HA] + n[A_n^{n-}] \quad [12]$$

Following the steps that led to eqn [2],<sup>1,19</sup> we now obtain<sup>39</sup>

$$\log S = \log S_0 + \log[1 + 10^{+(pH-pK_a)} + n10^{+\log K_n + n(pH-pK_a) + (n-1)\log S_0}] \quad [13]$$

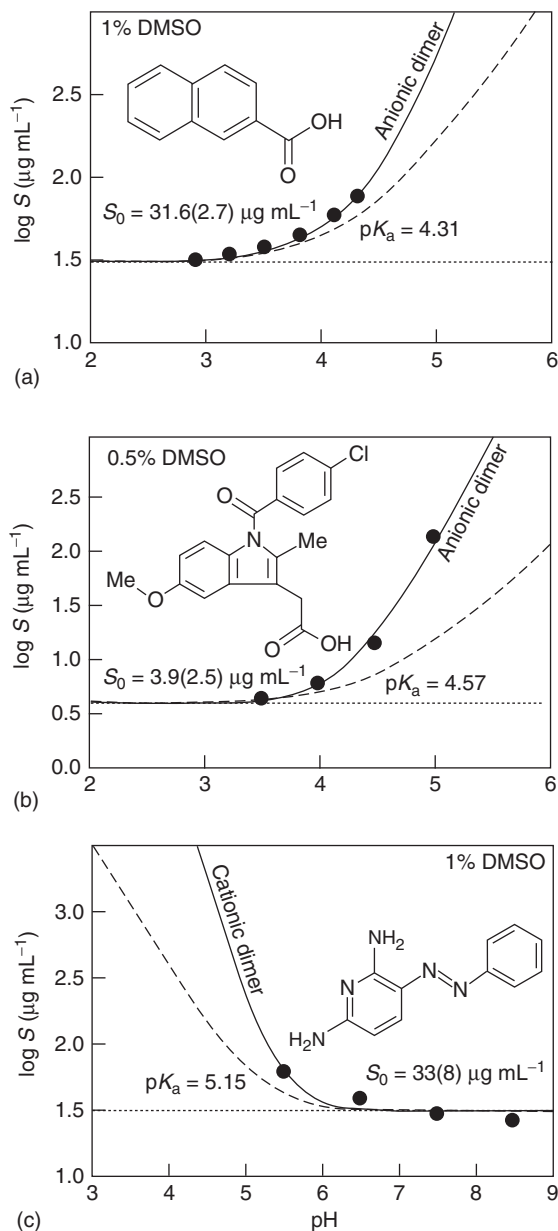

Two limiting forms of eqn [13] may be posed as (see [Figure 3c](#))

$$\log S = \log S_0 \quad \text{for } pH \ll pK_a \quad [14a]$$

$$\log S = \log n + \log K_n + n(\log S_0 - pK_a) + npH \quad \text{for } pH \gg pK_a \quad [14b]$$

Equation [14a] indicates that the formation of charged aggregates does not obscure the value of the intrinsic solubility in low-pH solutions. If high-quality data are available over an extensive range of pH, and aggregation takes place (as evidenced by an apparent  $pK_a$  significantly different from the true  $pK_a$ ) then eqn [14b] may be useful in assessing the stoichiometry of aggregation, provided that aggregates can be described by a single value of  $n$ . A plot of  $\log S$  versus pH (see eqn [14b] and Figure 3c) should indicate the value of  $n$  as the slope in the curve at high pH. The specialist reader is encouraged to explore other properties of eqn [13], using, for example, a spreadsheet.

Figure 4 contains  $\log S$  versus pH plots of three ‘anomaly’ molecules, 2-naphthoic acid, indomethacin, and phenazopyridine, all measurements done by the UV microtitre plate method in 0.01 M ionic strength solutions. One

**Figure 4** Specific examples of aggregation (cf. the schematic depictions in Figure 3). Solubility determined by the miniaturized ‘self-calibrating’ UV method.<sup>19</sup> (a) 2-Naphthoic acid, with an indication of anionic aggregation (0.2  $\mu\text{m}$  filtration after 17 h, 1% DMSO). (b) Indomethacin, with an indication of extensive anionic aggregation (centrifugation after 23 h, 1.0% DMSO). (c) Phenazopyridine, with indications of cationic aggregation (0.2  $\mu\text{m}$  filtration after 21 h, 1% DMSO). The dashed curves were calculated using the idealized Henderson–Hasselbalch equation, which neglects aggregation.

can see that the apparent  $pK_a$  appears to be different from the true  $pK_a$ . The direction of the shifts in the  $pK_a$  in the three cases suggest the presence of charged aggregates.

If one assumes that indomethacin forms a dimer ( $n=2$ ), then **Figure 4b** indicates that  $K_2 = 1.8 \times 10^5 \text{ M}^{-1}$ . For 2-naphthoic acid, a weaker dimerization constant is apparent ( $K_2 = 1.5 \times 10^3 \text{ M}^{-1}$ ), consistent with the small shift in **Figure 4a**.

It is interesting to note that indomethacin solubility characterized in 0.3 M KCl solution indicates  $pK_a^{\text{App}}$  4.81<sup>56</sup> ( $pK_a$  4.17 in **Table 1**, 0.5 M KCl, from the same laboratory), and  $-\log S_0^{\text{App}}$  5.06 ( $-\log S_0$  5.58 in **Table 1**, from the same laboratory), indicating the predominant presence of neutral aggregates under the high-salt condition, an entirely different behavior from that observed in 0.01 M ionic strength solution, as shown in **Figure 4b**.

#### 5.17.4.1.2 Phenazopyridine cation aggregation

**Figure 4c** show the log  $S$ -pH plot of phenazopyridine hydrochloride. As can be seen, the apparent  $pK_a$  is shifted to a higher value (cf. **Figure 3d**), consistent with the formation of cationic aggregates. An analysis along the lines of that described in **Section 5.17.4.1.1** may be performed to obtain an equation similar to eqn [13].<sup>39</sup> The dimerization constant consistent with the data is  $K_2 = 1.0 \times 10^4 \text{ M}^{-1}$ . We have seen cationic aggregation for other weak bases as well: chlorprothixene, cyproheptadine, fendiline, imipramine, and mifepristone (unpublished data). With today's all too often low-solubility discovery compounds, such phenomena are probably more common than is actually realized by pharmaceutical scientists. If such effects are ignored, then later applications of the measured solubility to rationalizing dissolution curves may lead to erroneous conclusions (see **Section 5.17.6.4**).

#### 5.17.4.1.3 Piroxicam neutral species aggregation effects

Shifts in the  $pK_a$  can also be expected if water-soluble aggregates form from the uncharged monomers (see **Figures 3a** and **3b**). This may be expected with stackable planar molecules, such as piroxicam.<sup>57</sup> Let us hypothesize that a specific neutral  $n$ -oligomer of piroxicam forms:

So,

$$S = [\text{H}_2\text{X}^+] + [\text{XH}] + [\text{X}^-] + n[\text{X}_n\text{H}_n] \quad [17]$$

Let us for the moment consider only  $pK_{a2}$  of amphoteric piroxicam, so that the treatment simplifies to that of a monoprotic acid. Consequently,

$$\log S = \log S_0 + \log(1 + K_a/[\text{H}^+] + nK_n S_0^{n-1}) \quad [18]$$

At pH values well below  $pK_{a2}$  (but above  $pK_{a1}$ ), eqn [18] reduces to (the horizontal solid line in **Figure 3a**)

$$\begin{aligned} \log S &= \log S_0 + \log(1 + nK_n S_0^{n-1}) \quad \text{for } pK_{a1} < \text{pH} < pK_{a2} \\ &= \log S_0^{\text{App}} \end{aligned} \quad [19]$$

From the schematic representation in **Figure 3a**, eqn [19] suggests

$$\log S_0^{\text{App}} - \log S_0 = \log(1 + nK_n S_0^{n-1}) \quad [20]$$

Aggregation of the neutral species elevates the apparent solubility of the neutral species (**Figure 3a**). However, if  $\text{pH} \gg pK_{a2}$  (past the  $pK_{a2}^{\text{App}}$  value, thus  $K_a/[\text{H}^+] \gg nK_n S_0^{n-1} \gg 1$ ), eqn [18] reduces to eqn [3b].

**Figure 5** Log solubility–pH profiles for piroxicam, 25 °C, 0.01 M ionic strength, miniaturized ‘self-calibrating’ UV method (see Section 5.17.3.3.3),<sup>19</sup> centrifugation after 23 h, in the presence of 0.5% DMSO (solid circles) and 1% DMSO (open circles). The solid curves are fitted to the points with the refined dimerization constants listed in the figure. The nearly identical dashed curves were derived by the shift-in-the- $pK_a$  procedure (see Figure 3a), with intrinsic solubility resulting in  $6.0 \pm 1.4 \mu\text{g mL}^{-1}$ . The structure shown is based on the known structure of the dimer present in the solid state.<sup>57</sup>

If the true  $pK_a$  is subtracted from  $pK_a^{\text{App}}$ , the difference then subtracted from the logarithm of the apparent solubility,  $S_0^{\text{App}}$ , yields the true aqueous solubility constant:

$$\log S_0 = \log S_0^{\text{App}} \pm (pK_a - pK_a^{\text{App}}) \quad [21]$$

with the ‘+’ sign for ionizable acids (Figure 3a) and the ‘–’ sign for ionizable bases (Figure 3b).

Figure 5 shows the  $\log S$ –pH plots for piroxicam, at 25 °C and 0.01 M ionic strength, in the presence of 0.5% and 1.0% DMSO. The plots indicate neutral species anomaly. It was possible to fit the data with a dimerization ( $n = 2$ ) model, with refined constants best fitting the elevated curves in Figure 5 as  $K_2 = 3.5 \times 10^4 \text{ M}^{-1}$  (0.5% DMSO) and  $6.4 \times 10^4 \text{ M}^{-1}$  (1.0% DMSO). The underlying (hidden) intrinsic solubility, indicated by the dashed curve in Figure 5, is the same  $6.0 \pm 1.1 \mu\text{g mL}^{-1}$ , regardless of which DMSO level data are used in its evaluation. It is interesting to note that Rozou *et al.*,<sup>57</sup> using nuclear magnetic resonance, detected the presence of dimers in low-pH solution, although binding constants were not reported. The dimerization constant appears to be sensitive to the level of DMSO present, although the same intrinsic solubility is calculated from either of the two sets.

#### 5.17.4.2 Effects of Excipients on Solubility

Jinno *et al.*<sup>58</sup> showed how excipient sodium lauryl sulfate (SLS) affected the solubility–pH profile of piroxicam, at 37 °C. For each level of SLS, the solubility–pH data were fitted by eqn [2], with  $pK_a$  refined as the apparent value. Table 2 summarizes the shift-in-the- $pK_a$  analysis of their data. Note that as the level of SLS increases from 0% to 2%, the  $pK_a^{\text{App}}$  value increases systematically. Figure 6 shows the data and the best-fit results. The application of eqn [21] indicates that the underlying intrinsic solubility,  $S_0$ , remains remarkably invariant, averaging  $21.3 \pm 1.6 \mu\text{g mL}^{-1}$ , even though the apparent intrinsic solubility rises to about  $500 \mu\text{g mL}^{-1}$  at 2% SLS.

#### 5.17.4.3 What the Shift-in-the- $pK_a$ Method Can and Cannot Do

The method based on shift in the  $pK_a$ , schematically illustrated in Figure 3, is best used as a ‘quick-alert’ tool. (As is implied, the molecule must have an ionization group within the accessible pH range, in order for the method to work.) When a  $\log S$  versus pH plot is inspected, and the true  $pK_a$  is known, the investigator can quickly surmise whether aggregates (or ‘anomalies’) may be present, and whether these effects are due to the neutral or the charged

**Table 2** Piroxicam intrinsic solubility<sup>a</sup>

| SLS (%) | $pK_a^{app}$    | $S_0$ ( $\mu\text{g mL}^{-1}$ ) |
|---------|-----------------|---------------------------------|
| 0.0     | $5.44 \pm 0.16$ | $24.6 \pm 8.9$                  |
| 0.5     | $6.32 \pm 0.13$ | $20.5 \pm 6.1$                  |
| 1.0     | $6.48 \pm 0.10$ | $21.8 \pm 5.0$                  |
| 2.0     | $6.77 \pm 0.12$ | $20.0 \pm 5.6$                  |

<sup>a</sup>Data from Jinno, J.; Oh, D.-M.; Crison, J. R.; Amidon, G. L. *J. Pharm. Sci.* **2000**, 89, 268–274 at 37 °C. The measured  $pK_{a2}$  of piroxicam is 5.34 at 37 °C (see **Table 1**). The calculated values are from the pDISS program.

**Figure 6** Log solubility–pH profiles for piroxicam as a function of excipient SLS, 37 °C, 0.1–0.2 M ionic strength, data (see [Section 5.17.4.2](#)) from Jinno, J.; Oh, D.-M.; Crison, J. R.; Amidon, G. L. *J. Pharm. Sci.* **2000**, 89, 268–274. The solid curve for 0% SLS was fitted to the points with the refined dimerization constants listed in the figure. The other solid curves were fitted to the shift-in-the- $pK_a$  analysis (see [Figure 3a](#)), with intrinsic solubility resulting in  $21.3 \pm 1.6 \mu\text{g mL}^{-1}$ .

form of the species. Furthermore, the intrinsic solubility may be calculated from the magnitude or the direction of the  $pK_a$  shift. So, one has the opportunity to measure solubility in the presence of excipients and at the same time to assess the solubility that would have been evident in the absence of added excipients. This is the best use of the shift method. Caution is needed not to overinterpret the measurement data, however.

#### 5.17.5 Convective Diffusion with Reaction: Rotating Disk Dissolution of Ionizable Drugs

The concentration gradients of all species present in the ABL determine how quickly the drug is transported from the solid state to the solution in the medium. When the solid drug is first placed in the dissolution medium, the concentration gradient that quickly establishes across the ABL is proportional to the solubility, according to the Noyes–Whitney equation.<sup>59–62</sup> The overall dissolution rates are dependent on how quickly the drug diffuses through the ABL, how strongly the drug interacts with the medium components in the ABL, such as excipients, and how pH gradients develop in the ABL, as a consequence of all ionizable components present. The pH gradient is a very important and subtle determinant of the rate of dissolution. For example, an often surprising observation (to a nonspecialist) is that the dissolution rate can double if the concentration of the medium buffer is doubled, even though the buffer pH stays the same (see [Section 5.17.6.6](#)). There are thus opportunities to improve drug dissolution properties by synthetic alterations of the molecules, to change solubility and excipient binding properties.

This section briefly summarizes the conceptual aspect of modern dissolution theory, applied to the rotating disk geometry (e.g., Wood's apparatus).<sup>39</sup> Dissolution of powders is covered in [Section 5.17.7](#). The medicinal chemist more interested in dissolution applications than theory may safely skip to [Section 5.17.6](#).

### 5.17.5.1 Equations in Convective Diffusion Mass Transport

In the rotating disk dissolution experiment, once an ionizable compound dissolves at the solid–liquid interface and begins to move across the ABL, which is in contact with the surface of the solid, the molecules may undergo chemical reactions in the ABL, such as ionization, complexation, micelle formation, and excipient interaction. (Also, the properties of the ABL are affected by non-API components, often critically affecting the pH gradient, which impacts on the overall dissolution process.) The dissolved molecules move through the ABL by the combined action of diffusion and the convective fluid flow generated by the action of the rotating disk. The convective flow equations due to the rotation in a viscous fluid were originally solved by von Kármán in 1921, and later substantially refined by Cochran in 1934. More recent discussions may be found in the classic books by Levich,<sup>64</sup> Cussler,<sup>65</sup> and Schlichting and Gersten,<sup>66</sup> and in research papers.<sup>39,63,67,68</sup>

The partial differential equation describing the convective diffusion process is

$$\partial C(x, t)/\partial t = \partial(D(x) \partial C(x, t)/\partial x)/\partial x + |V(x)| \partial C(x, t)/\partial x \quad [22]$$

where  $C(x, t)$  is the concentration of the reactant, at position  $x$  (distance from the surface of the rotating disk) and time  $t$ .  $D(x)$  is the diffusivity at position  $x$  (which indirectly has a time dependence), and  $|V(x)|$  is the absolute value of the axial velocity of the convective fluid flow, at the distance  $x$  from the rotating surface. Each different species in solution has its own form of eqn [22]. For example, for a diprotic weak acid, the different species are  $H_2A$ ,  $HA^-$ ,  $A^{2-}$ ,  $H^+$ , and  $OH^-$ . Normally, eqn [22] needs to be solved for  $C(x, t)$  of each of the species. (For the moment, the chemical reaction terms are left out in eqn [22]. We will come back to them later.)

In our treatment of the theoretical problem,<sup>39</sup> the diffusivity of species is not assumed to be constant throughout the ABL. We will show that in certain cases the diffusivity can vary by an order of magnitude (or even more) at various locations in the ABL. This can be explained by the Vinograd–McBain<sup>49</sup> electric field neutrality treatment, which addresses the spatial dependence of diffusivity, as a function of all ions present in solution.

### 5.17.5.2 Vinograd–McBain Treatment of the Diffusion of Electrolytes and of the Ions in Their Mixture

Electric fields, created in solutions containing ions migrating under concentration gradients, can act on each ion, to either retard or accelerate its diffusion velocity from the canonical value the ion would have ( $D^*$ ) in the absence of the gradients. If a solution contains a highly mobile ion, such as  $H^+$ , and a sluggish ion, such as the drug molecule,  $A^-$ , and there is an imposed concentration gradient, the faster ion has the innate tendency to diffuse ahead of the slower ion, which creates a charge separation. This in turn lowers the diffusivity of the fast ion and raises that of the slow one, so that very quickly both ions travel at the same steady state velocity, in order to maintain spatial charge neutrality. For example, the diffusivity of  $H^+$  in a dilute salt solution can be as low as  $10 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$  (see below). This is a surprisingly low value, since, in a solution containing 0.1 M KCl and no concentration gradients, the diffusivity of hydrogen ions is  $93 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ . Such swings in diffusivity need to be properly accounted for in the analysis of dissolution experiments, when the ionic strength of the solution is low.

By imposing the electrical neutrality condition for the ion mixture, Vinograd–McBain<sup>49</sup> derived the expression for the resultant diffusivity at position  $x$  in the diffusion layer for a given ion,  $D_j(x)$ , as a fraction of the diffusivity that the ion would have in the absence of concentration gradients,  $D_j^*$  (position independent),

$$\frac{D_j(x)}{D_j^*} = 1 \mp \frac{|z_j| C_j(x, t)}{dC_j(x, t)/dx} \left( \frac{\sum_i (z_i/|z_i|) D_i^* (dC_i(x, t)/dx)}{\sum_i D_i^* |z_i| C_i(x, t)} \right) \quad [23]$$

where the ‘ $-$ ’ sign in  $\mp$  is used if the species  $j$  is a cation, and the ‘ $+$ ’ sign used if it is an anion. The summations are taken over all the ions present in the solution. The shifts in the diffusivity coefficients predicted by eqn [23] are less dramatic when an appreciable amount of background salt (e.g., KCl) is added. In the weak acid example below, the coupling between  $A^-$  and  $H^+$  is relaxed by the  $K^+$  and  $Cl^-$  ions from the ‘swamping’ level of background electrolyte. Such changes in diffusivities as a function of the ion concentrations and concentration gradients in solution are automatically compensated for in the computer program developed to solve eqn [22].<sup>39</sup>

**Figure 7** Concentration–time profile in the ABL until the time steady state is reached, calculated by the numerical integration technique (see Section 5.17.5.3) for diprotic hydrochlorothiazide, under the conditions identified in the figure. The dashed lines indicate  $t = 0.01, 0.02, \dots, 0.05$  s, while the solid curves above those lines indicate  $t = 0.1, \dots, 0.4$  s, the latter value being approximately the steady state time.

### 5.17.5.3 Chemical Reaction during Convective Diffusion

Once an ionizable substance dissolves and begins to diffuse across the ABL, it may undergo chemical reactions, as noted above. Yet, eqn [22] does not explicitly contain reaction terms. It was shown by Olander<sup>69</sup> that if the differential equations for each species, such as eqn [22] applied to  $\text{H}_2\text{A}$ ,  $\text{HA}^-$ ,  $\text{A}^{2-}$ ,  $\text{H}^+$ , and  $\text{OH}^-$ , are combined to express total concentrations of weak acid drug,  $A$ , all reaction terms cancel out, provided the reactions are reversible and fast compared with diffusion.<sup>69</sup> It is simply not necessary to consider explicit chemical reaction rate constants, as Olander had demonstrated a long time ago. For example, the total partial differential expression for the diprotic weak acid becomes

$$\partial A / \partial t = \partial (D_{\text{H}_2\text{A}} \partial C_{\text{H}_2\text{A}} / \partial x) / \partial x + \partial (D_{\text{HA}} \partial C_{\text{HA}} / \partial x) / \partial x + \partial (D_{\text{A}} \partial C_{\text{A}} / \partial x) / \partial x + |V(x)| \partial A / \partial x \quad [24]$$

Equation [24] can be solved for the total concentrations  $A$ . With  $A$  calculated, then the nonlinear computation of all reactant and associated species can proceed, provided all the relevant equilibrium constants are known.<sup>1,32–34</sup> A general and robust numerical method to solve eqn [24] has been described.<sup>39</sup> This was compared with an analytical solution in the same study.

Figure 7 shows the time progression of the numerical solutions<sup>39</sup> to eqn [24] for diprotic hydrochlorothiazide, as a function of the distance from the rotating disk surface, at 600 rpm. The (gradient-free) diffusivity of hydrochlorothiazide was taken to be  $5.5 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ . Under these circumstances, the thickness of the ABL, according to the Levich equation,<sup>64</sup> is  $h = 0.00163$  cm. The dashed curves indicate  $t = 0.01, 0.02, \dots, 0.05$  s, while the solid curves above those lines indicate  $t = 0.1, \dots, 0.4$  s, the last value being approximately the steady state time. When the monoprotic indomethacin example<sup>42</sup> is considered, the resultant steady state curve is identical to that shown in Figure 7. The solution to the total concentration partial differential equations is entirely independent of the chemical reactions taking place, as originally recognized by Olander.

The numerical integration scheme is flexible and robust (albeit not fast). We demonstrated practical equivalence between the steady state concentration profile determined by the numerical procedure (which is very easy to manipulate for new boundary conditions and geometries) and that suggested by the much faster analytical equation procedure<sup>65,70</sup> (which is not easy to alter and manipulate). The program developed to do all these computations is called pDISS.<sup>39</sup>

## 5.17.6 Dissolution Apparatus and Measured Results

### 5.17.6.1 Wood's Rotating Disk Apparatus for Mechanistic Studies

Because of its well-characterized fluid hydrodynamics, the rotating disk method is a useful tool for mechanistic dissolution studies. The DIDR measurements have been used for many years to characterize solid drugs, including

studies of dissolution–pH rate profiles in the presence of buffers, complexing agents, and various excipients.<sup>2,41–47,53,58</sup> It is currently debated whether the DIDR method can be used to determine solubility class membership in the Biopharmaceutics Classification System, with encouraging early indications.<sup>71</sup>

In the various modifications of the method, a pure drug is generally compressed in a die with a hole of known diameter to produce a pellet of known exposed surface area (e.g., see<sup>50</sup>). It is assumed that during the dissolution period, the exposed area of the pellet remains constant.

Often, traditional thermostated baths, such as those available from Sotax or a number of other manufacturers, are used, accommodating USP volumes of 500 and 900 mL. However, when the experiments are performed in early preformulation, typical volumes can be in the range of 175–250 mL, and single-sample jacketed beakers are used, thermostated with a circulating bath.<sup>46</sup> The temperature is usually maintained constant at 37 °C, but in research settings it is not uncommon to use  $25 \pm 1$  °C.

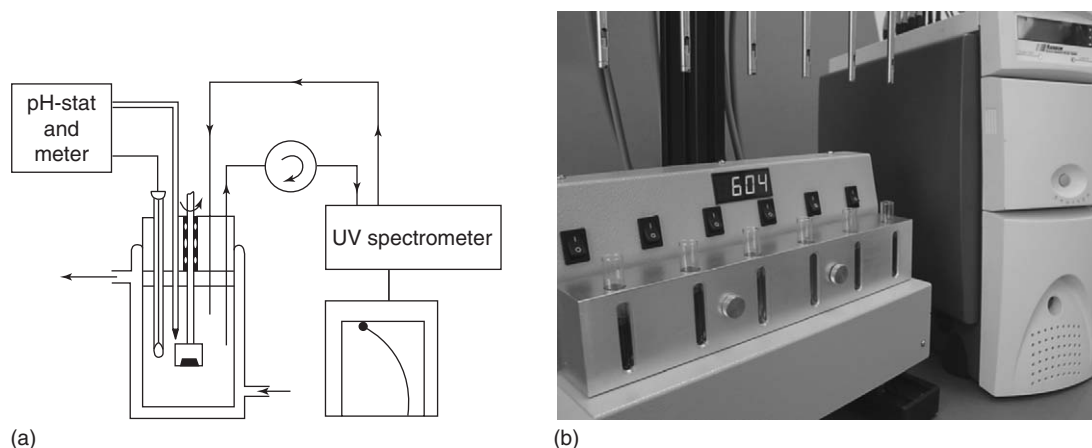

About 100–700 mg of pure drug substance are compressed into disks with a punch and die, using a hydraulic pump (Carver, Inc.). The typical surface area ranges from 0.5 to 1.3 cm<sup>2</sup>.<sup>41,71</sup> Typical pressures used are about 2000 lb in<sup>−2</sup> (14 bar), applied for about 1 min.

Rotational speeds between 15 and 250 rpm are often used, with a preference for 100 rpm,<sup>71</sup> although values as high as 600–900 rpm have been reported.<sup>41</sup> Usually the speeds are elevated to increase the dissolution rates of very insoluble compounds.<sup>46</sup>

Buffered media are often made with 0.1 M HCl (pH 1.2), 0.2 M acetate buffer (pH 4.5), or 0.2 M phosphate buffer (pH 6.8). However, unbuffered solutions, with 0.1 M KCl,<sup>45</sup> 0.5 M KCl,<sup>41</sup> and without background salt<sup>53</sup> have been used, where the pH was controlled with a pH stat, by titrating the solution with standard 0.01–1 M NaOH or HCl to maintain constant pH. A combination pH electrode is used to measure the pH of the solution directly in the bath. One such apparatus is illustrated in Figure 8a.<sup>41</sup> Usually, optical density data are collected at the isosbestic wavelength, where the molar absorptivity is pH-independent. The turbid solutions are traditionally filtered in order to read the UV spectra reliably. (Newer in situ methods do not require filtration; see Section 5.17.6.2.) A plot of absorbance versus time is made. A series of standard solutions of the drug is prepared in advance, and the dissolution versus time profile is calibrated against the standards. Experiments can run from 5 min to several hours, depending on the solubility of the compound.

#### 5.17.6.2 In Situ Fiber Optic Dip Probe Ultraviolet Spectrophotometry

As is seen from the above description, the dissolution testing method can be time-consuming and labor-intensive. The method can be made more efficient and quicker if the UV data-taking were performed directly in the assay vessel. To that end, Purdue Pharmaceuticals developed an in situ fiber optic dip probe UV apparatus, called the Rainbow Dynamic Dissolution Monitor (Delphian Technology), which eliminates external sampling of the solutions.<sup>14</sup> Since moving parts are eliminated, sampling errors due to sipper mechanism failure, sample contamination, filter clogging, adsorption to sampling tubing, etc., are not of concern. The UV system employs a photodiode array (Zeiss) for fast whole-spectrum

**Figure 8** (a) Apparatus for DIDR measurement used by Mooney and co-workers (see Section 5.17.6.1). (Reprinted from Mooney, K. G.; Mintun, M. A.; Himmelstein, K. J.; Stella, V. J. *J. Pharm. Sci.* **1981**, *70*, 13–22; Copyright © (1981) with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.) (b) Small-volume dissolution apparatus (Delphian Technology) used for polymorph rank-order screening (see Section 5.17.6.3). Reproduced with permission from Delphian Technology.

UV data-taking (one complete-curve scan per second). Slow-release or rapidly dissolving products can be characterized. For example, vitamin B<sub>12</sub>, whose tablet dissolution half-life is about 1 min, was successfully characterized.<sup>16</sup> Interference due to excipient background turbidity is minimized by a proprietary spectral second-derivative method.

### 5.17.6.3 Small-Volume Dissolution Apparatus for Polymorph Rank-Order Screening

Because of the increasing interest in characterizing intrinsic dissolution in early preformulation, where the tested API is not available in large quantities, a small-volume dissolution instrument, called  $\mu$ DISS, has been developed, as shown in Figure 8b. The working volume can be as low as 2–3 mL. Pure powder suspensions of the API are tested, with sample weights as low as 50–100  $\mu$ g (hence the name ' $\mu$ DISS'), instead of the usual 100–700 mg. Currently, the apparatus is used for three purposes: (1) to rank-order compounds for dissolution and detect any polymorphic changes, a problem that can occur during scale-up in synthesis in early preformulation, (2) to measure API stability over time, and (3) to determine solubility very precisely. In the first instance, the working premise is that if a compound undergoes a polymorphic transformation during the various stages of synthesis scale-up, redetermined dissolution curves will indicate a departure from previous determinations. Also, in some instances (e.g., unstable organic solvates of the API), a polymorphic transformation may be observed during the actual dissolution interval. This could suggest to the medicinal chemist to modify the isolation and purification methods used. Solubility determination is possible when enough solid API is added so that at the end of sufficiently long time, the solution reaches equilibrium and a state of uniform saturation, where the indicated bulk concentration of the API is its solubility. Given today's low-solubility molecules, it is not really necessary to have very much API to produce a saturated solution.

Figure 9 shows an example of the dissolution profile of powdered phenazopyridine hydrochloride, with each of the six dissolution vessels containing 20 mL 0.05 M HEPES buffer with the pH adjusted to 7.4. The data are quantitatively analyzed for both dissolution and solubility in Section 5.17.7, using the spherical particle model of Wang and Flanagan.<sup>51,52</sup>

**Figure 9** Powder dissolution-time profiles using the apparatus pictured in Figure 8b, in 0.05 M HEPES buffer at pH 7.4, stirred at 700 rpm, of phenazopyridine hydrochloride,  $0.75 \pm 0.04$  mg in 20 mL of buffer. The dash-dot-dot line corresponds to the calculated dissolution profile using the Wang–Flanagan model, with an assumed 24  $\mu$ m particle diameter, and the constants in Table 1 corresponding to 25 °C, adjusted to 0.05 M ionic strength. The inset is the expanded-scale view. The average rate of dissolution,  $dC/dt = 44.3 \pm 0.6 \mu\text{g mL}^{-1} \text{ h}^{-1}$ , corresponds to  $9.9 (\pm 2.7) \times 10^{-10} \text{ mol s}^{-1}$ .

### 5.17.6.4 Example of a Weak Acid Dissolution Measurement by the Disk Intrinsic Dissolution Rate Method

In this section, the DIDR dissolution simulation computer program, pDISS, is applied to indomethacin.<sup>42,46</sup> **Table 3** shows the Mooney data for indomethacin, the least soluble of the weak acids considered in our examples. The calculated flux fits the observed data reasonably well, but only at low pH. It is suspected that the formation of anionic aggregates may be the reason for the poor prediction at high pH (see **Figure 4b**). The last column in **Table 3** lists three calculated values, which agree with the observed fluxes, where the calculation assumed higher solubility constants than the value reported by Mooney. To explain the data at pH 9, it was necessary to assume an intrinsic solubility about 10-fold higher than that of Mooney. **Figure 4b** shows that solubility measurements of indomethacin indicate an enhanced solubility due to anionic aggregate formation, of the order of magnitude needed to explain the observed DIDR data. These new predicted insights need to be verified with further experimentation.

### 5.17.6.5 Example of a Weak-Base Drug: Phenazopyridine

The well-designed DIDR studies of phenazopyridine by Serajuddin and Jarowski<sup>53</sup> show extraordinary complexity, which can most easily be grasped with the aid of simulations using the improved computational procedures<sup>39</sup> briefly described in this review. Serajuddin and Jarowski determined at 37 °C the physicochemical constants  $pK_a = 5.20$ ,  $-\log S_0 = 3.83$  (molarity scale), and  $pK_{sp} = 3.53$  (chloride; see **Table 1**). A thorough dissolution–pH study was performed using Wood's rotating disk apparatus, operated at 200 rpm, with a pellet surface area of 0.95 cm<sup>2</sup>. Particular emphasis was placed by the researchers on characterizing the common-ion and self-buffering effects. Pellets of the free base and those of the hydrochloride salt of phenazopyridine were studied independently, and the possible formation of dual-solid phases at certain pH conditions were explored by the investigators, with scrapings of the pellet surfaces analyzed by differential scanning calorimetry. Adjunct ionic strength adjusters (e.g., NaCl) were not used. (Hence, it was particularly important to apply the Vinograd–McBain formalism (see **Section 5.17.5.2**) in the simulations.) Low-pH solutions were prepared with 0.1, 0.01, and 0.001 M HCl. Other pH values of working solutions were prepared by adding small volumes of standardized 1 M NaOH or 1 M HCl. A pH stat was employed to adjust the pH of the bulk solution. **Table 4** summarizes some of the results of the dissolution study.

#### 5.17.6.5.1 Diffusivity may reveal aggregation

The two right-most columns in **Table 4** are expected to be the experimental diffusivity. The value averages to  $7.5 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ . The theoretically expected diffusivity is  $8.6 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$  for a monomer and  $6.3 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$

**Table 3** Indomethacin dissolution data

<sup>b</sup>Approximate (due to the presence of supersaturation).

**Figure 10** Simulated flux profiles of a 100 mg phenazopyridine hydrochloride pellet, as a function of bulk pH, at 37 °C, 200 rpm, no ionic strength adjuster added, ABL thickness  $h = 0.00315 \text{ cm}$ ,  $D_B = 8.56 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ ,  $A = 0.95 \text{ cm}^2$ ,  $V = 1 \text{ cm}^3$ . The dotted curve represent the interfacial pH ( $x = 0$ ). The region past the bulk pH 3.22 contains the coprecipitate of  $\text{BH}^+ \text{Cl}^- (\text{s})$  and  $\text{B}(\text{s})$ .

for a dimer, using a formula related to molecular weight.<sup>1</sup> Figure 4c indicates that phenazopyridine forms a cationic aggregate in low pH solution. In Table 4, at pH 1.1, the phenazopyridine hydrochloride pellet experiment shows an apparent diffusivity of  $6.5 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ . This suggests the possibility that the pH 1.1 dissolution data are indicative of some aggregation of the cationic species, perhaps a dimer — a new perspective on the interesting 1985 study.

#### 5.17.6.5.2 Phenazopyridine hydrochloride dissolution as a function of pH: the self-buffering effect

Figure 10 shows plots of the calculated fluxes ( $x = 0$ ) for a pellet made from the hydrochloride salt  $\text{BH}^+ \text{Cl}^- (\text{s})$ , (solid and dash-dot curve) as a function of bulk pH. As the pH is lowered below 3.22, the flux decreases steadily, as more of the  $\text{BH}^+ \text{Cl}^- (\text{s})$  precipitates, and as solubility decreases. The HCl used to lower the pH below 3.22 introduces chloride ions, which interact with the positively charged form of the weak base to form the additional precipitate. This is known in solubility measurements as the common-ion effect. The interfacial pH ( $x = 0$ ) also linearly decreases from pH 3.14 to 1.1 (dotted curve in Figure 10).

However, above pH 3.22, the conditions become just right for the free base,  $\text{B}(\text{s})$ , to co-precipitate on the surface of the  $\text{BH}^+ \text{Cl}^- (\text{s})$  pellet. The Gibbs phase rule then applies, and both the pH and the solubility on the surface of the pellet becomes absolutely constant. The dotted line indicates the interfacial pH as a function of the bulk pH values. As can be seen, the pH at  $x = 0$  is fixed at 3.14, and remains so, as the bulk pH varies from 3.22 to 10.5 in that interval. This is the condition where the free base and the chloride salt of its conjugate acid co-precipitate, and the interfacial pH =  $\text{p}K_a^{\text{Gibbs}}$ . Furthermore, at the solid-liquid interface, the solubility becomes constant ( $4.88 \text{ mg mL}^{-1}$ ). The flux also becomes nearly constant, as indicated in Figure 10 by the dash-dot curve.

Above bulk pH 9.5, another very interesting phenomenon occurs: the free base not only precipitates on the surface of the  $\text{BH}^+ \text{Cl}^- (\text{s})$  pellet but is predicted also to precipitate throughout much of the ABL. Figure 11 shows the

**Figure 11** Calculated ABL cross-section for phenazopyridine hydrochloride, showing fractional concentration ( $C/C_{\max}$ ) profiles with the fractional distance across the ABL, up to  $x/h=2$ , at bulk pH 10.5.

**Figure 12** The predicted flux of 2-naphthoic acid dissolving at bulk pH 8.0 and 8.5, at various buffer concentrations.

relative concentrations of the species in the fractional coordinates of the ABL. Shown at bulk pH 10.5 is the region of the B(s) precipitate within the ABL, from  $x/h=0$  to  $x/h=1.7$ . Since this solid is constant in 'concentration' throughout most of the ABL, and since the solid is uncharged, there is no driving force (other than convection) to move the solid out of the ABL. One can imagine a 'fog of solid' suspended in the ABL. Serajuddin and Jarowski did observe the surface of the pellet change from brick red to yellow in color as the free base loosely attached to the rotating pellet. DSC analysis of the shavings of the yellow solid confirmed it to be the free base.

Once the free base starts to precipitate in the ABL, the flux is predicted to decline, as is shown in Figure 10 by the dash-dot curve for bulk pH > 9.5.

Even though the free base of phenazopyridine is quite insoluble at pH 7.4, the dissolution rate of a pellet of  $BH^+Cl^-$  (s) maintains a very high flux, due to the self-buffer effect mentioned above. This is a fascinating case of the Gibbs interfacial 'super buffer'.<sup>29</sup>

#### 5.17.6.6 The Effect of Buffer on the Intrinsic Dissolution Rate

Figure 12 shows the measured fluxes for 2-naphthoic acid in pH<sub>bulk</sub> 8.0 and 8.5 solutions, as a function of the concentration of the added buffer morpholine with measured data taken from Mooney *et al.*<sup>43</sup> The solid lines were calculated by pDISS.<sup>39</sup> The fit is excellent. What this illustrates, as has been well understood ever since the 1980s, with the studies of Mooney and co-workers, as well as those of McNamara and Amidon, is that the observed dissolution rates depend not only on the pH of the buffer but also on how much buffer is present in the dissolution medium. The amount of buffer affects the pH gradient in the ABL, and that impacts on the dissolution rate of the drug molecule, albeit indirectly.

## 5.17.7 Spherical Particle Dissolution (Powder Model)

### 5.17.7.1 Theory

So far, we have considered intrinsic dissolution of compounds from rotating planar surfaces, where, at steady state, the classical Nernst–Brünner thin-film model predicts a linear decrease in concentration of the dissolving species throughout the ABL. With a spherical particle, on the other hand, the concentration gradient is nonlinear (bowed) in the ABL, and decreases proportionately with the inverse distance from the surface of the particle. Dissolution of a spherical surface will not reach a conventional steady state, because the surface area continually changes with time, as the dissolving particles shrink in size. The most common expression used to describe the dissolution of a spherical particle follows the so-called cube root law.<sup>72</sup>

Wang and Flanagan<sup>51,52</sup> compared particle dissolution equations, and found that the classical equations in current use were only approximate, since assumptions made in their derivations were not valid under the broad range of practical conditions. These investigators proceeded to derive a general model for diffusion-controlled particle dissolution, the most comprehensive to date.

### 5.17.7.2 Application of the Wang–Flanagan Model to the Dissolution of Phenazopyridine Hydrochloride, as Powders of Known Particle Size Distribution

The small-volume dissolution apparatus pictured in [Figure 8b](#) ( $\mu$ DISS), was used to measure the dissolution rates of powders of phenazopyridine hydrochloride. By a different analysis, the specific surface area of phenazopyridine hydrochloride was determined to be  $1.31 \text{ m}^2 \text{ g}^{-1}$ , and the average size of particles was about  $24 \mu\text{m}$ .

About 0.75 mg of the hydrochloride salt of phenazopyridine were weighed into each of six test tubes of the  $\mu$ DISS apparatus. To each, 20 mL of 0.05 M HEPES buffer, pH 7.4, were added, and the stirring rate was set to 700 rpm. The thermodynamic calculation by pDISS<sup>39</sup> predicted that the solid, introduced as a powder in the form of the hydrochloride salt, should undergo a transformation into the free base solid at pH 7.4. This must be a very fast conversion, since the observed rate is relatively slow, and is comparable to that expected of the dissolution of free base solid.

In about 8 h, the dissolution reached a steady state. Simulations indicate that at pH 7.4, phenazopyridine is not completely dissolved. This was confirmed visually. [Figure 9](#) shows the six traces of the salt dissolution curves, as well as the calculated (Wang–Flanagan model) dissolution curve. The concentration–time profile was calculated by the  $\mu$ DISS processing software, based on the area under the second-derivative curves (optical density versus wavelength) in the wavelength interval 322–360 nm, a strategy minimizing the contributions due to the background scattering of the turbid solutions. The Wang–Flanagan model predicted the time course of the dissolution of the powder reasonably well, when the experimental surface area is calculated based on the average radius of assumed spherical particles.

After about 18 h, the concentrations in each of the six vessels leveled off to a constant value of  $15.1 \pm 0.6 \mu\text{g mL}^{-1}$ , very close to the  $14.5 \mu\text{g mL}^{-1}$  solubility determined independently by the ‘self-calibrating’ microtitre plate UV method (see [Table 1](#)).<sup>19</sup>

It is interesting to note that if more sample had been used (e.g., 750 mg of phenazopyridine hydrochloride, rather than 0.75 mg), the chloride–phenazopyridine solubility product would have been exceeded. There would have been enough compound to lead to the formation of the co-precipitates of the free base and the hydrochloride salt. Under this condition of the Gibbs ‘super buffer,’ the interfacial pH is predicted to drop to 3.14 (from a value slightly below pH 7.4 in the 0.75 mg case), and the flux to increase by more than 100-fold, corresponding to the conditions associated with the dash-dot line in [Figure 10](#). The equilibration time would drop from about 20 h to less than 1 h. However, this rapid rate of dissolution would only be sustained under an excessive amount of the compound. As the dissolution process decreases the amount of solid below the phenazopyridinium chloride solubility product limit, then the slower dissolution mechanism would take over (see [Figure 9](#)).

## 5.17.8 Outlook

The tools and methods described in this presentation are highly refined and are suitable for the measurement of solubility and dissolution of molecules which emerge out of today’s lead-finding and optimization programs, molecules that sometimes are very low in solubility. These are pharmaceutically problematic molecules, requiring considerable care and analytical experience and insight to characterize reliably. If the earlier measurements of the physicochemical properties are done well, the structural fine-tuning by medicinal chemists can be made more efficient. The selection

process can be expected to produce better behaving candidates, ones that formulation scientists can transform into drug products in a shorter time. Quality measurements can begin at the earlier stages, can be fast (made possible by thoughtful automation), and can benefit considerably from the state-of-the-art tools and strategies currently available.

## Biographies

**Alex Avdeef**, PhD, is the cofounder of pION Inc. (USA) and Sirius Analytical Instruments Ltd (UK). Formerly, he was Assistant Professor of Chemistry at Syracuse University (USA). He is on the Advisory Board of the *European Journal of Pharmaceutical Sciences*. He has authored nearly 100 technical papers in scientific journals and chapters in books, and has given nearly 300 invited talks. He recently authored *Absorption and Drug Development* (Wiley-Interscience, 2003). He has held various positions at pION inc. (USA), Sirius Analytical Instruments Ltd (UK), Orion Research (USA), Syracuse University (USA), the University of California (Berkeley, USA), and the California Institute of Technology (CALTECH) (Pasadena, USA).

**Dmytro Voloboy**, as a staff scientist, is primarily responsible for writing and maintaining scientific software code for high-throughput instrumentation at pION Inc. Prior to his employment at pION, Voloboy served as a developer for the SI Bridge of Dnipropetrovsk, developing scientific instruments for a broad range of applications. Dmytro Voloboy holds an MSc in physics from Dnipropetrovsk State University, Ukraine. Also, he finished 3 years of postgraduate study at Dnepropetrovsk State University in the Automation of Physical Experiments program.

**Alexis Foreman** is the product specialist for the fiber optic dissolution apparatus, and the designer of the  $\mu$ DISS small volume dissolution system. He holds a BSc in chemistry from Montana State University. He held positions at Montana State University and The Gillette Co. before joining pION Inc.

### 5.18.1 General Introduction

In the first edition of *Comprehensive Medicinal Chemistry*, chapters on lipophilicity were included in the Quantitative Drug Design section. In this second edition, published about 15 years later, they appear in Physicochemical Tools in absorption, distribution, metabolism, excretion, and toxicity (ADMET). This change reflects the revolution in medicinal chemistry itself, undoubtedly due to the elucidation of the human genome, along with new automated experimental technologies and progress in computer sciences. These brought an enormous increase in the number of newly discovered active molecules, but not in the number of drug candidates surviving early clinical trials.

This limitation is also due to poor ADMET properties, in particular poor bioavailability. In fact it is now clearly recognized that a successful drug candidate requires not only potency and selectivity, but also a suitable pharmacokinetic profile.<sup>1</sup>

Lipophilicity is an important property of drugs with a bearing on absorption/permeability, volume of distribution, plasma protein binding, metabolism, and toxicity.<sup>1–3</sup> It is a cornerstone of the well-accepted rule-of-five derived by Lipinski and co-workers.<sup>4</sup> Based on an analysis of the key properties of compounds in the World Drug Index (WDI), this alert states that compounds are most likely to have poor absorption when the molecular weight (MW) is  $> 500$ , the calculated *n*-octanol/water partition coefficient (CLOGP) is  $> 5$ , the number of H-bond donors is  $> 5$  and the number of H-bond acceptors is  $> 10$  (substrates for active transporters and natural products or mimics of these may be exceptions to this alert). These simple rules and some succeeding studies clearly demonstrate the reasons drug candidates must have ad hoc lipophilic properties to meet the demands of clinical studies.<sup>4–8</sup>

The original guidelines focused on  $\log P$  of the unionized species because of the ability to calculate that property for hundreds of marketed drugs. Today, attention is increasingly being given to  $\log D$  at physiological pH ( $\log D^{\text{pH}}$ ), including methods for its rapid measurement and its correlation with biological properties.

Some key areas for investigation today include finding solvents more membrane-like than *n*-octanol and the contribution of ionized forms to the overall molecular lipophilicity of drugs.

The lack of partitioning data for ion pairs (*see* Section 5.18.8 below for ion pair definition) has led to inaccurate calculation procedures, to assumptions that the ionized species is not important, and to compromises such as using  $\log D$ , a mixture of terms, as a single term. Certainly it is known that almost all drug candidates are either ionizable<sup>9</sup> or are converted in vivo to ionizable metabolites.<sup>10–12</sup> Ionized species are also involved throughout the ADMET pathways, so there is considerable incentive to understand their properties. Commercialization of equipment for automated measurements is making it easier to obtain specific data on the physicochemical properties of ionized species. Better  $\log P^{\text{I}}$  data (*see* definition in Section 5.18.2 below) should allow more attention to be given to the ionized portion of  $\log D$  (*see* Section 5.18.8.6).

Undoubtedly, an obvious consequence of the growing complexity of systems to measure lipophilicity is the increase in information content in related descriptors. This hidden information must be extracted and interpreted, but the debate is still open to understand which lipophilicity descriptors are really useful in ADMET profiling. Some determinants are largely superimposable and others are only relevant from a speculative point of view, but have poor application in drug discovery.

### 5.18.2 Lipophilicity Parameters and the Effect of Ionization

The most common lipophilicity descriptors are listed and defined in Table 1. Basically, we distinguish simple (= one value) from combined (= obtained from two  $\log P/\log D/\text{p}K_{\text{a}}$  values) parameters.

Among simple descriptors, the partition coefficients, expressed as  $P$ , are valid for a single electrical species, to be specified ( $P^{\text{N}}$  for neutral forms and  $P^{\text{I}}$  for ionized species). Whereas the partitioning of neutral species has been widely studied and understood in the past, the same cannot be said for ions that have received attention only in recent years.

**Table 1** Simple and combined lipophilicity descriptors

| Category | Symbol                             | Definition  |
|----------|------------------------------------|---|
| Simple   | $\log P_{\text{aaa}}^{\text{X}}$   | Logarithm of the partition coefficient $P$ of the electrical species $X$ in the aaa/water system  |
|          | $\log D_{\text{aaa}}^{\text{pH}}$  | Logarithm of the distribution coefficient $D$ at a given pH expressed as the concentration ratio of a solute present in more than one electrical state  |
|          | $\log P^{\text{N}}$                | Logarithm of the partition coefficient of the neutral form (in <i>n</i> -octanol/water)   |
|          | $\log P^{\text{I}}$                | Logarithm of the partition coefficient of an ionized form (in <i>n</i> -octanol/water); C and A may be used as a substitute for superscript I, denoting a cation or anion, respectively   |
| Combined | $\Delta \log P_{\text{aaa-bbb}}$   | Difference between the $\log P$ values of the same compound in the same electrical state, measured in the systems aaa/water and bbb/water   |
|          | $\text{diff}(\log P^{\text{X-Y}})$ | Difference between the $\log P$ of $X$ and $Y$ obtained with the same organic solvent. $X$ and $Y$ can be two electrical forms of the same compound (in which case the aqueous phases were different), or two closely related compounds |

The distribution coefficient, expressed as  $D^{\text{pH}}$ , is a pH-dependent simple descriptor for ionizable solutes and results from the weighted contributions of all electrical forms present at this pH, as illustrated by eqn [1]:

$$D^{\text{pH}} = f^{\text{N}} \times P^{\text{N}} + \sum (f^{\text{I}} \times P^{\text{I}}) \quad [1]$$

where  $f^{\text{N}}$  and  $f^{\text{I}}$  are the respective molar fractions of the neutral and ionized forms.

In practical terms, it is easily inferred from eqn [1] that  $\log D^{\text{pH}}$  is: (1) either lower or equal to  $\log P^{\text{N}}$ ; and (2) either higher or equal to  $\log P^{\text{I}}$ . Please note that the pH regions in which  $\log P^{\text{N}}$  and  $\log D^{\text{pH}}$  have the same value are opposite for acids and bases, since  $\log D^{\text{pH}}$  is  $\text{p}K_{\text{a}}$ -dependent. In particular,  $\log P^{\text{N}} = \log D^{\text{pH}}$  for acids when the pH is about 2 units below the  $\text{p}K_{\text{a}}$  and for bases when the pH is 2 units above the  $\text{p}K_{\text{a}}$ . A similar estimation for ampholites is more complex (see Section 5.18.8.5).

Equation [1] includes all species present at a given pH and is easily obtained from the definition of  $D$  as shown below for a generic acid HA:

$$D^{\text{pH}} = \frac{[\text{HA}]_{\text{org}} + [\text{A}^-]_{\text{org}}}{[\text{HA}] + [\text{A}^-]} \quad [2]$$

where  $[\text{HA}]$  is the weak acid concentration in the aqueous phase and  $[\text{HA}]_{\text{org}}$  is the weak acid concentration in the nonaqueous phase,  $[\text{A}^-]$  is the fully deprotonated acid concentration in the aqueous phase, and  $[\text{A}^-]_{\text{org}}$  is the fully deprotonated acid concentration in the nonaqueous phase.

Dividing each term of eqn [2] by  $[\text{HA}]$ , eqn [3] is obtained:

$$D^{\text{pH}} = \frac{\frac{[\text{HA}]_{\text{org}}}{[\text{HA}]} + \frac{[\text{A}^-]_{\text{org}}}{[\text{HA}]}}{1 + \frac{[\text{A}^-]}{[\text{HA}]}} \quad [3]$$

and substituting eqns [4], [5], and [6] in eqn [3], eqn [7] is found:

$$K_{\text{a}} = \frac{[\text{A}^-] \times [\text{H}^+]}{[\text{HA}]} \quad [4]$$

$$P^{\text{N}} = \frac{[\text{HA}]_{\text{org}}}{[\text{HA}]} \quad [5]$$

$$P^{\text{I}} = \frac{[\text{A}^-]_{\text{org}}}{[\text{A}^-]} \quad [6]$$

$$D^{\text{pH}} = \frac{P^{\text{N}} + P^{\text{I}} \times \frac{K_{\text{a}}}{[\text{H}^+]}}{1 + \frac{K_{\text{a}}}{[\text{H}^+]}} \quad [7]$$

which, rewritten by substituting the definition of pH and  $\text{p}K_{\text{a}}$ , becomes eqn [8], that corresponds to eqn [1] in the case of a generic acid HA:

$$D^{\text{pH}} = f^{\text{N}} \times P^{\text{N}} + f^{\text{I}} \times P^{\text{I}} \quad [8]$$

The fractionation of  $\log D$  into terms representing the distribution of individual species is discussed in Section 5.18.8.6.

The relevance of ion partitioning, and thus of the  $P^{\text{I}}$  terms in eqn [1], has been emphasized in several papers<sup>9,13–16</sup> and will be discussed more fully in Section 5.18.8. Nevertheless, a method has been proposed in the literature whereby, in some cases, it is possible when using  $\log D$  to dismiss the contribution of some ionized species. This can occur in conditions for which ion partitioning is not significant.<sup>17</sup>

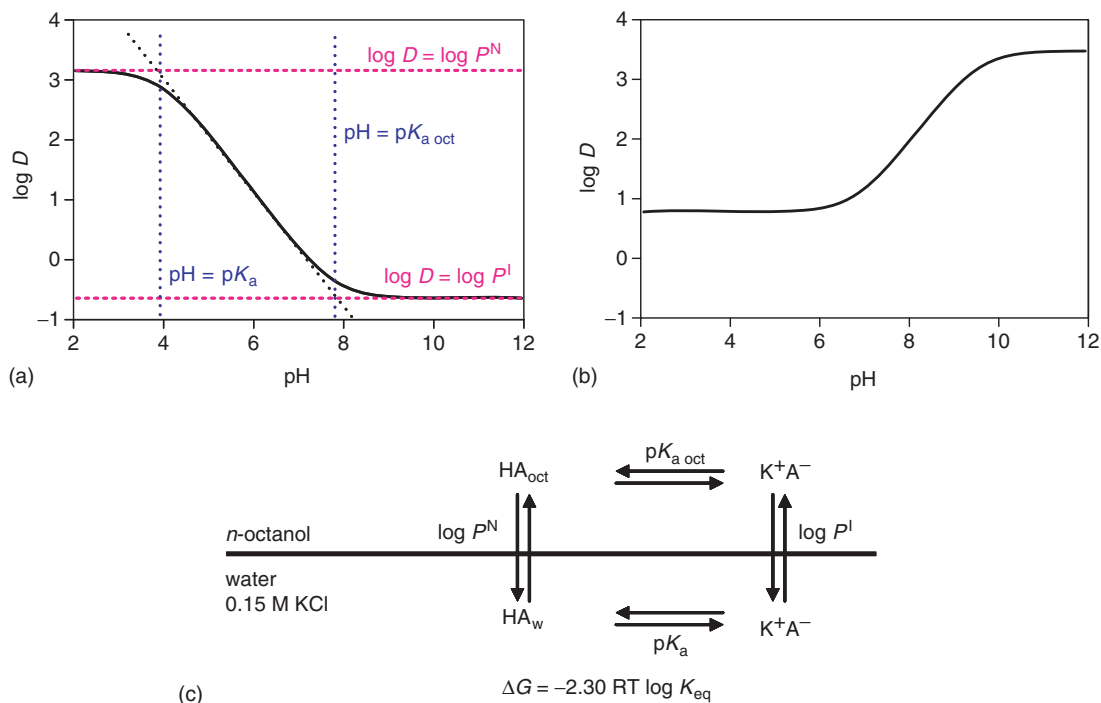

Combined lipophilicity descriptors have been classified into two groups<sup>15</sup>: those derived from  $\log P$  values obtained in the same solvent system (the *diff* descriptors), and those derived from  $\log P$  values obtained in different solvent systems (the  $\Delta \log P$  descriptors that have been used for a long time to investigate inter- and intramolecular hydrogen bonding properties that determine many pharmacokinetic processes<sup>4,15,18–22</sup>).

The *diff* parameters may refer either to two distinct states of a single solute (e.g., neutral and ionized), or to a pair of related chemicals in a given biphasic system (e.g., parent and metabolites). Another *diff* term refers to  $pK_a$ , *diff*  $pK_a$  ( $_{oct-W}$ ) for acids and *diff*  $pK_a$  ( $_{W-oct}$ ) for bases. The use of *diff* is more recent<sup>15</sup> and some examples will be discussed below.

The difference between the  $\log P$  of a neutral compound and its ion pair (*diff*( $\log P^N - 1$ )) can easily vary more than two log units, even within the same chemical class, depending on certain structural features. It is not correct to make broad generalizations that this difference for all carboxylic acids is the same, or for all phenols or all amines.

Anyone having trouble appreciating the concept of ionization in *n*-octanol can see the evidence of it in **Figure 1a** and **b**. These show the lipophilicity profile of the acid, ketoprofen, and the base propranolol as obtained by applying eqn [1].<sup>9,14,23</sup> The upper inflections in both cases occur at the aqueous  $pK_a$ . The lower inflections must occur at the corresponding octanol  $pK_a$  ( $pK_{a\ oct}$ ).<sup>14,24</sup> The  $pK_{a\ oct}$  is seen in **Figure 1a** at pH 7.78. The octanol  $pK_a$  is equal to the pH of the aqueous phase when the concentrations of neutral and ion pair species in the octanol phase are equal<sup>24</sup> (indicated in **Figure 1a**). The pH of the second phase is thermodynamically equivalent to the pH of the aqueous phase with which it is in equilibrium. Contrary to some thinking, when the ionization behavior of an acid or base changes as it enters *n*-octanol (or a biolipid phase), the pH has not changed; it is the  $pK_a$  of the solute that changes continuously as the compound progresses from water to octanol.

**Figure 1c** illustrates a valuable relationship between partitioning and ionization in water and *n*-octanol. These processes form a thermodynamic cycle. The Gibbs free energy of an equilibrium is given by the equation in **Figure 1c**. The net free energy around the cycle is zero. This provides the useful relationship that the difference between two of the equilibria,  $\log P^N$  and  $\log P^I$ , is the same as the difference between the  $pK_a$  and  $pK_{a\ oct}$  (eqn [9]).<sup>24</sup> An alternative expression that is gaining favor is to use *diff* terms (eqn [10]). These *diff* terms, when used to represent differences in

**Figure 1** (a) Lipophilicity profile of an acid, ketoprofen, in the *n*-octanol/water system. The aqueous and octanol  $pK_a$ 's can be read from this profile. The difference between these  $pK_a$ 's is the same as the difference between  $\log P^N$  and  $\log P^I$  ( $pK_a$  3.98;  $\log P^N$  3.16;  $\log P^I$  -0.64;  $pK_{a\ oct}$  7.78). (b) Distribution profile of a base, propranolol, in the *n*-octanol/water system. Note that in these profiles, the aqueous  $pK_a$  always occurs at the upper inflection ( $pK_a$  9.53;  $\log P^N$  3.48;  $\log P^I$  0.78;  $pK_{a\ oct}$  6.83). (c) The thermodynamic cycle of partitioning and ionization. The Gibbs free energy change associated with an equilibrium constant is given by the equation shown. The net free energy change around the cycle is zero.

equilibria, are free energy terms. One  $\text{diff log } P$  unit, or  $\text{diff}(\text{p}K_{\text{a}})$ , equals  $1.36 \text{ kcal mol}^{-1}$  at  $25^\circ\text{C}$ .

$$\log P^{\text{N}} - \log P^{\text{I}} = \pm (\text{p}K_{\text{a oct}} - \text{p}K_{\text{a}}) \quad [9]$$

$$\text{diff}(\log P^{\text{N}-1}) = \text{diff } \text{p}K_{\text{a}}^{\pm(\text{oct}-\text{W})} \quad [10]$$

The  $\pm$  sign is + for acids and – for bases; oct and W stand for the *n*-octanol and aqueous phases. These equations apply to multifunctional molecules as well, in which case, each ionized species is incorporated into its own thermodynamic cycle(s).

In water an ion and its counterion are independently solvated and require little molecular interaction. A useful way to look at the structure of an ion pair is in a stepwise progression following ionization in *n*-octanol. First, mentally convert the ionizable group, in a fixed conformation of the molecule, to the corresponding ion pair. This high-energy form will seek all possible ways to lower the energy of this charge. Most importantly, it will attract water from the solvent to form hydrogen bonds around the ion pair, so the more access water has to the charge, the lower its energy (e.g., in primary versus tertiary amines). It is also important how closely the counterions can approach each other. The next most important change will be a reorientation of the molecule to place as many H-bond donating and accepting groups as possible in the vicinity of the ion pair. The task then becomes quantifying these factors. For example, what size ring is formed when a hydroxy group or ether oxygen coordinates with the ammonium or the carboxylate ion pair? Are there steric interactions that decrease the benefit? Not every interaction can occur simultaneously. In triethanolamine, for example, the first two hydroxy groups will contribute to a much greater extent than the third. In addition, each class of acid or base has its characteristic  $\text{diff}(\log P^{\text{N}-1})$  from which the above kinds of adjustments are made. An observation is that, within a given class, the more acidic (or more basic) the group, the lower the  $\text{diff}(\log P^{\text{N}-1})$ . The positive message is that for a given ion pair and environment, a wide range of molecular structures are possible without affecting the difference between  $\log P^{\text{N}}$  and  $\log P^{\text{I}}$ .

Please note that there is another kind of  $\text{p}K_{\text{a}}$ , designated  $\text{p}K_{\text{a}}''$  (double prime), obtained by direct titrations in KCl/water-saturated *n*-octanol.  $\text{p}K_{\text{a}}''$  differs from  $\text{p}K_{\text{a oct}}$  by a constant,  $(0.8 \pm 0.1)$ ,<sup>25</sup> as discussed in [Section 5.18.5](#), and thus can be used in eqns [9] and [10].<sup>26</sup>

Since ADMET prediction studies require the analysis of large series of compounds (a significant data set and the rules to obtain it are given in references<sup>27–29</sup>), it is often informative to visualize the data graphically by ad hoc plots. In particular, in a series of congeneric compounds it is useful to look at the plot  $\log P^{\text{N}}$  versus  $\log P^{\text{I}}$ . Please note that the value of the Y-intercept is the average  $\text{diff}(\log P^{\text{N}-1})$  of the series. Specific examples are discussed below and in [Sections 5.18.8.1–5.18.8.1.4](#).

### 5.18.3 Chemical Forces Encoded in Lipophilicity

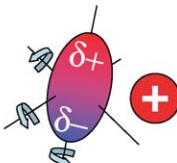

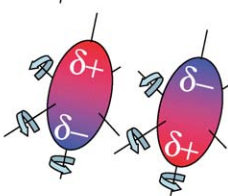

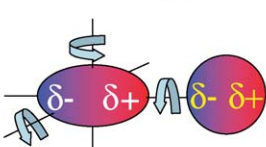

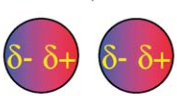

#### 5.18.3.1 Intermolecular Forces

Two or more molecules interact when they affect each other's state or evolution. The 'non-covalent' forces, which encompass an enormous range of attractive and repulsive components, are responsible for the interactions between molecules and may be grouped into two main categories: (1) the electrostatic forces that arise from the forces between the charged entities that make up the molecules<sup>30</sup>; and (2) the hydrophobic forces that occur in a wide range of compounds.<sup>31–33</sup>

The intermolecular forces can be further classified into two main categories ([Table 2](#)): the fundamental and the combined ones. The fundamental electrostatic forces are usually considered pairwise interactions and can be represented by a potential function (that basically depends on the nature of the interacting charges, e.g., permanent, induced, etc.). The combined forces are mainly of electrostatic origin and can be explained as a mixture of the fundamental ones.

The precise mechanism of fundamental hydrophobic interactions has been under debate for many decades and all the details are still not well understood.<sup>31,34</sup> Hydrophobic interactions do not primarily depend on attractive intermolecular interactions between the involved species. Rather, they are driven by the tendency of water molecules to retain their own water–water hydrogen bond interactions as much as possible, leading to a tendency to arrange nonpolar entities such that the contact surface area between these and water is minimized.<sup>34</sup> Classically, the 'iceberg model'<sup>32</sup> assumes that during the hydration of a nonpolar compound a reduction in the number of hydrogen bonds between water molecules occurs, but that water molecules next to the interface form stronger hydrogen bonds than those in the bulk water phase. Whereas the enthalpic contribution almost cancels out for this process at room temperature (fewer but

**Table 2** Main inter- and intramolecular forces in chemistry

| Steric factors around the charged center | Direct, medium.  | Related to solvation with water and closeness of approach of the counter-ion   |

<sup>a</sup> One-color circles refer to ions; two-color ovals to permanent dipoles; two-color circles refer to induced dipoles; the arrows are used to indicate the random motion of the object responsible for the averaging of the interaction.

<sup>b</sup>  $q_i$  is the charge of the ion  $i$ ;  $p_i$  is the dipole moment of the dipole  $i$ ;  $\alpha_p$  is the polarizability;  $r$  the distance between objects;  $k$  is the Boltzmann constant;  $\epsilon_0$  is the permittivity of the free space;  $T$  is the temperature; the subscript  $i$  is omitted where unnecessary;  $a$  and  $b$  constants are not represented in explicit form for brevity reasons.

stronger hydrogen bonds instead of many such bonds of medium strength), the entropy decreases because of a higher ordering of the water molecules. This step is entropically disfavored. This classical view, however, is not generally accepted. An alternative approach does not regard the structure of the water molecules as the main reason for hydrophobic interactions. Instead, it involves a positive enthalpy resulting from the rupture of several hydrogen bonds in order to create a cavity in the water structure that subsequently accommodates the nonpolar compounds.<sup>31</sup>

### 5.18.3.2 Intramolecular Interactions

Functional groups in solute molecules may interact with each other in a number of ways (see Section 5.18.3.1) depending on their own steric and electronic properties, on the number and nature of interconnecting bonds, and on intramolecular distances. It is thus evident that intramolecular interactions (summarized in Table 2) strongly affect the lipophilicity of compounds. In addition, since a polar group may exist in a neutral or charged state, the intramolecular interactions involving this group may dramatically vary according to its electrical state and the dielectric constant of the medium (see Section 5.18.8.1).

Testa *et al.* suggested that dichotomic classifications of intramolecular interactions are misleading since they tend to neglect overlaps and intermediate cases.<sup>35,36</sup>

Flexible compounds with suitable moieties may exhibit hydrophobic collapse in polar solvents, and hydrophilic folding in lipidic environments<sup>35,36</sup> (examples of hydrophobic collapse and hydrophilic folding are given in Figure 2). These conformational changes, which are postulated to allow flexible compounds to adapt and to mimic their environment, are difficult to predict but can strongly affect the fate of drugs in the body<sup>17,18</sup> and thus cannot be neglected as most commercial software does.

### 5.18.3.3 Factorization of Lipophilicity

Lipophilicity (expressed as  $\log P$ ) is a molecular parameter encoding both electrostatic and hydrophobic intermolecular forces as well as intramolecular interactions (Table 2), as shown by eqn [11], discussed in its original form some years ago.<sup>35,37</sup>

$$\log P = vV - \Lambda + I + IE \quad [11]$$

where  $v$  is a constant,  $V$  is the molar volume which assesses the solute's capacity to elicit nonpolar interactions (i.e., hydrophobic forces, and to some extent dispersive and repulsive forces),  $\Lambda$  accounts for the polarity of the molecule,  $I$  accounts for ionic interactions, and  $IE$  represents the intramolecular effects.

Equation [11] can be applied to all electrical species and all partitioning systems (a classification of systems is reported in Section 5.18.4).

**Figure 2** Examples of hydrophilic folding (upper plate) and hydrophobic collapse (lower plate): (a) and (b) represent two conformers for 7-hydroxy-heptan-2-one, of which (b) illustrates hydrophilic folding. Analogously, (c) and (d) show two conformers of *N*-decyl-*para*-methylbenzylamine, of which (d) illustrates the conformation in a hydrophobic collapse. (Reproduced with permission from Caron, G.; Ermondi, G. *Mini Rev. Medicinal Chem.* **2003**, *3*, 821–830.)

Please also note that eqn [11] clearly states that lipophilicity is not synonymous with hydrophobicity, as also indicated by their different International Union of Pure and Applied Chemistry (IUPAC) definitions.<sup>38</sup> Hydrophobicity is the association of nonpolar groups or molecules in an aqueous environment which arises from the tendency of water to exclude nonpolar molecules. Lipophilicity represents the affinity of a molecule or a moiety for a lipophilic environment.

To describe the intermolecular forces that govern the partitioning of simple, neutral solutes, the polar interactions encoded in lipophilicity are hydrogen bonds plus forces involving permanent dipoles, whereas the nonpolar interactions are the London (dispersion) forces and hydrophobic interactions (Table 2). This is expressed by the so-called solvatochromic approach,<sup>39</sup> conveyed by eqn [12] (a particular case of eqn [11])<sup>40</sup>:

$$\log P = v \times V/100 + p \times \pi^* + b \times \beta + a \times \alpha + c \quad [12]$$

where  $V/100$  is the calculated van der Waals volume;  $\pi^*$ ,  $\alpha$ , and  $\beta$  are the solvatochromic parameters (respectively, dipolarity/polarizability  $\pi^*$ , hydrogen bond donor acidity  $\alpha$  and hydrogen bond acceptor basicity  $\beta$ ) and  $v$ ,  $p$ ,  $a$ , and  $b$  are the regression coefficients reflecting the contribution of each parameter to  $\log P$ .<sup>29,41</sup>

More difficult is the definition of the  $I$  term of eqn [11] because little systematic work has been done on ionized species despite their particular importance. The same is true for the  $IE$  term. Work is in progress to address these concerns. In particular, two recent papers from Abraham and Zhao<sup>42,43</sup> report important advances in using the Abraham linear free-energy relationship approach to sort out the factors that correlate with the partitioning of ions into *n*-octanol. This work is in the very early stages and is focusing on the properties of the free ions by using tetra-phenyl-substituted counterions.

Finally, it is noteworthy that inter- and intramolecular interactions governing lipophilicity are of the same nature as those that govern drug recognition and binding to biological sites of action.<sup>36,44</sup>

#### 5.18.4 Lipophilicity Systems

The number of types of lipophilicity systems under study has grown to enhance the possibility of finding good mimic biomembrane models. Equation [11] holds for all systems, but the balance of its terms varies with the system investigated (i.e., sometimes ionic interactions represent the predominant system/solute interaction force, whereas in other cases hydrophobicity and/or polar forces govern the interaction<sup>45</sup>). Great caution must therefore be used to assume that what we learn in a given system can be applied to a second system, particularly when ionized species are considered.

We call standard those biphasic systems in which the two phases are the only components of the system and are in direct contact with each other.

When the second phase is an organic solvent (e.g., *n*-octanol), we have an isotropic system; when the second phase is a suspension (e.g., liposomes), it is an anisotropic system.<sup>45</sup> Anisotropic systems resemble biological systems more than do isotropic ones. Conversely, isotropic systems are easier to use and interpret experimentally.

A search for systems that are markedly easier to obtain and use is always in progress. In particular, because of the ready availability of data, chromatographic systems are often used as an alternative to standard systems.<sup>27,46–53</sup> The presence of chromatographic media along with the one or two liquid phases causes this system to be governed by a balance of intermolecular forces different from the corresponding standard methods.

#### 5.18.4.1 Isotropic Systems

Among biphasic systems, *n*-octanol/water remains the reference, and thus should always at least be used for comparison. Most of the lipophilicity profiles available to date were determined in that system, and even the shortened classification,  $\log D_{\text{oct}}^{7.4}$  data, can give useful information on implications for drug discovery.<sup>58</sup>

Besides *n*-octanol/water, some alternatives have been proposed in the literature. In particular standard isotropic lipophilicity systems (the ‘critical quartet’) can be classified by the characteristics of the second phase<sup>41,54,55</sup>: (1) amphiprotic solvents such as *n*-octanol; (2) hydrogen bond acceptor solvents such as di-*n*-butylether (dbe); (3) hydrogen bond donor solvents such as chloroform; and (4) apolar aprotic inert solvents such as alkanes.

Solubility and toxicity are two key issues that must be kept in mind when using organic solvents in partitioning measurements. In fact, most solvents show lower solubilizing power than *n*-octanol and higher toxicity (see below).

In practice,  $\log P/\log D^{\text{pH}}$  values will vary with the partitioning solvent. Collander<sup>56,57</sup> was the first to show that  $\log P$  (read as  $\log P^{\text{N}}$ ) values from different isotropic solvent systems are linearly correlated:

$$\log P_1 = a \times \log P_2 + b \quad [13]$$

where subscripts 1 and 2 refer to solvent systems 1 and 2, respectively.

This equation is only valid when the organic solvents have similar physical properties, in particular, similar hydrogen bonding capacity. In fact, for the dbe/water system a satisfactory correlation exists between the  $\log P_{\text{oct}}$  and  $\log P_{\text{dbe}}$  (Figure 3a;  $n = 70$ ;  $r^2 = 0.92$ ).<sup>29</sup> Conversely, when 1,2-dichloroethane (dce) is used, a similar plot of  $\log P_{\text{dce}}$  versus  $\log P_{\text{oct}}$  splits the training set into two lines (Figure 3b)<sup>28</sup> due to the  $\alpha$  properties of the solutes ( $\alpha$  = hydrogen bond donor acidity). 1,2-dce is an organic solvent replacing alkanes, as explained below.

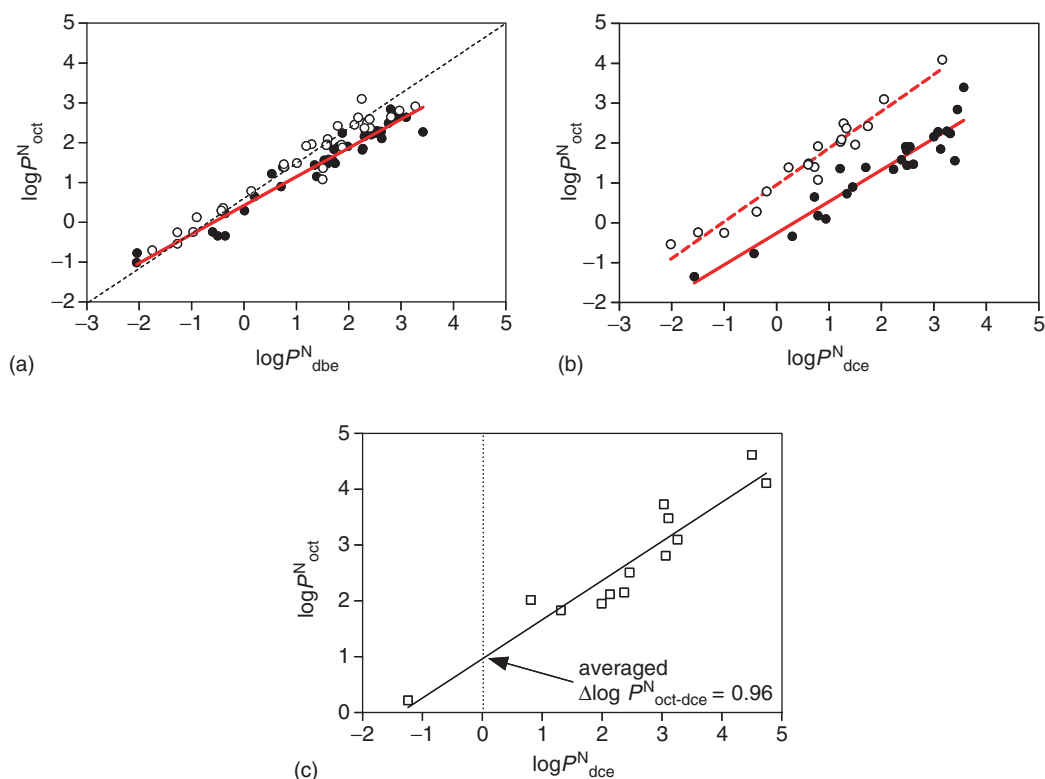

Alkane/water is a lipophilicity system largely employed in ADMET analyses. In fact,  $\log P_{\text{alk}}^{\text{N}}$  is very important alone and in combination with  $\log P_{\text{oct}}^{\text{N}}$  ( $\Delta \log P_{\text{oct-alk}}^{\text{N}} = \log P_{\text{oct}}^{\text{N}} - \log P_{\text{alk}}^{\text{N}}$ ) to investigate those inter- and intramolecular hydrogen bonding properties that determine many pharmacokinetic processes.<sup>4,15,18,22</sup> In particular, in addition to the relevance of  $\Delta \log P_{\text{oct-alk}}^{\text{N}}$  in determining brain penetration,<sup>19–21</sup> a close correlation has also been found between  $\log P_{\text{alk}}^{\text{N}}$  and permeability, as measured through artificial membranes.<sup>59,60</sup> It should be noted that  $\Delta \log D_{\text{oct-solv}}^{\text{pH}}$  is equivalent to  $\Delta \log P_{\text{oct-solv}}$  over the pH range from where  $\log D = \log P$  to within about 2 units of the  $\text{p}K_{\text{a}}$  in the more polar of the two solvents. This is evident by comparing the lipophilicity profiles for two solvents and water on the same plot. Beyond this point the ion pair begins to contribute and the relationship becomes much more complex.  $\log D^{\text{N}}$  and  $\log D^{\text{I}}$  terms are discussed in Section 5.18.8.6.

To overcome some experimental problems caused by the low alkane solubility of many compounds, dce<sup>28</sup> and, more recently, *ortho*-nitrophenyloctyl ether (*o*-NPOE)<sup>61</sup> have been proposed by a few academic labs as replacements. Unfortunately, dce is considered so toxic that its use in many industrial labs has been banned. On the other hand, *o*-NPOE shows a number of advantages over dce (higher viscosity, lower volatility, lower solubility in water, lower toxicity, and greater chemical stability<sup>61</sup>), but is too recent to have gained sufficient reliability among researchers. Alkanes (mainly *n*-dodecane and cyclohexane) remain the elective inert solvents applied in standard lipophilicity measurements.

From a practical standpoint it is convenient to use a graphical approach to extract information from  $\log P_{\text{alk}}$  data. In the literature the plot of  $\log P_{\text{oct}}^{\text{N}}$  versus  $\log P_{\text{aaa}}^{\text{N}}$  where subscript aaa represents a generic biphasic system is often applied.<sup>27–29</sup> In the cases for which a linear trend is found, the Y-intercept represents the average  $\Delta \log P_{\text{oct-aaa}}$  for the investigated series. In Figure 3c, aaa is dce, and the corresponding  $\Delta \log P$  is about 1.

For studying the lipophilicity of ion pairs, *n*-octanol/water stands far above any other isotropic system. Since  $\log P^{\text{I}}$  values are best determined by looking at the difference between the  $\log P$  of the parent neutral compound and the  $\log P$  of the ion pair, the library of known  $\log P_{\text{oct}}^{\text{N}}$  values provides a valuable starting point for such calculations.

Unfortunately, to date no gold standard regarding which solvent systems should be routinely used in ADMET studies has been proposed. In Section 5.18.7 some ideas are given, but since a lot of experimental data (especially for ion pairs) is unavailable, a complete comparative study among all descriptors has never been done. We rather think that the choice of measuring one parameter or another is based on lab equipment and traditions rather than on other more realistic aspects. Finally, it should be pointed out that predictive tools are rather deficient in this field (see 5.27 Rule-Based Systems to Predict Lipophilicity).

**Figure 3** (a) Partition coefficients measured in *n*-octanol/water ( $\log P_{\text{oct}}$ ) versus dba/water ( $\log P_{\text{dba}}$ ). Open circles, solutes with  $\alpha > 0$ ; filled circles, solutes with  $\alpha = 0$ .<sup>29</sup> The regression line is represented in red ( $n = 70$ ;  $r^2 = 0.92$ ); the ideal line of slope 1 and intercept 0 is in black. (b) Partition coefficients measured in *n*-octanol/water ( $\log P_{\text{oct}}$ ) versus 1,2-dichloroethane/water ( $\log P_{\text{dce}}$ ). Open circles, solutes with  $\alpha > 0$ ; filled circles, solutes with  $\alpha = 0$ .<sup>28</sup> Regression lines for both data sets are represented in red. (c) Averaged  $\Delta \log P_{\text{oct-dce}}^N$  (*n*-octanol and 1,2-dichloroethane) for a series of  $\beta$ -blockers<sup>111</sup>: a value of 0.96 is found (see text for details). It is the outliers from this fit that can provide clues to the role this difference might play in an ADMET process.

#### 5.18.4.2 Anisotropic Systems

In contrast to the isotropic solvents traditionally used in lipophilicity studies, artificial (liposomes) and natural membranes are anisotropic media and their use in lipophilicity studies has therefore led to the concept of anisotropic lipophilicity that looks for good biomembrane models in the effort to reproduce drug–membrane interactions which are involved in both pharmacokinetic and pharmacodynamic processes.<sup>45,62</sup>

In the simplest pharmacokinetic case, membranes are a barrier between two aqueous compartments in which a drug is distributed. Isotropic lipophilicity parameters can model such a situation for either neutral compounds or chemicals that are ionizable but neutral at physiologically relevant pHs (see Section 5.18.6), but their combination with anisotropic lipophilicity data is required when the contribution of ionized species is important (see Section 5.18.8.3).

In an anisotropic system, if the component providing the anisotropy contains no ionized groups, one would expect little difference from isotropic systems. In other words, anisotropic systems provide the most important information when they contain (or provide) ionized groups and one is dealing with ionizable compounds since the location of charges (Figure 4) also plays a role in determining the presence of ionic interaction (eqn [11]) which is very strong in a low dielectric environment.<sup>63</sup>

The entropy of a solute (related to the number of rotatable bonds and their flexibility) may be more affected by binding to a surface or a large molecule than to a simple counterion. The closeness of approach (steric factors) will also be more important. These are attributes not of concern in isotropic systems. Another difference is illustrated below in which a ‘negative’ phospholipid component of membranes is proposed to form an HIP with a basic solute (see Section 5.18.8.3).

Positive and negatively charged substrates will be affected differently in anisotropic systems containing charges. Each anisotropic system is dependent on the nature of its charged components. For this reason, a model system may apply only narrowly to related biological systems.

**Figure 4** Charge location governs the absence/presence of ionic interactions in isotropic/anisotropic systems.<sup>63</sup> (a) In isotropic systems, charges are carried by salt buffers and solutes and thus have no defined location. As a result no 'specific' electrostatic interaction occurs. (b) In anisotropic systems charges are located on the lipidic phase (e.g., the polar head of phospholipids). As a result these systems provide the most important information when one is dealing with ionizable compounds. (Reproduced with permission from Caron, G.; Ermondi, G. *New Insights into the Lipophilicity of Ionized Species*. In *Pharmacokinetic Profiling in Drug Research: Biological, Physicochemical and Computational Strategies*; Testa, B., Kraemer, S., Wunderli-Allenspach, H., Folkers, G., Eds.; Verlag Helvetica Chimica Acta: Zürich, 2005, pp 165–185.)

An example of a pharmacodynamic process involves membranes as targets of drug action. Anisotropic systems may help to rationalize the behavior of drugs whose target is a membrane, especially when used with a pool of sophisticated experimental techniques (i.e., small-angle x-ray diffraction and small-angle neutron diffraction to support partition coefficients determined by centrifugation assays). These are discussed in detail by Herbette and co-workers.<sup>62</sup> In other cases, membranes provide the matrix in which enzymes or receptors are embedded. Binding assays, coupled with dose-response experiments, are needed to assess specific drug-receptor interactions.<sup>45</sup>

Anisotropic lipophilicity represents an intermediate case between partitioning and binding. As discussed elsewhere, energetic criteria allow one to distinguish partitioning from binding mechanisms,<sup>63</sup> but not the nature of the intermolecular interactions involved, since they are the same, as explained above.

Other anisotropic systems (mainly micelles/water) have also been presented in the literature,<sup>64–70</sup> but their use is still not common.

#### 5.18.4.3 Chromatographic Systems

Chromatographic methods have recently been reviewed by Comer.<sup>58</sup> Most are HT methods and can be classified according to whether or not *n*-octanol is used. The presence of *n*-octanol tends to provide chromatographic systems that more closely reproduce the standard *n*-octanol lipophilicity values.

Although chromatographic retention parameters are good lipophilicity indices that can be used to generate predictive ADMET models, their transformation into  $\log D_{\text{oct}}$  values should in principle be avoided. This is especially true for ionized species, since ionic interactions with the stationary phase could significantly affect the balance of intermolecular forces (eqn [11]).<sup>27,53</sup> Even for neutral species, subtle effects such as differences in hydrogen bonding capacity can perturb the correlation between  $\log D_{\text{oct}}$  and chromatographic data.<sup>71</sup> In spite of these problems, some good methods are reported in the literature that, after a carefully analysis of the data, are able to convert chromatographic  $\log k$  into  $\log P/\log D$  parameters. Among them,  $E\log D$  by Lombardo and co-workers<sup>47,48</sup> is one of the most appreciated. Please note that the authors clearly underline the limits of the method to achieve high accuracy in determining data for anions, probably because of specific interactions with the stationary phase.

An HT chromatographic system using an octadecyl-poly(vinyl alcohol) column with a methanol/water gradient has been described by Donovan and Pescatore.<sup>72</sup> Their method has been applied to thousands of compounds and closely reproduces *n*-octanol  $\log P$  values ( $r^2 = 0.88$ ,  $s = 0.43$  for 120 fungicides, herbicides, and drugs). Routine use of pH 2 and 10 eluents (up to pH 13 when necessary) insures that values are for unionized species.

The preparation and validation of liposomes make their use in partitioning studies time-consuming and tedious. The use of immobilized artificial membranes (IAMs), in contrast, combines the speed of high-performance liquid chromatography (HPLC) technology with a model of phospholipid partitioning.<sup>73</sup> In fact, capacity factors measured on IAMs<sup>74–86</sup> are expected to reflect the partitioning of compounds in the liposomes/water system. (IAM columns are

prepared by covalent binding of a monolayer of phospholipids on silica particles.) Some examples of relationships between IAM data and other lipophilicity descriptors are discussed in [Section 5.18.8.4](#).

In immobilized liposome chromatography<sup>81,87</sup> phospholipid-based stationary phases of different chemical composition can be easily and reversibly immobilized on suitable gel supports, and thus chromatographic retention on phospholipids is devoid of any effect caused by the presence of a silica matrix. Still, the possible influence of polymeric support on retention and reproducibility of column performance remains to be fully understood.

Solid-supported lipid membranes (SSLM), commercially available as Transil, are systems in which porous silica beads are covered by a unilamellar liposomal membrane which is noncovalently bound to the bead and which retains its fluid character.<sup>88,89</sup> Schematically, a bead suspension and a solution of the test compound are mixed and left to equilibrate. The beads are then separated by centrifugation, and finally the supernatant is analyzed for quantification of remaining solute. The SSLM permit an HT determination of membrane partitioning, but more published work is needed to assess their potential and limitations better.

### 5.18.5 Low-Throughput and High-Throughput Methods to Measure Lipophilicity in Non-Chromatographic Systems

Methods for obtaining physicochemical properties for profiling drug candidates have been widely reviewed.<sup>15,58</sup> Even if in principle an optimized experimental technique to measure lipophilicity were able to produce the whole lipophilicity profile (*see* [Section 5.18.4.1](#)) in any system, any method has its own experimental window. In practice, the HT revolution often demands a single lipophilicity value (often  $\log D_{\text{oct}}^{7.4}$ ) and not the whole profile (*see* [Section 5.18.6](#)).

The strategy for measuring  $\log P/\log D^{\text{pH}}$  is determined by the solubility of a compound. The compound must be soluble (and stable) during any procedure to ensure equilibrium is maintained.  $\log P/\log D^{\text{pH}}$  determination of poorly soluble compounds is a problem. Provided the  $\log P/\log D^{\text{pH}}$  is high enough, the value may be determined by titration, adding the sample to the octanol first. The compound will then back-partition into the aqueous layer.

Though accurate, the classic manual shake-flask method<sup>90</sup> of measuring lipophilicity can be very time-consuming and thus emphasis has turned to HT modifications involving multiple samples using a modified titer plate. Examples of this shake-plate method include reports by Kratochwil *et al.*,<sup>91</sup> Zhu *et al.*,<sup>92</sup> and Valko.<sup>93</sup>

The reference method for measuring the partition coefficients of the neutral and ionized forms of a compound (and thus  $\log D^{\text{pH}}$  by eqn [1]) is the pH-metric method, namely a two-phase titration.<sup>14</sup> *n*-Octanol is the usual second phase,<sup>45,94–97</sup> but other organic solvents<sup>61,96,98–100</sup> and suspensions of liposomes<sup>45,101–105</sup> have been used. The aqueous phase is usually 0.15 M KCl or NaCl. The titration occurs in the aqueous phase. The method is based on the apparent shift in  $\text{p}K_{\text{a}}$  in the presence of the second phase due to partitioning of neutral and ionized species into that phase. The extent of the  $\text{p}K_{\text{a}}$  shift can be related to  $\log P^{\text{N}}$  and  $\log P^{\text{I}}$ . At least two titrations with different *n*-octanol:water ratios are required to solve for the two partition coefficients. Advantages and drawbacks of this method, which more recently has been fully automated, are listed and commented upon in the review of Plemper Van Balen *et al.*<sup>45</sup>

Single-phase titrations in KCl/water-saturated *n*-octanol is an alternative procedure for obtaining lipophilicity data.<sup>25,26</sup> The principle is based on the thermodynamic cycle in [Figure 1c](#) and the relationships derived in eqns [9] and [10]. It appears that  $\text{p}K_{\text{a}}''$  differs from  $\text{p}K_{\text{a, oct}}$  by a constant, the electrode correction factor discussed below, and this is the working hypothesis. Contrary to one's instinct, the curves are very smooth – almost like aqueous titrations. [Figure 5](#) shows the titration curve of pyridine-2-acetic acid. Calculation of  $\text{p}K_{\text{a}}''$  is by curve fitting to a Henderson–Hasselbalch equation using the Solver program in Excel. A key to accurate calculations was determination of the  $\text{p}K_{\text{a}}$ s of water in KCl/water-saturated 1-octanol:  $-1.31 \pm 0.09$  ( $n = 7$ ) and  $17.02 \pm 0.05$  ( $n = 8$ ). The  $\text{p}K_{\text{a}}$ s were determined by titrations of HCl and of triflic acid from pH 2 to 14, as well as by extending titrations of other acids to pH 14 and of bases to pH 2–3.

The titration procedure uses the same apparatus and general protocol as two-phase titrations. The few differences include preparing the titrants in ethanol, widening the criteria for equilibration at each point, and extending the stirring time after each pulse of titrant to compensate for a slower electrode response time. Typically, the titrant represents  $<1\%$  of the final volume. The procedure is automated for unattended multisample application. Details are reported on the CD accompanying the reference<sup>26</sup> and a full manuscript is in preparation.

The electrode correction factor (ecf), for the conversion of  $\text{p}K_{\text{a}}''$  to  $\text{p}K_{\text{a, oct}}$  (eqn [14]) is  $0.8 \pm 0.1$ , based on comparison of two-phase and single-phase titrations in *n*-octanol.<sup>25,26</sup> A component of ecf undoubtedly accounts for the different background counterion concentration in the two methods.

$$\text{p}K_{\text{a, oct}} = \text{p}K_{\text{a}}'' \pm 0.8 \text{ (+for acids, –for bases)} \quad [14]$$

**Figure 5** The titration curve for pyridine-2-acetic acid hydrochloride in KCl/water-saturated octanol. The  $pK_a''$ 's are determined by curve-fitting to a Henderson–Hasselbalch equation using the Solver and Excel programs. There are enough data points to solve simultaneously for the  $pK_a''$  of water in *n*-octanol. The equivalent volume for  $pK_{a1}$  was iteratively set equal to that for  $pK_{a2}$ . The appearance, statistics, and reproducibility of this method show a close approximation to titrations in water. See text for details.

Reymond *et al.*<sup>16</sup> indicate that cyclic voltammetry (CV) is the only method that can yield the intrinsic  $\log P^I$  (called  $\log P^{0,i}$ ) for the bare ion without a counterion. This contrasts with  $\log P^I$  values obtained by traditional methods (e.g., shake-flask and titration) which are strongly influenced by experimental conditions, and particularly by phase volumes and the nature of counterions. Even if the electrochemical approach is able to guarantee a very high number of reliable data,<sup>99,106–112</sup> it must be stressed that it cannot be routinely applied in medicinal chemistry because of its serious experimental limitations, particularly the very few usable organic solvents (dce and *o*-NPOE) and the resulting inaccessibility of most biphasic systems such as the standard *n*-octanol/water.

Faller and co-workers have adapted an HT permeation assay method (no stationary phase involved) to measure the partition coefficient of compounds in hexadecane<sup>59</sup> and now in *n*-octanol.<sup>113</sup> The method is based on the relation:

$$P_0 = P_{\text{solvent}} \times \left( \frac{D}{h} \right) \quad [15]$$

where  $P_0$  is the intrinsic permeability,  $P_{\text{solvent}}$  is the partition coefficient in the solvent/water system,  $D$  the diffusion coefficient in the solvent, and  $h$  the thickness of the fluid membrane.

Finally, anisotropic lipophilicity can be measured by a number of direct methods, such as potentiometry (see above), dialysis, ultracentrifugation, ultrafiltration, calorimetry, and spectroscopic techniques.<sup>45,114</sup>

### 5.18.6 Strategies for Determining the Optimum Lipophilicity Parameters to be Used in Absorption, Distribution, Metabolism, Excretion, and Toxicity Studies

Most scientists accept  $\log D_{\text{oct}}^{7.4}$  as one of the most relevant lipophilicity descriptors to be applied in ADMET studies. A proposed enhancement to  $\log D$  is discussed in [Section 5.18.8.6](#) which involves factoring  $\log D$  into separate terms for the neutral and ionized species. Comer has given some general guidelines about  $\log D_{\text{oct}}^{7.4}$  values and their implication for drug development.<sup>58</sup> Briefly, when  $\log D_{\text{oct}}^{7.4}$  is below zero, the compounds have intestinal absorption and central nervous system (CNS) permeability problems and are susceptible to renal clearance;  $0 < \log D_{\text{oct}}^{7.4} < 1$  generally indicates a good balance between solubility and permeability;  $1 < \log D_{\text{oct}}^{7.4} < 3$  is an optimum range for CNS and non-CNS orally active drugs;  $3 < \log D_{\text{oct}}^{7.4} < 5$  is a range in which metabolic liabilities tend to increase. Finally,  $\log D_{\text{oct}}^{7.4} > 5$  is synonymous with poor oral bioavailability.

It is noteworthy that modern screening technology and the trend to combinatorial synthesis has resulted in hits that are generally more lipophilic than marketed drugs or compounds currently undergoing clinical evaluation. High lipophilicity is often accompanied by poor aqueous solubility. This can bring with it many challenges, often making development of a seemingly promising drug candidate very difficult.

The application of  $\log D_{\text{oct}}^{7.4}$  in ADMET requires some alerts. Faced with the selected database(s) of drug candidates for which lipophilicity determinants are required, we can distinguish three classes of compounds: (1) chemicals that are neutral; (2) chemicals that are ionizable but neutral at physiologically relevant pHs; and (3) chemicals that are ionizable and partly or mostly charged at physiologically relevant pHs.

The first step of the study therefore consists in classifying each compound. To do that you have to know the  $\text{pK}_{\text{a}}(\text{s})$  and its (their) acidic or basic nature. Then one has to determine the required  $\log D_{\text{oct}}^{7.4}$ .

Basically, dealing with compounds belonging to the first two classes is an easier task than working with compounds charged at physiologically relevant pH. In most cases, for (1) and (2) the estimation of  $\log P_{\text{oct}}^{\text{N}}$  is sufficient since here  $\log P_{\text{oct}}^{\text{N}}$  is equal to  $\log D_{\text{oct}}^{7.4}$ . Only when anomalies are evident, i.e.,  $\log P_{\text{oct}}^{\text{N}}$  is not in line with values found for congeneric chemicals or with the calculated value (*see* [5.27 Rule-Based Systems to Predict Lipophilicity](#); and [Section 5.18.7](#)), is it advisable to do something more. This means checking the experimental value by an additional experiment (better with a different method) and testing a second isotropic solvent system very different from *n*-octanol/water, i.e., alkane/water.

The presence of a charge (compounds belonging to class 3) complicates the situation considerably. One must note the dominant species at the considered pH before any determination. Then  $\log D_{\text{oct}}^{7.4}$  can be measured by the selected method.

Once the  $\log D_{\text{oct}}^{7.4}$  values are obtained, it is possible to check relationships with ADMET parameters (i.e., absorption/permeability, distribution volume, clearance) for all compounds belonging to the series of projects. If no model can be developed, or a significant correlation is found, but contains outliers, further studies should begin with members of class 3 and the application of molecular modeling tools is advisable.

A number of successful correlations between lipophilicity and ADMET descriptors have been reported in the literature. The correlation found between  $\log D_{\text{oct}}^{7.4}$  and renal clearance ( $\text{mL min}^{-1} \text{kg}^{-1}$ ) for a series of  $\beta$ -adrenergic antagonists in healthy human subjects<sup>1</sup> is an excellent example. It demonstrates the role of lipophilicity in renal excretion. Compounds with  $\log D_{\text{oct}}^{7.4}$  above 0 will undergo near complete absorption in the kidney tube and then metabolism to render them more polar, while compounds with  $\log D_{\text{oct}}^{7.4}$  below 0 will be poorly reabsorbed and thus undergo considerable renal clearance.

When ions are the dominant species (or the sole species) at the pHs of interest, we suggest obtaining additional  $\log D^{\text{pH}}$  ( $\log P^{\text{I}}$ ) in anisotropic systems and comparing these side by side with  $\log D_{\text{oct}}^{\text{pH}}$ . By such comparison, and a careful analysis of data, one can check the influence of the charge on ADMET phenomena.

This approach has been applied to investigate peculiar pharmacokinetic properties of amlodipine<sup>62</sup> ( $\text{pK}_{\text{a}} = 9.07$  and  $\log D^{7.4} = 1.55$ ; the chemical structure is reported in [Figure 7](#), below) for which it has been demonstrated that ionic interactions are responsible for the long stay in membrane, which in turn is mandatory for the large volume of distribution,  $V_{\text{d}}$  ( $25 \text{ L kg}^{-1}$ ) and the long plasma half-life (30 h). The extent of ionization and the balance between ionic and hydrophobic interactions are therefore the crucial features that differentiate the membrane-binding mode of amlodipine from other long-acting calcium antagonists (e.g., lacidipine and lercanidipine).<sup>98</sup>

When dealing with zwitterions it is advisable to estimate the whole lipophilicity profile (*see* [Section 5.18.8](#)).

Finally, we also recommend a combination of experimental data with ad hoc computational studies whose description is beyond the scope of this chapter.

### 5.18.7 Unraveling the Lipophilicity of Neutral Species

The combined descriptor  $\text{diff}(\log P^{\text{exp}} - \text{calc})$  represents the difference between an experimental  $\log P$  and the corresponding calculated value (see 5.27 Rule-Based Systems to Predict Lipophilicity) by a favorite or best known method. As illustrated by Caron and Ermondi,<sup>17</sup> this *diff* descriptor (Table 1) has at least three applications of high utility in ADMET studies: (1) optimization of the adopted experimental procedure; (2) identification of the best predictive methods for a structurally related series of compounds; and (3) extraction of structural information from investigated drug candidates and from chemicals involved in hit characterization, lead profiling, and lead optimization.

A second approach to studying the lipophilicity of neutral species is based on graphs of  $\log P_{\text{oct}}^{\text{N}}$  versus  $\log P_{\text{aaa}}^{\text{N}}$ <sup>27–29</sup> (see Section 5.18.4.1 and Figure 3c). Once the relationship for an optimized training set of chemicals is known, the position of new compounds on these graphs can give useful information on the presence or absence of intramolecular effects affecting their neutral forms.<sup>98,111,115</sup> This approach allowed the elucidation of the peculiar intramolecular interactions affecting amlodipine<sup>98</sup> and some  $\beta$ -blockers.<sup>115</sup>

The use of these plots in drug design is strongly recommended by academics, but unfortunately, to date, is poorly accepted by those in industry. The plots allow early identification of compounds with unusual intramolecular H-bonding, molecular tautomerism, or conformational flexibility. It is crucial to be aware when such features are present. Any drug candidate of this type will be endowed with a peculiar physicochemical profile, and thus is likely to be an outlier in traditional classification schemes. These compounds could be excellent starting points for designing new chemical entities of pharmaceutical interest.

### 5.18.8 Unraveling the Lipophilicity of Ions and Zwitterions

It is widely assumed<sup>25,116,117</sup> that in partition phenomena the ionized species migrating into the nonaqueous phase is accompanied by a counterion, forming a charge-neutral ion pair.<sup>118</sup> According to IUPAC, an ion pair consists of a pair of oppositely charged ions held together by Coulomb attraction without formation of a covalent bond. Experimentally, an ion pair behaves as one unit in determining conductivity, kinetic behavior, and osmotic properties, etc.

The nature of the counterion and its concentration both influence  $\log P^{\text{I}}$ , so these have to be taken into account. Many feel that 0.15 M NaCl or KCl, corresponding to extra- and intracellular concentrations of these salts, respectively, is the logical choice for the aqueous phase in partitioning studies.<sup>14,94</sup>

#### 5.18.8.1 The Use of $\text{diff}(\log P^{\text{N}} - \text{I})$ and $\text{diff}(\text{p}K_{\text{a}}'')$ to Calculate the Lipophilicity of Ion Pairs in *n*-Octanol/Water

Generally speaking, the change in lipophilicity of a molecule when it ionizes is determined by its structure in the near vicinity of the charge center. This simplifies the prediction process since, whatever the size or makeup of the remainder of the molecule, if important features around the charge center do not change, the difference between  $\log P^{\text{N}}$  and  $\log P^{\text{I}}$  will be about the same. Titrations in *n*-octanol have proven to be an ideal method for identifying these important features and quantifying their influence. Four primary factors affecting  $\log P^{\text{I}}$ <sup>25</sup> are illustrated in Sections 5.18.8.1.1–5.18.8.1.4 using data from Table 3. The titration method is based on eqns [9] and [14]. A particular advantage for current purposes is that, when looking at differences between  $\text{diff}(\text{p}K_{\text{a}}'')$  values, the electrode correction factors cancel out, giving values sensitive to a few hundredths of a  $\text{p}K_{\text{a}}$  or  $\log P^{\text{I}}$  unit. A distinctive feature of this method is that it is insensitive to the magnitude of  $\log P$ , so a wide range of simple compounds is available. A glance at the variation in the  $\text{diff}(\text{p}K_{\text{a}}'')$  values in Table 3 shows the limited value in the generalization that  $\text{diff}(\log P^{\text{N}} - \text{I})$  is the same for all amines, and the same for all carboxylic acids.<sup>119</sup>

##### 5.18.8.1.1 The influence of steric factors on $\log P^{\text{I}}$

The hindered König's base, *N*, *N*-diisopropylethylamine (Table 3), has a  $\text{diff}(\text{p}K_{\text{a}}'')$  0.62 units larger than for triethylamine. This means its  $\text{diff}(\log P^{\text{N}} - \text{I})$  is also greater by the same amount. The more hindered amine has a lower  $\log P^{\text{I}}$  with respect to its neutral form than does triethylamine. On the other hand, the much smaller  $\text{diff}(\text{p}K_{\text{a}}'')$  for phenethylamine, compared to triethylamine, tells us that primary ammonium compounds are much more lipophilic compared to their neutral form than are simple tertiary amines, by about 1.4 log units in this case. This is reflected in their relative  $\text{p}K_{\text{a}}$ s in water and *n*-octanol. In *n*-octanol, phenethylamine is a stronger base than triethylamine ( $\text{p}K_{\text{a}}''$  column), just the opposite of their relative  $\text{p}K_{\text{a}}$ s in water ( $\text{p}K_{\text{a}}$  column). These property differences can have a direct bearing on biological activity, or on ADMET properties, particularly if only one

**Table 3** Titrations in KCl/water-saturated *n*-octanol illustrating structure–*diff*  $pK_a$  relationships. The lower the *diff*( $pK_a''$ ), the more lipophilic the ion pair in relation to its neutral form

of the species, the protonated or the neutral, is the active form. ('Active form' is the species involved in the rate-limiting step in the process being measured. It could be the species in equilibrium with the target biological receptor, the species that is the substrate of a metabolizing enzyme, or the form involved in active transport.) Whether one chooses to look at the lipophilicity of ionized species, or their *n*-octanol  $pK_a$ , these properties do not always parallel those of the neutral species. Such differences may provide an opportunity to identify the active species, but even if they do not, one can see the importance of giving specific consideration to the ionized form of compounds being modeled in ADMET studies.

#### 5.18.8.1.2 The influence of hydrogen bond donors and acceptors on $\log P^I$

The advantage of being able to use  $pK_a''$  instead of  $\log P$  values to study hydrogen bonding effects on  $\log P^I$  is that one is able to use much simpler compounds to isolate the property to be studied from other potential factors and interactions. Polyhydroxy compounds would need to have quite high molecular weights for their  $\log P^I$  values to be easily measured, for example. It would be difficult to isolate the influence of the hydroxy groups. Hydroxy groups can have a powerful influence on the lipophilicity of ionized acids and bases. The *diff*( $\log P^{N-1}$ ) for triethanolamine is 1.7 units smaller than that for triethylamine (Table 3). Similar comparisons can be made for *tris*(hydroxymethyl)aminomethane (tromethamine), which has a *diff*( $\log P^{N-1}$ ) 1.19 units lower than *t*-butylamine, and for the acids 3-hydroxybutyric acid and hexanoic acid, the two *diff*( $\log P^{N-1}$ )s differ by 0.72 units. At the extreme is *N*-methyl-D-glucamine

(meglumine),  $\text{CH}_3\text{NH-CH}_2(\text{CHOH})_4\text{CH}_2\text{OH}$ , which has a  $\text{diff}(\text{p}K_a'')$  of only 0.35, meaning the cationic form is almost as lipophilic as the free base. It is interesting that both tromethamine and meglumine have been used for the formulation of oral and injectable drugs and x-ray and magnetic resonance imaging contrast agents (e.g., carboprost tromethamine, flunixin meglumine, tetrazolast meglumine, iodoxamate meglumine, diatrizoate meglumine, and gadoterate meglumine).

#### 5.18.8.1.3 The influence of $\text{p}K_a$ on $\log P^I$

It is difficult to find a uniform series of acids or bases in which the  $\text{p}K_a$  varies over a wide-enough range to make useful conclusions about the influence of  $\text{p}K_a$  on the lipophilicity of their ion pairs. There is one excellent series of 24 chloro- and nitrophenols reported by Escher and Schwarzenbach<sup>120</sup> in which the  $\log P^I$  of each member was measured. The corresponding  $\text{p}K_{a\text{ oct}}$  values can be calculated using eqn [9]. The following regression equation obtained by Scherrer<sup>25</sup> showed the relation:

$$\text{p}K_{a\text{ oct}} = 1.19(\pm 0.04)\text{p}K_a + 0.33(\pm 0.08)I_{\text{Cl}} + 1.92(\pm 0.27) \quad [16]$$

$$r^2 = 0.98; s = 0.32; n = 23; F = 401(4 - \text{Cl omitted})$$

where  $I_{\text{Cl}}$  is an indicator term for the number of *o*-chloro groups. The coefficient of the  $\text{p}K_a$  term is  $>1$ , which means that the more acidic the phenol, the less the difference between  $\text{p}K_{a\text{ oct}}$  and  $\text{p}K_a$  (and between  $\log P^{\text{N}}$  and  $\log P^I$ ; eqn [2]). The  $\text{diff}(\log P^{\text{N}-I})$  decreases about 0.2 units for each unit decrease in  $\text{p}K_a$ . No special term is needed for nitrophenols. This equation validates the similar equation for 13 phenols based on  $\text{p}K_a''$  values<sup>25</sup>:

$$\text{p}K_a'' = 1.16(\pm 0.02)\text{p}K_a + 0.28(\pm 0.07)I_{\text{Cl}} + 1.16(\pm 0.19) \quad [17]$$

$$r^2 = 0.99; s = 0.19; n = 13; F = 1135$$

The coefficient of the  $\text{p}K_a$  term was also  $>1$  for a series of 22 benzoic and salicylic acids,<sup>25</sup> (eqn [18]). It appears to be general that the more acidic and resonance-stabilized an acid, the lower the  $\text{diff}(\log P^{\text{N}-I})$ . It seems reasonable to believe that this will apply to bases as well.

For benzoic acids,

$$\text{p}K_a'' = 1.25(\pm 0.06)\text{p}K_a + 0.60(\pm 0.08)I_{\text{Cl}} - 1.18(\pm 0.09)I_{\text{NO}_2} + 2.47(\pm 0.17) \quad [18]$$

$$r^2 = 0.99; s = 0.17; n = 22; F = 467$$

for which  $I_{\text{Cl}}$  is an indicator variable for *ortho*-chloro groups and  $I_{\text{NO}_2}$  an indicator for the presence of a nitro group *ortho* or *para* to the phenolic OH of salicylic acids.

In Table 3, the highly acidic diphenylphosphate,  $\text{p}K_a$  1.36, is seen to form a relatively lipophilic ion pair. The  $\text{diff}(\text{p}K_a'')$  is only 1.10. It would seem that many of the hydroxy phosphoric acid mono- and di-esters in nature and biochemistry, like phosphatidylinositol (PI), will form very stable low-energy ion pairs in low dielectric environments. These can be added to the list of reasons Westheimer gives for ‘Why Nature chose phosphates.’<sup>121</sup>

#### 5.18.8.1.4 The influence of the chemical class on $\log P^I$

Finally, various classes of acids and bases have characteristic  $\text{diff}(\log P^{\text{N}-I})$  values. For example, compare benzoic acid and phenyltetrazole in Table 3. Even though they have about the same aqueous  $\text{p}K_a$ , their  $\text{p}K_a''$ s differ much more, and therefore their  $\text{diff}(\log P^{\text{N}-I})$  will differ as well. This category overlaps some of the preceding ones. For example, primary, secondary, and tertiary amines could be considered separate classes. There are many classes for which it would be difficult to predict  $\text{diff}(\log P^{\text{N}-I})$  and for which specific data need to be obtained. Some examples are enolic acids, sulfonamides, acylsulfonamides, amidines, and nitroalkanes.

#### 5.18.8.1.5 The influence of the immiscible solvent phase on $\log P^I$

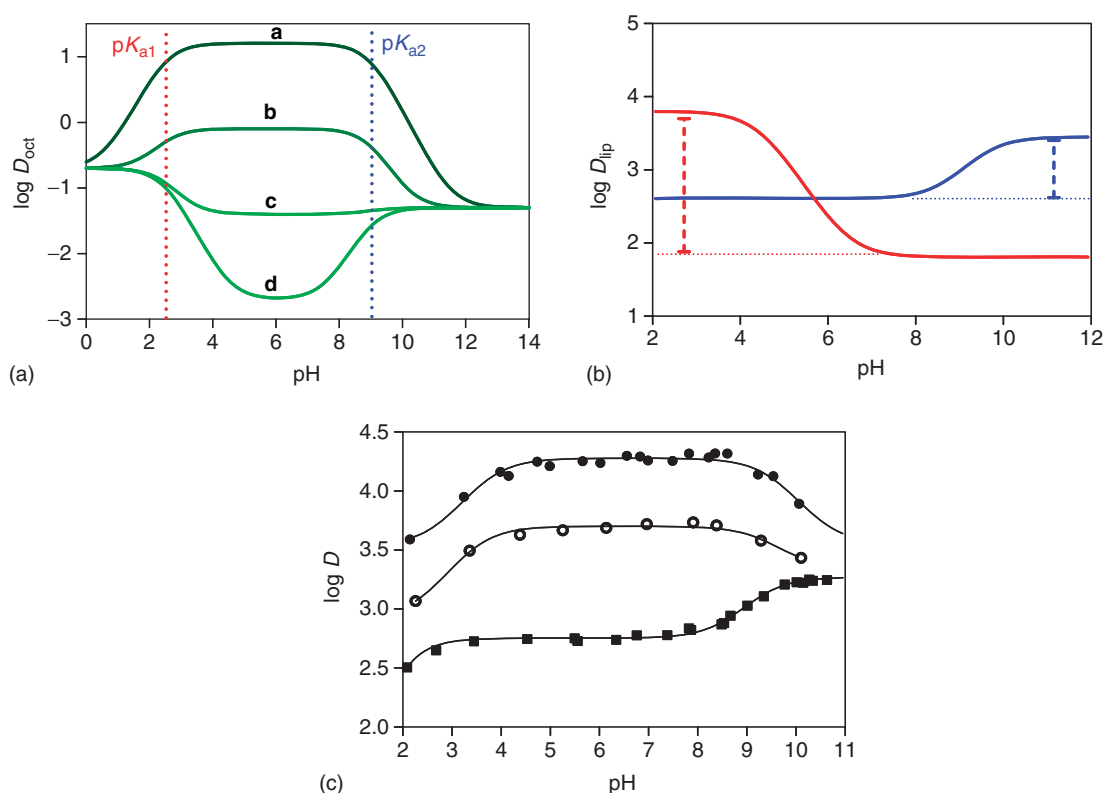

Ionized compounds put a unique demand on a solvent, so their lipophilicity may vary more widely between solvents than neutral species. *n*-Octanol is able to hold water and counterions and has both hydrogen donor and acceptor properties.<sup>122</sup> dce and *o*-NPOE provide partitioning information different from *n*-octanol because they lack H-bond donor and acceptor activity.<sup>13,61,107–109,111,123</sup> In particular, Bouchard *et al.* have proposed a  $\text{diff}(\log P^{\text{N}-I})$  scale in dce/water that provides useful information about the behavior of ions in different systems.<sup>13</sup>

### 5.18.8.2 Hydrophobic Ion Pairs

The first use of the term ‘hydrophobic ion pairing’ appears in a review by Meyer and Manning.<sup>124</sup> The concept is further discussed in their subsequent patents and publications<sup>125–128</sup> on drug delivery. HIP is an ion-pairing phenomenon that refers to the replacement of simple inorganic counterions with ionic detergent-like compounds that dramatically alter their partition coefficient. Examples include  $\alpha$ -chymotrypsin that can be solubilized in *iso*-octane with retention of activity, and insulin that can be transported through methylene chloride as an illustration of its unusual solubility properties.

The effect of HIPs on drugs can also be dramatic. A recent report<sup>126</sup> describes the preparation of a HIP of cisplatin with dioctyl sulfosuccinate (AOT), a US Food and Drug Administration-approved surfactant. The *bis* AOT ion pair had  $\log P_{\text{oct}}^I$  2.17, compared to  $\log P_{\text{oct}}^I$  of  $-2.35$  for cisplatin. When cells were exposed to equal concentrations of the HIP or the parent drug for 1 h, the HIP produced cellular platinum levels 4–5 times higher than the cisplatin. Studies on various tumor lines showed the AOT complex to be 1.7–5 times more potent.

HIPs are at one end of a continuum of salt forms of acids and bases with increasingly lipophilic counter ions. Their lipophilicity profile can be illustrated using the left or right half of Figure 6a.<sup>151</sup> Covering the left half of the figure leaves lipophilicity profiles that could represent a series of salts of a basic compound with  $pK_a$  9.0. The lowest curve, d, could

**Figure 6** (a) The distribution profile of a series of ampholytes showing a progression from type 3 (d) to type 4 (a) ampholyte. For comparison purposes, all have the same partition coefficients for their cationic and anionic species at extreme pH values. Their acidic and basic groups also have the same respective  $pK_a$  values, 2.5 and 9.0. The only difference is that the  $\log P^Z$  of their zwitterions varies. (Reproduced with permission from Berthod, A.; Carda-Broch, S.; Garcia-Alvarez-Cogue, M. C. *Anal. Chem.* **1999**, 71, 879–888 © American Chemical Society.) Note how the  $pK_{a \text{ oct}}$  at the lower inflection of each curve shifts through the series. (b) Partitioning in an anisotropic system. The distribution profile (data taken from reference<sup>101</sup>) of a monoacid drug (ibuprofen, in red) and of a monobasic drug (propranolol, in blue) in the PhC-liposome/water system. From the difference between  $\log P^N$  and  $\log P^I$  it is clear that charged forms of bases have larger affinity for liposomes than charged forms of acids. Comparison with Figure 1b shows that  $\text{diff}(\log P^{N-I})$  for propranolol is lower in liposomes than in octanol. (c) Partition profiles of (RS)-[3H]propranolol in: filled squares,  $P^C$ -; filled circles,  $P^L$ -, and open circles,  $P^C/P^I$  (7/3 mol/mol)-liposomes/SUBS systems. (Reproduced from Krämer, S. D.; Braun, A.; Jakits-Deiser, C.; Wunderli-Allenspach, H. *Pharm. Res.* **1998**, 15, 739–744, with kind permission of Springer Science and Business Media.)

be that for the base with a chloride counter ion. That ion pair has a lower lipophilicity than the neutral amine, and the  $pK_{a_{\text{oct}}}$  6.0 (lower inflection) is lower than the aqueous  $pK_a$  9.0, which is also typical. If one were to determine the lipophilicity profiles of this amine with a series of alkanesulfonate counterions, they would look like the right half of Figure 6a. The  $\log P$  of the ion pair will increase with chain length until it equals, and then exceeds, the  $\log P$  of the neutral parent amine. This cross-over might be called the defining point for a hydrophobic ion pair. Ion pairs with  $\log P$  values 2–4 units higher than the parent acid or base are readily obtainable.<sup>124</sup> Referring to Figure 6a again, for the upper curves one can see that the ion pair exists over an increased pH range and that the  $pK_{a_{\text{oct}}}$  is now higher than the aqueous  $pK_a$ . The shift reflects the lower free energy to form the ion pairs.

### 5.18.8.3 Lipophilicity of Ions in Anisotropic Systems

For neutral compounds, partition coefficients in isotropic and anisotropic media are known to be correlated.<sup>74,101</sup> In contrast, partition coefficients of cationic species are much enhanced in anisotropic media (liposomes and cell membranes) compared to *n*-octanol.<sup>100,103,129</sup> In Figure 6b, propranolol and ibuprofen are taken as examples to demonstrate this finding.

These data have been rationalized<sup>62,98,129–132</sup> by postulating that the cationic form of a drug interacts with the anionic oxygen of the phospholipid head group of the membrane bilayer, leading to an additional stabilization. In other words, when trying to model the partitioning of ionized compounds into membranes, the presence of phospholipids as potential counterions in the membrane is an important component missing from any isotropic medium.

A model for the interaction of basic compounds with the anion of phosphatidylcholine (PC) was described by Avdeef *et al.* as part of their ‘pH-piston’ hypothesis.<sup>101</sup> There is enough free energy gain from the phosphate/ammonium ion association that the choline of the zwitterion is displaced from the ion pair and extends outward to pair with chloride in the medium, resulting in the appearance of a positive charge on the surface. The field has progressed from proposals that basic drugs are present in membranes as unpaired cations,<sup>39</sup> to designing a series of long-acting dual  $D_2$ -receptor/ $\beta$ -adrenoceptor agonists based on their forming ion pairs with membrane phospholipids.<sup>133</sup> Austin *et al.*<sup>39</sup> have shown that there is little chloride ion pair in membranes, since, unlike the situation in octanol, increasing the aqueous chloride ion concentration does not appreciably increase the  $\log P^I$  of basic compounds.

It is interesting to note that ‘negative’ phosphatidyl esters, such as PI, have perfect properties for forming hydrophobic ion pairs. They are very lipophilic, detergent-like strong acids. Unlike PC, they have no competing built-in counterion. The powerful solubilizing effects of hydrophobic ion pairs can be seen in membranes. Krämer *et al.*<sup>134</sup> compared the pH distribution profile of tritiated propranolol in ‘negative’ and ‘neutral’ liposomes prepared from PI, PC, and mixtures of the two. The profile in PI liposomes is markedly different from that in PC liposomes (Figure 6c). In PI liposomes the propranolol cation is more lipophilic than the free base ( $\log P$  4.24 versus 3.49), a clear sign of a HIP (see Section 5.18.8.2). PI has an additional beneficial property: the inositol hydroxy groups offer additional charge stabilization, just as in the examples in Table 3. HIP formation also appears to take place with desipramine in PI membranes.<sup>135</sup>

The difference between the pure liposomes in Figure 6c is dramatic. The  $\log P^I$  of propranolol cation is 1.90 units higher in  $P^I$  than  $P^C$  liposomes. This is highly relevant to those building models of absorption and distribution, since Krämer showed that membrane phospholipids behave the same way in a mixed membrane as they do in pure liposomes.<sup>134</sup> Since membranes in nature contain on average about 10% negative phospholipids,<sup>64</sup> these could be major transporters of cations across cell membranes.

### 5.18.8.4 Chromatographic Systems

Many recent studies have used IAM columns to investigate the lipophilicity of ions, only some of which can be listed here.<sup>78,81,85,136,137</sup> The intense activity in this area in recent years comes from the advantage of this technique over traditional anisotropic systems in being suitable for HT screening. A perceptive review by Taillardat-Bertschinger and co-workers<sup>137</sup> indicates that the IAM capacity factors of neutral solutes often correlate with other lipophilicity parameters such as CLOGP,  $\log P/\log D^{pH}$ , capacity factors measured on reversed-phase HPLC columns, and liposomes/water partitioning. For ionized solutes, in contrast, IAM chromatography, liposomes/water, and *n*-octanol/water yield distinct lipophilicity scales, particularly for hydrophilic compounds. In fact, several studies have shown that the balance of recognition forces governing partitioning in liposomes and IAMs is not identical.<sup>63,74,138</sup> This may be explained by the marked structural differences existing between the two systems for which IAM cannot exactly emulate lipid dynamics and thus cannot replace liposomal systems.

### 5.18.8.5 Ampholytes and Zwitterions

Compounds containing both acidic and basic groups are called ampholytes. An important subset is zwitterions in which, at some pH, the acidic and basic groups are simultaneously ionized (5.16 Ionization Constants and Ionization Profiles). The further classification of zwitterionic ampholytes is discussed below. Examples of a number of current and formerly marketed zwitterionic drugs are shown in [Figure 7](#).

Many more examples of zwitterions occur in biology, including amino acids and peptides. Understanding the physicochemical properties of this class can sometimes be challenging. A useful review is provided by Pagliara *et al.*<sup>139</sup> A more recent analysis of ampholytes based on their  $pK_a$ s in water and *n*-octanol simplifies classification and helps in understanding their physicochemical properties.<sup>25</sup> Often-asked questions about ampholytes include whether or not a zwitterion is present in the aqueous or *n*-octanol phases, over what pH range they exist, and to what extent a zwitterion exists as a neutral versus a doubly charged species. These questions can be answered quantitatively using  $pK_{a, \text{oct}}$  values.

The classification of ampholytes and zwitterions into four types is shown in [Table 4](#). Type 1 is a simple ampholyte and the others are zwitterionic ampholytes. Types 3 and 4 cannot be distinguished by their aqueous  $pK_a$ s. Both are strong acids and bases and capable of forming a zwitterion in both phases. What distinguishes them is whether or not the two charges can be internally compensated, either by two groups being physically able to come into contact, or through resonance forms. When they can be compensated, the compound has a dramatically different lipophilicity profile, as seen for type 4 ampholytes. Put another way, the type 4 profile is diagnostic that internal compensation is occurring in octanol.

[Figure 6a](#) shows lipophilicity profiles for a series of zwitterions providing a regular progression from type 3 to type 4 ampholytes. They have the same aqueous  $pK_a$  values, 2.5 and 9, the same cationic and anionic partition coefficients, 0.2 and 0.05, respectively, but with the  $P$  of the zwitterion ( $P^Z$ ) varying from 0.002 to 16 in 20-fold intervals. The aqueous  $pK_a$  for each compound is found at the upper inflections of each curve (where the dashed lines intersect). The  $pK_{a, \text{oct}}$  values are always found at the lower inflections. One can see that the  $pK_{a, \text{oct}}$  values for the compound represented by curve **d** are 4.5 and 6.0. The compound represented by curve **a**, on the other hand, has  $pK_{a, \text{oct}}$  of 0.6 and 11.5. It is a much stronger acid and base in *n*-octanol than in water!

**Figure 7** Chemical structures of investigated chemicals.

**Table 4** Classification of simple and zwitterionic ampholytes

| Type | Example  | Lipophilicity profile | Water phase   | <i>n</i> -Octanol phase   | Charge interaction   |
|------|--|-----------------------|---|---|--|
| 1    | <b><i>m</i>-Aminophenol</b><br><chem>Nc1cccc(O)c1</chem><br>$pK_a$ 9.87<br>$pK_a$ 4.17   |                       | The base has a lower $pK_a$ than the acid.              | The acids and bases are even weaker in octanol.   | No interaction in either phase. The compound is a simple ampholyte.  |
| 2    | <b>Labetalol</b><br><chem>CN(C)CC(O)Cc1ccc(O)c(C(=O)N)c1</chem><br>$pK_a$ 7.4<br>$pK_a$ 9.4  |                       | The base has a higher $pK_a$ than the acid.             | In octanol, the base has a lower $pK_a$ than the acid.  | Zwitterion occurs in the aqueous phase only.   |
| 3    | <b>Acrivastine</b><br><chem>C1CCN1C/C=C/c2cccnc2/C=C/C(=O)[O-]</chem><br>$pK_a$ 9.55<br>$pK_a$ 2.2   |                       | A strong acid and base. Produces a zwitterion in water. | A weaker acid and weaker base in octanol, but the base still has a higher $pK_a$ than the acid.                 | Zwitterion is formed in both phases. No internal compensation of charges.  |
| 4    | <b>Cetirizine (Figure 7).</b><br>$pK_a$ 2.9 (carboxyl)<br>$pK_a$ 8.0 (distal piperazine N)<br><br><b>Azapropazone (Figure 7).</b><br>$pK_a$ 0.5 (endione)<br>$pK_a$ 6.9 (=N-C-NMe <sub>2</sub> ) |                       | A strong acid and base. Produces a zwitterion in water. | A stronger acid and stronger base in octanol than in water. A zwitterion over a greater pH range than in water. | Zwitterion in both phases. Internal compensation in octanol by contact.<br><br>Interaction in octanol of adjacent tautomeric ions. |

The curves in Figure 6a show a progression of profiles from type 3 zwitterions (d) to type 4 internally compensated zwitterions. The largest contribution to  $P^Z$  in this transition is the internal compensation of charges with the elimination of the counterions. Additional factors, such as the size of the ring, the nature and interaction of the charged groups, and steric interactions with axial substituents, will all contribute to the free energy of the ion pair, in a positive or negative way, and thus to  $\log P^Z$ . Examples of drugs of the type 4 zwitterion class include cetirizine, piroxicam, and azapropazone, and by their lipophilicity profiles (RA Scherrer, unpublished observations), should also include raclopride<sup>140</sup> and tetracycline<sup>141</sup> (chemical structures are shown in Figure 7).

The distribution profiles of hydroxyzine and cetirizine in Figure 8<sup>142</sup> provide an opportunity to illustrate the very large free energy change that takes place with the formation of internally compensated zwitterions. The  $pK_a$  change of the distal piperazine nitrogen of each tells the story. The  $pK_a$  of hydroxyzine (7.52) and cetirizine (8.00) are shifted in *n*-octanol by an amount equal to  $\text{diff}(\log P^{N-1})$  (eqn [10]). The hydroxyzine shift is in the usual direction for amines, down 2.57  $pK_a$  units. With cetirizine, the internal compensation of the cation by the carboxylate is so energy-favorable that the  $pK_a$  shift is up by 1.69 units (calculated again by  $\text{diff}(\log P^{N-1})$ ). Comparing the actual  $pK_{a \text{ oct}}$  of cetirizine to what it would have been without internal compensation gives a net change of 4.26  $pK_a$  units. This is equal to 5.8 kcal mol<sup>-1</sup> at 25 °C (from the Gibbs free energy equation). The free energy difference is undoubtedly reflected in its physicochemical properties. The cetirizine ion pair has a seven-membered cyclic form, but is likely predominantly in the open form in water. This drug has unusual properties, one being a very small volume of distribution.<sup>142</sup> Cetirizine is known as a non-sedating antihistamine, but its low brain level is not due to an inability to penetrate the blood–brain barrier.<sup>142</sup> On the contrary, experiments with labeled drug show that it enters the brain extremely rapidly, but exits the brain even faster. Active transport presumably, but then, that is an interesting property, too.

The classification of zwitterions by their aqueous and *n*-octanol  $pK_a$  exposes a previously unnoticed type of stabilization.<sup>25</sup> It occurs in zwitterions that lack the obvious neutralization of charges through a cyclic interaction. The compounds may appear to be too weakly acidic and basic to produce zwitterions in *n*-octanol, yet they have the lipophilicity profile of a type 4 zwitterion. The interaction is by what one might call a localized interaction of resonance forms. Marketed drugs in this category include piroxicam and azapropazone. They partition without counterions. Tetracycline appears to fall into this category.<sup>141</sup> The energy gain from internal neutralization in *n*-octanol is high enough that one can find members of this class with ring sizes not usually seen in chemistry, such as ten-member ring interactions found with tripeptides.<sup>25,143</sup>

In addition to the work of Plemper van Balen *et al.* about cetirizine,<sup>102</sup> a few studies in the literature report the lipophilic behavior of zwitterions in systems other than *n*-octanol/water.<sup>99,108,144,145</sup>

**Figure 8** The lipophilicity profiles of cetirizine and hydroxyzine in *n*-octanol/water. Hydroxyzine:  $pK_a$  7.52,  $pK_{a \text{ oct}}$  4.95; cetirizine:  $pK_a$  8.00,  $pK_{a \text{ oct}}$  9.69. In this instance, the net difference between an internally compensated zwitterion and a similar non-compensated ion pair is 4.26  $pK_a$  units, corresponding to a free-energy difference of about 5.8 kcal mol<sup>-1</sup> at 25 °C. ### 5.18.8.6 Getting the Most out of $\log D^{\text{pH}}$

$\log D$  has proven to be a useful physicochemical property for the analysis of ADMET-related activities. We see examples throughout this volume. When the use of  $\log D$  for QSAR was proposed in 1976,<sup>146</sup> it was to quantify the presence of the unionized species in the lipid phase at a particular pH. Partitioning of the ionized form was assumed to be insignificant. Today it is well accepted that the concentration of ionized species in the lipid phase can be significant and that  $\log D$  should account for all the forms of an agent in both phases. This is, of course, what is experimentally measured. Computations should only omit ionized species after deliberate consideration of their possible contribution and impact on the intended application (see Section 5.18.2).

This definition that the distribution coefficient,  $D$ , comprises neutral and ionic species presents a problem if the ionized and neutral species are not biologically equivalent for the activity or property being measured. One consequence is that regression analysis can find acids, bases, and neutral compounds falling into distinct groups, each correlating with  $\log D$ , and these groups still may contain mixtures of species. Binding of drugs to serum albumin is an example.<sup>147</sup> This suggests that, if one actually fractionated  $\log D$  into its neutral and ionized species before analysis, better results would be obtained. Two approaches have been proposed to improve on using  $\log D$ . One is to fractionate  $D$  into terms for its component species,  $D^{\text{N}}$  and  $D^{\text{I}}$ ,<sup>25</sup> illustrated in eqns [19]–[21].<sup>147</sup>  $D^{\text{N}}$  and  $D^{\text{I}}$  are called species-specific distribution coefficients. A disadvantage is that it requires knowing  $\log P^{\text{I}}$ ,  $\text{p}K_{\text{a oct}}$  or  $\text{p}K_{\text{a}}''$ .

The second approach, by Lombardo *et al.*,<sup>3,148</sup> uses the HT-determined  $E\log D_{7.4}$  and an additional term,  $f_{\text{i}}(7.4)$ , the fraction of ionized species in the aqueous phase. What is really needed is  $f_{\text{i oct}}$  instead. That way the exact representation of  $\log D$  could be obtained. The benefit of the practical approach of using the aqueous ionized fraction depends on the correlation between the fraction ionized in each phase. Regardless of theory, the Lombardo approach has led to the calculation of high-quality human volume of distribution values.<sup>3,148</sup>

As mentioned above, much more specific analysis of protein binding or biological activity is possible by incorporating physicochemical properties specific for cations, anions, and neutral species, namely,  $\log D^{\text{C}}$ ,  $\log D^{\text{A}}$ , and  $\log D^{\text{N}}$ , where C and A refer to cationic and anionic species. There are two requirements for this analysis: (1) access to good  $\log P^{\text{I}}$  values; (2) a proper data set. To distinguish between the activity of an ion pair and the neutral form,  $\text{diff}(\log P^{\text{N}-1})$  must vary within the series, otherwise, a correlation with  $\log P^{\text{N}}$  is equivalent to a correlation with  $\log P^{\text{I}}$ . In addition, the  $\text{p}K_{\text{a}}$  or  $\text{p}K_{\text{a oct}}$  of members of the series must cover a sufficient range, otherwise the percent ionized in equilibrium with the active site (the site which, when occupied, produces the benefit under study) will be a constant. A correlation with the neutral species will be equally valid for the ion pair. Small ‘proper’ data sets are difficult to find in the literature. Perhaps that is why  $\log D$  has been useful without (much) controversy, even as a mixture term. (One successful analysis is for uncoupling oxidative phosphorylation by phenols, which is highly correlated with  $\log D^{\text{I}}$  and not  $\log D$  or  $\log D^{\text{N}}$ .<sup>25</sup>)

On the other hand, the large series of diverse compounds used in ADMET studies are perfect for sorting out the role of ionized and neutral species. All that is needed are good  $\log P^{\text{I}}$  values from which to calculate  $\log D^{\text{I}}$ . Unfortunately, that is where the bottleneck to rapid advances regarding ion pair lipophilicity lies – the scarcity of physicochemical data. Hopefully, titrations in KCl/water-saturated octanol will be adopted by others able to meet this need. Each of the areas represented in ADMET, and covered in detail in other chapters in this volume, brings questions about the significance of ionized species. The use of species-specific  $\log D$  terms, as calculated below, may help provide some answers.

The distribution coefficient of a compound is the sum of the distribution coefficients of each of various charge-related forms it is capable of assuming (eqn [19]). This is merely rewriting eqn [1]. The individual terms are pH-dependent distribution coefficients for each ionic species in which the  $D^{\text{I}}$  terms represent the  $n$  ionizable groups.

$$D = D^{\text{N}} + D^{\text{I}(n)} + D^{\text{I}(n-1)} + \dots \quad [19]$$

Formulas for calculating the individual terms can be derived from eqn [7] (by fractionating and converting to pH and  $\text{p}K_{\text{a}}$  terms) and are illustrated below for  $D^{\text{N}}$  and only one of the  $D^{\text{I}}$  terms with its individual  $\text{p}K_{\text{a}}$  in the case of acids.

$$D^{\text{N}} = P^{\text{N}} / (1 + 10^{(\text{pH} - \text{p}K_{\text{a}})}) \quad [20]$$

and

$$D^{\text{I}} = P^{\text{I}} \times 10^{(\text{pH} - \text{p}K_{\text{a}})} / (1 + 10^{(\text{pH} - \text{p}K_{\text{a}})}) \quad [21]$$

### 5.18.9 Conclusion: Lipophilicity in Absorption, Distribution, Metabolism, Excretion, and Toxicity Studies

The concepts and applications of lipophilicity have evolved enormously since the first edition of *Comprehensive Medicinal Chemistry*. Today there is a huge amount of information contained in lipophilicity data, but what part, applied to any given series of potential drug candidates, will give the most useful results: a single-column table? a multi-column table? a collection of plots and graphs? It is evident that the more data available, the more time will be required to evaluate it, but also the more information that can be obtained. Just what information is truly useful for ADMET studies? We think it is difficult to make generalizations, but throughout this chapter we demonstrate that in the presence of one or more ionizable centers, lipophilicity studies become more complicated. At the same time the significance of  $\log P/\log D$  data goes beyond their numerical values.

Recently, Thomae and co-workers demonstrated that, in contrast to the expectations of the pH partition hypothesis, lipid bilayer permeation of an acidic compound can be completely controlled by the anion at physiological pH<sup>149</sup> (in the cited paper, liposomes have been used to describe not only membrane affinity but also membrane permeation kinetics). According to this and other papers we are led to believe that major progress in understanding and applying lipophilicity in ADMET areas will involve taking ionization into full account.

This area has long been held back by a lack of good physicochemical property values. To some extent, development has been slowed by the neglect of a fundamental physical property of all ionized compounds: their medium-associated  $pK_a$ .  $pK_a$  represents the quantifiable, analyzable free energy of ionization and allows a link to the free energy of partitioning. A number of advances in understanding and applying lipophilic properties have come from such a linking.

Up to now, in the absence of measured data on ionized species, one has been forced to use a crude estimate of properties, or to ignore the species. It should be a priority to accumulate more accurate and useable data. The shortcomings of commercial programs for calculating  $\log D$  are discussed in a recent paper by Tetko and Poda<sup>150</sup> and in 5.27 Rule-Based Systems to Predict Lipophilicity.

It is easy to believe that advances will come from being able to fractionate  $\log D$  into its component parts. Studies will be specifically designed to differentiate the biological activity of ionized and neutral species. In another area, it seems reasonable that the dramatic free-energy changes associated with the formation of internally compensated ampholytes will have an analogy in receptor pockets when a group on a drug finds an oppositely charged group on the receptor wall.

Given the theoretical complexity of these biological topics, a second big advance in understanding and applying lipophilicity in ADMET requires the combination of experimental data with ad hoc molecular modeling tools (not just software able to predict  $\log P$  data!).

Ionized species play important roles in nature – in protein folding, in binding, in signal transduction, in metabolism to highly ionized species, in enzyme and receptor site specificity, and in the evolution of low-energy, lipid-soluble forms of ion pairs. Researchers in this area are in a position to advance science beyond the confines of ADMET.

## Biographies

**Giulia Caron** studied at the University of Torino (Italy) where she received a BSc in Pharmaceutical Chemistry and Technology in 1992, and a BSc in Pharmacy in 1994. She then moved to the University of Lausanne for doctoral studies, and was awarded a PhD in Pharmaceutical Sciences in 1997. Since 1999, she is assistant professor at the Faculty of Pharmacy of the University of Torino where she also teaches pharmaceutical analysis. Her primary interests were experimental and computational lipophilicity, recently moved to the in silico prediction of ADMET properties.

**Giuseppe Ermondi** graduated as a chemist and obtained a PhD from the University of Torino (Italy) under the supervision of Prof Silvio Aime. He was a postdoc at the University of Lausanne, then became assistant professor at the University of Piemonte Orientale and now he is associate professor at the University of Torino, where he teaches pharmaceutical analysis. Following early work in NMR of paramagnetic ions, he rapidly became interested in computational chemistry and physical chemistry with applications in molecular modeling techniques and physicochemical properties as applied to drug design and ADMET prediction.

**Robert A Scherrer** received a BS in chemistry at the University of California, Berkeley, in 1954, and a PhD in organic chemistry under E J Corey at the University of Illinois, Urbana, in 1958. He then began a 44-year laboratory career in medicinal chemistry; at Parke-Davis for 9 years, followed by 35 years with 3M Pharmaceuticals in St Paul. Over this time he was an inventor or coinventor on 78 patents, coedited a two-volume work on antiinflammatory agents, was a Senior Editor of the *J. Med. Chem.* for 2 years, an author of 9 book chapters, 9 journal articles, and 24 national or international presentations. Two marketed drugs, mefenamic and meclofenamic acids, have come from his patents. Other areas include antibacterials, antiasthmatics, antioxidants, viscoelastic collagen, transmucosal patches, and hydrophobic ion pairs. A keen interest in QSAR, and the lack of partition coefficients for ion pairs, led to the first single-phase titrations in octanol in 1977. Promising results, and later collaboration with Frank Clarke (ChemClarke) on two-phase titrations, spurred a 25-year '15%-time' project on the lipophilicity of ion pairs. Today, through BIOpK, he continues promoting the benefits of thinking about biolipid  $pK_a$  and its applications to QSAR and drug design.

### 5.19.1 Permeability: An Intersection of Biology and Physicochemistry

Since the 1990s the paradigm of drug discovery has shifted from pharmacology-focused drug discovery to multidimensional drug discovery. In the multidimensional drug discovery paradigm, ADME, toxicology, and formulation suitability are simultaneously taken into account as well as pharmacological activity. Under this paradigm shift, the reductionism approach has been employed in ADME studies because it enables high-throughput screening and distinct structure–activity/property relationship studies.<sup>1–4</sup> In drug discovery today, many in vitro ADME assays are replacing in vivo assays. Cell-based assays (e.g., Caco-2 and MDCK cells) are widely used in drug discovery. However, cell-based assays still contain multiple mechanisms, so that they can be further reduced to individual enzyme level assays. Driven by advances in biotechnology, high-throughput enzyme level assays for each ADME process are becoming available for drug discovery.<sup>5</sup> Simultaneously, high-throughput assays for passive permeation across lipid bilayers have been required for drug discovery.

On the other hand, the relationship between the physicochemical properties of drugs and the ADME process has been extensively studied for more than 100 years.<sup>6</sup> The physicochemical properties of drugs affect the passive transfer and permeation processes in ADME. For example, intestinal brush border membrane (BBM) permeation, blood–brain barrier (BBB) permeation, the volume of distribution, uriniferous tubular reabsorption, and transdermal permeation are known to depend on the physicochemical properties of a chemical substance.<sup>7</sup> To evaluate the physicochemical properties required for passive ADME processes, isotropic solvent/water partition systems, such as octanol/water, have long been used in drug discovery. However, the in vivo predictability of isotropic solvent/water partition systems alone are insufficient for drug discovery, owing to the dissimilarity between the isotropic solvent and the biological membrane. Therefore, the construction of biomimetic physicochemical tools has been investigated.

The artificial membrane technologies can be mapped at the intersection of the biological reductionistic strategy and the physicochemical approach. In this article, artificial membrane technologies for transfer and permeation assessment in drug discovery are reviewed. The features of biological membranes will first be explained in detail, down to the molecular constituent level. Theories of passive permeation will then be briefly described. Finally, artificial membrane technologies for drug discovery will be reviewed in detail, mainly from the viewpoint of drug discovery utility and relevance to in vivo membrane permeation.

## 5.19.2 Biological Membranes: Constituents, Morphology, and Physicochemistry

There is marked variation between the biological membranes of the various organs. In this section, features of biological membranes will be reviewed from the chemical, morphological, and physical points of view. Active transporters and metabolisms are outside the scope of this article, and are reviewed elsewhere (*see* 5.04 The Biology and Function of Transporters; 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption).

### 5.19.2.1 Chemical Components

Typical lipid components of biological membranes are shown in [Figure 1](#). Phosphatidylcholine (PC) and phosphatidylethanolamine (PE) are zwitter ionic phospholipids with zero net charge at neutral pH. The difference in chemical structure between these two phospholipids is only at the amine moiety (amine and trimethylammonium); however, they show different phase structures in water.<sup>8</sup> In addition, although PE is a zwitter ionic phospholipid, the

**Figure 1** Chemical structures of phospholipids and cholesterol. R<sub>1</sub> and R<sub>2</sub> are fatty acid chains.

**Figure 2** Chemical structures of human SC CERs. E, ester-linked fatty acids; O, -OH fatty acids; S, sphingosine; N, non-OH fatty acids; P, phytosphingosine; A, -OH fatty acids. (Reprinted from, De Jager, M. W.; Gooris, G. S.; Dolbnya, I. P.; Ponc, M.; Bouwstra, J. A. *Biochim. Biophys. Acta* **2004**, 1664, 132–140, copyright (2004), with permission from Elsevier.)

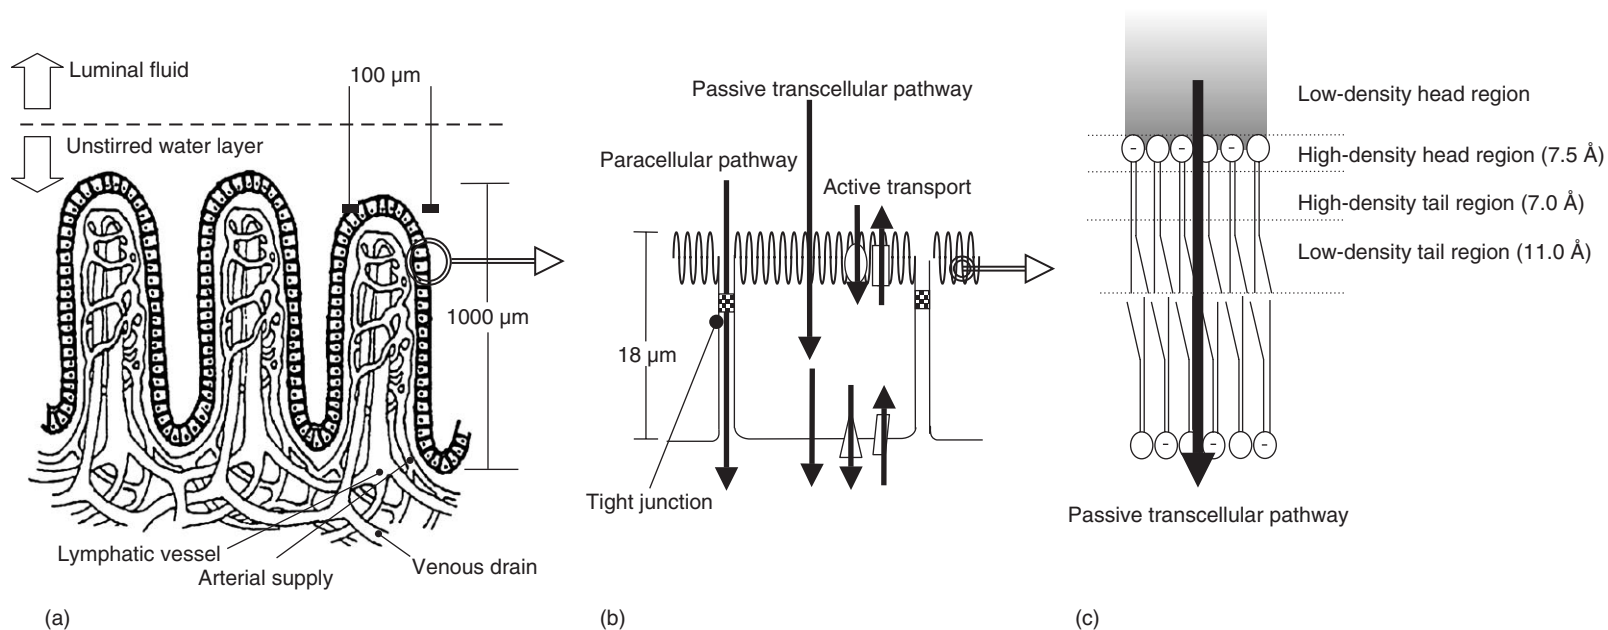

incorporation of PE into PC vesicles has been found to slightly enhance the negative charge of the phosphate group.<sup>9</sup> Phosphatidylserine (PS) has two negatively charged moieties ( $pK_a$  on the membrane, carboxylate ( $pK_a = 5.5$ ) and phosphate ( $pK_a < 1$ )) and one positively charged moiety (amine ( $pK_a = 11.3$ )), total  $-1$  net charge.<sup>10</sup> Phosphatidylinositol (PI) and phosphatidylglycerol (PG) have one negatively charged moiety (phosphate ( $pK_a = 2.7$  (PI),  $2.9$  (PG))).

Ceramides (CERs) are important components of the skin permeation barrier, the stratum corneum (SC) (Figure 2).<sup>11</sup> The CER head group can form lateral hydrogen bonds with adjacent CER molecule. CERs are categorized into several subgroups; CER1, CER4, and CER9 have exceptionally long acyl chains that affect the interlamellar distance (see Section 5.19.2.5).

### 5.19.2.2 Physicochemical Properties of Lipid Bilayers

Lipid bilayers mainly composed of phospholipids are a heterogeneous system which can be roughly divided into four regions (see Figure 3c)<sup>12,13</sup>; the boundary of each region is not explicit:

- *Low-density head group region.* This region ranges from the point where the presence of the membrane begins to perturbate the bulk water structure to the point where the water density and head group density are comparable. This region can be large because the perturbation of water molecules can extend over a long range.
- *High-density head group region.* This region is  $\sim 7.5 \text{ \AA}$  wide. In this region, bulk-like water no longer exists. It has a high dielectric constant ( $\epsilon = \sim 30$ )<sup>14</sup> and high viscosity, and is abundant in hydrogen bond acceptors.
- *High-density tail region.* This region is  $\sim 7 \text{ \AA}$  wide. It has a low dielectric constant and high viscosity. The hydrocarbon tail has a high density and is highly ordered. The region is suggested to resemble a soft polymer.<sup>15</sup>
- *Low-density tail region.* This region is  $\sim 11 \text{ \AA}$  wide (both halves of the bilayer). It has a low dielectric constant ( $\epsilon = \sim 2$ ) and low viscosity. The region is suggested to resemble a low-density alkane fluid, such as dodecane or hexadecane.

**Figure 3** Intestinal membrane structure. The bold arrows in the figure illustrate the permeation pathways of compounds. (a) Villous structure of intestine. Unstirred water layer is on the top of villi. (Adapted from Avdeef, A. *Curr. Top. Med. Chem.* **2001**, 1, 277–351, with permission from Bentham Science Publishers.) (b) Permeation pathways of compounds across the intestinal epithelial membrane. (c) Lipid bilayer. Four regions of the lipid bilayer are indicated: (1) low-density head group region (gray gradient); (2) high-density head group region; (3) high-density tail region; (4) low-density tail region.

### 5.19.2.3 Intestinal Membrane: Morphology, Physicochemistry, and Lipid Composition

#### 5.19.2.3.1 Morphology

The human small intestine is about 6–7 m in length, and loosely divided into three sections, the duodenum, jejunum, and ileum.<sup>16</sup> The human small intestine membrane has a fractal-like structure, i.e., the ridges (oriented circumferentially around the lumen), villi, and microvilli (Figures 3a and 3b).<sup>14</sup> The membrane surface is expanded approximately up to 600-fold by the villi and microvilli. Due to this large surface area, the small intestine is the main region of absorption for drugs.<sup>16</sup> The intestinal membrane has the mucus layer on the villi. This mucus layer is thought to maintain the unstirred water layer (UWL), about 30–100  $\mu\text{m}$  in thickness, where agitation from intestinal movement does not reach.<sup>17</sup> The villous structure can cause a concentration gradient along with the trough, and affects the effective surface area and effective permeability (see Section 5.19.3.3).<sup>18</sup>

The permeation pathways of compounds across the intestinal epithelial membrane can be categorized into three groups: the passive transcellular pathway, the paracellular pathway, and active transport. The passive transcellular pathway is the permeation across the lipid bilayer of the intestinal epithelial cells. Intestinal epithelial cells tightly adhere to each other by intercellular adhesion molecules, and construct a tight junction.<sup>19</sup> However, small hydrophilic compounds can permeate through this junction. This permeation route is called the paracellular pathway. Permeability through the paracellular pathway differs in each part of the intestine. In the jejunum, the pore radius is about 7–9 Å, and in the ileum the pore radius is about 3–4 Å.<sup>20</sup> In addition, the paracellular pathway differs among animal species: dogs have a much larger pore size than humans and rats<sup>21</sup>; and Caco-2 cells have a tighter paracellular pathway than the in vivo human intestine.<sup>22</sup>

#### 5.19.2.3.2 pH and transit time at each gastrointestinal site

The microclimate pH near the membrane surface is maintained at about pH 6.0–7.0, lower than that of the intestinal luminal fluid (Table 1).<sup>23–25</sup> The microclimate pH increases as the intestinal tract descends.<sup>23</sup> The transit time through each part of the intestine is an important factor that determines the fraction of a dose absorbed from each region. An administered drug passes through the stomach within about 0.5–1.5 h, through the small intestine in about 3–4 h, and through the large intestine in about 7–20 h.<sup>26</sup>

#### 5.19.2.3.3 Lipid composition

The brush border (apical) membrane of the intestinal epithelial cell is mainly composed of PC, PE, PS, PI, cholesterol, and sphingomyelin (Table 2).<sup>27</sup> In contrast to red blood cells, negatively charged lipids distribute to both the inner and outer leaflets of the bilayer (Table 3).<sup>28,29</sup>

#### 5.19.2.3.4 Other properties

Biles on the apical side of the membrane and plasma proteins on the basolateral side play an important role in the in vivo situation. Bile micelles can bind compounds and reduce the free concentration, resulting in a decreased flux.<sup>34</sup> On the other hand, biles increase the dissolution/solubility of a drug.<sup>35</sup> Plasma proteins may wash away the permeant from the basolateral side of the intestinal membrane, retaining a sink condition on the basolateral side.<sup>34,36</sup>

### 5.19.2.4 The Blood–Brain Barrier: Morphology

The structure of the BBB is shown in Figure 4.<sup>37</sup> In contrast to the intestinal membrane, the BBB has neither the mucus layer nor the UWL. The paracellular pathway is negligible for most compounds under physiological conditions.<sup>32</sup> The BBB has an estimated surface area of 12 m<sup>2</sup>.<sup>32</sup>

**Table 1** Variation of surface area, segment length, and pH in the gastrointestinal (GI) tract<sup>16,22–26</sup>

| Position in the GI tract | Surface area (m <sup>2</sup> ) <sup>a</sup> | Segment length (cm) | Luminal pH | Microclimate pH |
|--------------------------|---|---------------------|------------|-----------------|
| Stomach                  | 3.5   | 0.25                | 1.0–2.0    | 8               |
| Duodenum                 | 1.9   | 35                  | 4.0–5.5    | 6.3–6.4         |
| Jejunum                  | 184   | 280                 | 5.5–7.0    | 6.0–6.4         |
| Ileum                    | 276   | 420                 | 7.0–7.5    | 6.6–6.9         |
| Colon                    | 1.3   | 150                 | 7.0–7.5    | 6.9             |

<sup>a</sup>Expansion by the fold, villous, and microvillous structure was included in the calculation.

#### 5.19.2.5 The Skin Permeation Barrier (Stratum Corneum): Morphology and Lipid Composition

The transdermal permeation rate of most drugs is limited by the SC.<sup>38,39</sup> The thickness of the SC is different in each body part, about 15  $\mu\text{m}$  in the abdominal skin and 10  $\mu\text{m}$  in the dorsal skin. The pH near the surface of the skin is about 5. The structure of the SC is represented by the brick and mortar model, in which keratin-filled cells (corneocytes) (brick) are embedded within intercellular lipids (mortar) (**Figure 5**). The intercellular lipids form a lammellar structure, which orients parallel to the corneocyte surface. The primary transport pathway for most drugs traversing the SC is the intercellular lammellar lipid region. The path length relative to the thickness of the SC is about 13 due to the tortuous pathway.<sup>40</sup>

**Figure 4** The brain capillary endothelium (i.e., the BBB), showing the cell types forming the blood–brain interface of a capillary in mammalian brain parenchyma: E, endothelium; BM, basement membrane; P, pericyte; A, astrocytic process. Arrowheads indicate the interendothelial clefts closed by tight junctions (TJs). (Reprinted from Abbott, N. J. *Drug Disc. Today* **2004**, 1, 407–416, copyright (2004), with permission from Elsevier.)

**Figure 5** The SC. (a) The brick and mortar model. The arrow in the figure illustrate the primary permeation pathway for most drugs. (b, c) Lamellar structure of SC lipids. The interval of the lamellar structure is about 13 nm; CHO, cholesterol. A crystalline part is predominantly present, while most probably a subpopulation of lipids from a more fluidic part. (b, c: Reprinted from Bouwstra, J. A.; Honeywell-Nguyen, P. L.; Gooris, G. S.; Ponc, M. *Prog. Lipid Res.* **2003**, 42, 1–36, copyright (2003), with permission from Elsevier.)

The intercellular lipids are mainly composed of free fatty acids (FFAs, 10–15%), cholesterol (25%), sterol esters (5%), and CERs (50%). The phase behavior of the lamellar lipid is different from that of the lipid bilayer mainly composed of phospholipids. In the SC, a crystalline part is predominantly present, while, most probably, a subpopulation of lipids form a more fluidic region (Figure 5).<sup>38</sup>

### 5.19.3 Permeation Theory and In Vivo Extrapolation

#### 5.19.3.1 Transmembrane Permeation

##### 5.19.3.1.1 The solubility–diffusion model for a homogeneous membrane

First approximation of a biological lipid membrane is a homogeneous organic solvent membrane (Figure 6).<sup>41</sup> Fick's first law can be applied to the homogeneous membrane permeation. The passive permeation across a membrane is a diffusion process, the driving force of which is the concentration gradient across the membrane (i.e., Fick's first law). If the interfacial resistance at the lipid–water interface is assumed to be negligible, flux ( $J$ ,  $\text{mol cm}^{-2} \text{s}^{-1}$ ) can be

**Figure 6** The solubility–diffusion model. The vertical axis and the blue gradient indicate the concentration.  $C_{m0}/C_D$  is the partition coefficient ( $P$ ).

expressed as

$$J = \frac{D_m dC_m}{dx} = \frac{D_m(C_{m0} - C_{mh})}{h} \quad [1]$$

where  $D_m$  is the diffusion coefficient in the membrane ( $\text{cm}^2 \text{s}^{-1}$ ),  $x$  is the position in the membrane,  $C_{m0}$  and  $C_{mh}$  are the concentrations at positions 0 and  $h$  in the membrane, respectively, and  $h$  is the thickness of the membrane (cm).  $C_{m0}$  and  $C_{mh}$  can be expressed by a partition coefficient of the organic solvent ( $P$ ) and the concentration in the water phases of the donor and acceptor sides ( $C_D$  and  $C_A$ , respectively). Considering the sink condition,  $C_A$  is approximated by zero.

$$J = \frac{D_m P(C_D - C_A)}{h} \approx \frac{D_m P C_D}{h} = P_m C_D \quad [2]$$

$$P_m = \frac{D_m P}{h} \quad [3]$$

where  $P_m$  is membrane permeability ( $\text{cm s}^{-1}$ ). Equation [3] indicates that the permeability is determined by the partition coefficient (a static parameter) and the diffusion coefficient (a kinetic parameter), and the thickness of the membrane.

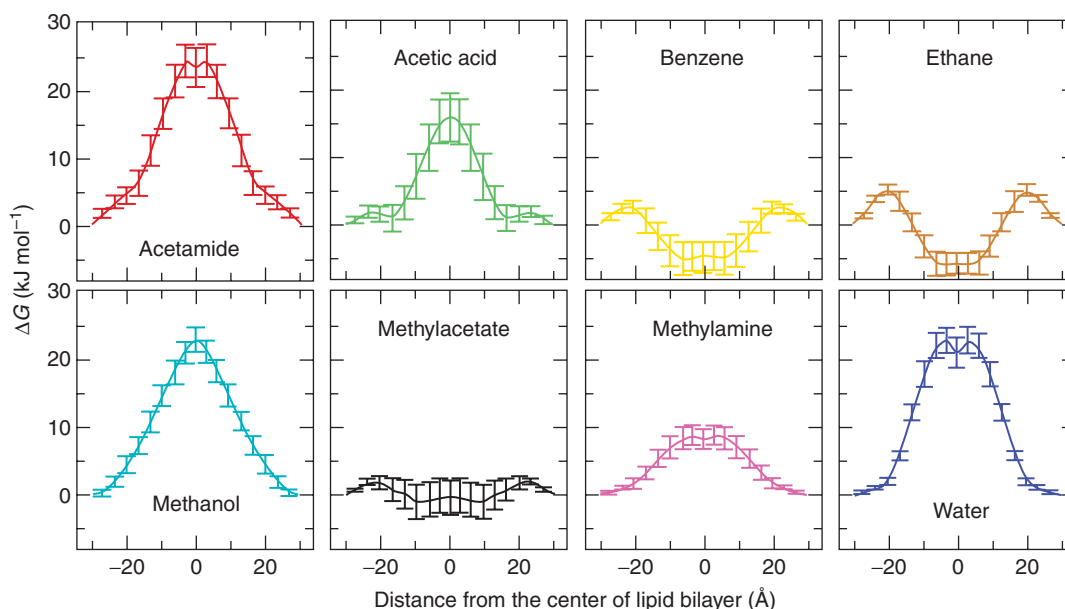

#### 5.19.3.1.2 The solubility–diffusion model for an inhomogeneous membrane

As shown in Figure 3c, the lipid bilayer is an inhomogeneous membrane. The solubility–diffusion model can be extrapolated to an inhomogeneous membrane. The permeability coefficient is the reciprocal of the permeation resistance, and the total permeation resistance connected in series is the sum of each resistance, similar to Ohm's law.

$$\frac{1}{P_m} = \int_0^h \frac{1}{P(x)} dx = \int_0^h \frac{1}{D(x)K(x)} dx \quad [4]$$

where  $P(x)$  is the local membrane permeability coefficient at position  $x$ ,  $D(x)$  is the local diffusion coefficient at position  $x$ , and  $K(x)$  is the local partition coefficient between water and position  $x$ .

The barrier domain solubility–diffusion model was introduced by Anderson and co-workers.<sup>42,43</sup> According to eqn [4], the lowest-permeability region (barrier domain) limits the total permeability. Therefore, eqn [4] can be

**Figure 7** Free energy profiles of small molecules in a phospholipid bilayer estimated by a molecular dynamic simulation. Error bars are standard errors calculated from the difference in the force of the five individual simulations from their average. (Reprinted from Bemporad, D.; Essex, J. W.; Luttmann, C. J. *Phys. Chem.* **2004**, *108*, 4875–4884. Copyright (2004) American Chemical Society.)

simplified to

$$P_m \approx \frac{D_{\text{barrier}} K_{\text{barrier/water}}}{h_{\text{barrier}}} \quad [5]$$

where  $h_{\text{barrier}}$  is the thickness of the barrier domain,  $D_{\text{barrier}}$  is the diffusion coefficient in the barrier domain, and  $K_{\text{barrier/water}}$  is the partition coefficient of a solute from water (not from the polar head group interface) to the barrier domain.

$K(x)$  can be expressed in terms of free energy as

$$K(x) = \exp\left(-\frac{\Delta G(x)}{RT}\right) \quad [6]$$

where  $R$  is the gas constant and  $T$  is the absolute temperature.  $\Delta G(x)$  is free energy difference between the water phase and position  $x$  in the membrane. Therefore, permeability can be expressed as

$$\frac{1}{P_m} = \int_0^h \frac{1}{D(x) \exp[-\beta \Delta G(x)]} dx \quad [7]$$

where  $\beta$  is  $1/RT$ . The diffusion coefficient in the membrane is suggested to be lower than that in a nonpolar solvent such as hexadecane.<sup>44</sup> The ordered region of the hydrophobic core (high-density tail region in [Figure 3a](#)) is suggested to behave as a soft polymer, leading to a reduction of the diffusion coefficient in this region.

Owing to recent increases in computation speed, massive molecular dynamics simulations of lipid bilayers have become available.<sup>45,46</sup> In the case of hydrophilic compounds, the main permeation barrier was suggested to be the high tail density region of the membrane. In the case of hydrophobic compounds, the main barrier to permeation was suggested to be the head group region (*see* [Section 5.19.2.2](#)). [Figure 7](#) shows the change in free energy for eight neutral small molecules calculated by a molecular dynamic simulation.

#### 5.19.3.1.3 The two-step model (flip-flop model)

The two-step model (or the flip-flop model) has been proposed to describe the transmembrane movement of a substrate, especially that of large amphiphilic molecules or peptide mimetic molecules (e.g., doxorubicin) ([Figure 8](#)).<sup>47–50</sup> The transmembrane movement can be described as (1) incorporation of a compound into one membrane leaflet, and (2) transfer (flip-flop) across the lipid core. In the case of fatty acids, the first step is much faster than the second flip-flop step, and the flip-flop rate decreases as the chain length increases.<sup>50,51</sup>

**Figure 8** The two-step model, and categories of physicochemical tools. (Adapted from Sugano, K. *PharmStage* **2002**, 2, 72–78.)

#### 5.19.3.1.4 The relationship between permeation and physicochemical properties of a drug

##### 5.19.3.1.4.1 The solubility–diffusion model

According to the solubility–diffusion model, the membrane permeability coefficient can be related to the partition coefficient between water and the highest  $\Delta G$  region, which is the rate-limiting barrier. If a suitable organic solvent that resembles the rate-limiting barrier were chosen, the membrane permeability coefficient would be calculated from the partition coefficient between water and the organic solvent, the diffusion coefficient, and the thickness of the barrier (eqn [5]).

In the case of a lipid bilayer mainly composed of phospholipids, simple alkanes<sup>44,52</sup> or alkenes<sup>53,54</sup> were suggested to reflect the rate-limiting permeation barrier. Octanol was suggested to be less suitable.<sup>53</sup> The solubility–diffusion model suggests that the membrane partition measurement cannot directly represent the transmembrane permeation,<sup>41,55</sup> because the region of maximum partition in the membrane is the lowest  $\Delta G$  region.

In the case of skin permeation, the permeability coefficient can be described by the solubility–diffusion model, so that by partition and diffusion coefficients of a drug in the permeation barrier.<sup>56</sup> Drugs permeate through the intercellular part of the SC mainly composed of CER, cholesterol, and FFAs, which organize a lamellar structure (see Section 5.19.2.5, the brick and mortar model). The octanol/water partition coefficient ( $K_{\text{oct}}$ ) is most often used as a surrogate for the partition coefficient into the SC ( $K_{\text{sc}}$ ).<sup>56,57</sup>  $K_{\text{sc}}$  was calculated as

$$\log K_{\text{SC}} = -0.024 + 0.59 \log K_{\text{oct}}$$

[8]

( $n = 45$ ,  $r^2 = 0.84$ , standard deviation = 0.32). The regression coefficient of  $\log K_{\text{oct}}$  was 0.59, indicating that the skin membrane permeation barrier is more polar than octanol,<sup>56</sup> or a partial desolvation of the solute caused by the water associated with CER polar head group.<sup>57</sup> The diffusion coefficient was found to decrease as not only the molecular weight but also the hydrogen bond acidity/basicity increase.<sup>57,58</sup> This finding is consistent with diffusion along a nonpolar pathway hindered by interaction with the immobilized polar head group of SC lipids.<sup>58</sup>

#### 5.19.3.1.4.2 The two-step model of lipid bilayer permeation

According to the two-step model of lipid bilayer permeation, in the first step, lipophilicity is the major driving force.<sup>59</sup> In the second step, interactions between the bilayer head group region and the polar part of the substrate are more important than lipophilicity.<sup>60</sup> In contradiction to the suggestion from the solubility–diffusion model, several reports show that the membrane partition measurement can predict the transmembrane permeation for a wide range of chemically diverse compounds (see Section 5.19.6 and see 5.18 Lipophilicity, Polarity, and Hydrophobicity). The membrane partition may represent the first step of the two-step model. The second step (flip-flop) is suggested to be more hydrogen bond-dependent, and related to  $\Delta \log P$ ,<sup>48</sup> the heptane/ethylene glycol partition coefficient,<sup>60</sup> and the polar surface area.<sup>61</sup>

### 5.19.3.2 The Paracellular Pathway and the Unstirred Water Layer

In the case of the intestinal membrane, the paracellular pathway and the UWL are important factors that affect the total passive membrane permeability (see Section 5.19.2.3.1).

#### 5.19.3.2.1 The paracellular pathway

The paracellular pathway permeability ( $P_{\text{para}}$ ) can be mathematically described as a size-restricted diffusion within a negative electrostatic force field (eqn [9]).<sup>62,63</sup> Renkin's function ( $F(r/r_{\text{para}})$ , eqn [10]) was employed as the molecular size restrictor.

$$P_{\text{para}} = A \frac{1}{r} F\left(\frac{r}{r_{\text{para}}}\right) \left( f_0 + \sum_{z(z \neq 0)} f_z E(z) \right) \quad [9]$$

$$F\left(\frac{r}{r_{\text{para}}}\right) = \left(1 - \frac{r}{r_{\text{para}}}\right)^2 \left[ 1 - 2.104 \frac{r}{r_{\text{para}}} + 2.09 \left(\frac{r}{r_{\text{para}}}\right)^3 - 0.95 \left(\frac{r}{r_{\text{para}}}\right)^5 \right] \quad [10]$$

$$E(z) = \frac{Cz}{1 - \exp(-Cz)} \quad [11]$$

where  $f_z$  is the fraction of each charged species ( $z$  is the charge number) calculated from  $\text{p}K_{\text{a}}$ ,  $r_{\text{para}}$  is the apparent pore radius of the paracellular pathway,  $r$  is the molecular radius of a permeant, and  $A$  is a fitting coefficient.  $C$  is in relation to the apparent electric potential of the paracellular pathway (for the intestine, 18–80 mV).<sup>62,64</sup>  $F(r/r_{\text{para}})$  decreases as the molecular radius of a permeant increase. This paracellular pathway model equation is a first approximation. The paracellular pathway permeability was suggested to be affected by the lipophilicity of the substrate, which is not incorporated in this model.<sup>65,66</sup>

The contribution of the paracellular pathway to the total permeability depends on the physicochemical characteristics of a substrate. Small (molecular weight <200–300) hydrophilic cationic compounds can permeate via the paracellular pathway more readily than large, neutral, or anionic compounds. Cimetidine<sup>67</sup> and atenolol<sup>63</sup> are typical compounds for which the paracellular pathway permeation contributes significantly.

#### 5.19.3.2.2 Unstirred water layer permeability

UWL permeability ( $P_{\text{UWL}}$ ) can be mathematically modeled as a simple diffusion process in a water layer, according to the Einstein–Stokes equation,

$$P_{\text{UWL}} = A' \frac{1}{\text{MW}^{1/3}} \quad [12]$$

where  $A'$  is a fitting coefficient and MW is the molecular weight. This UWL model equation is a first approximation. In the case of the intestinal membrane, the UWL is superimposed on the mucus layer, and the UWL permeability was suggested to be affected by the lipophilicity of a substrate, probably due to the interaction between the mucus and a substrate.<sup>68</sup>

### 5.19.3.3 The Effective Intestinal Membrane Permeability

The effective intestinal membrane permeability coefficient ( $P_{\text{eff}}$ ) is an *in vivo* or *in situ* intestinal membrane permeability.  $P_{\text{eff}}$  in humans is measured using a technique based on the single-pass perfusion of the human jejunum segment between two inflated balloons.<sup>17</sup> The villous structure of the intestinal membrane is not considered in the  $P_{\text{eff}}$  calculation. As an approximation,  $P_{\text{eff}}$  can be expressed as

$$\frac{1}{P_{\text{eff}}} = \frac{1}{aP_{\text{m}}} + \frac{1}{bP_{\text{para}}} + \frac{1}{cP_{\text{UWL}}} \quad [13]$$

The coefficients  $a$ ,  $b$ , and  $c$  are fitting coefficients, which include the ratio of the available surface area. However, this equation assumes that the intestinal membrane is a flat. As noted in Section 5.19.2.3.1, the intestinal membrane has a fractal-like structure. This fractal structure should be taken into account for a quantitative *in vitro/in vivo* correlation (IVIVC) in a wide permeability range, since this fractal-like structure causes a concentration gradient down the villous structure. The magnitude of the concentration gradient depends on the membrane permeability. The concentration gradient changes the available surface area. It is suggested that a high-permeability compound is absorbed mainly from the top of the villi, while a low-permeability compound is absorbed from the whole villous surface.<sup>18</sup> A mathematical model to treat the villous structure was reported by Winne *et al.*<sup>18</sup>

### 5.19.3.4 The Link to the Fraction of a Dose Absorbed (A%)

The effective permeability and A% can be related by the parallel tube model, and the relationship is a hyperbolic curve.<sup>69</sup>

$$A\% = (1 - \exp(-GP_{\text{eff}})) \times 100 \quad [14]$$

where  $G$  is the lump constant of the available intestinal surface area, the transit time through the absorption site of the gastrointestinal tract, and a fitting coefficient. The available intestinal surface area is estimated to be 800 cm<sup>2</sup> on  $P_{\text{eff}}$  bases.<sup>70</sup> To take into account the difference in permeability for each intestinal region, the compartment absorption transit (CAT) model has been proposed (*see* 5.38 Mechanism-Based Pharmacokinetic–Pharmacodynamic Modeling for the Prediction of *In Vivo* Drug Concentration–Effect Relationships – Application in Drug Candidate Selection and Lead Optimization).<sup>71</sup> The CAT model can be further connected to the physiologically based pharmacokinetic (PBPK) model.<sup>72–74</sup>

### 5.19.3.5 The pH–Partition Hypothesis and pH–Permeability Curves

A theoretical pH–permeability curve can be derived from the pH–partition hypothesis, allowing for the effect of the UWL in the calculation. According to the pH–partition hypothesis,<sup>75</sup> a molecule needs to be in its uncharged form to partition into (or flip-flop across) the lipophilic permeation barrier. The permeation of charged species is negligible. In addition, the UWL is adjacent to the membrane. Therefore, the apparent membrane permeability coefficient ( $P_{\text{m, app}}$ ) of a monoprotic acid and base can be expressed as

$$\frac{1}{P_{\text{m, app}}} = \frac{1}{P_0 f_{\text{u}}} + \frac{1}{P_{\text{UWL}}} = \frac{1 + 10^{-\text{p}K_{\text{a}} + \text{pH}}}{P_0} + \frac{1}{P_{\text{UWL}}} \quad (\text{monoprotic acid}) \quad [15]$$

$$\frac{1}{P_{\text{m, app}}} = \frac{1}{P_0 f_{\text{u}}} + \frac{1}{P_{\text{UWL}}} = \frac{1 + 10^{\text{p}K_{\text{a}} - \text{pH}}}{P_0} + \frac{1}{P_{\text{UWL}}} \quad (\text{monoprotic base}) \quad [16]$$

where  $f_{\text{u}}$  is the fraction of uncharged species and  $P_0$  is the intrinsic permeability coefficient of uncharged species. The fraction of uncharged species can be calculated from  $\text{p}K_{\text{a}}$  by the Henderson–Hasselbalch equation (*see* 5.16 Ionization Constants and Ionization Profiles) for a monoprotic acid and base.

A theoretical pH–permeability curve based on eqn [15] is shown in Figure 9. The slope of the logarithmic plot is 1. In this slope region, the fraction of uncharged species changes as the pH of the buffer varies. One unit difference of pH or  $\text{p}K_{\text{a}}$  (a logarithmic scale) corresponds to a 10-fold change in permeability on a normal scale. Therefore, pH and  $\text{p}K_{\text{a}}$  are important determinants when *in vitro* and *in silico* systems are constructed. When the effect of the UWL is negligible, the horizontal line corresponds to  $P_0$ . The cross-over point of the slope line and the horizontal line is the  $\text{p}K_{\text{a}}$ . When the UWL limits the permeability, the horizontal line is lower than  $P_0$ , and the cross-over point ( $\text{p}K_{\text{a}}^{\text{flux}}$ ) is not the same as the  $\text{p}K_{\text{a}}$ .

**Figure 9** A theoretical pH-permeability curve.  $P_0 = 0.1 \text{ cm s}^{-1}$ ,  $P_{UWL} = 1 \times 10^{-4} \text{ cm s}^{-1}$ ,  $pK_a = 5$ .

In the case of artificial membranes without surface charge, the pH-permeability profiles were found to follow the pH-partition hypothesis, and strictly adhere to the theoretical curve of eqns [15] and [16].<sup>76,77</sup> However, in the case of in vitro cells and the in vivo membranes, deviations from the theoretical curve are sometimes observed. These deviations can be due to (1) the effect of microclimate pH (see Section 5.19.2.3.2),<sup>78</sup> (2) active transport (see 5.04 The Biology and Function of Transporters; 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption), (3) paracellular pathway permeation (see Section 5.19.3.2.1),<sup>79</sup> and (4) ion pair transport.<sup>80,81</sup> In the case of negatively charged artificial membranes, the deviations were observed in some basic compounds while not for acidic compounds (see Section 5.19.5.1.2.1).<sup>10,82</sup>

Equations [15] and [16] are often employed to reduce the apparent permeability into intrinsic parameters ( $P_0$ ,  $pK_a$ , and  $P_{UWL}$ ), similarly to how the octanol/buffer distribution coefficient ( $D_{oct}$ ) is reduced to the intrinsic octanol/water partition coefficient of a neutral species ( $K_{oct}$ ) and  $pK_a$  (see 5.18 Lipophilicity, Polarity, and Hydrophobicity). Intrinsic parameters can be more directly related to the chemical structure of the substrate than apparent parameters.

### 5.19.4 Comparing In Vivo Predictability Among Physicochemical Tools: Precautions

Before moving onto the introduction of each technology, precautions to compare in vivo predictability (IVIVC) are reviewed in this section. It is difficult to quantitatively compare the IVIVC of each method by literature surveys.

#### 5.19.4.1 The Probe Compound Data Set

##### 5.19.4.1.1 Inconsistency of the probe compound data set

To examine IVIVC, dozens to hundreds of compounds were employed as probe compounds with their in vivo data. However, a selection of probe compounds was not consistent in the literature for each IVIVC. In addition, the in vivo protocol was not necessarily consistent.

##### 5.19.4.1.2 Structural diversity of the probe compound data set

In the literature, marketed drugs were most often employed as probes for the IVIVC study, because of (1) the availability of clinical ADME data, (2) the commercial availability of compounds, and (3) the confidentiality of in-house compounds. In addition, highly lipophilic compounds were not included in the probe compound set, probably because of experimental difficulties in obtaining in vivo data on intravenous administration, which is required to calculate the pharmacokinetic parameters. Therefore, the probe compound set was biased toward drug-like compounds, although structurally diverse compounds are often submitted for an assay in a drug discovery situation.<sup>83,84</sup> It is recommended that the IVIVC for structurally diverse compounds (or a chemotype series of each project) should be examined before implementation of an in vitro assay for practical use in drug discovery.

### 5.19.4.2 Complexity of the Biological Data for Oral Absorption and Blood–Brain Barrier Penetration

#### 5.19.4.2.1 Oral absorption data

Regarding oral absorption prediction, the fraction of a dose absorbed in humans ( $A\%$ ),<sup>85</sup>  $P_{\text{eff}}$ ,<sup>17</sup> and the Caco-2 permeability coefficient ( $P_{\text{app}}$ ) were often employed as biological data (see 5.02 Clinical Pharmacokinetic Criteria for Drug Research; 5.11 Passive Permeability and Active Transport Models for the Prediction of Oral Absorption, respectively). Typical  $A\%$  values are summarized in Table 4.  $A\%$  is determined by both solubility/dissolution and  $P_{\text{eff}}$ .<sup>69</sup>  $P_{\text{eff}}$  and  $P_{\text{app}}$  consist of passive transcellular permeation, paracellular permeation, and active transport (both influx and efflux). Artificial membrane technologies only reflect passive transcellular permeation. Therefore, those compounds which undergo solubility-limited absorption, paracellular pathway permeation, and active transport must be carefully excluded from the probe compound set. P-glycoprotein (P-gp) can reduce the oral absorption.<sup>86</sup> However, if the concentration of a drug in the intestine is high enough to saturate P-gp efflux, the effect of P-gp becomes less significant.<sup>87</sup> The  $K_m$  of P-gp substrates is relatively low, ranging from  $4\text{ }\mu\text{mol L}^{-1}$  to  $213\text{ }\mu\text{mol L}^{-1}$ .<sup>87</sup>

#### 5.19.4.2.2 Blood–brain barrier permeation data

The brain/plasma ratio in animal models has been often employed as probe data.<sup>37</sup> However, this parameter can be that of the steady state and unsuitable to relate directly to kinetic parameters. In addition, the effect of plasma protein binding was sometimes not corrected. Brain perfusion studies directly provide permeability data that can be a gold standard reference.<sup>37,88</sup> A binary expression of the central nerve system availability (CNS +/–) was often employed as an in vivo parameter.<sup>89</sup> This expression may include the in vivo results from (1) the perfusion method, (2) the brain/plasma ratio calculated from the area under the curve or at the steady state, and (3) the existence of pharmacological activity due to BBB penetration. In the case of BBB permeation, P-gp is well known to retard permeability.<sup>86</sup>

### 5.19.4.3 The Unstirred Water Layer of In Vitro Assays

The UWL thickness of in vitro planar membrane permeation assays (e.g., Caco-2<sup>90</sup>) and the parallel artificial membrane permeation assay (PAMPA),<sup>91,92</sup> can reach about 1500–4000  $\mu\text{m}$  without stirring. This is much thicker than in vivo situations (30–100  $\mu\text{m}$  in the intestine, and much less in the BBB; see Sections 5.19.2.3 and 5.19.2.4). Nevertheless, without stirring, in vitro planar membrane permeation assays were found to be able to predict  $A\%$ , suggesting that the UWL does not interfere with  $A\%$  prediction. The UWL permeability of an in vitro planar membrane system was reported to be approximately  $20\text{--}60 \times 10^{-6}\text{ cm s}^{-1}$ .  $A\% < 90\%$  corresponds to about  $< 10 \times 10^{-6}\text{ cm s}^{-1}$  in Caco-2 and PAMPA. Therefore, the contribution of the UWL is insignificant for  $A\%$  prediction. The expansion of the effective surface area by the villous structure cancels out the reduction of the UWL in the in vivo situation (the UWL is on the top of villi).<sup>17</sup> However, the UWL of planar in vitro assays can interfere with the prediction of the high intestinal membrane permeability ( $P_{\text{eff}} > \sim 1 \times 10^{-4}\text{ cm s}^{-1}$ ), as well as BBB permeability. In addition, the effect of the UWL should be eliminated to obtain a correct structure membrane permeability relationship in a high membrane permeability range, since the apparent permeability may just reflect the diffusion in water when the UWL limits the permeation.

## 5.19.5 Permeation Assessment Tools for Drug Discovery

In the following sections, features and the in vivo relevance of artificial membrane tools for drug discovery will be discussed. These tools can be categorized into two types: (1) permeation across the membrane, and (2) partition into the membrane (interfacial region and/or interior hydrophobic region) (see Figure 8).<sup>93</sup> Tools to investigate permeation across the membrane (PAMPA and Fluorosome) are reviewed in this section. Tools to investigate partition into the membrane (chromatography-based artificial membrane-binding assays, the surface plasmon resonance (SPR)-based liposome-binding assay, solid-supported lipid membrane (SSLM) technologies, etc.) are reviewed in Section 5.19.6. In addition, the surface activity assay is reviewed in Section 5.19.7.

### 5.19.5.1 Parallel Artificial Membrane Permeation Assay (PAMPA)

PAMPA has become widespread in drug discovery in recent years.<sup>94–97</sup> The first published study using PAMPA, by Kansy *et al.* in 1998,<sup>94</sup> attracted a lot of favorable attention. The first international symposium on PAMPA was held in 2002 in San Francisco.

PAMPA is an extension of the black lipid membrane (BLM), in which a planar membrane is constructed by brushing a lipid–organic solvent mixture over a small hole (0.5 mm diameter).<sup>98</sup> A serious drawback of BLM for use in drug

**Table 4** Typical probe set compounds employed for IVIVC of A%

| <i>No.</i> | <i>Drug name</i>     | <i>A%<sup>a</sup></i> | <i>Reference</i> | <i>No.</i> | <i>Drug name</i>   | <i>A%<sup>a</sup></i> | <i>Reference</i> |
|------------|----------------------|-----------------------|------------------|------------|--------------------|-----------------------|------------------|
| 1          | Acebutolol           | 80–90                 | 64,152           | 37         | Diclofenac         | 100                   | 64               |
| 2          | Acetaminophen        | 80                    | 64               | 38         | Dicloxacillin      | 35–76                 | 64               |
| 3          | Acetylsalicylic acid | 84–100                | 94,152           | 39         | Dilthiazem         | 80                    | 64               |

<sup>a</sup>The A% value employed for IVVC in the literature.

discovery is that the membrane is extremely fragile. This drawback can be overcome by using a microporous filter as a scaffold for the lipid membrane. This filter-immobilized artificial membrane was introduced by Thompson *et al.* in 1982.<sup>99,100</sup> In 1997, Camenisch *et al.* applied the filter-immobilized organic solvent membrane to compare the permeability of the organic solvent membrane and the Caco-2 membrane.<sup>101</sup> Kansy *et al.* applied the filter immobilized artificial membrane for 96-well plate formats to put it to practical use in drug discovery. The facileness and open accessibility of PAMPA are factors for its recent popularity. PAMPA does not require any special instruments, and is easily performed by standard laboratory instruments. Therefore, PAMPA is easily available regardless of the size of the budget of an organization.

#### 5.19.5.1.1 Parallel artificial membrane permeation assay experimental operation

The PAMPA sandwich is constructed of a 96-well microplate and a filter plate (Figure 10a). The artificial membrane is formed by impregnating an organic solvent solution of lipids to the filter bottom of the filter plate. A dimethyl sulfoxide (DMSO) stock solution can be used as a sample resource. The incubation time depends on the experimental conditions (i.e., the lipid composition, pH, the stirring speed, additives to the donor and acceptor solutions, etc.). After incubation, the concentrations of sample in the acceptor and/or donor plate ( $C_{ac}(t)$  and  $C_{do}(t)$ , respectively) are

**Figure 10** (a) The PAMPA sandwich, constructed of a 96-well microplate (bottom) and a filter plate (top). The bottom of the well of the filter plate is a filter. (b) Structures of filter supports: polyvinylidene difluoride (PVDF) membrane and polycarbonate isopore membrane. (b: Adapted with permission from the Millipore Inc. website.)

measured, for example by ultraviolet spectroscopy (UV)<sup>94</sup> or liquid chromatography–mass spectrometry (LC/MS).<sup>102</sup> Usually, the concentration is measured at one time point ( $t$ , s). In the case of a no-gradient condition, the permeability ( $P_e$ ,  $\text{cm s}^{-1}$ ) and the membrane retention ( $R_e$ ) are calculated as<sup>14,95</sup>

$$P_e = \frac{-0.203}{A_m t} \left( \frac{V_{ac} V_{do}}{V_{ac} + V_{do}} \right) \log \left[ 1 - \left( \frac{V_{ac} + V_{do}}{(1 - R_e) V_{do}} \right) \left( \frac{C_{do}(t)}{C_{do}(0)} \right) \right] \quad [17]$$

$$R_e = \frac{C_{do}(t)}{C_{do}(0)} - \frac{V_{ac} C_{ac}(t)}{V_{do} C_{do}(0)} \quad [18]$$

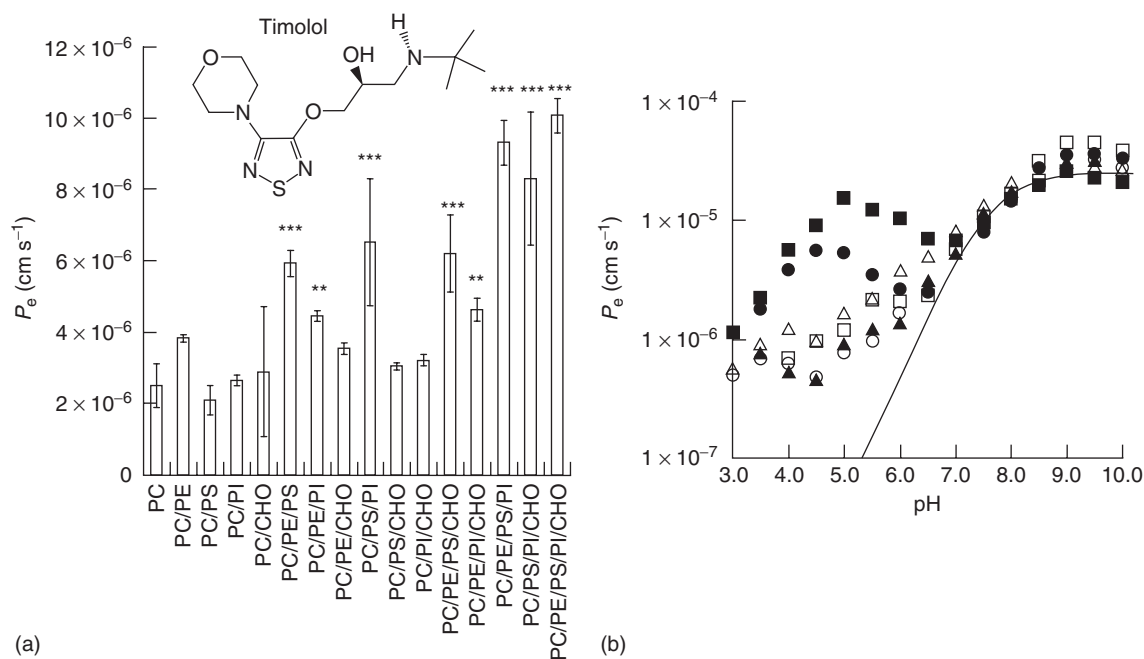

where  $A_m$  is the membrane area ( $\text{cm}^2$ ), and  $V_{ac}$  and  $V_{do}$  are the volume of the donor and acceptor wells, respectively. Equations for gradient conditions have also been introduced.<sup>10</sup>

#### 5.19.5.1.2 Effect of experimental conditions on parallel artificial membrane permeation assay permeability

The experimental conditions used for PAMPA vary; for example, lipid composition, the organic solvent used to dissolve the lipid, donor and acceptor buffer solutions, and stirring speed can all differ. These variations significantly affect permeability and in vivo predictability.

##### 5.19.5.1.2.1 Lipid composition

Many PAMPA variations contain anionic (phospho-)lipids in the membrane to increase the in vivo predictability.<sup>10,96</sup> As described in Sections 5.19.2.3 and 5.19.2.4, the intestinal BBM and the BBB membrane contain anionic phospholipids. Anionic phospholipids significantly increased the PAMPA permeability of hydrophilic basic compounds, such as metoprolol, timolol, procainamide, and pindolol (Figure 11).<sup>82,103,104</sup> The PAMPA permeability of hydrophilic basic compounds is saturable and inhibited by the co-addition of cationic compounds. The pH-permeability profile deviates from the pH-partition hypothesis. Quaternary ammonium compounds permeate the membrane by the aid of anionic phospholipids.<sup>82,104</sup> It has been suggested that the PAMPA permeability of cationic species is mediated by anionic

**Figure 11** Effect of lipid composition on the PAMPA permeability ( $P_e$ ) of timolol, a hydrophilic basic compound. Conditions: phospholipids (2%)/CHO (cholesterol) (1%)/1,7-octadiene (97%) (w/w) membrane, pH 6.0. PE, PS, and PI were added (0.8%, 0.2%, and 0.2%, respectively), and total phospholipids were adjusted to 2% by PC.<sup>103</sup> (a) Effect of various lipid compositions on the PAMPA permeation of timolol.<sup>103</sup> (b) pH-PAMPA permeability profile of timolol. Lipid composition: PC (○), PC/PE (Δ), PC/PS (□), PC/PI (●), PC/CHO (▲), and PC/PE/PS/PI/CHO (■). (Reprinted from Sugano, K.; Nabuchi, Y.; Machida, M.; Asoh, Y. *Int. J. Pharm.* **2004**, 275, 271–278, copyright (2004) with permission.)

phospholipids. Some PAMPA variations employ egg or soybean extracted lecithins as the lipid source. These lecithins are not necessary 100% pure PC, and may contain anionic lipids to some extent, depending on the grade.

For neutral and acidic compounds, the reported results of the effects of phospholipids are varied. Avdeef reported that the phospholipid concentration in the membrane affected both the membrane permeability and the membrane retention of neutral and acidic compounds.<sup>10</sup> He varied the phospholipid concentration from 0% to 74%, and measured the permeability of structurally diverse compounds. On the other hand, Anderson *et al.* reported that, based on the barrier domain solubility diffusion theory (see Section 5.19.3.1.2), 1,9-decadiene can mimic the chemical selectivity of the phospholipid bilayer.<sup>54</sup> Wohnsland *et al.* reported that a PAMPA with the hexadecane membrane without phospholipids could adequately predict  $A\%$  (see Section 5.19.5.1.3.2).<sup>95</sup>

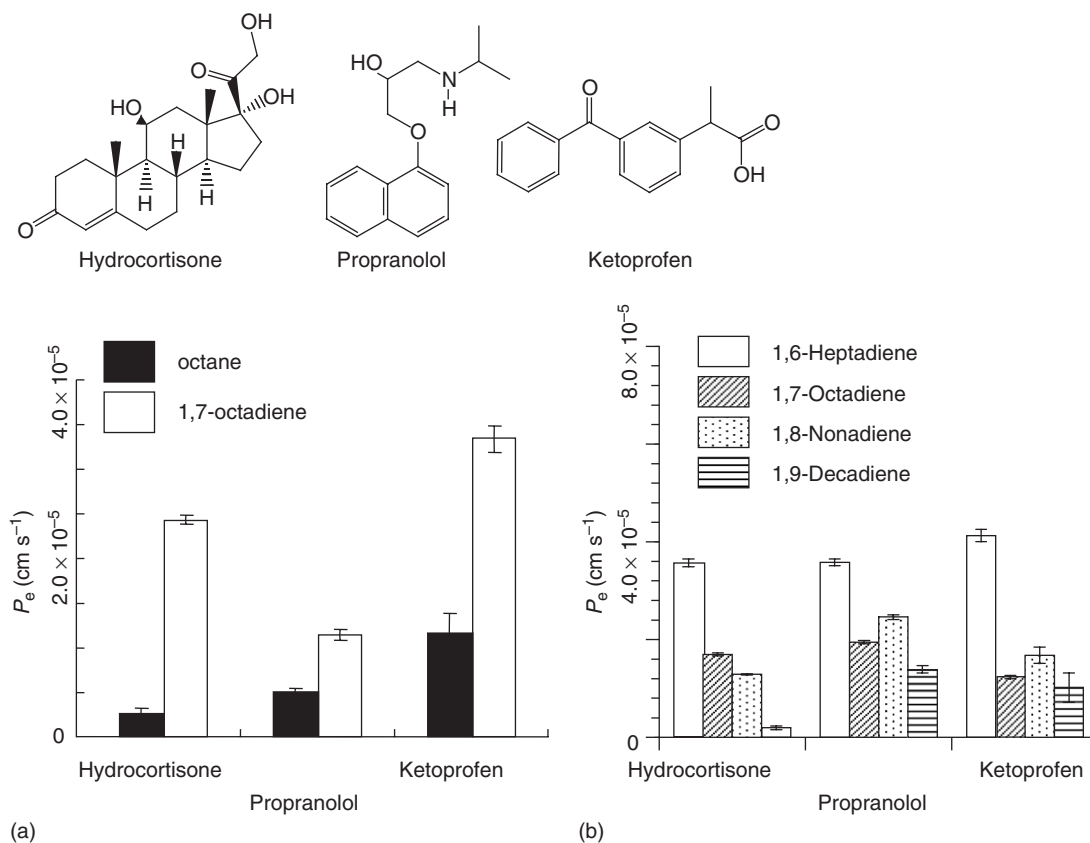

#### 5.19.5.1.2.2 Organic solvents in the parallel artificial membrane permeation assay membrane

In most cases, dodecane is employed as the organic solvent. It has been suggested that the organic solvent used to dissolve the lipids remains in the membrane, affecting membrane permeability. The permeability across an alkyl diene–phospholipid membrane was higher than that across an alkane–phospholipid membrane (Figure 12a).<sup>105</sup> The chain length of organic solvents also affects PAMPA permeability (Figure 12b).<sup>96</sup>

#### 5.19.5.1.2.3 pH and solubilizers in the donor and acceptor buffers

The pH condition largely affects PAMPA permeability in accordance with the pH–partition hypothesis (see Section 5.19.3.5). To reflect the pH variations during the gastrointestinal transition (see Section 5.19.2.3.2), multiple pH conditions can be used for in vivo prediction.<sup>94,95,106</sup>

Co-solvents are often employed to dissolve poorly water-soluble compounds. DMSO, ethanol, PEG400,<sup>107</sup> 1-propanol,<sup>10</sup> and acetonitrile<sup>108</sup> were investigated for their effect on permeability. It was reported that the effect of acetonitrile can be corrected by hydrogen bond parameters.<sup>109</sup> The addition of co-solvents increases the affinity of hydrophobic compounds to the water phase, resulting in a decrease in the partitioning to the lipophilic part of the lipid membrane. Simultaneously, the co-solvent lowers the dielectric constant and increases the fraction of uncharged species. These phenomena affect the permeability oppositely, and may differ among each substrate.

**Figure 12** Effect of organic solvent remaining in the membrane on PAMPA permeability ( $P_e$ ). (a) Octane versus octadiene (PC (0.8%)/PE (0.8%)/PS (0.2%)/PI (0.2%)/CHO (cholesterol) (1%)/organic solvent (97%) (w/w)).<sup>105</sup> (b) Chain length dependency (PC (2%)/organic solvent (98%) (w/w)). (Reprinted from Sugano, K.; Hamada, H.; Machida, M.; Ushio, H. *J. Biomol. Screen.* **2001**, *6*, 189–196, with permission from SAGE.)

Surfactants were also examined as the solubilizer. Glycocholic acid in the donor buffer was reported to have a minimal effect on permeability for most compounds.<sup>109</sup> On the other hand, taurocholic acid decreased the permeability of lipophilic compounds.<sup>10</sup> Tween 80 and Brij-35 at 0.5–5% (w/v) did not disrupt the PAMPA membrane, while Cremophor EL did at 0.5%.<sup>110</sup>

Surfactants in the acceptor buffer can increase the permeability of lipophilic compounds by facilitating the redistribution of lipophilic compounds from the PAMPA membrane to the acceptor buffer phase.<sup>10</sup>

#### 5.19.5.1.2.4 Filters

Hydrophobic polyvinylidene difluoride (PVDF),<sup>94</sup> hydrophilic PVDF,<sup>106</sup> and polycarbonate filters<sup>95</sup> have been employed as a scaffold of the lipid membrane (see [Figure 10b](#)). The exact structure of the PAMPA membrane built on the PVDF filters is not known. PVDF filters have a sponge-like structure, and the thickness is about 125  $\mu\text{m}$ . Polycarbonate filters have straightthrough pores, and the thickness is about 10  $\mu\text{m}$ . Microscope observations suggest that the pore size of the polycarbonate filter affects the integrity of the lipid membrane.<sup>67</sup> In the case of a 0.45  $\mu\text{m}$  pore size filter, the impregnated organic solvent (hexadecane) remains in the pore, and no defect (aqueous pores) was observed. In the case of a 3.0  $\mu\text{m}$  pore size filter, defects were observed.

#### 5.19.5.1.3 Variations in parallel artificial membrane permeation assay and their in vivo relevance

##### 5.19.5.1.3.1 The original parallel artificial membrane permeation assay (egg lecithin parallel artificial membrane permeation assay)

Kansy *et al.* reported the original PAMPA in 1998.<sup>94</sup> The original PAMPA employed the hydrophobic PVDF filter as a membrane support. Detail of the lipid composition was not explained in this original article; however, it was later

**Figure 13** A% predictability of the original PAMPA. The PAMPA permeability with higher Flux% at pH 6.5 or 7.4 was employed. High: A% > 70%, PAMPA flux > 25%. Mid: A% = 30–70%, PAMPA flux 5–25%. Low: A% < 30%, PAMPA flux < 5%. See **Table 4** for assignment of compounds. (Reprinted from Kansy, M.; Senner, F.; Gubernator, K. *J. Med. Chem.* **1998**, *41*, 1007–1010 and modified to exclude the substrates of active transporters. Copyright (1998) American Chemical Society.)

published to be 10% (w/v) egg lecithin in dodecane.<sup>104</sup> The incubation time was 15 h. The sample buffer solution contained 5% DMSO. The permeability was reported as Flux%. Flux% was measured at pH 6.5 and 7.4, and the higher Flux% at pH 6.5 or 7.4 was used to predict A% in humans. The A% predictability was examined using 25 marketed drugs (**Figure 13**). The original PAMPA adequately categorized the A% classes to high (> 70%), middle (30–70%), and low (30%). The number of probe compounds was relatively small, and A% data were biased to the high A% category.

Zhu *et al.* developed a similar PAMPA system, but employed a hydrophilic PVDF filter as a membrane support, resulting in a shorter incubation time (2 h).<sup>106</sup> The membrane lipid was 1% (w/v) egg lecithin in dodecane. The permeability was measured at pH 5.5 and 7.4. The higher permeability at pH 5.5 or 7.4 was used to correlate with oral absorption parameters. The A% predictability of PAMPA was examined using over 90 marketed drugs, and compared with that of Caco-2 permeability (pH 7.4), the octanol/buffer distribution coefficient at pH 7.4 ( $D_{\text{oct}, 7.4}$ , measured by a shake flask method), and the polar surface area (PSA). The A% prediction accuracy of PAMPA was comparable to Caco-2; however, it was significantly better than  $\log D_{\text{oct}, 7.4}$  and the PSA. The PAMPA permeability correlated well with the Caco-2 permeability at pH 7.4 ( $r = 0.82$ ,  $N = 49$ ).

#### 5.19.5.1.3.2 Hexadecane membrane parallel artificial membrane permeation assay (HDM-PAMPA)

Faller *et al.* used a simplified membrane, the hexadecane membrane (HDM-PAMPA).<sup>95</sup> The rationale why HDM-PAMPA without phospholipids can predict the bio-membrane permeation is the assumption that a distinct permeation barrier for most drugs is the interior region of the lipid bilayer and that hexadecane can offer a similar environment (see [Section 5.19.3.1.2](#) and [5.19.3.1.4.1](#), on the barrier domain solubility diffusion model). To construct a thin hexadecane membrane, a hexadecane–hexane mixture was added to the filter support, and the hexane was removed by evaporation. A polycarbonate filter (10  $\mu\text{m}$  thickness and 3  $\mu\text{m}$  pore size) was employed. Permeability was measured at pH 4–8, and the highest permeability was used to predict A% in humans. A% predictability was examined using 32 marketed drugs (**Figure 14**).

**Figure 14** The A% predictability of HDM-PAMPA. PAMPA permeability with the highest permeability within the pH range 4–8 was employed. See **Table 4** for the assignment of compounds. (Reprinted from Wohnsland, and modified to exclude the substrates of active transporters and compound with MW <200. Copyright (2001) American Chemical Society.)

In the case of an isotropic organic solvent membrane, the membrane permeability coefficient and the partition coefficient correlate as eqn [3]. Therefore, PAMPA can also be used to measure the organic solvent/water partition coefficient.<sup>95,111</sup>

#### 5.19.5.1.3.3 Biomimetic parallel artificial membrane permeation assay (BM-PAMPA)

Sugano *et al.* modified the original PAMPA to a more biomimetic assay (BM-PAMPA) (Figure 15).<sup>64</sup> The lipid composition was modified to PC (0.8%)/PE (0.8%)/PS (0.2%)/PI (0.2%)/cholesterol (1%) (w/w) to represent the lipid composition of the intestinal BBM. In addition, the organic solvent was changed from dodecane to 1,7-octadiene. The incubation time was 15 h. The sample solution contained 5% DMSO. In BM-PAMPA, permeability at pH 6.0–6.5 was found to be the best pH condition for A% prediction.<sup>64,107</sup> The A% and  $P_{\text{eff}}$  values of small and cationic drugs were underestimated by BM-PAMPA itself; however, they were adequately estimated when BM-PAMPA was combined with a paracellular pathway permeability model equation (A% prediction: root mean square error = 14%,  $N = 80$ ) (see Section 5.19.3.2.1).<sup>64,96</sup> The Caco-2 permeability was also adequately predicted.<sup>112</sup> BM-PAMPA is not suitable for robotic automation in an open laboratory because 1,7-octadiene is an irritant.

#### 5.19.5.1.3.4 Double-sink parallel artificial membrane permeation assay (DS-PAMPA)

After extensive examinations of assay conditions, Avdeef *et al.* developed the DS-PAMPA system. DS-PAMPA is commercially available from pION, Inc. As a source of phospholipids, Avdeef *et al.* employed a special lipid mixture similar to crude soybean lecithin, which is PI-rich (see Table 2).<sup>33</sup> The concentration of phospholipids was increased to 20%. To construct a double-sink condition, a pH gradient condition (pH 5.0–7.4 (donor) and pH 7.4 (acceptor)) and a lipophilicity gradient (surfactant in an acceptor compartment) were employed (sink conditions for acidic and lipophilic compounds, respectively). In addition, rapid stirring was introduced to adjust the UWL effect to that in the intestine.<sup>92</sup> These conditions reflect the in vivo situation. The in vivo predictability was examined by comparing with  $P_{\text{eff}}$  in humans (eight marketed drugs) and A% (21 marketed drugs).<sup>10</sup> In addition, the DS-PAMPA permeability was compared with the rat in situ intestinal membrane permeability using a series of fluoroquinolone derivatives (Figure 16).<sup>113</sup>

**Figure 15** The A% predictability of BM-PAMPA. Compounds with MW 129–654 and –2 to +2 charge are plotted. BM-PAMPA permeability was measured at pH 6.0. See **Table 4** for the assignment of compounds.  $r$  is the molecular radius. (Reprinted from Sugano, K.; Takata, N.; Machida, M.; Saitoh, K.; Terada, K. *Int. J. Pharm.* **2002**, 241, 241–251, copyright (2002), with permission from Elsevier.)

#### 5.19.5.1.3.5 Blood–brain barrier parallel artificial membrane permeation assay (BBB-PAMPA)

Di *et al.* modified PAMPA for the prediction of the BBB penetration (BBB-PAMPA).<sup>97</sup> They employed a crude extract from the porcine brain as a lipid source (**Table 2**). BBB-PAMPA was found to predict CNS +/CNS– of 25 marketed drugs (100% correct), as well as their in-house compounds. The palmitoyllecithin phosphatidylcholine (POPC)/dodecane membrane was found to have less predictability (88% correct, no false positives, false negatives: alprazolam, clonidine, oxazepam).

Recently, Avdeef *et al.* developed a new PAMPA system to predict the BBB permeability (**Figure 17**).<sup>114</sup> Brain perfusion data were used as probe data, and converted to the intrinsic permeability coefficient ( $P_0^{\text{BBB}}$ ). The apparent PAMPA permeability of probe compounds was also converted to the intrinsic permeability coefficient ( $P_0^{\text{PAMPA}}$ ) (see **Section 5.19.3.5**). A multiple linear regression model to calculate  $\log P_0^{\text{BBB}}$  from  $\log P_0^{\text{PAMPA}}$  in combination with other chemical descriptors (in combo PAMPA) was constructed with  $\log P_0^{\text{BBB}}$  as the dependent variable, and  $\log P_0^{\text{PAMPA}}$ , along with Abraham solute property molecular descriptors: excess molar refraction, solute dipolarity/polarizability, overall hydrogen bond acidity, overall hydrogen bond basicity, and McGowan molecular volume as independent descriptors.  $P_0^{\text{BBB}}$  was adequately predicted by in combo PAMPA for a  $10^7$  order range.

#### 5.19.5.1.4 Advantages, limitations, and utility of parallel artificial membrane permeation assay in drug discovery

PAMPA is especially advantageous in early drug discovery.<sup>115</sup> PAMPA is cost-effective, easy to automate, and compatible for a high percentage of solubilizers. In current drug discovery, we often encounter poorly water-soluble compounds.<sup>84</sup> PAMPA has good day-to-day reproducibility and small variability.<sup>106</sup> The cost of PAMPA is more than 10-fold lower than that of Caco-2 assay.<sup>115</sup> The PAMPA membrane can be instantly prepared at the time of use, while Caco-2 requires a 3–21 day culture before use. PAMPA enables studies of passive transcellular permeation without intervention by paracellular and active transports. This simplicity is advantageous for quantitative structure–permeability relationship (QSPR) studies. QSPR by Ano *et al.*<sup>116</sup> and Huque *et al.*<sup>117</sup> indicated that hydrogen bonds play a key role in PAMPA

**Figure 16** The logarithm of the apparent permeability coefficient for perfusion experiments in rats versus the logarithm of the intrinsic permeability coefficients based on DS-PAMPA. (Reprinted from Bermejo, M.; Avdeef, A.; Ruiz, A.; Nalda, R.; Ruell, J. A.; Tsinman, O.; Gonzalez, I.; Fernandez, C.; Sanchez, G.; Garrigues, T. M. *et al. Eur. J. Pharm. Sci.* **2004**, *21*, 429–441, with permission from Elsevier.)

**Figure 17** BBB permeation predictability of PAMPA in combo approach.  $P_0^{\text{BBB}}$  is the intrinsic BBB permeability coefficient, and  $P_0^{\text{PAMPA}}$  is the intrinsic PAMPA permeability corrected by the Abraham solute property molecular descriptors. (Reproduced from Avdeef, A. EUFAPS/AAPS Meeting, Nice, France, June 2005, with permission from pION, Inc.)

permeation. Veber *et al.* measured PAMPA permeability of 3061 in-house compounds, and QSPR performed.<sup>118</sup> In addition to the hydrogen bond parameters, an increase of the number of rotatable bond was suggested to decrease permeability. Hwang *et al.* showed that PAMPA data can help permeation assessment of a metabolically unstable compound.<sup>119</sup>

PAMPA has a synergistic effect when combined with other tools. For example, combination with the *in silico* paracellular model was found to increase *in vivo* predictability.<sup>64,120</sup> Several reports suggested that the combination of PAMPA and Caco-2 could diagnose the participation of active transporters.<sup>115,116,121</sup> For this use, PAMPA permeability can be corrected by an *in silico* paracellular pathway model for the Caco-2 tight junction.<sup>62,112</sup> If Caco-2 permeability is different to that estimated by PAMPA permeability, the compound undergoes active transport. This diagnosis can trigger further studies to confirm the permeation mechanism. A combination of PAMPA and a high-throughput solubility assay enables biopharmaceutical classification in early drug discovery (*see* 5.42 The Biopharmaceutics Classification System).<sup>122,123</sup> This application is important for the fine tuning of a biopharmaceutical profile considering the target disease and clinical utility. To overcome the lack of active transporters and metabolisms, high-throughput molecular enzymological assays or *in silico* prediction for these processes can be used together. These kinds of *in combo* approaches are synergistically effective in various drug discovery situations.

One limitation of PAMPA is that the membrane is not exactly same as the biological membrane. The PAMPA membrane contains an organic solvent, possibly resulting in a nonbilayer membrane structure. In PC–dodecane membrane PAMPA and BM-PAMPA, parabolic relationships were reported between lipophilicity and PAMPA permeability,<sup>109,124</sup> similarly to the case of cell-based permeation assays.<sup>125–127</sup> In both PAMPA cases, maximum permeability was observed around the octanol/buffer distribution coefficient of 1.5. Since the probe data set for IVIVC is biased to low to moderate lipophilicity drugs, the *in vivo* relevance of PAMPA for high-lipophilicity compounds might not be assured. In addition, PAMPA has neither active transport systems nor a paracellular pathway. The *in vivo* prediction accuracy of PAMPA is comparable to or less than Caco-2<sup>110,106,121</sup>; however, it is good for compound ranking. Consequently, PAMPA is used as a complement, rather than an alternative, to Caco-2 assay in early drug discovery.<sup>115,121</sup>

#### 5.19.5.2 Fluorosome

Fluorosome technologies are an application of liposomes.<sup>128</sup> In 1965, liposomes were introduced as a model for the cellular membrane, and have been used to study bilayer membrane permeation.<sup>53,129</sup> Liposomes almost exactly mimic the real biological lipid membrane. However, liposome permeability assays were difficult to implement in drug discovery because it was difficult to measure the concentration of a substrate in the aqueous phase inside the liposome cavity. Fluorosome technology overcomes this drawback by placing fluorescein-labeled proteins, which bind about 95% of all small molecules, in the liposome cavity. The advantage of Fluorosome technology is that it utilizes liposomes, an artificial membrane similar to the real biological membrane. In addition, in contrast to other liposome-based methods, membrane permeation is assessed separately from membrane binding. Fluorosome is commercially available from GLSynthesis, Inc.

##### 5.19.5.2.1 Method

A test compound dissolved in DMSO is added to a Fluorosome suspension in a standard spectrofluorometer and measured to obtain a fluorescence–time curve. This time dependence is directly related to the rate of compound permeation across the bilayer. The data are curve fitted to give a first-order rate constant  $k$ , which is used in conjunction with the Fluorosome diameter to calculate permeability.

##### 5.19.5.2.2 *In vivo* relevance

Fluorosome technology for assessing the membrane permeation has two variations, Fluorosome-trans-pc and Fluorosome-trans-ent. Fluorosome-trans-pc is composed of only phosphatidicholine, while Fluorosome-trans-ent is composed of a consensus mixture of the major lipids present in mammalian intestinal (enterocyte) membranes. The *in vivo* relevance was examined using 44–47 marketed drug A% values in humans (Figure 18). Similarly to PAMPA, a biomimetic lipid composition increased the *in vivo* predictability.

#### 5.19.6 Partition Assessment Tools for Drug Discovery

In this section, artificial membrane partition assessment tools are reviewed. Traditionally, the artificial membrane partition was measured by an equilibrium dialysis method with liposomes. However, this method is not suitable for drug discovery. Several new technologies have been introduced to measure the artificial membrane partition in drug

**Figure 18** A% predictability of Fluorosome-trans-ent. Permeability was measured at pH 7.4. See **Table 4** for the assignment of compounds. (Reproduced from, GLSynthesis, Worcester, MA, with permission from GLSynthesis, Inc.)

discovery. In this section, immobilized artificial membrane (IAM) column chromatography, immobilized liposome chromatography (ILC), liposome electrokinetic chromatography (LEKC), pH titration, the surface plasmon resonance (SPR)-based method, and the solid-supported lipid membrane (SSLM) techniques are reviewed. Some of these methods are described from the viewpoint of physicochemical characteristics in another article (*see* 5.18 Lipophilicity, Polarity and Hydrophobicity). In this article, these methods are reviewed mainly from the viewpoint of drug discovery utility and relevance to in vivo membrane permeation.

#### 5.19.6.1 Chromatography-Based Methods

When an artificial membrane is employed as the stationary phase of chromatography, retention indices correlate with the artificial membrane partition coefficient. An advantage of chromatography-based methods is that neither high sample purity nor establishment of quantitative analysis is required.

##### 5.19.6.1.1 Immobilized artificial membrane column chromatography

IAM column chromatography was introduced by Pidgeon and co-workers,<sup>130–132</sup> and has been widely investigated for its physicochemical characteristics and its in vivo predictability.<sup>133,134</sup> The IAM column is commercially available from Regis technologies, Inc. Phospholipids are covalently bound to the silica particle at a monolayer level (**Figure 19a**). PC, PE, PG, PS, and phosphatidic acid (PA) versions have been reported.<sup>135</sup> The capacity factor of IAM column chromatography ( $k_{IAM}$ ) correlated with liposome binding better than the octanol/water partition coefficient did.<sup>132</sup>

The retention time of a substrate on the IAM column can be measured utilizing conventional high-performance liquid chromatography (HPLC) instruments. To cover a wide range of compounds, organic solvents (e.g., methanol and acetonitril) can be added to accelerate elution.<sup>136–138</sup> The capacity factors obtained at a given percentage of organic solvents are then extrapolated to 100% aqueous mobile phase.  $k_{IAM}$  has been investigated for correlation with Caco-2 permeability,<sup>131,133,139</sup> and rat intestinal absorption (**Figure 19b**).<sup>131,133,140</sup> Correlation was improved when  $k_{IAM}$  was corrected by MW<sup>131</sup> and/or hydrogen bond factors.<sup>139</sup> The IAM column capacity factor has also been investigated for BBB permeability prediction.<sup>133,141–143</sup>

**Figure 19** (a) Structure of IAM. PC C10/C3 column. (Reprinted from Ong, S.; Liu, H.; Qiu, X.; Bhat, G.; Pidgeon, C. *Anal. Chem.* **1995**, 67, 755–762. Copyright (1995) American Chemical Society.) (b) Correlation of  $k_{IAM}$  with the rat intestinal drug absorption (Abs%). Retention time of substrate were measured at pH 5.4. 1, *m*-nitroaniline; 2, *p*-nitroaniline; 3, salicylic acid; 4, *p*-toluidine; 5, aniline; 6, *m*-nitrobenzoic acid; 7, phenol; 8, benzoic acid; 9, acetanilide; 10, antipyrine; 11, theophylline; 12, acetylsalicylic acid. (Reprinted from Pidgeon, C.; Ong, S.; Liu, H.; Qiu, X.; Pidgeon, M.; Dantzig, A. H.; Munroe, J.; Hornback, W. J.; Kasher, J. S.; Glunz, L. *J. Med. Chem.* **1995**, 38, 590–594. Copyright (1995) American Chemical Society.)

#### 5.19.6.1.2 Immobilized liposome chromatography

ILC is a more biologically relevant *in vitro* model for the cell membrane than the IAM stationary phase, because liposomes are noncovalently immobilized to gel beads as a stationary phase of chromatography.<sup>144–147</sup> PC, a PC/PS mixture, an egg phospholipid mixture, human red blood cell extract (with or without proteins), and porcine intestinal BBM extract have been reported as lipids for ILC.

Liposomes are remixed with dry gel beads and immobilized by gel bead swelling followed by freezing–thawing to induce liposome fusion. During the freezing–thawing process, the liposomes grow in size and are entrapped in the gel beads pore. The immobilized liposome has a multilamellar structure.<sup>148</sup> The liposome immobilized gel is packed into a column. The retention time of the drugs is measured using an HPLC apparatus, and the capacity factor ( $K_s$ ) calculated.

The correlation between  $A\%$  in humans and  $K_s$  (PC and human red blood cell extract liposomes, pH 7.4) were examined using more than a dozen marketed drugs (Figure 20).<sup>144,146</sup> A bell-shaped correlation curve was observed between  $A\%$  in humans and  $K_s$ . The correlation between  $P_{eff}$  in humans and  $K_s$  (egg yolk phospholipid and porcine intestinal brush border lipid) was also examined.<sup>147,149</sup>

#### 5.19.6.1.3 Liposome electrokinetic chromatography

LEKC is a capillary electrophoresis method where liposomes are incorporated in the buffer as a pseudo-stationary phase for the separation of charged and uncharged molecules.<sup>148,150</sup> In order to determine retention indices for charged molecules, the migration time was measured with and without the presence of liposomes. Recently, liposomes that reflect the lipid composition of the Caco-2 membrane were examined for usage in LEKC.<sup>151</sup>

**Figure 20** A% in humans versus  $\log K_s$  values obtained by ILC on the PC vesicles. The drugs are: 1, polyethylene glycol (average MW 200); 2, mannitol; 3, atenolol; 4, acetylsalicylic acid; 5, metoprolol; 6, salicylic acid; 7, hydrocortisone; 8, corticosterone; 9, warfarin; 10, alprenolol; 11, propranolol; 12, terbutaline; 13, sulphasalazin. A single gel bed was used to determine the  $\log K_s$  values. The equation for the curve is  $y = -390.38 + 967.75x - 711.67x^2 + 232.93x^3 - 29.106x^4$ . (Reprinted from Beigi, F.; Gottschalk, I.; Lagerquist Hagglund, C.; Haneskog, L.; Brekkan, E.; Zhang, Y.; Osterberg, T.; Lundahl, P. *Int. J. Pharm.* **1998**, *164*, 129–137, with permission from Elsevier.)

## 5.19.6.2 Other Partition Assessment Tools

### 5.19.6.2.1 Surface plasmon resonance

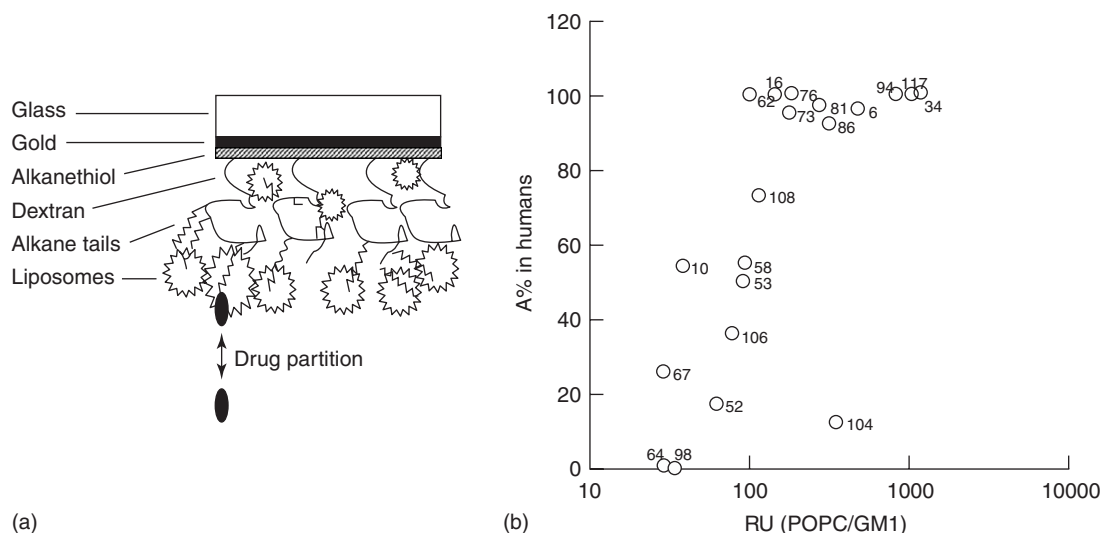

The phenomenon of SPR is sensitive to changes in refractive index at the sensor surface caused by change in mass. When liposomes are fixed on the sensor surface, the interaction between liposomes and drugs can be measured (**Figure 21a**).<sup>152</sup> Since SPR measures a change in mass on the sensor surface, concentration determination (i.e., UV, HPLC, LC/MS, etc.) is not required. In addition, the SPR instrument is medium-throughput adaptable. One 96-well plate can be analyzed in 24 h, with a total hands-on time of less than 3 h.<sup>153</sup> In addition, sample precipitation can be easily detected as an irregularly shaped sensorgram.<sup>153</sup> These features of this method are advantageous for drug discovery. Another distinctive advantage of the SPR method is that it can measure the kinetics of adsorption and desorption, which indicates differences in binding mode.<sup>154</sup> However, the SPR instrument is expensive.

Liposomes are attached to a sensor chip, the surface of which is coated with alkyl tails. During injection, the SPR signal shows the binding of a compound to the liposomes, and at the end of injection, it shows the release of a compound from the liposome surface. Steady state levels are rapidly achieved during injection.

The presence of 10% DMSO decreased the amount of liposome captured on the sensor surface by 30%, as well as the drug-binding affinity by twofold (desipramine, POPC liposome). The liposome diameter did not affect the binding affinity of each drug (0.05–2  $\mu\text{m}$ , equivalent to a 64 000-fold difference in volume).<sup>154</sup>

In the first report of this method applied to oral absorption prediction, the correlation between A% in humans and the sensor response was examined using POPC and POPC/ganglioside GM1 liposomes. The POPC liposome surface has no net charge, while the POPC/GM1 liposomes have a net negative charge derived from the carboxylic group of GM1. Seventeen marketed drugs were employed as a probe set (**Figure 21b**).<sup>152</sup> The sensor response was measured at pH 7.4 with injection of a 500  $\mu\text{M}$  sample solution containing 0.1% DMSO. POPC/GM1 liposomes were found to have slightly better A% predictability than POPC liposomes.

Frostell-Karlsson *et al.* reported that a two-dimensional plot of membrane binding (PC and PC/PE/PS (2:5:3) liposomes, pH 6.5) could classify A% into three ranges (high (>80%), medium (<80%, >20%), and low (>20%)).<sup>153</sup> The PC/PE/PS (2:5:3) system, which mimics the lipid composition of the intestinal membrane, enabled adequate A% prediction of basic compounds. In addition, the assay condition was adapted to a lower concentration (150  $\mu\text{M}$ ), a higher temperature (37 °C) and an increased DMSO concentration (3%). These conditions make this assay better suited for poorly water-soluble compounds.

**Figure 21** (a) SPR sensor chip and attachment of liposome. Liposomes are captured on alkane tails covalently attached to a dextran matrix. (b) Correlation between the signal from POPC/GM1 (in response units, RUs) and A% in humans. See **Table 4** for the assignment of compounds. (Reprinted from Danelian, E.; Karlen, A.; Karlsson, R.; Winiwarer, S.; Hansson, A.; Lofas, S.; Lennernas, H.; Hamalainen, M. D. *J. Med. Chem.* **2000**, 43, 2083–2086. Copyright (2000) with permission from the American Chemical Society.)

#### 5.19.6.2.2 pH titration

The liposome partition coefficient of dissociable compounds can be determined by the pH titration method.<sup>155–157</sup> A substrate solution is titrated with and without the coexistence of liposome, and the partition coefficient is calculated from the difference in the titration curves. This method has low to medium throughput, but can provide the pH–partition profile of both nonionized and ionized species.

The correlation between A% in humans and the liposome partition coefficient at pH 6.8 was examined using 21 marketed drugs. The liposomes employed were mainly composed of PC. After converting to the absorption potential in which solubility and the clinical dose were taken into account, a good correlation was observed.

#### 5.19.6.2.3 Solid-supported lipid membrane

In the SSLM technique, a unilamellar liposomal membrane noncovalently surrounds porous silica beads.<sup>158,159</sup> The SSLM permits a high throughput determination of the membrane affinity. To measure SSLM binding, an SSLM is added to the sample solution ( $\mu\text{g}^{-1}\text{mL}^{-1}$  range). A short mixing and incubation step of 2 min allows complete partitioning, and the beads are then separated by vacuum filtration or low-speed centrifugation. Quantitative analysis of the supernatant yields the membrane affinity. The SSLM membrane affinity has been related to A% in humans of nearly 30 compounds. The SSLM is commercially available from Nimbus Biotechnology as TRANSIL.

### 5.19.7 Surface Activity

Surface activity parameters may be classified as a family of purely physicochemical parameters (i.e., the bulk organic solvent water partition coefficient, hydrogen bond acidity/basicity, etc.) rather than as biomimetic physicochemical parameters. Nevertheless, surface activity parameters are closely related to membrane partition and permeation.

Surface activity parameters have been studied for their relevance to in vivo BBB penetration,<sup>160–162</sup> and  $K_m$  of the P-gp substrate.<sup>163,164</sup> Surface activity parameters are a quantitative measure of the tendency to move to the air–water interface. At the air–water interface, molecules are organized to expose the hydrophobic part of a molecule part to the air, while the hydrophilic part maximizes contact with the water. Surface activity parameters can be calculated from the Gibbs adsorption isotherm (Figure 22).

**Figure 22** The Gibbs adsorption isotherm. Surface activity parameters are obtained from the adsorption isotherm: concentration ( $c$ ), surface pressure ( $\pi$ ), onset concentration ( $C_{on}$ ), critical micelle concentration (CMC), air–water partitioning coefficient ( $K_{aw}$ ), and molecular cross-sectional area ( $A_s$ ). (Reprinted from Suomalainen, P.; Johans, C.; Soderlund, T.; Kinnunen, P. K. *J. Med. Chem.* **2004**, 47, 1783–1788. Copyright (2004) American Chemical Society.)

### 5.19.7.1 Method

The surface tension is measured with a tensiometer (a multi-channel microtensiometer is commercially available). A probe hung down from the microbalance is soaked in the sample buffer solution. The maximum force exerted by the surface tension is recorded as the probe is lifted up from the solution.

The surface pressure ( $\pi$ ) is related to the surface tension through

$$\pi = \gamma^0 - \gamma \quad [19]$$

where  $\gamma^0$  is the surface tension of the bare interface and  $\gamma$  is that in the presence of surface-active substrates. A typical surface pressure–concentration plot (Gibbs adsorption isotherm) is shown in [Figure 22](#).<sup>161,162</sup> From the pressure–concentration plot, the critical micelle concentration (CMC), the air/water partition coefficient ( $K_{aw}$ ), the concentration of surface activity onset ( $C_{on}$ ), and the molecular cross-sectional area ( $A_s$ ) can be obtained.

The membrane partition coefficient ( $K_{memb}$ ) is estimated as<sup>161,162</sup>

$$\log K_{memb} = \frac{RT \ln(K_{aw}) - \pi_{memb} A_s N_A}{2.302 RT} \quad [20]$$

where  $\pi_{memb}$  is the surface pressure of a lipid bilayer, and  $N_A$  is Avogadro's number.

### 5.19.7.2 In Vivo Relevance

#### 5.19.7.2.1 Blood–brain barrier

Seelig *et al.* found that a combination of surface activity parameters could distinguish the CNS+/CNS– of model compounds ([Figure 23](#)).<sup>160,161</sup> Before the in vivo relevance study, possible P-gp substrates were excluded from the probe data set.<sup>163,165</sup> A three-dimensional plot using  $K_{aw}^{-1}$ , CMC and  $A_s$  was found to distinguish CNS+/CNS– ([Figure 23](#)). In addition, compounds with  $pK_a < 4$  for acid and  $pK_a > 10$  for base were found to be CNS–, even if they were predicted to be CNS+ from the surface activity parameters.

Suomalainen *et al.* performed a similar study, but using only  $K_{memb}$  as a parameter.<sup>162</sup> They employed a multi-channel microtensiometer, and demonstrated the adaptability of this method to drug discovery.

#### 5.19.7.2.2 P-Glycoprotein

Seelig *et al.*<sup>163</sup> and Onishi *et al.*<sup>164</sup> suggested that surface activity parameters can predict P-gp activity. The rationale for this relationship is that a substrate accumulated in the membrane is transported by P-gp.<sup>166</sup> The  $\log K_{aw}$ – $\log 1/K_m$  plot yielded a straight line with the correlation coefficient of 0.95 ([Figure 24](#)).<sup>163</sup>

**Figure 23** Three-dimensional plot using  $K_{aw}^{-1}$ , CMC, and  $A_s$  to classify CNS +/–: closed circles, CNS–; open circles, CNS +; half-filled circles, hydrophilic compounds which are pharmacologically applied at low concentration and therefore appear as CNS–. See <sup>161</sup> for the assignment of compounds. (Reproduced from Fischer, Fischer, H.; Gottschlich, R.; Seelig, A. *J. Membr. Biol.* **1998**, 165, 201–211, with permission from SpringerLink.)

**Figure 24** Correlation between the air–water partition coefficient ( $K_{aw}$ ), determined from measurements of the surface pressure as a function of drug concentration (Gibbs adsorption isotherm) and the inverse of the Michaelis–Menten constant ( $K_m$ ) of P-gp substrates in a buffer solution (50 mM Tris–HCl, containing 114 mM NaCl) at pH 7.4. Compounds measured: progesterone (1), propranolol (2), amitriptyline (3), diltiazem (4), amiodarone (5), racemic verapamil (6), colchicine (7), gramicidin S, (8), daunorubicin (9), vinblastine (10), and cyclosporin A (11). (Reprinted from Seelig, Seelig, A.; Landwojtowicz, E. *Eur. J. Pharm. Sci.* **2000**, 12, 31–40, with permission from Elsevier.)

### 5.19.7.3 Advantages, Limitations, and Utility in Drug Discovery

Concentration determination (i.e., UV, HPLC, LC/MS, etc.) is not required for surface tension determination. A multichannel microtensiometer compatible with the 96-well plate format is commercially available from Kibron, Inc. This system enables a theoretical throughput of over 1500 compounds per day.<sup>162</sup> These features of the method are

advantageous for drug discovery. One limitation of this method might be the lack of surface activity for a subset of compounds.<sup>162</sup> Surface activity parameters have definitive physicochemical meaning related to membrane binding, therefore enabling straightforward interpretation.

## 5.19.8 Conclusion and Outlook

Since the mid-1990s, with the evolution of the drug discovery paradigm, several high-throughput technologies for passive membrane permeability assessment have been invented, accompanied by scientific progress in the field of the passive membrane permeation. Even though passive membrane permeation has been under investigation for over 300 years, since the time of Isaac Newton, the current state of the science and technology in this area indicates that there are still many questions to answer and technical issues to overcome. We have vast frontiers to explore in this area.

## Biography

**Kiyohiko Sugano** graduated from Waseda University (Department of Chemistry) in 1995, studying under Prof Masaru Tada (Organic Chemistry), and joined Chugai Pharmaceutical Co., Ltd. In 2002, he received his PhD from Toho University (Department of Pharmaceutics) under the mentorship of Prof Katsuhide Terada. In 2004, he joined Pfizer Inc. His main interests as a pharmaceutical industrial researcher are physicochemical properties, especially in relation to pharmacokinetics, preformulation studies, and structure–pharmacokinetics relationships.

### 5.20.1 Introduction: Needs and Scenarios

Chemical stability is not usually one of the highest priority issues on the minds of medicinal chemists during the effort to discover new drugs. Issues such as novelty, potency, and selectivity typically demand greater attention. Nevertheless, in recent years pharmaceutical research organizations have placed increasing emphasis on the study of compound properties. Physicochemical, metabolic, and pharmacokinetic properties have emerged as key determinants of success in drug discovery and development.<sup>1–5</sup> If the liabilities of a compound series can be identified and corrected during the lead optimization phase, then the development candidate is likely to be more successful. Chemical instability can result in significant liabilities for development candidates and discovery leads.

In development and clinical application, instability adds time and expense to the development of stable dosage forms. Decomposition causes problems with chemical processes and clinical batch release. It reduces the amount of drug delivered to the therapeutic target in living systems. Degradants may cause side effects and toxicity in patients.

In discovery, drugs are exposed to various conditions in the medicinal chemistry laboratory that can facilitate decomposition reactions. These include storage conditions in the solid or solution state, which expose the compound to oxygen and water from the air, light, elevated temperature, or various solution pHs. Basicity from glassware can catalyze reactions. Purification protocols may produce decomposition products, such as when high-performance liquid chromatography (HPLC) mobile phases that contain acid modifiers are evaporated. When compounds are placed in libraries for high-throughput screening (HTS), they are often plated in dimethyl sulfoxide (DMSO) solution and stored; exposure to oxygen or water from the air can induce decomposition and produce incorrect structure–activity relationship (SAR) during screening.

Instability can also occur in biological or property assay laboratories. This will misdirect the research efforts through inaccurate biological or property data, which leads to erroneous SAR for the chemical series. Compounds may be chemically unstable in the assay media by reacting with media components, or the pH of the media may catalyze hydrolysis. Reduction of the concentration of the putative compound will reduce the apparent activity. Decomposition products may have enhanced or reduced activity in the target activity assay or selectivity assays, compared to the putative compound. Series analogs can have different rates of decomposition due to their structural differences, which might be mistaken as real SAR. They can also produce false results from property assays. Compounds may not be active when dosed orally, owing to instability in the pHs or enzymes of the gastrointestinal system.

Several key chemical mechanisms lead to compound decomposition. These include hydrolysis, hydration, oxidation, and isomerization. As background, common destabilizing reactions are examined in this chapter. The potential reactions of a chemical series may be immediately obvious to the medicinal chemist, or they may be temporarily overlooked as higher priority issues take precedence in research.

To assist in screening for potential chemical instability mechanisms, several tools and methods have been developed and reported in the literature. These give the medicinal chemist tools to detect and study compound stability. At the simplest level, it is useful to be aware of common structural features that are susceptible to chemical instability. High to moderate throughput methods have been described for profiling a large number of compounds in a short period of time. These are consistent with the demands of modern drug discovery strategies. Customized methods may be designed to diagnose specific mechanisms for a compound series. Also, in-depth methods, which are adapted from development laboratories, are used to study the mechanisms and kinetics of reactions for a few selected late-stage compounds.

Having these tools in place allows medicinal chemists to efficiently and effectively deal with stability issues. A consistent pattern of modern drug research is to move the investigation of issues, which were traditionally studied during development (e.g., toxicity, metabolism, pharmacokinetics, stability), forward into the discovery period. This approach allows advancement of the highest quality candidates that have the lowest risk. Thus, modern discovery organizations have increasingly made the tools for these investigations available to medicinal chemists. With the many possibilities for chemical instability in drug discovery and development, vigilance and testing are reasonable considerations for medicinal chemists.

## 5.20.2 Chemical Aspects

### 5.20.2.1 Decreasing Chemical Instability

Care can be exercised in the chemical laboratory when handling compounds, in order to reduce chemical decomposition. Compounds can react with oxygen or water from the air. Solids are penetrated by gaseous molecules, especially at or near the surface of the particle and if the material is amorphous. Oxygen and water from the air dissolve in solutions and can react. To reduce these reactions, compounds can be stored under inert gas in sealed containers. Storage at reduced temperature decreases the rate of decomposition reactions. Reactions can also be induced by light in the laboratory. Therefore, they should be stored away from the light or in amber containers. Counter ions can react with the compounds, especially if they are strong acids or bases. Storage at reduced temperature may slow such reactions. Lipinski<sup>6</sup> has discussed the dissolution of water in DMSO solutions, which is also enhanced by freeze–thaw cycles that are common in biological testing laboratories. HTS scientists have, in recent years, taken steps to store DMSO testing plates for long periods of time at low temperature and under inert dry gas. However, when plates are transferred to the biological laboratory, they can be repeatedly taken in and out of the refrigerator, creating opportunities for dissolution of water from the air. Lipinski advises storing these plates at room temperature, if they are to be used within a few days. When compounds are purified by preparative HPLC, mobile phase components can react with compounds, especially if the solutions are concentrated on a rotary evaporator.

Compound testing for biological, physicochemical, metabolic, or pharmacokinetic properties always involves dissolution in aqueous solution. Care should be taken to insure that the compound is not unstable in the buffer. A prime

consideration is the buffer pH. Decomposition can also occur from reaction with assay buffer components in assay media used for in vitro enzyme, receptor and cell-based assays or for nuclear magnetic resonance (NMR) binding studies.

Decomposition reactions of functional groups commonly found in drugs are treated in detail in several texts and reviews.<sup>7-14</sup>

### 5.20.2.2 Decomposition Reactions

Chemical decomposition reaction mechanisms, kinetics, and their minimization are a primary focus of development pharmaceutical scientists.<sup>8-13</sup> However, insights from these extensive studies are important for medicinal chemists to keep in mind during the discovery phase.

#### 5.20.2.2.1 Hydrolysis

Hydrolysis has been observed for many drugs. This can occur for compounds that contain the functional groups: ester, amide, thioester, imide, imine, carbamate, acetal, alkyl chloride, nitrate, lactam, lactone, and sulfonamide.<sup>7-9</sup> Such reactions may be catalyzed by acidic solutions, basic solutions, or enzymes. General schemes for hydrolysis are shown in **Figure 1**. Two product fragments are formed unless the hydrolyzed group is part of a cyclic structure (e.g., lactam). Reaction rates are affected by the moieties attached to the hydrolyzable functional group<sup>7</sup> and they decrease with a decrease in dielectric constant.<sup>8</sup> Examples of hydrolysis include aspirin, which contains an ester and hydrolyzes to salicylic acid and acetic acid (**Figure 2**). Chloramphenicol, which contains an amide group, hydrolyzes to the corresponding amine and dichloroacetic acid<sup>8</sup> (**Figure 3**). Under basic conditions, penicillin G (I) hydrolyzes to benzylpenicilloic acid (II), which further decomposes to benzylpenilloic acid (III) and benzylpenicilloaldehyde (IV) plus carbon dioxide plus penicillamine (V)<sup>8</sup> (**Figure 4**).

Hydrolysis also occurs in vivo as compounds are exposed to endogenous hydrolase enzymes that occur in locations such as the intestine, blood, and liver. Hydrolytic metabolism is discussed elsewhere (*see* 5.06 Principles of Drug Metabolism 2: Hydrolysis and Conjugation Reactions). Hydrolases catalyze reactions of endogenous compounds and may have affinity for some drugs, thus increasing their hydrolysis rate. Testa and Mayer have extensively discussed hydrolytic drug metabolism in a volume that is very useful to medicinal chemists.<sup>7</sup>

The prodrug strategy makes use of in vivo hydrolases. Prodrugs (*see* 5.45 Drug–Polymer Conjugates) are derivatives of active drugs that are designed to improve a compound's liability, such as solubility or permeability, in order to improve oral absorption. After the functional group produces its desired effect (e.g., increasing intestinal solubility), in vivo enzymes cleave the functional group, typically by hydrolysis, to release the active drug.<sup>7</sup> In vitro assays are used to screen various prodrugs prior to in vivo study.

**Figure 1** General schemes for (a) acid-catalyzed hydrolysis and (b) base hydrolysis, where X is O, NH, NR', or S.

**Figure 2** Hydrolysis example: acetylsalicylic acid (Aspirin).<sup>8</sup>

**Figure 3** Hydrolysis example: chloramphenicol.<sup>8</sup>

**Figure 4** Hydrolysis example: penicillin G under basic conditions.<sup>8</sup>

#### 5.20.2.2.2 Hydration

A molecule of water may also be added to a structure without cleavage of a fragment. This reaction is termed hydration. One example is the hydration of an epoxide to form a dihydrodiol. These reactions can occur in laboratory solutions and can be catalyzed by enzymes.

#### 5.20.2.2.3 Oxidation

Oxidation occurs by way of free radical reactions.<sup>8</sup> Trace metal ions isolated with the compound material can catalyze oxidation. Light can initiate oxidation by free radical mechanism. In aqueous solution, pH and temperature affect the reaction rate. Many drugs are subject to autoxidation. Double bonds can be oxidized to hydroperoxides and then to aldehydes. Amines can form N-oxides and sulfides can form sulfoxides and sulfones. Benzylic sites, aldehydes, and ketones are also susceptible to oxidation. Dimerization can result from oxidation, such as for morphine at the phenolic oxygen, and captopril at the sulfide to form the disulfide (Figure 5). Such reactions primarily occur in aqueous solution. In the solid state, the presence of absorbed water at the solid surface can enhance oxidation. Oxidation mechanisms are complex. Furosemide, for example, is unstable in sunlight, forming several oxidized and reduced forms.<sup>9</sup> A major source of drug oxidation in vivo is metabolic enzymes (e.g., cytochrome P450). These greatly enhance the rate of oxidation (see 5.05 Principles of Drug Metabolism 1: Redox Reactions).

Photolysis involves the absorption of a photon of light to activate the molecule. This can lead to dissociation of the molecule or oxidation via a free radical mechanism. In solution, the photon may also be absorbed by a solution component, which in turn reacts with the drug compound. In the solid state, photolysis is confined to the surface of the particle. Photolytic reactions are possible for compounds having carbonyl, nitroaromatic, N-oxide, alkene, aryl chloride, sulfide, polyene, and weak C-H or O-H functional groups.<sup>13</sup> The photostability of drugs is treated in detail by Tonnesen *et al.*<sup>14</sup>

**Figure 5** Oxidative dimerization of captopril.<sup>8</sup>

**Figure 6** Base induced degradation of paclitaxel (I) in methanol to 7-epipaclitaxel (II), 10-deacetyl paclitaxel (III), baccatin III (IV), and side chain methyl ester (V).<sup>19</sup>

#### 5.20.2.2.4 Stereochemical conversion

Stereoisomers having instability at a stereogenic center can react to produce stereochemically modified forms.<sup>15–18</sup> This can be triggered by an adjacent group that decreases stability at the chiral center.<sup>15</sup> An enantiomer can irreversibly ‘racemize’ and reach the racemic mixture at equilibrium. It can also ‘enantiomerize,’ or reversibly interconvert to the other enantiomer. Diastereomers can ‘diastereomerize’ or ‘epimerize’ by conversion of an unstable stereogenic center. For example, paclitaxel (I) epimerizes in organic solutions under basic conditions at the 7 position (II) in addition to other decomposition reactions (Figure 6).<sup>19</sup> Thalidomide enantiomerizes at basic pHs and in solution with human serum albumin (likely due to catalysis by Arg and Lys residues).<sup>18</sup>

### 5.20.3 Considerations on Analytical Methods for Chemical Stability

#### 5.20.3.1 Choice of Stability Conditions to Monitor

The study of chemical stability requires analytical methodology. In considering what methods to implement or have access to, it is useful to consider the various stability challenges that compounds encounter in the laboratory, during in vitro testing and in vivo.<sup>3</sup> Even before testing, chemists can consider if these conditions could be anticipated to cause compound reaction.

In the laboratory, compounds are exposed to light, oxygen, and water. As compounds are stored in solid or solution form, they are exposed to fluctuations in temperature and relative humidity. These challenges are rigorously addressed when compounds reach development. Several references detail these stability conditions, including the US Food and Drug Administration (FDA) guidance documents to industry<sup>20,21</sup> and practical guides to their implementation.<sup>22</sup> FDA

**Table 1** FDA guidance on stability testing<sup>20,21</sup>

| <i>Chemical stability question</i> | <i>Stress test conditions</i>   |
|------------------------------------|---|
| Storage                            | 12 months at 25°C/60% relative humidity<br>6 months at 30°C/60% relative humidity<br>6 months at 40°C/75% relative humidity                             |
| Oxidation                          | High oxygen atmosphere  |
| Photolysis                         | D65/ID65 standard (or cool white fluorescent lamp), 1.2 million lux h and UV (320–400 nm); overall illumination $\geq 200$ watt hr m <sup>-2</sup> (UV) |
| Hydrolysis                         | A wide pH range   |
| Decomposition Structures           | Identity and chemical structure for mechanism of formation  |

documents define regulatory tests, but they serve as useful guides to conditions that cause decomposition of drugs and also serve as guides for test methodology. A summary of FDA guidance on stability testing is listed in [Table 1](#).<sup>20,21</sup> FDA tests usually focus on accelerated testing, which increases the rate of chemical decomposition using enhanced conditions (e.g., higher temperature) for the purpose of calculating kinetic parameters for the prediction of drug product expiration date. The terms accelerated testing and stress testing are used. FDA also emphasizes the importance of testing in open containers. This enhances air circulation. In discovery, the focus is on the drug substance in its various forms in short-term experiments. Development methods can be simplified for discovery stability studies.

During in vitro activity and selectivity testing, compounds encounter new challenges as they are exposed to aqueous solutions, mixed aqueous/organic solutions, and a range of pHs. Compounds can also assume various physical or equilibrium forms (e.g., aggregates,<sup>23</sup> micelles) that increase or decrease their apparent activity.

In vivo testing presents new challenges. Following oral dosing, compounds encounter the highly acidic environment of the stomach, which can be as low as pH 1–2. Compounds also encounter hydrolytic enzymes in the stomach, intestine, liver, and blood. These hydrolases have been used to advantage in the development of prodrugs.<sup>24</sup>

### 5.20.3.2 Quantitative and Qualitative Data Needs

The study of stability in support of medicinal chemistry utilizes two types of data, quantitative and qualitative. Quantitative data are derived from methods that measure the concentration of a compound at time points during incubation under a set of conditions that are designed to simulate a stability challenge. The data are used to compare analogs for their relative stability, resulting in structure–property relationships (SPRs), which is analogous to SAR. Medicinal chemists use this data to rank order compounds. It also assists with understanding whether stability is a major concern and with selecting compounds to go to the next stage, such as in vivo testing and advancement to development. Quantitative data are also used to determine the kinetics of the decomposition reaction. Kinetic rates are helpful in determining the extent of decomposition expected at key time points.

Additional insight is gained from qualitative data. This involves the identification of structures of the decomposition products of the reaction. Structures are very useful in determining the mechanism of the reaction. This in turn allows chemists to decide on strategies for structural modification to enhance chemical stability in subsequent analogs. In some cases, the decomposition products may be tested for activity and selectivity, in order to estimate potential efficacy complications. Toxicity testing may also be indicated in order to assess potential liabilities that may terminate the project if the decomposition cannot be eliminated. In these cases, material will need to be isolated for further testing. Structural information is obtained using HPLC, mass spectrometry (MS), and NMR techniques.

### 5.20.3.3 Appropriate Methods for Different Research Stages

While it is satisfying to have detailed data for every research question, modern drug discovery has continuously dealt with the need for cost efficiency. Therefore, a strategy has arisen: use an appropriate method for the question and stage of research. This requires tailoring the methodology to the situation. A three-tier strategy has proven to be useful.

#### 5.20.3.3.1 Tier one: high-throughput methods in early drug discovery

In early discovery, only milligram quantities of compounds are available for testing. Thus, methods must provide useful data from a small quantity of material. In addition, a typical research organization examines compounds from many research projects. These compounds have diverse structures, so the testing methods must be 'generic' and accommodate compounds of widely differing physicochemical properties. Discovery projects can produce thousands of compounds per year, so methods should have high capacity, often using robotics and well plate technology. Medicinal chemists also need data quickly. Current strategies call for property profiles to be produced at the same rate as biological data, which is typically a few days to 2 weeks. This allows the data to be included in decision-making along with activity data during the fast-paced stages of research. Finally, for efficiency, organizations need to select the highest priority properties to monitor at this stage. Thus, potential issues of stability must compete with other physicochemical and metabolic properties for inclusion in the property-profiling scheme.

#### 5.20.3.3.2 Tier two: diagnostic methods to answer specific questions

When specific questions arise regarding a compound series or an unexpected observation, it is useful to design specific diagnostic methods for targeted information. These methods usually deal with a smaller set of compounds and can still utilize milligram amounts of compound. Assay conditions are more specific than the generic screening methods discussed above. Turnaround time for the data may be increased in order to accommodate the more detailed conditions or experiment time periods. More time-consuming procedures, such as incubation protocols, or advanced analytical instruments, may be used. In many cases, the questions addressed with diagnostic assays are not covered by high-throughput methods. They arise because of a specific concern about a structural moiety in the molecule(s) or a specific question. The questions are not usually sufficiently generic to warrant testing of all compounds with high-throughput methods. Another application of these assays is to diagnose more complicated processes, such as bioavailability in vivo or decomposition in solution, by breaking the complex phenomenon down into individual properties that can be measured to pinpoint the specific cause.

#### 5.20.3.3.3 Tier three: in-depth methods to meet specific criteria

In late stages of discovery, organizations often impose criteria for advancement. For example, decision-makers may want to see a profile of the stability of a development candidate under a range of physical and physiological conditions. Specific methods have been devised in many organizations to obtain data under these specific conditions. Many of these methods are adapted from development methods, anticipating the testing and stability challenges that a drug will encounter in development. The methods often require a larger amount of material (tens to hundreds of milligrams for each test), longer times (weeks to months), and are performed in low throughput. Detailed quantitative, kinetic, structural, and mechanistic data and interpretations are provided.

Another useful application of this information, that is gathered during the drug discovery medicinal chemistry phase, is for drug development laboratories to anticipate issues they will face. For example, the chemical process research and development laboratory can anticipate conditions under which the compound will be unstable. They may need to avoid process steps that include exposure, of the compound to basic conditions, light exposure, or heating if the compound has been shown to be unstable under these respective conditions. The analytical research and development laboratory can anticipate the major degradants and conditions under which they will be formed, to assist their development of stability indicating HPLC methods. Pharmaceutical science laboratories can gain insights for initial studies on formulations for phase I clinical trials. Pharmacokinetics groups can learn whether compounds are unstable in plasma, which will affect the bioanalytical methods that are developed. Thus, stability data can be part of a comprehensive technology package that is transferred from the medicinal chemistry discovery department to development colleagues to accelerate the time-line leading to phase I studies.

### 5.20.4 High-Throughput and Diagnostic Chemical Stability Methods

In vitro assays are used to test compounds rapidly against key stability challenges. The following sections discuss methods to screen stability under physicochemical conditions in the chemical laboratory: solution pH, light, heat and humidity, and oxidation. Then methods for chemical stability in biological systems are discussed: biological assay matrices, and plasma and gastrointestinal.

#### 5.20.4.1 pH Stability

Compounds are exposed to various pHs in the laboratory, in biological testing, and in vivo efficacy and pharmacokinetics studies. The most generally applicable pHs for stability in earlier stages of drug discovery are pH 1–2, indicating stability in the stomach, pH 6.6, indicating stability in the small intestine, and pH 7.4, indicating stability in neutral assay buffers and body fluids. At later stages, a fuller profile of pH stability assures that all cases are covered.

Several methods have been described for pH stability profiling. For low sample throughput, it is usually sufficient to conduct the studies in small vials, such as HPLC autosampler vials. For higher throughput, 96-well plates are quite useful for incubating larger numbers of compounds in small quantities. It is advisable to protect the samples from light and control the temperature, which are both factors that will affect the reaction rate.

pH stability can be screened as part of a high-throughput process for several physicochemical properties, in order to get an overview of each new compound. For example, Kibbey *et al.*<sup>25</sup> reported an efficient instrumental method for screening chemical stability at multiple pHs, along with  $\log P$  and  $pK_a$ . Chemical stability was measured by overnight incubation at 100  $\mu$ M in pH 2, 7, and 12 buffers, and in 3% hydrogen peroxide (see oxidation stability below). Samples were incubated in 96-well plates. In methods of this type, low solubility should always be monitored, because of the large number of low solubility compounds that occur in drug discovery. Low solubility can cause erroneous results if the compound precipitates from solution. In this case, solubility was enhanced by using a solution of 50% acetonitrile and 50% aqueous buffer. Because organic solvent is likely to have an effect on reaction rate, due to the reduced dielectric constant, an alternative would be to lower the test compound concentration so that less organic solvent content is needed to solubilize the low solubility compounds. The method is also an example of incorporating robotics (Gilson 215 robot) for unattended operation, including automated addition of reagents and sample injection into an HPLC running a short mobile phase gradient cycle of 5 min. As in many higher-throughput methods, a classification system was used for data reporting on a scale of 1 to 5. This is because high-throughput methods often have lower precision and accuracy than would be desired for in-depth methods, so it is prudent to use data in ranges (sometimes called 'bins'). A method of this type has a throughput of up to 350 compounds per week. This method approach allows a widely applicable screen for stability across a wide pH range.

pH stability studies may be targeted to specific research questions, such as the prediction of in vivo absorption. For example, Caldwell *et al.*<sup>26</sup> reported using a stability assay at pH 2 as part of a preclinical compound property evaluation scheme. An in vitro pH 2 stability assay was run for 75 min (the mean human stomach residence time) to model stomach conditions. This data was combined with data on solubility at pH 2 to produce a 'liberation ranking,' which combines the effects of dissolution and stability. When compounds had stability at pH 2 that was greater than 50% and solubility that was greater than 0.1 mg mL<sup>-1</sup>, then a 'high' liberation ranking was predicted. This ranking was combined with other in vitro assays for absorption and metabolism to predict oral bioavailability classification prior to in vivo dosing.

pH stability studies can also be a part of the evaluation of prodrug designs, Nielsen *et al.*<sup>27</sup> performed pH stability studies over the range of pH 0.1–9.8 at 37 °C. The method description provides useful guidance on pH buffer preparation for pH stability studies. Buffers were prepared at 0.02 M concentration with: acetate (pH 5.0), phosphate (pH 3.0, 6.9, 7.4), borate (pH 8.5 and 9.75) and hydrochloric acid below pH 1.1. Constant ionic strength was maintained, because it affects reaction rate, by adding a calculated amount of potassium chloride. Several references are available for preparing buffers at different pH ranges, including *The Chemist's Companion*.<sup>28</sup> Test compound was added at 100  $\mu$ M. The test was run in an HPLC autosampler vial and samples of the supernatant were withdrawn at selected time points and immediately injected into an HPLC.

Studies may be conducted in microtiter plates for higher throughput. Kerns *et al.*<sup>29</sup> incubated test compounds in 96-well plates with 0.1 mL of HCl (pH 1) for 2 h to simulate acidic conditions in the stomach. After 2 h, 0.2 mL of phosphate buffer at pH 7.4 was added to adjust the pH and samples were analyzed by LC/MS. One problem with this approach is that compounds continue to sit in aqueous buffer for an undetermined time prior to injection into the HPLC. Even at or near neutral pH, compounds may continue to decompose and there is a 2–4 h time gap between injection of the sample in the first well of the plate and injection of the 96th sample in the last well, thus exposing different samples to decomposition for different time periods.

The problems of inability to quench decomposition and the time lag between analysis of samples in the same set may be eliminated with the method of Di *et al.*<sup>30</sup> The programmable injection and temperature control features of modern HPLC autosamplers were used to perform the stability experiment completely within the instrument. Samples were placed in a well plate in solution and the plate was placed in the autosampler. The autosampler was programed to add samples to stability matrix (e.g., buffers at various pH) at a preprogramed time. The solution was

**Table 2** pH Stability applications and methods

mixed using up- and downagitation of the injection needle and the sample was immediately injected for the time zero sample. The autosampler was maintained at a constant preset temperature between 0 and 40 °C and continued to inject aliquots of the sample at preprogramed time points. Multiple samples were analyzed simultaneously in the same manner, with the instrument tracking when to reinject each sample. In this manner, each sample was incubated for a specified time and did not sit for a variable time prior to injection. Furthermore, the experiment was conducted in an unattended mode. An overview of pH stability methods is found in [Table 2](#).

#### 5.20.4.2 Light Stability

Some compound series react when irradiated with light. This is a particular problem for topical drugs or drugs that accumulate in the skin. Outdoor light is the most intense, but indoor lighting in laboratories, pharmacies, clinics, and storage facilities can cause decomposition. Most organizations do not screen light stability for all compounds in high throughput. However, in selected cases there may be an interest in diagnosing light stability when it is suspected by an observation, or when the structure of the compound or historical information from analogous structures suggests the potential for instability in light. These tests are usually conducted under lights that simulate the wavelength spectrum and intensity of fluorescent lights. As indicated by the FDA guidance, the spectrum should cover the visible and near ultraviolet (UV) spectrum ([Table 1](#)). Care should be taken to control the temperature of the irradiated samples during the exposure, because they will tend to heat up under the lights and the rate of the photoinduced or other decomposition reactions may increase.

A traditional approach for studying photostability was described for RG 12915.<sup>31</sup> Compound in solution at 100 µg mL<sup>-1</sup> in pH 6.8 phosphate buffer, with NaCl added for an ionic strength of 0.2, was placed in a 2 mL borosilicate glass vial. The vial was held at 22–25 °C in the open air and was exposed to 180-foot-candle light from a daylight fluorescent light source. Aliquots were withdrawn for HPLC analysis on a time course experiment.

For diagnostic or higher-throughput methods a light box with the brand name Rayonette, model RPR-200 from Southern New England Ultraviolet Co. has been used to generate high-intensity light for accelerated stability assays.<sup>29</sup> These instruments are often used as photochemical reactors in the synthetic chemistry laboratory. Light bulbs with various wavelength spectra can be selected according to need. A 96-well plate can be accommodated within the light chamber on a shelf that can be cut out to expose the under side of the plate in addition to illumination from above. This allows higher throughput or studies of different sets of solution conditions (e.g., pH, mix of aqueous and organic solvents, ionic strength). For studies in drug discovery, exposure for 24 h at high intensity is usually sufficient to determine if a major photostability liability exists or to diagnose if photostability is the cause of an unexplained observation.

Photostability chambers that meet the FDA guidelines can be obtained from several manufacturers (e.g., Harris Weathering Products, Caron Products, Lunaire). The units are typically larger than what is needed for discovery

studies, but they are well designed and are reliable. Some groups have built their own smaller light chambers for late discovery applications. An engineering department can assist in measuring the intensity and spectrum of the light, because this is critical to the experiment and must be controlled. As light bulbs age, the intensity of their light tends to decrease and the spectrum of emission tends to shift; thus these should be monitored periodically. For these studies, the material is spread in a thin layer on an open dish to maximize surface exposure to light and air. International Conference on Harmonization (ICH) guidelines stipulate no more than a 3 mm depth. Alternatively, the samples can be tumbled in vials for uniform light exposure.<sup>13</sup>

Light-induced chemical reactions differ between the solid state and solution state and vary with solvent. Study conditions should best simulate the light exposure and solution state that the compound will receive in the discovery laboratory, process laboratory, or storage environment.

#### 5.20.4.3 Heat and Humidity Stability

FDA guidelines endorse the use of elevated temperature to accelerate chemical decomposition of drugs in the solid phase in order to simulate long-term storage. This suggests that, in discovery, elevated temperatures may be used to accelerate decomposition reactions in air that would normally require much longer times to develop. Reactions such as unimolecular decomposition, hydrolysis or oxidation with water or oxygen from the air, respectively, may be observed. A rule of thumb for the effect of temperature on reaction rate comes from the Arrhenius equation. For an average compound, reaction rate doubles for each 10 °C of temperature increase.

FDA guidelines<sup>20–22</sup> point out the importance of maintaining humidity in studies of solid materials. Heating in an oven will lower the relative humidity unless additional water is introduced. A commercial chamber that is designed for heat and humidity testing can best maintain humidity at established levels with little variation during heating. Such studies should at least be conducted for compounds being considered for development, in order to reveal any liabilities. In the solid state, compounds should have full exposure to air in an open vessel, by having only a thin layer or continuous agitation.

During drug discovery, heat and humidity stability studies may be performed to diagnose the possible causes of observed compound degradation, but are uncommon in high throughput. In late discovery, they provide estimates of the stability of compounds prior to development.

For the in-depth study of temperature, pH, and dielectric strength on chemical stability in solution, Shah *et al.*<sup>32</sup> described an integrated system that controls all of these variables for kinetics studies. A thermostated/heated reaction vessel surrounds the sample solution. Samples of the solution are taken at regular time points by sampling with a microdialysis probe that is placed in the solution. The microdialysis samples are automatically introduced into an on-line HPLC with UV detection for quantitation of the compound. Decomposition products could also be readily measured. Temperature control allows good kinetic analysis.

#### 5.20.4.4 Oxidation Stability

Oxidation experiments were performed by Won *et al.* by placing a 1 mg mL<sup>−1</sup> aqueous solution in a 100 mL volumetric flask in a constant 60 °C water bath with protection from light.<sup>31</sup> Samples were withdrawn at time points and analyzed by HPLC. Subsequent experiments were conducted with the addition of cupric sulfate (0.1 to 1 × 10<sup>−5</sup> M), to study the effect of metals, and at different pHs (2.1, 4.8, and 7.6), to study the effect of pH.

Oxidation has been studied by incubation with 3% hydrogen peroxide in pH 7.4 buffer for 10 min.<sup>33</sup> This method may be used in microtiter plates for high throughput. Hydrogen peroxide at 3% is a standard test that has been submitted to the FDA. It provides a convenient probe of labile substructures in the molecule. Some development laboratories prefer using an oxidation initiator and incubation under molecular oxygen at high pressure. This is because peroxide oxidation can follow a different pathway than oxygen oxidation, and there is no way to quench a peroxide oxidation, so it usually goes to completion.<sup>13</sup> Quantitation can be followed up with qualitative structural studies of the degradants, in order to better understand the oxidation site and mechanism.

Lombardo and Campos<sup>34</sup> recently discussed various oxidation-profiling methods and reported an instrumental method for rapidly assessing oxidative stability. The method was carefully studied and well developed and validated. Test compounds are diluted in aqueous buffer and injected into electrochemical cells (ESA, Inc.) of increasing voltage. The cells are designed to operate as HPLC detectors, so they are amenable to being on-line with HPLC separations. This allows individual sample components to be studied separately from impurities. The extent of oxidation at various voltages can be measured. Comparison of the oxidation potentials and extent of conversion permits rank ordering of compounds. Implementation of the method involves comparison to compounds of known oxidation liability. Oxidation stability methods are listed in Table 3.

Other researchers have previously used electrochemical cells to qualitatively study oxidative reactions. Coupling to a tandem mass spectrometry allows on-line structure elucidation of the oxidative products. Volk *et al.*<sup>35</sup> studied endogenous oxidative biochemical pathways. Jurva *et al.*<sup>36,37</sup> used this methodology to study the structures of oxidized drugs in an attempt to produce phase I metabolites. One-electron oxidations were observed, but oxidations via direct hydrogen atom abstraction were not observed.

These studies indicate the potential for rapid structural identification of oxidative reaction products.

#### 5.20.4.5 Buffer and Biological Assay Matrix Stability

Occasionally, unexpected or variable results are obtained from bioassays for enzyme/receptor binding or cell-based assays. Solubility may be a major cause of this, but, occasionally, stability in assay buffer may be the cause. Bioassay matrices may be at a pH at which some compounds are unstable, as discussed above, or they may contain components that react with some compounds. An assay using bioassay matrices is useful for diagnosing stability as a problem under these conditions.

The assay (above) of Di *et al.*<sup>30</sup> can also be used for this purpose. Instead of pH buffer, the sample can be added to biological assay matrix by the HPLC autosampler. This assay can be run with multiple time points to obtain kinetic data, or it can be operated with a single time point injection for high throughput.

It was previously shown<sup>38</sup> that a single time point method can be accurately run in drug discovery settings to assay large numbers of compounds when the reaction kinetics are first order. Three quantitative factors were examined: (a) half-life, (b) assay variability, and (c) the nonlinear relation of half-life to percent remaining for first-order kinetics. For short half-life (1–10 min) compounds, little compound remains unreacted when sampled at 30–60 min and half-life estimates would be of questionable value. In addition, resolution of significantly different quantitative values, which is needed for differentiating structure–stability relationships, is limited by the variability of the assay. There is insufficient resolution of unstable compounds when sampling is performed at late time points. Conversely, stable compounds with half-life greater than 30 min are not resolved using samples obtained at early time points (5–10 min). The method variability sets the resolution of calculated half-lives, based on statistical confidence. As a general guide, single-point sampling at 15 min permits resolution of compounds with low stability and allows statistically significant half-life calculation up to about 30 min. If the compounds are all more stable and the desired upper range of half-life resolution is higher than 30 min, then the single time point for sampling should be adjusted upward. This study provides a foundation for selecting a single time point for sampling in higher-throughput methods. At the higher-throughput level, single time point screening allows rapid throughput for a large number of compounds. When greater detail is needed, the method can be repeated for a smaller number of selected compounds and more time points can be obtained for more detail for making decisions. For high-throughput methods, instead of fitting a line by regression, the quantitative values from time zero and after incubation (e.g., time equals 3 h) can be used with the linear rate equation to calculate the half-life. More time points simply add more precision and accuracy to the measurement. The single time point approach is very effective for efficiently screening a large number of compounds in drug discovery.

#### 5.20.4.6 Plasma and Gastrointestinal Stability

Hydrolytic enzymes in the blood can be responsible for compound degradation in vivo and result in higher clearance and reduced in vivo pharmacokinetic half-life. Incubation of test compounds with plasma is more convenient than

incubation with blood and can reveal the potential for decomposition in the blood stream (*see* 5.10 In Vitro Studies of Drug Metabolism).

A moderate-throughput plasma stability assay was described by Wang *et al.*<sup>39</sup> It uses an HPLC autosampler to incubate the compounds in plasma. Plasma samples are much more complex than aqueous buffers and usually require some type of cleanup prior to MS analysis, because of interference by plasma to proper ionization of the test compound in the MS ion source. Wang demonstrated that this problem could be solved, by using a mixed function HPLC column (Capcell MF C8) to separate the major plasma components from the test compounds, prior to the mass spectrometer. The major plasma components, that would produce interference and rapidly build up in the ion source, causing reduction of signal generation, are diverted to waste as they elute early from the HPLC column. The MS/MS instrument can be operated in the multiple reaction monitoring (MRM) mode to selectively and sensitively detect the test compound.

Plasma is often used as a surrogate for blood in studying prodrugs in vitro prior to in vivo studies. Nielsen *et al.*<sup>27</sup> incubated prodrug compounds with human plasma and simulated intestinal fluid (SIF). Plasma was prepared at 4:1 (v/v) with 67 mM phosphate buffer at pH 7.4. Samples were incubated at 37 °C. At selected time points, sample was withdrawn and mixed with 2 volumes of acetonitrile to precipitate the protein, followed by centrifugation (14 500 rpm for 5 min), a common technique in the analysis of plasma samples. The centrifugate was diluted 1:1 with mobile phase and injected onto the HPLC.

An optimized high-throughput method was developed and reported by Di *et al.*<sup>40</sup> It was shown in earlier studies on liver microsome stability<sup>41</sup> that assay conditions can greatly affect the results. The present studies showed that plasma, instead, has a high catalytic capacity and can tolerate a range of incubation conditions. Approximately, the same rate of decomposition occurred at test compound concentrations from 0.5  $\mu$ M to 20  $\mu$ M, at dilutions of plasma in pH 7.4 buffer from undiluted to 1:4 (100% to 20% plasma), in the presence of DMSO from 0.5% to 5% and for incubation times up to 22 h. The final selected incubation conditions for plasma degradation studies were: 1  $\mu$ M compound concentration, 50% plasma in pH 7.4 buffer, 2.5% DMSO and 3 h incubation. Dilution of plasma in buffer allowed pH stabilization of the plasma and reduced viscosity for improved liquid handling. Considerable plasma batch variation was observed, indicating the need for quality control (QC) samples and testing of each new batch before it is used in analysis. Conditions can be adjusted (e.g., time of incubation) to achieve the same QC results from batch to batch. Incubations were in 96-well plates and LC/MS/MS was used for quantitation, allowing a throughput of up to 10 samples h<sup>-1</sup>. Incubates can also be analyzed qualitatively using LC/MS and LC/MS/MS to identify the reaction products. This aids in planning synthesis of more stable analogs. It was suggested that the method can be used to obtain an early alert to labile substructural motifs, prioritization of compounds for in vivo studies, screening prodrugs, and the structural identification of hydrolytic products. Plasma stability methods are listed in Table 4.

It is crucial to remember that plasma from different species can produce different rates of hydrolysis.<sup>40</sup> When performing in vitro experiments in order to predict in vivo hydrolysis, the same species and strain of plasma should be used as in the in vivo efficacy model.

Additional insights are gained from incubating compounds with simulated gastrointestinal fluids. These consist of simulated gastric fluid (SGF) and SIF. The components of these mixtures are specified in the United States Pharmacopoeia (USP). SGF and SIF contain hydrolytic enzymes from successive portions of the gastrointestinal tract to which drugs are exposed.

**Table 4** Plasma stability applications and methods

| <i>Tier</i> | <i>Conditions</i>  | <i>Application</i>     | <i>Method</i>                                      | <i>Throughput per week</i> | <i>Reference</i> |

#### 5.20.4.7 Stereochemical Methods

Many of the previous sets of conditions can produce stereochemical inversions. Owing to the different pharmacological and toxicological properties of stereoisomers, there will be cases when it is important to determine the stereochemical effects of conditions to which the compound is exposed. A number of chiral analytical methods are available for this purpose. Diastereomers can usually be separated using standard reversed phase HPLC methods. Enantiomers usually require special chiral HPLC phases. It is necessary to have the racemate material to be assured of resolution and it is necessary to have each purified enantiomer to be assured of the peak assignment. Chiral separation methods are also available that utilize chiral gas chromatography phase, supercritical fluid chromatography and capillary electrophoresis. Chiral shift reagents can be used with NMR. An 'indirect' NMR method uses deuterated water to substitute for the mechanism of the chiral interconversion,<sup>18</sup> which has been shown to follow the same mechanism. This has the advantage of not requiring purified enantiomers and can be used for reactions that are too rapid for other methods.

### 5.20.5 Low-Throughput In-Depth Chemical Stability Methods

#### 5.20.5.1 Pharmaceutical Solution and Solid State Stability

Advancement of a compound to development requires an in-depth data package, which examines the major issues that indicate development success or potential liabilities. Chemical stability is a standard requirement of such reviews. The methods used need not be as rigorous as those used in development for regulatory filings, but they parallel the development protocols in order to indicate consistent trends. Examples of in-depth conditions for chemical stability examination may include the following:

- Aqueous buffers (37 °C, pH 1–12)
- Simulated intestinal fluid (USP, 37 °C, 1–24 h)
- Simulated gastric fluid (USP, 37 °C, 1–24 h)
- Simulated bile/lecithin mixture (37 °C, 1–24 h)
- Human plasma (37 °C, 1–24 h)
- High-intensity light (room temperature, 1–7 days)
- Heat (30–75 °C, 1–7 days).

Tests over a prolonged time reveal trends and kinetics of chemical decomposition. For solution-based studies, vials for each condition can be prepared and placed into an HPLC autosampler, which can be programed to inject samples at specific time points. This eliminates the need to quench the reaction, which can be difficult. Multiple time points are sampled in order to enhance the statistical accuracy, indicate the order of the reaction and calculate the kinetics. Cosolvent may be necessary to completely dissolve low-solubility compounds; however, it is important that these not be reactive, such as alcohols would be in hydrolysis of carboxylic acid derivatives. The information is also useful for providing development departments with initial data to start to their work.

#### 5.20.5.2 Structure Elucidation of Chemical Decomposition Products

The identification of decomposition product structures can be considered a diagnostic or in-depth method. An example of degradants identification was described by Volk *et al.*,<sup>19</sup> in the study of degradants of paclitaxel when it was exposed to various conditions. Paclitaxel was treated with methanolic/aqueous Na<sub>2</sub>CO<sub>3</sub> at pH 8 for 10 min to produce accelerated basic pH stress. It was also treated with HCl at 0.7 M for 4 h to simulate acidic stress. Hydrogen peroxide in buffer at 3% produced an oxidative stress. Finally, solid drug was exposed to 1000 foot-candle intensity light for 92 days to produce a light stress. These conditions were selected based on experience with paclitaxel and with common procedures in early development. LC/MS in the full scan mode was used to separate and determine the molecular weights of the decomposition products. Then, LC/MS/MS (tandem quadrupole instrument) in the product ion mode was used to obtain fragment ions from which the structures of the reaction products were identified. Nine major decomposition products were identified. Treatment of paclitaxel (I) with base in the presence of methanol (Figure 6) resulted in cleavage of the side chain to produce the sidechain methyl ester (V) and the baccatin III core (IV), as well as 7-epipaclitaxel (II) and 10-deacetyl paclitaxel (III). Acidic treatment produced 10-deacetyl paclitaxel. Under light (Figure 7), a C3–C11 bridged paclitaxel isomer (VI) and oxetane ring opened paclitaxel (VII) were formed. Isolation and NMR were necessary to determine the acyl migration. The structures of three minor degradants resulting from loss

**Figure 7** Light induced degradation of paclitaxel (I) to C3–C11 bridged paclitaxel (VI) and oxetane ring opened paclitaxel (VII).<sup>19</sup>

of CO from paclitaxel following light treatment could not be definitively determined using LC/MS/MS. The portion of the work involving LC/MS/MS analysis and structural interpretations was performed in less than one day. Other examples of drugs for which rapid identification of drug degradants by LC/MS/MS techniques were used include cefadroxil<sup>42</sup> and butorphanol.<sup>43</sup>

Following LC/MS studies, any unresolved structural details typically require NMR. Individual decomposition products can be readily isolated in sufficient quantity (20–50  $\mu\text{g}$ ) by fraction collection from HPLC. While LC/NMR can be used, isolation for NMR allows long-term NMR data acquisition and two-dimensional NMR spectroscopy for enhanced structural evidence.

In another example, two major degradants of risperidone were identified using LC/MS/MS (two-dimensional ion trap instrument), along with isolation and NMR.<sup>44</sup> Samples were prepared by incubating the compound in: acid (0.5 N HCl, reflux, 3 h), base (1:1 v/v of 0.1N NaOH:methanol, reflux, 3 h), oxidizer (3%  $\text{H}_2\text{O}_2$  in methanol, 1 h). Two major degradants were identified: 9-hydroxy risperidone and risperidone *N*-oxide (piperidyl).

Identification of degradants provides several opportunities. Structural identities enable the modification of structures during lead optimization, in order to enhance chemical stability. The degradant compounds can be obtained through synthesis and used as quantitative standards in monitoring stability studies during development. Such material can also be used to check the toxicity or reactivity of the degradants. Knowing the identities of the decomposition products allows a kinetic study of the appearance and disappearance of individual products, so that the mechanisms of formation and further reaction may be better understood.

#### 5.20.6 Applications of Stability Information in Medicinal Chemistry

Chemical stability data can assist medicinal chemistry in many ways. Overall, the data are part of the comprehensive data package that is used for decision-making that affects selection and redesign of structures.

The data can be effectively used in selecting compounds to move to the next level of investigation. For example, in one research program over 200 analogs were synthesized and screened for *in vitro* activity as well as physico-chemical and metabolic properties. The most significant differentiation among compounds was found in the *in vitro* activity and plasma stability. Compounds that were unstable contained peptide bonds. Thus, the plasma stability data were useful in selecting compounds that would be stable *in vivo* in the bloodstream during *in vivo* activity studies. In another program, compounds were screened for their stability in SIF and SGF, because of the presence of esters and amides. This provided predictions of compounds that were expected to be stable *in vivo* in the gastrointestinal tract.

Another application of stability data is in the optimization of structures. Structure–stability relationships can be developed that indicate how the structure may be modified to improve stability in plasma. Figure 8 indicates the structure–stability relationships of a series from a human cytomegalovirus (HCMV) protease program.<sup>45</sup> It was observed that increasing the steric hindrance and increasing the electron withdrawal at the lactam result in improved stability. An analog was found that balanced activity and stability.

Figure 9 provides another structure–stability relationship example.<sup>45</sup> The stability against SN1 hydrolysis at pH 1 was improved by electron withdrawing R groups. Pharmacological activity was maintained, while the structural modification improved acid stability.

Stability data can also assist with understanding the kinetics of a reaction and the conditions to avoid when processing or storing the compound. Figure 10 shows the pH–stability relationships of a beta lactam antibiotic using the HPLC autosampler method<sup>30</sup> described above. Such information can be used during lead optimization to diagnose the source of observed inconsistencies and during late discovery to anticipate storage stability of compounds.

Nielsen *et al.*<sup>27</sup> used pH, plasma, and SIF stabilities to screen *N*-acyloxymethyl prodrugs of bupivacaine and lidocaine. The prodrug moiety provided a quaternary amine to enhance solubility in the gastrointestinal tract. The prodrug was then cleaved at the brush border of the intestine, in order to produce a supersaturated solution at the surface of the gastrointestinal membrane to enhance permeability. Study of the rates of conversion in vitro provided a proof of the concept in advance of in vivo pharmacokinetic studies.

Compounds may also be screened for stability in biological assay buffer. An entire plate of compounds can be assayed in a matter of hours using a single time point experiment, in order to detect if there is a potential problem with stability

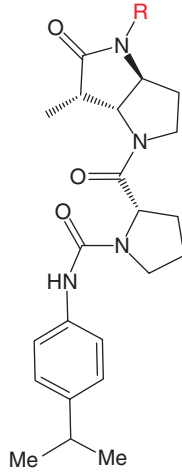

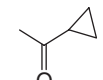

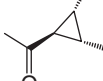

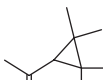

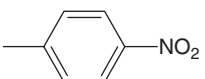

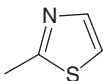

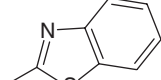

| Effect of steric hindrance of the lactam carbonyl                                   |   |                                      |                       |                     |
|---|---|--------------------------------------|-----------------------|---------------------|

**Figure 11** A possible strategy for stability profiling in drug discovery.

and to diagnose if poor activity was due to instability in the assay medium. For biological assays, inconsistencies can be diagnosed retrospectively using such an approach.

As projects approach development candidate selection, predevelopment pharmaceuticals departments begin preparations by developing a 'stability indicating method.' This is an HPLC method that is likely to separate all of the chemical decomposition products that are likely to be observed in development stress testing. Rao *et al.*<sup>46</sup> described the development of a stability indicating method for rivastigmine. To provide test samples, they incubated the drug under the following conditions: light (254 nm, 10 days), heat (60 °C, 10 days), acid (0.5 N HCl, 48 h), base (0.5 N NaOH, 48 h), and oxidation (3% H<sub>2</sub>O<sub>2</sub>, 48 h). This insures that the method separates key potential impurities and degradants.

## 5.20.7 Conclusions

Chemical stability is important to consider in the comprehensive assessment of pharmaceutical properties, activity, and selectivity during drug discovery. There are many sources of guidance on what chemical stability issues are a concern: medicinal chemistry experience, FDA guidance, and issues that occur during the research project. Methods can be implemented or customized with high, moderate, or low throughput, to meet the needs for the number of samples, and depth of data needed. Both quantitative and qualitative data may be obtained for answering various questions.

For a drug discovery program, it may be useful to decide how and when to study different stability challenges. The scheme in Figure 11 provides one approach. In early research, the focus is on finding a diverse set of structures that produce sufficient activity to indicate their future potential. It is important at this stage to insure that the compounds will be stable under laboratory handling and biological assays, thus, pH and bioassay buffer become important conditions to test for stability. After this stage, the series scaffold is locked in and these studies serve to insure that the scaffold is stable. During lead optimization, the focus is on in vivo stability as oral dosing and in vivo efficacy studies are planned. Thus, screening for metabolic and plasma stability are important during optimization. At this stage, stability may be modified by chemical modifications to the scaffold. During candidate selection for development, a series of stability challenges that are indicative of drug storage problems, can be employed. This insures that the candidate meets established criteria for advancement.

It is useful to establish the rate of crucial stability reactions. If the half-life is on the order of minutes or hours, then there will be an effect on the 'pharmacological timescale' and this affects activity in vivo. If the half-life is on the order of months or years, then there will be an effect on the 'pharmaceutical timescale' and this affects formulation and storage conditions.<sup>15</sup>

Chemical stability profiling as part of medicinal chemistry provides several opportunities:

- Select quality leads for optimization that have stable scaffolds and few liabilities
- Diagnose the cause(s) of unexpected observations or inconsistent results
- Modify structures to enhance stability of a lead series
- Better plan and interpret biological, metabolic, and physicochemical studies
- Select among compounds for crucial studies, such as in vivo efficacy and pharmacokinetics
- Provide data that accelerates early development activities
- Avoid candidates that shift a burden to development in time, expensive packaging and storage, or short expiration dates.

Integration of physicochemical properties, such as chemical stability, into the entire data package available to medicinal chemists, helps to make the drug discovery process more successful in producing high-quality clinical candidates.
