require more expertise; it requires more powerful computer hardware and software; and it requires additional hard disk space. This means that a user should normally run the lowest dimensionality experiment that answers the question at hand. It is usually found in practice that the six disciplines of drug discovery use these multidimensional NMR techniques differently. Medicinal chemists, combinatorial chemists, drug production and quality control groups, and, to a lesser extent, metabolism groups usually use 1D NMR data to get most of their structural information. Medicinal chemists usually need only to confirm a suspected structure, and rarely use 2D NMR. Drug production and quality control groups will use 2D techniques if they encounter a tough enough problem. Combinatorial chemists might like to have 2D NMR data, but they do not have the time to acquire it, whereas metabolism chemists would often like to get 2D NMR data but do not have enough samples. Natural products chemists routinely depend on 2D NMR techniques to unravel their total unknowns. Rational drug design groups use 2D and 3D (and sometimes 4D) NMR techniques routinely.

2.12.18.2.2 High-field nuclear magnetic resonance

Multidimensional NMR was developed to simplify complex NMR spectra. Another way to simplify a complex or overlapped NMR spectrum is to place the samples in higher field-strength magnets to generate more dispersion along each axis. This helps resolve overlapping signals and simplifies second-order multiplets, while at the same time increasing NMR sensitivity. These benefits have driven magnet technologies to improve to the point where magnets having proton resonance frequencies of 800 MHz (18.8 T) are now routinely available. The disadvantage of these very high-field magnets is that they are much more expensive. (They primarily cost more to purchase, have higher installation and operational costs, especially for cryogenics, and require bigger rooms with more sophisticated environmental controls.) These additional costs must be weighed against the time that can be saved by the improved performance, and both factors are balanced against the difficulties of the problems encountered. In practice, field strengths of 14.1 T (600 MHz) and above are routinely used in rational drug design programs, and occasionally in metabolism programs (due to their limited sample sizes). Natural products groups, and some drug production and quality control groups, usually use 400–600 MHz systems, while combinatorial chemistry, and especially medicinal chemistry groups, tend to use 300–500 MHz systems.

Improvements in magnet and shim coil technologies are also allowing the homogeneity of the magnetic field to be improved. This has allowed line shape to be cut in half over the last 15 years, and has improved the quality of solvent suppression in the NMR spectra of samples dissolved in fully protonated solvents.

2.12.18.2.3 Broadband decoupling

Another way to simplify spectra is to use heteronuclear decoupling.⁸⁸² This both collapses a coupled multiplet into one single frequency, and (through other mechanisms) produces taller resonances. Decoupling can also increase the sensitivity of certain X nuclei (e.g., ^{13}C) through nuclear Overhauser enhancements. In some triple-resonance experiments (discussed later), heteronuclear decoupling improves sensitivity by eliminating some undesirable relaxation pathways.

Although decoupling is generally desirable, the first available methods caused too much sample heating to be of routine use. More efficient decoupling schemes were eventually developed that produced a wider bandwidth of decoupling for a given amount of power. Starting from CW (unmodulated) decoupling, wider decoupling bandwidths were obtained with the development of noise – WALTZ, MLEV, XY32, TYCKO, GARP, and DIPSI decouplings (not necessarily in this order).^{882,883} These modulation schemes allowed decoupling to become quite routine and allowed new techniques, such as indirect detection (discussed below), to become practical. As knowledge of shaped pulses improved (discussed below), ever more efficient decoupling schemes such as MPF1-10,⁸⁸⁴ WURST,⁸⁸⁵ and STUD⁸⁸⁶ were developed; the last two by using advanced pulse shapes called adiabatic pulses.⁸⁸⁷ No decoupling scheme is perfect for all applications or even for all field strengths. Each scheme provides a different balance of performance in terms of bandwidth per unit power, minimum linewidth, sideband intensity, complexity of the waveform (what hardware is needed to drive it), and tolerance of mis-set calibrations ('robustness'). The advantage of all these developments is that there is now a large set of different decoupling tools that are available to be used as needed.

2.12.18.2.4 Spin locks

Better theories and understanding of spin physics resulted from advances in broadband decoupling, and this allowed better spin locks to be developed. Spin locks were initially designed for experiments on solid state samples, but in the 1980s it was shown that spin locks could also be used for solution state experiments. Bothner-By and co-workers used a CW spin lock to develop the CAMELSPIN experiment (later known as rotating-frame Overhauser enhancement

spectroscopy (ROESY)) to get dipolar coupling (through-space) information.⁸⁸⁸ Other groups subsequently reported the use of both lower radiofrequency (RF) field strengths⁸⁸⁹ and pulsed spin locks⁸⁹⁰ to improve the quality of the ROESY data. Braunschweiler and Ernst used a spin lock to develop the homonuclear Hartmann–Hahn experiment (HOHAHA; later known as TOCSY), which provides a total scalar-coupling correlation map.⁸⁹¹ Bax and Davis showed that the MLEV-16 modulation scheme, used for broadband decoupling (discussed above), improved the quality of TOCSY data.⁸⁹² Kupce and co-workers built on their experience with adiabatic pulses to improve decoupling schemes to develop a spin lock using adiabatic pulses.⁸⁹³ As discussed later, these spin locks are proving useful in obtaining TOCSY data on MAS samples. This is helping combinatorial chemists acquire better data on SPS resins. The hardware required to run spin-locked experiments is now routinely available, and these experiments usually provide better and more complete data than alternative experiments such as COSY.

The typical use of a spin lock is as a mixing scheme to allow the spins to exchange information. This is how they are used in TOCSY and ROESY experiments. However, spin locks have also been used to destroy unwanted magnetization. For this application, the pulse sequence is usually written so that the spin lock only affects resonances at a specific (selective) frequency.⁸⁹⁴ This allows them to be used to perform solvent suppression experiments for samples dissolved in protonated solvents (e.g., H₂O). Non-frequency-selective spin locks have also been used to destroy unwanted magnetization.⁸⁹⁵ This use of a spin lock as a general purge pulse is a viable alternative to the use of homospoil pulses,⁸⁹⁶ and is in routine use.

The spin physics of the decoupling and spin lock sequences are related, and any given modulation scheme can often serve both purposes. In general, however, the sequences are usually optimized for only one of the two applications. Hence, MLEV-16, MLEV-17, and DIPSI are most commonly used as spin lock sequences, whereas WALTZ, GARP, WURST, and STUD are most commonly used as decoupling schemes.⁸⁸²

2.12.18.2.5 Shaped pulses

In addition to new decoupling and spin lock schemes, shaped RF pulses have also been developed. They are called ‘shaped pulses’ because all of these pulses change amplitude, phase, or frequency (or some combination) as a function of time.⁸⁹⁷ In doing so, the pulse can be designed to be more frequency selective, more broadbanded in frequency, more tolerant of mis-set calibrations, or capable of multifrequency or off-resonance excitation. Different applications require different balances of these characteristics.

If a pulse is made more frequency selective, it can be used in a variety of new applications. One application is ‘dimensionality reduction,’ in which a selective 1D experiment is used in place of a 2D experiment, or a selective 2D experiment is used in place of a 3D experiment. Selective experiments let you obtain a selected bit of NMR information faster and with a higher signal-to-noise ratio – but only if you already know what you are looking for. This can be useful for studying smaller amounts of samples (or more dilute samples), as is often required for natural products. Examples include the use of 1D COSY,⁸⁹⁸ 1D TOCSY,⁸⁹⁹ 1D NOE,⁹⁰⁰ DPGFSE-NOE (also sometimes erroneously called GOESY),^{901,902} 1D HMQC (also called SELINCOR),⁹⁰³ 1D HMBC (also called SIMBA),⁹⁰⁴ and 1D INADEQUATE.⁹⁰⁵ These sequences are less useful if you have many questions to be answered or do not know what you are looking for. Then, it is usually advantageous to go ahead and run the complete 2D or 3D experiment and analyze it as completely as is required to solve the problem at hand.

Another use of selective pulses is to perform frequency-selective solvent suppression. Presaturation is the simplest example of the use of a frequency-selective pulse for solvent suppression (although the pulse used in presaturation is typically not shaped). Examples of frequency-selective shaped pulses that are used in solvent suppression include the S and SS pulses,⁹⁰⁶ Node-1,⁹⁰⁷ and WET.⁹⁰⁸ Note that although many commonly used water suppression sequences, such as 1331⁹⁰⁹ and WATERGATE,⁹¹⁰ are frequency selective, they achieve that selectivity by using a train of nonshaped pulses, in the so-called DANTE technique,⁹¹¹ instead of using shaped pulses. (The DANTE technique permits the use of simpler hardware but results in a less accurate frequency profile.)

Historically, the primary application of solvent suppression was to obtain spectra of biomolecules (proteins, RNA, etc.) dissolved in H₂O:D₂O mixtures. However, more recent work, especially on direct-injection NMR (discussed below), indicates that it is now practical to obtain ¹H NMR spectra of organic samples dissolved in fully protonated nonaqueous solvents. This is being used especially in combinatorial chemistry to obtain ¹H NMR spectra on samples dissolved in DMSO-*d*₆, CHCl₃, and aqueous solutions of CH₃CN and CH₃OH.

Frequency-selective pulses can also be used for narrowband selective decoupling. Such pulses can be placed in evolution periods to simplify spectra.⁹¹²

Not all shaped pulses are frequency selective (narrow bandwidth). In recent years, there have been many fine examples of the use of both band-selective and broadband-shaped pulses. Sometimes, these are used as single RF

pulses, but more typically they have been used in decoupling schemes designed to hit either a selected, controlled, moderately wide region, or a very broadband region. A well-known example of band-selective pulses is the use of pulses⁹¹³ or decoupling schemes^{914,915} to treat carbonyl-carbon resonances differently from aliphatic-carbon resonances in triple-resonance experiments (discussed below). Here, band-selective pulses are pulsing or decoupling regions of the spectrum that are from 1 kHz to 4 kHz in width. Applications using adiabatic pulses that are region selective have also been described.^{916,917}

The use of shaped pulses that affect very wide (broadband) regions of a spectrum is also becoming more popular. Most of these examples exploit adiabatic pulses.⁸⁸⁷ There are three advantages to using adiabatic pulses. First, they are uniquely capable of creating a good excitation profile over a wide frequency region. Second, they deposit less power into a sample (and hence cause less sample heating) for a given bandwidth than most other pulses. Third, they are quite tolerant of mis-set calibrations. This feature was originally exploited in applications that used surface coils – to compensate for the characteristically poor B_1 homogeneity of these coils – but some groups use this feature to simply make routine solution state NMR spectroscopy more robust and less sensitive to operator calibration errors. Adiabatic RF pulses are being used in high-field ^1H – ^{13}C correlation experiments (e.g., HSQC) to achieve wider and more uniform inversion over the wide ^{13}C spectral width.^{885,918} Adiabatic pulses are also being heavily used to create more efficient and wider bandwidth decoupling schemes (as discussed above in [Section 2.12.18.2.3](#)). Both of these applications are being used to facilitate high-field NMR spectroscopy of biomolecules.

One of the final tools in the shaped-pulse toolbox is the shifted laminar pulse (SLP),⁹¹⁹ which is sometimes (imprecisely) called a phase-ramped pulse. SLPs deliver their effects off-resonance without changing the transmitter frequency. (It is undesirable to change the frequency of a frequency synthesizer during a pulse sequence because this affects the phase of the transmitter.) SLPs that affect only one off-resonance frequency change phase linearly as a function of time; hence, the alternative name ‘phase-ramped pulses.’ SLPs that affect two (or more) off-resonance frequencies are both phase and amplitude modulated due to the interaction of the two different phase ramps. SLPs can be created to affect any number of frequencies (as long as enough power is available). They can also be created using any pulse shape or duration (or combination of shapes and durations). This means, for example, that an SLP can be made to hit three different frequencies, each with a different pulse width, and each with a different pulse shape (or phase) if desired. We will see later (in the discussion on LC–NMR – [Section 2.12.18.3.5](#)) how SLPs are being used to obtain multiple-frequency solvent suppression using only one RF channel.

2.12.18.2.6 Indirect detection

The development of indirect detection has probably had a bigger impact on all stages of drug discovery than any other NMR technique. Indirect detection is one of two methods for acquiring heteronuclear correlation data. The conventional method for acquiring 2D heteronuclear correlation data – called ‘direct detection’ and exemplified by the HETCOR experiment described above – measures a series of X nucleus spectra (typically ^{13}C) and extracts the frequencies of the coupled nuclei (typically ^1H) by using a Fourier transform in the t_1 dimension. The concept of indirect detection, first published in 1979,⁹²⁰ inverts the process by acquiring a series of ^1H spectra, then Fourier-transforming the t_1 dimension of this data set to (indirectly) obtain the X (^{13}C) frequencies.^{876,877} The major benefit of using indirect detection is improved sensitivity – up to 30-fold or more, depending on the nuclei involved.

In hindsight, indirect detection seems like an obvious development, but because the instrumental requirements of running indirect detection are more demanding (two-scan cancellation, broadband X nucleus decoupling, indirect-detection probes designed for water suppression), the method did not become truly routine until more than a decade later. They do not completely replace X-detected correlation experiments (which have superior X nucleus resolution), but these ^1H -detected experiments are now the default for most users. When sensitivity is an issue, the indirect detection version of an experiment is usually used.

There are three classic indirect-detection experiments: HMQC, HMBC, and HSQC. HMQC and HSQC detect one-bond H–X couplings, whereas HMBC detects long-range H–X scalar couplings. HMQC uses a multiple-quantum coherence pathway, while HSQC uses single-quantum coherence. HMQC was technically easier to run in the early days, but because the B_1 homogeneity of most NMR probes has improved since then, HSQC is now a better tool for most applications. Virtually all modern biomolecular experiments, and many natural product experiments, currently use HSQC-style (rather than HMQC-style) coherence pathways.^{921,922} HMBC is the primary tool for de novo structure elucidations of small molecules, particularly for natural products.^{923–927}

A big advantage of indirect detection is its increased sensitivity. A big disadvantage is its cancellation noise. Because only the ^{13}C satellites of a ^1H resonance are of interest in a $^1\text{H}\{^{13}\text{C}\}$ HSQC, the rest of the ^1H signal (98.9%) must be eliminated. In conventional pulse sequences this is accomplished by using a two-step phase cycle in which the ^{13}C

satellites are cycled differently from the central ^1H – ^{12}C resonance. Unfortunately, many spectrometer installations are not stable enough to provide clean cancellation (this is heavily dependent on the local environment), and the poorly canceled central-resonance signal ends up creating excessive t_1 noise in the spectrum. This is most visible in the study of unlabeled compounds, that is, those that have natural-abundance levels of ^{13}C (or ^{15}N). It becomes even more problematical in long-range HMBC-style experiments. Here, the t_1 noise is often greater than the signals of interest, and more experiment time is spent signal averaging to raise the signals of interest above the t_1 noise than to raise them above the thermal noise.

2.12.18.2.7 Pulsed-field gradients

In 1973, Paul Lauterbur discovered that linear gradients of B_0 (the magnetic field) could be used in NMR experiments to generate spatial information about what was located in the magnet.⁹²⁸ This ultimately gave rise to the technique called magnetic resonance imaging, now used in many hospitals and clinics. As imaging technology developed, it became possible to generate pulses of linear B_0 gradients, of different strengths, in a controlled fashion. Barker and Freeman were the first to demonstrate that these pulsed magnetic field gradients could be used for coherence selection to acquire 2D NMR data.⁹²⁹ This capability was expanded and popularized by Hurd and co-workers in the early 1990s, who showed that PFGs could be used in a number of different NMR experiments.^{930–932} Thus, the PFG revolution was born.

PFGs can be used in several ways.^{932,933} The original application was for imaging, and while this is usually used for clinical purposes, imaging techniques are also being used in drug discovery, primarily to study the metabolism of drugs.⁹³⁴ PFGs are also useful in automating the shimming of high-resolution NMR samples.^{935,936} Both ^1H and ^2H gradient shimming are in routine use for research samples as well as for samples being analyzed by routine automation. PFG techniques also allow old experiments to be run in different ways, and allow entirely new pulse sequences to be developed (discussed below).

PFGs embody experiments with a number of desirable attributes. One is that they allow some experiments to be acquired without phase cycling. This allows the data to be acquired much faster, as long as the quantity of sample is sufficient. This is especially useful for indirect detection, as well as for COSY experiments. PFGs also allow data to be acquired with less t_1 noise. This is useful for experiments in which the quality of the data acquired with conventional methods is significantly degraded by the presence of t_1 noise. A classic example of this is indirect detection. Conventional (phase-cycled) indirect-detection experiments use a two-step phase cycle to cancel the large signals from protons not bound to ^{13}C (or ^{15}N) nuclei, which is 98.9% of the signal in unlabeled samples (discussed above). Any imperfections in the cancellation leave residual signals that cause the t_1 noise. In HMBC in particular, because it detects the long-range multiple-bond correlations, which are often small, this t_1 noise may be greater than some of the desirable signals.^{937,938} Since the PFG versions of HMBC select the desired signals (coherences) within a single scan, and hence contain no t_1 noise induced by the two-step cancellation technique, better-quality data can be obtained, and usually in less time. This is especially useful for elucidating the structures of natural products. Because the structures are usually unknown and the sample sizes are often quite small, every improvement in the quality of HMBC data is welcomed.

PFG experiments can also suppress unwanted solvent resonances, often easily and without any extra setup effort by the operator. In addition, the quality of this suppression is much less dependent on the quality of the NMR lineshape than with other experiments. (Presaturation of the water resonance in an H_2O sample is a classic example in which the NMR spectral quality depends heavily on how well the lineshape of the water resonance can be shimmed to have a narrow base. The corresponding PFG experiments typically do not need such exacting shimming.) This attribute is important because of the large number of NMR studies performed on biomolecules dissolved in $\text{H}_2\text{O}:\text{D}_2\text{O}$ mixtures.⁹³⁹

2.12.18.2.7.1 Pulsed-field gradient variations of existing experiments

The many beneficial attributes of using PFG experiments (listed above) have made PFG experiments quite popular. PFG versions of the indirect-detection experiments^{940–942} are the most heavily used, but the PFG versions of many COSY-style experiments^{943,944} are also popular. PFG-HMBC is a very striking example, and one that is very popular in natural products programs.^{937,945} Alternatives such as GHSMBC,⁹⁴⁶ ADEQUATE,^{947,948} EXSIDE,⁹⁴⁹ psge-HMBC,⁹⁴⁵ and ACCORD-HMBC⁹⁵⁰ have also been developed. Most people would benefit by using PFG-COSY more routinely, as opposed to a non-PFG (phase-cycled) COSY.⁹⁵¹ PFG-HSQC⁹⁵² has become a standard experiment in biomolecular NMR (for rational drug design programs). PFG versions of the selective experiments 1D TOCSY and 1D NOESY experiments have also been developed.⁹⁵³

2.12.18.2.7.2 New experiments made possible by pulsed-field gradient

PFGs have also allowed new pulse sequences to be developed. The WATERGATE spin-echo sequence was developed for biomolecular water suppression.⁹¹⁰ A newer nonecho solvent suppression technique called WET,⁹⁰⁸ which combines PFG, shaped pulses, and SLP pulses, is now the standard for use in LC-NMR⁹⁵⁴ – a technique that is becoming a popular tool for metabolism studies.⁹⁵⁵ PFG-based WET suppression is also being used in the NMR analysis of combinatorial libraries dissolved in nondeuterated solvents.⁹⁵⁶ Automated ²H (and ¹H) gradient shimming, using gradients from both PFG coils as well as room temperature shim coils, is becoming routine for the automated walk-up NMR spectrometers used in medicinal chemistry programs.⁹³⁶ Diffusion experiments,⁹⁵⁷ which rely heavily on PFG, are being used to study ligand binding and evaluate library mixtures for compounds that bind to receptors in rational drug design programs.^{958,959} Other PFG-based diffusion experiments are being used for solvent suppression.⁹⁶⁰

2.12.18.3 Specialized Nuclear Magnetic Resonance Tools

2.12.18.3.1 Biomolecular structure elucidation

Rational drug design programs are built on the idea that if the complete 3D structure of a receptor could be determined, one could custom design a small molecule to bind to its receptor site. The challenge in this process is to determine the structure of the receptor (a protein). While 3D protein structures can be determined using x-ray crystallography, it became apparent in the 1980s that this could also be done by using NMR spectroscopy, and NMR allows the solution-state structure of the protein to be determined.

Once the primary structure of a protein is known, the secondary and tertiary structure of the protein is determined with NMR by first making chemical shift assignments and then by measuring NOEs and coupling constants.⁹⁶¹ A ¹H–¹H NOE provides information about through-space distances. (If two protons show an NOE, and if they are located in different parts of the peptide chain, then this provides an intrastrand structural constraint that indicates that these protons must reside close to each other in the final 3D structure of the protein.) Proton homonuclear or heteronuclear coupling constants provide information about the torsion angles of the bonds in the peptide backbone. Either of these methods can provide a 3D structure if enough structural constraints can be determined.

Structure determinations can be very difficult for proteins whose molecular weights are greater than 10 kDa (even if the primary structure is obtained by other means). First, the chemical shift assignments become more difficult as the spectral complexity increases, and, second, the faster relaxation of larger molecules produces broader linewidths that make it harder to obtain coupling-constant information.

Biomolecular NMR became more important and grew significantly when three things happened. First, methods were developed for incorporating NMR-active isotopic labels (namely ¹³C and ¹⁵N) into proteins. Second, indirect-detection techniques were developed that facilitated the chemical shift assignments of these labeled proteins.^{962,963} Third, 3D and 4D NMR techniques were developed to simplify and sort the vast amount of information needed to determine the structure of these large molecules.⁹⁶⁴ These three developments greatly simplified the interpretation of protein NMR data, and made the determination of protein structures both more routine and more powerful. Although the techniques for acquiring indirect-detection NMR data on small molecules were well developed by the late 1980s, the requirements (and possibilities) of performing these experiments on proteins are a bit different. Much of this was worked out in the early 1990s, and the field of multiple-resonance protein NMR blossomed.^{880,913,961,965} The resulting experiments (described below) are certainly powerful, and initially required new NMR hardware, but conceptually one can think of them as simply being composed of combinations of the fundamental techniques that had already been developed (described above).

2.12.18.3.1.1 Multiple radio frequency channel nuclear magnetic resonance

Since isotopically labeled proteins typically contain three kinds of NMR-active nuclei – ¹H, ¹³C, and ¹⁵N – the one-step heteronuclear coherence transfers normally used in heteronuclear correlation experiments can be concatenated into a multiple-step transfer. An example of a multiple-step transfer would be magnetization transfer from ¹H to ¹³C, then to ¹⁵N, where it evolves, back to ¹³C, and then to ¹H for detection. Indirect-detection experiments allow any X nucleus to be examined, simply depending on where in the pulse sequence the *t*₁ evolution time is placed. 3D and 4D experiments allow multiple evolution times to be used. Proteins exhibit a range of homonuclear and heteronuclear scalar coupling constants (*J*), and the 1/2*J* delays in a pulse sequence can be finely tuned so as to select between several different scalar coupling pathways in the molecule. These capabilities, combined with the ability to select either complete or partial isotopic labeling within a protein, allow experiments to be designed that can correlate almost any two kinds of spins. In practice, at least one of these spins is usually a proton bound to an amide-bonded nitrogen. The identity of the second or third spin depends on the structural data needed. It may even be one of several

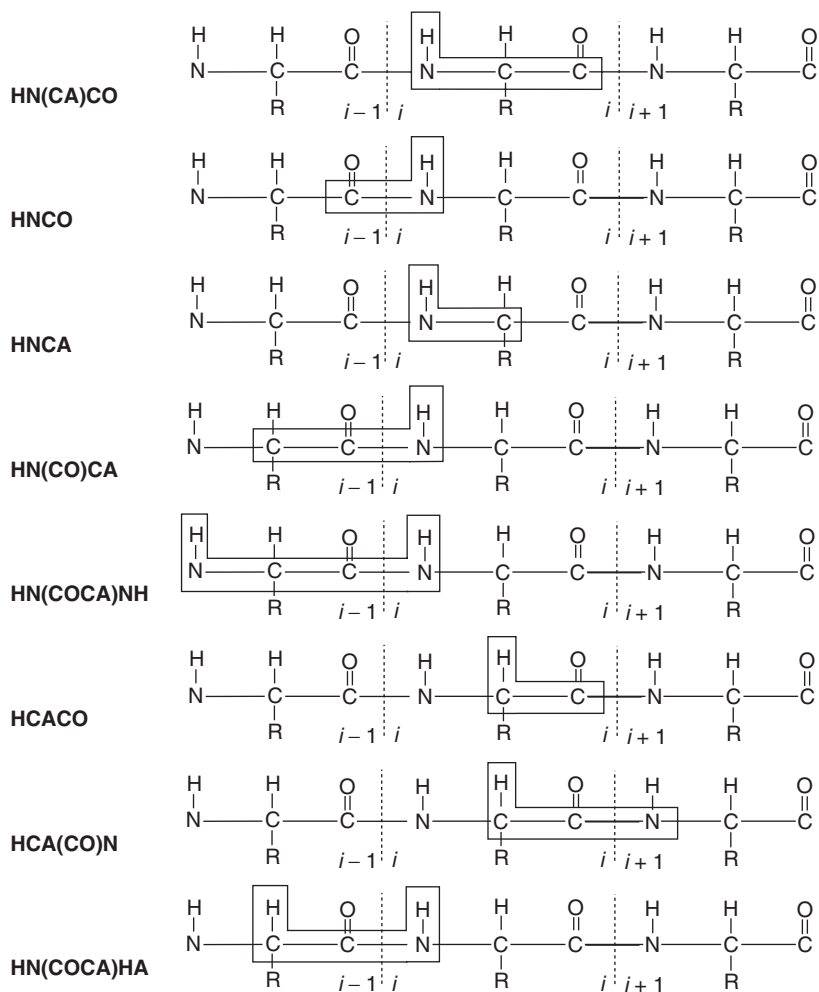

Figure 138 Internuclear correlations that can be detected on an isotopically labeled protein backbone using the listed triple-resonance experiments. Boxes with a solid outline designate the nuclei involved in each correlation experiment. Dashed vertical lines indicate the location of the peptide bonds.

structurally different carbon nuclei, since NMR can easily distinguish carbonyl carbons from all other carbon resonances quite easily (using frequency-selective pulses). **Figure 138** shows the intraresidue correlations that can be made using the HN(CA)CO experiment, as well as the interresidue correlations (to the previous adjacent carbonyl carbon) that can be made using the HNCO experiment. In HN(CA)CO, the magnetization starts on the NH proton, is transferred to the directly bonded ^{15}N (where there is an evolution time), is then transferred to the C- α ^{13}C (no evolution), and finally to the carbonyl ^{13}C , where it has its second evolution. It then reverses its path (CO to CA to N to H) for detection of ^1H . The parentheses around the CA in HN(CA)CO indicates that the C- α nuclei are used in the transfer, but there is no evolution time and they are not actually detected. To make correlations to the C- α carbons (instead of the carbonyl carbons), the corresponding experiments would be HNCA (for intraresidue assignments) and HN(CO)CA (for inter-residue assignments to the previous C- α carbon). In a similar manner, experiments such as HN(COCA)NH, HCACO, HCA(CO)N, and HN(COCA)HA, as well as many more, can be constructed (**Figure 138**).

As proteins (and other biomolecules) are large, their T_2 relaxation times are usually much shorter than those of small molecules. This causes their NMR resonances to have broader linewidths. Because most methods for determining accurate scalar coupling constants measure the separation of antiphase signals, and since this becomes less accurate as the linewidths increase, these experiments become less useful as the molecular weight of the compound increases. As a consequence, DQFCOSY experiments are less useful for large proteins, and so the determination of the 3D structure via torsion angle measurements becomes harder. Experiments have been designed in an attempt to overcome this limitation, principally through the use of combined hetero- and homonuclear scalar couplings.^{966,967}

2.12.18.3.1.2 Newer biomolecular experiments: transverse relaxation-optimized spectroscopy, hydrogen bond J couplings, and dipolar couplings

Because large biomolecules have a faster T_2 relaxation than smaller molecules, their NMR signals will sometimes decay before they get through some pulse sequences. There are several schemes for addressing this problem. First, HSQC experiments can be used instead of HMQC experiments, because transverse magnetization in a single-quantum state (HSQC) relaxes even more slowly than transverse magnetization in a multiple-quantum state (HMQC).⁹²¹ Second, some pulse sequences now use a variety of heteronuclear and homonuclear decoupling schemes during evolution times to reduce T_2 decay rates. Third, some groups have resorted to perdeuteration of those large proteins that relax rapidly; this reduces the decay rate of signals in the transverse plane.^{968,969} Fourth, the introduction of TROSY, which manipulates spins in a way that maintains those signals having longer relaxation times, is also allowing much larger proteins to be studied by NMR.^{970,971}

Another tool for structural elucidation became available with the discovery that NMR allows observation of correlations due to scalar couplings across hydrogen bonds. This indicates that hydrogen bonds can have a measurable amount of covalent character, so the phenomenon has been called 'hydrogen bond J coupling.' Among the correlations observed are one-bond $^1J_{\text{HN}}$ correlations,⁹⁷² two-bond $^2J_{\text{NN}}$ correlations,⁹⁷³ and three-bond $^3J_{\text{CN}}$ correlations,^{974,975} all of which have been explained theoretically.⁹⁷⁶ Much like a long-range NOE correlation, these correlations add structural constraints to 3D structures (especially for nucleic acids).

There is a lot of interest in using NMR to study ligand–receptor binding. This is normally done by looking for intermolecular NOEs between the ligand and the receptor, but because the NMR spectrum of a protein–ligand complex can be complicated, small NOEs can be hard to detect. The problem is simplified if isotopically labeled ligands are mixed with unlabeled proteins and an isotope-filtered NMR experiment used to selectively observe the labeled resonances.⁹⁷⁷ As more complex ligands and receptors are studied, techniques to do the opposite – selectively observe the resonances of just the unlabeled molecules – were developed (in part through the use of adiabatic pulses).⁹⁷⁸

The final trend in biomolecular NMR is to use the internuclear dipolar couplings of oriented molecules to determine structures.⁹⁷⁹ When molecules are in solution and tumbling freely, these couplings are averaged to zero; however, if the molecules are aligned with the magnetic field even partially, these couplings will be nonzero and measurable. If one measures the one-bond ^{15}N – ^1H and ^{13}C – ^1H dipolar couplings and knows the internuclear distances, then the orientation of the vectors of these bonds (with respect to the magnetic susceptibility tensor of the molecule) can be determined. This gives direct information about the torsion angles of the bonds, and hence information about the structure of the biomolecule. This information also complements that which can be obtained from analyses of NOEs and J couplings.

Because many molecules naturally exhibit only weak alignments with magnetic fields, a recent trend has been to use different kinds of liquid crystals and bicelles not only to create more alignment but to allow control over the degree of alignment.⁹⁸⁰ Once aligned, measurement of the changes in the one-bond coupling constants (typically $^1J_{\text{NH}}$) or the ^{15}N chemical shifts, measured at a variety of magnetic field strengths, gives the dipolar couplings.⁹⁸¹ A more recent alternative is to measure the differences in chemical shifts and coupling constants between data acquired with and without MAS (using solution state samples and a nanoprobe; discussed below). The advantage of this technique is that only one set of measurements need to be made.

2.12.18.3.2 Water (solvent) suppression

In all of these biomolecular experiments, signals from the protons bound to the amide nitrogen are critical. Unfortunately, these amide protons also readily exchange with water, so the samples cannot be dissolved in D_2O . To keep the samples in a predominately H_2O environment yet still supply a small amount of D_2O for a ^2H lock, they are usually dissolved in 90:10 or 95:5 H_2O : D_2O . Because that makes the H_2O signal 100 000 times larger than that of a single proton in a 1 mM protein, new techniques had to be developed for acquiring NMR data on these kinds of samples.

There are essentially three ways to deal with the problem. One is to suppress the water signal, the second is to not excite it in the first place, and the third is just to live with it. None of these strategies are perfect, and a wide range of techniques have been developed in an attempt to exploit at least the first two strategies. Many good reviews of water suppression techniques exist elsewhere.^{982,983} It is of interest, however, to note two things. First, virtually all of the common water suppression techniques are combinations of shaped pulses, PFGs, and indirect-detection methods (all discussed above). Second, most techniques are designed only for water suppression, not for the more general concept of solvent suppression. Suppressing the NMR resonances of organic solvents is more difficult than water suppression because the ^1H signals contain ^{13}C satellites in addition to the central resonance. General solvent suppression is becoming important in several flow-NMR techniques, and will be discussed later.

2.12.18.3.3 Hardware developments

There are many examples of how developments in NMR techniques have required improvements in the hardware and software as well. The ever-higher magnetic fields used to simplify complex spectra have required improvements in superconducting magnet materials and magnet designs. FT-NMR required the development of pulsed RF, whereas 2D NMR required the development of RF hardware and pulse sequence control software that was capable of more flexible phase cycling and power level control. Indirect detection required the design of both more stable RF and of magnet antivibration hardware to improve the signal cancellation possible via RF phase cycling. Spin lock sequences (e.g., TOCSY) required phase-coherent RF to be developed. The complex pulse sequences of biomolecular multiple-resonance NMR required multiple RF channels (as many as five), each capable of delivering not only more but a wider variety of pulses per sequence. For example, any one RF channel may be called on to deliver high-power uniform-excitation broadband pulses, region-selective pulses, broadband or region-selective decoupling, broadband or region-selective spin locks, or highly frequency-selective pulses. These RF requirements have driven the development of faster and more flexible RF control, including more powerful pulse-shaping hardware and software. In addition, because PFG pulses of a variety of amplitudes are also freely intermixed with RF pulses, stronger gradients with ever-faster recoveries are always being sought.

2.12.18.3.3.1 Probe developments

In addition to hardware developments in the spectrometer console and magnet, advanced NMR experiments have also driven improvements in probe designs. The emphasis on water (solvent) suppression has created an emphasis on lineshape specifications. NMR lineshape specifications – defined as the width of the NMR peak at 0.55% and 0.11% of the height of the peak (0.55%/0.11%) – are now half as wide as they were a decade ago. Proton NMR linewidths of 4/6 Hz have been obtained. Narrower lineshape specifications do not guarantee good water suppression, but are often considered to be an essential element. The better specifications arise from improvements in probe designs, magnet designs, shim set designs, and installation procedures. Although NMR resolution (the width of the NMR peak at 50% of the height of the peak) for spinning samples has not improved, most high-field NMR spectrometers are now capable of – and specified to have – much better nonspin resolution than in the past. Since most n D NMR experiments, and all water suppression experiments, are run nonspinning, this is also now considered an important specification.

The second-most important probe development pertains to the ever-increasing probe sensitivities. The ^1H sensitivity specifications of modern probes are severalfold better than they were a decade ago. Instrument time is always precious, and a 3.2-fold increase in the signal-to-noise ratio can reduce the total time of an NMR experiment by an order of magnitude.

The emphasis on multiple-pulse NMR experiments (such as HSQC and the triple/multiple-resonance experiments) has driven improvements in three other parameters of probe design: shorter pulse widths, better RF homogeneities, and improved ‘salt tolerance’. The first parameter is important because spectral widths in higher field NMR – as measured in hertz – are wider. This requires the RF pulses to become shorter (in time) to maintain the same excitation bandwidth (as measured in ppm). One way to get shorter pulses is to use higher power RF amplifiers, but as magnetic fields continue to increase, not only must the corresponding probes be redesigned to handle the ever-increasing power, but unfortunately the components that can handle these increased voltages are also usually larger. The space inside a triple-resonance PFG probe is already crowded, so the demands of increased power handling create conflicts that cause 800 MHz probes to be more difficult to make than 500 MHz probes (assuming the probe diameter remains the same). This is also why the first few probes for a new magnetic field strength often do not produce as much signal-to-noise improvement as would be predicted by theory.

The second parameter – better RF homogeneities – arises because every probe produces RF pulses that are spatially nonuniform to different extents, so that different parts of the sample receive RF irradiation equivalent to slightly different pulse widths. The net effect of this is that every pulse in an NMR experiment can degrade the resulting sensitivity, with the degradation directly proportional to the nonuniformity (inhomogeneity) of the pulse. Five 90° pulses in a sequence may generate only 80–95% of the sensitivity of a single 90° pulse. The specification is often quoted as the ratio of signal intensities for a 450° versus a 90° pulse (the $450^\circ/90^\circ$ ratio) or, on better probes, as the $810^\circ/90^\circ$ ratio. The homogeneities of both the observe (inner) and decoupler (outer) coils must be taken into account for multiple-channel experiments.

The third probe design factor – better salt tolerance – is driven by the need to study biomolecular samples dissolved in aqueous ionic buffers. As the salt concentration increases and the sample becomes more conductive, two things happen. The first is that the NMR sensitivity drops. A sample dissolved in a 0.5 M buffer may have only 90% of the sensitivity of the same sample dissolved in plain water. This means that a probe optimized for high sensitivity for

organic samples (e.g., ethylbenzene) is not necessarily optimized for samples dissolved in aqueous buffers. With salty samples, the signal-to-noise ratio will decrease as the filling factor of the probe increases, as the probe volume increases, as the Q of the probe increases, and as the salt concentration increases. Large-volume (8 or 10 mm) ^1H probes, or superconducting probes, are particularly prone to this problem, and care must be taken when using them to study aqueous samples.

The second problem with acquiring NMR data on conductive samples is that they heat up as power is applied to the sample. For a given amount of power, the more conductive the sample is, the hotter it gets. Although this is a minor but measurable problem when running spin lock experiments (e.g., TOCSY), it is a significant problem with indirect-detection experiments because the X nucleus decoupling may use a relatively high power to increase its bandwidth. The resulting temperature increases change the chemical shifts of the solute (actually, the frequency of water changes with temperature, and this moves the ^2H lock frequency of D_2O) and can also change lineshapes and cause sample degradation. This has required probes to have better variable-temperature performance, partly to maintain more stable temperatures and partly to dissipate any heat generated within the sample by RF heating.

2.12.18.3.3.2 Probes for larger and smaller volume samples

Some samples do not allow acceptable signal-to-noise NMR data to be easily acquired with conventional NMR techniques. For solution state samples, there are two ways to resolve this problem. One, if the sample solubility is the limiting factor, use a probe whose RF coil can hold a larger volume of the solution. Two, if the sample quantity is the limiting factor, dissolve it in a smaller volume of solvent and place it in a more efficient small-volume probe. Samples dissolved in a smaller volume of solvent and run in a smaller-volume probe can exhibit higher NMR sensitivities and fewer interfering signals arising from excess solvent or solvent impurities.

The default probe geometry for solution state NMR is normally a '5 mm' probe (i.e., a probe with an RF coil optimized for 5 mm (OD) sample tubes; [Figure 139a](#)). If higher NMR sensitivity is needed and enough sample exists, probes that handle 8 and 10 mm sample tubes can be used. (Probes that use sample tubes larger than 10 mm in diameter were more common in the past but are rarely used anymore.) X observe probes of 10 mm diameter have been available for many years, whereas 8 mm and 10 mm diameter ^1H observe probes (including indirect-detection probes) have been available only for the last few years. Although data can be acquired on samples in 5 mm tubes placed in larger diameter (8 or 10 mm) probes ([Figure 139b](#)) (even though this decreases the net NMR sensitivity), the converse is not true; that is, 10 mm sample tubes cannot be placed in 5 mm probes.

Figure 139 Representations of the various sample tube geometries available for acquiring solution state NMR data. Black areas represent the sample solution. Outlines of the RF coils for each probe geometry are shown to illustrate the active volume of the RF coils. Shown from left to right in order are: (a) a sample in a standard 5 mm tube and the RF coil from a 5 mm probe; (b) a 5 mm tube in a 10 mm probe; (c) a 5 mm tube with susceptibility-matched restrictive inserts; (d) a 3 mm microprobe sample; (e) a 1.7 mm submicroprobe sample; (f) a nanoprobe sample; (g) a flow probe. The nanoprobe tube has a 40 μL total (and active) volume; the flow probe has a 60 μL active volume. All tubes are drawn to the same scale.

Larger-diameter sample tubes are useful if samples have limited solubility and if plenty of solute exists. This is classically encountered when acquiring X-observe NMR spectra on inorganic complexes of limited solubility, but some groups studying biomolecules (i.e., those doing rational drug design) often use dilute solutions to minimize problems caused by aggregation, and sometimes they try to compensate for the reduced signal-to-noise ratio by using larger sample tubes. For the opposite situation, in which the amount of solute is limited but the solubility is not, better NMR sensitivity can be obtained by concentrating the sample. This is a common scenario in small-molecule pharmaceutical applications, especially when studying natural products or metabolites.

2.12.18.3.3.2.1 Microprobes and microcells Once the sample has been concentrated into a smaller volume of solution, there are several options for obtaining NMR data. One option is to use a 5 mm- diameter sample tube with ‘susceptibility plugs’ (or certain types of microcells) – of which a variety of types are available – to reduce the depth (length) of the sample (Figure 139c). This gives higher sensitivity than Figure 139a, but the lineshape usually suffers a bit, and sample preparation can be significantly more difficult, largely because all air bubbles must be removed from the sample. A second option is to use a smaller-diameter sample tube in a probe with a smaller-diameter RF coil (Figure 139d). This also gives higher sensitivity than Figure 139a, and the lineshape is as good or often better. The increased sensitivity (in Figure 139d as compared with Figure 139a) is due in part to the ability to place a larger fraction of the sample volume in the active region of the RF coil without lineshape degradations. The better lineshape is due to the use of a smaller cross-section of the magnet. The sample volume depends on the diameter of the RF coil of the probe (which itself ranges from 2.5 to 3 mm in diameter), but typically ranges from about 80 to 150 μL . Probes like this are now usually referred to as ‘microprobes.’^{927,984,985}

Probes designed for even smaller volumes now exist. The most conventional option is to use an even smaller-diameter sample tube, typically with a diameter of 1.0 mm or 1.7 mm, in a probe with a matched-diameter RF coil (Figure 139e). Probes like this were first made available in the 1970s,⁹⁸⁶ and might be making a comeback under the current moniker of ‘submicroprobe.’⁹⁸⁷ Higher NMR sensitivities per amount of sample can often be achieved with submicroprobes, but the small size and fragility of the sample tubes has made sample handling difficult.

2.12.18.3.3.2.2 Nanoprobes A totally different solution to the problem of obtaining NMR spectra on small-volume solution state samples was introduced in the early 1990s. It uses a hybrid of MAS and traditional high-resolution probe technology. The resulting product, marketed by Varian as the NanoProbe, has had a large impact on pharmaceutical research, and is covered in detail in two review articles.^{988,989}

All previous sample geometries for solution state samples were approximations of an infinite cylinder (the sample is long relative to the RF coil), because this is a reliable and convenient way to obtain good lineshapes. This geometry moves all discontinuities of magnetic susceptibility (e.g., liquid–air and liquid–glass interfaces) far away from the active region of the RF coil. The closer the discontinuities (interfaces) are to the RF coil, the more NMR line broadening they can introduce. Because perfectly cylindrical interfaces do not cause lineshape problems, the sample tubes themselves are made to be cylindrical. (Theory says that sample geometries that are spherical should also give good lineshapes; however, in practice the lineshape is usually substandard, presumably due to imperfections in the sphere such as the hole used to introduce the sample.)

Unfortunately, this ‘infinite-cylinder approximation’ sample geometry means that only a fraction of the sample can actually contribute to the NMR sensitivity. The available percentage that can be utilized depends on the diameter of the RF coil, but in a 5 mm probe the RF coil obtains most of its signal from the central 35% of the sample, and even a 3 mm probe uses only about 50% (Figure 139). (For any given probe style, the percentage claimed can vary among different vendors and generations of probes, and for a 5 mm probe may even be as high as 45% or 50%; however, higher percentages always cause a performance trade-off such as a worse lineshape or a reduced RF homogeneity.) Susceptibility plugs can constrict the entire sample to within the active region of the RF coil, but as the percentage approaches 100% the lineshape usually degrades. (This is because the plugs can never be a perfect match to the magnetic susceptibility of the sample.) Sample handling also becomes more difficult when susceptibility plugs are used.

Nanoprobes, on the other hand, work on an entirely different principle.^{988–990} To maximize sensitivity, 100% of the solution state sample is placed the RF coil of the probe (Figure 139f). Normally this would result in severe broadening of the NMR lines because of the various liquid–air and liquid–glass interfaces (magnetic susceptibility discontinuities) close to the RF coil. To eliminate these magnetic susceptibility line broadenings and regain a solution-state-quality lineshape, the samples are spun about the magic angle (54.7° relative to the z axis).^{991,992} This also allows samples that are smaller than the volume of the RF coil (40 μL in the case of a standard nanoprobes) to be properly studied by NMR. Smaller samples just leave a larger air bubble in the nanoprobes sample cell, and MAS completely eliminates this line broadening.

Figure 140 A ^1H NMR spectrum acquired using a ^1H nanoprobe. Several micrograms of the unknown oligosaccharide were dissolved in an $\text{H}_2\text{O}:\text{D}_2\text{O}$ mixture. The sample was spun about the magic angle at 1.8 kHz; the data were acquired in 1024 scans using presaturation to saturate the water resonance (at 4.8 ppm). The narrow water resonance is characteristic of nanoprobe spectra, regardless of the sample volume. (Sample courtesy of A. Manzi, University of California, San Diego.)

Good NMR data have been obtained on samples dissolved in less than 2 μL of solvent; linewidths and lineshapes are good, water suppression is outstanding, and even a stable ^2H lock can be maintained on this volume of solvent.

Nanoprobes were initially designed to allow NMR spectra to be obtained on small-volume (40 μL) solution state samples.^{988,989} This use is illustrated by five kinds of sample-limited applications. First, nanoprobes capable of ^1H -only detection have solved the structures of several unknowns using the data from a variety of 1D and 2D ^1H NMR experiments (Figure 140).^{993,994} Second, ^{13}C -observe nanoprobes have used conventional 1D $^{13}\text{C}\{^1\text{H}\}$ NMR data to solve the structures of unknowns.^{995,996} Third, ^{13}C -observe nanoprobes have generated high-sensitivity INADE-QUATE data that determined the complete carbon skeleton of unknowns (in a more rigorous manner than an indirect-detection method such as HMBC could).^{997–999} Fourth, nanoprobes have been used to acquire solvent-suppressed ^1H NMR spectra on samples dissolved in 90:10 $\text{H}_2\text{O}:\text{D}_2\text{O}$ to solve structures using 1D and 2D NMR (homonuclear) techniques.^{1000–1003} Fifth, nanoprobes capable of generating indirect-detection and PFG data are now available as well.¹⁰⁰⁴ These kinds of applications are primarily of benefit to natural product and metabolism chemists, both of which typically suffer from limited amounts of sample, but there is also an unrecognized potential to rational drug design programs (especially for the removal of dipolar couplings in large oriented molecules).

The advantages of nanoprobes are that they are the highest sensitivity per nucleus NMR probes commercially available, they shim equally easily for 40 and 4 μL samples, and have the unique capability of producing lineshapes for samples in H_2O that are very narrow at the base (which facilitates water suppression) (Figure 140). However, acquiring solution state data while using MAS does have some experimental limitations. Because the sample is spinning during the entire experiment, spinning sidebands may be present in all spectra (even multidimensional spectra). The sample spinning also diminishes the signal stability, and thus causes additional t_1 noise. This is a problem for experiments that utilize phase-cycled cancellation of large signals (e.g., phase-cycled indirect detection), although the availability of nanoprobes capable of running PFG experiments addresses this problem.

MAS is not a new invention. It has been in use since 1958 for narrowing linewidths in solid state samples. It was never used before for fully solution state samples for two reasons. First, MAS was initially designed to remove the much larger line broadenings that occur only in solid state samples (i.e., those that arise from interactions such as dipolar coupling and chemical shift anisotropy). The capability of MAS to eliminate the much smaller line broadenings that arise from magnetic susceptibility discontinuities was not considered nearly as important, although its utility was recognized early on by several groups.^{988,989,1005,1006} Second, to obtain high-quality solution state lineshapes (<1 Hz, 10 Hz, and 20 Hz at the 50%, 0.55%, and 0.11% levels, respectively), NMR probes also need to be built using materials

and designs that are susceptibility matched. While this has long been a criteria in the design of vertical-spinning solution state probes,¹⁰⁰⁷ it was never considered important in the design of solid state MAS probes until recently.¹⁰⁰⁸ The nanoprobe was the first MAS probe designed to handle solution state samples, and as such, it was the first MAS probe to incorporate this magnetic susceptibility-matched probe design technology. (Solid state samples often have ^1H linewidths of 100 Hz or more, so that an additional line broadening of 5–20 Hz coming from the probe design was considered insignificant. This additional line broadening is large, however, for solution state samples, whose natural linewidths can be well under 1 Hz.) Conventional MAS probes are built to emphasize very high-speed spinning and the ability to handle high RF powers. These characteristics are needed for solid state NMR but are unnecessary for (and often conflict with the requirements of) solution state NMR.

After the (Varian) NanoProbe demonstrated the virtues of using MAS on solution-state samples (and on a variety of semisolid samples, as discussed below), a variety of high-resolution MAS (HR-MAS) probes became available from several NMR probe vendors (including Bruker, Doty Scientific, and JEOL). The different probes exhibit a variety of performances caused by different balances of the contrasting needs of solution state versus solid state NMR. The biggest differences among the various HR-MAS probe designs are in the lineshape specifications and the filling factors (the sensitivity efficiencies). Less emphasized – but still important – differences include the maximum spin rate, the integrity of the sample container against leakage, the cost of the sample container, the cost and ease of automation, and the ease of changing between MAS and non-MAS probes. The reliability of sample spinning is usually not an issue with liquid (or semisolid) samples. There is one very big difference between MAS probes and microprobes (or other non-MAS probes). Non-MAS probes (those that orient samples along the vertical z axis of the magnet) use cylindrical (or spherical) sample geometries to eliminate line broadenings arising from those magnetic susceptibility discontinuities surrounding the sample, but this has no effect on magnetic susceptibility discontinuities within the sample itself. Only MAS can eliminate line broadenings that arise from these internal magnetic susceptibility discontinuities (those within the sample). This is a crucial and critical difference. A homogeneous (filterable) solution state sample has a uniform magnetic susceptibility only as long as there are no air bubbles in the sample. If any heterogeneity is introduced anywhere near the RF coil, either accidentally or purposefully – and this can be an air bubble, flocculent material, any amount of solid or liquid precipitate, or any form of emulsion, suspension, or slurry – the sample becomes physically heterogeneous to the NMR, and only MAS can be used to regenerate narrow lineshapes. (The author has encountered a surprising number of situations in which spectroscopists thought their samples were physically homogeneous – because they were visually clear and produced reasonable NMR spectra – until it was found that the spectra acquired under HR-MAS were measurably different.) This means that cylindrical (or spherical) microcells must be filled completely, with no air bubbles, or the NMR resonances will be broadened, whereas an MAS microcell will generate the same lineshape regardless of how completely the microcell is filled. Note that MAS does not necessarily guarantee that all resonances will be narrow: although MAS removes some line broadening effects, it does not affect other parameters (such as rapid T_1 or T_2 relaxation) that can broaden linewidths.

Probes are a very important part of an NMR spectrometer, and as such there are other styles of probes yet to be discussed. In particular, flow probes will be discussed in [Section 2.12.18.3.5](#), and cryoprobes will be discussed in [Section 2.12.18.3.7](#). However, the next section covers an important application of HR-MAS NMR in more detail. This attention is justified because an understanding of the physics involved in sample composition, sample preparation, and experimental parameters is necessary if optimal HR-MAS spectra are to be acquired. This contrasts with most other kinds of NMR spectroscopy, in which sample preparation, data acquisition, and data interpretation are usually more straightforward.

2.12.18.3.4 Nuclear magnetic resonance of solid phase synthesis resins

Techniques for obtaining NMR data on samples still bound to insoluble SPS resins have been a topic of considerable importance during the last few years, especially to combinatorial chemists.^{988,989} The typical chemist wants to obtain a solution state-style spectrum, which normally means obtaining spectra with narrow lineshapes. This requires a consideration of magnetic susceptibilities, molecular motions, and how the three main types of NMR probes behave for heterogeneous SPS resin slurry samples.^{990,1009}

The first thing a solid phase resin chemist needs to do to obtain narrow NMR linewidths is to swell the resin to a slurry with an excess of solvent. This increases the mobility of the bound substrates, and mobile nuclei typically exhibit narrower resonances than do solid state samples. (Solid state samples exhibit broader resonances than solution state samples because of several parameters, including faster relaxation, chemical shift anisotropy, sample heterogeneity, and homonuclear dipolar couplings.) Although NMR data can be obtained on SPS resins in the solid state by using traditional solid state tools such as cross-polarization MAS, this is of more interest to the fields of material science and polymer chemistry, and is not useful to organic or combinatorial chemists.

2.12.18.3.4.1 The observed nucleus

The second parameter to consider is which nucleus will be observed (^1H , ^{13}C , etc.). Different nuclei are affected differently by the sample heterogeneity of an SPS resin slurry. A slurry of SPS resin is a physically heterogeneous mixture that contains regions of free solvent, bound solvent, cross-linked polymer, bound samples, and possibly even long tethers, and each of these regions may possess its own unique magnetic susceptibility. This mix of magnetic susceptibility discontinuities causes an NMR line broadening for nearby nuclei that scales with the frequency of NMR resonance. This means that ^1H spectra suffer four times as much magnetic susceptibility line broadening as ^{13}C spectra because protons resonate at four times the frequency of ^{13}C nuclei. (For example, if ^{13}C nuclei resonate at 100 MHz, ^1H nuclei will resonate at 400 MHz.) This also means that resin spectra obtained on a 600 MHz NMR spectrometer will have linewidths twice as broad as those obtained on a 300 MHz system. Although this doubling of the linewidth may be completely offset by the corresponding doubling of the chemical shift dispersion (the number of hertz per ppm also doubles when going from 300 to 600 MHz), this is only true if all the line broadenings observed in a given spectrum arise from magnetic susceptibility discontinuities. This is certainly never the case for the resonances of the less mobile backbone of the cross-linked polymer, but it is a good approximation for the signals arising from the nuclei bound to the surface of the resin.

2.12.18.3.4.2 Choice of the resin and solvent

The third and fourth parameters that control the NMR linewidths in an SPS resin slurry are the choice of the resin used and the solvent used to swell the resin.^{1009,1010} The more mobility the nuclei of interest have, the narrower their resonances will be. Many resins used today for solid phase organic synthesis contain long ‘tethers’ that allow bound solutes to be located a significant distance away from the more rigid cross-linked polymer portion of the resin bead. Since the tethers are usually flexible straight chains, the bound solute enjoys considerable freedom of motion. This is desirable for organic synthesis because it allows ready diffusion of reagents to the solute, and it is desirable for NMR because the additional freedom of motion decreases the efficiency of T_2 relaxation, and hence produces narrower NMR resonances. This means that the NMR spectra of resins with either short or no tethers (like the original Merrifield resins) contain NMR linewidths that are broad compared with the linewidths obtained on resins with long tethers (e.g., Tentagel or Argogel resins).

Then one must consider the solvent. Solvents that swell and properly solvate the resin (at least those portions of the resin that are around the bound solute) are more likely to produce narrow NMR linewidths. If parts of the resin are not properly solvated, the reduced molecular motion will increase the NMR linewidths.

In summary, this means that to acquire an NMR spectrum with narrow linewidths, you need both a proper resin and a proper solvent; a poor choice of either will produce a low-quality NMR spectrum (i.e., one with only broad NMR resonances).

2.12.18.3.4.3 Choice of nuclear magnetic resonance probe

The final parameter is the choice of which NMR probe is to be used: a conventional solution-state probe, an MAS probe, or a nanoprobe or HR-MAS probe. The importance of this parameter depends on the previous four parameters. Conventional solution state probes can generate high-resolution spectra for homogeneous liquids (because they use magnetic susceptibility-matched probe design technology, as discussed above) but they cannot eliminate magnetic susceptibility line broadening caused by heterogeneous SPS resin slurries. Conventional MAS probes can remove magnetic susceptibility line broadening caused by heterogeneous SPS resin slurries, but, because they do not use magnetic susceptibility-matched probe design technology, the probe induces additional line broadening of its own (about 3–30 Hz, depending on the resonance frequency). This is one reason why conventional MAS probes are inappropriate for acquiring NMR data on homogeneous liquids. Nanoprobes (and, to a lesser extent, other HR-MAS probes) use both MAS and magnetic susceptibility-matched probe design technology, and so they can acquire high-quality narrow-linewidth NMR spectra on both homogeneous liquids and heterogeneous resin slurries.

Does this mean a nanoprobe is required for all SPS resin spectra? No, it depends on what you need to do. A conventional solution state probe produces acceptable ^{13}C NMR data; this technique is common enough to have acquired the name of ‘gel phase NMR,’^{989,1011,1012} but ^1H NMR spectra acquired in this way are usually considered to exhibit unacceptably broad linewidths. A conventional MAS probe produces acceptable ^{13}C NMR data but poor-quality ^1H NMR data (although the data are better than they would be if a conventional solution state probe was used). A nanoprobe produces the best ^1H NMR data, and also produces the highest-resolution ^{13}C NMR spectra, but often the additional resolution in the ^{13}C spectrum is not needed, and data from either of the other two probes would have been just fine.⁹⁹⁰ Most people agree that a nanoprobe (or other HR-MAS probe) is the only way to

Figure 141 A multiple-bond ^1H – ^{13}C PFG HMBC spectrum of a SPS resin acquired using a PFG indirect-detection nanoprobe. The sample consisted of 0.5 mg of Fmoc-Asp(OtBu)-NovaSyn TGA (Calbiochem) slurried in 20 μL of CD_2Cl_2 . The absolute-value HR-MAS data set was acquired in 90 min using 32 scans for each of the 140 increments. The MAS spin rate was 2.1 kHz.

generate ^1H NMR data on SPS resins (Figure 141).^{988,989,1013,1014} Nanoprobes were the first probes capable of acquiring high-resolution ^1H NMR spectra of compounds still bound to SPS resins,¹⁰¹⁵ and they are responsible for starting the HR-MAS revolution. Nanoprobes are still the only probes capable of acquiring data on single 100 μm beads.¹⁰¹⁶

Note that if you are using a resin with no tether or have chosen a poor solvent, your spectra will contain broad lines regardless of which probe you use. (A nanoprobe may allow the resonances to be narrower by 50 Hz, but if the lines are already 200 Hz wide it will not help much.) All of these conclusions can also be extended to acquiring NMR data on any other kind of semisolid, slurry, emulsion, or membrane-bound compound; they are all examples of physically heterogeneous samples that contain enough localized mobility to allow NMR resonances to be narrow if the data are acquired properly. Biological tissues are another kind of semisolids; methods for using NMR to study them are an area of considerable interest to the pharmaceutical community,¹⁰⁰⁴ and investigations into the use of MAS and HR-MAS to acquire NMR spectra of tissues and intact cells are in progress.^{1017–1019} This capability has the potential to have a big impact on both medical diagnostics and drug efficacy screening.

One final note about high-resolution MAS NMR: not all solution state experiments translate directly into the realm of MAS. It has been found that spin-locked experiments such as 2D TOCSY and ROESY do not always behave the same way as they do on conventional solution-state probes.¹⁰²⁰ The RF inhomogeneities of solenoidal coils, combined with sample spinning during the experiment, cause destructive interferences during the spin-locks that lead to signal intensities, which are a function of the sample spinning rate. The solution is to use either different spin locks⁸⁹³ or different sample geometries (unpublished results).

2.12.18.3.5 Flow nuclear magnetic resonance

Some groups in the pharmaceutical industry are trying entirely different approaches to introducing samples into the NMR spectrometer. All of these techniques can be grouped into a category called ‘flow NMR,’ and they all use ‘flow probes’ (see Figure 139g), even though the samples may or may not be flowing at the time of NMR acquisition. The first example of this approach is HPLC–NMR, more commonly called just LC–NMR. More recently, direct-injection

NMR (DI-NMR) and flow injection analysis NMR (FIA-NMR) have been developed as ways to acquire NMR data without the use of the traditional precision-glass sample tubes. By interfacing robotic autosamplers and liquid handlers to NMR spectrometers, samples in disposable vials and 96-well microtiter plates are now routinely being analyzed by NMR.

2.12.18.3.5.1 Liquid chromatography–nuclear magnetic resonance

The traditional way to separate a complex mixture and examine its individual components is to perform a chromatographic separation off-line, collect the individual fractions, evaporate them to dryness (to remove the mobile phase), redissolve them in a deuterated solvent, and examine them by conventional NMR using microcells and microprobes if needed. This off-line technique has its place but is inappropriate if the solutes are volatile, unstable, or air sensitive. LC–NMR offers a way to perform an immediate analysis after an on-line separation, and as a technique it is becoming both powerful and more popular.

Although LC–NMR was first developed in 1978, for the first 10–15 years it was regarded more as an academic curiosity rather than a robust analytical tool. Early reviews^{1021,1022} and later reviews^{1023,1024} of LC–NMR exist, but the technique has evolved rapidly as flow probes have become more common, probe sensitivities have increased, and as techniques for working with nondeuterated solvents have been developed.⁹⁰⁸ LC–NMR has now become almost a routine technique for metabolism groups,^{955,1025} and is proving useful for drug production and quality control groups,^{1026,1027} combinatorial chemistry groups,¹⁰²⁸ and groups doing natural products research.^{1029–1031}

The unique advantage of LC–NMR over all other NMR techniques lies in its ability to separate components within a sample in situ. To many spectroscopists, this may seem either obvious or nonessential (by thinking that the separation could always be performed off-line), but it has been shown that there are some analyses that do not lend themselves to off-line separations.^{1032–1036} Whenever the analyzed component is unstable to light, air, time, or the environment, LC–NMR will probably be the preferred NMR technique.

The hardware for LC–NMR consists of an HPLC system connected to an NMR flow probe. The experiments can be run either in an on-flow mode, in which the mobile phase moves continuously (useful for preliminary or survey data acquisition), or in a stopped-flow mode, in which peaks of interest are stopped in the NMR flow probe for as long as needed for NMR data acquisition (useful for careful examination of individual components). In the stopped-flow mode, either 1D or 2D NMR data can be acquired, although the limited amounts of sample usually tolerated by HPLC columns sometimes makes the acquisition of extensive 2D heteronuclear correlation data difficult. The stopped-flow mode can employ any one of three different kinds of sample handling. First, the samples may be analyzed directly as they elute from the chromatography column, one chromatographic peak at a time. This is often the first, or default, mode of operation. Second, the LC pump may be programmed to ‘time slice’ through a chromatographic peak, stopping every few seconds to acquire a new spectrum. This is useful for resolving multiple components (by NMR) within a peak that are not fully resolved chromatographically or for verifying the purity of a chromatographic peak. (Alternatively, on-flow acquisition with a very slow flow rate has been used for similar purposes.¹⁰³⁷) The third method is to collect the chromatographic peaks of interest into loops of tubing (off-line) and then flush the intact fractions into the NMR flow probe one at a time as needed. A variation of this technique is to trap the eluted peaks onto another chromatographic column, to allow concentration of the solute, and then re-elute them with a stronger solvent into the flow probe as a more concentrated slug.¹⁰³⁸

There are several aspects of acquiring LC–NMR data that are challenging. The first is that all mobile phases in LC–NMR are mixtures, and the solvents are rarely fully deuterated, so that usually several solvent resonances need to be suppressed. Additionally, the resonances of the organic solvents contain ¹³C satellites that need to be suppressed. Also, when the samples are flowing through the probe, solvent suppression sequences such as presaturation take too much time and do not work well. All of these problems were solved when the WET solvent suppression experiment was developed.⁹⁰⁶ WET uses a combination of shaped-pulse selective excitation, multifrequency SLP pulses, PFG, and indirect-detection ¹³C decoupling during the shaped pulses to quickly and efficiently suppress multiple resonances using only a simple two-channel spectrometer.

Another challenge in acquiring LC–NMR data is that, by definition, the solvent composition changes during the experiment. In reversed-phase LC–NMR, one of the cosolvents is virtually always water, and unfortunately the chemical shift of water changes as the solvent composition changes. (It has been observed that this is also true, to a much lesser extent, for the resonances of several other solvents and modifiers.) In addition, if the mobile phase is fully protonated (nondeuterated) there will be no ²H lock to keep the frequencies constant. (Also, D₂O serves as a poor lock signal because its chemical shift changes with solvent composition.) All of this means that the frequencies of solvent suppression are constantly changing. To allow this to be compensated for, and to allow the frequencies to be

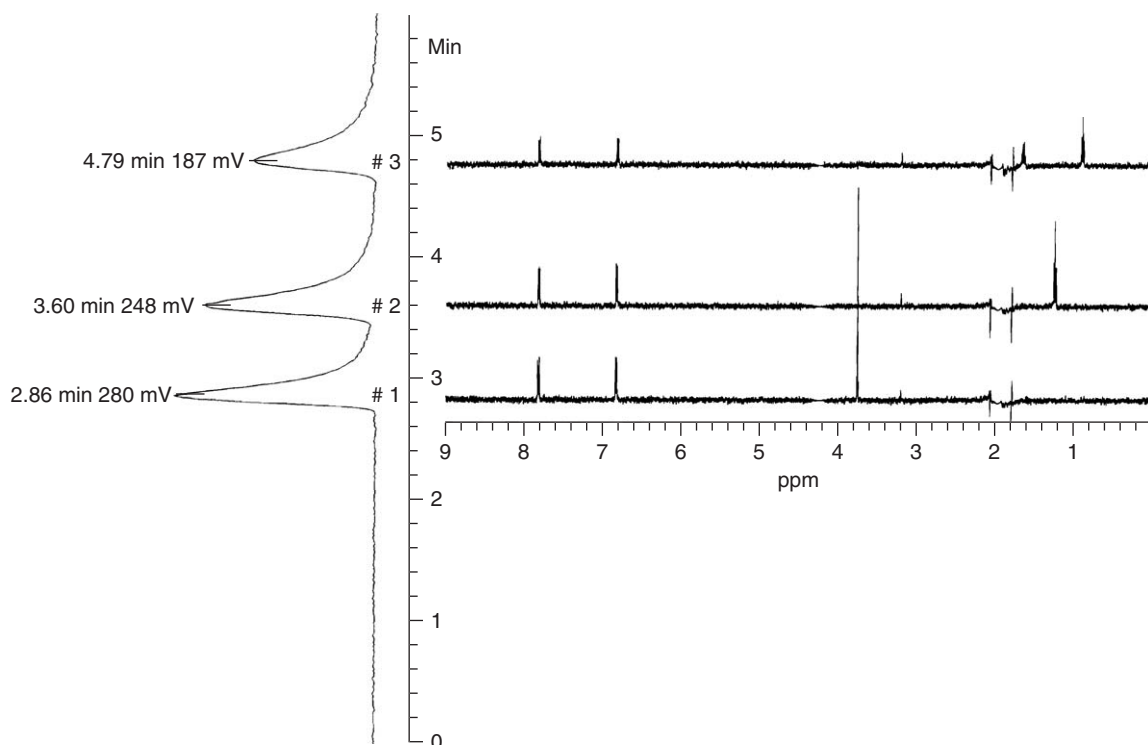

Figure 142 An on-flow LC-NMR spectrum. The three substituted benzoates were separated using a $\text{CH}_3\text{CN}:\text{D}_2\text{O}$ mobile phase. The ^1H chemical shift axis runs horizontally; the chromatographic time axis runs vertically. On the left is an 'NMRgram' showing the summed ^1H signal intensity between 7.5 and 8 ppm; this display is analogous to a chromatogram. On the top is the 1D spectrum (the 'trace') of the methyl benzoate LC peak that eluted at 2.9 min. The data were acquired while the sample flowed continuously through the probe by using two-frequency WET solvent suppression (at 1.95 and 4.2 ppm); suppression frequencies were automatically determined using the SCOUT scan experiment. The small signals flanking the CH_3CN resonance are traces of its ^{13}C satellites.

automatically optimized, the SCOUT scan technique was developed.⁹⁰⁶ This technique takes a single-scan, small-tip-angle, nonsuppressed ^1H spectrum, moves the transmitter to the constant resonance (serving as a ^1H lock), measures where the other peaks moved to, and creates an SLP that suppresses these peaks. This whole process takes only a few seconds. It can be used in an interleaved fashion during an on-flow solvent gradient run or as a precursor to the signal-averaged stopped-flow data acquisitions. We will see later how it forms an integral part of the DI-NMR and FIA-NMR techniques.

The presentation of the resulting LC-NMR data depends on the type of experiment being run. On-flow LC-NMR data are usually displayed as a contour map, like a conventional 2D data set, although the Fourier transform is only applied along one axis (the F_2 axis) to give a frequency versus elution time plot. The 1D data plotted along the 'pseudo- t_1 ' axis may either be the LC detection output or a projection of the NMR data (Figure 142). Stopped-flow LC-NMR data, on the other hand, are usually presented as a series of individual 1D spectra either one spectrum per page or as a stacked plot (Figure 143).

LC-NMR is usually considered a very powerful (although usually not a fast) technique. Its power can be exploited by combining it with mass spectrometry, to produce LC-NMR-MS. Usually a fraction of the chromatographic effluent prior to the NMR flow cell is diverted to the mass spectrometer. LC-NMR-MS is considered by some to be the ultimate tool for pharmaceutical analysis, and although it is still in its early days, it is proving its worth in one-injection analyses of compounds that are either sample limited or proving to be tough structural problems.^{954,955,1039,1040}

2.12.18.3.5.2 Flow injection analysis and direct-injection nuclear magnetic resonance

FIA-NMR and DI-NMR are essentially sample changers that exploit the speed and robustness of flow NMR. Neither technique uses chromatography, so they are not designed to analyze mixtures. DI-NMR is well suited for the analysis of

Figure 143 Stopped-flow LC-NMR data. The three substituted benzoates were separated using a $\text{CH}_3\text{CN}:\text{D}_2\text{O}$ mobile phase. The ^1H chemical shift axis runs horizontally; the chromatographic time axis runs vertically. On the left is the HPLC chromatogram; the corresponding ^1H NMR spectra are aligned with each peak. This is Varian's default (and automatic) output display for stopped-flow LC-NMR data. The data were acquired by using two-frequency WET solvent suppression (at 1.95 and 4.2 ppm) and a two-frequency DSP notch filters; suppression and filter frequencies were automatically determined using the SCOUT scan experiment. Each ^1H NMR spectrum was acquired in seven scans on a $25\text{ }\mu\text{g}$ on-column sample injection.

combinatorial chemistry library samples, whereas FIA-NMR appears to be more useful as a tool for repetitive quality control style analyses.

The hardware for FIA-NMR is similar to that for LC-NMR except that there is no chromatography column, so it is sometimes referred to as 'columnless LC-NMR'.^{988,989} No additional detectors (other than the NMR spectrometer) are needed, nor is a pump capable of running solvent gradient methods. FIA-NMR uses the mobile phase as a hydraulic push solvent, like a conveyor belt, to carry the injected plug of sample from the injector port to the NMR flow cell. After the pump stops, the spectrometer acquires the SCOUT scan, analyzes it, and acquires the signal-averaged data (again using WET solvent suppression). When finished, a start signal is sent to the solvent pump, so that it can flush the old sample from the NMR flow cell and bring in the next sample. In classic FIA-NMR, as in LC-NMR, the sample always flows in one direction, and enters and exits the NMR flow cell through different ports. The flow cell is always full of solvent.

DI-NMR, which was also first developed by Keifer's group,^{988,989} is significantly different. Rather than starting off with an NMR flow cell full of solvent and suffering the sensitivity losses caused by the ensuing dilution of the injected sample, the flow cell starts off empty in DI-NMR. A sample solution is injected directly into the NMR flow cell. The spectrometer then acquires the SCOUT scan, analyzes it, and acquires the signal-averaged data (with WET). When finished, the syringe pump pulls the sample back out of the NMR flow cell, in the reverse direction, and returns it to its original (or an alternative) sample container. Once the flow cell is emptied, clean solvent is injected and removed from the flow cell to rinse it. The solvents used for both the sample and the rinse must at least be miscible, and ideally should be identical, to avoid lineshape degradations caused by magnetic susceptibility discontinuities (due to liquid-liquid emulsions or precipitation of solutes in the flow cell) or any plugging of the transfer lines.

DI-NMR uses very different hardware than FIA-NMR. It uses the syringe pump in a standard Gilson 215 liquids handler to deliver samples to the NMR flow probe. Samples go directly into the NMR flow cell, through the bottom, via an unswitched Rheodyne injector port. The Gilson liquids handler is capable of accepting a wide variety of sample container formats, including both vials and microtiter plates.

One of the justifications for the development of DI-NMR was to improve the robustness and speed of automated NMR. The improvement in robustness has occurred, partly through the elimination of techniques such as sample spinning, automatic gain adjustment, automatic locking, and simplex shimming (PFG gradient shimming is used instead). This has allowed 96 samples at a time (stored in 96-well microtiter plates) to be run without error, and some installations have run tens of thousands of samples in a highly automated fashion. Sample turnaround times are from 1 min to 4 min per sample, but the speed at which it can be run depends quite heavily on the solvent being used. Although most solvents can be pumped in and out of the probe rapidly, dimethyl sulfoxide, which is used commonly, is viscous enough that sample flow rates are decreased and the resulting analyses may not be much faster than traditional robotic sample changers.

In comparison, FIA-NMR and DI-NMR have different advantages and disadvantages, and are designed for different purposes. The advantages of DI-NMR are that it generates the highest signal-to-noise ratio per sample and consumes less solvent. The disadvantages are that it has a minimum sample volume (if the sample volume is smaller than the NMR flow cell, the lineshape rapidly degrades), and no sample filtration is possible. The advantages of FIA-NMR are that it has no minimal sample volume (since the flow cell is always full) and can filter samples (with an in-line filter), and that it can rinse the NMR probe better in a shorter time (albeit by consuming more solvent). The disadvantages of FIA-NMR are that it generates a lower signal-to-noise ratio (because of sample dilution), and it consumes more solvent. Both techniques will always have some degree of carry-over (although it may be $<0.1\%$) and be subject to blockages from solid particles. The only way to avoid these problems is to use a conventional robotic sample changer for glass tubes. In applications, FIA-NMR is more valuable for repetitive analyses or quality control functions, especially when there is plenty of sample and the samples are to be discarded. In contrast, DI-NMR is more valuable when there is a limited amount of sample and the samples must be recovered. DI-NMR, as implemented by Varian in the VAST instrument, is becoming well regarded as a tool for the analysis of single-compound combinatorial chemistry libraries,^{956,1004,1041} biofluids, and for 'SAR-by-NMR' studies (described in [Section 2.12.18.3.5.4](#)).

2.12.18.3.5.3 Direct-injection nuclear magnetic resonance: data processing and analysis

Now that DI-NMR (VAST) is becoming routine, the next big challenge is the presentation and analysis of the data. As an example, we can examine how to display the spectral data acquired on the samples in a 96-well microtiter plate. Because these are combinatorial chemistry samples, there will be relationships between samples located in each row and each column of the plate, and we may choose to examine each of those relationships separately.

The most conventional way to present the data is as a stack of 96 spectra, plotted one spectrum per page. After acquiring data on several plates, this option tends to prove less popular to the chemists responsible for interpreting all of the information. Another option is to display all 96 spectra (and/or their integrals) on one piece of paper ([Figure 144](#)). This works best if only part of the chemical shift range is plotted, and serves better as a printed record of the data rather than as a means to analyze the data. An alternative, which is better for on-screen interactive analysis but is less useful as a printed record, is to display the data in a manner similar to that used to display LC-NMR data; namely, as a contour (or stacked) plot with the ^1H frequency axis along F_2 but in which the t_1 axis corresponds to individual wells ([Figure 145](#)). A third option is to display the spectral data as a stacked plot, either from one row, one column, or from a discrete list of well locations ([Figure 146](#)). The last option, which appeals to many, is to display integral information in one of three ways. First, one can extract integral intensities for different regions across the chemical shift range, for each of the 96 spectra, and list them serially in a text file. Second (and more usefully), one can take this text file and extract just one integral value per spectrum (all from the same region) and display it in a spreadsheet database. Third, one can display this same information as a color map, with color intensity representing integral intensity (or peak height or any other quantitative information). A more complete description of these various options appears elsewhere.⁹⁵⁶

Obviously, the most desirable way to interpret the data is automatically with a computer. Although the technology does not yet exist to determine the structure of an unknown compound *de novo* from its 1D ^1H spectrum, it is currently possible for a computer to determine if a given NMR spectrum is consistent with a suspected structure. This is relatively routine with ^{13}C data, but is harder for ^1H data because of the presence of homonuclear couplings (especially second-order couplings) and increased solvent effects, although software to accomplish this does exist.¹⁰⁴² This capability is expected to be of great interest in combinatorial chemistry, since normally the expected structure already exists in an electronic database somewhere and can easily be submitted to the analysis software along with the experimental NMR spectral data.

2.12.18.3.5.4 Other techniques, applications, and hardware: SAR-by-NMR

Rational drug design programs have also been using DI-NMR. Starting in 1996, a group at Abbott Laboratories published a series of articles about 'SAR-by-NMR'.¹⁰⁴³ Structure-activity relationship (SAR) mapping, has been around

Figure 144 DI-NMR data automatically acquired on samples stored in a 96-well microtiter plate using VAST. This is an 8×12 matrix plot of the 96 $1D\ ^1H$ NMR spectra acquired on a plate of samples dissolved in $DMSO-d_6$. This represents one way to plot the data from an entire titer plate on one page. Each spectrum was acquired, processed, and plotted with identical parameters, and is labeled with its alphanumeric position coordinates. For clarity, only an expansion of the proton spectrum (6–8 ppm) is displayed here. Data were acquired using WET solvent suppression as set up by the SCOUT scan experiment. Although the data presentation differs, these data are identical to those in **Figure 141**.

for many years, but the premise of SAR-by-NMR is to use changes in NMR chemical shifts to do the mapping. This is accomplished by first acquiring and assigning a $^1H\{^{15}N\}$ 2D correlation map (typically a PFG HSQC) of an ^{15}N -labeled receptor (a protein). Then, $^1H\{^{15}N\}$ correlation maps are acquired on a series of samples made by adding different ligands (small molecules) to different aliquots of this receptor solution. If the ligand binds to the receptor, individual 1H - ^{15}N correlations within the $^1H\{^{15}N\}$ HSQC spectrum will change positions, with the largest changes usually occurring for those nuclei that are closest to the active site of the receptor. (If the ligand does not bind to the receptor, the $^1H\{^{15}N\}$ HSQC spectrum will remain unchanged. The ligand itself is not ^{15}N labeled and will not appear in the HSQC spectrum.) By correlating the resonances that change position with the structures of the ligands, one can literally map the active site of the receptor. This technique has stimulated a flurry of interest in the primary literature.^{1044,1045} One of the drawbacks to this technique is that, because a number of ligand–receptor complexes must be studied, a significant amount of purified ^{15}N -labeled protein is needed, which is not always easy to obtain.

Another issue is that, because a significant number of 2D NMR spectra must be acquired, automated techniques for handling the samples and acquiring the data are desirable. Although conventional automated NMR sample changers can be used, more recently DI-NMR systems have also proven useful. A DI-NMR system uses less sample than is required by a 5 mm tube, and the robotic liquids handler can be programmed to prepare the samples as well.

2.12.18.3.6 Mixture analysis: diffusion-ordered and relaxation-ordered experiments

One of the challenges of NMR is working with mixtures. In the past, NMR has always focused on the bulk properties of the solution, and – with the exception of LC-NMR – few attempts have been made to resolve the individual components of mixtures. The following three methods show that this is changing.

Figure 145 A contour plot of the 6–8 ppm region of the proton spectra of 96 1D ^1H NMR spectra acquired on the DMSO- h_6 microtiter plate using VAST. Although the data presentation differs, these data are identical to those in **Figure 140**. This represents an alternative way to plot the data from an entire titer plate on one page. This style of data presentation is especially useful when it can be displayed on the computer screen in an interactive mode, and a user can select the 1D spectra for individual wells at the top of the screen. Each spectrum was acquired, processed, and plotted with identical parameters.

The most well-known method for analyzing mixtures by NMR is diffusion-ordered spectroscopy (DOSY). It uses PFG to separate compounds based on their diffusion rates. PFG has been used since 1965 to measure diffusion rates;⁹⁵⁷ but starting in 1992 it was shown how this technique could be used as a separation tool as well.^{1046–1048} DOSY data are presented as a 2D contour (or stacked) plot where F_2 is the ^1H chemical shift axis and F_1 is the diffusion rate axis. Compounds having different diffusion rates are separated along F_1 . Multiple components within a 5 mm tube have been separated.¹⁰⁴⁹ The technique can also be combined with other experiments, and extended to multiple dimensions, to create COSY-DOSY, DOSY-TOCSY, DOSY-NOESY, ^{13}C -detected INEPT-DOSY and DEPT-DOSY, and DOSY-HMQC, among others.¹⁰⁴⁷

In a related technique, Shapiro and co-workers combined PFG-based diffusion analysis with TOCSY to analyze mixtures in which the diffusion coefficients for each component are similar or in which there is extensive chemical shift overlap. Calling their version ‘diffusion-encoded spectroscopy’ (DECODES),^{958,959} they combined the standard longitudinal encode and decode (LED) sequence¹⁰⁵⁰ with a 2D TOCSY sequence. Multiple 2D TOCSY data sets are acquired, each with a different diffusion delay. The TOCSY component resolves the chemical shift overlaps, and the peak intensities of resolved resonances are plotted against the diffusion delay, to identify different chemical species in solution. (Each different chemical species in a mixture is likely to exhibit at least slightly different diffusion rates.) A variation of this technique, called ‘affinity NMR,’ was developed in which an unlabeled receptor was added to a mixture of ligands and a 1D or 2D DECODES spectrum was acquired.¹⁰⁵¹ If the diffusion delay is set long enough, only the resonances of the receptor and the bound ligands are visible. The TOCSY component then helps to resolve the

Figure 146 A stacked plot of the proton spectra (6.4–8.1 ppm) acquired on the ‘4’ wells (wells A4 through H4 – top to bottom) of the DMSO- d_6 microtiter plate using VAST. These data are a subset of those in **Figures 140** and **141**. This style of data presentation allows comparisons to be made between spectra acquired on different wells. Each spectrum was acquired, processed, and plotted with identical parameters.

chemical shifts of the detected (actively bound) individual components. A diffusion-filtered NOESY version of this technique has also been developed.¹⁰⁵² Unlike SAR-by-NMR, binding is detected by observing the ligand resonances and not by changes in the receptor resonances.

The third method for analyzing mixtures is relaxation-edited (or relaxation-resolved) spectroscopy. Large molecules have longer rotational correlation times than small molecules, and this results in shorter T_2 relaxation times (and larger NMR linewidths). These differences in T_2 relaxation can be used to edit the NMR spectrum of a mixture, based on the different relaxation rates of the individual components, in a manner analogous to diffusion ordering or diffusion editing.^{1053–1055} A combination of diffusion and relaxation edited experiments (DIRE) was also reported, and applied to the analysis of biofluids.¹⁰⁵⁴

A big advantage of LC–NMR is that the chromatography column can take a mixture and separate it into individual chromatographic peaks. However, one disadvantage is that no single combination of mobile phase and column can completely resolve all compounds, and a single chromatographic peak may still contain multiple components. Often, this can still be resolved by NMR because the individual components usually will have different chemical shifts, but this is only valid if the compounds and their chemical shifts assignments are already known in advance.¹⁰³⁷ The combination technique LC-DOSY-NMR (or DI-DOSY-NMR) would be a powerful way to analyze a mixture using as many as three different physical characteristics. Although this experiment has not yet been performed and the limited sample quantities used in LC–NMR may preclude its success, it remains an intriguing idea.

2.12.18.3.7 Other probes: superconducting probes, supercooled probes, and microcoils

Two other probe developments have also sprung from efforts to extract better signal-to-noise ratios from a given sample. The first is the use of probes that employ low-temperature RF coils to reduce the noise level. The RF coils are typically maintained at about 20 K while the samples are left at room temperature. Probes with coils of either superconducting metal^{1056,1057} or normal metal¹⁰⁵⁸ have been made, although probes that have full PFG and indirect-detection capability have only become available in recent years. (The term 'cryoprobe' is often loosely applied to both kinds of probes as a group.) The advantage of these probes is that they exhibit higher sensitivities, and at a cost lower than that of the purchase of a higher field magnet (although without the increased dispersion). The current disadvantages are their significantly higher cost and limited availability. (They have also been associated with somewhat increased levels of t_1 noise because of their use of mechanical pumps.) The cost and delivery issues have precluded them from being widely used, yet. Although that is changing rapidly, there are still a very limited number of published reports of their use.^{1059,1060} One very good illustration of their usefulness was made by using an ^{19}F version of a superconducting probe to study the kinetics of protein folding.¹⁰⁶¹ Here, the higher sensitivity provided was critical because the reaction rate was too fast to allow signal averaging, so spectra acquired in only one scan each had to be used to follow the reaction.

The other probe development is the use of small-scale microcoils for the data acquisition of very small samples. This work, done by Sweedler and Webb at the University of Illinois starting in 1994,¹⁰⁶² is allowing NMR data to be acquired on samples ranging in size from roughly 1 μL down to 1 nL.^{1063,1064} The primary justification is to enable applications in flow NMR, that is, to allow NMR data to be acquired on capillary HPLC and capillary electrophoresis effluents.¹⁰⁶⁵ The biggest problem in using microcoils is dealing with the magnetic susceptibility interfaces;¹⁰⁶³ however, probes have developed to the point that 2D indirect-detection data have been generated.¹⁰⁶⁶

2.12.18.3.8 Combination experiments

It is now routine in modern NMR spectroscopy to find that many of the above-mentioned techniques are combined in an ever-increasing number of ways. Many such examples can be observed. The resolution and sensitivity of the HMBC experiment for poorly resolved multiplets was improved significantly by using semiselective pulses.¹⁰⁶⁷ The 3D version of HMBC has been advocated for the elucidation of natural product structures.¹⁰⁶⁸ Selective excitation has been combined with a PFG version of a 3D triple-resonance experiment, to make a 2D version (SELTRIP) for the study of small biomolecules.¹⁰⁶⁹

PFGs and selective excitation have been combined into a powerful tool called 'double-pulse field gradient spin echo' (DPFGSE), also known as 'excitation sculpting'.⁹⁰² This tool offers a lot of flexibility in selecting desirable (or discriminating against undesirable) NMR signals, to produce both cleaner and more sensitive NMR data. As such, it has been used in a number of applications. One example is the DPFGSE-NOE experiment,⁹⁰² which produces significantly cleaner data than the conventional 1D-difference NOE experiment. Another example is the HETGOESY indirect-detection experiment used for detecting heteronuclear NOEs.¹⁰⁷⁰ DPFGSE sequences have been used to perform isotopic filtering to select only ^{13}C -bound protons¹⁰⁷¹ and for removing t_1 noise in 2D experiments.¹⁰⁷² It has also been used in band-selective homonuclear-decoupled (BASHD) TOCSY¹⁰⁷³ and ROESY¹⁰⁷⁴ experiments.

2.12.18.3.9 Software

Software tools to massage and analyze data are constantly becoming more powerful and more important. Digital signal processing (DSP) techniques that use low-pass filters are being used to enhance the spectral signal-to-noise ratio (through oversampling) and to reduce data size.¹⁰⁷⁵ High-pass DSP filters, or notch filters, are being used to remove solvent resonances.^{908,1076} Linear prediction techniques are being used to flatten baselines and remove broad resonances.¹⁰⁷⁷ Bayesian data analysis is providing more powerful and statistically meaningful spectral deconvolution, which can facilitate quantitative analysis.¹⁰⁷⁸ FRED software is providing automated interpretation of INADEQUATE data,^{998,1079} and is allowing complete carbon skeletons of unknown molecules to be determined both automatically and with higher effective signal-to-noise ratios.⁹⁹⁷ ACD software¹⁰⁸⁰ is not only generating organic structures from 1D ^1H and ^{13}C data, but is also helping analyze NMR data acquired on combinatorial chemistry libraries.¹⁰⁴² The filter diagonalization method shows promise for very rapid 2D data acquisition, and has greatly reduced data storage requirements.^{1081,1082} This too should prove useful for combinatorial chemistry.

2.12.18.3.10 Quantification

One of the big applications for NMR that seems to be on the verge of a growth spurt is in the area of quantitative analysis, especially in high-throughput techniques such as combinatorial chemistry. Part of this seems to arise from the

difficulty of performing accurate quantification with mass spectrometric techniques, especially for samples still bound to SPS resin beads.¹⁰⁸³ NMR data can be highly quantitative, but certain precautions must be observed.^{1084,1085} These include the need to use broadbanded excitation, generate flat baselines, minimize spectral overlap, minimize NOE interferences, and, in particular, ensure complete relaxation.¹⁰⁸⁶

The other issue is the use of internal standards. Most internal standards have some drawbacks, such as too much volatility to be reliable (e.g., tetramethylsilane (TMS)) or too little volatility for easy removal from the solute after measurement (e.g., (trimethylsilyl)propionate (TSP)). Some standards have also been shown to interact with glass sample containers.¹⁰⁸⁷ To minimize spectral overlap, the NMR resonance(s) of the standard should be sharp singlets (e.g., TMS, TSP, hexamethyldisiloxane, or CHCl_3), yet such resonances often exhibit very long T_1 relaxation rates (which complicates quantification). Recently, 2,5-dimethylfuran was proposed as an internal standard because the integrals of the two resonances can be compared to verify complete relaxation.¹⁰⁸⁸

2.12.18.3.11 Automation

Of course, tools are needed to automate the acquisition and data analysis of all these experiments in a repetitive fashion. There are different levels and kinds of automation for NMR. The most primitive level lets a user change the sample manually but use software macros to automate the setup, acquisition, or processing of one or more data sets. The next level of automation entails the use of robotic devices to change samples automatically, and this is usually done in combination with software automation to acquire and plot (but not necessarily analyze) the data automatically. Some open-access NMR spectrometers run in this latter mode, although more open-access systems probably run in the former mode. Many service facilities operate in a highly manual mode.

Conventional tube-based NMR spectrometers equipped with robotic sample changers never run at 100% reliability. Estimates of reliability probably range from 75% to 99%, with autospin, autolock, and autoshim software failures being the most common hazards. The strengths of tube-based robotics is that the probe and spectrometer are always intact, and any failed sample is usually just ignored, so that the spectrometer can move on to the next sample. Automation of sample preparation is often neglected.

The increased sample-throughput requirements of modern drug discovery programs are driving the development of more robust methods of NMR automation. Flow NMR techniques (the VAST DI-NMR system in particular) are being used to avoid failure-prone steps. This has pushed reliability up to 99.9% or higher, and this is important when thousands of samples are being analyzed. One advantage of DI-NMR is that sample preparation is minimal. One often forgotten limitation of DI-NMR is that dirty samples (those that contain precipitates, solids, emulsions, or immiscible mixtures) can clog up flow cells and degrade NMR lineshapes and solvent suppression performance. This suggests that DI-NMR is not ready for use in open-access environments and that tube-based NMR spectrometers are more appropriate for seeing nonfiltered samples.

2.12.18.3.12 Research nuclear magnetic resonance versus analytical nuclear magnetic resonance

This brings up a final point about the dual nature of NMR spectroscopy. NMR started off as a tool for research. For several decades it continued to serve in that role, and to a large extent it still does (and will for the foreseeable future). However, eventually it will also become an analytical tool, serving to provide answers to repetitive questions. The current drive to develop automation and high-throughput techniques is a reflection of the beginning of this trend, which is expected to grow.

2.12.18.4 Overview

The field of NMR spectroscopy has matured significantly, although this does not mean that the pace of development has slowed; rather, it means that this is a time of great opportunity. Many hardware and software tools have been developed to solve specific problems, and the key now is to apply these tools to new problems. One might even go so far as to say that the hardware and pulse sequence tools we have available are ahead of the potential applications, meaning that what remains are for users to find new ways to use the tools that have already been developed. Some of the most exciting possibilities undoubtedly lie at the boundaries of interdisciplinary problems; that is, scientists who are unfamiliar with NMR often have problems that could be solved with current technology if only these problems could be matched up with both people of vision and people with the correct technical expertise. As a result, it behooves all scientists in the field of drug discovery to – as much as possible – stay abreast of these many developments in NMR spectroscopy.

2.12.19 Materials Management

2.12.19.1 Introduction

During the rational drug design phase of the 1980s, effective materials management was an important, but not crucial, aspect of the drug discovery process. However, during the 1990s, as drug discovery methods became increasingly automated and probabilistic, efficient management of materials became a critical component of the drug discovery process.

This section will define materials management, describe its current role in drug discovery, and discuss future trends in the field. With a focus on the management of chemical reagents, natural products, and proprietary compounds, the section will explore both automation technology, which is used for management of the physical materials, and materials management information technology, which is central to an overall drug discovery informatics environment.

2.12.19.2 Materials Management: A Definition

Materials management refers to the systems, work processes, facilities, and technology involved in selecting, acquiring, receiving, storing, tracking, controlling, safely handling, distributing, and disposing of the materials defined below:

- Reagents – materials, usually available commercially from a chemical supplier, that are used throughout the performance of an experimental method. Within this section, the term ‘reagents’ refers to the specialty organic chemicals used by chemists as starting materials (including catalysts and solvents) in the synthesis of novel compounds.
- Compounds – proprietary chemicals synthesized or acquired for the purpose of testing for biological activity. A compound may be synthesized by an in-house medicinal chemist through manual or combinatorial methods or may be acquired from an external organization, such as a university or a government agency, or from an alliance partner. The term ‘compound’ may refer to one known chemical structure or to a mixture of multiple chemical structures.
- Natural products – naturally occurring materials that a drug discovery organization acquires and screens for biological activity.

Materials management processes are designed to:

- maximize the throughput of chemical synthesis by streamlining the process of selecting, acquiring, and managing reagents;
- minimize the costs involved in managing reagents by identifying duplicate inventory and excessive carrying and disposal costs;
- maximize screening throughput by streamlining the process of preparing proprietary samples for screening;
- reduce the risk of materials handling errors by creating an integrated informatics environment that obviates the collection and entry of incorrect data; and
- improve safety and regulatory compliance by providing tools for environmental, health, and safety personnel to monitor hazardous material usage and support preparation of regulatory reports.

In summary, materials management processes are designed to reduce cycle times, maximize productivity and efficiency, control costs, and enhance environmental health and safety.

2.12.19.3 Role of Materials Management in Drug Discovery

Figure 147 shows how materials management fits into the drug discovery process. Reagents are selected and acquired by medicinal chemists to support synthesis processes during both lead generation and lead optimization. To support screening processes, compounds are received, stored, and distributed for screening. Following results analysis, leads are requested for follow-up. Central to the overall materials management process is a materials management system that provides the foundation of a drug discovery informatics environment.

Figure 148 shows how SciQuest’s Enterprise Substance Manager solution integrates the overall discovery informatics environment. The informatics environment shown in the figure breaks down as follows:

- Supply-chain data, which includes such information from reagent suppliers as product description, package quantity, and pricing information.

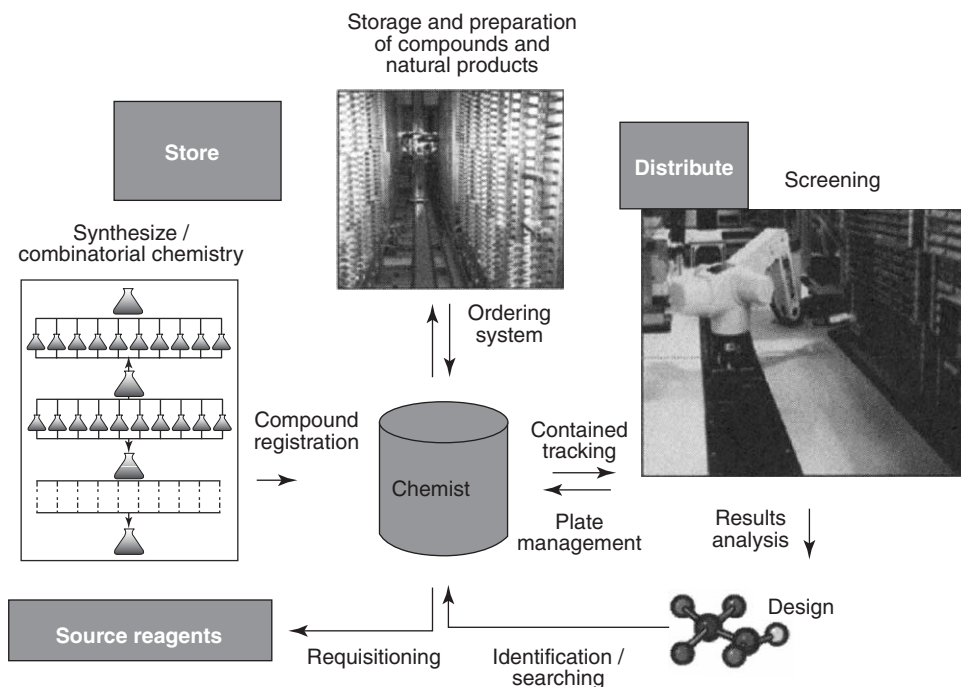

Figure 147 Materials management in drug discovery.

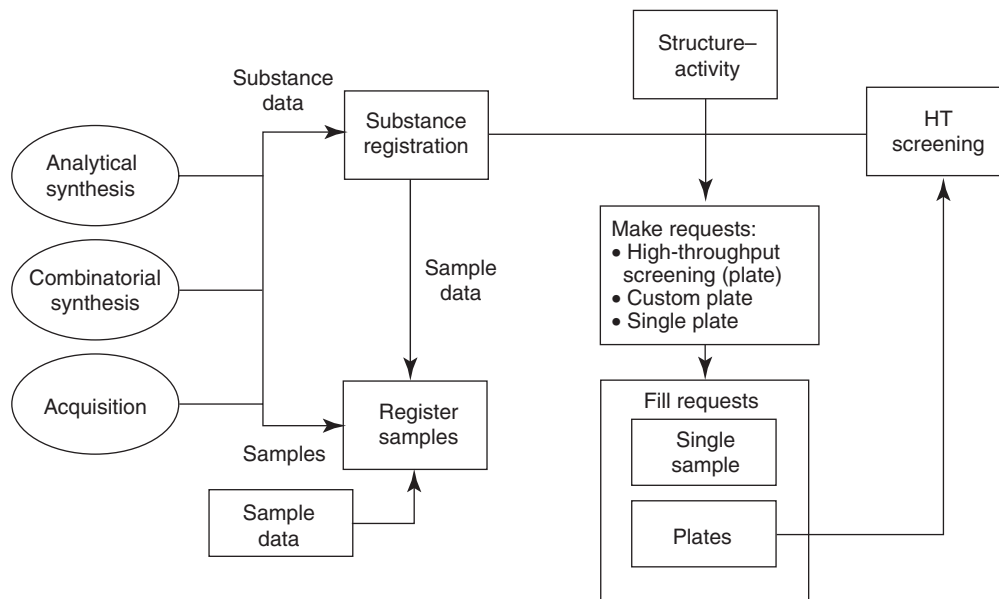

Figure 148 Materials management system.

- Enterprise resource planning systems, which provide purchasing and payment of reagents acquired from reagent suppliers.
- Cheminformatics and bioinformatics systems, which provide chemical, physical property, and biological activity data associated with materials. Compound registration systems and biological activity management systems are all integrated through a centralized inventory or materials management system.
- Process automation, such as robotic liquid-handling equipment and automated sample storage and retrieval systems.

After establishing the physical sample as the primary object with which all components of an informatics framework are integrated, a materials management system matches the attributes of materials with the attributes of containers, to provide an underlying data structure that integrates all of the components. As described by Frank Brown¹¹¹³:

“Using the sample object allows for simple change and additions to the description of the sample without a complete rewrite of the data structures. The hub of the chemical information system is the inventory system. The registration number should be considered a name and not a primary key for building relationship given the complexity of parsing needed to break the registration number into its pieces.”

2.12.19.4 Job Functions Involved in Materials Management

Now that we have discussed how materials management fits into the drug discovery process and the informatics environment, it is important to discuss the way various job functions are involved in the materials management processes. Following is a description of these job functions:

- Medicinal chemists – select, order, track, and dispose of reagents as well as synthesize, register, and distribute proprietary compounds.
- Purchasing personnel – place orders for reagents, interact with suppliers on pricing and availability, and provide status updates to requesters of materials.
- Receiving/stockroom personnel – receive reagents at the facility, label containers of reagents, maintain and replenish stock, and provide delivery services to scientists for requested reagents.
- Waste management personnel – collect waste, prepare waste manifests for waste haulers, and provide reports of what material has been removed from a facility by what mechanism.
- Compound management personnel – receive, store, and track proprietary compounds and prepare samples for screening.
- Registrar – ensures integrity of chemical and physical property data entered into the corporate compound registration database. May or may not be part of the compound management group.
- HTS scientists – request samples for screening and perform plate management functions (including plate replication and combination) to support HTS activities.
- Therapeutic area biologists – select compounds of interest and place requests for samples for follow-up screening.
- Information technology personnel – assist with the design, development, integration, maintenance, and support of materials management systems.
- Environmental health and safety personnel – maintain lists of materials that require monitoring; track training requirements of personnel handling hazardous materials; and monitor and provide reports for regulatory purpose on acquisition, usage, and disposal of hazardous materials. They are responsible for the chemical assessment and clearance procedures.

2.12.19.5 Materials Management Work Processes

Figure 149 provides a summary of the key work processes – by job function – involved in materials management. The five primary work processes are (1) reagent sourcing; (2) reagent receiving and tracking; (3) new compound registration and sample submission; (4) master plate preparation and distribution for HTS and (5) follow-up screening. Each is discussed in detail below.

2.12.19.5.1 Reagent sourcing

Reagent sourcing refers to the selection and sourcing of reagents to support synthesis processes. The steps in the process are as follows:

- (1) A medicinal chemist will establish a synthesis plan and design a virtual library of chemical structures.
- (2) The chemist conducts a search for commercially available reagents that can be used as starting materials for the synthesis of the library. The ‘hit list’ may be further refined using chemical structure analysis tools to eliminate undesirable functional groups and maximize structural diversity; it ensures that the molecular weights of the desired products are within acceptable ranges.
- (3) The chemist conducts an inventory search for reagents on his or her list that are already available in-house, and researches paper and/or electronic catalogs for products that can be purchased. For desired reagents that are not available, the chemist may consider custom synthesis. In some organizations, environmental health and safety personnel are part of the approval process for orders of hazardous materials but not part of the order approval process; they passively monitor orders, prepare reports of hazardous material usage, and identify any regulatory issues.

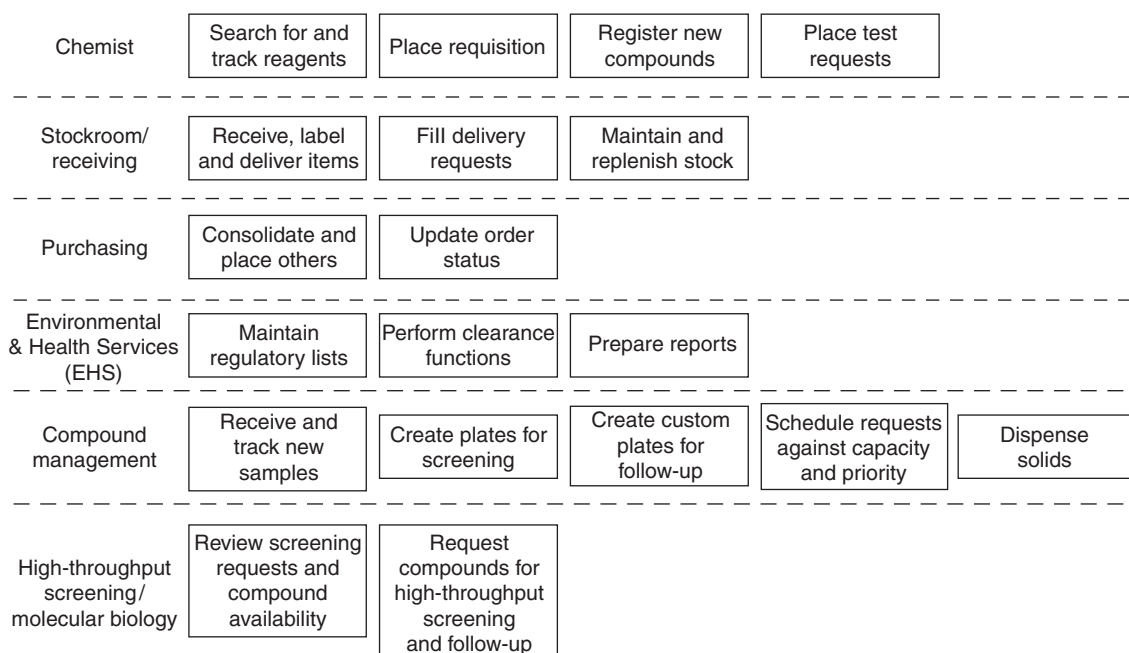

Figure 149 Materials management work processes.

(4) For items available in-house, the chemist will retrieve the item from another laboratory or place an internal requisition to a stockroom. For items not available in-house, the chemist will submit a purchase requisition. Depending on the organization, the purchase order is placed by routing a paper requisition, through integration with a purchasing system or directly to suppliers via the internet or electronic data interchange mechanisms. Some companies have preferred relationships with suppliers, and allow chemists to place orders directly, using credit cards. In other cases, the purchasing department or a third-party purchasing agent may be responsible for placing orders with suppliers and communicating the order status from the suppliers back to the original requester; this process can be automated as part of a business-to-business e-commerce application.

2.12.19.5.2 Reagent receiving and tracking

Once reagents are received by a facility, they are delivered to the requester, tracked, and disposed of. The steps of the process are as follows:

- (1) The supplier delivers the ordered items to the loading dock.
- (2) Receiving personnel unpack the box and match the packing slip to the original order and note any discrepancies. In some organizations, all orders for chemicals are processed by a chemical stockroom and are delivered directly by receiving personnel to the stockroom. When the item is unpacked, the purchasing system is updated to note receipt and process payment. Most organizations then update an internal tracking system to generate bar code labels and start tracking individual containers.
- (3) Receiving personnel deliver the item to the original requester.
- (4) The original requester uses the reagent and then places the remainder in a disposal bin, stores it in the laboratory, or returns the item to a centralized storeroom for reuse. The storeroom may update the quantity-available information.
- (5) When items are ready to be disposed of, the individual responsible for waste management removes the material and prepares a manifest in conjunction with the waste hauler.

2.12.19.5.3 New compound registration and sample submission

Once the chemist completes the synthesis of a new compound or library of compounds, the compound has to be registered and the physical sample submitted for storage and distribution. The steps in the process are as follows:

- (1) Once the chemist synthesizes new proprietary compounds (or compounds are received from outside), he or she enters the chemical and physical attributes of the compounds into the corporate database or registration system.

In some organizations, the processes of registering the compound and submitting it for analytical testing are integrated. In some cases, the chemist does the registering; in others, a centralized registration group handles the registration process. At a minimum, the centralized registration group will have final quality control, to ensure that the chemical structure of the compound is consistently entered into the corporate database for consistent data retrieval. Following registration of the compound(s), a company code number is assigned, to provide an internal naming convention. The registration database is then used as the chemical structure/information source in support of structure and biological activity database searches. In some companies, registration of the physical sample precedes compound registration. This happens more and more often in high-throughput processes where the structure characterization of the compound is done following completion of biological screening activities. Furthermore, as part of collaboration agreements, some companies might do 'blind' screening of plates without knowing the structures of the screened compounds.

(2) In conjunction with the registration of both the chemical and physical attributes of the new compound, the physical sample is usually distributed to a centralized compound management group for storage, distribution, and inventory management.

(3) Along with logging the new sample into the materials management system and placing the sample in storage, the compound management group may be responsible for the initial registration of the compounds and natural products received from external sources.

2.12.19.5.4 Master plate preparation and distribution for high-throughput screening

Once compounds are synthesized, they are plated and distributed for screening. The steps of the process are as follows:

(1) On receiving the compounds from the chemist, the compound management group will create master plates from the source compounds at standardized concentrations and volumes. This may be an automated process, using liquid-handling automation equipment and robotic weighing equipment, or it may be a semiautomated process, with technicians manually flicking small amounts of material to support plate preparation.

(2) Once the master plates are prepared, they are replicated and stored, usually in cold storage.

(3) Replicates are distributed for screening, either on demand or as part of a standard work process. Usually, when plates are distributed for screening, the contents of the plates are also entered into the biological activity database for future association with screening results. There may be manual population of plate data from the biological database or automated population via integration between the materials management system and the biological screening database.

2.12.19.5.5 Follow-up screening

Once hits are identified, samples must be prepared for follow-up screening. The steps of the process are as follows:

(1) When screening is completed, the results are entered into the biological activity database.

(2) After the hits are identified via searches against the biological activity database, a request for samples is submitted to the materials management system based on the hit list.

(3) The materials management system logs the request and identifies source containers that can be used to fill the request. Frequently, custom plates are prepared by 'cherry picking,' or removing materials from individual wells across multiple source plates. Often, serial dilutions are performed to generate dose-response results.

(4) When follow-up screening yields positive results, additional follow-up screens and solid samples are requested from the materials management system and obtained from solid storage.

2.12.19.6 Materials Management Technologies

A variety of technologies are in use to support the above work processes. Following is a description of available technologies.

2.12.19.6.1 Chemical structure-based reagent selection tools and products

Chemists select reagents via chemical structure criteria. A variety of chemical structure-based software tools are available on the market to search chemical databases by chemical structure, substructure, structural similarity, and other mechanisms. Numerous tools are also available to provide chemical structure searching capabilities. Among these are MDL's ISIS products, Accelrys, Inc.'s RS3 product, Daylight, Tripos tools, MSI's tools, CAS, Scifinder, and CambridgeSoft's tools.

In the realm of materials management, these tools are at their most powerful when incorporated into an overall materials management system. SciQuest has incorporated chemical structure searching tools into their reagent manager materials management product line, just as MDL has incorporated chemical structure searching tools into their product. Another example of how chemical structure searching information technology is applied to materials management is MDL's Reagent Selector. Both SciQuest and MDL products evaluate result sets of reagent-product chemical structures, based on criteria such as molecular weight and structure diversity, and easily allows for the elimination of structures with undesirable functional groups or elements.

2.12.19.6.2 ERP systems, supplier catalogs, and electronic commerce

Chemical structure searching tools are only as good as the content data they are searching against – which in turn are only as good as the level of integration with purchasing applications. The most widely used electronic catalog of reagents is MDL's Available Chemicals Directory. This product is a compilation of several catalogs providing chemical structures, as well as packaging and pricing information. Periodically, MDL provides these data to its customers in the form of a database that can be searched by chemical structure tools. Other vendors, such as CAS, provide similar products. Suppliers such as Sigma-Aldrich provide product information either through CDs or directly through their website. Some suppliers (e.g., Sigma-Aldrich) also provide detailed chemical information and safety information through their website.

Whereas chemists will search through electronic catalogs to select reagents, enterprise resource planning systems, such as SAP, are used to place orders to suppliers. Technology is also available to place orders directly with suppliers by electronic data interchange mechanisms or via suppliers' websites. Companies such as SciQuest provide third-party mechanisms to aggregate catalogs of available materials and support sourcing and procurement functions.

2.12.19.6.3 Robotic weighing and liquid-handling workstations

Plate preparation processes involve a number of repetitive steps in weighing samples and transferring liquids to solubilize samples, as well as preparing plates at desired concentrations and volumes. A number of robotics weighing systems, such as those provided by Zymark, are on the market to tare-weigh empty vials and gross-weigh vials full of solid material. The robotic workstations are integrated with laboratory balances to collect weight information and transfer data to formatted files.

Similarly, liquid-handling systems automate repetitive plate preparation tasks, including solubilizing samples, transferring liquid samples from a source container to a plate, adding top-off volumes to achieve desired concentrations, creating replicate plates for distribution and screening, and combining multiple plates into single plates. Examples of liquid-handling systems are the workstations provided by TECAN and Hamilton. Both robotic weighing and liquid transfer workstations exchange data to and from materials management systems, usually via formatted file transfers.

2.12.19.6.4 Materials management systems

As mentioned earlier, materials management systems provide the foundation for an integrated discovery research informatics architecture. The physical sample is the key data element that integrates supplier data, process automation systems, and chemical and bioinformatics systems. A robust materials management system supports such functions as:

- selecting reagents by chemical structure;
- placing orders, either directly with suppliers or via enterprise resource-planning systems;
- receiving items from suppliers;
- tracking container usage;
- submitting sample proprietary materials;
- submitting and fulfilling requests for samples in support of screening; and
- preparing, replicating, and combining plates.

Such a system requires integration with supplier catalogs, purchasing systems, compound registration systems, biological results databases, robotic plate preparation equipment, laboratory balances, and automated sample storage and retrieval systems.

SciQuest's product line is one such materials management system currently on the market. SciQuest refers to its offerings as research supply chain solutions, given its foundation level within the informatics environment and its focus on logistics functions. MDL's SMART product also provides some materials management capabilities across tracking containers of reagents and supporting capabilities to track proprietary samples. Some organizations have also built their own materials management systems, with Affymax being an example of one that is reported in the literature.

2.12.19.6.5 Automated sample storage and retrieval systems

As the numbers of samples begin to stretch into millions, the larger drug discovery organizations are procuring sample storage and retrieval systems that will automate their materials management functions. Such systems integrate a wide variety of functions, including submitting samples for storage, solubilizing and replicating plates, retrieving samples from storage, and weighing out and dispensing solid samples – all within an environmentally controlled secure, usually cold storage area. Usually provided by systems integration firms, these systems encompass both the equipment and technology to handle robotic weighing and liquid-handling equipment, laboratory balances, storage units (such as Kardex's Lektriever), and software to integrate all of these components. Usually, such systems integrate tightly with an external materials management system or have scaled-down versions of these systems as part of the overall solution. Examples of these solutions include TAP's Haystack system as well as systems provided by RTS Thurnall, REMP, and Aurora.

2.12.19.7 Future Directions

The future in drug discovery materials management technology is all about miniaturization, factory automation, leveraging the internet, and object-oriented information technology. As screening technology gets smaller, sample sizes and plate formats also continue to get smaller – meaning the use of 1536-well plates and microfluidic technology for the management of samples in the chip format.

Automation technology will improve throughput, further automating the discovery process and resulting in the application of factory automation principles to the discovery research process. Discreet automated components will be integrated, leading to tighter integration of automated storage and retrieval systems, and ultrahigh-throughput screening technology. Materials management systems will extend to provide production management and work scheduling functions to support automation processes. This high degree of automation and the unimaginable volumes of data that will be generated will introduce even more downstream bottlenecks.

The internet will be leveraged to integrate drug discovery organizations more tightly with their suppliers and partners. Chemists will be able to obtain real-time product, pricing, and availability information from their suppliers, minimizing out-of-date information and reducing bottlenecks. Furthermore, as drug discovery organizations continue to partner with other companies, the internet will support the establishment of virtual-project-based organizations to seamlessly share, track, and handle materials management information.

With the increase in throughput, the need for seamless informatics integration will continue. The migration to object-oriented systems using standards such as CORBA will allow discrete systems to integrate tightly, provided that an overall data architecture is established by information management professionals.

Biographies

Anthony W Czarnik received his BS degree (cum laude) from the University of Wisconsin-Madison in 1977, majoring in biochemistry. He received his graduate training at the University of Illinois at Urbana/Champaign, obtaining both an MS degree (1980) in biochemistry and a PhD (1981) in organic chemistry. From 1981 to 1983, he was an NIH Postdoctoral Fellow at Columbia University, working with Prof Ronald Breslow on the design of artificial enzymes. He began his academic career in 1983 at Ohio State University, in the Faculty of the Department of Chemistry.

Czarnik has received both DuPont and Merck awards for new faculty, and in 1986 was presented with an American Cyanamid award in recognition of excellence in the advancement of science and the art of chemical synthesis. He was named an Eli Lilly awardee in 1988, a Fellow of the Alfred P Sloan Foundation in 1989, and a Teacher-Scholar Fellow of the Camille and Henry Dreyfus Foundation in 1990. He is the author of over 100 scientific publications and an editor of seven books, and serves on the editorial board of a number of journals.

From 1993 to 1996, Czarnik served as the Director of BioOrganic Chemistry at Parke-Davis Pharmaceutical Research. In 1996, he accepted a position at IRORI in San Diego, CA, serving as the Senior Director and Vice President, Chemistry. From 1998 to 2000, he was the Co-Founder and Chief Scientific Officer of Illumina, Inc., which is involved in the discovery and development of ways of using bead-based combinatorial libraries of fluorescent receptors to invent and fabricate sensors. From 2001 to 2003, he served as the Chief Scientific Officer of Sensors for Medicine and Science, Inc. in Germantown, MD.

Czarnik is currently the Founder and Manager of a Nevada-based startup company, Protia, LLC, and is a Visiting Professor of Chemistry at the University of Nevada, Reno. Additionally, he is a member of the Scientific Advisory Board of Biopraxis, Inc.

Czarnik's current research interests include combinatorial chemistry as a tool for drug discovery, nucleic acids as targets for small molecule intervention, and fluorescent chemosensors of ion and molecule recognition.

Houng-Yau Mei is the President and Chief Executive Officer of Neural Intervention Technologies, a leading medical device company developing liquid embolic systems for treating endovascular diseases. Mei has extensive management and operations experience in both biotechnology and pharmaceutical industries. In his 10 year tenure with Parke-Davis and Pfizer Pharmaceuticals, he took on increasing responsibilities in drug discovery research and technology management. He was a principal investigator in anti-infective therapeutics and novel technology development for combinatorial chemistry and therapeutics against RNA targets. As the Director of Discovery Technologies at Parke-Davis/Pfizer, Mei played a critical role in global strategic planning, and was the program manager for implementing the US \$25 million ultrahigh-throughput screening system and the automated compound management system at the Ann Arbor facility. Prior to joining Neural Intervention Technologies, Mei was the Vice President of Operations and Officer at Rubicon Genomics, responsible for operations, technology validation, commercialization of new products, and contract services for genome and transcriptome amplification applicable to pharmacogenomic, cancer diagnostic and biodefense research.

Mei received his PhD from Columbia University, his postdoctoral training at the University of California in Santa Barbara, and his MBA from the Executive Program at Michigan State University.

2.13 How and When to Apply Absorption, Distribution, Metabolism, Excretion, and Toxicity

For the past 5 years or so, a major trend in the industry has been to move away from the straight-line, serial R&D strategy that simply moved compounds in a preordained, generally linear fashion from internal department to internal department as more information was gained and internal criteria for promotion were met at each stage. This notion of a fixed R&D path for every new screening hit from the chemistry bench to clinical testing is all but dead in today's highly cost-conscious and competitive biopharmaceutical world. The key strategic dictums for R&D today, as well as into the foreseeable future, are flexible, creative, individually designed project plans, with clinically oriented go/no-go decision points applied as early in the R&D process as possible, and an uncompromising focus on the critical pharmaceutical qualities that a new lead candidate must have in order to be commercially successful.

Many of these market- and clinically oriented pharmaceutical qualities can be effectively evaluated during the nonclinical, ADMET (absorption, distribution, metabolism, excretion, and toxicity) phase of R&D. Of equal importance, the evaluation of these critical pharmaceutical qualities is not only tractable during nonclinical development; the increasing application of *in silico* and *in vitro* methodologies offers the potential to reduce both the costs and time required to assess these criteria compared to more traditional *in vivo* approaches. Some of these *in silico* and *in vitro* technologies are relatively mature today and readily applied. On the other hand, substantial amounts of additional data remain to be acquired in order to compare and validate these techniques against the *in vivo* databases of

not only the industry, but also the various worldwide regulatory bodies. Clearly, in this regulated environment, the industry and the regulators must partner and reach consensus on the place and role of these new development technologies in the drug application and review process, as well as at all phases of clinical and nonclinical development.

The focus of this chapter will not be on these emerging technologies and methodologies, which are presented and reviewed elsewhere in this work (*see* Volumes 2, 3, and 5), but rather on the strategic incorporation of these new approaches, as well as the more typical ADMET procedures and technologies, into the most efficient nonclinical evaluation plan possible. From the bench scientist to the senior management team, there must be an organizational willingness to think beyond their company's traditional, internally established and politically acceptable R&D pathways and project milestones. It should be obvious to any participant or observer that these low-risk, often culturally embedded compound-vetting paradigms have proven themselves to be highly inefficient, very expensive, and nonsustainable.

While many members of senior management, project managers, and even team members typically regard the formal, Investigational New Drug (IND)-enabling Good Laboratory Practice (GLP) toxicology studies as the slowest and most expensive part of the project plan, in reality these studies are only the last phase of nonclinical development. In a creative, individually designed project plan focused on the critical pharmaceutical qualities of a given lead compound, many other potential go/no-go milestones should have been passed by the time these studies are undertaken.

Making the right decision as to how and when to evaluate ADMET parameters during R&D can lead to key strategic advantages for an organization, with the potential to decrease both resource utilization and the time required to eventually reach the market with a high-quality compound. The economic realities of pharmaceutical R&D today demand nothing less.

2.13.1 Introduction

Generally discussed numbers for the achievement of a successful marketing application from the initiation of clinical testing are in the range of 10–20%. Coupled with the substantial time (7–15 years) and resources devoted to bringing a new molecular entity to market (estimates range from \$0.8 billion to twice that amount), the strategic advantage to be gained by improving these numbers is obvious. Of course, the cost of a single success is a direct function of the large number of failed candidates in big pharma's pipeline. Certainly smaller companies have brought drugs to market with far fewer resources available to them. In fact, biotechnology-derived products have typically had higher success rates and shorter development times compared to new chemical entities. Nonetheless, while there may be debate around the exact numbers, there is no debate concerning the desirability to increase the success rate while reducing the time and costs required to bring a new drug on to the commercial market.^{1–3} Not only will just the commercial imperatives of the industry be addressed, but so will the medical needs of patients as well. There are numerous examples of clinical indications for which the standard of care is inadequate. An industry able to bring higher-quality drugs to patients more quickly serves everyone's interests better.

There are several conceptual strategies that might be considered reasonable options to achieve this goal, independent of the regulatory review and approval process: (1) more efficient clinical testing in order to shorten the time to establish efficacy and/or toxicity profiles; (2) increase the throughput rate of new leads into clinical testing with minimal or no increases in the upfront costs; or (3) increase the quality of the leads going into clinical testing in order to reduce the drop-out rate and thereby improve the overall clinical success rate.

The subject of this chapter is option 3: strategies to increase the quality and efficiency of the preclinical candidate-vetting process in order to select higher-quality clinical candidates with a greater chance of clinical success. Option 1, improving the efficiency of clinical development, is beyond the scope of this chapter and reference work. Nonetheless, this approach certainly appears to be an achievable goal, particularly given the expressed cooperation of the US Food and Drug Administration (FDA) and other regulatory bodies to use the latest in medical sciences regarding study design, patient enrollment, and approvable endpoints.

Option 2 cannot be seriously considered in and of itself in today's R&D world. The evaluation of larger numbers of weak candidates, obviously, only increases overall R&D costs. There was a phase, perhaps 7–10 years ago, during which the industry experimented with moving more clinical candidates into early development in an effort to gather human data quickly, with limited success. This move was initiated by double-digit increases in R&D spending during this period (a trend which has only slightly slowed in recent years). Further, as industry-wide mergers and acquisitions created larger and larger organizations, business analysts called on these companies to launch multiple newly approved drugs annually in order to be economically viable.

At present, as a whole, the industry has now opted for the strategy of finding higher-quality clinical candidates based on state-of-the-art biomedical science, over the strategy of simply increasing the quantity of leads. Therefore, this chapter will explore strategies to achieve this goal of taking better leads into clinical development through the strategic application of ADMET during the nonclinical R&D phase.

2.13.1.1 Attrition Rates: Shifting Clinical Failures to Nonclinical Failures

Despite significant annual increases in R&D spending over the past 10 years or more in the pharmaceutical industry, the US FDA recently reported that the number of both drug and biological product submissions has been steadily following a downward trend since the peak observed in 1996 and 1997 ([Figure 1](#)). They report similar trends at their peers' offices around the world.⁴ However, the newest data from 2004 at the FDA show an increase in the number of New Drug Applications (NDAs) and biologics license application (BLAs) received, from 109 in 2003, to 137 during 2004, a 5-year high.⁵ Whether or not this increase in 2004 represents a sustainable increase will be an interesting part of the human genome-sequencing story and the variety of emerging 'omics' technologies associated with this period and their potential ultimately to improve the efficiency of the R&D process.

Approximately 20–30% of new drugs entering clinical trials fail because of unexpected toxicities in humans. Fortunately, these adverse events are generally recognized relatively early in clinical development. About twice that percentage of drug failures are attributed to a lack of efficacy, in either phase II or III. These late terminations are obviously much more expensive and time-consuming, and may be not seen until the end of phase III. A key strategic goal of any state-of-the-art ADMET evaluation program must be to address failures associated with human toxicity. Further, a lack of human efficacy due to an unfavorable pharmacokinetic-pharmacodynamic (PK/PD) relationship or other human exposure issues is again something that should be aggressively addressed whenever possible with nonclinical studies. The role of pharmacology and pharmacogenomics in effectively modeling human disease is discussed in Volumes 1, 2, and 3 of this reference work.

The time from discovery to market has been increasing for the past decade, despite the remarkable achievements in basic biomedical sciences over this period and increasingly larger investments in pharmaceutical R&D. Notwithstanding these advancements in technology, knowledge, and commitment, there have not yet been observable decreases in either the discovery or the development phases of pharmaceutical R&D. Most available data would in fact suggest that just the opposite has occurred – all phases of R&D have lengthened in the past decade compared to the previous one.^{4,6,7} As noted by several commentators, it is quite clear that new, innovative technologies must be created and applied, particularly to the development phase. The need for advances in translational research has never been greater, as the gap widens between basic biomedical knowledge and expertise and innovation in all phases of development. Many of the tools used today for ADMET evaluation are decades old. The goal of these efforts in translational research is to identify potential issues prior to a drug entering the clinic. Obviously, it is far cheaper to end an unpromising project during the nonclinical phase than after it enters clinical testing.

Figure 1 10-year trends in major drug and biological product submissions to the US FDA. Number of submissions of new molecular entities (NMEs) – drugs with a novel chemical structure – and the number of BLA submissions to the FDA over a 10-year period.

2.13.1.2 Intervention Points for Improvements: Process and Management

Figure 2 illustrates some of the fundamental activities that typically occur, and approximates their relative timing, between the time of target-hit identification in ultra-high-throughput screening (UHTS) and entry into clinical development. Another critical topic related to this discussion surrounds the selection of targets for screening, the application of human (and animal) genomic and proteomic information, and the presumptive relationship of these screening targets to causative features of human disease. This subject is presented in detail in Volumes 3 and 5 of this work. However, the need to understand the characteristics and behavior of potential lead compounds on human and appropriate animal drug targets is self-evident, as related to the selection of pharmacology and toxicology models, and should be included in any strategic planning discussion.

Perhaps the most important strategic goal of reengineering the R&D project plan is to effectively stop unpromising projects as soon as possible. R&D budgets are a zero-sum game: the sooner projects that have unacceptable pharmaceutical qualities are recognized and stopped, the more rapidly those resources can be shifted to the next most promising program. This willingness to stop projects with fatal flaws must become part of the entire corporate culture, not just among the nonclinical departments. It is widely acknowledged that termination of a project is one of the most difficult things to do in the biopharmaceutical industry. Nonetheless, it is essential to reduce resource utilization, including both scientific talent as well as research dollars.

The difficulty surrounds the issue of why a project is stopped, and effectively communicating those reasons to the team and the organization. Stories abound, that are retold until they have legend status, of the dead projects that were kept alive by impassioned scientists working underground at night until the problems were solved, and now the compound is an approved drug with a large market. No doubt, projects have been terminated for poor reasons that perhaps should have been allowed to continue. Sometimes unexpected budget shortfalls terminate good programs. Whatever the reasons, the decision-makers must have buy-in from the team, and effective communication. Senior management must support the concept of completely stopping a project on scientific or commercial grounds, and strongly encourage the team to move on to the next best one as soon as possible.

Another key element of this decision paradigm is to focus on learning from the biology as soon as possible. Biomedical science is a series of exercises to uncover information that is present in biological systems, yet currently unknown to the investigator. One must be fully focused on discovering the reality of the biological information, not

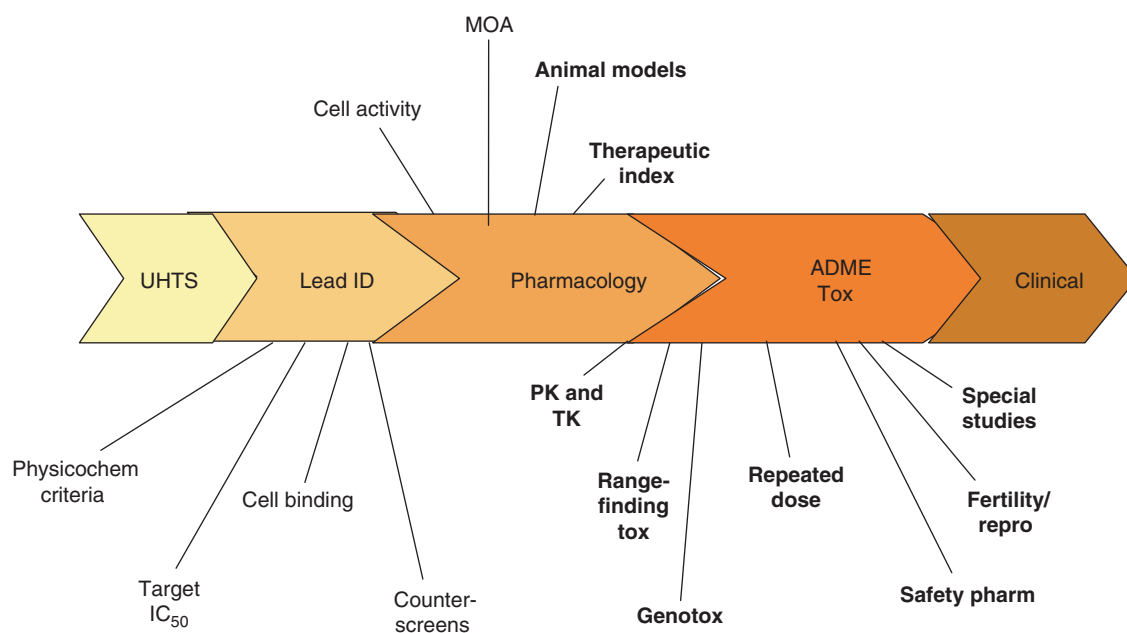

Figure 2 A model of the conventional, linear progress of compounds from hit identification through the initiation of clinical testing with selected R&D activities shown. Activities typically associated with ADMET are set in **bold**. ID, identification; MOA, mechanism of action; TK, toxicokinetics; IC₅₀, inhibitory concentration₅₀ (the concentration of drug that inhibits 50% of an activity).

wasting time being hopeful that nature might cooperate and support a hypothesis favored by the project team. It is absolutely essential to identify the one or two key biological questions as soon as possible, and to design and perform the best possible experiments to test those hypotheses or questions. Project team members should be rewarded for creating the fastest, most efficient experiment that most clearly tests the critical biological assumptions underpinning a project. Such an experiment will allow the biology to provide the answer.

Too often, team members in industry are only rewarded when projects move forward or achieve milestones. This mistake is easy to make, as everyone in the organization knows that when projects move further down the development path these achievements are positive for the organization. In reality, however, unquestionably the most valuable work is that which addresses the go/no-go biological issues as quickly as possible, irrespective of the outcome. After all, one cannot change nature's rules, but only hope to discover them more rapidly than anyone else. This philosophy must become part of an organization's strategic culture in order for it to become ruthlessly efficient in nonclinical R&D.

For the remainder of this chapter, a variety of potential scientific strategies to improve the nonclinical development process from the ADMET perspective will be presented and evaluated. Aspects of the conventional, linear R&D process shown in [Figure 2](#) will ultimately be rearranged in order to illustrate how newly emerging technologies allow the application of ADMET criteria at increasingly earlier stages of the cycle.

2.13.2 Walking Backward to Leap Forward

The most efficient nonclinical R&D strategy is the one created and driven by the critical pharmaceutical qualities needed in the targeted drug in order to make it a commercial success. 'Write the package insert first' is the mantra behind this concept. This strategic methodology must include input from marketing and business development, clinical and clinical laboratory functions, regulatory affairs, and research. This strategy takes into account the targeted indication's standard of care (present and anticipated) and evaluates competitive clinical candidates known to be in clinical development. Whether one is looking to be a fast-follower with essentially comparable benchmarked activities, or to develop a novel product with a clear strategic advantage, experience has shown that this must be the starting place of the project plan.

2.13.2.1 Write the Package Insert First

Even with what are believed to be completely novel mechanisms of action or products, it is vitally important to define what one ultimately wants to have available for patients and physicians as soon as possible in a program. Of course, it cannot be fully fleshed out in some cases, but the exercise is illuminating no matter how incomplete the end product may be. By attempting to write the package insert at the beginning of a project, it is often readily apparent how to evaluate the candidate most efficiently in ADMET testing. Out of this process comes the identification of critical pharmaceutical qualities that the lead candidate must possess in order to be acceptable in the clinic. Many of these pharmaceutical qualities are related to a drug's nonclinical behavior, and therefore highly tractable by the nonclinical scientist.

2.13.2.2 Identify Critical Pharmaceutical Qualities

Many larger companies have created tables or lists of various criteria that present generally desirable pharmaceutical qualities for new projects in a given indication. Often, these criteria have been obtained by benchmarking against competitors' drugs in the same indication, and by marketing assessments of what healthcare consumers, providers, and insurers will accept and pay for. These criteria are the underlying assumptions used in marketing and commercial assessments of how large the market might be for a given product possessing a given set of these criteria. Such benchmarking is an important exercise, and should be done by all new project teams if such information is not already available. However, these general criteria should be only a start.

Further detailed work (beginning with a draft of the package insert) must be done in order to accomplish the overall goal of improving the efficiency of the biopharmaceutical R&D process through picking the best programs prior to clinical entry, and conversely, and more importantly, by quickly stopping unpromising projects as soon as possible. From this exercise, one must identify the critical pharmaceutical qualities: those whose presence is absolutely essential for project success, and whose absence would be unacceptable to its commercial application.

From the ADMET perspective, there are often a number of such critical pharmaceutical qualities. Examples of these are presented in [Table 1](#).

Table 1 Examples of critical pharmaceutical qualities that impact ADME drug development strategy: conventional approaches compared to state-of-the-art strategies

<i>Critical pharmaceutical quality</i>	<i>Conventional ADME strategy/experiment</i>	<i>SOTA ADME strategy/experiment</i>	<i>Experimental criteria or goals</i>
Clinical regimen: patient compliance is key	Evaluate viability of proposed clinical regimen: establish PK/PD and/or TK/TD relationships	In silico PBPK modeling linked to pharmacogenomics and toxicogenomics analyses. Evaluate potential for SNPs in humans, with either favorable or unfavorable effect	Establish PK predictions of anticipated exposure in humans and relate to PD or TD markers and/or effects. Evaluate efficacy at dose levels below those expected to induce adverse patient compliance. Screen patients and enroll only those for which the SNP data suggest higher probabilities of compliance
Clinical regimen: must be more convenient than competitors' drugs	Establish PK parameters; evaluate new formulations or delivery technologies. Link PK/PD to ensure efficacy maintained	In silico PBPK modeling	Establish appropriate predictive scaling to model anticipated blood levels and duration of exposure in humans. Predict human regimen needed to achieve these activities
Must be an oral drug	Evaluate oral bioavailability; consider role of nonplasma compartments as related to target tissue distribution. Evaluate impact of formulations or drug modifications if needed	In silico PBPK computer modeling, microsampling of tissue compartments, AMS-based distribution studies, chemogenomics analysis	Oral availability must be linked to activities, both PD and TD. Distribution to relevant target tissues should be evaluated
Cannot impair fertility or reproductive function	Evaluate appropriate species for fertility/repro endpoints	In silico structural chemistry scan, chemogenomics analysis, in vitro cell assays, perform fertility/repro tox very early	Incorporate into early compound selection criteria/lower chances of late failure in vivo
Efficacy is x-fold greater than competitor's drug	Evaluate in pharmacology models of human disease, establish therapeutic index	Establish PK/PD and TK/TD relationships, predict therapeutic index	Determine if exposure required for efficacy can be safely achieved
Toxicities typically associated with target X were not observed	Evaluate in appropriate in vivo toxicology model(s)	Toxicogenomics analysis, pathways analysis	Establish QSAR/SAR around avoidable activities
No drug–drug interactions were observed	Evaluate in vitro and in animal models	Evaluate in in vitro models and/or in silico models	Establish QSAR/SAR around drug–drug interactions
No metabolic liabilities	Labeled drug in ADME animal studies, in vitro assays	Metabonomics in silico analysis, including human polymorphism analysis	Predict likely metabolite profiles. Establish QSAR/SAR. Evaluate potential for influence of human SNPs

SOTA, State-of-the-art; TK, Toxicokinetics; TD, Toxicodynamics; PBPK, Physiological-based pharmacokinetics; SNP, Single nucleotide polymorphism; QSAR, Quantitative structure–activity relationship; SAR, Structure–activity relationship; AMS, Accelerator mass spectrometry.

2.13.3 Quality Absorption, Distribution, Metabolism, Excretion, and Toxicology Data and Decisions

As illustrated in [Table 1](#), there are clearly situations in which the draft package insert identifies critical pharmaceutical qualities whose absence or presence would result in a nonviable program. Application of the conventional, linear drug development model shown in [Figure 2](#) would be a costly mistake in such an instance, as the typical linear order of hand-offs will likely burn both time and money until the most important ADMET experiment(s) was conducted much later than necessary in the project's life.

A major strategic challenge is how best to approach these ADMET issues as early as possible in the R&D cycle. It could be argued that so long as a decision to cut an unpromising program was made prior to clinical trial initiation, then that decision certainly was a better one than if it had been made on the basis of clinical data. Certainly that logic is hard to argue with; however it could also be applied in the case of the data safety-monitoring board closing down enrollment in a Phase III trial with only half the patients treated. This situation is perhaps somewhat better than finding the problem at the end of the trial, but it is still a very expensive decision at that point in a program's life. The strategic imperative is to make critical go/no-go decisions as early as possible in the R&D cycle, based on rich, high-content, high-quality data.

2.13.3.1 High-Content Absorption, Distribution, Metabolism, Excretion, and Toxicology Data: The Challenges

Broadly speaking, the tremendous strides that have been made in target-based screening and other discovery research tools in the past 5–7 years have today far outstripped the throughput capacity of the development scientists. Computer-driven database applications and the automation of many heretofore manual laboratory tasks and assays have vastly improved both the speed of acquisition and the density of the data available during discovery, hit identification, and lead optimization. Rich, high-content data are created at such rates that laboratory information management systems (LIMS) must often be in place simply to organize, search, and analyze these data. At the other extreme of the R&D cycle are the *in vivo* experimentalists, conducting a handful of studies with decades-old technology over the same time it takes the screening labs to analyze a million-compound chemical library against the next generation of potential drug targets.

Conventional *in vivo* ADMET models are of course very data-rich and can be used to make excellent decisions, but they are much too low in throughput to be of value during lead optimization and selection. 'Pathologists know everything, but too late,' as the saying goes. As shown in [Figure 3](#), the funnel-shaped diagram used to illustrate the R&D screening cascade also clearly portrays the problem.

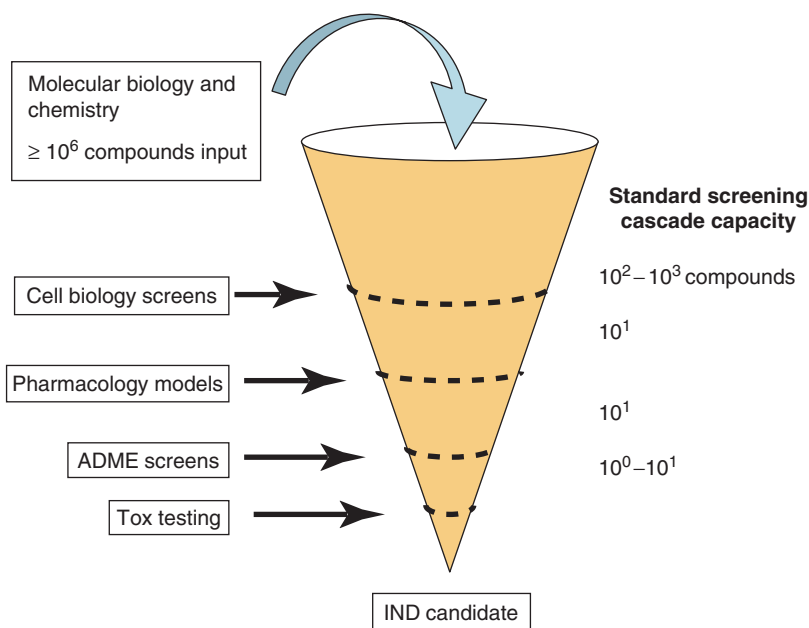

Figure 3 The capacity of the screening cascade at the ADMET level is currently orders of magnitude less than the input capacity at the discovery level.

Figure 4 Application of chemogenomics technologies to improve preclinical lead selection vastly increases the throughput capacity and ADMET data content of lead prior to in vivo testing.

What is the value of generating millions of data points on over 10^6 compounds at one end of the screening cascade while, at the other end, compounds are being administered to animals one at a time? The most desirable screening cascade would allow the chemists and ADMET scientists to work side by side in real time with more comparable screening capacities. Strategically, these evaluations should be focused on the most relevant critical pharmaceutical quality required for success. It would be a significant improvement to introduce higher-throughput, development-oriented, in silico and in vitro procedures much earlier in the screening cascade.

Naturally these automated, computer-driven processes cannot be intended to replace in vivo testing in the foreseeable future. While this may certainly be the ultimate goal, and substantial strides have been made in recent years in computer models of various physiological processes, it is presently difficult to imagine that a validated, completely virtual physiological model of any mammalian species will be available in less than 10 years. In the meantime, ‘in vivo veritas’ must remain the guiding principle of the drug development scientist, as this principle is certainly likely to continue to guide the regulatory authorities as well for some time.

Rather than using a funnel to illustrate the overall screening cascade, the challenge for ADMET development is to make it much more cylindrical before the in vivo experiments are undertaken. As discussed later in this chapter, there are computer programs available today that have successfully modeled many ADME properties at the chemical structure level that could, in principle, be applied as far back as at the computational chemistry compound selection and/or design stages. Using these technologies, collectively referred to as chemogenomics, and those still under development, it should not be difficult in the very near future to show this much more desirable shape of the state-of-the-art screening cascade, as shown in [Figure 4](#).

This screening cascade introduces in silico modeling of ADMET properties (chemogenomics) at the compound screening, hit identification, and lead optimization stages of the R&D cycle. As discussed below, currently available computer models have already become reasonably good at correlating chemical structure with ADMET features of molecules, including at the level of quantitative structure–activity relationship (QSAR).

2.13.4 Gathering High-Content Absorption, Distribution, Metabolism, Excretion, and Toxicology Data: Developing Technologies

There are a number of computer algorithms currently available that claim to be able to derive various ADMET parameters on the basis of chemical structure and previous in vivo experience. The technologies are presented and

reviewed in detail in Volume 5 of this reference work. They will only be very briefly mentioned here in order to illustrate the direction these technologies are headed, and their current impact, as well as probable future impact, on the drug-screening cascade from the ADMET perspective.

The quality of the decisions that can be taken during drug development directly correlates with the density and richness of the available data. It should be appreciated that any new technologies that simply create reams of computer-generated data without linking these data to practical utility will not have a place in the new molecule ADMET development strategy. The essence of quality drug development work is the generation of applied data that have practical applications in the real world of preclinical testing and clinical development. In order to address this issue, many of the *in silico* chemogenomics approaches link structural features of molecules, and classes of molecules, with previously obtained animal and human *in vivo* data.

While the ultimate goal is to have fully validated expression data able to predict biological changes, examples of these outcomes are presently rather rare. Therefore, at present, there is an ongoing intermediate validation stage of chemogenomics that combines molecular expression profiling (mRNA and protein), chemical structural information, and *in vivo* data acquisition. For example, it may be possible to observe changes in the expression pattern in the liver of a treated rat weeks before the later appearance of a histopathologically confirmed lesion. With sufficient validation, these expression-profiling experiments may pick up those changes earlier, accurately predict the formation of the lesion, and thereby save time in the toxicology screen decision-making process. Therefore, while *in vivo* veritas remains a critical guidepost today, increasingly better decisions can be made based on *in silico* modeling of many ADMET elements of the R&D cycle using these existing validated tools, with newly validated data constantly being generated. Short summaries of some of these approaches and their strategic roles in ADMET screening are presented below.

2.13.4.1 Chemogenomics Applied to Pharmacokinetics and Absorption, Distribution, Metabolism, and Excretion Modeling

For many years, empirically based predictions of a molecule's pharmacokinetic behavior in humans have been made based on allometric scaling from animal data. A number of drugs scale on the basis of body weight rather well. Protein drugs, in particular, scale well on the basis of body surface area. Knowledge of physiology, such as the fact that the proportion of blood distributed to a given organ system scales with body surface area because mammals have solved the surface-area-to-volume ratio problem in effectively the same way, was the underpinning of these allometric projections. However, there are now many examples of molecules for which these empirical methods were not sufficient to predict pharmacokinetic behavior across species, and in particular in humans. As a result, more complex predictive models have been built that incorporate much more physiology data into the analysis parameters. These models are grouped under the term PBPK, or physiological-based pharmacokinetic, models. An example of the architecture of one such ADME model is presented in [Figure 5](#).⁸

As suggested by [Figure 5](#), there are various computer-based models available in each of the key knowledge areas. Some of these models are now commercially available, off-the-shelf programs that are relatively user-friendly, whereas others are custom modifications of existing programs to fit specific needs and applications.^{9–16}

The overall experience with these predictive PBPK approaches can be judged to have been encouraging to date. As more training sets are introduced into these models, their predictive values will improve. In general, the availability of training sets is a current issue with many chemogenomics techniques. Large pharmaceutical companies have access to confidential information on thousands of compounds, and thus can build proprietary databases to incorporate this experience into their predictive models. While this ability may be viewed as one of their competitive advantages, at another level regulatory agencies such as the FDA and European Agency for the Evaluation of Medicinal Products (EMA) are expected to protect the public health. Obviously, access to these corporate databases would broadly extend their ability to extract chemogenomic data and evaluate potential health risks of new and existing drugs. Public/private consortia have been assembled to address these issues, and their impact on predictive toxicology technologies and drug safety will be discussed later in this chapter. Inevitably, the publication of information from these databases will have a major impact on future ADMET development strategies.

2.13.4.2 Metabonomics: Predicting Absorption, Distribution, Metabolism, and Excretion Behavior *In Vivo*

Metabonomics is the name given to computer-based integrated analysis tools that attempt to predict the *in vivo* metabolite profile of a compound.¹⁷ These models, of which there are several, produce information to predict potential

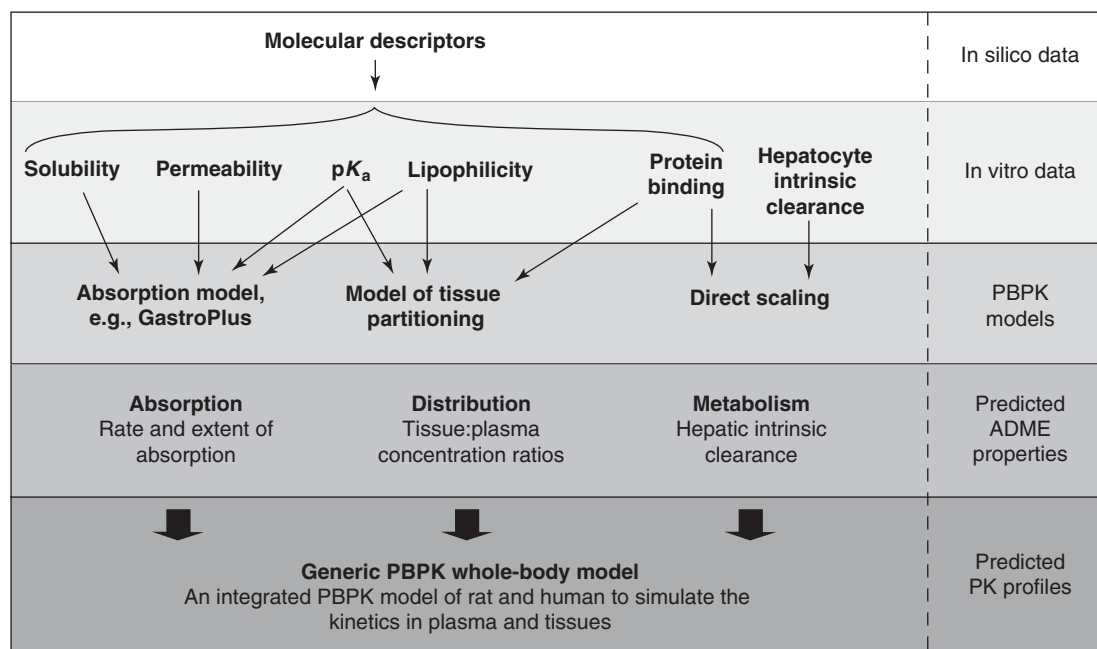

Figure 5 An example of an integrated PBPK model for prediction of ADME in a whole-body model. (Reproduced with permission from Parrott, N.; Jones, H.; Paquereau, N.; Lave, T. *Basic Clin. Pharm. Tox.* **2005**, 96, 193–199.)

metabolic risks,¹⁸ drug–protein-binding,^{19,20} drug–drug interactions,²¹ or similar metabolic features that might impact the disposition of the parent molecule and perhaps lead to systemic toxicities.²² The recognition that human gene polymorphisms in certain metabolic enzymes markedly impact metabolism of certain classes of drugs has resulted in a focus on human pharmacogenomics and biomarkers in these models.

This concept is an extension of knowledge that began to appear in the mid-1990s regarding the presence of genetic polymorphisms associated with certain drug-metabolizing enzymes, in particular CYP2D6 and CYP2C19. In situations where drugs are metabolized by these enzymes, which are relatively common, genetic variations of these enzymes were found to result in widely varying drug exposure in humans.¹⁸ A logical extension of this observation is to employ the tools of pharmacogenomics to these, as well as other, human drug-metabolizing enzymes that are less well characterized, such as P-glycoprotein, in order to assess the frequency of polymorphisms in humans and the effects these protein modifications may have on drug metabolism. As is now done almost routinely with CYP2D6, such knowledge could be easily inserted into the screening criteria rather early in the screening and optimization process.

2.13.4.3 Predictive Toxicology Models: Toxicogenomics

mRNA and protein expression analysis techniques have been increasingly applied to the characterization of toxic signs since their introduction over a decade ago. These tools provide the promise of molecularly characterizing the biology behind toxicologic events and outcomes. Combined with QSAR, SAR, and chemogenomics, the integration of molecular toxicology data with structural information holds the potential of someday performing initial toxicology screens in silico.^{23–27} The strategic advantages of screening out undesirable compound characteristics before an animal is ever dosed are clear, and a long-sought-after goal in strategic drug development. There are well-recognized challenges, however, to the attainment of this long-term goal which should not be overlooked in the enthusiasm to embrace these technologies.^{28–30}

As described by Waters *et al.*,²³ one of the primary goals of toxicogenomics is to establish ‘phenotypic anchors’ that link particular expression profiles or signatures to structural classes and biological changes and endpoints, with the goal of being able to predict such activities in untested compounds. A simple description of which genes or proteins are up- or down-regulated is only the very beginning of the work, because initially it will be unknown which of those altered expression patterns are directly related to the action of the compound, or due to the reaction of the animal to that damage, for example. In theory, the principles behind toxicogenomics are not much different from those highly validated principles that support the collection of clinical pathology data from peripheral blood. Patterns of changes in

certain clinical chemistry or hematology data are known to be highly predictive of particular types of pathologic changes, based on decades of experience. The same type of validation may ultimately come to predictive toxicogenomics tools using molecular surrogates rather than blood markers.

2.13.5 **Integration: Absorption, Distribution, Metabolism, Excretion, and Toxicology, and Chemogenomics**

As occurred during the race to sequence the human genome, the developers of chemogenomics technologies in both the private and public sector have a variety of interests in accumulating large databases of structures and biological information. Such databases are essential in order to properly address the challenges posed by drug development efficiency, environmental health and safety, and the development of the appropriate regulatory environment to assess and utilize these new data. The competitive advantage of having large internal chemical libraries and biological data may drive some decisions in the private sector that are not completely aligned with the interests of the public sector.

However, as was seen with the single nucleotide polymorphism (SNP) Consortium and the Human Genome Project, public/private consortiums can work together to address key issues without compromising their competitive needs. Likewise, it appears that initiatives are currently underway with the promise to address database access issues in order to provide much larger sets of training data than might be possible through any one organization, whether public or private. These data may eventually level the playing field in the drug development world as higher-quality, validated models of various biological processes associated with ADMET characteristics will become more broadly available.

For example, the FDA launched the Critical Path Initiative in the spring of 2004 in order to help facilitate the growth of novel drug development tools. Having watched the growth on the discovery side of the modern techniques of molecular biology, the Agency has expressed concern that the lack of similar tools on the development side is hurting not only drug development, but patient access to effective new medicines, as the number of marketing applications has been steadily declining since the early 1990s.⁴ The FDA, similar to the EMEA, is uniquely positioned to contribute to these consortium databases by having access to decades of information concerning chemical structures and biological effects. Hopefully, confidentiality issues and concerns will be allayed by the proposals made by FDA to industry, which will greatly facilitate moving forward on these initiatives.

In addition, the National Center for Toxicogenomics was created in September 2000 by the US National Institute of Environmental Health Services (NIEHS) in order to apply gene expression technologies to understand the relationships between gene expression and drug exposure, and the biological consequences of that exposure, among other related goals. As part of this initiative, the NIEHS Toxicogenomics Research Consortium was formed, which is structured to include corporate research members (CRMs). Through this consortium, microarray and other technical issues will be addressed and standardized, and data will be deposited into the Chemical Effects in Biological Systems (CEBS) database. This CEBS development process, which has many of the same elements as other chemogenomics and toxicogenomics projects, is illustrated in [Figure 6](#).

With these types of public/private consortiums working together, there will hopefully be few barriers presented to any pharmaceutical organization, from start-up to multinational, to the incorporation of such state-of-the-art information into their ADMET R&D cycles.

2.13.6 **Strategic Application of the New Absorption, Distribution, Metabolism, Excretion, and Toxicology Technologies**

It follows quite clearly from the above discussion that various crucial elements of the R&D cycle can include ADMET measures far earlier in that process than is typically done. There are two ways to accomplish this: (1) through the incorporation of state-of-the-art chemogenomics-based studies that are focused on ADMET issues known to be critical to the success of the project (for examples, see [Table 1](#)); or (2) simply through the identification of, and testing for, critical pharmaceutical qualities using standard models earlier in the R&D cycle through the use of nonlinear development strategies.

The incorporation of modern computer-based technologies holds the greatest potential both to shorten the R&D cycle, and to drive early termination decisions on programs with potentially fatal flaws, thereby improving the overall efficiency of the process. The strategic goal of using these technologies can be illustrated in [Figure 7](#).

With the barely adequate amount of validation currently available, many of these technologies already have the potential to improve the yield of the R&D process by introducing ADMET-based criteria much earlier in the pathway.

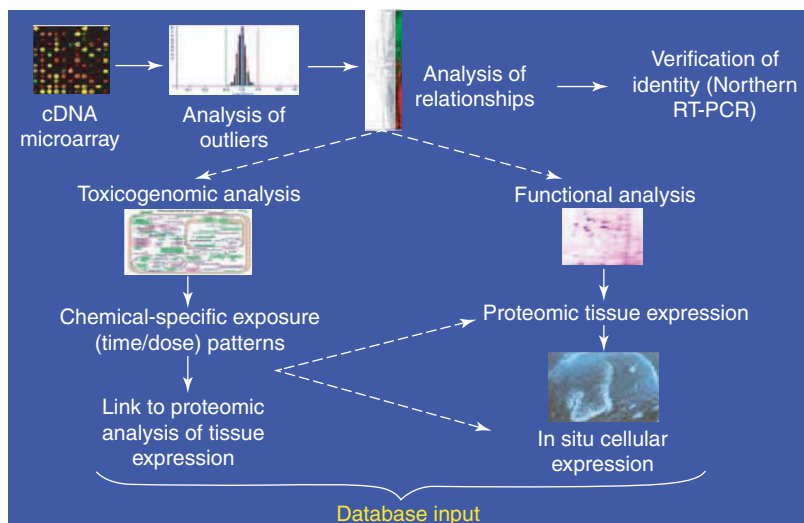

Figure 6 Microarray data are first verified, then coupled with biological data, in the process of building validated relationships between expression profiles and biological changes. RT-PCR, reverse transcriptase polymerase chain reaction. (Reproduced with permission from Waters, M. D.; Olden, K.; Tennant, R. W. *Mut. Res.* **2003**, 544, 415–424.)

Chemogenomics: rich data, early use

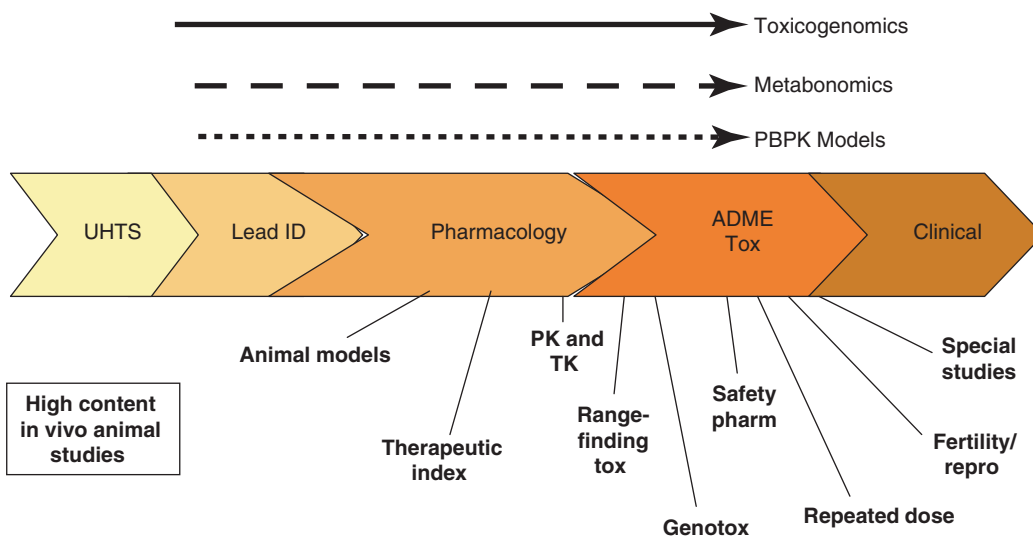

Figure 7 Incorporation of chemogenomics technologies early in the lead selection stage has the potential to vastly improve decision-making during the R&D cycle by gathering critical ADMET data much earlier in the process. ID, identification; TK, toxicokinetics.

As increasingly more validation, or ‘phenotypic anchoring,’ becomes available, the value of the data output from these systems will be correspondingly higher. There should be no doubt concerning the limitations of these technologies today. On the other hand, there can likewise be no doubt as to the direction they are headed over the next 5–7 years, and as to their ultimate utility.

That being the case, it must be acknowledged that it is still a long road from microarray data to biological endpoints. Starting with the microarray systems themselves, it is known that different technologies can give quite different output from the same input mRNA. Standardization of these systems and cross-technology comparisons are underway to understand these differences. Similarly, the input material, the mRNA preparations, can also be sources of significant

variation. It is absolutely essential to have high-quality mRNA input that allows for the interrogation of both high- and low-frequency messages and that is fully representative of the cells or organs from which it was prepared.

An additional piece of information must also be sought when organ sources are used for these mRNA or protein preparations: which cell type in the organ is responsible for the observed changes? Hence the need to incorporate relatively sophisticated histopathology techniques such as in situ expression analyses on tissue preparations.

Caution must also be used in the interpretation of microarray expression profiling data that are not linked to protein expression (proteomics) and tissue distribution data. It is of course well known that there is not a 1:1 correspondence between the up- or down-regulation of the expression of mRNA and protein translation. It is not even enough, in some cases, to know that particular proteins are overexpressed without also knowing the status of their cognate receptor. If a cell is producing a lot of a particular protein but there is no receptor to acknowledge that production, this overproduction is irrelevant to the biology of the system.

A final problem that is likely to take considerable effort to resolve is that each of the mRNA or protein preparations taken from a particular biological system is only a snapshot of the movie of biology. The kinetics problem, the interpretation of changes in mRNA or protein expression levels over time, and how these expression changes ultimately impact biological endpoints, will be complicated at best. The solution may be one of the more distant goals of chemogenomics. A series of proof-of-principle experiments using known compounds is one of the standard ways to begin to address this challenge. The ability to link the kinetics of changes in molecular signatures to biological endpoints and more conventional toxicology parameters is obviously an important factor in selecting when and how to use these technologies during development.

2.13.7 Conclusion

There can be no doubt of the need to reduce the overall failure rate of new compounds, to increase the quality of pipeline candidates, and to reduce the time and costs of pharmaceutical R&D. Several strategic shifts from conventional drug development thinking have the potential to improve the efficiency of the R&D cycle from the ADMET perspective: (1) increased use of the new state-of-the-art tools associated with the term chemogenomics much earlier in compound vetting; (2) a stronger focus in nonclinical R&D on the marketing and clinical goals of the project as defined by the draft package insert and the critical pharmaceutical qualities that the successful drug candidate must possess; and (3) a willingness to perform the most critical experiment that addresses the key biological assumption as soon as feasible. While the application of these strategies may actually increase the failure rate of compounds early in the R&D cycle, dropping an unpromising candidate at these stages is much less expensive, resource-intensive, and time-consuming than any stage of clinical development failures. More importantly, higher-quality candidates are likely to be taken into clinical testing, thereby increasing the success rate to market.

These strategic shifts must be accompanied by a management team with the will to rapidly terminate unpromising projects based on sound scientific and commercial criteria, and to effectively reassign those resources on to the next best program. Similarly, the organization's staff members at all levels must become a part of this strategic paradigm for it to be successful. Small groups committed to keeping 'dead' projects alive can sometimes undermine a strongly committed management team. Therefore, the organization must strive to develop a strong culture that is committed to these principles.

The technology revolution that swept through the discovery end of the R&D process during the past decade must now be applied to the development piece of the puzzle. There is no doubt that such applications will be developed; indeed, the first generation of these tools is already available. The competitive advantage will come to those organizations that are smart and nimble. They must first understand these technologies, and how and when to apply them judiciously, as they must be sufficiently validated such that the potential risks are balanced by the rewards. Further, with the increasing knowledge of human pharmacogenomics and molecular disease mechanisms, those nimble organizations that are willing to shift their commercial strategy to consider launching higher-quality new products designed for smaller, more defined patient populations, may develop a competitive advantage through the use of these tools.

2.14.1 Introduction

Polypeptides and proteins play critical roles throughout the human body, indeed throughout all living systems. Many of these roles developed as the primordial system of controls evolved for the coordination of multicellular organism function and thus control the most basic physiological activities. The role of peptide signaling molecules has expanded to fill a vast array of control and modulatory systems in vertebrates. For example, the peptide hormones of just the pituitary gland control the fundamental aspects of gamete production, birth, suckling, fluid and salt balance, growth, response to stress, etc. Peptide hormones from the gut control insulin response, gut motility, and appetite, at a minimum (see incretins, below). Thus peptides have powerful signaling and control functions (e.g., autocrine, endocrine, paracrine, neuromodulatory, host defense roles, etc.) in all tissues, typically displaying high potency and selectivity for their target receptor classes. However despite these highly favorable characteristics as ligands, they are

considered to be underrepresented as commercially viable targets and pharmaceuticals. Despite this view, roughly 20% of the top 200 commercial drugs in 2004 are proteins or peptides. This chapter will focus on the advantages and principal shortcomings of polypeptides as drug candidates, and on approaches that have been used to overcome these deficits successfully. With the completion of the sequencing of the human genome, it is certain that many more opportunities to evaluate new polypeptides and proteins will be recognized. Additionally, advances in peptide synthesis¹⁻⁴ and protein production by recombinant DNA methods or chemospecific chemical ligation^{5,6} of protein fragments (meant broadly⁷) mean that it is becoming far easier to produce (to metric ton scale) and test such agents.

For the purposes of this chapter, peptide or polypeptide will be used interchangeably and will mean a polypeptide structure of <40 residues or so while 'protein' means larger than that. A better distinction might be that a protein has a unique tertiary structure in solution and therefore is subject to denaturation. The hundreds of monoclonal antibodies in clinical development will not be addressed as we focus on the novel medicinal chemistry lessons that we can learn from manipulation of the structures of polypeptides and proteins (especially the former). The exceptional diversity of structure and function that can be derived from assembling the 20 proteinogenic amino acids into protein and peptide structures, and the creativity of scientists working in this field, has generated a tremendous diversity in approaches. This complexity has resulted in excellent book-length reviews on synthesis^{1,8} and design approaches.² There also are reviews of peptide drug design that focus on aspects such as constrained analogs,⁹⁻¹² an important route toward antagonism and receptor specificity. Although a great deal of progress has been made on the design of peptidomimetics (mimicking specific peptide interactions) or ligands that bind to peptide receptors (an important distinction), to date these are mostly antagonists. Agonistic action at a receptor requires many interactions to happen with great specificity and peptide analogs remain the most straightforward route to obtaining potent agonists. This appears to be especially true for the mid-sized peptide hormones of >30 residues.

The various approaches to 'peptidomimetics' that are remote from the starting structures or nonpeptide ligands for peptide receptors will not be addressed in detail (however *see* 2.15 Peptidomimetic and Nonpeptide Drug Discovery: Receptor, Protease, and Signal Transduction Therapeutic Targets; and reviews^{13,14}). Due to space limitations, this chapter will focus on broad themes of practical use in specifically addressing the shortcomings of peptides and proteins as pharmaceutical agents (*see* reviews^{15,16}).

Broadly, the shortcomings of peptides and proteins as drug candidates relate to their typically short biological $t_{1/2}$ due to rapid clearance, to low oral bioavailability, and to a lack of receptor subtype specificity. There are now very useful approaches to each of these challenges and they will be reviewed below. Several very exciting drug candidates in current development are polypeptides and this chapter will analyze how these challenges have been overcome. The summary message will be that, despite the issues outlined above, polypeptide research remains an exciting area for the identification of important therapeutics because of the approaches outlined below.

2.14.1.1 Major Therapeutic Target Classes

Each of the polypeptide and protein therapeutic families has developed in somewhat different fashions, depending on particular requirements of ligand or receptor structure, need for agonists or antagonists, and creativity of the practitioners. For ease of synthesis reasons, smaller peptide ligands have offered more opportunity for incorporation of unnatural amino acids to accomplish changes in physical properties (*see* Sections 2.14.4.1 and 2.14.4.2). Large proteins have been modified by PEGylation (*see* Section 2.14.4.2.3) and protein conjugation (*see* Section 2.14.4.2.4). Interestingly, the lessons from each class are now being brought to the other. How does the character of the therapeutic target's receptor structure affect drug design?

2.14.1.1.1 G protein-coupled receptors

G protein-coupled receptors (GPCRs) are unique integral membrane proteins comprising seven transmembrane helical regions with an N-terminal region (extracellular), a C-terminal region (cytosolic), and three loops on each of the interior and exterior faces of the cell membrane. The GPCR typically binds a ligand on the external face and transduces a signal by conformational change of the receptor protein assemblage to affect interactions with the heterotrimeric G protein (GTP-binding protein; $G\alpha\beta\gamma$) assemblage bound to its cytosolic face (Figure 1). Thus an agonistic ligand must accomplish a binding and an activation step. Activation of the GPCR causes exchange of the G-protein-bound guanosine diphosphate (GDP) molecule for a guanosine triphosphate molecule, dissociation of the heterotrimeric $G\alpha\beta\gamma$ protein from the receptor and into the $G\alpha$ (18 forms) and $G\beta\gamma$ (5 β forms; 11 γ forms) proteins. These proteins transduce the signal to multiple activation signaling pathways to cause changes in cellular function. The activated GPCR then typically binds an arrestin molecule and is internalized in a desensitization process that culminates with

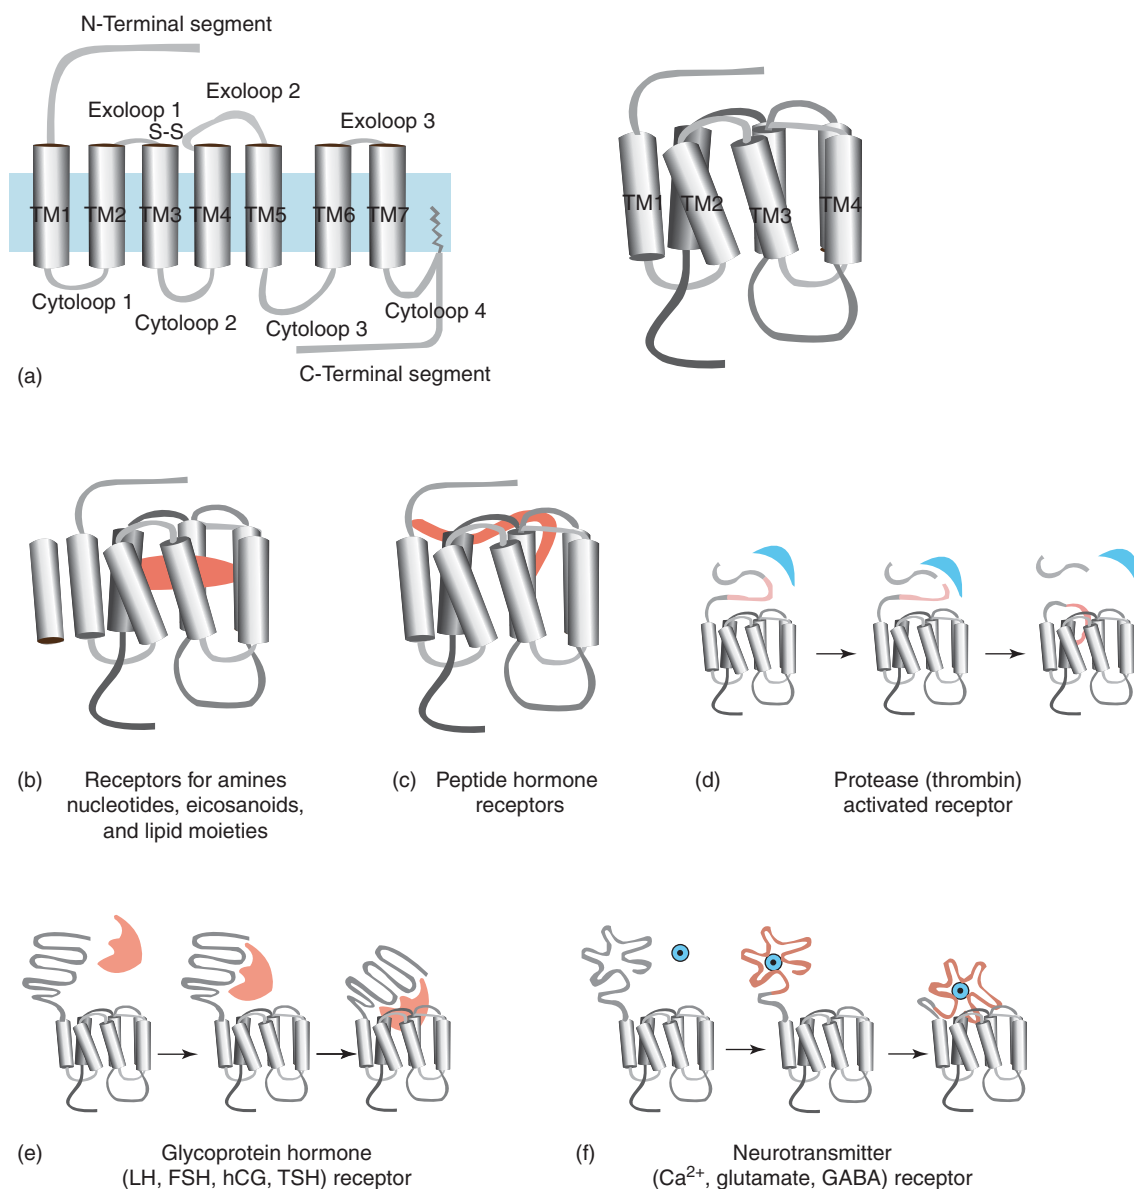

Figure 1 Schematic presentation of the general structure of GPCRs and receptor–ligand interactions. (a) General structure and terminology. Several distinct modes have been observed for ligand binding and signal generation. (b)–(f) indicate the manner in which different ligand classes make use of interactions in the core, using core plus extracellular loops, using proteolysis, or using the N-terminal extension plus the loops and core. eventual return to the surface. A caveat for this discussion is that the specifics of these processes are constantly being shown to have variants which specialist reviews will discuss.

The members (>1000) of this family have been grouped into various classes.¹⁷ Many receptors appear to be olfactory receptors and, while not of primary interest to this discussion, represent a very active area of research of which much will be heard in the future. Of most interest to this chapter are those members of the rhodopsin family (Type A receptor; e.g., angiotensin, CCK, endothelin, galanin, neurokinin, neurotensin, vasopressin, etc.) and secretin/glucagon family (Type B receptor; e.g., calcitonin, GLP-1, PTH, etc.) that bind to endogenous peptide hormones. Within each family there are multiple subfamilies and within subfamilies there typically are subtypes.¹⁸ For example, within the Type B family, the somatostatin family has five known subtype receptors (sst1, sst2, sst3, sst4, sst5). Different subtypes may be expressed on different tissues, exhibit differential affinity for ligands, and activate different signaling

pathways.¹⁸ Thus subtype selectivity is an important direction for future research on peptide ligands. In addition, there are different capabilities for association with other receptors, different desensitization pathways, etc. The number of receptors and of the G proteins may change with further research and there appears to be even greater variability possible due to the multiple splice and editing variations.

Of most significance to this chapter is the mechanism of binding of polypeptide ligands to these GPCRs. Peptides typically bind to GPCRs through the use of the N-terminal extension and extracellular loops of this transmembrane protein assemblage (Figure 1). The type A peptide receptors have short N-terminal extensions and their ligands typically are small polypeptides, thought to use the extracellular loops and transmembrane core for critical binding and activation interactions. The type B polypeptide receptors have a large N-terminal region containing multiple disulfide bonds to generate stable structure. The typically larger polypeptide ligands for these latter receptors are believed to have important interactions in their C-terminal regions with this large N-terminal extension, while the N-terminus of the ligand interacts with the transmembrane region to activate the receptor. The significance of these aspects will be addressed below under 'Efficacy.' Much of the discussion of drug design that follows will focus on GPCR ligands.

2.14.1.1.2 Receptor protein tyrosine kinases

The transmembrane receptor protein tyrosine kinases (RPTKs; 58 members in 20 subfamilies), targeted by many growth factors (epidermal growth factor, insulin, fibroblast growth factor, etc.), are again a highly diverse family and differ fundamentally from GPCRs in the manner and mechanisms of their interaction and activation in response to ligands. A prototypical growth factor receptor will have a single transmembrane domain with a ligand-binding region on the extracellular face and various domains for dimerization, protein binding, activation, and kinase activity on the cytosolic side. Typically ligand binding will cause homo- or heterodimerization of the receptors and activation of the signaling mechanism by trans- or autophosphorylation of domains in the receptor dimer partners (see diagrams¹⁹). Receptor binding modes have been worked out in detail for some receptors.

These receptors typically bind large protein hormones and the mimicking of such large protein surfaces by polypeptides or small molecules has been expected to be difficult. Aside from insulin, the emphasis in this class has been on blocking function, since abnormal activation of this class is the most common source of oncogene-driven carcinogenesis.¹⁹ Thus pharmaceuticals targeting ErbB2 (HER2/Neu in breast cancer; antibodies or kinase inhibitors) are important new cancer pharmaceuticals (trastuzumab, cetuximab, erlotinib, gefitinib, etc.).²⁰ Long-acting peptide/protein antagonists could be effective, but monoclonal antibodies appear to be a quicker approach, currently. The issues addressed for these proteins (duration of action, drug delivery) are relevant to the polypeptide drugs and will be addressed in the section on PEGylation.

2.14.1.1.3 Cytokine receptors

Cytokine ligands and their receptors have similarities to the growth factors discussed above.^{21,22} Typically these ligands cause heterodimerization (or dimers of heterodimers) of a type 1 and a type 2 receptor (single transmembrane proteins), which initiates activation of the Janus kinase (Jak/Stat) signal transduction system by transphosphorylation. In many cases the heterodimers comprise a 'private,' type 1, ligand-specific receptor and a 'public,' class-specific signal transducer that functions with multiple type 1 receptors. Again there is substantial diversity of receptors and pathways for activation and signaling. These bind large protein ligands, some of the best known of which are growth hormone (GH), tumor necrosis factor alpha (TNF- α), the interferons (IFN), and the interleukins. In this large family of receptors, both agonistic (e.g., IFNs, GH) and antagonistic functions²³ (antagonism of TNF- α ; soluble TNF receptor-IgG1 (immunoglobulin G1) conjugate, below) have current pharmaceutical roles. Lessons from these protein ligands in improving pharmaceutical characteristics (PEGylation, protein conjugation) are applicable to smaller peptide ligands, as we shall see. The research on ligand receptor binding interactions for this class of proteins is best thought of in general terms as protein-protein interactions.

2.14.1.1.4 Protein-protein interactions

Protein-protein interactions are an attractive area for the application of polypeptide drug discovery. An important aspect of this general area is the understanding of the interaction of the protein ligands for the RPTK and cytokine receptors above. This can be approached by minimizing protein structures through truncation (with the aid of phage display to increase affinity or to select new binding elements) with retention of binding and function²⁴ or from the perspective of Ala scanning of receptors or ligands to develop a detailed understanding of protein surface interactions.²⁵ The former would appear to be more straightforward to contemplate while the latter, when accomplished and generalized, appears to offer unlimited potential. An example of the former is the use of a recombinant display vector to

allow selection of a small peptide (20 residues) that is capable of binding to and dimerizing the erythropoietin receptor.^{26,27} A related peptide was reported to have agonistic activity in phase I and to be moving into phase II clinical trials. In a related study, a dimeric, 28-residue peptide with agonistic activity on the thrombopoietin receptor equivalent to the native protein ligand (332 residues) was reported.²⁸

Re the second approach above, an intriguing observation was that a single GH molecule bound to and formed a homodimer of two of its receptors using completely different binding regions on the GH molecule. This was a completely unexpected result at the time²⁹ but led to the observation that the site for binding the second receptor could be modified to yield a monovalent ligand for the GH receptor incapable of binding the second receptor, thus yielding a potent antagonist. Analysis of this receptor ligand interaction led to the concept that the critical binding feature was a hydrophobic patch that generates most of the binding energy. Extensive study of this interaction has led to the development of an intriguing 'hot spot' approach^{30–33} to understanding the critical binding interactions of large protein surfaces.³⁴ Although this further study has again demonstrated that nature is characterized by tremendous diversity and that general rules are hard to find,³⁴ much of the developing knowledge on rational design of ligands for binding to large protein surfaces is being generated in this area and it appears to have tremendous potential for the discovery of new peptide pharmaceutical leads. These will then need to be modified using the medicinal chemical approaches described below.

2.14.1.1.5 Proteases

Proteases would seem to be a rich target class and, although there are a number of blockbuster drugs inhibiting members of this class (see enzyme inhibitor product review³⁵), most of the action has centered around a few enzymes with multiple products in each class: HIV protease (8 products), peptidyl-dipeptidase A (angiotensin-converting enzyme; 12 products), and thrombin (10 products). While these inhibitor classes began as peptidelike structures they have developed into areas that focus on peptidomimetics. However, initial inhibitors typically make use of a peptide-like framework and initial products have had substantial peptide character with high potency. For example, the initial ACE and HIV protease inhibitors had clear peptidic character (Figure 2). The modifications that led to high potency can be analyzed in terms both of binding efficacy and balanced physical properties that affect clearance by glomerular filtration (Section 2.14.4.2).

An additional major success with a peptide-based structure is the 28S proteasome inhibitor, bortezomib (Figure 3). This is a relatively nonspecific, dipeptide boronic acid serine protease inhibitor with chymotrypsin-like selectivity that appears to have not had a lot of medicinal chemistry optimization. It is proving to have widespread use in cancer treatment, and it is interesting that duration of protease inhibition is an important factor here. Apparently tumor cells are more sensitive to generalized protease inhibition than normal cells.³⁶ It is toxic to tumors but not to normal cells when the duration of protease inhibition is 24 h or less. However, longer periods of inhibition cause toxicity in normal cells as well, so episodic administration is required and very prolonged duration of action would be detrimental.

A substantial amount of work has been done on caspase inhibitors (see reviews^{37,38}) because of the involvement of caspases in programmed cell death (apoptosis). Both computational and structure-based approaches to design of peptide³⁹ and peptidomimetic^{40,41} inhibitors has been reported. Positional scanning to select optimal peptide frameworks as a starting point for optimized drug design is a powerful approach⁴¹ that can be used broadly to accelerate programs. Since the caspase apoptosis machinery is present in all cells, however, selectivity or side effects are a concern. Modified and constrained peptide-based inhibitors have been investigated here and compounds are moving forward in clinical development.³⁷

Certainly one of the most active research areas at present is the design of inhibitors of the dipeptidyl peptidase IV (DPPIV) enzyme, because of its role in terminating the effect of GLP-1 ($t_{1/2}$ on the order of 1 min in vivo) and GIP, both incretin hormones that potentiate the pancreatic islets' response to glucose.^{42,43} Potent nonpeptide DPPIV inhibitors are the major focus and are in advanced clinical studies. It seems certain that pharmaceutical products will result, despite concerns that the DPPIV also terminates the function of multiple other polypeptide hormones⁴⁴ and side effects are to be expected.

In the area of protease inhibitor research, the HIV protease design area may offer the most medicinal chemistry lessons re peptide–protein interactions, but this is best left to specialist reviews.^{45,46} The general lessons that have come out relate to the common binding conformation found for peptide substrates in proteases (bound as a beta sheet conformation) and the power of structure-based design of peptidomimetics.⁴⁵ In this research, actual peptide–protein interactions have actually been possible to mimic because of the availability of x-ray structures. Although much work continues on peptide protease inhibitors,^{47,48} because of the applicability of structure-based drug design, in a broad sense, the protease inhibitor area appears to be ideal for nonpeptide rather than peptide inhibitor design and will not be treated in detail in this chapter.

2.14.2 Current Peptide Pharmaceuticals

Table 1 lists the Food and Drug Administration (FDA) approved ‘polypeptide pharmaceuticals’ that are available in the USA in 2005, using the definition given earlier. This limitation is imposed since this list is to be used for illustrative

Table 1 USFDA-approved Peptide Pharmaceuticals (<40 residues) in 2005^a

<i>Target receptor or binding protein (native ligand size)</i>	<i>Chemical name</i>	<i>Indication</i>	<i>Comment</i>
Amylin	Pramlintide	Diabetes	Substitution with 3 Pro residues breaks up beta-sheet aggregation
Corticotropin-releasing hormone (41 residues)	Human CRH* Cortirelin	Diagnostic – ACTH release	Native ovine CRH
Calcitonin (32 residues)	Human calcitonin* Salmon calcitonin	Paget's disease, osteoporosis	Native human Extended duration
Cyclophilin (11 residues)	Cyclosporin	Immunosuppressive	Fungal product, many D-residues
Gonadotropin hormone-releasing hormone (10 residues) (All have extensive modifications; see text)	Leuprolide	Prostatic cancer	Controlled release
	Nafarelin	Endometriosis	Intranasal
	Triptorelin		Pamoate salt
	Goserelin	Prostatic cancer	Controlled release
	Histrelin	Precocious puberty	Controlled release
	Ganirelix (antagonist)	Controlled ovulation	
	Cetrorelix (antagonist)	Controlled ovulation	
Growth hormone-releasing hormone (44 residues)	Abarelix (antagonist)	Prostatic cancer	Controlled release
	Sermorelin*		Native human
Glucagon (29 residues)	Glucagon*	Hypoglycemia, radiography	Native human
Glucagon-like peptide-1 (39 residues)	Exenatide	Type 2 diabetes	Incretin mimetic; Gila monster saliva hormone; native sequence
HIV protease	Saquinavir	HIV-1 infection	All are modified peptide/peptidomimetics, typically containing a statin-like residue for interaction with the catalytic Asp residues
	Indinavir		
	Ritonavir		
	Nelfinavir		
	Amprenavir		
	Lopinavir		
Natriuretic peptide (32 residues)	Atazanavir		
	Nesiritide*	Congestive heart failure	Native sequence
Oxytocin receptor (9 residues)	Oxytocin*	Induction of labor	Native sequence
Parathyroid hormone (34 residues)	Teriparatide*	Postmenopausal osteoporosis	Native sequence
Platelet receptor glycoprotein IIb/IIIa	Eptifibatide	Acute coronary syndrome	Cyclic binding fragment, all L
28S proteasome	Bortezomib	Multiple myeloma	Dipeptidyl boronic acid; chymotrypsin-like inhibitor

continued

Table 1 Continued

<i>Target receptor or binding protein (native ligand size)</i>	<i>Chemical name</i>	<i>Indication</i>	<i>Comment</i>
Secretin (27 residues)	Secretin*	Diagnostic	Native human
Somatostatin	Octreotide	Acromegaly, carcinoid tumors	Cyclic binding fragment, multi-D substituted
Thrombin	Bivalirudin	Anticoagulant for coronary angioplasty	D-Phe ¹
Vasopressin (9 residues)	[Arg ⁸]Vasopressin*	Diabetes insipidus, roentgenography	Native human
	Desmopressin	Diabetes insipidus, enuresis	1-deamino,D-Arg ⁸
Viral fusion structure	Enfuvirtide	Blockade of HIV-1 fusion with CD4 ⁺ cells	All L residues

^aDepsipeptide antibiotics like daptomycin etc. are considered outside the scope of this table and review, since they are natural products without medicinal chemistry input.

*Native sequence.

purposes, rather than as a comprehensive listing of products available worldwide. The unnatural sequences offer examples of a number of approaches to the achievement of increased potency and improved pharmaceutical properties, which will be treated in detail below.

A number of these products are unchanged from the native peptide and therefore exhibit the advantages/disadvantages of the parent structure. Thus molecules like oxytocin (induction of labor) and glucagon (transient stasis of the gut for clearer x-ray photos; transient elevation of blood glucose to reverse acute hypoglycemia) are applied for acute applications and, with their high potency with low toxicity, are well accepted. Teriparatide (native huPTH 1–34) for postmenopausal osteoporosis is used for chronic administration; however, the application requires episodic administration (once daily), since prolonged administration results in bone loss rather than the desired anabolic effect. Thus a short-acting molecule is acceptable. Teriparatide's $t_{1/2}$ is 5 min following intravenous and 1 h following subcutaneous administration.

Use of a natural analog for increased potency is indicated by the use of salmon calcitonin rather than human calcitonin for some applications. The salmon sequence is altered at a number of residues (e.g., adding positively charged residues in its amphiphilic α -helical region), resulting in a 10-fold increase in potency⁴⁹ and slowed metabolism. However it also causes generation of antibodies (typically nonneutralizing) in 50% of patients.

A step toward a sequence modification to improve pharmaceutical characteristics is represented by pramlintide, an analog of the pancreatic hormone, amylin. Amylin has low stability in solution because of its tendency toward β -sheet formation which causes aggregation.⁵⁰ Replacement of one Ala and two Ser residues in its C-terminal region by Pro residues improved the stability by reducing this amyloid-forming tendency, resulting in the recently marketed pramlintide (diabetes; slows gastric emptying, inhibits glucagon secretion, inhibits appetite). Early research on vasopressin analogs, where agonistic activity is desired, used a kind of prodrug approach (terlipressin), wherein Gly-Gly-Gly was attached to the N-terminus of the native sequence in order to provide slowed release. Desmopressin ([D-Arg⁸]1-deamino vasopressin) illustrates two modifications designed to block proteolysis (trypsin, aminopeptidase). We will address far more radical modifications and their medicinal chemistry lessons in the sections below.

Polypeptide hormones and neuromodulators address many types of targets.⁵¹ Among the important receptor classes are the GPCRs and cytokine classes. Peptides also play a neuromodulatory role where the target frequently is the GPCR class, although ion channels, proteases, etc. may also be affected. Since polypeptide signaling represents the primordial control system, the 'creativity' of natural selection means that all niches of signaling and control are filled with polypeptides. In this review we will focus primarily on GPCR and cytokine receptor ligands to examine medicinal chemistry approaches that are presumed to have wide application.

2.14.3 Initial Approaches

2.14.3.1 Efficacy

An important type of peptide or protein drug is that which has agonistic or antagonistic action at peptide hormone GPCRs. Knowledge developed from the modeling of small-molecule ligands interacting with GPCRs, where

penetration to the lumen of the GPCR is the critical element required for activation of the receptor, suggests that a similar requirement may exist for peptide ligands (Figure 1c) to have an agonistic effect.⁵² This implies that certain portions of the ligand must be presented in a very specific conformation in order for the receptor to transduce the agonistic signal through the G-protein effector system. A pharmacologist's perspective would be that the ligand actually stabilizes a receptor structure that is either an agonistic, antagonistic, or 'inverse agonistic' conformation, thereby allowing the receptor to activate the G-protein complex that transmits signal, or maintain the inactive conformation.

An early concept was that peptides comprise an address and a message region.⁵³⁻⁵⁵ In modern terms this may be thought of as a region required for binding with high affinity to the receptor and a region required for receptor activation, respectively. A remarkable insight in that analysis was the suggestion that small peptides, which tend not to have an organized structure in water/plasma, might adopt the bioactive conformation on the cell membrane, prior to loading the integral membrane receptor.⁵⁴ A peptide with both regions acting in a functional manner would then be an agonist, while one lacking a functional message region but with a high-affinity address region would be an antagonist. Thus one would expect that deletion, rigidification, or altering of the conformation of particular regions of a peptide ligand might generate receptor subtype specific agonists and/or potent antagonists. Nature, in its diversity, has examples for these message regions being confined to various localized positions in the peptide (N-terminal, C-terminal, and in the middle) and some examples are examined below.

2.14.3.2 Agonism

A central issue in peptide design is a preliminary determination of (1) the required size of the peptide structure, and (2) an understanding of the critical residues required for function. The first is usually accomplished by N- and C-terminal truncation to find the active length, followed by various 'scans' of the structure to find the critical residues. Many peptides can to be shortened with retention of activity while others can yield antagonists when shortened (see Section 2.14.3.3). In general the longer peptide ligands are more likely to survive shortening, but much depends on the site of truncation.

An example of truncation to the active core of a peptide hormone and cyclization is the discovery of octreotide (Table 1), a somatostatin agonist. Somatostatin is found in 14- or 28-residue residue forms with a cystine disulfide-imposed cyclic structure (12 residue ring) and both forms are enzymatically processed from the same precursor. Somatostatin-14 is found throughout the body and its functions in the pancreas (suppression of glucagon secretion), gut (suppression of endocrine tumor secretion), and pituitary (suppression of growth hormone release) have attracted the most interest. A series of peptide analog syntheses involving truncation, Ala-scan, and D-amino acid scan (see below) generated potent shortened forms, and structural studies using nuclear magnetic resonance (NMR) indicated interacting Phe residues across the disulfide ring. This led to smaller cyclic structures⁵⁶ with substantially greater potency and duration of action compared to the parent hormone (MK-678) (Figure 4). These data⁵⁷ illustrate the

Structure	Designation	K _i (nM) cloned hu sst				
		h1	h2	h3	h4	h5
Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp Cys-Ser←-Thr←-Phe←-Thr←-Lys	Somatostatin-14	0.38	0.04	0.66	1.76	2.32
Pro-Tyr-D-Trp Phe←-Thr←-Lys	L-383,377	5654	0.49	3072	>10 000	2000

Figure 4 Receptor subtype potencies of somatostatin and several important analogs. (Reproduced with permission from Yang, L.; Berk, S. C.; Rohrer, S. P.; Mosley, R. T.; Guo, L.; Underwood, D. J.; Arison, B. H.; Birzin, E. T.; Hayes, E. C.; Mitra, S. W. *et al. Proc. Natl. Acad. Sci. USA* **1998**, 95, 10836–10841. Copyright (1998) National Academy of Sciences, USA.)

selectivity issue discussed above: the high potency but lack of receptor subtype specificity of the native hormone as well as the effect of constraint of the peptide structure on receptor subtype specificity. The wide range of *in vivo* effects of the native hormone is related to this lack of specificity and interest in subtype specific analogs is driven by such observations. For example, evidence suggests that receptor subtype sst2 is responsible for suppression of growth hormone release from the pituitary and glucagon secretion from the pancreas, but insulin release is not suppressed by action at this receptor. Thus a highly sst2-specific agonist might be a useful diabetes drug.⁵⁷

This drug discovery program illustrates several features that are relevant to a medicinal chemistry analysis. In the case of somatostatin, the agonistic trigger appears to be in the center of the molecule, focused on a beta turn region containing Trp and Lys. Stabilization of the beta turn by D-amino acid substitution (D-amino acid scan⁵⁸) resulted in substantially higher potency and has remained the focus of most of the subsequent work, which resulted in the design and launch of octreotide (Table 1; Figure 4). Examination of octreotide shows several interesting features: (1) D-Phe at the N-terminus to block aminopeptidase cleavage, (2) D-Trp to stabilize the beta turn, and also to block chymotryptic action, and (3) a reduced C-terminal residue, threoninol, to block carboxypeptidase action. Explicit attention in the issues raised in the section below on biological $t_{1/2}$ could have resulted in selection of an analog of greater potency (see an example of hydrophobic depotting, lanreotide: Section 2.14.5.1.2). Much recent work has been devoted to searching for ligands exhibiting selectivity among the growing number of somatostatin receptor subtypes.

As illustrated above for somatostatin, scans of a peptide structure can identify critical information for analog design. For proteins or larger peptides this is sometimes carried out by a homolog scan,⁵⁹ using sequences from related hormones or receptor binding sequences spliced into the structure being analyzed. A more detailed analysis is usually carried out through use of sequential replacement of each residue in turn by an Ala residue (Ala scan,⁶⁰ see overview⁶¹ and cautions^{62,63}) or by divergent side chain types (e.g., a Lys scan). Ala scans are now used very frequently in the dissection of binding elements in the protein–protein interaction space.²⁵ A D-Ala scan⁹ or D-residue scan (illustrated for somatostatin⁵⁸) can provide useful information since D-residues are known to stabilize beta turn structures,⁶⁴ block proteolysis, and generate antagonists (see Section 2.14.3.3). Scanning with *N*-methyl amino acids is another approach that adds protection from proteolysis and altered flexibility in the peptide side chain.⁶⁵ The use of azamino acids to scan structures⁶⁶ has been used less frequently, but this residue offers several potential benefits, including resistance to proteolysis. Incorporation of scan residues can be done synthetically^{67–71} or by recombinant DNA procedures⁶⁰ for native amino acids in longer peptides. A more comprehensive approach has been advocated, substituting all positions by all proteinogenic amino acids using high-throughput analoging, illustrated by synthesis of 532 fluorescently labeled VIP analogs on spots on cellulose membranes.⁶⁸

Use of β -diamino acids^{72–74} to scan peptide structures was advocated ('betide scan'; substituted β -aminoglycine). These amino acids typically were used as β -acylaminoglycine or β -acyl, β -methylaminoglycine residues that were designed to be roughly isosteric with the proteinogenic amino acids while offering increased rigidity.⁷² This offers an additional route to identification of receptor subtype selective ligands.⁷⁴

Cyclization of peptides through amino acid side chains is the subject of many studies. Cyclization rigidifies the structure, can block proteolysis, may lead to receptor subtype selectivity, and may result in higher receptor affinity by reducing the entropy cost of binding. For example, rigidification of calcitonin (Ct) with an $i-i+4$ side chain cyclization (cyclo 17–21[Asp17,Orn21]huCt), gave a 400-fold increase in potency.⁷⁵ Similar studies have been carried out in additional members of the mid-sized peptide hormone families,⁷⁶ where an helical conformation is predicted for much of the mid to C-terminal region of the molecule. Thus sequential cyclization scans¹¹ can provide much information about active conformation and receptor selectivity as well as advancing the identification of a development candidate. Cyclization scan ($i-i+3$) in corticotrophin-releasing factor (CRF) resulted in a stabilization of the alpha-helical character and dramatically improved the potency of a lead antagonist series (Astressin).⁷⁷ As a further example of cyclization scanning, rolling-loop scanning has been proposed, making use of olefin metathesis to join alkylation points on a peptide structure for global rigidification.⁷⁸ Other examples that illustrate several of the above approaches are the use of cyclization scans and D-amino acid scans to examine requirements for receptor subtype selectivity in the CRF⁷⁷ and MSH family of peptides.⁷⁹ Side chain to side chain cyclization modifies structures that may be critical for receptor interaction, so backbone to backbone cyclization was proposed⁸⁰ and tools were developed.^{81,82} Examples of these approaches are given below.

An additional and quite interesting approach is to use 'positional scanning' to identify binding requirements at each site in a peptide sequence.^{83–85} For example, if one were analyzing a tripeptide sequence, one would make three groups of libraries (O–X–X; X–O–X; X–X–O) wherein each group represents 20 libraries where the position labeled O is fixed as a single amino acid, but the positions labeled X contain a mixture of all 20 natural amino acids. Thus each grouping

contains 20 libraries containing 400 tripeptides in each. Readout by the activity measure of interest has been demonstrated to indicate the favored amino acid(s) in each of the three positions. There have been many applications^{41,86} of this approach to finding the preferred amino acid substitutions.

2.14.3.3 Antagonism

As discussed above, mid-sized peptide ligands (>30 residues) need to bind to the receptor's extracellular elements and activate the receptor. If penetration of the lumen of the receptor is required for activation, one might expect that either the N-terminus or C-terminus might be needed to carry out this function. Thus one might expect that truncation or modification of the terminus might generate antagonism or increased receptor selectivity. In fact there are a number of clear examples of such N-terminal truncation leading to antagonists, discussed below (RANTES, VIP, PACAP, GLP-1, PTH, CRF, etc.).

Chemokines are important hormonal signals that control lymphocyte trafficking into tissues through their GPCRs. In many cases they are important proinflammatory signals and potential drug discovery targets. Modification of the N-terminus of several chemokines has resulted in highly potent antagonists with unusual receptor selectivities.⁸⁷ For example, modification of the N-terminus of the chemokine RANTES (truncation of seven residues, extension of one residue, or extension of N-terminus with aminoxypentane) results in sub-nM antagonists. An interpretation of this result is that the more C-terminal region gives high-affinity binding but the N-terminus is now unable to trigger agonism.

Similarly, in vasoactive intestinal polypeptide (VIP),⁸⁸ truncation of the N-terminus results in antagonism⁸⁹ while acylation (i.e., extension) of the N-terminus can lead to increased receptor selectivity or antagonism, depending on the length of the chain. Thus the N-terminally truncated VIP(10-28) and N-terminally acylated myristoyl[Lys¹²]VIP-(1-26)-Lys-Lys-Gly-Gly-Thr or N-myristoyl[Nle¹⁷]VIP are high-affinity receptor binders⁹⁰ (VPAC1 and VPAC2) with partial agonistic action (low cAMP stimulation). In contrast, *N*-acetylVIP is a high potency agonist. Substitution of D-amino acids in the N-terminus also generates potent partial agonists (e.g., [D-Phe²]VIP).⁹¹ An Ala scan of VIP was used to elucidate the residues that had critical receptor binding interactions.⁹² Thus many of the themes described above re generation of antagonism or partial agonism are demonstrated for this hormone.

Pituitary adenylate cyclase activating peptide (PACAP) is a 38 residue, C-terminally amidated, neuromodulatory peptide with homology to VIP. It has a number of roles in the body, one of which is potentiation of glucose-dependent insulin secretion, similar to the incretins (see below). Like VIP, it binds nonspecifically to multiple receptors (PAC1, VPAC1, VPAC2).⁹³ While activation of VPAC2 has desirable effects in causing potentiated insulin secretion, PAC1 and VPAC1 activation causes side effects.⁹⁴ Thus strong selectivity and strong agonistic efficacy are desirable for agents to treat type 2 diabetes. Acylation of the N-terminus of PACAP by long acyl chains results in antagonism, while acylation with a shorter chain (hexanoic acid) results in an analog with increased potency and selectivity for the VPAC2 receptor.⁹⁵ Thus long-chain acylation yields partial agonism or antagonism while short-chain acylation yields an agonist with increased potency and selectivity. Again, N-terminal truncation of PACAP is found to yield a potent antagonist, PACAP-(6-38).⁹⁶

Analogues of the incretins (peptide hormones secreted, e.g., by L and K cells lining the gut) are an important new class of therapeutic agents for treatment of type 2 diabetes.^{97,98} These hormones prime the pancreas to make more insulin mRNA and to give a rapid and potentiated response to glucose coming from a meal. First to be pursued was glucagon-like peptide 1 (GLP-1) and this was followed by elucidation of a similar, and perhaps predominant, role for glucose-dependent insulinotropic polypeptide (GIP). These molecules have extremely short duration of action in vivo (see Section 2.14.3) but a peptide hormone in Gila monster saliva was found to bind to the GLP-1 receptor with high affinity and longer duration of action in vivo. This molecule, exendin-4, was recently approved for treatment of type 2 diabetes (exenatide, Byetta). Truncation by removal of the first two residues from the N-terminus of exendin-4 yields a potent antagonist.⁹⁹

As mentioned above, incorporation of D-amino acids has resulted in antagonistic ligands on a number of occasions. A few examples are the antagonists [D-Phe²]LH-RH; [D-Phe⁷]bradykinin; [D-Phe⁶]bombesin(6-13)OMe. From these initial leads, very extensive analog programs have used medicinal chemistry modifications to improve potency and duration of action (see below).

2.14.4 Biological Half-Life Solutions

Rapid clearance from the circulation is one of the principal issues cited against peptide drug candidates and proteolysis is routinely cited as the central issue. Much attention has been paid to this issue and advances have led to important

new drug candidates. However, while proteolysis is an important route for peptide degradation, it is not the only challenge to prolonged duration of action. The glomeruli, capillary nets in the kidney, allow water and plasma components below a molecular-weight of about 60 kDa to filter out and form the initial dilute urine. Serum albumin and other high-molecular-weight proteins are not lost, but peptides and other components free in the plasma are lost. Glomerular filtration in the kidney can result in very rapid clearance and strategies to overcome this serious problem have been devised (see below). To reach its full potential, a peptide pharmaceutical thus needs both a degree of protection from rapid proteolysis and a mechanism for protection from rapid clearance by other routes, such as glomerular filtration.

2.14.4.1 Proteolysis

As an example of current interest, the incretin GLP-1 (see discussion above) has a $t_{1/2}$ in humans of only around 0.9 min, due to rapid clearance by DPPIV, a widely dispersed, membrane-bound, serine aminodipeptidase that cleaves many protein hormones in the plasma.⁴⁴ DPPIV favors an Ala or Pro residue as the amino acid in the second position from the N-terminus, so incorporation of other residues here can provide substantial protection from proteolysis. Similarly, D-residues and α -methyl amino acids (e.g., Aib) can completely block DPPIV degradation.¹⁰⁰ Pyroglutamic acid at the N-terminus is known to block aminopeptidase action, and this structure also blocks DPPIV degradation.¹⁰¹ Similarly blocking the N-terminus of GLP-1 with an Ac function effectively blocks DPPIV degradation while retaining agonistic function.¹⁰¹ The GLP-1 series thus illustrates a number of the most popular and effective routes to block N-terminal proteolysis. Some additional routes for proteolysis are summarized in Table 2.

There are a number of general routes to protection from proteolysis that have been used: (1) N- and C-blockade; (2) D-amino acid substitution; (3) unnatural amino acid side chain substitution; (4) unnatural peptide backbone substitution (e.g., azaamino acids,^{102,103} *N*-methyl amino acids,⁶⁵ pseudopeptide linkages^{104,105}); (5) constrained peptides^{10,11} (cyclized, side chain constrained,¹⁰⁶ C α -alkyl); (6) peptoids (*N*-alkylglycines¹⁰⁷); (7) beta and gamma amino acid substitution,¹⁰⁸ etc. Again, there are book-length reviews of these individual areas, so just a few of the most successful examples will be sampled.

N-Terminal blockade by pGlu or N-acylation is typically well accepted, with the former being found on many natural peptide sequences. The latter may result in changes to receptor selectivity or function (see Section 2.14.3.3). D-Amino acid substitution has been the most successful substitution re commercially available peptides (LHRH agonists and antagonists, somatostatin agonists, vasopressin agonists) (Table 1). A further type of rapid proteolysis is carboxypeptidase cleavage and C-terminal amidation is routinely used to block this action, both in nature and in the lab. Many peptide hormones are cleaved from their prohormone forms at Arg/Lys-Arg-X sites¹⁰⁹ by the enzyme furin to yield the C-terminal amide form. Elaboration of this concept to alkyl amides has yielded significant potency increases both due to proteolytic protection and also likely due to hydrophobic interactions (see leuprolide, Table 1). Additional examples are given in Table 2.

Pseudopeptide linkages have not been a first line type of modification, but are favored in peptidomimetics. Nonetheless, examples of active peptide analogs exist and the reduced amide bond is particularly interesting in this class. This results in the introduction of a positive charge, which may result in concentration on negatively charged membranes (increased Gouy–Chapman potential).¹⁵ This may have relevance re Schwyzer's concept for receptor selectivity and loading by membrane interaction.^{110,111} The use of azaamino acids has several potential benefits.

Table 2 Principal proteolysis sites and commonly used protection

<i>Enzyme class</i>	<i>Selectivity</i>	<i>Protection examples</i>
Aminopeptidase	H-X-	pGlu ¹ , D-AA ¹ or D-AA ² , N-terminal acylation
DPPIV	H-X-Ala	Other residue, pGlu ¹ , D-AA ² , Aib ² , Acyl-X-
Neutral endopeptidase	Multiple	Case by case
Trypsin	-Arg/Lys-X	Arg(R ₂), Lys(iPr)
Chymotrypsin	-Hydrophobic-X	D-residue, α -azaaminoacid
Post-proline cleaving enzyme	Pro-X	Pro-NH-alkyl, aza-Gly
Carboxypeptidase	-X-OH	-X-NH ₂

Azaamino acid residues have a rigidified conformational preference and are not attacked by proteases.¹⁰² In addition, they are thought to stabilize a type VI beta turn structure.¹¹² Perhaps most importantly, they have resulted in potent, biologically active peptide analogs (see review¹⁰³) and at least one peptide product (goserelin, [Table 1](#)).¹¹³

Scanning with *N*-methyl amino acids is another approach that adds protection from proteolysis and altered flexibility in the peptide chain.⁶⁵ This approach has provided potent analogs¹¹⁴ and shifts in expected structure–activity relationships.¹¹⁵ For example, replacement of the customary D-Phe residue found at position 7 in potent bradykinin antagonists by D-*N*-methylPhe converted these structures to potent agonists.¹¹⁵

Modifications to constrain peptides are an exceptionally rich area of research going forward. Such constraint may block proteolysis, but, importantly, may also limit the receptor subtypes to which a ligand can bind. Constraint has the theoretical benefit of reducing the entropic price paid as a ligand binds to a receptor as well. Constraint is also invoked as a mechanism to cause conversion of ligands from agonists to antagonists.⁹ As peptide research moves forward to subtype selective drug candidates, constrained analogs will certainly contribute in a major fashion.

Beta amino acids have high stability to proteolysis and instances of high biological activity for beta peptide analogs have been seen.¹¹⁶ Although these novel amino acids do form stable structures in solution,¹¹⁷ experience in design of active peptides is at an early stage and it is expected that such analogs will be a fruitful future direction. Their novelty means that proprietary analogs of existing active peptide motifs may be readily obtained. Peptoids (*N*-alkylglycines) are another type of unnatural amino acid that can develop structure and has been explored extensively, generating some molecules with biological activity.¹¹⁸

2.14.4.2 Glomerular Filtration

Although proteolysis is an important factor, as outlined above, any polar molecule free in the plasma with a molecular weight lower than about 60 kDa is rapidly cleared by filtration from the plasma into the urine in the kidney. About 25% of such low-molecular-weight, soluble material is cleared on each pass through the kidney. As an example of the significance of this clearance, inulin, a carbohydrate that is not metabolized, nonetheless has a rapid clearance with a $t_{1/2}$ of around 1 h. This would not be acceptable in a drug candidate. The parallel to a metabolically stabilized peptide suggests that even a peptide with no susceptibility to proteolysis that was exclusively free in plasma would also be cleared rapidly, based on its size and physical properties. This is a very important consideration that has become a fertile route to important new peptide and protein drugs. Several methods are now used to avert this rapid clearance with clearcut benefits. The medicinal chemistry approaches using unnatural amino acids to modify physical properties are addressed below as ‘hydrophobic depotting’ and ‘hydrophilic depotting.’

Another approach, conjugation of active species to prolong duration of action, has become one of the most important mechanisms to prolonging the duration of effectiveness for protein and peptide drugs. Since glomerular filtration is so important,¹¹⁹ increasing the effective molecular weight of a drug active species can be a very effective approach. Two methods stand out as having been successful in the clinic and one method is clearly successful on the market. PEGylation of protein products has resulted in a rapidly growing list of currently marketed pharmaceuticals and this has led to increasingly creative and complex applications.¹²⁰ Conjugation to a higher-molecular-weight protein has been promoted as well, with albumin being the principal carrier protein used. These approaches are discussed below ([Sections 2.14.4.2.3 and 2.14.4.2.4](#)).

2.14.4.2.1 Hydrophobic depotting

Perhaps the earliest explicit approach to addressing glomerular filtration as a critical factor in peptide clearance, and therefore a subject for drug design, was based on the concept of ‘hydrophobic depotting’ of the peptide.^{16,121} Thus a substantial increase in the hydrophobicity of the peptide might cause it to form a depot in the body, dissolving slowly and reversibly binding to cell membranes and to hydrophobic carrier proteins throughout the body (whole body depot effect).¹⁶ While bound to hydrophobic carrier proteins (e.g., serum albumin, molecular weight 66 kDa) the peptide would not be cleared by glomerular filtration (molecular weight cutoff for filtration into the urine is below the molecular weight of serum albumin) or by membrane bound proteases lining the circulatory system. In this manner it would be continuously released back to the plasma compartment over a period of hours, thereby prolonging its duration of action. ‘Hydrophobic depotting’ is, in fact, a powerful method to obtain increased duration of action for peptides.¹⁵ Following this idea, a group of 15 highly hydrophobic, unnatural amino acids of the D-configuration were incorporated into position 6 of GnRH.¹²¹ The potencies varied from 80 to 190 times the potency of the parent hormone, when tested in vivo in a stringent 2-week antiovarulatory assay in rats. Nafarelin ([D-Nal(2)⁶]GnRH, [Table 1](#)) was the most potent member of this series at 190 times the native hormone.¹²¹ This analog also had the very substantially increased $t_{1/2}$ of 5–6 h in humans, compared to several minutes for GnRH.

This series bears further examination for medicinal chemical insight, because additional analogs were used to fine-tune the hydrophobicity. Following completion of this work, a quantitative structure–activity relationship (QSAR) was reported, suggesting a relationship between potency and hydrophobicity of the side chains in position 6 of published GnRH analogs.¹²² Such relationships are frequently cited for small-molecule drugs and generally exhibit a parabolic or bilinear relationship, reaching a maximum and then falling off in potency as the molecules become too hydrophobic for easy partitioning in the tissues. Analysis of the much more hydrophobic series above indicated a bilinear relationship, with D-Nal(2) in position 6 being close to the optimum hydrophobicity for the monosubstituted GnRH analogs series. Combination of D-Nal(2) with the more polar aza-Gly modification¹¹³ in position 10 increased the potency¹²³ to 230 times that of GnRH while combination with the more hydrophobic Pro-NHEt in this position decreased the potency to 80 times that of GnRH.¹²¹ Both C-terminal modifications had previously been shown to yield highly potent GnRH analogs, but here the relative additive hydrophobicity, when near the optimal, was shown to have had a substantial negative effect on potency, allowing fine-tuning to yield the highest potency analog at a slightly less hydrophobic position.

Examination of the mechanism by which this duration of action was achieved for nafarelin indicated that there was strong binding to plasma protein. An equilibrium dialysis experiment was carried out with one chamber containing buffer and the other containing plasma.¹²⁴ The peptide was added to the buffer side and subsequent analysis indicated an excess of peptide on the plasma side for the parent hormone of 23% but for nafarelin the preference for the plasma side resulted in an excess of 80%. The identity of the binding protein was determined by removing serum albumin by a chromatographic step and demonstrating that the preference for the plasma chamber was abolished. Thus there was a substantial increase in binding of nafarelin for serum albumin and one can visualize that albumin can thus function as both a carrier and delivery protein, as projected. This type of protection can be a very important factor for extending peptide duration of action and another example is given below (see acylated GLP-1 analogs). Thus hydrophobic amino acid substitution appears to be an important and general approach to increasing the potency and duration of action of peptide analogs, when properly positioned in the structure.¹⁵

A similar example in the GnRH field was the design of [D-His(im-Bzl)⁶,Pro⁹-NHEt]GnRH, wherein the protected His residue could be protonated at lower pH for higher solubility for formulation purposes, but would become unprotonated and very hydrophobic at physiological pH.¹²⁵ This analog is a potent GnRH agonist histrelin; precocious puberty (Table 1) with 200 times the potency of the parent hormone *in vitro*. This is an interesting modification that was used also in the GnRH antagonist area, but has not seen much use since. Its behavior is dependent on the basic properties of the imidazole side chain, which is deprotonated near physiological pH (pK_b about 6.5). This type of reversible protonation appears to be highly attractive and worthy of wider exploitation. Although an analysis of the reasons for its potency has not been put forward, it seems likely that hydrophobic depotting in the injection site and on serum albumin also is at work for this hydrophobic molecule.

Another powerful approach to the prevention of clearance by glomerular filtration through hydrophobic depotting is exemplified by approaches using hydrophobic acylation of larger peptides. An example of this comes from research on insulin where acylation with fatty acids resulted in protracted biological efficacy due to the binding of the fatty acid chains to serum albumin.¹²⁶ As we have seen, serum albumin is a general carrier protein for a number of molecules including fatty acids. Much as described above for nafarelin, where strong affinity for serum albumin was found, this type of ‘hydrophobic depotting’ for insulin has several advantages. The authors cite slow uptake into the plasma phase due to the hydrophobicity at the injection site and depotting on albumin in the injection site. When circulating the serum albumin bound form will be protected from glomerular filtration and proteolysis. The bound insulin will be slowly released to the plasma phase to have its biological effect. [LysB²⁹-tetradecanoyl des-(B30)]insulin (insulin detemir, Levemir) had a clearance $t_{1/2}$ of 14 h¹²⁷ and a relative affinity for the insulin receptor of 50%. Importantly, the degree of albumin binding was found to vary 50-fold between species (human albumin affinity was lowest of those tested).¹²⁸ Importantly, the interinjection variability also was found to be reduced and this drug was approved by the FDA in late 2005 as a long-acting, basal insulin for once or twice daily administration. The authors point out that this approach may be a general one¹²⁶ for increasing the duration of action of peptide hormones and, shortly, investigated it on another peptide hormone, GLP-1.

Albumin binding by acylation with fatty acids also provides highly potent and very long-acting analogs of GLP-1. As described above, the incretins (peptide hormones from the gut lining cells that cause potentiated glucose-dependent insulin secretion) represent an exciting new class of treatment⁹⁷ for type-2 diabetes, but duration of action due to cleavage by DPPIV was a critical impediment. Building on the studies that showed that acylation of insulin with aliphatic chains could prolong duration of action, the effect of acylation of the C-terminus of GLP-1 with aliphatic chains and spacers was examined.¹²⁹ These workers found that a relatively wide range of chain lengths on a variety of spacers would give potent analogs with a substantially increased duration of action. Acylation near the C-terminus was

acceptable broadly, but acylation near the N-terminus caused losses in binding affinity. This spatial sensitivity would fit with the notion that the N-terminal region is required for the specific receptor interactions required for agonistic action, while the C-terminus has more of an 'address' function. In fact, examination of the structure of peptides of this class shows a rigid helical region near the C-terminus and a flexible N-terminal region, suitable for adopting a receptor bound conformation.¹³⁰

The prolonged duration of action was specifically related to the ability of such analogs to avoid rapid glomerular filtration due to serum albumin binding. A peptide analog from the series described (liraglutide, [(γ -L-glutamyl(*N*- α -hexadecanoyl))-Lys26, Arg34]GLP-1(7-37)) has a $t_{1/2}$ in humans of 8 h following subcutaneous administration and is progressing through clinical trials using once daily injection.⁹⁷ This is a dramatic improvement over the native hormone ($t_{1/2} < 1$ min).

In a similar study, the other well-studied incretin (GIP) also was modified by acylation near the C-terminus with fatty acids. GIP is released by K cells in the gut, has a similar structure to that of GLP-1, and is considered an excellent candidate for investigation as a new diabetic therapy.¹³¹ Investigation of the solution structure by NMR indicates a helical structure from residue 6 at least through 28.¹³² It binds to a different receptor than GLP-1, but similarly, is very rapidly cleaved by DPPIV ($t_{1/2}$ c. 5 min). The framework used in these studies relies on pGlu at the N-terminus to block DPPIV cleavage and the structure was modified with palmitic acid at different positions (i.e., [pGlu¹, Lys(palmitoyl)]¹⁶GIP and [pGlu¹, Lys(palmitoyl)]³⁷GIP).¹³³ Both of these analogs appear to be more potent in vitro than GIP and show prolonged duration of action. For example, the second peptide still shows strong glucose lowering activity 4 h post administration in mouse models.¹³³ A similar analog¹³⁴ also is undergoing testing (*N*-Ac[Lys(Palmitoyl)]¹⁶GIP) and it appears likely that a member of these series will be carried forward into clinical studies.

Thus we have seen that 'hydrophobic depoting' of peptides can be a very powerful route to prolonged duration of action; however, it has not received much discussion and analysis in the literature as such. This seems likely to change. These approaches of hydrophobic amino acid substitution^{15,16,125} and fatty acid acylation¹²⁶ (for larger peptides) appear to be quite general for peptide hormones and many more such analogs certainly will be seen. A similar approach involves acylation with 2-(sulfo)-9-fluorenylmethoxycarbonyl residues to provide slow delivery of active substance by hydrolysis.¹³⁵

2.14.4.2.2 Hydrophilic depoting

Amino acid substitution in small peptides was recognized as a route to modified physical properties and, thereby, to altered pharmacokinetic behavior.¹⁶ Thus substitution by Nal(2) was used as a way to increase hydrophobicity and duration of action by hydrophobic depoting (see above) for GnRH agonists. The use of GnRH agonists relied on down regulation of receptors and signaling systems due to continuous hyperstimulation by 'superagonists.' Thus treatment resulted in biochemical and physiological sequelae that maintained a suppressed state for an extended period of time (perhaps days). However the field of peptide antagonists is more challenging since one must compete with the native hormone that is being presented, typically in large pulses, throughout the day. Since as little as 10% receptor occupancy of the GnRH receptor can result in a stimulatory signal,¹³⁶ very tight binding, slow receptor off-rate, long-acting peptide antagonists are needed. The Nal(2) modification above was therefore incorporated into GnRH antagonists and lead to some of the most potent antagonists^{16,137} at that time. Unfortunately, these analogs became so hydrophobic that they were administered to animals by subcutaneous injection in corn oil.

In an attempt to increase water solubility, polar amino acids (Glu, Arg, Lys) were incorporated into position 6 of the receptor series [N-Ac-D-pCl-Phe¹, D-pCl-Phe², D-Trp³, D-X⁶, D-Ala¹⁰] LRHR and, in the case of the D-Arg⁶ substitution, unexpectedly high potency and duration of action were observed.¹³⁸ We developed the hypothesis that a form of 'hydrophilic depoting' was responsible, rather than specific receptor interactions, and that this followed from interaction of the positively charged Arg side chain interacting with the negatively charged phosphate head groups on the phospholipids making up cell membranes throughout the body. Further stabilization of this interaction by the addition of alkyl chains led to a novel class of amino acids (Figure 5), the Ng,Ng'-dialkylarginines and -homoarginines.¹³⁹ These amino acids are readily made by guanylation of the ϵ -amino group on the side chain of Lys or Orn to make the corresponding hArg or Arg analogs.¹⁴⁰ A perhaps related class of modification is the use of *N* ϵ -alkyl-lysine residues to generate potent GnRH analogs. Although originally introduced¹⁴¹ to be a basic amino acid that might improve oral absorption, it would be expected to show the type of phospholipids interaction suggested for the hArg(R₂) residue. It has been used in many analogs because it also has a shielded basic function that reduces potential for histamine release.

Incorporation of these amino acids in place of the Arg residue in the analog cited above produced a peptide with dramatically prolonged duration of action (> 24 h in the castrated male rat model) compared to the parent structure. Detirelix ([N-Ac-2Nal¹, D-pCl-Phe², D-Trp³, D-hArg(Et₂)⁶, D-Ala¹⁰]GnRH) had very prolonged duration of action in man¹⁴² with blood levels detectable at > 72 h after a 1 mg subcutaneous dose ($t_{1/2}$ = 29 h). This long duration of action is believed to be due to both the 'whole body depot effect' alluded to earlier and depoting in the site of injection.

Figure 5 Proposed interaction between Arg(R₂) and phospholipid cell membrane.

Examples of much longer duration of action caused by depot formation at the injection site have been seen more recently and are discussed in Section 2.14.5.1.2.

Further modification of the structure (3 Pal for Trp replacement) to give a sharper profile of compound influx from the injection site and higher C_{\max} led to the more soluble ganirelix [*N*-Ac-D-2Nal¹, D-pCl-Phe², D-3 Pal³, D-hArg(Et₂)⁶, hArg(Et₂)⁸, D-Ala¹⁰]GnRH) (Table 1), the first GnRH antagonist registered in the USA (Antagon). This analog has a $t_{1/2}$ in humans¹⁴³ of 15 h and a threefold higher C_{\max} than detirelix.¹⁵ Ganirelix is suitable for once daily administration and is used for controlled ovulation. This same aminoacid modification was carried into additional analog studies. For example when incorporated into an enalapril analog (ACE inhibitor) it controls hypertension in the spontaneously hypertensive rat model for roughly fivefold longer (> 30 h) than enalapril.¹⁵

These studies illustrate the concept of using unnatural amino acids to modify the physical properties of a small peptide in order to alter its pharmacokinetic profile. This is a very rich area for research and offers the opportunity to generate analogs with designed pharmacokinetic behavior and strong patent protection. This type of design work has further evolved to generate peptides with exceptionally prolonged duration of action and unusual properties, as can be seen in Section 2.14.5.1.2 on self-forming depots.

2.14.4.2.3 PEGylation

Prevention of rapid clearance by glomerular filtration in the kidney is now being recognized as a critical, in some cases predominant, factor in the development of long-acting peptides and proteins.¹¹⁹ For example, the finding that modification of the larger peptide hormones with polyethyleneglycol moieties (PEGylation) is a route to increased duration of action and increased potency is widely recognized.¹⁴⁴ Although a detailed discussion is outside of the scope of this chapter, there are several mechanisms that have been invoked to explain this observation: (1) protection from immune surveillance,^{145,146} (2) protection from proteolysis, and (3) prevention from glomerular filtration.^{119,144} Recent thinking has given greater importance to the prolongation by reduction in glomerular filtration as a major factor. This is illustrated by detailed studies of the relationship between PEG molecular weight and $t_{1/2}$ in the blood which show a discontinuous relationship with a sharp increase in $t_{1/2}$ at about 34 kDa (Figure 6). The $t_{1/2}$ of PEG chains in the bloodstream increased from 18 min to 1 day as the molecular weight increased from 3 to 190 kDa.¹¹⁹ The cut-off for allowing filtration into the urine is below the molecular weight of serum albumin (66 kDa) and the hydrated PEG chain behaves like a corresponding protein structure severalfold larger than its actual molecular weight. Thus all PEGs with a molecular weight above 35 kDa show similarly prolonged duration in the bloodstream, with little relationship to actual molecular weight. Similarly, their protein conjugates show substantially prolonged increases in $t_{1/2}$ once this range is reached.

The effects on duration of action and potency can be quite substantial.¹⁴⁷ For Interferon α 2a, PEGylation increased the $t_{1/2}$ from 3–8 h to 65 h, with a 12–135-fold increase in antiviral potency. Similarly for IL6, PEGylation increased the $t_{1/2}$ from 2 min to > 200 min with a 500-fold increase in thrombopoietic potency.

There is also evidence that the immunogenicity of proteins is reduced and that specific aspects of the PEGylation can be important in masking this propensity. For example, in early studies serum albumin's immunogenicity was shown to be suppressed by PEGylation¹⁴⁵ and this was extended to other proteins.¹⁴⁸ However, the first-generation

Figure 6 Correlation plot between PEG molecular weight and half-life in blood after intravenous administration. Note the discontinuity near 35 kDa. (Reprinted with permission from Caliceti, P.; Veronese, F. M. *Adv. Drug Deliv. Rev.* **2003**, 55, 1261–1277 © Elsevier.)

PEGylated dimer of the soluble tumor necrosis factor receptor I (sTNF-RI, denoted TNFbp) was highly antigenic. A subsequent construction, modified with a monomeric 30 kDa PEG chain at the N-terminal amino acid, was found to be highly efficacious and nonimmunogenic.¹⁴⁹

Thus while the early studies focused on multiple short PEG chains (e.g., molecular weight 5 kDa), examples in later work focus on single chains of larger molecular weight, in a number of cases resulting in the retention of higher activity. For example, interferon- α (19 kDa) coupled to a single PEG chain of 12 kDa has been commercialized for treatment of hepatitis C and has a $t_{1/2}$ that is eight times that of native Ifn- α . Thus PEGylation to yield 31 kDa will effectively block clearance by the glomerular filtration route, as described above. More recently, much larger PEG chains (e.g., to 40 kDa) are being used preferentially since single site modification results in better characterization and biological activity.

PEGylation has been extended to smaller peptides. For example modification of salmon calcitonin with one or two 12 kDa PEG chains results in a prolongation of $t_{1/2}$; 10-fold for the bis-PEGylated form.¹⁵⁰ Extension to releasable conjugates and small-molecule PEGylated drugs is an area of current/future development,^{151,152} but it is already clear that this type of modification can be useful in the design of peptide drugs with prolonged duration of action. One area that needs to be considered relates to the finding that large proteins with large PEG groups may have restricted areas of permeation and certain applications may be either favored (e.g., permeation through the 'leaky vasculature' of tumors¹⁵³) or disfavored (lack of permeation into sites for antiviral¹⁵⁴ or other action).

2.14.4.2.4 Protein conjugation

Another approach to prevent rapid clearance of a ligand by glomerular filtration is to attach it to a high-molecular-weight protein carrier. Attachment of ligands to serum albumin now has been used successfully to increase duration of action substantially for a number of peptide ligands, while retaining biological activity.^{155,156} Initial studies examined the attachment of a dynorphin A (a 17-residue μ/κ opioid peptide) analog to the Cys residue at position 34 of human serum albumin by means of an ϵ -(3-maleimidopropionyl) function on a Lys residue at the C-terminus.¹⁵⁶ Use of the mouse acetic acid writhing assay showed that morphine, dynorphin A, and this conjugate (CCI-1035) showed activity at 5 min, but only CCI-1035 showed antinociceptive activity at 4 and 8 h, and does so at doses comparable to that of dynorphin A. This study demonstrated the retention of high agonistic potency and a very long duration of action.

Similarly, GLP-1 analogs suitable for conjugation were constructed through the substitution of an $N\epsilon$ -(2-{2-(3-maleimidopropylamido)ethoxy}ethoxyacetyl)lysine residue at various positions on the chain.¹⁵⁷ As expected from earlier studies with GLP-1 analogs, the favored position for substitution was at the C-terminus and a D-Ala residue was substituted at the second residue to block DPPIV activity. This analog, CJC-1131, reacts with human serum albumin (HSA) in vivo to form the circulating, long-acting form. The sequence had somewhat reduced potency when coupled to HSA, but a long duration of action in vivo is to be expected during ongoing in vivo trials. An analog that accomplishes a similar goal uses a GLP-1 sequence spliced directly onto that of HSA and is produced recombinantly (albugon). Albugon exhibits reduced acute potency, but much prolonged duration of action.¹⁵⁸ An extension of this approach proposes the use of transferrin as a carrier protein.

Thus this approach appears to have substantial potential for broad application to peptide and small protein ligands. This type of conjugation also was extended successfully to C-terminally conjugated analogs of human growth hormone-releasing factor¹⁵⁹ and atrial natriuretic factor.¹⁶⁰ Prior to contemplating its use, one may want to compare it to the use of PEGylation for a similar application. Conjugation to either gives prolonged effect and, in the case of PEGylation, immunogenicity is suppressed. Conjugation of ligands to proteins previously has been used as a way to raise antibodies against haptens, and this remains a concern for the protein conjugation approach, although researchers have explicitly stated that it has not been a problem with specific and single sites of conjugation. It seems clear that, since use of protein carriers and amino acid polymers in the past has been immunogenic, there is potential to observe that here. However, given this caveat, protein conjugation remains an intriguing and apparently general approach to increasing $t_{1/2}$ of peptides and proteins.

Another type of protein conjugation is represented by the use of an antibody Fc domain and taking advantage of its long $t_{1/2}$. For example, a number of cytokine receptors are found in a cleaved, soluble form in the plasma with the hypothesized role of modulating the function of that inflammatory system. Etanercept is a genetically engineered, dimerized, fusion protein composed of such a 'soluble TNF receptor 2' (endogenous antagonist of TNF function) linked to an IgG1 antibody Fc domain. This conjugate binds tightly to TNF- α and is highly effective in treating rheumatoid arthritis. This agent is long-acting and is administered twice weekly.

2.14.4.3 Structural Motif Replacement

As we have seen above, the class of peptide ligands in the range between 20 residues and 40 residues holds many attractive drug candidates and approaches to increased efficacy and potency will result in additional, important drugs. Some examples are the VIP/secretin family and PTH. Many of these hormones appear to have structural similarities, where this information is known. A typical finding is that the N-terminus is flexible and required for efficacy, while the more C-terminal region adopts a helical conformation and has regions that contribute to binding potency or just to helical structure.^{161,162} Thus modifications of the correct portion of the C-terminus might yield agonistic activity with modified binding and/or pharmacokinetic behavior. We have seen that PEGylation and acylation with fatty chains can result in very prolonged duration of action and high potency for GLP-1. Cyclization of more C-terminal regions of PTH can result in improved biological activity.¹⁶³

PTH offers an interesting challenge, because it must be present for a period of time, but not too long, in order to have a beneficial effect. Once daily injection of PTH or PTHrp has an agonistic effect on the PTH receptor on the osteoblast. This episodic treatment stimulates osteoblastic function¹⁶⁴ (laying down of matrix for new bone) and stimulates bone-lining cells to differentiate into active osteoblasts. However continuous treatment with PTH causes the osteoblasts to secrete a signal that activates osteoclastic action, with a resulting net bone loss. Interestingly, it is the time during which PTH levels remain elevated, rather than the total dose, that determines whether an anabolic or catabolic effect is seen on bone in the animal.¹⁶⁵ Therefore a superior PTH based drug for osteoporosis would have increased potency and longer duration of action, but not too long.

Human PTH is present in the body as an 84-residue polypeptide. SAR studies determined that the N-terminal 2 amino acids are required for agonistic action and the N-terminal 34 residue peptide is fully active. PTHrp is a related structure, frequently found as a secretion product from tumors (but in a developmental role in many tissues), which binds to the same receptor with similar potency and efficacy. A project in the author's laboratory directed at single amino acid substitutions in the C-terminus to achieve hydrophobic or hydrophilic depotting, as described above, did not yield substantial effects on potency for analogs of PTHrp.¹⁶⁶ PTHrp had been chosen for modification because a triple basic sequence, hypothesized to be critical for function, was located closer to the N-terminal region and it was felt that more extensive C-terminal truncation could be accepted with retention of activity. However the incorporation in place of residues 22–31 by a 10-residue model amphiphilic polypeptide helical structure,^{167,168} originally designed as a lung surfactant peptide, led to remarkable increases in efficacy in vivo.^{169,170} Although the increased efficacy may be due to the use of a stabilized helical motif, the compound (semparatide) may also exhibit altered behavior due to the amphiphilicity of the modification. Further study confirmed its enhanced helical character¹⁷¹ and bone anabolic efficacy, but suggested that it had sharply reduced affinity for the PTH receptor¹⁷² (see however studies¹⁷³ indicating high affinity for the G-protein-bound, receptor high-affinity state). This compound was carried into phase III clinical studies with excellent efficacy. One would surmise that a molecule that combined the features of somewhat prolonged duration of action, but with increased receptor affinity, might be a very desirable clinical development candidate.

The comparison of the lack of strong effect on protein function in this series by single amino acid substitutions, but strong effects by motif incorporation, suggests to the author that this may be a paradigm for future research on protein

ligands of this size. While stabilization of the helix of a ligand may yield favorable entropic effects re binding thermodynamics (not seen here), the ability to modify protein behavior and PK thereby has obvious benefits.

Study of analogs of corticotrophin-releasing factor (CRF) showed that cyclization⁷⁷ and incorporation of residues to optimize alpha-helical character (C-alpha amino acids)¹⁷⁴ could result in increased potency. This is another example of a mid-sized polypeptide hormone where the biologically active conformation appears to have a predominantly alpha-helical motif.

2.14.4.3.1 Expression-modified proteins

An approach that shows great promise for incorporation of unnatural amino acids into proteins and has the potential for extension to the incorporation of larger motifs is that developed by Schultz and co-workers.¹⁷⁵ It makes use of in vitro selected, unique tRNA /aminoacyl tRNA-synthase pairs that load specific unnatural amino acids and that make use of the amber nonsense codon, TAG. Some examples of this approach demonstrated the incorporation of amino acids with side chains that have sugar functionalities,¹⁷⁶ redox potential,¹⁷⁷ *p*-iodo-phenylalanine for x-ray phasing (single wave-length anomalous dispersion),¹⁷⁸ PEG for site-specific PEGylation,¹⁷⁹ and alkyne functionality (for 3 + 2 electrocyclic cyclizations, CLICK chemistry),¹⁸⁰ etc. Expansion to a four-base codon system¹⁸¹ offers the opportunity to increase greatly the number of types of amino acids that can be incorporated successfully into proteins. Thus the use of multiple, or critically placed, unnatural amino acid substitutions offers the opportunity to incorporate substantially modified motifs, and thereby proteins with significantly altered physical properties, with attendant beneficial effects on protein behavior in vivo as described in the previous section. As usual, the question of potential immunogenicity for modified proteins of >50 residues must be considered and even native proteins can be immunogenic.¹⁸² However the frequent experience is that such antibodies are not neutralizing,¹⁸³ although serious instances of immunogenicity are known. Nonetheless, this approach appears to have great promise and flexibility for future development.

2.14.5 Drug Delivery to Overcome Bioavailability Issues

The most important challenge that faces a peptide or protein drug candidate is that of achieving the bioavailability required for therapeutic effect in the body and drug delivery technologies offer very powerful ways to add value to peptide and protein products. The challenges of duration of action and receptor selectivity have many solutions as we have seen above, but the physical barriers that the body erects to keep unwanted agents (viruses, toxins, antigens, etc.) outside, also prevents peptides or proteins from finding easy access. The routes across the mucosal barriers are either transmembrane (dissolving in the membrane, crossing the cell, and dissolving in the basolateral side membrane to exit), paracellular (passing through the 12 Å radius pores¹⁸⁴ between the intercellular tight junctions), or by active transport (e.g., the peptide¹⁸⁵ or amino acid transporters). The small-molecule drugs with a balanced hydrophobic/hydrophilic character are able to equilibrate across membrane barriers driven by a concentration gradient. Small molecules and salts can pass through the paracellular route. Some polar molecules like amino acids, and up to tripeptides,¹⁸⁵ are actively transported, as are some drugs (e.g., penicillins, cephalosporins) and prodrugs (e.g., valganciclovir, valcyte). It is apparent then that the bulk of peptide and protein drugs normally are not able to make use of any one of these three transport routes. Thus the challenge has been approached by injection, transient breaching of the barrier (mucosal, dermal, enterocyte), and inhalation. There are many books and specialist reviews of these areas, and what follows is an overview of selected areas that appear to have high promise or clear efficacy. Briefly, these routes are intranasal, inhalation, and controlled-release injectable.

For agonistic applications, episodic administration may be favored since many hormonal systems become desensitized (receptor downregulation, signaling system uncoupling) with continuous stimulation. In the case of GnRH, a well-studied case, continual administration of highly potent agonists actually leads to a 'medical castration' that is the basis of the therapeutic benefit. Thus for treatments where an antagonistic effect is desired, controlled-release formulations with continual delivery of the active agent have clear potential advantages. Some other hormonal systems appear to be less sensitive to this type of desensitization. For example, administration of GLP-1 or exendin-4 (Byetta) to cells in culture induces a clear state of receptor desensitization, but treatment in vivo appears not to.¹⁸⁶ It is possible that the variable levels seen during in vivo treatment (blood levels rapidly drop following the initial pulse) offer the opportunity for the system to resensitize. Early reports say that exenatide, a potent, longer-acting GLP-1 receptor agonist, does not exhibit diminished response following treatment periods of moderate length. However, longer, higher-dose treatment with more potent analogs might well cause diminished response. An extreme case is seen

with PTH. As we have seen above, for treatment with PTH, episodic treatment is required. Thus the form of administration, episodic or continual release, may be critical to the pharmacological effect seen and desired. Careful evaluation of these considerations is needed on a case-by-case basis.

2.14.5.1 Injection

The oldest, most straightforward, and most widely used form of administration of peptide and protein drugs is by injection. This route has its own issues but typically one can achieve high bioavailability and deliver episodic pulses of the agent of interest. The issues for simple injection are well known (solubility, stability, denaturation, immunogenicity, etc.), but relatively straightforward for experienced pharmaceutical groups. We will focus on alternative formulations.

2.14.5.1.1 Controlled release

Controlled release of peptide drugs using polymeric matrices has become a widespread and successful approach, with effective delivery times of 3 months and more. Although controlled release from polymer matrices initially began with hydrophobic small molecules diffusing out of silicone rubber,¹⁸⁷ many different types of polymers¹⁸⁸ have been evaluated. Polyamino acids, polyesters, polyorthoesters, polyacetals, polyketals, polyurethanes, etc. are some of the most frequently cited. This type of research offers a route to improved behavior, ease of processing, or just proprietary formulations. Lactic/glycolic copolymers have been the most successful and most widely- used for peptide and protein delivery, and a brief illustration of development of this area is given below.

The observation that copolymers of lactic acid and glycolic acid (poly-D,L-lactic-co-glycolic acid; PLGA) could be used to form sutures that slowly eroded and resorbed with time to yield components that are naturally present in the body led to their application in the development of early formulations for agents such as naltrexone,¹⁸⁹ sulfadiazine,¹⁹⁰ and contraceptive agents.^{191–193} Extension to the more polar polypeptides required some modifications and was carried out in studies with nafarelin.^{194,195}

Characteristics of such a formulation include hydration and homogenous erosion of the polyester matrix. The hydration rate, and therefore the release rate, depends on the hydrophobicity of the polymer matrix, so variation in the percentage of lactic acid can vary the duration of release. In early studies, 50/50 lactic glycolic copolymer microcapsules (i.e., injectable by standard syringe) gave 21 days of essentially linear release of nafarelin in female rats with prompt return to estrus cycling at day 24.¹⁹⁶ This type of microcapsule formulation for GnRH analogs was subsequently applied to [D-Trp⁶]GnRH¹⁹⁷ and others. Eventually it was out-licensed to become the formulation (with modifications in manufacture) used in Leupron Depot, a peptide ‘blockbuster.’ The importance of formulation for peptide delivery is illustrated in this latter product because leuprolerin is relatively short-acting and required up to six times daily injection for treatment in some early rat models. In contrast, in an early microcapsule formulation, only once-monthly delivery was required.

The duration of release is dependent not just on the percentage lactic acid in these formulations, but also on the molecular weight of the polymer or mixture of polymers used and on the use of homochiral or racemic polylactic acid. In addition, the size of the structure determines the release rate. Formulation of zoladex into rods (1 mm × 3–6 mm) and implantation subcutaneously released the analog over a period of > 28 days.¹⁹⁸ Thus longer-term release patterns were also possible with the same underlying chemical components and later modifications (dosage increased from 3.6 to 10.8 mg) have resulted in microcapsule formulations requiring administration once every 3 months.¹⁹⁹

A very interesting approach, that may simplify the development of controlled release formulations, is the development of soluble formulations²⁰⁰ for injection that contain the active ingredient and a mixture of polymers in a biocompatible solvent. This solution is then injected to the subcutaneous space where the solvent is leached away to precipitate the polymer and provide a solid polymer matrix containing the drug. Formulations for leuprolide (Eligard) which last for 1 month (7.5 mg), 3 months (22.5 mg), and 4 months (30 mg) have been approved by the FDA. The potential advantage is that some of the variables in the manufacture of a controlled-release formulation, which give rise to variations in the release profile, presumably can be avoided, perhaps saving many months in the development process.

The logical extension of these formulation design efforts is Vantas (histrelin hydrogel) for once-yearly administration. This formulation is a 3-cm tube containing 50 mg of the hydrophobic GnRH analog histrelin and stearic acid. On the negative side, a small incision is required and the tube must be removed at the end of its use. Another very long-term formulation is Viadur (4 × 45 mm implant), which is a once-yearly implantable device for osmotically driven release of leuprolide over a period of 1 year.²⁰¹ The use of polylactic/glycolic microspheres for the delivery of therapeutic proteins (serum albumin,²⁰² IL2²⁰³) and immunogens (e.g., CTL vaccine against Her-2/neu²⁰⁴) also has been demonstrated.

2.14.5.1.2 Self-forming depots

A relatively new approach to the design of long-acting forms of delivery for peptides is the use of self-forming depots. This approach can be broken into the use of solubilized polymeric depots that solidify at the injection site when the solubilizing agent leaches away (see above, Eligard) or active agents that have had this property designed into their structures. These latter agents typically exhibit characteristics that lead to the formation of intermolecular aggregates, combining hydrophobic and hydrophilic elements. Evolution of the latter agents can best be demonstrated in the GnRH and SRIF areas.

Early work on compounds designed with prolonged duration of action resulted in nafarelin¹²¹ and detirelix,¹³⁹ very hydrophobic GnRH analogs that exhibited a propensity to form liquid crystals in solution.²⁰⁵ It was felt that the prolonged duration of action of such molecules derived in part from depotting on serum albumin and cell membranes, but also from retention in the injection site.^{206,207} Clearly such molecules showed the potential for the self-assembly of complex structures in solution. Thus detirelix showed a $t_{1/2}$ of 7 h following intravenous injection in monkeys (0.08 mg kg^{-1}) but a much-prolonged $t_{1/2}$ of 32 h from a subcutaneous injection of 1 mg kg^{-1} . For Ganirelix (Table 1) in monkeys, the $t_{1/2}$ was 19 h following a 1 mg kg^{-1} subcutaneous dose.²⁰⁷ In vitro plasma binding was >80%, similar to nafarelin. Depot formation was indicated by the retention of 12% and 4% of the dose of radiolabeled analog in the injection site after 3 and 10 days, respectively.²⁰⁷

A similar set observations have developed around the hydrophobic somatostatin analog, lanreotide (cyclic [D-2Nal-Cys-Tyr-D-Trp-Lys-Val-Cys-Thr-NH₂]).²⁰⁸ This analog, which is essentially a D-2Nal analog of octreotide, springs from the observation that N-terminal Nal substitution in GnRH analogs and internal substitution in agonists provided increased potency. Like octreotide, this analog is selective for the sst2 receptor, which is present on >80% of digestive tract tumors.²⁰⁹ This substitution led to a decrease in potency acutely, but to a substantial increase in duration of action. This was hypothesized to be due to slowed uptake from the site of injection and subsequent work detailed a self-association process that proceeded from the formation of beta-sheets to development of large nanotubes.²¹⁰ This self-assembly into nanotubes occurs through the formation of beta-sheets driven by amphiphilicity and a systematic aromatic/aliphatic side chain segregation.²¹¹ The physical state is concentration dependent and drives toward nanotube formation at higher concentrations. Thus this product is not a polymer type, controlled-release formulation; the depotting character is built into the molecule through this ability to form a slow release, self-associated form that further assembles as stable nanotubes, with a terminal $t_{1/2}$ in humans of 4 weeks. Remarkably, lanreotide acetate hydrogel (30% w/w) thus has a very simple formulation in water and is administered every 4 weeks by deep subcutaneous injection.²⁰⁹

While the analogs above form a type of aggregation driven by hydrophobic character, another class of analogs with unusual properties spring from observations related to side chain urea functional groups such as that on citrulline. Thus cetorelix ([N-Ac-D-2Nal¹,D-pClPhe²,D-3Pal³,D-Cit⁶,D-Ala¹⁰]GnRH) is an approved pharmaceutical that appeared to have somewhat prolonged action. Other GnRH analogs containing urea functionality have been demonstrated to exhibit 'gelling' and delayed release from the injection site (2.6% of radioactive dose present at injection site at 264 h post dosing²¹²), and in some cases local tissue reaction has been documented.²¹³ Further studies directed at long-acting GnRH analogs containing ureido functionality resulted in molecules such as azeline B, which showed very substantial potential for gelling in the injection site. Such analogs exhibited prolonged duration of action (14 days for azeline B following 2 mg kg^{-1} subcutaneous in rats).

A very detailed study of structure–activity relationships related to structures with side chain urea functional groups²¹⁴ resulted in the selection of degarelix (FE200486; [N-Ac-D-2-Nal¹,D-pClPhe²,D-3-Pal³,Aph(Hor)⁵,D-Aph(Cbm)⁶,Lys(iPr)⁹,D-Ala¹⁰]GnRH) (Figure 7) for preclinical development. Very dramatically prolonged action was demonstrated for this material when injected subcutaneously, in contrast to that obtained by intravenous injection implicating a depotting effect at the injection site. It is hypothesized that the urea functional group has unique properties that favor a 'slow diffusion from the subcutaneous sites of administration.'²¹⁴ While a detailed type of biophysical study²¹⁰ like that done with lanreotide autogel does not appear to have been published, the prolonged duration of action seen here may have a similar source in the self association to elaborate structures that 'do not mount to detectability as gels.'

2.14.5.2 Intranasal

Transmucosal administration of peptides and proteins has been successful and there are multiple products on the market. The advantage of using the nasal passages are that they are readily available, have a thin squamous cell lining, have a relatively large surface area (150 cm^2), allow the drug to avoid first-pass clearance, and minimize overdose since drainage is to the gut where the peptide is destroyed. Several smaller peptides are commercially administered in this fashion: [D-Arg⁸]vasopressin, nafarelin, and desmopressin. In addition, and, somewhat surprisingly considering its

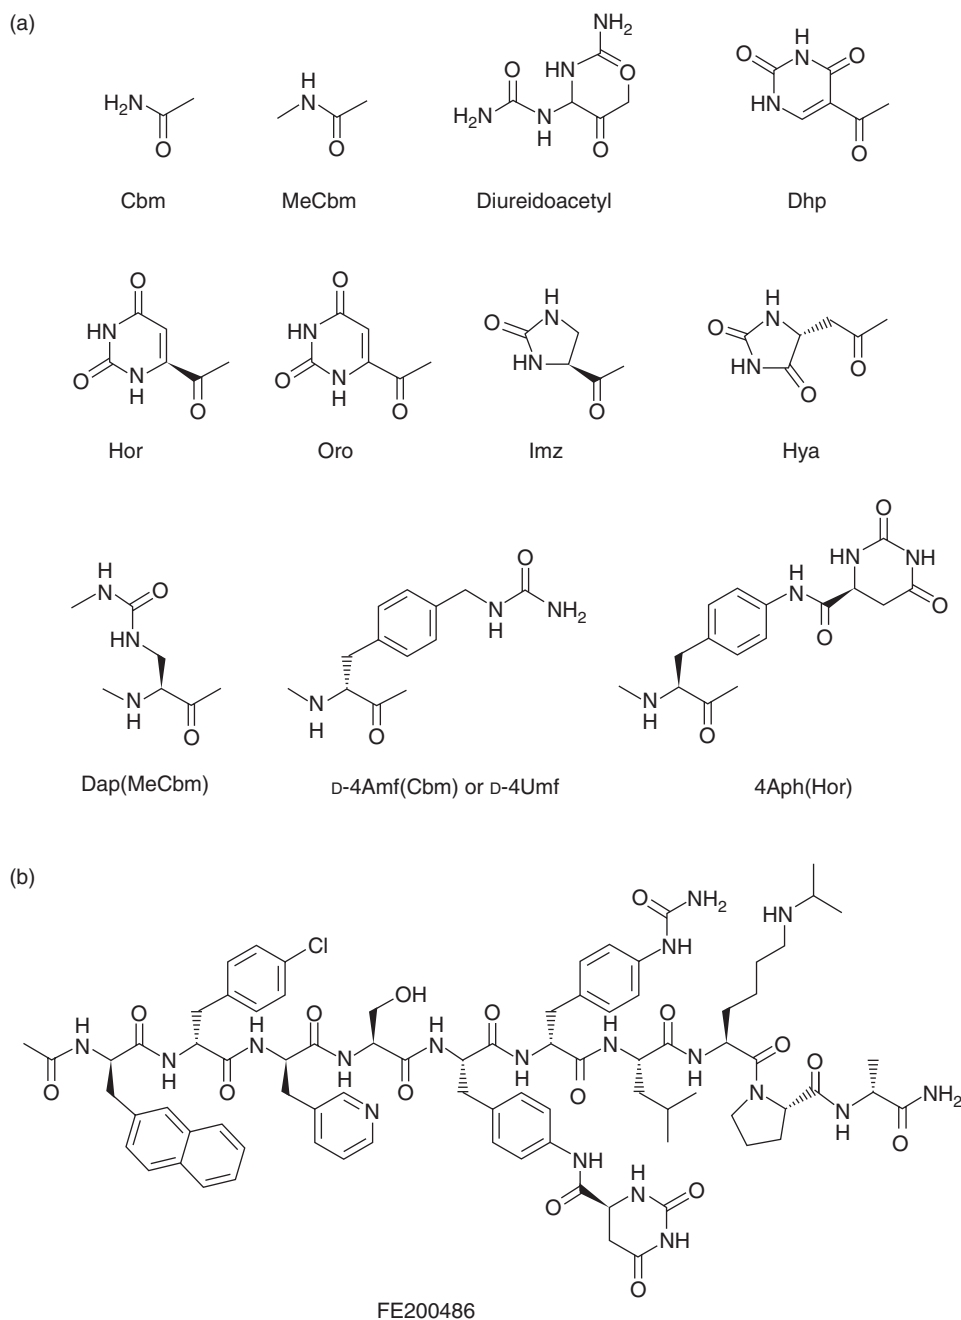

Figure 7 Structures of some *p*-ureido substituted Phe residues and of degarelix. (Reproduced with permission from Jiang, G.; Stalewski, J.; Galyean, R.; Dykert, J.; Schteingart, C.; Broqua, P.; Aebi, A.; Aubert, M. L.; Semple, G.; Robson, P. *et al. J. Med. Chem.* **2001**, 44, 453–467 © American Chemical Society.)

size, salmon calcitonin is reported to have relatively good bioavailability by this route, without added enhancers (however, see below).

In early studies with GnRH analogs, they were typically found to have bioavailabilities in the 2–5% range. In animal studies with nafarelin, the bioavailability was found to be nonlinear, with higher absorption being seen at higher concentrations of peptide. Thus a 2.2-fold increase in concentration resulted in a 6.5-fold increase in bioavailability and a further 2-fold increase in concentration resulted in a fourfold increase in bioavailability (solubility limited to 2.5 mg mL^{-1}). The addition of protease inhibitors like Trasylol did not increase absorption.²¹⁵ Studies in humans using

various enhancers found that instillation of a solution of 1.75 mg mL^{-1} in saline containing 2% sodium glycocholate showed an average bioavailability of 21%.²¹⁶ Unfortunately, detailed study of such enhancers in the past have turned up evidence of irritation and unsuitability for continuous use.²¹⁷

Looking forward, there are new approaches to enhancers for nasal delivery. Studies with the peptide PYY and peptide enhancers designed to interfere with the protein structures that comprise the tight junctions between cells²¹⁸ have resulted in a clinical program that is moving forward with the intent to cause appetite suppressing effects in order to treat obesity. In a similar vein, very substantial improvements in nasal bioavailability of peptides and proteins have been reported with alkyl sugar enhancers.^{219,220} For example, these researchers report that although the bioavailability of intranasal salmon calcitonin is highly variable (0.3% to 30%) in the commercially available formulation or in saline, it is 53% when administered in the presence of 0.125% tetradecylmaltoside.²¹⁹ Similar bioavailability values were demonstrated for insulin and leptin with this system with minimal effects on the structure of the nasal cilia.²²⁰ This is a remarkable result and, if reproducible in humans without irritation, opens the way for additional mid-sized peptide drugs to be developed by intranasal administration.

2.14.5.3 Inhalation

The evaluation of the lungs for the administration of peptide and protein therapeutics²²¹ has been considered attractive because of the very large surface area (140 m^2), thin epithelium, good blood flow, and immunotolerant nature.²²² Many peptides and proteins are in evaluation and insulin has been studied in the most detail. Insulin inhaled as a dry powder has a bioavailability of 6–10% and a rapid onset of action (T_{max} 24 min versus 106 min for subcutaneous regular insulin). The duration of action is somewhat longer and it appears to be well accepted by patients.²²³ This formulation is now approved by the FDA (Exubera) and validates the inhalation route for administration of peptides and even small proteins.

2.14.5.4 Oral Administration

Although oral administration of peptides and proteins has been studied for many years there still appear to be no reproducible data confirming substantial bioavailability.^{222,224} Desmopressin (nonapeptide) is available for oral administration, but the bioavailability is very low. A similar statement could be made for the rectal and vaginal routes of administration. As noted above, the three normal routes of permeation are closed to peptides and proteins. Transient disruption of the barrier function of the tight junction between the enterocytes would seem to have more serious consequences than doing so in the nose or lungs, due to the potential for uptake of endotoxin due to the bacteria in the lower gut. It would appear that intranasal, inhalation, and controlled release injectable remain the best options for delivery of peptides.

2.14.6 Peptidomimetics

The detailed analysis of peptidomimetic approaches is outside of the scope of this chapter (*see* 2.15 Peptidomimetic and Nonpeptide Drug Discovery: Receptor, Protease, and Signal Transduction Therapeutic Targets; and reviews^{1,13,14,106,225–232}), but is highly relevant, given that drug discovery relating to peptides is moving strongly in that direction. There are some important points that need clarification: (1) not all ligands that compete with a peptide in binding with its receptor represent true ‘peptidomimetics’ and (2) the results to date have largely yielded antagonists when applied to GPCRs. The latter is particularly true when addressing mid-sized peptide hormones (> 20 residues).

Although initial interpretations were that the small-molecule ligands binding to peptide GPCR receptors were true peptidomimetics and specific features were hypothesized as representing specific amino acid side chains, site-specific mutagenesis studies soon demonstrated that there was no commonality in the receptor features required for binding the native ligand and the small molecule antagonist. For example, a comprehensive study of the critical interaction residues of the substance P/neurokinin (NK1) receptor for the native ligand and a small-molecule antagonist showed that different regions of the receptor, with little overlap, were involved in binding to the two different molecules.²³³ Similarly, the critical interaction residues of the bradykinin 2 receptor for the native peptide ligand and for the structurally quite similar undecapeptide antagonist HOE-140 (three residues differ) show very little overlap,²³⁴ suggesting very different critical binding interactions. It seems clear that in most cases of GPCR ligands, the small molecule antagonists should be assumed to not have the same binding mode or faithfully represent the critical amino

acid residues characteristic of the native ligand. Nonetheless, a structurally related molecule to that mentioned above has now reached the market as an NK1 antagonist (aprepitant) for emesis.

'Peptidomimetics' have been classified, based on which were characterized first,²²⁵ as Type I (backbone modifications to block proteolysis), Type II (functional mimetic, without structural overlap), and Type III (topographical mimics with the relevant amino acid side chains faithfully represented on a novel scaffold). By this definition, Type III is the type that has long been sought, but for antagonistic function, any type may be efficacious. An alternative to this type of classification was the term suggested by Veber and co-workers,²³⁵ 'limetic,' for that class of small-molecule ligands for a peptide GPCR that is not truly mimicking a peptide's critical binding interactions, which would be peptidomimetic.

In general it has been felt that peptides interact strongly with both the N-terminal region of the GPCR receptor and the extracellular loops, but that interactions with the transmembrane region are critical for agonistic action. Thus a relatively large and complex assembly of interactions is required for agonistic action. Presumably this is the reason that there have been many more antagonists than agonists found in peptidomimetic research.

Research generating enzyme inhibitors and cytokine class receptors appear to be areas where the design of true, or Type III, peptidomimetics has been fruitful more directly. In these cases, x-ray structures allow the direct comparison of the peptide bound structure with that of the peptidomimetics. Particularly impressive have been the results of structure-based drug design programs in the HIV and matrix metalloproteinases (MMP) areas where many examples of direct design of potent inhibitors have been published.

2.14.7 Conclusions and Outlook

As we have seen above, the issues of duration of peptide/protein action in vivo, receptor subtype selectivity, and bioavailability are being answered effectively with medicinal chemical and drug delivery approaches. The diversity of chemical structural topologies available from the 20 natural and hundreds of unnatural amino acids is virtually unlimited. Approaches to increasing the speed of synthesis and testing of such structures have been developed and instituted broadly. Thus, despite advances in peptidomimetics and small-molecule drug design, peptide and protein chemistry would seem to be poised to multiply their impact on medicine.

An aspect of peptide and protein chemistry that is a powerful driver for future development is the tremendous improvement in production methods. One of the ongoing concerns re development of peptide and protein drugs has been cost of goods. However the rapid synthesis of even quite large polypeptides is now routine and the scale-up to production for clinical trials³ or the remarkable achievement of ton-scale production⁴ of enfuvirtide for commercialization has enabled us to think very creatively, with few remaining synthetic boundaries. In the case of enfuvirtide, the cost of synthesis has come down to the range of <\$1 per gram per amino acid residue.⁴

An area of growth for protein-based therapeutics is chronic inflammation. Although this has been a major area of research for many years, it is now becoming generally recognized that inflammation lies at the core of the 'metabolic syndrome,' sepsis, and cachexia. This grouping is perhaps the major healthcare crisis facing the developed countries worldwide. For example, the metabolic syndrome encompasses obesity, type 2 diabetes, atherosclerosis, hypertension, and the prothrombotic state. Congestive heart failure may also have a related causation. One-half of cancer patients experience cachexia, an adipose and muscle-wasting syndrome that leads to death. The most recent thinking in each area is that a type of chronic inflammation lies at the heart of the disease. Inflammation is driven by protein signals (cytokines, chemokines, proteases²³⁶) that are still being elucidated and antagonists beyond the current anti-TNF approaches will likely be important new pharmaceuticals.

Interactions at large protein surfaces are being analyzed in detail³⁴ and this area offers almost unlimited potential to uncover novel pharmaceutical candidates. The use of protein ligand motifs, rational design, or phage display^{24,237} to identify peptide ligands that can be optimized with the medicinal chemical approaches discussed above appears to be extremely attractive.

Biography

John J Nestor, Jr, PhD – CSO, Founding CEO; TheraPei Pharmaceuticals, Inc., has more than 25 years of pharmaceutical industry experience in drug discovery and scientific management, much of that time at the VP level in major pharma. He is co-inventor of 10 compounds selected for clinical development, including three that are now marketed drugs (Synarel, Antagon, Valcyte).

Prior to founding TheraPei Pharmaceuticals, John was Executive Vice President, Drug Discovery at Sequenom, leading the target validation and drug discovery groups. *Prior to* joining Sequenom, he served as President and Chief Scientific Officer at Consensus Pharmaceuticals. John was Vice President, Syntex Discovery Research and Director of the Institute of Bio-Organic Chemistry. Following the acquisition of Syntex by Roche, he served as Distinguished Scientist in the Roche Bioscience organization, until co-founding a chemistry-focused, drug discovery company, Helios Pharmaceuticals.

John obtained his BS in chemistry from the Polytechnic Institute of Brooklyn and a PhD in organic chemistry from the University of Arizona. After post-doctoral research at Cornell University with the Nobelist, Prof Vincent du Vigneaud, Dr Nestor joined Syntex Research to initiate peptide drug discovery. Dr Nestor is co-inventor of more than 40 issued US patents, author of more than 60 scientific articles, co-editor of 2 books. He also is an Associate Editor of the journal *Letters in Drug Design and Discovery* and on the Editorial Advisory Boards of *Current Medicinal Chemistry* and *Medicinal Chemistry* (Bentham Publishers).

2.15 Peptidomimetic and Nonpeptide Drug Discovery: Receptor, Protease, and Signal Transduction Therapeutic Targets

2.15.1 Introduction

Peptidomimetic and nonpeptide drug discovery has progressed tremendously over the last 25 years to become an extraordinary field of multidisciplinary research. It has engaged synthetic, computational, and biophysical chemists, biochemists, pharmacologists, and drug development scientists worldwide to advance novel small-molecule lead compounds, clinical candidates, and breakthrough medicines. The foundation for peptidomimetic drug discovery has evolved by way of countless academic, industrial, and government campaigns to achieve the rational transformation of first-generation peptide lead compounds to highly modified analogs possessing minimal peptide-like chemical structure.^{1–18} Such work is typically illustrated by systematic backbone and/or side chain modifications, transformation

to macrocyclic compounds, structure–conformation analysis (e.g., x-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy), and a medley of sophisticated *in silico* drug design methodologies. Thus, a plethora of prototype peptidomimetic second-generation lead compounds has arisen from initial peptide lead compounds and extensive structure–conformation–activity studies.

Independently of peptide structure-based drug design strategies, noteworthy success using high-throughput screening of corporate chemical collections, natural product, or synthetic chemical libraries has dramatically impacted nonpeptide drug discovery. Furthermore, examples of nonpeptides having intriguing three-dimensional pharmacophore relationships with known peptide ligands have been proposed for a few receptor therapeutic targets, and a number of case studies providing detailed comparative molecular mapping of nonpeptide and peptide (or peptidomimetic) ligands at either protease or signal transduction therapeutic targets have been determined experimentally. Indubitably, such increased understanding of the three-dimensional structures and the identification of intermolecular interactions between peptide, peptidomimetic, or nonpeptide ligands and their therapeutic targets has greatly transformed the paradigm of such drug discovery. Overall, the emergence of three-dimensional structural information on therapeutic targets (e.g., receptors, proteases, and signal transduction proteins) has contributed dramatically to peptidomimetic and nonpeptide drug discovery strategies. Most noteworthy is the accomplishment of the *de novo* design of small-molecule, proof-of-concept lead compounds that possess very limited peptide-like substructure, but include structure-based functional group modifications exploiting unique intermolecular interactions with the therapeutic target (versus a first-generation peptide lead compound).

In this chapter a synopsis of peptidomimetic and nonpeptide drug discovery is given, providing a conceptual framework for drug design and describing the chemical diversity of such second- and third-generation small molecules. Particular emphasis is given to a few superclasses of therapeutic targets (e.g., receptors, proteases, and signal transduction proteins).

2.15.2 Peptide Chemical Diversity and ϕ – ψ – χ Space

Relative to all known classes of biologically active ligands, peptides exhibit extraordinary chemical diversity by virtue of their variety of primary structures (Figure 1). For many peptides (e.g., hormones, neurotransmitters, and secretagogues) the substructures of the amino acids that contribute to their molecular recognition (binding) and biological activity (signal transduction) at their therapeutic targets have been determined. Indeed, investigations focused on receptors have led to the generation of three-dimensional pharmacophore models of either agonist or antagonist peptide ligands and, in some cases, peptidomimetics. Yet, for most peptide growth factors, cytokines, and very large (> 50 amino acids) peptide hormones, the identification of the amino acid substructure that accounts for binding and signal transduction has been difficult, and proposals for three-dimensional pharmacophore models remain challenging. In this regard the term ‘three-dimensional pharmacophore’ is defined as the collection of the relevant groups (substructure) of a ligand that are arranged in three-dimensional space in a manner complementary to the therapeutic target (e.g., receptor, protease, or signal transduction protein) and are responsible for the functional properties of the ligand as a result of its binding to the therapeutic target.⁸

The three-dimensional structural properties of peptides (Figure 2) are defined in terms of the torsion angles (ψ , ϕ , ω , χ) between the backbone amine nitrogen atom (N^α), the backbone carbonyl carbon atom (C'), the backbone methine carbon atom (C^α), and the side chain hydrocarbon functionalization (e.g., C^β , C^γ , C^δ , C^ϵ of Lys) derived from the amino acid sequence. A Ramachandran plot (ψ versus ϕ) may define the preferred combinations of torsion angles for ordered secondary structures (conformations), such as the α -helix, β -turn, γ -turn, or β -sheet. With respect to the amide-bond torsion angle (ω) the *trans* geometry is more energetically favored for most typical dipeptide substructures. However, when the carboxyl terminal (C-terminal) partner is Pro or some other *N*-alkylated (including cyclic) amino acid, the *cis* geometry is possible and may further stabilize the β -turn or γ -turn conformations. Molecular flexibility is directly related to covalent and/or noncovalent bonding interactions within a particular peptide. Even modest chemical modifications at N^α -methyl, C^α -methyl, or C^β -methyl (see the Phe analogs in Figure 2) can have significant consequences on the resulting conformation.

The peptide N^α – C^α – C' scaffold may be further transformed by introduction of alkene substitution (e.g., C^α – C^β → $C=C$, or dehydroamino acid¹⁹) or insertion (e.g., C^α – C' → C^α – $C=C$ – C' , or vinylogous amino acid²⁰). Furthermore, the C^β atom may be substituted to create ‘chimeric’ amino acids. Finally, with respect to *N*-substituted amides it is also noteworthy to point out the intriguing approach of replacing the traditional peptide scaffold by achiral *N*-substituted glycine building blocks.²¹ Overall, such N^α – C^α – C' or C^α – C^β scaffold modifications provide significant opportunities to enhance peptide-like chemical diversity as well as to expand our knowledge of the three-dimensional structure of peptide (protein) ϕ – ψ – χ space.

Peptide	Primary structure
Thyrotropin-releasing hormone	<Glu ¹ -His-Pro ³ -NH ₂
Enkephalin(Met)	Tyr ¹ -Gly-Gly-Phe-Met ⁵
Cholecystokinin-8	Asp ¹ -Tyr[SO ₃ H]-Met-Gly-Trp-Met-Asp-Phe ⁸ -NH ₂

2.15.3 Therapeutic Targets for Peptides, Peptidomimetics, and Nonpeptides

Peptide, peptidomimetic, and nonpeptide drugs comprise a major area of pharmaceutical research and development, including work on receptor agonists and antagonists, protease inhibitors, and intracellular signal transduction protein modulators (Table 1). Of such therapeutic targets, major strides in drug discovery have been achieved for G protein-coupled receptors (GPCRs) with respect to agonists and antagonists (see below). Nevertheless, it is important to mention that the impact of high-throughput screening in the discovery of nonpeptide ligands (typically antagonists) at GPCRs has also been highly successful. Although screening-based nonpeptide drug discovery is not reviewed extensively in this chapter, it is possible that common pharmacophores exist, with respect to receptor binding, between peptide and nonpeptide ligands. Interestingly, however, many receptor mutagenesis studies suggest the existence of different binding pockets for peptide and nonpeptide ligands, regardless of whether they are functionally similar in terms of agonism or antagonism.²² With respect to protease and signal transduction therapeutic targets, the emergence of three-dimensional structural information from high-resolution molecular maps of the catalytic (or noncatalytic) domains has given rise incredible opportunities for structure-based drug design to advance peptidomimetic and nonpeptide drug discovery.

Figure 2 Three-dimensional structural properties of peptides (backbone and side chain).

2.15.4 Peptide Structure-Based Drug Design and Peptidomimetic Lead Compounds

A major focus of peptidomimetic design first evolved from receptor-focused drug discovery, and has not been directly impacted by an experimentally determined three-dimensional structure of the target protein. From such pioneering studies, a hierarchical approach of peptide → peptidomimetic drug design concepts and synthetic chemical modifications were advanced to focus on a systematic transformation of a peptide ligand using iterative analysis of the structure–activity relationships and three-dimensional structural determination (Figure 3). Such work has typically integrated biophysical techniques (x-ray crystallography and/or NMR spectroscopy), in silico drug design methodologies, and biological testing to advance the discovery of peptidomimetic drugs.

2.15.4.1 Peptide Structure-Based Drug Design of Peptidomimetics

Many synthetic chemistry methodologies have been utilized to advance the elucidation of novel peptidomimetics relative to peptide structure-based drug design. Such approaches include unnatural amino acids and dipeptide surrogates that incorporate backbone or side chain modifications to impart increased stability against peptidases, enhance biological potency, and afford improved bioavailability and/or other properties important to the genesis of key proof-of-concept lead compounds.^{1–18} Examples of amide bond replacements (Figure 4) include: aminomethylene or $\Psi[\text{CH}_2\text{NH}]$ (1), ketomethylene or $\Psi[\text{COCH}_2]$ (2), ethylene or $\Psi[\text{CH}_2\text{CH}_2]$ (3), alkene or $\Psi[\text{CH}=\text{CH}]$ (4), ether or $\Psi[\text{CH}_2\text{O}]$ (5), thioether or $\Psi[\text{CH}_2\text{S}]$ (6), tetrazole or $\Psi[\text{CN}_4]$ (7), thiazole or $\Psi[\text{thz}]$ (8), retroamide or $\Psi[\text{NHCO}]$ (9), thioamide or $\Psi[\text{CSNH}]$ (10), and ester or $\Psi[\text{CO}_2]$ (11). Overall, such amide bond surrogates provide insight into the conformational and hydrogen-bonding properties that may be necessary for peptide molecular recognition (binding) and/or biological activity at receptor targets. Other nonhydrolyzable amide bond isosteres that have had a particular impact on the structure-based drug design of protease inhibitors include: hydroxymethylene or

Table 1 Receptor, protease, and signal transduction therapeutic target superfamilies

<i>Receptor superfamily</i>	<i>Protease superfamily</i>	<i>Signal transduction superfamily</i>
G protein-coupled receptor	Aspartic protease	Tyrosine kinase
AT ₁ (angiotensin II)	Pepsin	Abl (SH ₃ -SH ₂ -kinase)

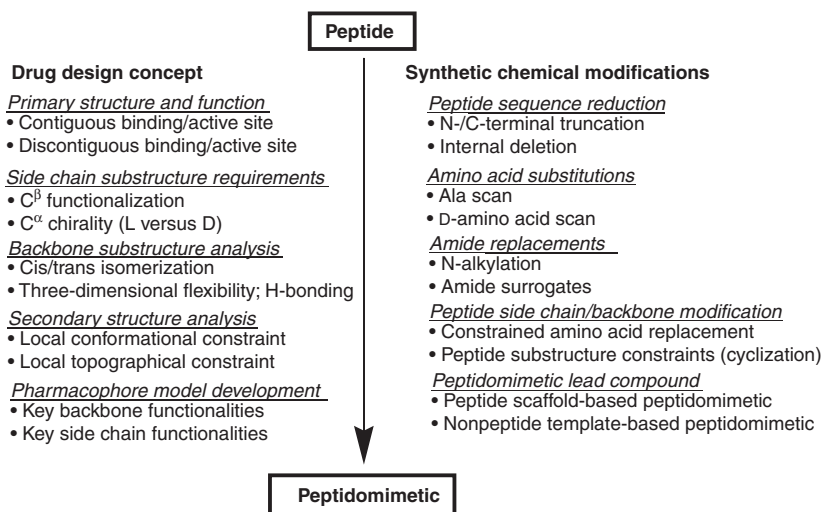

Figure 3 Hierarchical approach in peptidomimetic drug design from peptide ligands.

$\Psi[\text{CH}(\text{OH})]$ (**12**), hydroxyethylenes or $\Psi[\text{CH}(\text{OH})\text{CH}_2]$ (**13**) and $\Psi[\text{CH}_2\text{CH}(\text{OH})]$ (**14**), dihydroxyethylene or $\Psi[\text{CH}(\text{OH})\text{CH}(\text{OH})]$ (**15**), hydroxyethylamine or $\Psi[\text{CH}(\text{OH})\text{CH}_2\text{N}]$ (**16**), C₂-symmetric hydroxymethylene (**17**), and dihydroxyethylene (**18**). Of particular importance to aspartyl protease inhibitor drug design (see below), these backbone modifications may be viewed as transition-state bio-isosteres of the hypothetical tetrahedral intermediate (e.g., $\Psi[\text{C}(\text{OH})_2\text{NH}]$) for substrate peptide cleavage.

Peptide backbone and side chain modifications may also align with drug-design strategies focused on secondary structure mimetics.^{23–33} More specifically, substitution of D-amino acids, N^α-Me-amino acids, C^α-Me-amino acids, and/or dehydroamino acids within a peptide lead compound may induce or stabilize regiospecific β-turn, γ-turn, β-sheet or α-helix conformations. Historically, a variety of secondary structure mimetics have been designed and incorporated in peptides or peptidomimetics (Figure 5), and the β-turn has perhaps been of the greatest interest with respect to peptidomimetic drug discovery for receptor therapeutic targets. The β-turn secondary structural motif exists within a tetrapeptide sequence, whereas the first and fourth C^α atoms are separated by <7 Å and there is a ten-membered intramolecular hydrogen bond between the *i*th and *i*+4 amino acid residues. One of the initial approaches of significance to the design of β-turn mimetics was the monocyclic dipeptide-based template (**19**),²³ which employs a side chain to backbone constraint at the *i*+1 and *i*+2 sites. Over the past decade a variety of monocyclic or bicyclic templates have been developed as β-turn mimetics (e.g., **20**,²⁴ **21**,²⁵ **22**,²⁶ **23**,²⁷ and **24**²⁸). The monocyclic β-turn mimetic **25**²⁹ illustrates the potential opportunity to design scaffolds that may incorporate each of the side chains (*i*, *i*+1, *i*+2, and *i*+3 positions) as well as five of the eight NH or C=O functionalities within the parent tetrapeptide sequence. Similarly, the benzodiazepine template **26**^{30,31} provides a β-turn mimetic scaffold that may be multi-substituted to replicate side-chain functionalization (particularly at the *i* and *i*+3 positions) of the corresponding tetrapeptide sequence modeled in type I–VI β-turn conformations. The γ-turn mimetic **27**³² illustrates an approach to incorporate a retroamide surrogate between the *i* and *i*+1 amino acid residues, with an ethylene bridge between the N' (i.e., a nitrogen atom replacing the carbonyl C' atom) and N atoms at the *i* and *i*+2 positions to allow for the possibility of all three side chains of the parent tripeptide sequence. Finally, the β-sheet mimetic **28**³³ provides a template that constrains the backbone of a peptide to one simulating an extended secondary structure conformation; the β-sheet mimicry is of particular interest to peptidomimetic drug discovery focused on protease therapeutic targets.

The discovery of peptidomimetic drugs follows convergent pathways (Figure 6), which may involve both native and foreign (of biological or chemical origin) peptides as well as nonpeptides (see below), and may provide additional insight into three-dimensional pharmacophore models and further development of novel small-molecule lead compounds.

2.15.4.2 Peptidomimetic Lead Compounds: Receptor Agonists and Antagonists

Both peptide-scaffold-based and nonpeptide-template-based drug design strategies have been successfully exploited to advance novel peptidomimetic agonist or antagonist lead compounds of receptor therapeutic targets (Figure 7). Such

Figure 4 Peptide bond surrogates: $\psi[\text{CONH}]$ replacements.

compounds include the μ -opioid endorphin (END) agonist **29**,³⁴ thyrotropin-releasing hormone (TRH) agonist **30**,¹³ fibrinogen (GPIIa/IIIb) antagonists **31**³⁵ and **32**,³⁶ CCKA antagonist **33**,³⁷ CCKB/gastrin antagonist **34**,³⁸ endothelin antagonist **35**,³⁹ growth hormone secretagog (GHRP) **36**,⁴⁰ somatostatin agonist (partial) **37**,⁴¹ substance-P (NK₁) antagonist **38**,⁴² neurokinin-A (NK₂) antagonist **39**,⁴³ and neurokinin-B (NK₃) antagonist **40**.⁴⁴ These peptidomimetics have typically resulted from extensive structure–activity studies and focused three-dimensional structural studies using NMR on a conformationally constrained (linear or cyclic) peptide ligand. Most importantly, such structure–conformation–activity studies have inspired the development of three-dimensional pharmacophore models to guide iterative peptide structure-based drug design strategies.

Integrin receptor gpIIb/IIIa antagonists⁴⁵ are structurally derived from the tripeptide sequence Arg-Gly-Asp, a sequence that is common to several gpIIb/IIIa protein ligands (e.g., fibrinogen, vitronectin, fibronectin, von Willebrand factor, osteopontin, thrombospondin, and the collagens). Specifically, transformations of the linear peptide ligand Arg-Gly-Asp-Phe by both peptide scaffold (at the Arg-Gly backbone) modification and substitution of the Arg side chain by a benzamidine moiety provided the peptidomimetic lead compound **31** (Figure 8), which has been shown to be active in vivo as an antiplatelet agent.³⁵ In contrast, other known peptidomimetics, such as **32**, illustrate nonpeptide-template-based design strategies that have resulted from iterative transformations of a cyclic peptide Ac-Cys-N-Me-Arg-Gly-Asp-Pen-NH₂, in which a γ -turn about the Asp residue was conceptualized in a three-dimensional

Figure 5 Peptide secondary structure modifications: β - or γ -turn and β -sheet replacements.

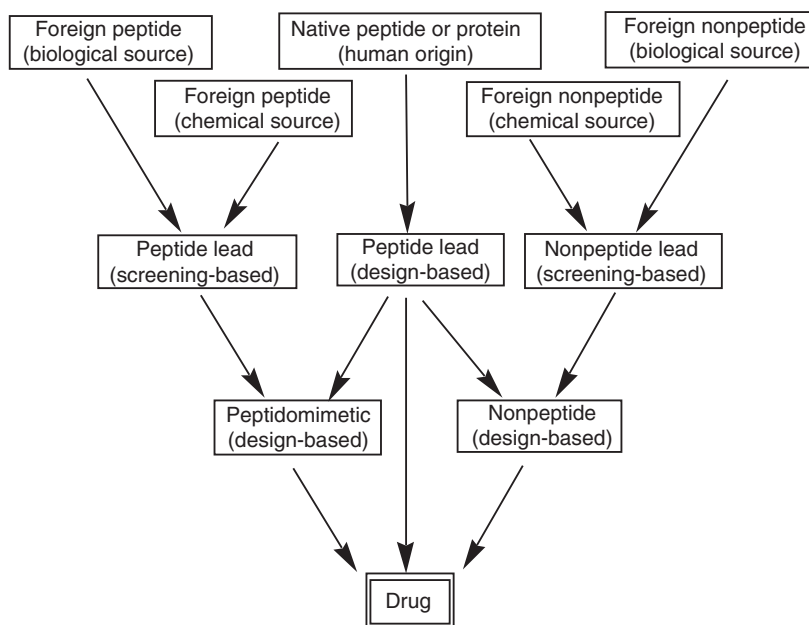

Figure 6 Convergent pathways in peptide, peptidomimetic, and nonpeptide drug discovery.

Figure 7 Some known peptidomimetics exemplifying receptor agonists or antagonists.

pharmacophore model for the bioactive conformation of the peptide ligand.³⁶ Specifically, the benzodiazepinone template of **32** may effectively replace this predicted γ -turn conformation about the Asp residue, and replacement of the N-Me-Arg sequence with piperidine has been shown to correlate with high-affinity receptor binding.

A glucopyranoside nonpeptide template has been shown^{41,46} to yield novel peptidomimetics for the somatostatin (SRIF) and substance-P (NK₁) receptors. Specifically, a hexapeptide SRIF agonist provided a macrocyclic lead compound that was correlated structurally with a glucopyranoside template designed to substitute for a postulated β -turn about the Tyr-D-Trp-Lys-Thr substructure of the parent peptide ligand (Figure 9). The prototype small-molecule **37** was found to be a moderately potent SRIF-like agonist (partial) in cell assays.⁴¹ Such studies extended previous work on TRH,¹³ utilizing a cyclohexane ring system as a nonpeptide template to functionalize with the pGlu

Figure 8 Integrin gpIIb/IIIa receptor: peptidomimetic and nonpeptide antagonists.

Figure 9 Somatostatin and neurokinin-1 receptors: nonpeptide agonists and antagonists.

and His side chains as well as the C-terminal carboxamide group of the parent peptide ligand **30** (Figure 7). A comparative analysis of analogs of the SRIF-mimetic **37** showed that *N*-acetylation of the alkylamine side chain moiety yields a potent NK₁ receptor (substance-P) antagonist. Interestingly, a 'reverse-design' strategy to correlate the latter glucopyranoside-based NK₁ ligand to a cyclic peptide (Figure 9) successfully led to the discovery of a novel cyclic peptide ligand that also exhibits potent NK₁ receptor binding and antagonism.⁴⁶

The examples of peptide-scaffold-based or nonpeptide-template-based peptidomimetic agonists or antagonists illustrate various strategies for elucidating bioactive conformations and/or three-dimensional pharmacophore models of peptide ligands at their receptors. Such studies also include the biological screening of synthetic-chemical libraries of highly modified peptide molecules (e.g., *N*-substituted Gly oligomers²¹) and expanded three-dimensional pharmacophore modeling of novel small-molecule agonists or antagonists at GPCRs and other receptor types. Although the three-dimensional structures of GPCRs remain elusive, it is noteworthy that intriguing three-dimensional homology models have been constructed from experimental three-dimensional structures of bacteriorhodopsin or rhodopsin (see below). These models are providing insight into peptide, peptidomimetic, and nonpeptide structure-activity relationships and are assisting in drug discovery endeavors.

2.15.4.3 Peptidomimetic Lead Compounds: Protease Substrates and Inhibitors

Both peptide-scaffold-based and nonpeptide-template-based drug design strategies have been successfully exploited to advance novel peptidomimetic inhibitors of protease therapeutic targets (Figure 10), including: the renin inhibitors **41**⁴⁷ and **42**,⁴⁸ HIV protease inhibitors **43**⁴⁹ and **44**,⁵⁰ angiotensin-converting enzyme inhibitors **45**⁵¹ and **46**,⁵² collagenase inhibitor **47**,⁵³ gelatinase inhibitor **48**,⁵⁴ stromelysin inhibitor **49**,⁵⁵ elastase inhibitor **50**,⁵⁶ thrombin inhibitors **51**⁵⁷ and **52**,⁵⁸ and interleukin-converting enzyme inhibitor **53**.⁵⁹ For many of these peptidomimetics, drug-design strategies have focused on the natural substrate (primary structure), the mechanism of substrate cleavage, and the molecular recognition between peptide ligands, in terms of both hydrophobic and hydrogen-bonding interactions with the protease active site. Mechanistically, the traditional approach has been to incorporate nonhydrolyzable dipeptide surrogates (see above and Figure 4) as P₁-P_{1'} modifications. Furthermore, substitution of the scissile amide (substrate) by 'transition state' bioisosteres or electrophilic ketomethylene moieties has provided tight-binding peptide or first-generation peptidomimetic inhibitor lead compounds.

Peptide-scaffold-based drug design strategies have been successfully used in the development of potent HIV protease inhibitors. For example, the natural product peptide pepstatin (Figure 11), an archetypical inhibitor of the aspartyl protease family of enzymes, was determined to be the first relatively potent HIV-1 protease inhibitor.⁶⁰ The central P₁-P_{1'} statine (i.e., Sta or LeuΨ[CH(OH)]Gly) moiety of pepstatin was further evaluated within the context of an 'optimized' N- and C-terminal amino acid sequence using a chemical library strategy,⁶¹ to provide a potent tetrapeptide inhibitor, Ac-Trp-Val-Sta-D-Leu-NH₂ (Figure 11). In other approaches, a renin inhibitor **55** (Figure 11) was determined to be a highly potent HIV protease inhibitor.⁶² Further optimization studies led to the first reported⁴⁹ peptidomimetic inhibitor of HIV protease (Tba-ChaΨ[CH(OH)CH₂]Val-Ile-Amp; **43**). This compound exhibited cellular anti-HIV activity and provided a key proof-of-concept for HIV protease as a key therapeutic target for AIDS. Replacement of the peptide scaffold by the pyrrolidinone-type β-sheet mimetic **28** in a chemically related P₁-P_{1'} PheΨ[CH(OH)CH₂]Phe-modified lead compound was shown⁶³ to yield effective peptidomimetic inhibitors of the HIV-1 protease **56** (Figure 12). The pyrrolidinone-type lead has been shown to have enhanced cellular permeability relative to its peptide backbone-type counterparts. In yet another approach guided by HIV substrate-based drug design, the cleavage site dipeptide Phe-Pro was substituted by 'transition state' bioisosteres to provide the highly potent and selective HIV protease inhibitor **57**, a P₁-P_{1'} PheΨ[CH(OH)CH₂N]Pro modified heptapeptide.⁶⁴ Such work led to a series of highly potent, selective, and cellularly active HIV protease inhibitors,⁵⁰ as represented by the first US Food and Drug Administration (FDA) approved anti-HIV drug **44** (saquinavir). Finally, innovative drug-design strategies for HIV protease inhibitors incorporating a C₂-symmetric scaffold and/or cyclized P₁-P_{1'} 'transition state' bioisosteres have been successfully advanced (for a review see Kempf and Sham⁶⁵), and such work has been validated by three-dimensional structure determinations by x-ray crystallography (see below).

A second case of protease inhibitor design exemplifying a peptide-scaffold-based approach is that for peptidomimetic inhibitors of thrombin, a serine protease that cleaves a number of substrates (e.g., fibrinogen) and activates its platelet receptor (a GPCR) by proteolysis of the extracellular N-terminal domain to effect self-activation (for a review see Das and Kimball⁶⁶). Initial thrombin inhibitor lead compounds were substrate-based, including the fibrinogen P₃-P₁ Phe-Pro-Arg sequence⁶⁷ and simple Arg derivatives such as Tos-Arg-OMe.⁶⁸ In addition, the natural product cyclothreonide-A, a macrocyclic peptide containing a Pro-Arg ketoamide sequence, was determined to be an effective lead compound.⁶⁹ Compounds **52** and **58-60** (Figure 12) illustrate different strategies for advancing the work on thrombin inhibitors. Particularly noteworthy within these studies is the thrombin inhibitor **52** (agatroban), a sulfonamide-modified Arg derivative,⁷⁰ which incorporates an unusual cyclic amino acid substituent C-terminal to the P₁ moiety, rather than reactive electrophilic groups (e.g., ketone, aldehyde, or boronic acid). Interestingly, replacement of the Arg side chain moiety within a structurally similar analog **60** by an amidinobenzyl group was determined⁷¹ to be optimal when the stereochemistry at the P₁ α-carbon has a D-configuration, suggesting different binding modes for **52**

Figure 10 Some known peptidomimetics exemplifying protease inhibitors.

and **60**. In this regard, x-ray crystallographic analyses of thrombin-inhibitor complexes (see below) have provided insight into the structure–activity relationships of such peptidomimetic lead compounds.

Beyond thrombin, peptidomimetic inhibitors of the serine protease TTP-II (tripeptidyl peptidase-II) further illustrate peptide-scaffold-based design strategies.⁷² Specifically, relative to a known TTP-II cleavage site on the endogenous neuropeptide CCK-8 (i.e., Asp-Tyr[SO₃H]-Met-Gly-Trp-Met-Asp-Phe-NH₂), the design of a highly potent inhibitor **61** (Figure 12) was successfully achieved by iterative structure-based optimization of the P₃–P₁ sequence. It is noteworthy that the TTP-II inhibitor **61** contains no functional group C-terminal to the P₁ α-carbon atom. This exemplifies a unique case of a substrate-based inhibitor of a protease not incorporating an electrophilic moiety, ‘transition state’ bioisostere, or other type of nonhydrolyzable amide replacement.

Figure 11 HIV protease: peptide and peptidomimetic inhibitors.

2.15.4.4 Peptidomimetic Lead Compounds: Signal Transduction Modulators

A multitude of catalytic and noncatalytic proteins have been identified that are critical components of intracellular signal transduction pathways. These signal transduction proteins provide the molecular basis for communication from extracellular ‘effectors’ (e.g., hormones, neurotransmitters, growth factors, and cytokines) to modulate cellular activity in a specific and regulated manner. Signal transduction pathways often involve protein–protein interactions, including examples of enzyme–substrate (e.g., kinases, phosphatases, transferases, and isomerases) as well as nonenzymatic

Figure 12 Thrombin: peptide and peptidomimetic inhibitors.

(e.g., ‘adapter’ proteins, exchange factors, and transcription factors) complex formation. Both peptide-scaffold-based and nonpeptide-template-based drug design strategies have been successfully exploited to advance novel peptidomimetic inhibitors of signal transduction therapeutic targets (Figure 13), including: the *Ras* farnesyl transferase inhibitors 62,⁷³ 63,⁷⁴ 64,⁷⁵ and 65;⁷⁶ the Src SH₂ domain inhibitors 66,⁷⁷ 67,⁷⁸ and 68;⁷⁹ and the protein tyrosine phosphatase PTP1B inhibitor 69.⁸⁰

The discovery of *Ras* farnesyl transferase inhibitor drugs was originally perceived to be a promising new approach for treating *Ras*-related carcinogenesis.⁸¹ Known substrate sequences for farnesyl transferase have the ~Cys-AA₁-AA₂-Met motif (AA refers to Val or Ile), and substrate-based inhibitors have led to potent lead compounds.^{73–75,82,83} Of note, a series of non-Cys-containing peptide inhibitors have been identified.^{76,84} A ‘collected’ substrate-based inhibitor 70 (Figure 14) illustrates drug-design strategies in which a farnesyl moiety is covalently linked to a peptide via a phosphinic acid moiety.⁸² Relative to peptide substrate, structure-based design efforts, peptidomimetics incorporating Ψ[CH₂NH] substitutions (e.g., 62⁷³) or replacement of the central dipeptide moiety by a benzodiazepinone (e.g., 63⁷⁴) have yielded high-affinity inhibitors of *Ras* farnesyl protein transferase. Another series of potent peptidomimetic inhibitors have been designed in which the central dipeptide is substituted by various isomeric and/or homologous derivatives of aminobenzoic acid (e.g., 64⁷⁵), including a particularly effective analog biphenyl derivative 71.⁸³ Interestingly, although compounds

Figure 13 Some known peptidomimetics exemplifying signal transduction modulators.

such as **62–64** have ‘free’ sulfhydryl groups (i.e., Cys), there is no evidence that these become farnesylated, and therefore the binding mode and the effect on the catalytic function of the target enzyme must be unique compared with their peptide substrate counterparts. Finally, a novel Ras farnesyl protein transferase inhibitor exemplified by Cbz-His-Tyr (*O*-benzyl)-Ser(*O*-benzyl)-Trp-D-Ala-NH₂ is a particularly surprising peptide lead compound.⁷⁶ These inhibitors do not contain a Cys residue and iterative drug-design efforts successfully led to a series of peptidomimetics (e.g., **65**) that have only a single chiral center. The surprising aspect of this lead compound series is the competitive inhibition of farnesyl pyrophosphate binding, rather than that of the peptide substrate. Nevertheless, peptide-substrate-based inhibitors that incorporate substitution of Cys by His (cf., **72** and **73** in [Figure 14](#)) have also been reported.⁸⁴ In the above cases, a divalent metal ion (e.g., Zn²⁺) likely coordinates with the inhibitor sulfhydryl or imidazole groups in terms of their binding interactions at the farnesyl protein transferase active site.

The elucidation of Src homology-2 (SH2) domain inhibitor drugs was first conceptualized as a promising new strategy for blocking signal transduction with respect to several diseases.⁸⁵ The Src SH2 domain is a prototype of a large family of structurally homologous SH2 domains that specifically recognize cognate phosphoproteins in a sequence-dependent manner relative to a critical phosphotyrosine (pTyr) residue (i.e., ~pTyr-AA₁-AA₂-AA₃~). Furthermore, x-ray crystallographic studies of a several SH2 protein targets (and phosphopeptide complexes thereof) have led to opportunities for iterative structure-based drug design (see below⁸⁶). With respect to Src SH2 domain inhibitor drug discovery, peptide library studies⁸⁷ have shown that ~pTyr-Glu-Glu-Ile~ is a preferred consensus sequence. Peptide-scaffold-based approaches to replace the internal dipeptide, Glu-Glu, by both flexible and rigid linkers were initially investigated,⁸⁸ but such studies failed to yield potent lead compounds. However, the prototype peptidomimetics **66**⁷⁷ and **67**⁷⁸ exemplified a successful drug design strategy relative to stereoinversion at the second residue (P₊₂ relative to the pTyr) to the *D*-configuration, and side chain substitution for hydrophobic functionalities (e.g., cyclohexyl and naphthyl) conferred accessibility to the P₊₃ hydrophobic binding pocket (Figure 15). Substitution of the pTyr residue of **66** by a difluoromethylphosphonate-modified analog (F₂Pmp) provided a metabolically stable derivative **74** (Figure 15) that could be used to advance cellularly active second-generation compounds. Finally, x-ray crystallographic structures of Src SH2 complexed with such peptidomimetic inhibitors⁸⁹ have provided insight into iterative drug-design strategies (see below).

Figure 14 Ras farnesyl protein transferase: peptide and peptidomimetic inhibitors.

2.15.5 Therapeutic Target Screening, Chemical Diversity, and Nonpeptide Lead Compounds

As mentioned above, the convergent pathways in drug discovery have enabled the generation and optimization of peptides, peptidomimetics, and nonpeptides. In the case of nonpeptides, it is important to point out that both biological (e.g., natural products) and chemical (e.g., corporate collections or combinatorial libraries) compounds have provided lead compounds for drug discovery (for reviews see ^{12,15}). Furthermore, the three-dimensional pharmacophore relationship between peptides and peptidomimetic and nonpeptide ligands has provided some intriguing opportunities (see below).

2.15.5.1 Therapeutic Target Screening and Chemical Diversity of Nonpeptides

The initial success of nonpeptide drug discovery can be traced to the identification of morphine (**75**; **Figure 16**) as a nonpeptide natural product agonist at μ -opioid peptide receptors.⁹⁰ Since this initial discovery, the momentum of nonpeptide drug has continued. The range of drugs elucidated illustrates the significant chemical diversity and range of

Figure 15 Src SH2 domain: peptide and peptidomimetic inhibitors.

therapeutic targets of screening-based nonpeptide lead compounds (Figure 17). Such compounds include the substance-P (NK₁) antagonist **76**,⁹¹ angiotensin AT₁ antagonist **77**,⁹² growth-hormone-releasing peptide (GHRP) agonist **78**,⁹³ cholecystokinin CCKA antagonist **79**,⁹⁴ CCKB/gastrin antagonist **80**,⁹⁵ CCKA agonist **81**,⁹⁶ endothelin antagonist **82**,⁹⁷ gonadotropin-releasing hormone (GnRH) antagonist **83**,⁹⁸ vasopressin V₁ antagonist **84**,⁹⁹ gastrin-releasing peptide antagonist **85**,¹⁰⁰ glucagon antagonist **86**,¹⁰¹ neurotensin antagonist **87**,¹⁰² angiotensin AT₁ agonist **88**,¹⁰³ oxytocin antagonist **89**,¹⁰⁴ and HIV protease inhibitor **90**.¹⁰⁵ Interestingly, a significant number of screening-derived nonpeptide lead compounds have been identified for GPCRs and, with few exceptions, they are competitive antagonists. The use of three-dimensional homology models and site-directed mutagenesis studies on GPCRs provides an opportunity to understand further the structure–activity relationships of nonpeptide ligands, including comparative analysis with peptide or peptidomimetic ligands (see below).

2.15.5.2 Nonpeptide Lead Compounds: Three-Dimensional Pharmacophore Relationships to Peptides

A vast number of screening-derived nonpeptide leads are multifunctionalized five- to seven-membered ring heterocycles (e.g., alkaloids and benzodiazepines) and contain conformationally rigid substructural elements (e.g., biphenyls, spirobicyclic rings, and *N*-substituted amide or amine linkages). This suggests that such compounds are likely to bind with highly favorable entropic driving forces than would more conformationally flexible peptide ligands. In this regard, efforts to ‘rigidify’ peptide-based scaffold or replace it with nonpeptide templates has been the underlying aim of many strategies of peptidomimetic drug design, and such concepts date back to the proposed use of multifunctionalized cycloaliphatic ring systems to create ‘topographically designed’ peptidomimetics.¹⁰⁶ Screening-based, nonpeptide-drug discovery has provided a treasure trove of structure–function information with which to investigate structure-based drug design and molecular recognition,^{12,15,107} and in some cases there is the possibility of similar pharmacophores or substructural elements between such nonpeptides and their candidate peptide ligand counterparts (Figure 17).

Historically, opioid GPCR receptor (e.g., μ , δ , and κ) drug discovery has provided insight to explore the pharmacophores of both agonists and antagonists, including endogenous peptides (e.g., enkephalin, endorphin, and dynorphin) and nonpeptides (e.g., the μ -receptor selective agonist morphine and its *N*-allyl substituted antagonist derivative naloxone). It is likely that the *N*-terminal Tyr side chain and α -amino functionalities of Met-enkephalin show the same pharmacophoric features as the *N*-methyltyramine substructure of morphine (Figure 17) in terms of μ -receptor binding.¹⁰⁸ In the case of angiotensin II receptor antagonists, both peptide and nonpeptide (screening derived) studies have taken into consideration the likelihood of common three-dimensional pharmacophores. The

Figure 16 Some known nonpeptides exemplifying screening-based lead identification.

proposed possible substructure relationships between the C-terminal His-Pro-Phe-OH sequence of angiotensin II and the nonpeptide **91** (Figure 17)¹⁰⁹ inspired drug-design strategies that culminated in the clinical candidate **77** (losartan). Another case for correlating peptide and nonpeptide three-dimensional pharmacophore models is that for neuropeptide-Y (NPY) versus the benextramine-based derivative **92**¹¹⁰ or the arpromidine-based derivative **93**.¹¹¹ In both cases the C-terminal Arg-Gln-Arg-Tyr-NH₂ sequence of NPY may be correlated with the nonpeptide ligands (Figure 18) such that the guanido functionalities of NPY are superimposed on the corresponding basic (i.e., guanido or imidazole) moieties of either **85** or **91**. Finally, three-dimensional pharmacophore models of a cyclic hexapeptide oxytocin antagonist and a conformationally constrained, tolylpiperazine camphorsulfonamide nonpeptide antagonist (**89**) exemplify an interesting study lead compound optimization.¹¹² Specifically, three-dimensional pharmacophore

Figure 17 Comparative pharmacophores of peptide and nonpeptide ligands: μ -opioid receptor agonists, angiotensin receptor antagonists, and neuropeptide-Y receptor antagonists.

models (Figure 18) of the peptide and nonpeptide ligands suggest a common substructural element for molecular recognition at the oxytocin receptor, and drug-design strategies were undertaken that led to a highly potent second-generation nonpeptide lead compound **94**.

Nevertheless, such comparative three-dimensional pharmacophore ‘mapping’ studies are relatively limited because the three-dimensional structures of the receptor therapeutic targets (and, more importantly, the ligand complexes thereof) are not known. The creation of chemical diversity to augment nonpeptide agonist drug discovery would provide critical information to understand the molecular recognition (binding) and activation of receptors. In this regard, the nonpeptides **78** (growth-hormone-releasing peptide receptor agonist) and **81** (cholecystokinin receptor CCKA agonist) are noteworthy lead compounds in terms of exemplifying screening-based agonists for their respective GPCR therapeutic targets. Also noteworthy is the screening-based nonpeptide HIV protease inhibitor **90**,¹⁰⁵ which incorporates a pyrone template and functional-group elaboration that matches a known peptidomimetic inhibitor of HIV protease (Figure 18). Iterative structure-based drug design and lead-compound optimization has advanced this novel series of nonpeptide inhibitors of HIV protease into clinical candidates (see below).

Figure 18 Comparative pharmacophores of peptide and nonpeptide ligands: oxytocin receptor antagonists and HIV protease inhibitors.

2.15.6 Therapeutic Target Structure-Based Drug Design: Peptidomimetic and Nonpeptide Lead Compounds

Peptidomimetic and nonpeptide drug discovery has evolved significantly as a result of the determination of the three-dimensional structures of an increasing number of therapeutic targets by x-ray crystallography or NMR spectroscopy^{113–119}) and the exploitation of sophisticated in silico drug-design methodologies (e.g., quantitative structure–activity relationship (QSAR), three-dimensional QSAR/comparative molecular field analysis (CoMFA),

ligand docking, virtual screening, two-/three-dimensional database searching, and de novo structure-based drug design).^{115,120–122} Overall, the iterative cycle of structure-based drug design (Figure 19) has led to a successful ‘engine of invention’ for several examples of peptidomimetic and nonpeptide drug discovery, as exemplified by the studies described below.

2.15.6.1 G Protein-Coupled Receptors: Peptidomimetic and Nonpeptide Lead Compounds

Among the known types of cell membrane anchored receptors is the GPCR superfamily (Table 1), which consists of seven transmembrane-spanning (TM) helices. The structural homology between TM helices of GPCR is approximately 25–30%, and between some subtypes 50–70% homology is known.^{22,123–132} The initial development of three-dimensional structural models of GPCR targets emerged from homology-building methodologies using a relatively low-resolution structure of bacteriorhodopsin.¹³³ A few studies of GPCR agonist and antagonist drug discovery that provide insight into three-dimensional pharmacophore modeling and structure-based drug design of peptide, peptidomimetic, and nonpeptide ligands are discussed below.

Early investigations to explore therapeutic target receptor binding interactions (e.g., site-directed mutated or chimeric receptors) and/or to probe the three-dimensional pharmacophore models of peptide, peptidomimetic, and/or nonpeptide ligands relative to the three-dimensional structural models of GPCRs include those of: angiotensin II AT₁ and AT₂ subtypes,¹³⁴ neurokinin NK₁ and NK₂ subtypes,¹³⁵ cholecystokinin/gastrin CCKA and CCKB subtypes,¹³⁶ opioid μ -, δ -, and κ -subtypes,¹³⁷ vasopressin V_{1A} subtype,¹³⁸ bradykinin B₂ subtype,¹³⁹ neurotensin,¹⁴⁰ and α -melanotropin MC₁ subtype.¹⁴¹ Collectively, this work has implicated that different binding-site interactions exist for peptide and nonpeptide antagonists in terms of the different sensitivities of the ligands to site-directed mutants of the native GPCR. Furthermore, this work has provided a correlation between the structure–activity relationships and the experimentally determined (NMR) structures of ligands and their predicted therapeutic target molecular contacts.

In one study, the neurotensin C-terminal octapeptide was subjected to conformational searching (\sim Arg-Pro-Tyr \sim sequences from the Brookhaven Protein Databank), manual docking to the homology-built neurotensin GPCR receptor model, and constrained molecular dynamics simulation to provide a three-dimensional structure of the ligand–receptor complex.¹⁴⁰ A compact structure of the peptide in its complexed conformation was consistent with a type-1 β -turn, as had been previously determined in structural and structure–activity studies. Key molecular contacts predicted from this neurotensin GPCR model include hydrophobic interactions with the C-terminal Ile and Leu side chains, π -cation

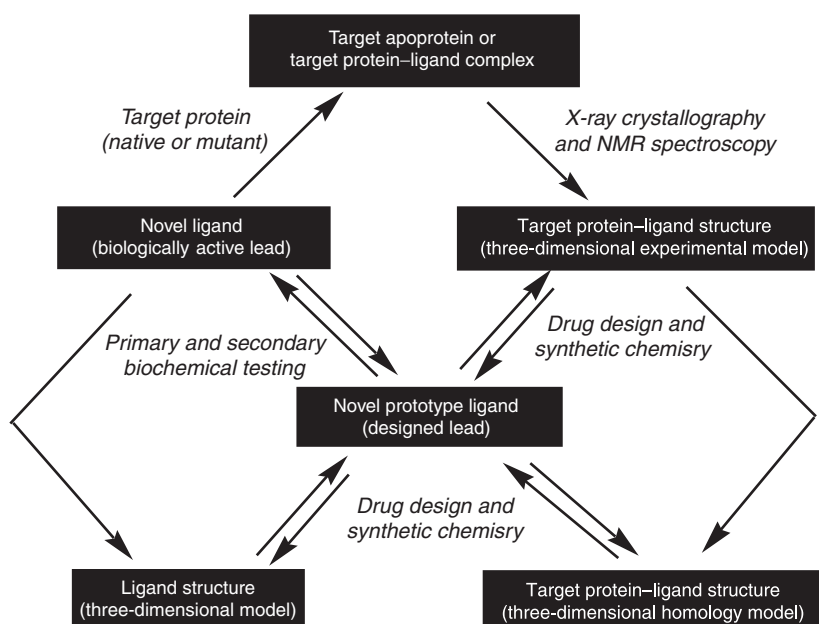

Figure 19 Iterative cycle for structure-based drug design: x-ray crystallography, NMR spectroscopy, and three-dimensional models (ligand or protein–ligand complexes).

interactions with each Arg residue side chain, and a 'cluster' of aromatic-aromatic interactions with the Tyr side chain (Figure 20). Finally, both mutagenesis analysis and structure-activity studies provide opportunities to further challenge such three-dimensional drug design studies.

In another study, the α -melanotropin (MC_1) GPCR model was constructed¹⁴¹ by homology-building methods relative to both bacteriorhodopsin and rhodopsin fingerprint maps, and the MSH superagonist peptides [Nle⁴, D-Phe⁷]-MSH and Ac-cyclo[Nle⁴, Asp⁵, D-Phe⁷, Lys¹⁰]-MSH₄₋₁₀-NH₂ were modeled in conformations derived in previous experimental studies (i.e., a type-II' β -turn at the common tetrapeptide sequence \sim His-D-Phe-Arg-Trp \sim). Of the alternative binding modes that were described for the above the two MSH peptide ligands, one predicts the possibility of a network of aromatic-aromatic and hydrophobic interactions between the MC_1 receptor and the D-Phe and Trp side chains of the MSH ligand (Figure 20). In addition, this MC_1 receptor model predicts multiple electrostatic and π -cation interactions between the MC_1 receptor and the Arg side chain of the peptide ligand. The primary contact residues of this particular MC_1 receptor model were all derived from the transmembrane domain, and lie within 4–7.5 Å (centroid to centroid). Such three-dimensional models are being further challenged by mutagenesis studies and structure-activity relationships of an increasing range of agonist and antagonist ligands (e.g., peptide, peptidomimetic, and nonpeptide).

Figure 20 Three-dimensional models of neurotensin and the melanocortin receptor binding sites: peptide agonists.

2.15.6.2 Aspartyl Proteases: Peptidomimetic and Nonpeptide Lead Compounds

Both mechanistic and structure-based research into protease inhibitor drugs has been significantly successful for each of the representative compound classes (i.e., aspartyl, serinyl, metallo, and cysteinyl) (see Table 2; for a review see Leung *et al.*¹⁴²). The pioneering advances in the design of peptidomimetic inhibitors of angiotensin-converting enzyme, including compounds **45** (captopril⁵¹) and **46** (enalapril⁵²), provided the impetus to for protease inhibitor drug discovery. Over the past two decades there has been a pervasive effort in research in this area, integrating substrate-based inhibitor design, x-ray crystallography of protease-inhibitor complexes, high-throughput mass screening, and combinatorial chemistry technologies.

The aspartyl proteases include pepsin, renin, cathepsin-D, chymosin, and gastricsin, as well as microbial enzymes (e.g., penicillopepsin, rhizopuspepsin, and endothiapepsin) and retroviral proteases (e.g., HIV protease). The first high-resolution x-ray crystallographic structures of the aspartyl protease family were determined for penicillopepsin,¹⁴³ rhizopuspepsin,¹⁴⁴ endothiapepsin,¹⁴⁵ pepsinogen,¹⁴⁶ and pepsin.¹⁴⁷ Based on homology-building strategies, three-dimensional structural models of renin were subsequently constructed¹⁴⁸ to guide the initial structure-based drug design of peptidomimetic inhibitors (for a review see Abdel-Meguid¹⁴⁹). Furthermore, in several cases the x-ray crystallographic structures of renin inhibitors were determined¹⁵⁰ as enzyme-ligand complexes with rhizopuspepsin, endothiapepsin, or pepsin. Eventually, the x-ray crystallographic structures of renin (apo/complexes) were achieved to provide high-resolution molecular maps of the target enzyme.¹⁵¹ Substrate-based inhibitors, such as the highly potent peptidomimetic **95**,¹⁵¹ showed well-defined hydrophobic pockets for the P₃-P_{1'} side chains and hydrogen-bonding to the backbone of the inhibitor, which exists in a β -sheet type extended conformation (Figure 21). Although structure-based, drug-design strategies for renin inhibitors have mostly focused on systematic transformation of the substrate (angiotensinogen) relative to its tetrapeptide substructure \sim Phe⁸-His-Leu-Val¹¹ \sim , there have been some noteworthy exceptions, such as the topographically designed P_{1'} \rightarrow P₃ inhibitors **96**,¹⁵² **97**,¹⁵³ **98**,¹⁵⁴ and **99**.¹⁵⁵ The latter macrocyclic inhibitor is novel in terms of having two D-aromatic amino acids and lacking a 'transition state' bioisostere replacement at the P₁-P_{1'} site.

In contrast to renin, the x-ray crystallography studies of HIV protease inhibitors show a high degree of synchronization with the iterative structure-based, drug-design efforts, and the binding mode of nonpeptide ligands has been identified by mass screening (e.g., coumarins and pyrones) or three-dimensional computational searching (e.g., haloperidol) to advance what has become a milestone achievement in structure-based drug design¹¹³ (for a review on HIV protease see Kempf and Sham¹⁵⁶). Representative of the range of the drugs discovered with respect to both peptidomimetic and nonpeptide inhibitors of HIV protease (Figure 22) are the C₂-symmetric inhibitors **100** (157) and **101** (158), the nonsymmetric peptidomimetics **44**⁵⁰ and **102-106**,¹⁵⁹⁻¹⁶³ and a series of nonpeptides derived originally from either three-dimensional computational searching (**107**¹⁶⁴) or high-throughput screening (**108-110**¹⁶⁵⁻¹⁶⁸). Of these compounds, the US FDA has approved **102** (indinavar), **103** (ritonavir), and **44** (saquinavir).

Currently, there exist >100 x-ray crystallographic structures of HIV protease-inhibitor complexes, not including mutated forms of the target enzyme, which have also been identified as being important to the development of inhibitors effective against HIV resistant strains. The initial series of x-ray crystallographic structures of HIV protease included the apo¹⁶⁹ and enzyme-inhibitor complexes derived from substrate-based analogs being substituted at P₁-P_{1'} by Nle Ψ [CH₂NH]Nle,¹⁷⁰ Leu Ψ [CH(OH)CH₂]Val,¹⁷¹ Phe Ψ [CH(OH)CH₂N]Pro,¹⁷² and Leu Ψ [CH(OH)]Gly or statine.¹⁷³ The first reported HIV protease-inhibitor complex¹⁷⁰ with the pseudopeptide **111** also provided a high-resolution map of the active site of the enzyme (Figure 23) as formed in a C₂-symmetric fashion by the homodimer, and the 'flaps' of each monomeric subunit (i.e., residues 35-57), which undergo intermolecular interactions with the backbone of the inhibitor by both direct hydrogen-bonding and through a structural water molecule (i.e., W301). Relative to the C₂-symmetry of HIV protease, the discovery of C₂-symmetric inhibitors was achieved by the design of Phe Ψ [CH(OH)]gPhe- and Phe Ψ [CH(OH)CH(OH)]gPhe-modified peptidomimetics (gPhe refers to gem-diamino-Phe, wherein the C α -CO₂H moiety was replaced by C α -NH₂), as exemplified by **101**.¹⁵⁷ Among the plethora of other structure-based, drug-design strategies focused on HIV protease inhibitor discovery, it is noteworthy to highlight the nonpeptide leads **100** and **108-111**, as each of these displaced a key structural water molecule (i.e., W301) and, in contrast to all previous substrate-based inhibitors, were each capable of direct hydrogen-bonding interactions with the HIV protease 'flap' regions (Figure 23). As a matter of precedence, previous x-ray crystallographic structural studies on a streptavidin-biotin complex¹⁷⁴ showed that structural water displacement (relative to the apoprotein) by the ligand (biotin) was possible. It is further noted that HIV protease is unique among the members of the aspartyl protease family in terms of the role of structural water W301 in the substrate/inhibitor binding. In contrast, the catalytic water, which is critical to the mechanism of substrate cleavage for all aspartyl proteases, has been a key feature in the design of a plethora of transition state, biostere-modified inhibitors and various tetrahedral hydroxymethyl-containing,

Table 2 Some known three-dimensional structures of proteases (Apo and/or complexes thereof with peptide, peptidomimetic, and nonpeptide inhibitors)

<i>Proteases</i>	<i>Apo or inhibitor complex</i>	<i>Method (resolution)</i>	<i>Reference</i>
Aspartic protease			
Penicillopepsin	Apo	X-ray (1.8 Å)	James <i>et al.</i> ¹⁴³

Figure 21 Models of the active site of renin: peptidomimetic inhibitors.

nonhydrolyzable surrogates of the scissile amide bond (e.g., $\Psi[\text{CH}(\text{OH})]$, $\Psi[\text{CH}(\text{OH})\text{CH}_2]$, and $\Psi[\text{CH}(\text{OH})\text{CH}_2\text{N}]$; see above) have been created. In addition, there exist examples of potent inhibitors of renin (e.g., the $\Psi[\text{CH}_2\text{NH}]$ -modified **41**⁴⁷ and the macrocyclic peptide **99**¹⁵⁵) and HIV protease (e.g., the pyrone-based series **108–111**^{165–168}) that do not possess a tetrahedral $\text{CH}(\text{OH})$ moiety per se.

2.15.6.3 Serinyl Proteases: Peptidomimetic and Nonpeptide Lead Compounds

The serinyl proteases include trypsin, chymotrypsin-A, elastase, thrombin, kallikrein, cathepsins-A, G, and R, factor VII, factors IXa–XIIa; and tissue plasminogen factor. High-resolution x-ray crystallographic structures of this protease family have been determined, including those of thrombin (for a review see Stubbs and Bode¹⁷⁵; also see Table 2^{176–182}), factor Xa,¹⁸³ trypsin,¹⁸⁴ kallikrein-A,¹⁸⁵ and elastase.^{186–190} For example, a substrate-based inhibitor of thrombin having a boronic acid, $\text{B}(\text{OH})_2$ (Figure 25), substitution for the scissile amide was determined by x-ray crystallography to form a covalent bond with the active site Ser-195 residue.¹⁷⁶ The N-terminal Ac-D-Phe-Pro moiety of this inhibitor binds in a β -sheet-type extended conformation that involves hydrogen-bonds with the enzyme and well-defined hydrophobic and aromatic–aromatic (edge-to-face) stacking interactions. The inhibitor Arg side chain binds in an extended conformation, and the guanidino moiety forms bidentate hydrogen-bonding interactions with an Asp-189 residue at the base of the S_1 ‘specificity’ pocket and additional hydrogen-bonds to the enzyme, one of which is mediated through a structural water. Related to the substrate-based peptidomimetic inhibitors of thrombin having C-terminal electrophilic groups (e.g., aldehyde, ketone, and boronic acid), a series of nonpeptide inhibitors devoid of P_1 electrophilic functionalization have been successfully advanced, as represented by **52**,⁷⁰ **60**,⁷¹ and **113**.¹⁸² The design of a highly potent and selective amidinopiperidine-based thrombin inhibitor **113** (Figure 24) was derived from analysis of the x-ray crystallographic structures of thrombin complexed with inhibitors **52** and **60**. The latter two compounds showed different trajectories of their P_1 side chains (i.e., guanidinoalkyl and amidinophenyl moieties, respectively) into the S_1 pocket, which accounts for the observed opposing chiral preferences at the C^α -position of the P_1 amino acid residues. Furthermore, the C-terminal cycloalkyl moieties of both **52** and **60** were observed to bind to the so-called inhibitor ‘P-pocket’ (i.e., the P_2 substrate pocket), and these compounds therefore provide a unique model of binding versus the substrate-like

Figure 22 Models of the active site of HIV protease: peptidomimetic and nonpeptide inhibitors.

conformation adopted by the peptidomimetic inhibitors Ac-D-Phe-Pro-boroArg-OH described above. The design of the novel amidinopiperidine-based inhibitor **113** illustrates a ‘transposition’ of the P-pocket binding group to an N-substituted Gly-β-Asp scaffold.

Other serinyl proteases, such as factor Xa, kallikrein, and elastase, exemplify the availability of x-ray crystallographic structures (apo/complexes) for structure-based drug design (see [Table 2](#)). In particular, research into elastase inhibitor drugs is highlighted in terms of substrate-based peptidomimetic inhibitor drug-design strategies, which have focused on key P₂–P₃ side chain and backbone hydrogen-bonding interactions with the enzyme (for a review see Peisach *et al.*¹⁹¹). Several x-ray crystallographic structures have been determined for elastase^{186–190}, including complexes with peptide-substrate-based inhibitors having P₁ electrophilic functionalities such as benzoxazole,¹⁸⁸ trifluoromethyl ketone,^{56,187,189} and α,α-difluoro-β-ketoamide.¹⁹⁰ Peptidomimetic inhibitors of elastase incorporating nonpeptidyl P₂–P₃ replacements led to highly potent compounds.^{56,187} A lead compound series of highly potent trifluoromethylketone-based inhibitors of human leukocyte elastase incorporating a *N*-carboxymethyl-3-amino-6-arylpyridone template (**50** and **116**; [Figure 25](#)) was shown by x-ray crystallography to exhibit backbone hydrogen-bonding and a novel trajectory of a P₂ group from the pyridone ring to the enzyme. Further modification of the pyridone ring to give the bicyclic pyridopyrimidine derivative **117** was predicted from molecular modeling studies to provide additional hydrogen-bonding to the enzyme, as well as another to site on the bicyclic heteroaromatic ring system, for tethering various hydrophobic or hydrophilic groups. Finally, the design of a series of novel dipeptide-based inhibitors (e.g., trifluoromethylacetyl-Leu-Phe-isopropylanilide and a peptidomimetic derivative) is particularly intriguing because analysis of the x-ray crystallography structures of their complexes with pancreatic elastase were determined to bind ‘backwards’.^{191,192}

2.15.6.4 Cysteiny Proteases: Peptidomimetic and Nonpeptide Lead Compounds

The cysteinyl proteases include papain, calpains I and II, cathepsins B, H, and L, proline endopeptidase, and interleukin-converting enzyme (ICE), and homologs thereof. The first highly investigated cysteinyl protease was papain, and the first x-ray crystallographic structures of papain, including apo¹⁹³ and a peptide chloromethylketone inhibitor complex,¹⁹⁴ provided early high-resolution molecular maps of its active site. Pioneering studies in the discovery of papain substrate peptide-based inhibitors having P₁ electrophilic moieties, such as aldehydes,¹⁹⁵ ketones

Figure 23 Models of the active site of HIV protease: peptidomimetic and nonpeptide inhibitors.

(e.g., fluoromethylketone, which has been determined¹⁹⁶ to exhibit selectivity for cysteinyl proteases versus serinyl proteases), semicarbazones, and nitriles, are noteworthy in that ¹³C-NMR spectroscopic studies have shown that the active site Cys-25 of papain forms a reversible covalent bond with these electrophiles (for a review see Leung *et al.*¹⁴²). The x-ray crystallographic structures of apo cathepsin-B¹⁹⁷ and apo picornaviral 3C protease¹⁹⁸ have also been determined. With respect to ICE (for a review see Ator and Dolle¹⁹⁹), a number of high-resolution x-ray crystallographic structures of ICE-inhibitor complexes have been determined.^{200,201} This enzyme is unique among the cysteinyl proteases in that it has a heterodimeric architecture in which two subunits form the catalytically active enzyme site. More specifically, two p10/p20 heterodimers apparently create a tetrameric form of the competent protease. An x-ray crystallographic structure of ICE complexed with a substrate peptide-based chloromethylketone inhibitor (118²⁰¹) shows that it is irreversibly bonded at the active site Cys-285 and that the P₁ Asp specificity pocket comprises two Arg residues at the base of the S₁ binding pocket (Figure 26). Relative to other side chain binding pockets, a hydrophobic ‘channel’-type S₄ site exists for the P₄ Tyr of the inhibitor, whereas the P₃–P₂ Val–Ala side chains are well exposed to solvent. With respect to the peptide backbone of the inhibitor, hydrogen-bonding interactions are predicted between the P₃ Val (both NH and CO) and the P₁ Asp (NH) and the p10 monomer.

An x-ray crystallographic structure of ICE complexed with a reversible inhibitor Ac-Tyr-Val-Ala-Asp-aldehyde (119²⁰²) provided correlative structure–activity relationships with respect to *N*-methyl-amino acid substitutions and the three-dimensional mapping of hydrogen-bonding interactions between the inhibitor and the enzyme. These studies predicted that only *N*-Me-Ala replacement at the P₂ site would be tolerated. Subsequent ICE inhibitor design strategies, including C-terminal modification of P₁ Asp by alkylating groups such as the aryloxymethyl ketone analog 120,²⁰³ led to the first reported peptidomimetic inhibitor of ICE (121²⁰⁴), which incorporated a pyridone template as a P₂–P₃ replacement. Finally, the x-ray crystallographic structure of the ICE homolog referred to as apopain, or CPP32, as a complex with a peptide–aldehyde inhibitor²⁰⁵ provided additional insight into the specificity of substrate recognition as related to both the S₁ (P₁ Asp) and S₄ (P₄ Asp) subsites. Overall, these studies provided the framework for iterative structure-based drug design to advance novel peptidomimetic and nonpeptide inhibitors of ICE and/or its homologs.

Figure 24 Model of the active site of thrombin: peptide and peptidomimetic inhibitors.

2.15.6.5 Metalloproteases: Peptidomimetic and Nonpeptide Lead Compounds

The metalloproteases include both exopeptidases (e.g., angiotensin-converting enzyme, aminopeptidase-M, and carboxypeptidase-A) and endopeptidases (e.g., thermolysin, endopeptidase 24.11 or NEP, collagenase, gelatinase, and stromelysin). The first x-ray crystallographic structures²⁰⁷ were provided for thermolysin (for a review see Matthews²⁰⁶ with several structurally distinct peptide inhibitors (see Table 2^{208–212}), providing insight into the mechanistic roles of the metal ion for substrate hydrolysis. These studies exemplify inhibitor binding interactions of the P₁–P_{1'} ‘transition state’ amide bond isosteres (e.g., Ψ[P=O(OH)NH]) as well as the metal chelating functionalities (e.g., hydroxamate, carboxylate, and sulfhydryl groups) introduced as *N*-substitutions on the P₁–P₂ peptide scaffolds.^{208–212} Furthermore, at the time such structural and mechanistic information provided insight into drug-design strategies focused on other metalloprotease inhibitors, including the angiotensin-converting enzyme (ACE) (for a review see Leung *et al.*¹⁴²). An x-ray crystallographic structure of carboxypeptidase, a related metalloprotease of the exopeptidase group, for both the apo and a GlyΨ[P=O(OH)NH]Phe-modified inhibitor complex have been reported.²¹³ An x-ray crystallographic structure of the PheΨ[P=O(OH)NH]Leu-modified peptidomimetic inhibitor **122** complexed with thermolysin (Figure 27) shows the Zn²⁺ coordination and P₁–P₂ (or P₁–P_{2'} collected product) mode of binding. Such three-dimensional structural studies enable the molecular interactions between ACE and its inhibitors (e.g. captopril,⁵¹ enalaprilat,⁵² and fosinoprilat²¹⁴) and between ‘dual specific’ inhibitors of ACE and NEP (e.g., **123**²¹⁵) to be predicted.

Figure 25 Model of the active site of elastase: peptide and peptidomimetic inhibitors.

The discovery of specific inhibitors of matrix metalloproteases (MMPs) is rapidly developing (for a review see Beckett *et al.*²¹⁶), and is focused on several key MMP targets, including fibroblast collagenase (MMP-1), gelatinase-A (MMP-2), and stromelysin (MMP-3). Both x-ray crystallography and NMR spectroscopy have provided three-dimensional structural information about several MMPs as well as MMP-inhibitor complexes (see Table 2^{217–226}). For collagenase, early substrate-based inhibitor design strategies focused on modifying the P₁-P_{1'} cleavage site (e.g., Gly-Phe, Ala-Tyr, and Ala-Phe) by N-terminal functionalities capable of Zn²⁺ coordination (e.g., sulfhydryl, carboxyl, phosphonoalkyl, and hydroxamate^{227–229}). An x-ray crystallographic structure of the *N*-hydroxamate-modified peptide **124** complexed with fibroblast collagenase (Figure 28) provided a molecular map of both its hydrogen-bonding interactions with the enzyme active site and its binding to bound Zn²⁺.²¹⁹ Potent MMP-1 inhibitors have been designed which tether the P_{2'} side chain to the inhibitor's C-terminus as macrocyclic rings.^{53,230} In the example of gelatinase-A, potent inhibitors have been designed (e.g., **48**, Figure 10⁵⁴) by modifying the P_{1'}-P_{3'} peptide scaffold at the *N*-terminal hydroxamate and the P_{1'} extended aromatic side chain.⁵⁴ Finally, in the example of stromelysin-1, potent inhibitors have been designed (e.g., **49**, Figure 10⁵⁵) by *N*-terminal carboxyalkylamino functionalization relative to a P₁ substituent. An x-ray crystallographic structure of a related MMP-3 inhibitor **125** shows (Figure 28) the hydrogen-bonding interactions at the active site and coordination of the carboxylate with the Zn²⁺.²²³ Finally, the x-ray crystallographic structure of an PheΨ[P=O(OH)CH₂]Ala-modified peptide inhibitor **126** complexed with astacin (Figure 28) reveals the extensive hydrogen-bonding network between the inhibitor, enzyme, Zn²⁺, and a structural water group.²²⁶

2.15.6.6 Src Homology-2 Domains: Peptidomimetic and Nonpeptide Lead Compounds

Beyond proteases, the opportunity for structure-based drug design is being realized in the rapidly developing area of signal transduction research (e.g., intracellular protein and nucleic acid targets). Both x-ray crystallography and NMR spectroscopy have significantly contributed to a wide scope database of three-dimensional structural information for various catalytic and noncatalytic signal transduction protein targets (Table 3). These include tyrosine kinases (e.g., growth factor receptor kinases and Src family kinases²³¹), serine/threonine and dual-specificity kinases (e.g., mitogen-activated protein kinases, CDK2- and cAMP-dependent protein kinases²³²), phosphotyrosine phosphatases (e.g., PTP1B and CD45 Syp²³³), phosphoserine/phosphothreonine and dual-specificity phosphatases (e.g., VH1 and CDC25²³⁴), noncatalytic 'adapter' proteins (e.g., Crk, Grb2, Shc, and IRS-1⁸⁵), transferases (e.g., Ras farnesyl transferase⁸¹), proline *cis-trans* isomerases (e.g., FKBP-12 and cyclophilin A²³⁵), and GTP-binding proteins (e.g., p21 Ras²³⁶ and the α - β / γ -heterotrimeric G-protein for the GPCR superfamily²³⁷). Indeed, it was recognized more than decade ago that the opportunity for signal transduction drug discovery was remarkable, in terms of both the mechanistic diversity of the therapeutic targets (e.g., enzyme-substrate or regulatory protein-protein interaction) and their emerging structural biology.²³⁸⁻²⁶⁷

The identification of noncatalytic regulatory domains referred to as Src homology (SH) domains has advanced rapidly over recent years as a critical link in deconvoluting both enzyme-substrate and regulatory protein-protein interactions for a number of signal transduction pathways (for a review see Cohen *et al.*²⁶⁸). This emerging superfamily of proteins includes SH2 and SH3 domains, the so-called 'choreographers of multiple signaling pathways'.⁸⁵ The SH2 domains have been determined to bind cognate phosphotyrosine (pTyr) containing proteins in a sequence-dependent

Figure 27 Models of the active sites of thermolysin and ACE: peptide and peptidomimetic inhibitors.

manner relative to the amino acids contiguous to the C-terminal side of the pTyr residue (e.g., for Src SH2 a preferred sequence is \sim pTyr-Glu-Glu-Ile \sim versus \sim pTyr-Tyr-Asn-Tyr for Grb2^{87,269}).

With respect to SH2 domain structure-based drug design, the first x-ray crystallographic structures of pTyr-containing peptide ligands complexed with the Src SH2 domain²³⁹ have been utilized to design the first peptidomimetic antagonists.⁸⁹ As illustrated in Figure 29, a molecular map of the tetrapeptide sequence \sim pTyr-Glu-Glu-Ile \sim complexed with Src SH2²³⁹ shows the pTyr binding pocket and a second binding site for the P₊₃ Ile residue. As described previously, a prototypic peptidomimetic Ac-pTyr-Glu-D-Hcy-NH₂ (**66**) was first discovered using a peptide-scaffold-based drug-design strategy (see Figure 15⁷⁷) that took into account the x-ray crystallographic structure of the Src SH2-phosphopeptide (Glu-Pro-Gln-pTyr-Glu-Glu-Ile-Pro-Ile-Tyr-Leu, **127**) complex. Further structure-based, drug-design modifications led to the discovery of a series of potent peptidomimetics having novel C-terminal functionalization (e.g., the 'transposed' side chain of the P₊₁ Glu, or conformational constraint using a pyrrolidine ring; see Figure 29), as represented by **128**–**130**.^{89,270} Studies focused on Src SH2 have shown that the phosphate ester of pTyr is particularly critical for molecular recognition, and that significant loss in binding occurs by replacement with sulfate, carboxylate, nitrosyl, hydroxy, and amino groups.⁸⁸ However, backbone modifications of pTyr, which replace its acylated amino functionality with aromatic rings, designed to form π -cation type interactions with the Arg- α A2 were effective substitutions.²⁷⁰

Figure 28 Models of the active sites of stromelysin and collagenase: peptide and peptidomimetic inhibitors.

Src SH2 structure-based drug design has also led to a series of nonpeptides utilizing a *m*-aminomethylbenzamide template, as first exemplified by **131** (Figure 30), and validated by x-ray structural studies²⁷¹ that revealed binding of both its pY + 3 group and the benzamide CONH₂ moiety, as predicted. Modifications to incorporate pTyr (**132**) and further elaboration of the template led to a second-generation series^{272–274} of bicyclic benzamide analogs (**133–136**) that have increased potency and, in the case of **134** (AP22408), the first in vivo active lead compound.²⁷² Of note is the bicyclic benzamide template, which provides increased hydrophobic binding interactions with Src SH2 as well as the entropic advantage of locking the conformation of the benzamide via the fused cycloaliphatic ring system.^{272–274} Furthermore, the pTyr mimetics incorporating phosphonate moieties (e.g. **133** and **134**) were designed to confer tissue selectivity by virtue of bone-targeting.^{272,274} Another series of cyclic lactam-based, nonpeptide inhibitors of Src SH2,

Figure 29 Models of the binding site of the Src SH2 domain: peptide and peptidomimetic inhibitors.

as exemplified by **137–139**, has also been described.^{275–277} This series of nonpeptide inhibitors incorporated a caprolactam template in which the carbonyl moiety was designed, and confirmed by x-ray structure, to displace structural water (i.e., the same as displaced by the aforementioned benzamide template inhibitor **131**). Furthermore, the tricarboxy-modified pTyr mimic incorporated in the nonpeptide **139** yielded a high-affinity Src SH2 inhibitor.

High-resolution three-dimensional structures have been described for the noncatalytic ‘adapter’ protein Grb2 with respect to the apoprotein (SH3–SH2–SH3¹⁵³) as well as the individual SH2 and SH3 domains.^{246,252} In the case of the SH2 domain of Grb2, an x-ray crystallographic structure of a phosphopeptide complex provided insight to the molecular basis of the specificity of the Grb2 SH2 binding of ~pTyr-Xxx-Asn-Yyy~ sequences. The binding interactions of Lys-Pro-Phe-pTyr-Val-Asn-Val (**140**) showed that the phosphopeptide adopts a β -turn conformation about the P–P₊₃ residues, and that the P₊₂ Asn side chain carboxamide moiety is extensively hydrogen-bonded to the protein (**Figure 31**). In contrast to the well-defined binding pocket for the P₊₃ Ile of **127** to bind Src SH2, the P₊₃ Val of **140** engages in limited surface hydrophobic interactions because the Trp-121 residue of Grb2 SH2 sterically blocks the phosphopeptide from attaining a similar binding mode. First-generation peptidomimetic and nonpeptide Grb2 SH2

Figure 30 Some known peptidomimetic and nonpeptide inhibitors of Src SH2 domain.

inhibitors **141–143**^{278–281} illustrate drug-design strategies exploiting the known β -turn conformation of cognate phosphopeptide ligands complexed with Grb2 SH2, as determined from x-ray structural studies. The peptidomimetic **142** was cellularly effective and provided the first proof-of-concept lead compound relative to disrupting the Ras-Grb2 pathway by the inhibition of Grb2 SH2. The nonpeptide **143** was a moderately potent Grb SH2 inhibitor and provided a template for further lead compound optimization.²⁸¹

2.15.6.7 Tyrosine Phosphatases: Peptidomimetic and Nonpeptide Lead Compounds

PTP1B was the first member of the tyrosine phosphatase superfamily to be discovered and have its structure determined by x-ray crystallography, both as the apo catalytic domain and as a complex using a catalytically inactive Cys215Ser PTP1B mutant and the phosphopeptide Asp-Ala-Asp-Glu-pTyr-Leu-NH₂ (**144**).²⁵⁸ The molecular interactions between the tyrosine phosphatase and the phosphopeptide are dominated by electrostatic (i.e., the pTyr, P-1 Glu and P-2 Asp residues) and hydrogen-bonding contacts to key amide functionalities of the backbone of **144** (Figure 32). The P₊₁ Leu side chain forms hydrophobic contacts with several PTP1B residues at the surface proximate to the well-defined pTyr binding pocket. This three-dimensional structural information provided a useful molecular map of PTP1B active site for drug-design strategies focused on peptidomimetic and nonpeptide inhibitors such as compounds **145**,²⁸² **146**,^{283,284} and **147**.^{285,286} (Figure 32). The peptidomimetic inhibitor **145** was generated using a combinatorial library strategy, and was found to be a potent and selective inhibitor of PTP1B.²⁸² The peptidomimetic inhibitor **146** was designed from the tripeptide Ac-Asp-Tyr[SO₃H]-Nle-NH₂ and was also found to be a potent and selective inhibitor of PTP1B.^{283,284} The nonpeptide **147** is a tetrahydrothienopyridine template-based inhibitor of PTP1B, and provided a prototype lead compound for further drug development.^{285,286}

2.15.7 Recent Progress and Future Perspectives

Beyond the many key pioneering studies described in this chapter, there has been significant further progress in peptidomimetic and nonpeptide drug discovery in the last few years. Such work includes the integration of increasingly sophisticated in silico drug-design, structural biology (x-ray crystallography and NMR spectroscopy), chemical diversity,

Grb2 SH2 binding to the peptide sequence Lys-Pro-Phe-pTyr-Val-Asn-Val

Figure 31 Models of the binding site of the Grb2 SH2 domain: peptide, peptidomimetic, and nonpeptide inhibitors.

and high-throughput screening technologies, which continue to facilitate innovative peptidomimetic and nonpeptide drug discovery. In terms of therapeutic targets for peptidomimetic and nonpeptide drug discovery, genome sequencing and unraveling of the proteome will also build upon the knowledge gained from past scientific endeavors. With respect to synthetic chemistry, the use of combinatorial chemistry is expected to expand dramatically the chemical space of known peptidomimetics and nonpeptides, including exploiting key functional groups and building blocks (e.g., D-amino acids, N_α -alkyl or C_α -alkyl amino acids, N -substituted Gly, and dipeptide surrogates ($X_{xx}\Psi[Z]Y_{yy}$), and providing a collection of multifunctionalized templates (monocyclic or bicyclic) to mimic the three-dimensional pharmacophores of peptide ligands or complement three-dimensional binding sites of therapeutic targets. Finally, chemoinformatics and bioinformatics will significantly impact peptidomimetic and nonpeptide drug discovery in the future, in terms of harnessing the extraordinary amount of structure–property relationships that have emerged to date and those which are yet to come.

Biography

Tomi K Sawyer received a BSc degree in Chemistry at Moorhead State University (now Minnesota State University – Moorhead) and PhD in Organic Chemistry at the University of Arizona. His research has integrated synthetic chemistry, drug design, structural biology, chemoinformatics, biochemistry, cell biology, and in vivo disease models with a focus on cancer. Tomi's drug discovery track record includes contributions to clinical candidates and/or noteworthy molecular tools for several therapeutic targets, including GPCRs (melanocortin), aspartyl proteases (renin and HIV protease), and protein kinases (Src and Abl). He has published more than 200 scientific articles, reviews, commentaries, monographs, and books. Tomi is an inventor of more than 50 issued patents and patent filings. He worked at Upjohn Company and Parke-Davis/Warner-Lambert (now both Pfizer Global Research & Development), and is currently Senior-Vice President, Drug Discovery, at ARIAD Pharmaceuticals. He is concurrently adjunct professor, Chemistry as well as Biochemistry & Molecular Biology, University of Massachusetts, and also adjunct professor, Cancer Biology, at University of Massachusetts School of Medicine. Tomi has served on the highlights advisory panel of Nature Reviews Drug Discovery and the editorial advisory boards of Trends in the Pharmacological Sciences, Expert Reviews in Molecular Medicine, Expert Opinion on Investigational Drugs, Journal of Medicinal Chemistry, Chemistry and Biology, Current Medicinal Chemistry (Anti-Cancer Agents), Current Organic Synthesis, Expert Reviews in Molecular Medicine, Expert Opinion on Therapeutic Patents (Oncology), Drug Design and Discovery, Pharmaceutical Research, Molecular Biotechnology, and Biopolymers (Peptide Science). Most recently, Tomi was appointed Editor-in-Chief, Chemical Biology & Drug Design.

2.16.1 Introduction

2.16.1.1 The Scope of Bioisosterism

The concept of isosterism is based on the replacement in an active molecule of an atom or a group of atoms by another atom or group of atoms, presenting a comparable electronic and steric arrangement. The physicist Langmuir,¹ who was mainly interested in the physicochemical relationships of isosteric molecules, introduced the term isosterism in 1919. When, in addition to their physicochemical analogy, compounds share some common biological properties, the term bioisosterism, introduced by Friedman in 1951,² is used, even if the physicochemical resemblance is only vague. The term ‘nonclassical isosterism’ is often used interchangeably with the term bioisosterism, for example, when one has to deal with compounds not possessing the same number of atoms, but having in common some key parameters of importance for the activity in a given series. Preparing isosteric and bioisosteric replacements represents one of the main activities of medicinal chemists. Indeed, in the long history of medicinal chemistry, as soon as new natural or synthetic active principles were discovered, numerous attempts to prepare their analogs were undertaken. The main objective of analog design is to end up with compounds with enough resemblance to the model in order to guarantee a similar kind of biological activity. However, some differences from the model compound are not only accepted but are also actually welcomed insofar that they often reflect an improvement. Iterative improvements obtained by bioisosteric changes can yield a gain in potency, selectivity, bioavailability, deletion of an unwanted side effect, ease of administration, chemical stability, or cost of production. Historical examples of analog design are: the progressive passage from the alkaloid cocaine to the local anesthetic procaine; the change from the natural antibiotic penicillin to the orally active large-spectrum antibiotic amoxicillin; or the synthesis of potent HMG-CoA reductase inhibitors (‘statins’) such as atorvastatin or rosuvastatin inspired from the mevinolin structure (Figure 1).

Similar evolutions are found in the development of neuroleptics, antidepressants, or drugs to treat hypertension. Instead of natural models, analog design can use marketed drug structures as leads.

Figure 1 The passage from the natural lovastatin to the synthetic analogs atorvastatin and rosuvastatin.

2.16.1.2 The Importance of Analog Design

In the pharmaceutical industry, when a company launches a pioneer drug (i.e., resulting from an original invention and corresponding to a real therapeutic need), or considerably before then, competitors initiate immediately the search for similarly acting drugs in order to keep their market position. The analogs can be simple copies or display some improvements over the original drug molecule.

A survey of the novel therapeutic small molecules (molecular weight (MW) <600) that were launched or approved for the first time during the period 2000–03^{3,4} reveals that most of them resulted from the continued exploitation of already well-established structural classes (drug analogs) or the rapid expansion of newer structural classes (early phase analogs⁵). The market value of analog drugs can be estimated to be two-thirds of all small molecule sales. The continued preference for analog-based approaches has been criticized as being mainly restricted to the synthesis of ‘me-too’ compounds.⁶ In reality, the situation is more subtle and needs to establish a distinction between three different types of analogs (see below).

2.16.1.3 Analog Design and Bioisosterism

The term ‘analog’ is derived from the term analogy, which is itself derived from the latin and greek *analogia*, and has been used in natural sciences since 1791 to describe structural and functional similarity.⁷ Extended to drugs, this definition implies that the analog of an existing drug molecule shares chemical and therapeutic similarities with the original compound. Formally, this definition anticipates three categories of drug analogs: (1) those presenting chemical and pharmacological similarity; (2) those presenting only chemical similarity; and (3) those displaying similar pharmacological properties but presenting totally different chemical structures.

Analogues belonging to the first category showing both chemical and pharmacological similarities can be considered as direct analogs. These analogs correspond to the class of drugs often referred to as ‘me-too’ drugs. Usually they are improved versions of a pioneer drug over which they present a pharmacological, pharmacodynamic, or biopharmaceutical advantage. Examples are the angiotensin-converting enzyme (ACE) inhibitors derived from captopril, the histamine H₂ antagonists derived from cimetidine, and the hydroxymethyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors derived from mevinolin, etc. Such analogs are designed for the same industrial and marketing reasons as those that are valid for any other industrial products such as laptop computers or cars.

The second class of analogs made up of chemically similar molecules and for which we propose the term ‘structural analogs,’ contains compounds originally prepared as close and patentable analogs of a novel lead, but for which the biological assays revealed totally unexpected pharmacological properties. A historical example of the emergence of a new activity is provided by the discovery of the antidepressant properties of imipramine, which was originally designed as an analog of the potent neuroleptic drug chlorpromazine. Another example, illustrating that chemical similarity does not necessarily mean biological similarity, is that of the steroid hormones testosterone and progesterone, which although being chemically very similar have totally different biological functions, albeit both at nuclear receptors. Observation of an ‘emergent’ activity can be purely fortuitous or can result from a voluntary and systematic investigation.

For the third class of analogous compounds, chemical similarity is not observed; however, they share common biological properties. We propose the term ‘functional analogs’ for such compounds. Examples are the neuroleptics chlorpromazine and haloperidol or the tranquilizers diazepam and zopiclone. Despite their totally different chemical structures, they show similar affinities for the dopamine and benzodiazepine receptors, respectively. The design of such drugs is presently facilitated thanks to virtual screening of large libraries of diverse structures.

The search for analogs is helped very often by the concept of isosteric replacement and the derived concept of bioisosterism. Isosteric replacement requires substitution of one atom or group of atoms in the parent compound by another, with similar electronic and steric configuration. A typical example of isosteric replacement is given in [Figure 2](#) where four clozapine analogs derive one from the other by simple changes, the oxygen atom being successively replaced by the S and CH₂ isosteric groups. The claimed objective of isosterism is to produce an improved version of the pioneer drug; sometimes, however, compounds with modified pharmacological profiles and even with antagonistic properties are obtained.

The term bioisosterism is used to describe replacements of generally more important pieces of the original molecule. Thus, the replacement of the methylated carboxamide function of diazepam by its bioequivalent methylated triazole group in alprazolam ([Figure 3](#)) preserves the high affinity for the central benzodiazepine receptor.

Finally, taken in its broadest meaning, bioisosterism can consist of a complete replacement of the initial molecular structure by another one, isofunctional, but based on a different scaffold. This approach, called scaffold hopping, is illustrated by the passage of diazepam to zolpidem and to zopiclone ([Figure 4](#)).

Figure 2 Isosteric replacements in clozapine analogs.

Figure 3 The passage from diazepam to alprazolam represents a typical bioisosteric change.

Figure 4 Scaffold hopping can be considered as an extreme application of the bioisosterism concept.

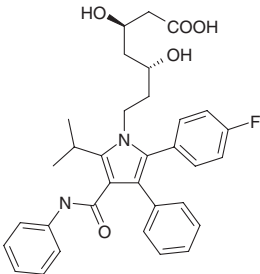

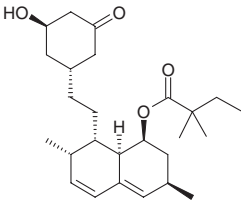

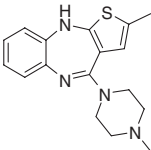

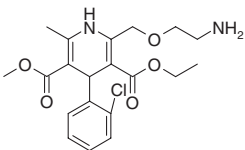

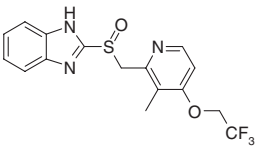

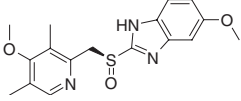

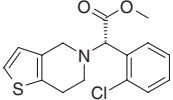

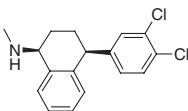

2.16.2 Currently Encountered Bioisosteric Modifications

2.16.2.1 Ring Equivalents

2.16.2.1.1 Introduction

Chemical rings are fundamental for drug molecules. A typical drug molecule consists of a combination of chemical rings, chains, and functional groups. Chemical rings represent an important portion of the drug structures. A brief look at the best-selling drugs in 2004⁸ (Table 1) gives a better idea of the importance of this class of chemicals.

Table 1 Best selling drugs in 2004⁸

<i>Structure</i>	<i>Drug</i>	<i>Purpose</i>	<i>Company</i>	<i>Global sales \$billion</i>
	Atorvastatin	Lowers cholesterol	Pfizer	10.3
	Simvastatin	Lowers cholesterol	Merck	6.1
	Olanzapine	Antipsychotic	Eli Lilly	4.8
	Amlodipine	Lowers blood pressure	Pfizer	4.5
	Lansoprazole	Treats ulcers	Takeda & Abbott Laboratories	4.0
	Esomeprazole	Treats ulcers	AstraZeneca	3.8
	Clopidogrel	Bloodthinner	Sanofi-Aventis & Bristol-Myers Squibb	3.7
	Sertraline	Antidepressant	Pfizer	3.4

Figure 5 In thiophene the sulfur atom is approximately equivalent to an ethylenic group (size, mass, and capacity to provide an aromatic lone pair).

Figure 6 Classical ring equivalents.

The drugs reported in [Table 1](#) as well as almost all the other marketed drugs present at least one chemical ring. In some cases, the ring is used as a platform supporting the pharmacophoric elements to orient them in the right direction for optimal interaction with the receptor. In other examples, it is the ring itself that possesses intrinsic bioactive properties. There are also some examples where heterocyclic rings are used as bioisosteres of metabolically unstable functional groups.

The substitution of $-\text{CH}=\text{CH}-$ by $-\text{N}=\text{N}-$ or $-\text{CH}=\text{CH}-$ by $-\text{S}-$ in aromatic rings has been one of the most successful applications of classical isosterism. Thus, the equivalence in size and lone pair participation to aromaticity between $-\text{CH}=\text{CH}-$ ($M = 26$) and $-\text{S}-$ ($M = 32$) explains the well-known analogy between benzene and thiophene ([Figure 5](#)). Early examples of ring equivalents are found in the sulfonamide antibacterials with the development of sulfapyridine, sulfapyrimidine, sulfathiazole, etc. ([Figure 6](#)).

The efforts to replace rings form a large part of medicinal chemistry practice. A typical lead optimization program often involves a trial and error process of replacing chemical functionalities including rings. In many cases this intellectual exercise is based on a chemist's knowledge and recollection of his or her past experience.

2.16.2.1.2 Bioisosteres of pyridine

One of the most used cyclic structures in medicinal chemistry is the pyridine heterocycle. The bioisosteres of this ring are well known as ligands for the central nicotinic cholinergic receptors. The pyridine ring of nicotine can be replaced

by different rings like methyl-isoxazole or methyl-isothiazole^{9–11} (Figure 7a). A novel series of nicotinic agonists was described by Olesen and co-workers.¹¹ In their paper, the bioisosteric replacement of the isoxazole ring in the (3-methyl-5-isoxazolyl)methylene-azacyclic compound (**1**) with pyridine, pyrazine, oxadiazole, or an acyl group resulted in ligands with moderate to high affinity for the central nicotinic cholinergic receptors ($IC_{50} = 2.0$ nM to $IC_{50} > 1000$ nM) (Figure 7b).

Two other publications on the bioisosteric replacement of pyridine show similar results. The first paper reports the study of bioisosteric potential of diazines in the field of combined antithrombotic thromboxane A_2 synthetase inhibitors and receptor antagonists.^{12,13} On the basis of the structure–activity relationships observed in this study, it turned out that only the 2-pyrazinyl, 4-pyridazinyl, and 5-pyrimidinyl systems are appropriate bioisosteric moieties for the 3-pyridyl system in the dual active platelet antiaggregatory compound ridogrel (Figure 8). Gohlke and colleagues¹² also observed the bioisosteric potential of diazines in the structure–activity relationships (SARs) of the compound DUB-165. The replacement of the 3-pyridyl group of DUB-165 by a 4-pyridazinyl, 5-pyrimidinyl, or 2-pyrazinyl moiety resulted in ligands retaining affinity for nicotinic acetylcholine receptor (nAChR) subtypes, thus demonstrating that the three isomeric diazines are appropriate bioisosteres of the 3-pyridyl moiety (Figure 8).

N-(6-Chloronaphthalen-2-)sulfonylpiperazine derivatives **2** and **3** (Figure 9) are potent factor Xa inhibitors. Haginoya and co-workers¹⁴ proposed to replace the pyridine-phenyl or the pyridine-piperidine residue by a fused bicyclic ring that contains an aliphatic amine and a pyridine to yield the compound **4**, which has an interesting factor Xa

Figure 7 Ligands for central cholinergic receptors with different nonclassical bioisosteres of the pyridine ring.

Figure 8 Bioisosteric moieties for the 3-pyridyl ring.

Figure 9 Bioisosteric replacements of the pyridine ring in a series of factor Xa inhibitors.

inhibitor activity. The bioisosteric replacement of the pyridine moiety of the 6-methyl-5,6,7,8-tetrahydro-[1,6]naphthyridine by phenyl, thiophene, or thiazole analogs yielded analogs with similar or better anti-factor Xa activity, but also conserved a moderate bioavailability.

2.16.2.1.3 Imidazo[1,2-a]pyridine bioisosteres

Abe and co-workers¹⁵ reported that the imidazo[1,2-a]pyridine moiety of the basic framework of a class of the nonpeptide bradykinin B2 receptor antagonists (**5**) could be successfully replaced by several heterocyclic bioisosteres (**Figure 10**). Among those, the 1-methyl-2-methoxy-1*H*-benzimidazole (**8**), 2-methylquinoxaline (**6**), and 2-methylquinoline (**7**) derivatives showed potent B2 binding affinities against both human and guinea pig B2 receptors.

2.16.2.1.4 Pyridazine bioisosteres

Since the antidepressant minaprine was launched, several pyridazine analogs have been proposed and synthesized. Most of them showed different effects on the central nervous system. A series of these compounds (**Figure 11**) are acetylcholinesterase inhibitors with variable bioisosteres of the central pyridazine.^{16,17} The replacement by pyridine, 1,2,4-thiadiazole, and triazines yields compounds with weaker but still acceptable activity.

As we have seen, there are several nonclassical bioisosteres that could be found for the pyridine system or the pyridazine system. It is important to have a good rationale to choose the most appropriate analogs to start with. An indication could be given by the comparison of the boiling points of these heterocycles (**Figure 12**) assuming that the more similar the boiling point is, the most appropriate the bioisostere is.¹⁸ For example, while searching for a bioisostere of the pyridine ring, it appears that the best candidates are the pyrimidine, the pyrazine, the 1,3,4-oxadiazole, the

Figure 10 Novel class of orally active nonpeptide bradykinin B₂ receptor antagonists showing valuable examples of imidazo[1,2-*a*]pyridine analogs.

Figure 11 In vitro inhibition of acetylcholinesterase in rat striatum homogenates; pyridine, thiadiazole, and triazine replacement of the pyridazine ring.

1,2,4-oxadiazole, or the 1,2,4-thiadiazole systems. The same is true for the pyridazine ring where this comparison permits the selection of the 1,2,4-triazine or the 1,3,4-thiadiazole rings. In fact, those findings confirm the examples found in the literature and reported earlier in this chapter.

A possible interpretation of these results can be the fact that in the heterocyclic series, the boiling point is correlated to the dipolar moment of the molecule and that, for two heterocyclic rings having the same aromatic geometry, the similarity of the dipolar moments may represent the dominant feature.

2.16.2.1.5 Bioisosteres of other heterocycles

Chemical rings are fundamental to the structure of drug molecules, as a typical drug molecule consists of a combination of chemical rings, chains, and functional groups. The high proportion of chemical rings in drug molecules argues in favor

Figure 12 Structures and boiling points of pyridine and pyridazine isosteres.

Figure 13 Examples of selective cyclooxygenase-2 inhibitors showing different ring equivalents.

of the great need to synthesize and find new chemical ring equivalents, whether it is to design a new platform for a better patent position, replace a metabolically unstable moiety, look for a more favorable receptor interaction, or create a better pharmacodynamic profile.

There are many examples of the concept of ring equivalents and so far it seems impossible to rationalize a method that gives an indication of which heterocycle could be the best substitute for another one. The best approach is to look at the examples reported in the literature. One of the most fascinating heterocycle analogies is given by the class of selective cyclooxygenase-2 (COX-2) inhibitors. The comparison of the most potent selective COX-2 inhibitors (**Figure 13**) suggests that isoxazoles, pyridines, and pyrazoles are good bioisosteres of each other as well as nitrophenol, indole, and indanones.¹⁹ Another nice example of heterocycle bioisosteres is given by the oxazolidinone antibacterials. Since scientists at Upjohn discovered linezolid as a potent antibacterial for Gram-positive organisms,²⁰ many efforts have been devoted to identifying new and potentially improved antibacterial agents. Some of these efforts have used the oxazolidinone silhouette as a starting point,²¹ while others have taken advantage of the bioisosterism rationale to replace the central oxazolidinone heterocycle.²²

The work of Snyder and co-workers, together with other examples found in the literature, shows that several levels of activity can be identified among the different isosteres. It should be kept in mind that the replacement of a ring by

Figure 14 Oxazolidinone bioisosteres synthesized as antibacterial agents.

its isosteres does not always lead to an iso-active or more active compound (**Figure 14**), but, in general, it is possible to obtain at least one or more equivalent systems.²¹ In **Table 2** we have listed some more 'exotic' examples of bioisosteric replacements of cyclic systems.^{23–25}

2.16.2.2 Groups with Similar Polar Effects: Functional Equivalents

2.16.2.2.1 Carboxylic acid bioisosteres

The term nonclassical isosterism is often used interchangeably with the term bioisosterism, for example, when one has to deal with isosteres that do not possess the same number of atoms, but which have in common some key parameter of importance for the activity in a given series. Thus, the two GABAergic agonists isoguvacine and THIP (**Figure 15**) have similar pharmacological properties to GABA itself. The key parameters in these compounds are the acidic ($pK_a \approx 4$) and the basic (protonated nitrogen) functions with an interchange distance of $\approx 5.1 \text{ \AA}$.

For the carboxylic function of active compounds, three different classes of bioisosteres can be distinguished: the direct derivatives (**Table 3**) such as hydroxamic acids: $R\text{--CO--NH--OH}$, acyl-cyanamides: $R\text{--CO--NH--CN}$, and acyl-sulfonamides: $R\text{--CO--NH--SO}_2\text{--R'}$; the planar acidic heterocycles (**Table 4**) such as tetrazoles, hydroxy-isoxazoles, etc.; and the nonplanar sulfur- or phosphorus-derived acidic functions (**Table 5**).

2.16.2.2.1.1 Direct derivatives

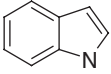

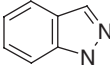

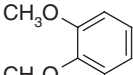

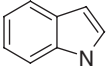

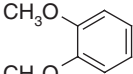

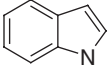

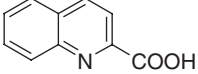

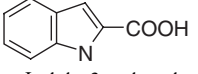

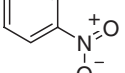

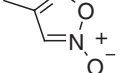

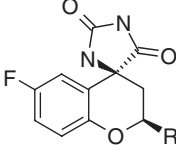

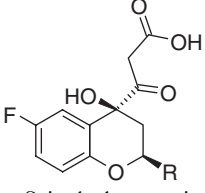

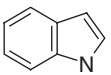

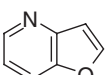

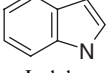

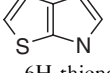

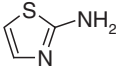

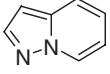

We consider as direct derivatives different functional groups that have similar specific interactions with the receptor as they maintain an acidic proton and a hydrogen bond acceptor. Among the most common direct derivatives are hydroxamic acids,^{32,46} acyl-cyanamides,^{40,41} and acyl-sulfonamides⁴² in which an acidic NH group replaces the acidic OH group and the carbonyl is left unchanged.

2.16.2.2.1.1.1 Hydroxamic acids The hydroxamic acids have a high chelating power and they have found a wide application as inhibitors of enzymes having a Zn^{2+} in the active site, like matrix metalloproteinases (MMPs),^{35–38} tumor necrosis factor alpha (TNF- α) converting enzyme,³⁹ and histone deacetylase (HDAC)^{33,34} yielding potent and bioavailable compounds despite the hydroxamic acid group is particularly prone to hydrolysis, reduction, and glucuronidation.⁴⁷ Another interesting example of exploitation is given by the anti-inflammatory hydroxamates bufexamac,⁴⁶ ibuproxam,⁴⁸ and oxametacin⁴⁹ (**Figure 16**). While ibuproxam is classified as prodrug being metabolized to ibuprofen ($\text{CONHOH} \rightarrow \text{COOH}$) in man,⁵⁰ oxametacin is a true bioisostere rather than a prodrug being metabolically stable in man.^{51,52}

2.16.2.2.1.1.2 Acyl-sulfonamides Acyl-sulfonamides are also quite commonly used in drug discovery and have been employed in several therapeutic areas such as β_3 adrenergic receptor agonists,⁴⁴ chemokine receptor 1 (CXCR1) inhibitors,⁵³ hepatitis C virus (HCV) inhibitors,⁴⁵ angiotensin receptor agonists,⁵⁴ antitumoral compounds with antiproliferative properties,^{55,56} and prostaglandin EP4 receptor antagonists.⁵⁷

Acyl-cyanamides are mainly of academic interest.

Table 2 Other ring bioisosteres

2.16.2.2.1.2 Planar acidic heterocycles and aryl derivatives

Table 4 gives the planar acidic heterocycles and aryl derivatives that are commonly used as carboxylic acid bioisosteres. The most commonly used is the tetrazole ring, which has found wide application in different therapeutic fields ranging from type 2 diabetes^{69,70} to hepatitis C virus (HCV),⁴⁵ malaria,⁷¹ Alzheimer's disease (AD),⁷² anxiety treatment,⁷³ pain management,⁷⁴ erectile dysfunction,⁷⁴ and inflammation.⁷⁴ The tetrazole has been employed to fix different issues, for example, to improve bioavailability,⁷¹ or to improve blood–brain barrier penetration,^{73,74} to enhance potency,^{70,75} to increase chemical stability,⁷² to bring some selectivity (the GABA tetrazole analog inhibits GABA-transaminase, but not

Figure 15 An example of bioisosterism, or nonclassical isosterism: GABA, isoguvacine, and THIP are all agonists for the GABA_A receptor. The 3-hydroxy-isoxazole ring has a comparable acidity to that of a carboxylic acid function.

succinic semialdehyde dehydrogenase)⁷⁶ or to be used as a prodrug.⁷⁷ However, in some instances, tetrazole analogs are poorly active.⁷⁸

Hydroxy-isoxazoles and other cognate heterocyclic phenols encompassing an acidity range from 3.0 to 7.1 were incorporated in GABA agonists, antagonists, and uptake inhibitors.^{79,80} The experience gained with 3-hydroxy-isoxazoles in the GABA field was also transferable to glutamate receptor ligands and led to selective antagonists for glutamic acid receptor subtypes.⁸⁰

Thiazolidinediones are another class of heterocyclic carboxylic acid surrogates commonly used for PPAR agonists,^{65,81} as potent antihyperglycemic and lipid activity modulators.

Other interesting, but less studied heterocyclic surrogates are: 3,5-dioxo-1,2,4-oxadiazolidine,⁸² 3-hydroxy-1,2,5-thiadiazoles,⁶³ and 3-hydroxy-γ-pyrones.^{64,83}

2.16.2.2.1.3 Nonplanar sulfur- or phosphorous-derived acidic functions

The most extensive use of phosphonates (Table 5) occurred in the design of amino acid neurotransmitter antagonists such as glutamate⁸⁶ and GABA_B antagonists.⁸⁴ Among a set of cholecystokinin (CCK) antagonists derived from the nonpeptide CCK-B selective antagonist CI-988, Drysdale and colleagues⁸⁷ prepared a series of carboxylate surrogates spanning a pK_a range from <1 (sulfonic acid) to >9.5 (thio-1,2,4-triazole). The affinity and the selectivity of the compounds were rationalized by considering pK_a values, charge distribution, and geometry of the respective acid mimics (Table 6).

2.16.2.2.1.4 Comparison of pK_a and log *P* values

An interesting study comparing pK_a and log *P* values of some aryl phosphonic acids, aryl tetrazoles and aryl sulfonamides has been published by Franz.⁸⁸ The value of pK_a and log *P* are very important parameters in drug design. Several published examples show that the interchange of carboxylic acid for tetrazole and sulfonamide often results in useful drugs. This study indicates that the log *P* will be lowered by about 1 log unit substituting a phosphonic acid by a carboxylic acid group. There is an increase in acidity, which may be a limiting factor in the absence of active transport.

Table 4 Carboxylic acid isosteres: planar acidic heterocycles and aryl derivatives

	Sulfonamides	Weak acids, used rather as equivalents of phenolic hydroxyls in the design of catecholamine analogs	von Kohler <i>et al.</i> ⁴⁰

Replacing a carboxylic acid group by a phosphonic acid group gives a much more acidic compound; replacing it with a sulfonamide group results in a much less acidic compound; and with a tetrazole replacement, acidity is essentially unchanged (Figure 17). If one wants to lower the log *P*, and if increased acidity of the compound was not a limiting factor, substitution of a phosphonic acid group for a carboxylic acid would be a viable approach (Figure 18).

Figure 16 Hydroxamate isosteres of anti-inflammatory drugs.

2.16.2.2.1.5 Diamino-cyclobutene-diones as α -amino carboxylic acid surrogates

Diamino-cyclobutene-dione was proposed by Kinney and co-workers⁸⁹ as an original surrogate of the α -amino carboxylic acid function (Figure 19).

2.16.2.2.1.6 Carboxylic functions as phosphonate surrogates

Nonhydrolyzable phosphotyrosyl (pTyr) mimetics serve as important components of many competitive inhibitors of protein-tyrosine kinases. To date, the most potent of these inhibitors have relied on phosphonate-based structures to replace the 4-phosphoryl group of the parent pTyr residue (Figure 20). Interestingly, it was found that carboxy-based pTyr analogs can be utilized to introduce the anionic oxygen functionality of the parent phosphate. Particularly, when *p*-(2-malonyl)phenylalanine (Pmf) was incorporated as pTyr replacement in the high-affinity Grb2 SH2 domain binding sequence, potencies approaching those of phosphonate mimetics were obtained.⁹⁰

The above example is an elegant illustration of the possibility to mimic the pyramidal structure of phosphates or phosphonates by means of two planar carboxylic groups, the three-dimensionality originating from the malonic methylenic carbon atom.

2.16.2.2.2 Bioisosteres of carboxylic esters

Ester-containing drug molecules are highly labile in vivo due to the widespread presence of esterases, which can be found in the blood, liver, kidney, and other organs. Bioisosteric substitution of this group has been extensively investigated in order to improve the metabolic stability of an ester-containing drug molecule, leading to improved pharmacokinetic and pharmacodynamic profiles.

The change from ester to amide (procaine \rightarrow procainamide) is already illustrated above as an example of classical isosterism. Similarly, the lactone ring of the muscarinic agonist pilocarpine was changed into various, still active isosteres such as the corresponding thiolactone, lactam, lactol, and thiolactol.⁹¹ A series of aspirin isosteres has been prepared by replacing the carboxylic ether oxygen successively by a nitrogen, sulfur, or carbon isosteric equivalent.⁹² None of the isosteric compounds showed any activity. This result is readily understood since the particular role of aspirin as an acylating agent of the enzyme cyclooxygenase has been demonstrated.⁹³

In addition to these classical changes, 1,2,4-oxadiazoles or 1,2,4-thiadiazoles have been commonly used as carboxylic ester surrogates in series of benzodiazepine and muscarinic^{94,95} receptor ligands (Figure 21). For muscarinic agonists, numerous successful attempts to replace the oxadiazole ring by other heterocyclic ring systems were published.^{96–98} Pilocarpine is widely used as a topical miotic for controlling the elevated intraocular pressure associated with glaucoma. Besides its low lipophilicity, which stimulated the search for prodrugs,⁹⁹ pilocarpine has a short duration of action, its lactone ring being rapidly opened to yield pilocarpic acid. In pilocarpine, by substituting the lactone ester function by its carbamate equivalent, a much more stable analog, which is as effective as pilocarpine, was obtained.¹⁰⁰

Several 1,2,4-oxadiazoles and the other five-membered heterocycles are employed also for other therapeutic indications such as monoamine transporter and opioid receptors,^{101,102} 5HT agonists,¹⁰³ and bradykinin B₁ receptor antagonists.¹⁰⁴ Regarding this last study, it is noteworthy to observe the use of N-2 substituted methyl tetrazole as ester surrogates.

Another uncommon ester bioisostere is the *N*-methoxy imidoyl nitrile that was reported for a muscarinic M1 agonist (Figure 22). An interesting replacement of the ester group with a more metabolically stable one is given by the ethyl oxime ether. In the case of human rhinovirus, this change improved the oral bioavailability of the corresponding ester derivative¹⁰⁵ (Figure 23). The change in (–)-cocaine of the carbomethoxy substituent into carbethoxyisoxazole doubles the potency in [3H] mazindol binding and [3H] dopamine uptake (Figure 24). Astonishingly the replacement

of the carbomethoxy group by a chlorovinyl moiety produces a comparable gain in potency thus arguing against the involvement of the carbomethoxy group in H-bonding.¹⁰⁶

Another rather unusual example of ester isosterism is the replacement of the ether oxygen by a fluoro-nitrogen (Figure 25a) as mentioned by Lipinski.¹⁰⁷ Other uncommon examples are found in the replacement of the ester function of acetylcholine by exo-endo amidine functions of 3-aminopyridazines in muscarinic agonists (Figure 25b)¹⁰⁸ and of the carbomethoxy group of α -yohimbine (rauwolscine) by an *N*-methylsulfonamide function (Figure 25c).¹⁰⁹

2.16.2.2.3 Carboxamide bioisosteres

Carboxamides are usually converted to sulfonamides as illustrated by the synthesis of the hypoglycemic sulfonyl isostere of glybenclamide.¹¹⁰ The isosteric replacements for peptidic bonds have been summarized by Spatola¹¹¹ and by Fauchère.¹¹² The most used and well-established modifications are: *N*-methylation, configuration change (*D*-configuration at $C\alpha$), formation of a retroamide or an α -azapeptide, use of aminoisobutyric or dehydroamino acids, replacement of the amide bond by an ester [depsipeptide], ketomethylene, hydroxyethylene or thioamide functional group, carba replacement of the amidic carbonyl, and use of an olefinic double bond (Figure 26).

Figure 25 (a) Replacement of ester ether oxygen by a fluoro-nitrogen; (b) exo-endo amidine in place of a carboxylic ester functionality; and (c) *N*-methylsulfonamide analog of α -yohimbine (rauwolscine).

More unusual isosteric replacements for the peptidic bond were recently proposed (Figure 27). Among them, hydroxyethylureas were used in the design of a novel class of potent HIV-1 protease inhibitors, diacycyclopropanes in the design of novel renin inhibitors, and pyrroline-3-ones for various proteolytic enzyme inhibitors.^{113,114} Vinyl fluorides can probably be considered as representing the closest possible bioisosteres of the peptide bond. The synthetic methods available allow, by an appropriate selection of the precursors, the preparation of analogs of dipeptidic combinations of amino acids bearing no other functionalities in their side chains, e.g., Gly, Ala, Val, Phe, Pro.¹¹⁵ Vinyl fluorides have been used in the design of bioisosteres of peptide bonds as in the case of the analgesic dipeptide 2,6-dimethyl-L-tyrosyl-D-alanine-phenylpropionamide.¹¹⁶

Other structural modifications of the amide bond proposed to create more chemically stable and orally available molecules include heterocyclic rings such as 1,2,4-oxadiazoles and 1,3,4-oxadiazoles (Table 7). 1,2,4-Oxadiazoles have been used as bioisosteres of the carboxamide moiety in SH2 inhibitors of tyrosine kinase ZAP-70,¹¹⁷ 5HT_{1D} receptor agonists,¹⁰³ histamine H₃ receptor antagonists,¹¹⁸ and 5HT₃ receptor antagonists.¹¹⁹ An example worthy of note is given by the β_3 adrenergic receptor agonists where the replacement of the amide bond with 1,2,4-oxadiazoles led to compounds with improved oral bioavailability retaining the β_3 adrenergic receptor (AR) agonist activity.^{120–124} 1,3,4-Oxadiazoles have also been used as amide bond surrogates in several therapeutic areas like benzodiazepine receptor agonists,¹²⁵ muscarinic receptor agonists,¹²⁶ neurokinin 1 (NK1) receptor antagonists,¹²⁷ and they have also been used as Phe-Gly peptidomimetics.¹²⁸

Other heterocyclic replacements of the amide bond include oxazole rings,^{129,130} cyclic amidines,^{131,132} pyrrole rings,¹³³ and phenylimidazole¹³⁴ (Table 7).

2.16.2.2.4 Urea and thiourea bioisosteres

The very successful urea \leftrightarrow cyanoguanidine \leftrightarrow dimethylnitroethylene bioisosterism¹³⁵ was applied to the sulfonyl-urea function of torsemide,¹³⁶ a diuretic loop agent (Figure 28). This investigation led to the design and synthesis of the corresponding thiourea, cyanoguanidine, and dimethylnitroethylene group. The structure, the electronic features (charges, molecular electrostatic potential, molecular orbitals) and the lipophilic properties of these three analogs were

Figure 26 Well-established isosteric replacements for peptidic bonds.

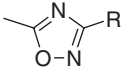

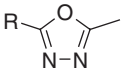

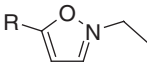

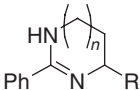

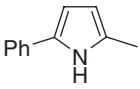

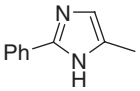

Figure 27 Unusual isosteric replacements for peptidic bonds.

determined. In conclusion, cyanoguanidine and diaminonitroethylene turned out to be valuable isosteres of the (thio)urea function as they share common geometric and electronic properties. In addition, they cover a range of lipophilicity that makes them suitable for compound pharmacomodulation as illustrated by the diuretic and antiepileptic properties of analogs of torsemide.

In a study undertaken on antagonists of the dihydropyridine neuropeptide Y₁ (NPY 1) receptor, common bioisosteres such as thiourea and cyanoguanidine and also heterocycles were examined as urea replacements (**Figure 29**).^{137,138} Both cyanoguanidine and thiourea derivatives demonstrated potent binding affinity at the Y₁ receptor. The two known urea

heterocycle replacements, squaric acid and thiadiazole oxide, demonstrated good binding affinity although both were 10 times less active compared to parent urea.

Among more exotic surrogates, the 3,4-diamino thiadiazole dioxide moiety was proposed as a weakly acidic urea equivalent.¹³⁹ The similar thiatriazole dioxide is found in the H₂ antagonist tuvatidine (HUK 978). Other bioisosteres are exo-endo amidinic heterocycles bearing an electron-attracting function in the α position^{140,141} (Figure 30).

2.16.2.2.5 Phenol and catechol bioisosteres

Phenol and catechol functions frequently use the same bioisosteric resources. However, due to the vicinity of the two hydroxylic functions in catechols, a few specific solutions are possible for them.

2.16.2.2.5.1 Bioisosteres of the phenol function

The bioisosteric groups of the phenolic function should not be much larger than the hydroxyl itself and should have approximately the same acidity range (weak acid) and be able to form hydrogen bonds. The most popular bioisosteric

Figure 29 Binding affinities for various urea bioisosteres acting as antagonists at the NPY Y_1 receptor.

Figure 30 Less common urea equivalents.

substituents^{142,143} are methanesulfamide ($\text{CH}_3\text{SO}_2\text{NH}-$), hydroxymethyl (HOCH_2-) or hydroxyisopropyl ($\text{HOC}(\text{CH}_3)_2-$), various amide groups ($-\text{NHCHO}$, $-\text{NHCOCH}_3$, $-\text{NHCOC}_6\text{H}_5$, methanesulfamidomethyl ($\text{CH}_3\text{SO}_2\text{NHCH}_2-$), dimethylaminosulfonamide ($(\text{CH}_3)_2\text{NSO}_2\text{NH}-$), and others with an ionizable proton next to or near an aromatic ring.

Using this analogy, Wu and co-workers¹⁴⁴ prepared a series of phenolic bioisosteres of benzazepine D_1/D_5 antagonists (Figure 31). Compared to the reference compound SCH 38393 they exhibit similar or more potent activities, high selectivity over D_2-D_4 receptors, and improved in vivo pharmacokinetics. The optimization of the hydrogen bond donating capacity of various heterocycles allowed the identification of several potent D_1/D_5 antagonists with high selectivity D_2-D_4 , α_{2a} adrenergic receptors, and the 5HT transporter, keeping at the same time excellent pharmacokinetic profiles.

The most popular surrogates for phenolic functions are NH groups rendered acidic through the presence of an electron-attracting group. Table 8 shows an application of this bioisostery in the design of *N*-methyl-D-aspartate (NMDA) receptor antagonists.¹⁴⁵ In this case, the replacement of the phenol by heterocyclic NH-containing rings was performed in order to slow metabolism and hence to improve oral bioavailability. Indeed, the potent and NR1A/2B-receptor selective benzimidazolone analog was obtained demonstrating oral activity in a rodent model of Parkinson's disease at 10 and 30 mg kg^{-1} .

Hacksell and colleagues¹⁴⁶ described the compound (\pm) -3-(1-propyl-3-piperidinyl)phenol [(\pm) -3-PPP] as a highly selective agent for presynaptic brain dopamine (DA) receptors. However, the clinical potential of these molecules (Figure 32) as antischizophrenic or antiparkinsonian agents may be limited by their relatively low oral bioavailability and their short duration of action.¹⁴⁷ Thus, a heterocyclic analog of 3-PPP might retain some of its pharmacological activity while having improved oral bioavailability and duration of action.¹⁴⁸ In the case of talipexole (B-HT 920) (Figure 32), a DA agonist which has been reported to be selective for DA autoreceptor, 2-aminothiazolyl moiety was used as a replacement for the phenol ring. This successful example led to the discovery of the PD 118440, a dopamine autoreceptor agonist,¹⁴⁸ and pramipexole, a DA agonist with preference for the DA D_3 (over DA D_2) receptor.¹⁴⁹⁻¹⁵¹

Figure 31 Phenol bioisosteres of benzazepine D₁/D₅ antagonists.

2.16.2.2.5.2 Catechol bioisosteres

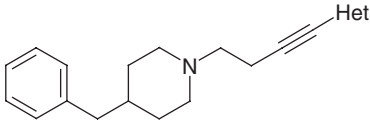

All of the previous examples can be applied to the catechol family. Many of these bioisosteres share with the catechols the ability to chelate metal atoms and to form hydrogen-bonded second rings. In benzimidazole this H-bond ring is mimicked by way of a covalent ring structure (Figure 33). A recent case described the synthesis of more stable bioisosteres of inhibitors of the insulin-like growth factor-1 receptor kinase (IGF-1R; Figure 34). Based on the structure of AG 538,¹⁵² which contains two catechol rings and is sensitive to oxidation in cellular environments, a new series of kinase inhibitors was developed. The catechol moiety was replaced by a benzoxazolone ring resistant to oxidation yielding two compounds GB19 and AGL2263, which maintain the same potency as AG 538.

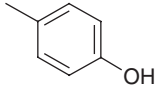

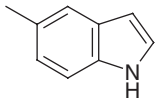

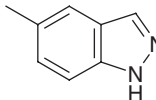

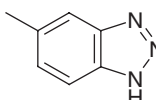

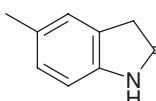

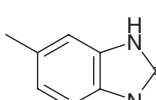

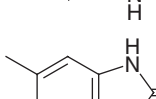

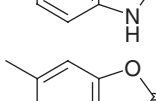

2.16.2.2.5.3 Fancy catechol bioisosteres

Until now, 2-aminothiazole derivatives or other aromatic heterocyclic systems have been used as a bioisosteric surrogate for the catechol nucleus (see studies around the pramipexole). Hübner and colleagues^{149,153–155} evaluated nonaromatic catechol bioisosteres (Figure 35). They were able to demonstrate that the π -electronic system of the nonaromatic enediyne FAUC 88 and 73 can be used as an efficient bioisostere for the catechol fragment of dopamine. Combined with conformational rigidization, this approach led to dopamine receptor agonists with high affinity for the subtypes of the D₂ family and especially for D₃.

2.16.2.2.6 Sulfonamides

The introduction of the serotonin 5HT_{1D} receptor agonist sumatriptan for the acute treatment of migraine has marked an intense research effort to discover more potent and selective 5HT_{1D} receptor agonists with improved pharmacokinetic profiles.¹⁵⁶ The H-bond acceptor ability of the 5-position is crucial for 5HT_{1D} receptor affinity and selectivity as it was revealed by reference compounds (5HT and sumatriptan). The first analog was an oxadiazole, L-695,894 (Figure 36), which had better oral bioavailability but had significant affinity for 5HT_{2A} and 5HT_{2C} receptors.¹⁰³ This work was then extended to explore alternative 5-membered heteroaromatic rings, which are also H-bond acceptors. Compounds were sought that had log *D*s < 0.5 in order to minimize central nervous system penetration.¹⁵⁶ Simple unsubstituted imidazoles, triazoles, and tetrazoles (Table 9) have high affinity and good selectivity for the 5HT_{1D} receptor. The 1,2,4-triazole 1, MK-462, was shown to have the optimal pharmacokinetic profile with rapid oral absorption and high bioavailability.

Table 8 Bioisosteric replacements of the phenol function

Using a different approach, Glen and co-workers¹⁵⁷ built a pharmacophore based on the pharmacological activities of a series of novel C- and N-linked hydantoin analogs. Their model was used as a framework for the design of a diverse series of analogs with good affinity and selectivity for 5HT_{1D}. Suitable with the constraints required for good oral absorption, a potent selective 5HT_{1D} agonist, *S*-5-methyl-2-oxazolidinone analog, has been described. The dipolar azido group is a bioisostere¹⁵⁸ of the SO₂NH₂ and SO₂Me hydrogen bonding pharmacophores present in many selective COX-2 inhibitors and the azido analogs X and Y are useful biochemical agents for photoaffinity labeling of the COX-2 enzyme (Figure 37).

2.16.2.3 Reversal of Functional Groups

The reversal of the peptidic functional groups is often used in peptide chemistry. The obtained retropeptides are generally more resistant to enzymatic attacks (see Section 2.16.2.2.3). For thiorphan and *retro*-thiorphan an identical binding mode to the zinc protease thermolysin was demonstrated.¹⁵⁹ Similar inhibition values for thermolysin and

neutral endopeptidase were observed, whereas, for another zinc protease, ACE, noticeable differences for inhibition were found ([Figure 38](#)).

Nevertheless, the strategy of functional inversion can also be applied to nonpeptidic compounds. A historical example is the change from orthoform to neo-orthoform (orthocaine; [Figure 39](#)). The unwanted side effects, often encountered with aromatic para-amino substituted compounds ('para effects,' essentially of allergic origin) are abolished in the *meta* amino isomer whereas the local anesthetic activity is maintained. Similarly, the *meta* isomer of benoxinate has local anesthetic activity identical to that of benoxinate itself.¹⁶⁰

A first example is given by the guanethidine analogs.¹⁶³ As the original guanethidine patents covered ring sizes varying from five-membered to ten-membered rings, a possible way to get around them was the design of isolipophilic spiro systems (Dausse compounds a and b^{164,165}; **Figure 43**). Another possibility, originating from Takeda scientists, involves the use of an azetidine surrogate for the ethylene-diamine chain.¹⁶⁶ Finally, polycyclic systems can replace the

2.16.3.1.2 Splitting benzo compounds (benzo cracking)

Dissociation of a fused ring system (Figure 45), particularly by splitting a benzo compound, can sometimes improve its solubility but only slightly alters its pharmacokinetic profile and its long-term toxicity.

2.16.3.1.3 Restructuring ring systems

Among the above-mentioned molecular variations on ring systems, some can be used simultaneously. Thus, the splitting of the benzimidazole heterocycle in the anthelmintic thiabendazole and the concomitant association of the two five-membered rings yields tetramizole (Figure 46). One of the two enantiomers of tetramizole, the L-(–)-form or levamisole, is also a potent anthelmintic.

The change from the D1 selective dopaminergic agonist DPTI 3-(3,4-dihydroxyphenyl)-1,2,3,4-tetrahydroisoquinoline to the equally D1 selective compound SKF 38 393 is a combination of benzo cracking, a new benzo fusion, and ring enlargement (Figure 46). As a result, the compounds still resemble each other and are both recognized by the dopamine D1 receptor.¹⁷¹ An interesting example of a restructured ring system was designed by Meyer and

Figure 45 Splitting of fused rings often yields drugs with similar activity, sometimes with improved solubility and/or less toxicity.

co-workers¹⁷² for the design of 2-methoxybenz-[c]-hexahydro-indole as a surrogate of the very frequently used *ortho*-methoxy-*N*-aryl piperazine. It led to an enhancement of affinity and improved selectivity for α_{1A} receptor antagonism (Figure 47).

2.16.3.1.4 Ring dissociation

The natural compound khellin generated two families of cardioactive drugs: on one side the benzopyrones, illustrated by the 3-methyl-chromone¹⁷³ and chromonar (carbochromen), on the other side the benzofurans, illustrated by amiodarone (Figure 48). Both families possess antiarrhythmic and antianginal properties.

Figure 48 Cardioactive drugs obtained by dissociation of the khellin molecule into benzopyrones and benzofurans.

2.16.3.2 Scaffold Hopping

The goal of scaffold hopping is to design new structurally diverse compounds by a significant modification of the platform of a known active drug (the template). Other terms such as ‘leapfrogging,’ ‘lead-hopping,’ and ‘structure morphing’ have also been used to point out the discovery of novel molecules with biological activity comparable to a template and with a significantly different architecture. The concept is based on the assumption that structurally and chemically diverse structures interact with the same receptor eliciting similar biological activity. This can appear to be in contradiction to the usual way of performing the drug discovery process. In fact, for a long time, medicinal chemists have relied on the principle that structurally similar molecules have similar biological activity¹⁷⁴ to be inspired for modifying the structure of biologically active compounds in order to get new drug entities. However, there are also a large number of examples that contradict this principle¹⁷⁵ by showing that similar chemically related molecules have a different mechanism of action, interacting with different receptors. A notorious example of structurally similar molecules with different mode of action is given by the neuroleptic compound chlorpromazine, the antidepressant imipramine, and the antiallergic drug promethazine (**Figure 49**). It is remarkable that such structurally related compounds act on three different receptors. Speculation about chemical diversity and chemical similarity is beyond the scope of this chapter, and is considered here only in its broadest sense. Here, the scope and limitations of scaffold hopping in the drug discovery process is analyzed. Medicinal chemists usually adopt the scaffold hopping approach, which is in fact an enlargement of the bioisosterism concept, to fix some issues encountered during the lead optimization process; this has often successfully led to marketed drugs. The changes made in a scaffold hopping process may include the variation of the central core with a different heterocycle in order to get a better patent position, or the change of a lipophilic scaffold by a more polar one to improve the solubility and the pharmacological profile of the molecule. The improvement of the pharmacokinetic profile by changing a metabolically unstable scaffold for a more stable and less toxic one could also be considered as scaffold hopping or scaffold morphing.

2.16.3.2.1 Successful examples of scaffold hopping

The idea of scaffold hopping is not new. It is rather a new term to designate a very useful tool used quite often by medicinal chemists. In fact, an analysis of the marketed drugs reveals that many of them have different molecular structure though keeping the same substantial biological activity. Often, the different templates were suggested from the medicinal chemist’s intuition and experience; others were derived from hits yielded from high-throughput screening (HTS) of different compound libraries.

Figure 50 shows some COX-2 preferential inhibitors. It is noteworthy that structurally different scaffolds such as nimesulide, indomethacin, and valdecoxib have been successfully used as nonsteroidal anti-inflammatory drugs (NSAIDs)

Figure 49 Highly structurally similar molecules with completely different mode of action: chlorpromazine is a neuroleptic drug acting as a dopamine antagonist, promethazine is a H_1 antagonist agent used as an antiallergic, and imipramine is an antidepressant acting as a neurotransmitter uptake inhibitor.

Figure 50 A literature example of classical scaffold hopping: COX-2 preferential inhibitors.

with a preferential COX-2 inhibitor activity. On the other hand, all of the most recently approved ones have rather similar structures (see celecoxib, etoricoxib, and valdecoxib)^{176,177} and represent a good example of bioisosterism among pyrazole, isoxazole, and pyridine.

Another well-known example of successful scaffold hopping is given by the GABA_A ligands to the benzodiazepine site (**Figure 51**).¹⁷⁸ In this case two categories of scaffold hopping can be identified, one for the full agonist and the other one for the inverse agonist. It is interesting to notice that structurally diverse molecules like diazepam, zolpidem, zaleplon, and zopiclone all exert the same biological activity on the GABA_A receptor as anxiolytics and sedatives acting as full agonists. The same comment can be extended to the inverse agonist's class of compounds such as DMCM, compounds **18** and **19**, FG 8094, and compound **20**, which, despite a different molecular architecture, maintain a similar anxiogenic and convulsant activity together with learning and memory enhancing properties. It is important to underline the dualism of those ligands keeping in mind that structurally related molecules such as DMCM and FG 7142 interact with the benzodiazepine site of the GABA_A receptor but with different profiles, DMCM being an inverse agonist and FG 7142 a partial inverse agonist. A similar example is given by Ro 15-1788, FG 8094, and bretazenil where minor modifications of the structure led to an antagonist (Ro 15-1788), a selective inverse agonist (FG 8094), and a partial agonist (bretazenil).

2.16.3.2.2 Computational approaches to scaffold hopping

In the above paragraph some successful examples of classical scaffold hopping confirmed that structurally diverse molecules might be ligands of the same receptor inducing similar biological activity. Alternatively, one of the principles of modern medicinal chemistry is founded on the concept that structurally similar compounds will have similar modes of action. The corollary of this is that the more two molecules are structurally different, the fewer are the chances that these two molecules may have the same biological activity. The conclusion could be that a rational approach to scaffold

Figure 51 A literature example of scaffold hopping: GABA_A ligands binding to the benzodiazepine site.

hopping is not achievable for a medicinal chemist and that the discovery of different templates eliciting similar biological activity relies upon a serendipitous discovery or upon HTS screening. Efforts from experts in molecular modeling and cheminformatics have supplied useful tools to address this paradox and many publications have proposed different computational approaches to solve the challenge of finding a rational way to perform scaffold hopping.¹⁷⁹ The four principal types of computational approaches for scaffold hopping are: (1) shape matching, (2) pharmacophore searching, (3) fragment replacement, and (4) similarity searching.

One of the crucial steps of the drug discovery process is to find an optimal chemical entity (a hit) that interacts with a specific target. The hit must then be validated to identify a more potent, better absorbed, and less toxic lead compound that undergoes the optimization process to yield a valuable drug candidate. Starting with a good lead can save a lot of money and can shorten significantly the entire drug discovery process. The most widely used method for hit discovery is HTS. However, this method turned out to have some drawbacks and not to be the panacea for the hit identification. In fact, a good hit search relies upon the chemical diversity and druglike features of the screened library, and the number of compounds contained in it. It is useless pointing out that HTS performed on a library of hundreds of thousands of similar molecules is going to yield similar hits. In addition, the HTS approach can be rather expensive and time consuming, particularly when it is applied to functional receptor assays. There are two possible alternatives to the HTS of large libraries with a poor drug likeness feature: one is to screen smaller but smarter libraries, as highlighted in the selective optimization of side activities (SOSA) approach¹⁸⁰; the other is to perform a virtual screening based on pharmacophore models, shape matching, and similarity searching.

A successful example of topological pharmacophore search is given by Schneider¹⁸¹ in a prospective test using the program 'CATS' (Chemically Advanced Template Search) to predict a novel cardiac T-type Ca^{2+} channel blocking agents. Starting from mibefradil (**21**), a known T-channel blocking agent from Roche ($\text{IC}_{50} = 1.7 \mu\text{M}$) (Figure 52), as 'seed' for CATS, several molecules were identified. The 12 highest ranking molecules were tested for their ability to inhibit cellular Ca^{2+} influx. Nine compounds (75%) showed significant activity ($\text{IC}_{50} < 10 \mu\text{M}$) of which one compound (**22**, clopimozid) had an $\text{IC}_{50} < 1 \mu\text{M}$. This example shows that significantly diverse structural scaffolds maintain the same biological activity while preserving the essential function-determining points.

There are several computer-aided methods to build a pharmacophore model according to the information available on the ligand and/or on the receptor and several software programs exist on the market.¹⁸² Once the pharmacophore has been determined, there are two ways to identify new molecules that share its features and can elicit the same biological response: one is the de novo design that is based on the fragment recombination of known ligands; the other is the 2D topology or the 3D database searching.

Recently, an application of the de novo generation of chemotypes has been reported in the absence of receptor information¹⁸³ with the use of the software Skelgen^T. In order to verify if the scaffold hopping for ligand generation could be achieved where the nature of the 'lock' is unknown, an attempt was made to generate ligands for the estrogen receptor in the absence of any consideration of the actual receptor protein structure.

Through use of ligand superposition or a single bound conformation of a known active, a pseudoreceptor can be generated as a design envelope, within which novel structures are readily assembled. A set of five known estrogen receptor active training ligands (**23a–23e**) were selected (Figure 53). A pharmacophoric representation for these ligands was obtained allowing full ligand flexibility in the superposition process, which was then coded as site-point design constraints for use in Skelgen structure generation. A total of 446 ligands were generated, which satisfied the volume and pharmacophoric constraints. Figure 54 shows a few representative scaffolds that resulted from this study.

Virtual screening based exclusively on topological similarity (e.g., Daylight fingerprints) may produce sets of molecules that are structurally similar to the original query molecule. On the other hand, a pure 3D pharmacophore

Figure 52 Query structure **1** (mibefradil) and a high-ranking isofunctional structure **2** (clopimozid) derived from **1** by CATS.

Figure 53 Known ER ligands used for pharmacophore generation.

Figure 54 Representative scaffolds produced by Skelgen for the receptor for estrogens in de novo structure generation.

query has the potential to yield scaffolds with substantially different structures, which therefore risks losing binding affinity if compared to more topologically similar hits. A group from Hoffmann-La Roche has reported a successful example of virtual screening¹⁸⁴ based on a hybrid approach containing 3D pharmacophore information and topological elements using Catalyst software. In the quest for NPY5 receptor antagonists, three reference compounds from Banyu (24), Amgen (25), and Roche (26) (Figure 55) were chosen as seeds to build a 3D pharmacophore hypothesis containing topological elements also. Virtual screening of the Roche library yielded 632 molecules of which 31 compounds had an $IC_{50} < 10 \mu M$. The most interesting compound class is represented by 27 (Figure 56), which showed an IC_{50} of 40nM at the mouse Y5 receptor. Moreover, the 4-aminothiazole hit class was free of patent claims. This hit class was submitted to a chemistry optimization process to establish a structure–activity relationship and in

Figure 55 Seed compounds used to derive a 3D pharmacophore hypothesis including topological features.

Figure 56 Aminothiazole (**27**) with IC_{50} 40 nM.

Figure 57 Some potent analogs issued from the first exploratory SAR around the aminothiazole hit **27**.

only two rounds of iterative optimization by parallel synthesis, a broader understanding of the factors influencing the potency was obtained. **Figure 57** shows some of the most potent analogs identified by this process.

Another application of virtual screening to the hit-to-lead optimization process for the design of optimized hit series is the rational morphing strategy based on the bioisosteric approach. Balakin and co-workers¹⁸⁵ used the program BIOISOSTER module of ChemoSoft to design a second-generation series against the *abl* tyrosine kinase in order to reduce some toxicological issues and to improve the intellectual property (IP) position of the initial hits. **Figure 58** illustrates a hit that showed low potential to generate new IP, and **Figure 59** shows a hit containing a potentially toxic *N*-aroylhydrazone group. The algorithm of BIOISOSTER found some bioisosteric analogs of these primary hits that were synthesized. The novel chemotypes, though structurally different from the primary hits, showed similar or slightly increased potency. In this case, a better patent position was developed (**Figure 58**) and molecules without toxic functionality were obtained (**Figure 59**).

2.16.4 Analysis of the Modifications Resulting from Bioisosterism

It is rare that the replacement of a part of a molecule by an isosteric or bioisosteric group leads to a strictly identical active principle. In practice, this is not actively sought, and it is preferable that the new compound produces a change as compared to the parent molecule. In general, the isosteric replacement, even though it represents a subtle structural change, results in a modified profile: the essential properties of the parent molecule will remain unaltered, while others will be changed. Bioisosterism will be productive if it increases the potency, selectivity, and bioavailability or decreases

Figure 58 Bioisosteric transformations of the primary pyrazolopyrimidine scaffold and novel active chemotypes.

Figure 59 Bioisosteric transformations of an indol-2-one-hydrazone scaffold and novel active chemotypes.

the toxicity and undesirable effects of the compound. In proceeding to isosteric modifications, one will focus predominantly on a given parameter, structural, electronic, or hydrophilic, but this modification can lead simultaneously to the alteration of several other parameters.

2.16.4.1 Structural Parameters

These will be important when the portion of the molecule involved in the isosteric change serves to maintain other functions in a particular geometry. That is the case for tricyclic psychotropic drugs (**Figure 60**). In the two antidepressants (imipramine and maprotiline), the bioisosterism is geometrical insofar that the dihedral angle α formed by the two benzo rings is comparable: $\alpha = 65^\circ$ for the dibenzazepine and $\alpha = 55^\circ$ for the dibenzocycloheptadiene.¹⁸⁶ This same angle is only 25° for the neuroleptic phenothiazines and the thioxanthenes. In these examples, the part of the molecule modified by bioisosterism is not involved in the interaction with the receptor. It serves only to orient correctly the other elements of the molecule.

The structure of various bioisosteric retinoic acid receptor agonists highlights the dominantly geometric parameter of this bioisostery and thus can also be considered as scaffold hopping (**Figure 61**).¹⁸⁷

Figure 60 The tricyclic antidepressants (imipramine and maprotiline) are characterized by a dihedral angle of 55° to 65° between the two benzo rings, this angle is only 25° for the tricyclic neuroleptics (chlorpromazine, chlorprothixene).

Figure 61 Bioisostery in its broadest sense can be considered as scaffold hopping.

2.16.4.2 Electronic Parameters

Electronic parameters govern the nature and the quality of ligand–receptor or ligand–enzyme interactions. The relevant parameters will be inductive or mesomeric effects, polarizability, pK_a , capacity to form hydrogen bonds, etc. Despite their very different substituents in the *meta* position, the two epinephrine analogs (**Figure 62**) exert comparable biological effects, both being alpha adrenergic agonists. In fact, the key parameter lies in the similar acidity as shown by their pK_a values.¹⁸⁸

2.16.4.3 Solubility Parameters

When the functional group involved in the isosteric change plays a role in the absorption, the distribution, or the excretion of the active molecule, the hydrophilic–lipophilic parameters become important.

In order to better illustrate this concept, we can quote the example of the replacement of $-\text{CF}_3$ ($\pi = +0.88$) by $-\text{CN}$ ($\pi = -0.57$) in an active molecule (**Figure 63**). The electron-attracting effect of the two groups will be comparable, but the molecule with the cyano function will be clearly more hydrophilic. This loss in lipophilicity can then be corrected by attaching elsewhere on the molecule a propyl, isopropyl, or cyclopropyl group.

Figure 62 An example of bioisosterism, or nonclassical isosterism; the methylsulfonamide substituent has comparable acidity to the phenolic hydroxyl group.

Figure 63 The loss of lipophilicity resulting from the bioisosteric exchange of a CF_3 for a CN has to be compensated for by the equivalent of a three carbon residue.

2.16.5 Anomalies in Isosterism

In this section two unusual applications of the bioisosterism concept are developed. They concern the exchange between fluorine and hydrogen and between oxygen and methylene groups.

2.16.5.1 Fluorine–Hydrogen Isosterism

Fluorine is one of the most commonly used classical bioisosteric replacements. Although it neither resembles the other halogens nor hydrogen, it has been used as a reasonable hydrogen mimic.¹⁸⁹

2.16.5.1.1 Steric aspects

It has been claimed for long time that fluorine is nearly the same size as hydrogen. This has turned out to be incorrect. If we take the commonly accepted van der Waals values of Bondi¹⁹⁰ or Williams and Houpt¹⁹¹ instead of the obsolete Pauling values, fluorine is in actual fact close to the size of oxygen, and considerably smaller than the rest of the halogen atoms, and even than chlorine (Table 10).

The C–F bond length (1.39 Å) is also in the same range as the C–O bond length (1.40 Å), much bigger than C–H (1.09 Å). As a consequence, the effective van der Waals radius of trifluoromethyl (CF_3) is equal to isopropyl ($\text{CH}(\text{CH}_3)_2$) with 2.20 Å, and larger than methyl (CH_3 , 1.80 Å).¹⁹² However, there is a difference between the steric effect of fluorine, which is dependent on the transition state, and its steric size, which is an absolute value.¹⁹³ For example, if the internuclear distance is 2.5 Å, there is no H— (see similar examples)—> H or H—F steric effect (steric repulsion energy = 0 kcal mol^{−1}). But if the distance is 2.0 Å, the H—F steric repulsion energy is 1.3 kcal mol^{−1}, whereas the H—H steric repulsion energy is still negligible.

2.16.5.1.2 Electronic aspects

The electronic properties of fluorine make it a unique atom in its properties. It is the most electronegative atom in the periodic classification, and it forms particularly stable bonds with carbon atoms. The C–F bond energy is higher than

Table 10 Van der Waals radii (Å)

	<i>Pauling</i>	<i>Bondy</i> ¹⁹⁰	<i>Williams and Houpt</i> ¹⁹¹
H	1.20	1.20	1.15
F	1.35	1.47	1.44
Cl	1.80	1.75	–
O	1.40	1.52	1.44

Reproduced with permission from Smart, B.E. *J. Fluor. Chem.* **2001**, 109, 3–11.

**Figure 64** Fluorine atoms in the para position of the phenyl rings prevent metabolic hydroxylation.**Figure 65** The half-life of quinine is approximately 11 h (oxidation in position 2 by CYP). For its analog, mefloquine, the half-life is 2–4 weeks.

the C–H or C–O bond (with 116, 99, and 85 kcal mol^{−1}, respectively), which makes the C–F bond less sensitive to metabolic degradation as found in flunarizide or in flufenisal (**Figure 64**). This particular stability explains the unaltered incorporation of fluoroacetic acid by living organisms in place of acetic acid¹⁹⁴ or the use of 5-fluoro-nicotinic acid and 5-fluoro-uracil as antimetabolites.

Fluorine also differs from the other halogens because it is rarely ionized or displaced. (An exception is made for aromatic systems if there is a para strong electron-withdrawing group.) Thus, for the β-haloalkylamines (nitrogen mustards), the alkylating activity is lost when chlorine or bromine are replaced by fluorine or by hydrogen.¹⁹⁵ This remarkable stability makes the C–F bond more resistant to direct chemical attack by cytochrome P450 (CYP) oxidases. It can also block oxidation at specific positions (**Figure 65**). A fluorine on a phenyl ring decreases the rate of interaction between the π-system and the CYP(FeO)³⁺. Fluorine is also involved as a replacement for CH₃, which is prone to metabolism by CYP oxidases, whereas the CF₃ group is not susceptible to oxidation.¹⁸⁹

Finally, hydrogen – fluorine bioisosterism is used to obtain analogs more resistant to metabolic degradation therefore increasing the biological half-life of the drug candidate and avoiding the formation of toxic metabolites.

2.16.5.1.3 Absence of d orbitals

The fact that fluorine has no d orbitals does not allow it to participate in resonance effects with a π electron donor (**Figure 66**). This explains why *p*-fluorophenol is slightly less acidic than phenol, while for other *p*-halogenated phenols the acidity changes in parallel with the atomic number¹⁸⁹ (**Table 11**).

Figure 66 The resonance between the OH lone pair and the X group is not possible if X = F.

2.16.5.1.4 Lipophilicity

One interest of bioisosterism replacements is to change the physical properties of the analog. Fluorine has particular properties (Table 12) and its presence in a molecule could dramatically change its physical characteristics compared to the nonfluorinated analog. The effects of fluorination depend on the aromatic or the aliphatic nature of the fluorinated compound. In aromatic systems, fluorination always increases lipophilicity, and sometimes in a very significant manner (Table 13). When the fluorination takes place on aliphatic compounds, the prediction of the effect on lipophilicity is more difficult. Hereafter we formulate some general rules, and summarize the corresponding examples in Table 14¹⁹³:

1. With alkanes, fluorination decreases the lipophilicity of the molecule.
2. With alcohols, the lipophilicity depends on the distance between the fluorine and the oxygen. If it is less than three C–C bonds in length, it increases, and if it is more, it decreases.
3. With acids and ketones, the presence of fluorine clearly modifies the electronic properties of the compounds. The hydration of aldehydes and ketones is increased, as is the acidity and hydrogen bonding capability of carboxylic acids. In these conditions, the mixture of solvents used to determine the lipophilicity plays a major role, and its transposition in biological systems is very difficult.

When the lipophilicity effect of fluorine is studied on ionizable compounds, it is important to consider other parameters such as pH. In these cases, the electronic effect of fluorine on the pK_a of these molecules is as important as its direct contribution to lipophilicity. Table 15 summarizes the $\log D$ and pK_a values of fluorinated propranolol analogs.¹⁹⁶ For propranolol analogs the introduction of fluorinated amine substitutions (R = CHF₂, CF₃, CH₂CF₃) close

to the basic nitrogen exerts a double effect on lipophilicity: (1) the fluorinated analogs are more lipophilic than their nonfluorinated analogs; and (2) fluoro substitution diminishes the basicity of the molecule and thus augments the proportion of the nonionized species and contributes to the elevation of the global lipophilicity expressed as $\log D$.

For an acid, the introduction of fluorine in the α -position enhances the acidic character of the molecule, because of the electron-withdrawing effect. So, the pK_a is decreased, as is the lipophilicity at physiological pH.¹⁹⁷

2.16.5.1.5 Case studies

2.16.5.1.5.1 Tripelennamine analogs

Starting from tripelennamine (**Figure 67**, $X = H$), an antihistaminic drug, a series of 4-phenyl halogenated analogs have been synthesized. In vivo, *para*-hydroxylation of the phenyl ring seems to happen readily. To avoid it, the best candidate is the *para*-fluoro compound.

2.16.5.1.5.2 Roflumilast analogs

Piclamilast and its difluorinated analog, roflumilast, are both selective phosphodiesterase inhibitors (PDE4) with the same potency *in vitro*. However, *in vivo*, roflumilast and its *N*-oxide, the primary metabolite, have superior potency, probably due to a weak oral bioavailability of piclamilast¹⁹⁹ (Figure 68). Roflumilast is in phase III clinical trials for asthma and in phase II for chronic obstructive pulmonary disease (COPD).

2.16.5.2 Exchange of Ether Oxygen and Methylene Group: The Friedman Paradox

Ether oxygen atoms and methylene groups possess a similar tetrahedral structure and should normally be isosteric. In fact $O \leftrightarrow CH_2$ isosterism very often yields anomalous results and brought Friedman² to the interesting observation “that the omission of the ether oxygen changes biological activity much less in some cases than the replacement by the isosteric methylene group” (Figure 69). In the meperidine series, for example, the change from the *N*-phenoxypropyl derivative to the isosteric phenoxybutyl decreases the analgesic potency by a factor of ten, whereas the omission of the ether oxygen yields a slightly more potent compound.¹⁶¹ A possible explanation for this anomalous behavior may be that the omission of the ether oxygen yields a compound closer in terms of lipophilicity than its replacement by a methylene. Other examples are given by Schatz in the second edition of Burger’s *Medicinal Chemistry*.²⁰⁰

Close examples, which do not correspond strictly to the Friedman paradox, can be found in the resemblance of the phenylethyl type β -blockers (e.g., sotalol, dichloroisoprenaline) to the phenoxypropanol type (e.g., practolol, acebutolol) and in the affinity for the same receptor of nicotine and the longer chain analogs of the ABT series^{201,202} (Figure 70). According to docking experiments performed on a series of nicotinic agonists by Bisson *et al.*²⁰³ on nicotine and the ABT compounds, the aromatic rings of the different molecules, overlap and interact with a same site in the receptor while the side chains of the different molecules do not overlap with each other and occupy a different part of the binding pocket.

Figure 68 Suppression by piclamilast, roflumilast, and its *N*-oxide metabolite of LPS-induced circulating TNF α in Sprague-Dawley rats.

Figure 70 Two examples for which the omission (or, in the reverse way, the insertion) of a methylene-oxy group leads to similarly acting compounds.

Figure 71 Unusual bioisosterism between a methylene-oxy group and a carboxamide.

A very unusual bioisosteric relationship between the methyleneoxy group and a carboxamide was observed by Sugimoto and colleagues²⁰⁴ during early SAR studies, which led to the acetylcholinesterase inhibitor donepezil (Figure 71).

2.16.6 Minor Metalloids-Toxic Isosteres

This section is dedicated to more ‘exotic’ applications of the bioisosterism concept that involve the use of elements such as silicon, germanium, boron, and selenium. The use of these elements as carbon replacements in existing drugs is an approach for new drug-like candidates with new biological profiles and a strong IP position.

2.16.6.1 Carbon–Silicon Bioisosterism

In the periodic table of the elements, silicon is directly below carbon, which makes them, according to Erlenmeyer’s expansion of the isosterism concept,²⁰⁵ real isosteres. That is why the replacement of carbon by silicon in biologically active substances has been an attractive proposition for many organic chemists. However, this similarity remains limited. For reviews on the subject, see Fessenden and Fessenden,²⁰⁶ Tacke,^{207–209} Ricci *et al.*,²¹⁰ or more recently Liu *et al.*²¹¹

2.16.6.1.1 Toxicological aspects²¹²

From a chemical point of view, the synthesis of silicon analogs can add substantial chemical diversity and also adds interesting biological functionalities for drug discovery. However, this has not been fully exploited, mainly because of the potential toxicity of silicon-containing molecules. However, most of the acute toxicological data (LD_{50} values) for organosilicon compounds are in the range of their carbon analogs. In 1971, Garson²¹³ said that “evidence is also now available to establish that organosilicon compounds *per se*, are not toxic.” In a more recent perspective,²¹⁴ 74 compounds from different families were studied, and the conclusion was that, for chemically stable molecules, silicon conveys no systematic toxicological liability.

2.16.6.1.2 Silicon in medicinal chemistry

The silicon-containing bonds are always longer than their carbon analogs. For example, in the sp^3 hybridization state, the length of the C–Si bond is around 1.87 Å but the C–C bond is 1.54 Å.²¹⁵ The fact that silicon is more electropositive than carbon (and even more so compared to oxygen and nitrogen) allows the silanols to be stronger hydrogen bond donors than the corresponding carbinols.²¹⁶ This difference can produce stronger interactions with pharmacophores where carbinol acts as a hydrogen bond donor, and increases the potency of the compound.

Regarding lipophilicity, silicon-containing molecules are more lipophilic than their carbon bioisosteres. This modification of lipophilicity can be clearly observed *in vivo*.²¹⁷ A small increase in lipophilicity can dramatically increase the volume of distribution and therefore the tissue penetration. So, these silicon bioisosteres will be less prone to hepatic metabolism and will improve the plasma half-life when liver metabolism is significant. It will also help these drug candidates to cross the blood–brain barrier.²¹⁸

From a chemical point of view, silicon-containing molecules are in general more sensitive to hydrolysis and nucleophilic attack. That is why, due to the chemical reactivity of silicon, carbon–silicon isosterism is generally

Figure 72 Organosilicon active substances.

practiced when the silicon can replace a carbon present in the center of a quaternary structure. These organosilicon compounds can exhibit various biological activities (**Figure 72**):

- acetylcholinesterase inhibitors (*m*-trimethylsilyl-phenyl *N*-methylcarbamate and *m*-trimethylsilyl- α -trifluoroacetophenone (zifrosilone))^{219–221};
- CNS depressant (sila-meprobamate)²²²;
- anticholinergic (sila-pridinol)²²³;
- fungicide for agricultural use (flusilazole)²²⁴;
- potent and selective 5HT_{2A} antagonism ((+)-RP 71,602)²²⁵;
- steroid analog (silabolin, tested for the treatment of muscle wasting disease, chronic ‘cor pulmonale’ (ischemic heart disease and chronic circulatory insufficiency))^{226–228}; and
- α_2 -adrenergic antagonism (sila-atipamezole),²²⁹ etc.

2.16.6.1.3 Reactivity toward S_N2 and metabolic attacks

The reactivity of silicon is very different from that of carbon. Indeed, even when the silicon is tetrasubstituted, it can be easily attacked. This is due to the vacant d orbital of silicon that can still be hydroxylated by a lateral attack.²³⁰ As an example, 1-chloro-1-sila-bicyclo-(2,2,1)-heptane can undergo an S_N2 reaction, whereas it is not possible with the corresponding carbon derivative (**Figure 73**). The fact that a lateral attack is possible explains why sila-meprobamate has a shorter duration of action than its carbon isostere on a model of tranquilizing activity in mice (rotarod test, potentiation of hexobarbital-induced sleep; intraperitoneal injection).²²² When sila-meprobamate is given orally, it is practically inactive. Indeed, it is quickly metabolized. The first metabolite formed has been characterized.²³¹ It is a di-siloxane (**Figure 72**), obtained by condensation in acidic conditions of unstable silanols.

Another metabolic oxidation known with organosilicon compounds is that of the trimethylsilyl group. In this case, the metabolism occurs not on the silicon but on one of methyl groups (Si-CH₃ \rightarrow Si-CH₂-OH).²²⁰ This is what happens for the two phenyl-trimethylsilyl-derived acetylcholinesterase (AChE) inhibitors, where the trimethyl-silyl group mimics the trimethyl-ammonium function present in acetylcholine.

Figure 73 Owing to the presence of a vacant d orbital, a lateral attack can substitute for dorsal attacks in organo-silicon derivatives.

Figure 74 The tetrahedral intermediate **28** and the corresponding silicon-diol mimetic **29** are stabilized by the interaction with the protease.

Figure 75 The structure of some silicon diol-based protease inhibitors.

2.16.6.1.4 Silicon diols²³²

Even if silicon-containing molecules are more sensitive toward nucleophiles, in some cases they are more stable than their carbon analogs, for example, regarding the interaction of a protease toward amino acids. The reaction mechanism of protease is to convert the carbonyl group of the target peptide bond into an enzyme-stabilized tetrahedral diol (**Figure 74**). Unfortunately, this diol collapses quickly to give two peptidic side products. Here, the replacement of the $C(OH)_2NH$ group of the transition state by a more stable $Si(OH)_2CH_2$ moiety represents an ideal, nonhydrolyzable analog of the tetrahedral transition state. Thanks to the stronger hydrogen bonding, it results in potent and selective inhibitors of metallo- (angiotensin-converting enzyme),²³³ aspartic (HIV protease),²³³ and serine (human elastase) protease²³² (**Figure 75**).

2.16.6.1.5 Diphenylpiperidine analogs²³²

The diphenylpiperidine moiety, with a quaternary carbon bearing two phenyl rings, can be considered to be a privileged structure, as it is found in many classes of biologically active molecules. The corresponding sila analog has been

investigated as a possible bioisostere of quaternary carbon. In the case of budipine, studied as an agent to treat Parkinson's disease, the sila analog has shown increased lipophilicity that allows improved blood–brain barrier permeability.²³⁴ Another example is given by niguldipine, where sila substitution of the quaternary carbon does not affect the in vitro pharmacological profile. These data suggest that sila-niguldipine derivatives may therefore be of potential benefit in the treatment of diseases such as benign prostatic hyperplasia²³⁵ (Figure 76).

2.16.6.1.6 Clinical studies²¹²

To date, no silicon-containing drug has been approved by the regulatory authorities in the US or Western Europe. However, some organosilicon compounds have been (or are still) studied in clinical phase II trials. Among them the following compounds can be cited (Figure 77):

- silperisone, a centrally acting muscle relaxant²³⁶;
- Am-555S/TAC-101 from Taiho Pharmaceutical, an orally active retinoic acid receptor (RAR)- α - β -agonist for the treatment of lung cancer²³⁷; and
- karenitecin (BNP1350) from Bionumerik, a camptothecin analog.²³⁸

2.16.6.1.7 A few words about C/Si/Ge isostery

During the 1980s, germanium was listed as a possible anticancer drug, and even spirogermanyl and Ge-132 were sold (Figure 78). However, a decade of human clinical trials failed to conclusively show a benefit.²³⁹ The major problem

Figure 76 Diphenylpiperidine sila-analogs.^{234,235}

Figure 77 Silicon-containing drugs in phase II trials.

Figure 78 Organogermanium active substances.

with organogermanium compounds is their purity, as it is extremely difficult to separate the final compounds from the germanium salt used as starting material, and the germanium salts are known to be toxic.²⁴⁰ Some examples of SARs with germanium-containing molecules are available in the literature,^{241–243} and their biological results indicate strong bioisosterism among carbon, silicon, and germanium.

2.16.6.2 Carbon–Boron Isosterism

Boron is well known to be an essential element for higher plants. Indeed, its use in medicinal chemistry is generally limited to that of a coupling reagent. The potential of boron-containing compounds in medicine thus lags behind other elements. The most important medical use of boron derivatives today is the treatment of certain tumors by boron neutron capture therapy (BNCT),^{244–246} which consists of delivering a ^{10}B nucleus directly inside the tumor cells. The major challenge of this therapy is to ensure effective concentrations of the product in the treated tumor ($20\text{--}30\text{ }\mu\text{g }^{10}\text{B g}^{-1}$)²⁴⁷ – thereby keeping toxicity below the acceptable threshold.

2.16.6.2.1 Toxicity

In vivo, organoboron derivatives are sensitive to hydrolytic degradation, leading to the formation of boric acid. The long-term effects of boric acid in several species have been reported, with some toxicity on the male reproductive system and on developmental stages. The most sensitive toxicity endpoint for boric acid appears to be developmental toxicity in rats with a NOAEL (no observed adverse effect level) of $55\text{ mg of boric acid kg}^{-1}\text{ day}^{-1}$,²⁴⁸ which represents a daily consumption of 3.3 g of boric acid for humans.²⁴⁹

It has been shown that the use of boric acid at a high dose level has teratogenic effects in chickens, owing to a deficiency in riboflavin (vitamin B_2). The damage can be prevented by the administration of riboflavin.^{250,251} In man, chronic utilization of boron-containing compounds can induce borism,²⁵² whose symptoms include dry skin, gastrointestinal disturbances, etc. Owing to the high quantities needed to observe a toxic effect, boric acid is classified by the World Health Organization (WHO) as very low in toxicity when ingested²⁵³ (oral rat $\text{LD}_{50} = 2660\text{ mg kg}^{-1}$; as an estimation, oral man $\text{LD}_{50} = 15\text{--}20\text{ g kg}^{-1}$ ²⁵⁴). Investigations of the effects of boric acid on reproduction have not detected any effect on male fertility^{255,256}; hence, boric acid is classified as a group E carcinogen,²⁵⁷ which means that it is not considered to cause cancer (based on results from animal studies).

2.16.6.2.2 Interest and applications

Boron is peculiar in its ability to form trigonal as well as tetrahedral bonding patterns and to create complexes with organic functional groups, many of biological importance.²⁵⁸

Only a few medicines containing boron are known. The only two boron-containing natural products isolated so far are boromycin²⁵⁹ (the first isolated) and aplasmomycin.²⁶⁰ Both have a tetrahedral boron atom in the center of the structure, complexed with two vicinal diol groups,²⁶¹ and have antibiotic activity against Gram-positive bacteria. Most of the synthetic medicines in this class possess a boric acid or a boronic acid moiety used to esterify an α -diol or an *o*-diphenol. As an example, we can mention the antimony borotartrates used for injectable catecholamine solutions, like tolboxane,²⁶² a tranquilizer commercially available some decades ago. A more recent example is given by the phenylboronic esters of chloramphenicol.²⁶³

Boron-containing molecules, some examples of which are shown in **Figure 79**, have been tested on several targets and have shown different biological activities. Boronic analogs of amino acids have been identified as chymotrypsin and elastase inhibitors,²⁶⁴ and more recently as an antineoplastic agent (Velcade, a proteasome inhibitor) (**Figure 79**).

Figure 79 Organoboron active substances.

Figure 80 The dodecaborane analog has a potency 10-fold greater than that of the estradiol (luciferase reporter gene assay).²⁶⁹

Carboxyboranes complexed with a tertiary amine ($R_3N \cdot H_2B-COOH$) are considered as boron amino acid isosteres due to the isoelectronic features. Compounds containing carboxy boranes have shown anticancer, hypolipidemic, and antifungal activity.²⁶⁵ Diazaborines are active against malaria,²⁶⁶ and oxazaborolidines possess antibacterial activity.²⁶⁷

Boronic chalcones are reported to be antitumor agents. Some of them are able to inhibit the growth of human breast cancer cells and are 5- to 10-fold less toxic toward normal breast epithelial cells.²⁶⁸ The remarkable hydrophobic character and geometry of carboranes (where both carbon and boron are hexacoordinated) allows their use for scaffold hopping in biologically active molecules that interact hydrophobically with receptors^{269–271} (Figure 80).

2.16.6.2.3 Boranophosphate salts

Phosphate and phosphate-containing molecules play a major role in numerous biological systems.²⁷² However, the unwanted lability of the P–O bond has promoted the search for more stable bioisosteres.²⁷³ The borane group (BH_3) is

Structure of nucleoside triphosphate (NTP) and 5'-(α-P-borano)triphosphate (NTP-α-BH₃)

When X=BH₃, the incorporation efficiency is increased 9-fold compared to compound where X=O (presteady-state conditions with viral reverse transcriptase).

Figure 81 α-P-Boranotriphosphates.^{274,276,277,281,282}

isoelectronic and isosteric with oxygen, but boranophosphate analogs have a different charge distribution and polarity than the corresponding natural nucleotides.²⁷⁴ Nucleoside borano-phosphonate analogs are not expected to form H bonds, or to coordinate with metals,²⁷⁵ but they are highly soluble in water because the borane group brings about a significant change in the nucleotide lipophilicity.²⁷⁴

The boranophosphate moiety is a new type of nucleotide modification expected to improve metabolic and chemical stability of the nucleotide derivative. A common example is given by the nucleoside 5'-(α-P-borano) triphosphate (NTP-α-BH₃),^{274,276,277} in which a borane group (BH₃) substitutes one of the nonbridging α-phosphate oxygens in nucleoside 5'-triphosphate (NTP) (Figure 81). This group is nontoxic²⁷⁴ though it is not a natural constituent of the organism. Moreover, the presence of the BH₃ group at the α-phosphate of clinically relevant dideoxy compounds, such as 3'-azido-3'-deoxythymidine,²⁷⁸ 2',3'-didehydridideoxythymidine (D4T),²⁷⁸ and 2',3'-dideoxyadenosine (ddA),^{279,280} improves both phosphorylation by nucleotide diphosphate kinase and incorporation by HIV-1RTs.^{278–280}

With the isosteric replacement of oxygen by borane, Nahum and co-workers have developed potent (in the range of ATP) and stable (under physiological conditions) purinergic P2Y₁-R agonists.²⁸¹ The same replacement on the phosphate chain of acyclothyridine triphosphate has led to more active compounds²⁸² (Figure 81).

2.16.6.2.4 Boron-containing molecule designed for boron neutron capture therapy

In this kind of biological approach, the goal is to deliver a ¹⁰B nucleus directly inside the tumor cells. Accordingly, a variety of boron-containing molecules have been used: carboranes,^{283,284} polyamines,²⁸⁵ amino acids,²⁸⁶ nucleoside,²⁸⁷ antisense agents,²⁸⁸ porphyrins,²⁸⁹ and peptides²⁹⁰ (Figure 82).

2.16.6.3 Bioisosteres Involving Selenium

In addition to the isostery between selenium and sulfur, as one appears below the other in the periodic table, these two atoms have very similar physical properties. The radius of selenium is only 12.5% bigger than that of sulfur, i.e., 1.17 Å for 1.04 Å (for comparison, the difference between oxygen and sulfur is about 43%), and their electronegativity is rather similar. Selenium is an essential trace element because it has been found to be a component of mammalian glutathione peroxidase as selenocysteine (SeCys). SeCys is also found in the active site of two mammalian enzymes: phospholipid hydroxide glutathione-peroxidase (GSH-Px) and 5-deiodinase. Nowadays, selenium and its derivatives are generally studied as cancer chemopreventive agents in a variety of organs,^{291–296} and not only as mineral supplements.

Figure 82 Examples of compounds designed for BNCT.

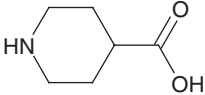

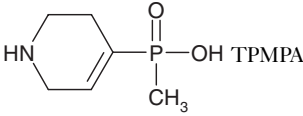

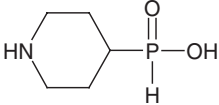

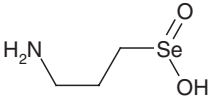

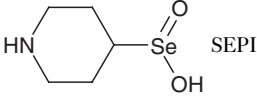

Figure 83 Organoselenium compounds with biological activities.

2.16.6.3.1 Toxicity

Before the 1950s, selenium was considered only as a poisonous substance. Then, its nutritional role was appreciated, and 30 years later, it was found to have a role in the antioxidant defense system.^{297,298} Nevertheless, selenium and its inorganic derivatives are toxic for long-term or high-dose administration in humans^{299,300} due to their metabolic conversion to H_2Se . The only exceptions are ^{75}Se derivatives used for diagnostic purposes (e.g., ^{75}Se -selenomethionine,

used as a radioactive imaging agent in pancreatic scanning). Organoselenium compounds are usually found to be less toxic than the inorganic forms of selenium, and they are comparatively more bioavailable.³⁰¹ Finally, on the basis of extensive studies, the upper limit of selenium per day was defined as 400 µg.^{302–304} However, a consumption of 700 µg selenium per day has been reported in humans without adverse clinical symptoms.^{304,305}

2.16.6.3.2 Applications

In 1973, a review containing a large number of selenium derivatives considered as chemotherapeutic agents was published.³⁰⁶ Since then, organoselenium compounds have been mostly studied for their cancer preventive activities. We can cite the dietary *p*-methoxybenzeneselenol, found to inhibit azoxymethane-induced hepatocarcinogenesis in female rats without clinical toxicity,³⁰⁷ or *p*-methoxybenzyl selenocyanate and 1,4-phenylenebis-(methylene)selenocyanate, which prevent both precancerous cell and tumor growth with no side effects.³⁰⁸ Compared to sulfur compounds, the selenium isosteres appear to be much more effective in cancer prevention.³⁰⁹

Seleno-containing molecules have also been tested on other targets (Figure 83). 1,3-Selenazol-4-one derivatives are inhibitors of nitric oxide (NO) production, which plays a deleterious role in brain inflammation and neuronal death, and inducible NO synthase (iNOS) expression in LPS-induced BV-2 cells. Selenazolidine molecules can be considered prodrugs of SeCys used to deliver selenium.³¹⁰

The relative toxicity of seleno-containing molecules is an interesting characteristic for photodynamic therapy (PDT) as a protocol for treating cancer, as well as other diseases.³¹¹ The molecule should have a great ratio between toxicity in the dark (LD₅₀) and phototoxicity (EC₅₀). Selenopyrylium molecules are good candidates because of the heavy atom effect increasing singlet oxygen yield.^{312,313} A recent study³¹⁴ on isonipecotic bioisosteres has shown that the seleno bioisosteric replacement can lead to compounds with interesting biological activity: selective GABA_C receptor antagonists (Table 16).

The only selenium-containing drug candidate, currently in phase III trials, is ebselen (Figure 84). It possesses antioxidant and anti-inflammatory properties due to its ability to mimic the hydroperoxide reducing ability of the selenoenzyme glutathione-peroxidase.³¹⁵ Because of its strongly bound selenium moiety, only metabolites of low toxicity are formed.³¹⁶

For a review on synthetic organoselenium compounds as mimics of GPx, see Mugesh and Singh.³¹⁷

Biographies

Camille Georges Wermuth, PhD, Professor and Founder of Prestwick Chemical, was Professor of Organic Chemistry and Medicinal Chemistry at the Faculty of Pharmacy, Louis Pasteur University, Strasbourg, France from 1969 to 2002. He founded the Prestwick Chemical Inc. in 1999 in which he acts as President and CSO. Professor Wermuth's main research themes focus on the chemistry and the pharmacology of pyridazine derivatives. Particularly, the 3-aminopyridazine pharmacophore allowed him to accede to an impressive variety of biological activities. Among them one can cite: antidepressant and anticonvulsant molecules; inhibitors of enzymes such as monoamine oxidases, phosphodiesterases, and acetylcholinesterase; ligands for neuro-receptors: GABA-A receptor antagonists, serotonin 5-HT₃ receptor antagonists, dopaminergic and muscarinic agonists.

Besides about 300 scientific papers and about 60 patents, Prof Wermuth is co-author or editor of several books. Particularly, the second edition of his book *The Practice of Medicinal Chemistry* was published by Academic Press in May 2003. The first and the second editions were translated into Japanese and the first edition into Italian. Together with Dr P H Stahl, he also published the *Handbook of Pharmaceutical Salts, Properties Selection and Use* by Wiley-VCH in 2002.

Professor Wermuth has been President of the Medicinal Chemistry Section of the International Union of Pure and Applied Chemistry (IUPAC) from 1988 to 1992 and from January 1998 to January 2000 was President of the IUPAC Division on Chemistry and Human Health.

Paola Ciapetti, PhD, Head of Medicinal Chemistry, joined Prestwick Chemical, Inc. in October 2001 as Senior Chemist in charge of the Medicinal Chemistry Department with Bruno Giethlen. Paola came to Prestwick Chemical, Inc. from the Medicinal Chemistry Department of Albany Molecular Research, Inc. (Albany, NY) where she worked for more than 1 year as Senior Research Chemist. While at AMRI she brought a relevant contribution to an oncology project developed in collaboration with Eli Lilly & Co. She is one of the co-inventors of the patent issued from that work. Prior to this experience Paola spent more than 2 years as Visiting Scientist at Eli Lilly & Co. (Indianapolis, IN). During this tenure she worked on CNS-related projects. Paola has acquired a broad and deep experience in both organic and medicinal chemistry. She is fluent in three languages (Italian, English, and French).

Paola graduated Magna Cum Laude with an MSc in chemistry from the University of Florence (Italy) in 1994. In 1998, she received a PhD in organic chemistry from the same university under the supervision of Prof Maurizio Taddei. During her thesis she completed a tenure at the University of Strasbourg under the supervision of Dr André Mann. Her studies have focused on the development of new methodologies for the synthesis of nonnatural alpha amino acids, inhibitors of proteases, and nucleic acids analogs. She is author of eight peer-reviewed scientific papers and 10 patents.

Bruno Giethlen, PharmD, PhD, is Head of Medicinal Chemistry in charge of the Medicinal Chemistry Department with Paola Ciapetti, PhD at Prestwick Chemical, Inc. in Strasbourg. Prior to joining Prestwick Chemical, he was Senior Research Chemist at Albany Molecular Research, Inc. (Albany, NY) for 1 year where he worked on oncology programs in collaboration with Eli Lilly & Co. Before this period, he spent 3 years at Eli Lilly & Co. (Indianapolis, IN) as a Visiting Scientist working on CNS projects in medicinal chemistry. His contribution to several serotonin projects has been

relevant. Bruno is co-inventor of one patent and co-author of one peer-reviewed scientific paper. He has attained a broad knowledge of medicinal chemistry and a wide experience in organic chemistry.

Bruno graduated from the Faculty of Pharmacy of the Louis Pasteur University (ULP) in Strasbourg, France in 1990. He obtained an MSc in pharmacology and medicinal chemistry from the same university in 1991, before his PhD in medicinal chemistry under the supervision of Prof C G Wermuth. His thesis, developed in collaboration with Sanofi-Synthelabo, has set up an exhaustive SAR of the first nonpeptidic antagonists of Corticotropin Releasing Factor. This work has yielded three patents. After having spent 1 year as assistant professor at the ULP, he engaged himself for a 2-year postdoctoral fellowship at the same University in collaboration with Eli Lilly & Co. He spent part of this tenure at Eli Lilly in Indianapolis. Bruno is co-inventor of 14 patents and co-author of one peer-reviewed scientific paper.

Patrick Bazzini, PhD, is Research Chemist at Prestwick Chemical, Inc. in Strasbourg. Prior to joining Prestwick, Dr Bazzini prepared a PhD at the University of Aix-Marseille III, under the supervision of Prof M Santelli and in collaboration with Pierre Fabre MÈdicament. During this period, his interests focused on the development of a total synthesis of new steroids with interesting biological activities. After his PhD, he joined Prof C G Wermuth's research group at the Louis Pasteur University in Strasbourg for a postdoctoral fellowship. There, with a grant from Eli Lilly, he developed an SAR study around muscarinic receptor ligands potentially useful as symptomatic treatment of Alzheimer's disease. After his postdoctoral fellowship, he worked on anticancer project in collaboration with Sanofi-Synthelabo.

2.17.1 Scientific Rationale for Chiral Drugs

One generation ago, that is roughly 25–30 years back in time which takes us to the mid to late 1970s, hardly anyone could have imagined the enormous changes that the pharmaceutical industry would undergo. On the macroscopic level we have seen a virtually continuously ongoing concentration of activity creating companies of ever-bigger size by series of acquisitions and mergers.¹ We have also witnessed the evolution of a versatile and blooming biotechnology sector capable of producing antibodies and proteins to be utilized for treatment of diseases with high-unmet medical need, many of which are not accessible via small-molecule therapy.^{2,3} Furthermore a considerably less pleasant development has been the upward spiraling costs involved in taking a drug from the drawing-board through all stages and on to the market,^{4–7} the declining rate of achieving approval from regulatory authorities to launch a new product,⁸ and the inability to come to grips with the business-wide attrition, which keeps lingering around an average value of about 90% (9 out of 10 projects will be discontinued somewhere along the timeline from nomination of candidate drug to launch).^{9–12} Also as the timeline itself has become more and more the focus of attention with particular emphasis on how long it takes to make new drugs available to patients – the current industrial norm is about 7.2 years¹³ from first toxicology dosing to first file submitted for marketing approval, which means that easily another 3–5 years will have to be added on to cover the entire range from start of project to commercial launch – there have been many initiatives toward speeding up the work process and productivity.^{14–16} Thus, as one of the rate-limiting activities is concerned with the identification of developable molecules, methods (often highly automated and robotized) for generating comprehensive compound libraries using parallel synthesis and combinatorial techniques are seen as major advancements.^{17,18} Coupled with tailor-made screening cascades, notably in high-throughput architecture, considerable streamlining has been achieved in the low probability search for hits, leads, and later on candidate drugs (CDs). From a

Table 1 In 2004 7.5 (1/2 stems from the mixture of two actives in Advair) of the best-selling pharmaceuticals on the world market are represented by single enantiomers according to IMS (www.imshealth.com)

<i>Rank</i>	<i>Name (generic/trade)</i>	<i>Company</i>	<i>Molecular characteristics of API</i>
1	Atorvastatin/Lipitor	Pfizer	Single enantiomer
2	Simvastatin/Zocor	Merck	Single enantiomer
3	Clopidogrel/Plavix	Sanofi-Aventis	Single enantiomer
4	Salmeterol + fluticasone/Advair	GSK	Racemate + single enantiomer
5	Amlodipine/Norvasc	Pfizer	Racemate
6	Olanzapine/Zyprexa	Lilly	Achiral
7	Paroxetine/Paxil	GSK	Single enantiomer
8	Esomeprazole/Nexium	AstraZeneca	Single enantiomer
9	Sertraline/Zoloft	Pfizer	Single enantiomer
10	Celecoxib/Celebrex	Pfizer	Single enantiomer

microscopic perspective there has also been a revolutionary change in our understanding of many of the complex phenomena occurring at the medicine–biology–biochemistry–pharmacology–chemistry interface. At the beginning of the twenty-first century the mapping of the entire human genome, the linking of diseases to particular genes, and the identification of a multitude of biological targets and receptors prone to artificial interactions¹⁹ would probably stand out as being among the most prominent areas. A lot of our previous thinking has been revised or even turned upside down based on current knowledge. On the molecular level this period has seen the definite breakthrough and acceptance of the three-dimensional nature of drug–target interactions. While the number of stereochemically pure products in therapeutic use was 20–25% 30 years ago – the vast majority of which represented by various antibiotics produced in fermentation processes – the bulk of the marketed portfolio was built up by racemates and achirals. The situation has changed dramatically and in 2003 the global top 10 list of drug sales contained six small-molecule active pharmaceutical ingredients (APIs) as single enantiomers and just two as racemic products (besides one achiral and one protein).²⁰ In the future this strong dominance of developing pure stereoisomers whenever the compound is chiral will remain or be even further enhanced²¹ and it is only in cases where a clear benefit can be demonstrated from the antipode(s) that a racemic mixture will be approved. As a matter of fact the use of enantiomerically pure compounds for medical purposes is now so established that patenting authorities have signaled their reluctance to accept new intellectual property (IP) filings on stereoisomers of known racemic molecules. In other words, the link from racemate to antipodes falls under the obviousness headline and can, therefore, not be (easily) patented any more. Table 1 shows the 2004 market statistics for the top 10 selling drugs worldwide.²¹

While on the surface of things it appears rather logical that molecular stereochemistry is deeply involved in the creation of a biologic response, there has been an ongoing discussion over decades on the exact mechanistic causes for this and, maybe more importantly, how to interpret the findings. The debate has by no means seen an end and as recently as in 2003 a paper on the subject²² was entitled “Three-dimensional pharmacology, a subject ranging from ignorance to overstatements,” which can hardly be misinterpreted as it points toward diametrically opposing views being expressed about this topic. Actually, this controversy was initiated some decades ago and here Ariëns’ famous paper from 1984²³ probably stands out as one of the most important discussions on the subject catching a lot of attention. The perceived reluctance in disciplines like clinical pharmacology and pharmacokinetics to realize the stereoselective nature of drug–target interactions are addressed in a very critical and outspoken manner (by using phrases such as ‘sophisticated nonsense’). Instead the then newly coined expression ‘isomeric ballast’ was introduced as a means to describe the therapeutically useless 50% (or potentially even more in cases with several stereogenic centers) of impurity present in a racemic API. The situation is extremely complex, however, which is underpinned by many notable exceptions to the stereospecific nature of molecular interactions with bioreceptors,²⁴ for example at mammalian taste buds where there is no discrimination between L- and D-sugars.²⁵ From a regulatory perspective, the governing authorities in the USA²⁶ and Europe dealing with approval of new medicines have provided clear guidance on how to deal with molecules displaying features of chirality. Thus, it is requested that the stereoisomeric composition of such compounds is quantified and, if possible, safety and pharmacological data have to be recorded for both racemate

and pure enantiomers. It is important to point out, by no means is the development of racemic mixtures or of those represented by any other ratio between antipodes forbidden, but the documentary demands have discouraged most from making efforts in this area. The trend over the past 20 years has, therefore, been strongly in favor of only taking single stereoisomers into clinical studies in humans while aiming to reduce residual amounts of undesired enantiomer (including diastereomers whenever more than one stereogenic center is present) to levels as low as technically feasible (often <1%). It is not surprising then that during this period we have witnessed the transformation of known marketed racemic products to their enantiopure, or at least enantiomerically enriched, counterparts. An entire industrial branch pursuing these so-called chiral switches has been formed building on the often highly praised benefits – both in a medical sense and from a marketing point of view – but in spite of some successes far from all practically possible cases have, for various reasons, survived this transition.^{27,28}

2.17.2 How to Obtain Chiral Compounds in Stereoisomeric Form

In order to satisfy the ever-increasing demand of compounds in stereochemically pure or at least highly enriched state a whole raft of methods have been put at our disposal. These range from the simplest possible technique where the antipode can be separated off mechanically by the sheer difference in macroscopic appearance as pioneered by Pasteur in his renowned experiment in 1848 when picking one of the tartaric acid enantiomers with a pair of pincers. A highly sophisticated transition metal catalyzed process using a tailor-made chiral ligand, which is capable of operating at high productivity and efficiency, will represent another extreme. These options as well as other methodologies are schematically displayed in [Figure 1](#).

For the end user it is of course very tempting and attractive to simply resort to purchase of starting materials in enantiopure form. And with the tremendous development that the market has seen over the past 10 to 20 years, to a large extent driven by the commercialization of various asymmetric technologies, many useful and versatile compounds are now available, increasingly so also in bulk quantities.^{33–37} In cases where the stereochemical information – more precisely expressed as the absolute configuration of the stereogenic center(s) in the starting material – is retained in the target molecule there is, in theory, no need to be worried about enantiomeric purity as long as the reaction conditions applied along the synthetic pathway are not causing any (appreciable) racemization. [Figure 2](#) shows an industrially significant example describing this procedure.³⁸

From a practical point of view this is rarely the case, simply because the stereochemical purity of the acquired starting material does not match the demand but also because of the risk of having to face a sacrifice in purity to a higher or lesser degree during the synthesis, in particular as the sequence gets longer and longer. For example when preparing a polypeptide it is of utmost importance to carefully control each coupling reaction between the growing chain and every newly added amino acid to avoid ending up with a messy mixture of stereoisomers that might become very troublesome and yield-consuming to purify. If, however, the original stereocenter(s) can be manipulated, meaning that transformations will be carried out directly at the stereogenic position, then it is more a matter of ensuring that the conditions utilized for this purpose guarantee that the reactions proceed in a selective fashion in order to always exert full stereocontrol. This control is also essential when operating in a mode where the stereochemistry is retained, but the risks of causing detrimental racemization are likely to be much higher in the former case. An illustration of this is when during a nucleophilic substitution on a particular substrate believed to follow a clean S_N2 pathway which would result in the expected full inversion of configuration instead some retention product is formed due to competition from a reaction following the S_N1 mechanism. In this case the overall outcome would be partial racemization, which demands a purification procedure to regain the stereochemical purity.

The workhorse when it comes to generating products with desired absolute stereochemistry still remains the classical diastereomer resolution.^{39,40} Exact figures describing the current situation in industry are hard to access, but indications point in the range of as much as roughly half of what is produced having been made by this method.²⁰ And this is in spite of the normally perceived low technical grade of the technology, which, superficially, requires one antipode to be precipitated by an auxiliary of high enantiomeric purity. The waste of 50% of the material can, if environmentally or economically justified, be compensated for by an in-built process loop allowing racemization of the undesired isomer. Repetition of this cycle can in principle drive the yield close to quantitative and this concept has seen some real advances recently with the introduction and refinement of dynamic kinetic resolution (DKR).^{41–44} Thus, in an in situ arrangement the wanted stereoisomer is accumulated while its antipode is continually being transformed either bio- or chemocatalytically so that at full conversion, in theory, only the desired product remains in the system. An elegant application⁴⁵ of this technique is shown in [Figure 3](#).

With the third approach – stereoselective syntheses – we enter a field that has experienced a tremendous development since the mid-1960s when it was demonstrated that reductions could be effected in homogeneous phase

(a)

(b)

Figure 1 Conceptually different ways to create single stereoisomers. (a) A racemic material is subjected to resolution and then taken forward to the desired enantiomer represented by the local anesthetic ropivacaine²⁹, (b) a prochiral substrate is selectively transformed to one enantiomer in excellent purity as exemplified with L-Dopa synthesis.^{30–32}

Figure 2 Starting from (S)-proline, an abundantly available natural chiral building block, a key intermediate is manufactured with preserved stereochemistry en route to the class of benzamide neuroleptics.

using transition metals in combination with chiral phosphorous compounds as ligands.^{46–48} The versatility of what asymmetric reactions can achieve is just breathtaking and the whole area has been extremely innovative and prosperous.^{49–67} Therefore it might seem somewhat surprising that not very many of these processes have in fact been scaled up to commercial production. Latest surveys indicate that less than 20 chemocatalytic processes are operative at full industrial scale, the majority of which are represented by various reductive transformations (hydrogenations).^{68,69}

Figure 3 Dynamic kinetic resolution coupled with an asymmetric transfer hydrogenation using formic acid (HCO_2H) as hydrogen equivalent to form intermediates useful in the synthesis of benzazepine class of dopamine D1 antagonists.

The volumes produced per annum vary considerably depending on the intended usage of the product and so the span is from less than 1 metric ton (t) for certain intermediates used to prepare fine chemicals or pharmaceuticals up to the stunning level of more than 10 000 t of (*S*)-metolachlor, the active ingredient in a widely used herbicide; **Figure 4** shows details of this process.^{70,71}

Given this situation of infrequent application of asymmetric technology at large scale there is an interesting disjunction observable between the high attention received by this area in academia and its practical use in industry. Thus, while figures based on journal citations concerning chiral technologies show that 72% fall into the arena of asymmetric methods, the corresponding figure is less than half (35%) when looking at what is actually utilized.²⁰ In fairness, however, it has to be said that the dominant role played by processes building on resolutions and starting materials from the chiral pool is underpinned by the fact that, in the latter case, Mother Nature has provided us with an enormously rich and abundant reservoir of useful compounds, exemplified by amino acids, carbohydrates (sugars), terpenes, and alkaloids.

2.17.3 Supplying Stereoisomers: What the Market Can Offer

Never have there been more opportunities for a buyer to find the chiral material of interest in enantiomerically pure or enriched form from a commercial source. This is not to say that there will always be a chiral building block available to serve your needs at any time, but the selection of compound classes and their breadth of structural variation is simply enormous. A word of caution, however, is justified when examining what the term ‘availability’ means. Namely, does it mean virtually any quantity being accessible in bulk from the shelf for immediate purchase or do we have to take long delivery times into account because the particular product has to be manufactured first? It could even be the case that the market only supplies small quantities for laboratory use and these amounts are prepared using a method unsuitable for upscaling. The following case story nicely describes this situation. For a certain project the nonproteinogenic amino acid (*S*)-azetidine-2-carboxylic acid (**Figure 5**) was required as a key raw material for the preparation of an API. This compound, naturally available from hydrolysates of plant proteins⁷² albeit in fractions of 1%, was on offer in gram quantities for laboratory use⁷³ and given its structural simplicity it was, not surprisingly, believed to be also available in bulk amounts. The reality turned out to be rather different. After huge efforts trying to identify a source with capacity to deliver kilogram quantities it was serendipitously found that a mere 75 kg was located in a warehouse and this was all that could be rounded up on the entire globe. And this was not the only discouraging news. As it turned out the manufacture of this lot had been achieved by a tremendously effort-consuming extraction process starting off from hundreds of tons of molasses and as this was seen as a nonviable route for making this material there was in fact not any commercial route in operation that could support the large-scale needs of the project. Consequently, it became an extra

Figure 4 The largest volume enantioselective process to date produces (S)-metolachlor at an impressive catalytic efficiency of $>10^6$ expressed as mol product over mol catalyst (also called turnover number, TON).

Figure 5 (S)-Azetidine-2-carboxylic acid.

task to devise, as quickly as possible, such a route with the potential to be scaled up to production size, a challenge that was far from trivial but which, fortunately, was concluded in a successful manner.^{58,59}

Looking at the market situation it is striking to see how many useful compounds are available.^{74,75} Besides the already mentioned classical chiral building blocks, notably amino acids and carbohydrates, there now exist a whole raft of new materials that have been put at our disposal many of which produced via asymmetric methodologies or kinetic resolution protocols. Thus, the C-3 synthons and other short chain or ring-containing compounds (**Figure 6**) have become particularly versatile and useful by virtue of a stereogenic center (or occasionally several) and a functionality that allows further chemical manipulations. Using these molecules displaying their linear carbon core or cyclic architecture offers easy access to a defined stereochemistry as well as possibilities for an array of substitutions as part of a wider synthetic scheme.

It is important to emphasize that many of the chiral compounds reported in the literature, in databases, and in product catalog have been made in only small quantities awaiting a market to be established which will eventually drive demand upward. Therefore, no guarantee can be given that a particular molecule will be accessible in the relatively

Figure 6 Structures of a few C-3 and other synthons.

short term (within weeks or a few months at the most) and this may have a profound influence on the design of the synthetic route as the time element is crucial when it comes to delivering your own product. This will not allow for extended lead times before receiving your starting material and, furthermore, the effort to quickly define the final sequence will also be influenced by what is available at scale and what is not.

2.17.4 Stereospecific Analyses: An Overview

A prerequisite for the breathtaking advances we have seen in the field of chirality – both from a chemistry point of view as well as in pharmacology, biology, and related areas – has certainly been the tremendous development in analytical methodologies achieved since the late 1970s and early 1980s.⁷⁶ Starting from a point many years back when the measurement of optical rotation was the sole source of determining enantiomeric purity, the situation today allows very precise identification and quantification of single stereoisomers using the plethora of techniques at hand. These advances offer the possibility of determining not only the intrinsic configuration of a compound but also of measuring its presence in sample matrices down to trace amounts, which often equals levels below 0.1% and into the ppm and ppb ranges. Partly as a consequence of this trend there have been continuously increasing demands from regulatory authorities to document and identify chiral impurities (and achiral as well) in active drug substances to at least the $\geq 0.1\%$ limit.

A list of major techniques in current practical use to determine stereochemical integrity and purity would include the following.

2.17.4.1 Determination of Absolute Configuration

2.17.4.1.1 X-ray diffraction (XRD)

This is the recognized standard for a priori determination of the absolute configuration of chiral molecules. Bijvoet⁷⁷ technique relies upon the interpretation of anomalous scattering of x-rays caused by atoms present in a crystal lattice. This is a highly refined technique today with many technical improvements since its introduction.^{78,79} The major drawback with this technique is the requirement for a pure single crystal.

2.17.4.1.2 Vibrational circular dichroism (VCD)

This is a recently introduced technique offering a novel alternative to XRD. There is no requirement for derivatization or preparation of a single crystal. It is defined as the differential absorption of a molecule for left versus right circularly polarized infrared (IR) during a vibrational transition. Absolute stereochemistry is established by comparing solution-phase VCD spectra to results of ab initio quantum chemistry calculations.⁸⁰

2.17.4.1.3 Other methods

Other methods under development and exploration include the use of optical rotation, electronic circular dichroism, and Raman optical activity.

2.17.4.2 Determination of Enantiomeric Purity

2.17.4.2.1 Polarimetry

Polarimetry is the oldest and most widely used method constituting a nonseparation technique. It relies upon measurement of a net effect. Data from pure enantiomers are required for comparison. The technique is based on the fact that chiral molecules rotate the plane of polarization of plane polarized light.⁸¹

2.17.4.2.2 Nuclear magnetic resonance (NMR)

This represents a nonseparation technique that relies upon the use of chiral derivatizing agents or a chiral solvent to form diastereomers, which may have different chemical shifts in the NMR spectrum.^{82,83}

2.17.4.2.3 Direct enantioselective chromatography/electrophoresis

This is the most widely used to determine enantiomeric purity. Enantioselective separations have been realized in all possible separation techniques: high-performance liquid chromatography (HPLC), gas chromatography (GC), thin layer chromatography (TLC), supercritical fluid chromatography (SFC), capillary electrophoresis (CE), capillary electrochromatography (CEC).^{84–92} This technique depends on the formation of transient diastereomeric complexes with either a chiral bonded phase or chiral additive to afford separation. Many phases/additives are now available.^{93–95}

2.17.4.2.4 Indirect enantioselective chromatography/electrophoresis

This technique involves the use of chiral derivatizing agents to form diastereomers, which can be resolved without the need for chiral stationary phases or chiral additives.⁹⁶ The approach is still used for analytes such as amino acids.

Perhaps needless to say, but it is worth mentioning that in spite of the tremendous advances seen over the past couple of decades the development and improvement of techniques such as the ones mentioned above have not come to a standstill. In all likelihood we will be witnessing continuing efforts in these areas increasing our possibilities to analyze complex chiral chemical moieties with even higher accuracy.

2.17.5 From Drawing Board to Consumer: Progression of Drug Compounds in Process R&D

The complex and multifunctional task represented by discovering and developing a drug from initial idea through all stages to market approval and launch requires the input of enormous resources, in terms of both people and money. As many of the diverse activities throughout the various disciplines in R&D are strongly time-driven it is of the utmost importance that a free flow of information across functional boundaries is insured in order not to slow down any actions or transfer of knowledge. In other words, in order to keep up the speed in a project streamlined internal work processes need to be adopted as well as securing minimum slowdown at the interfaces with other departments. For Process R&D offering a skill base that covers the whole range from small-scale glassware experimentation up to pilot plant operation in several hundred or thousand liter vessels and bridging the entire gap between Medicinal Chemistry and commercial production, there is an early entry in the lifetime of a project and a late departure unless there is a premature discontinuation. For this purpose a model of a global work process has been constructed spanning the entire timeline from start to finish with the different Process R&D specific activities aligned in sequential order; see [Figure 7](#) for a graphical representation of the model.^{58,59,97,98}

From the viewpoint of the wider pharmaceutical business it is entirely relevant to challenge a technically oriented function like Process R&D with questions like: How can you provide better support to our drug projects, and what would allow you to progress an increased number of CDs through your pipeline at a constant resource level? To sensibly address these queries, though, it is essential that the general comprehension and awareness of the main contributions from a Process R&D department is much higher. Here, the tighter integration of the various components in drug R&D that we have witnessed over recent years has supplied a remedy.⁹⁹ Today a good and robust process that can deliver the desired pharmaceutical compound with the required quality and at an acceptable cost of goods level is appreciated, and, as a matter of fact, is expected as never before. Historical precedents are available and a classical yet still intriguing case of successful methods development demonstrating the power of Process R&D is constituted by the synthesis of cortisone. Thus starting at a mind-boggling cost of \$200 g⁻¹ the level was drastically reduced to a mere \$3.50 g⁻¹ over a period of only a few years in the beginning of the 1950s, which equals a price drop of more than 98%.^{98,100}

Contributions in the form of quantities of active molecule, a manufacturing method, and regulatory documentation to support clinical studies and marketing applications are widely acknowledged and valued. To be able to quickly respond to new compounds coming through the pipeline, a back-integration into the earlier stages of Discovery is

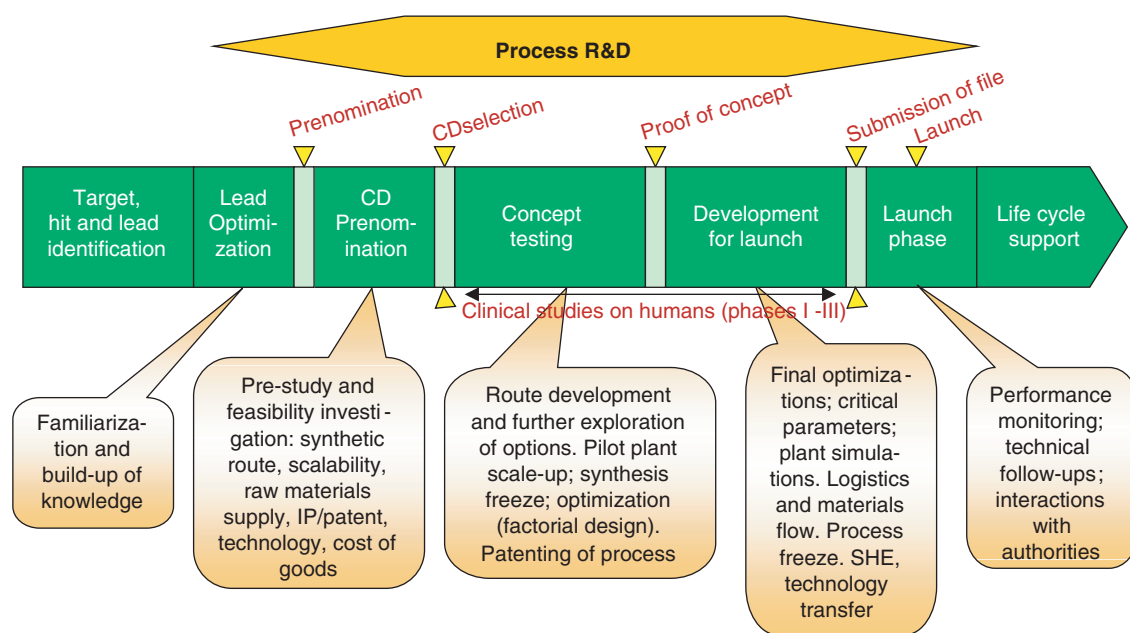

Figure 7 The value chain of R&D in the pharmaceutical industry is stretched from biological target to commercial launch. Stages of Process R&D involvement are specifically indicated.

essential, not stopping at the prenomination stage but pushing further back into lead optimization (LO) and maybe even lead selection. If this mode of operation is not present there will, inevitably, be a loss of valuable time once the new chemical entity (NCE) is appointed as CD, which, as a knockon effect, could delay market launch later on in cases where the project is successful. The strong need for speedy and timely manufacture of a first scaled-up batch is further underpinned by the desire to quickly document the compounds, mainly in the form of extended safety studies in various animal species, in order to allow entry into the first-time-in-human phase. From a purely statistical viewpoint, on the average roughly three out of four projects will face discontinuation up to the proof of principle point, which is where signs of desired pharmacological effect have been demonstrated in patients after single dosing. Understandably, it is of prime interest to reach this stage where the majority of attrition will have affected the pipeline and to successfully achieve this as fast as possible, API delivery cannot be tolerated as a bottleneck. Therefore, an early start to route design and development of methods is crucial, which still maintaining a balanced view on the actual resource input depending on the nature of the project – first in class, best in class, or backup – as the scientific and economic risks may vary widely including your own risk preparedness as well as the speed with which the process will be conducted.

As an aspirational target, the work should preferably be initiated to allow route freeze – the point where the synthetic sequence is decided, that is the timely order from starting material via intermediates to product is fully defined – to be reached prior to the first time-critical upscaling of the synthesis alluded to previously. The benefits from this are twofold: a quick concentration on a single synthetic path enabling all resources to be devoted only to this task and an advantageous regulatory situation as safety and human studies, from this point onward, will be conducted using active ingredient prepared by a fixed sequence, which, however, does not preclude changes in the manufacturing process such as switching of reagents or solvents and altering conditions. At the same time it must be made absolutely clear that this task is very stretched and to succeed a sophisticated set of tools needs to be at the disposal of highly skilled experts in route design of organic molecules. The data mining capabilities and information retrieval systems have to be of top-notch quality to aid in the expedient and mostly theoretical exercise of shortlisting plausible synthetic sequences. As the literature in the field of organic chemistry, which has its roots as far back as maybe 180 years, is too vast for any individual to grasp, huge efforts have gone into the construction of artificial systems to provide support. This in silico approach has seen a tremendous development over recent years and today several commercial data packages are available that to varying degrees can perform retrosynthetic analysis of given target compounds and propose ways of assembling the desired product, with cross-referencing to published sources. Specifically for application in the Process R&D environment the route design feature should, preferably, be complemented with safety, health, and environment (SHE) directed information as well as to give data on commercial availability of starting

materials and reagents, in particular if prices are quoted together with delivery lead times. The former will present a vital part when making judgements on potential scale-up challenges and the latter could steer the selection of route of synthesis by discarding alternatives where there are no bulk quantities of the chemicals needed available on the market or where the cost of goods target would not be met. A model representing the desired state to aim for when it comes to computer directed use of databases is shown in [Figure 8](#).¹⁰¹

At the Medicinal Chemistry–Process R&D interface the diversity expressed in the form of a multitude of chemical structures being prepared and investigated by the former is matched by an exploration of a variety of syntheses leading to the target molecule by the latter. From both ends it is essential to cover enough space so that important aspects are not left out, but also to narrow down the number of options to enable focusing of efforts. [Figure 9](#) shows an illustration of the context thus described and highlights the need for functional overlap.^{101–104}

Thus far there has been no particular mention per se of structural features displayed by the molecules up for scrutiny. However, they do have an influence, and a fairly strong one as well for that matter. Focusing on the sheer number of new CDs to be brought forward is one thing, albeit of tremendous importance to the success criteria of the drug industry, but from a strict Process R&D perspective the number of steps that it takes to make each one of them is of considerably higher relevance. Superficially speaking, the efforts needed to pursue a single CD requiring 20 synthetic steps would be equal to running five CDs at four steps each. Hence, a major task in Process R&D during the phase of optimizing the structural architecture is to analyze and communicate the consequences that various changes will have on the synthesis. We could be looking at an overly complex substitution pattern on a cyclic core structure, the incorporation of substituents that are not easily compatible with each others (from a synthetic point), making use of esoteric or unusual heterocyclic units difficult to prepare, or incorporation of too large a number of stereochemical features such as several stereogenic centers or even torsional isomerism. The aim should not be to disqualify promising compounds per se because they would pose some rather awkward synthetic hurdles. Quite the contrary, but in cases where options in fact do exist pros and cons have to be pointed out for each alternative when examining the routes envisaged for their assembly. In the selection procedure, this can then be taken into appropriate account amongst all the other parameters that will have to be evaluated. And there, biology, pharmacology, and toxicology should be given preference, though without ignoring realities, capabilities, and limitations in chemistry and pharmaceutical formulation.

Model for future database usage:

- supporting chemist's knowledge and creativity
- contributing to better route design
- aiding reaction optimization and process understanding

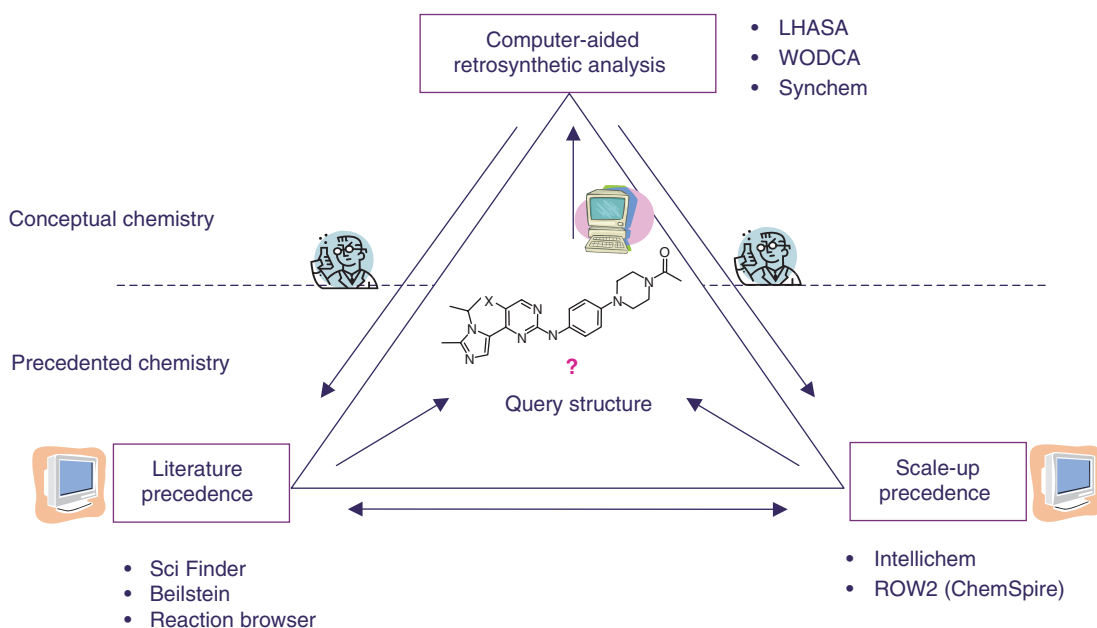

Figure 8 Database architecture tailored for Process R&D purposes. Note that the listed software provides examples of largely commercial systems, which have had varying degrees of industrial application.

Figure 9 The crucial integration of Process R&D with the pre-CD work during the Discovery phase, notably at the Medicinal Chemistry interface, extends back into lead optimization.

Admittedly, in the life science industry, communicating matters of the technological nature of process science and concerning bulk production is not the easiest thing, which is altogether understandable given the focus of the business (to provide products capable of improving quality of life and addressing diseases where there are unmet medical needs). Perhaps one way forward to better reach out with the messages would be to create a mimic of the renowned Lipinski's¹⁰⁵ rule of five, but now describing different parameters of the process.¹⁰¹

So far the discussion has been strictly generic in the sense that specific structural features of the API have not been explicitly highlighted. The question is thus obvious whether other characteristics besides the length of the synthesis, for example presence of one or more stereogenic centers will exert a major impact on Process R&D? The answer is to a surprisingly small extent today compared with the situation one or two decades ago. The tremendous advances seen in the methodologies available to conduct a great variety of stereoselective transformations have no doubt triggered this change in attitude toward increasingly complex molecules. A striking example of how far the capabilities in this regard have reached in less than three decades is given by comparison of L-Dopa (**Figure 1b**) and (+)-discodermolide (**Figure 10**). The former, a famous anti-Parkinson compound consisting of one stereogenic center, became industrially available during the 1970s via the seminal asymmetric hydrogenation technology masterminded by Knowles^{30–32} and his team at Monsanto (**Figure 1**). With the latter, a highly potent inhibitor of tumor cell growth (via microtubule stabilization), we are facing no fewer than 13 such centers, which leads to the theoretical existence of 2^{13} (= 8192!) unique stereoisomers (or 4096 pairs of enantiomers). And yet, in spite of its scarce availability from the natural source (the Caribbean marine sponge *Discodermia dissoluta*) pilot production on several tenths of grams scale has been successfully achieved and was to be succeeded by an intended batch size of several hundred grams.^{106–108} Unfortunately, this wholehearted endeavor has now been discontinued (during 2004) allegedly due to toxic side effects and, therefore, we will never know whether a commercially viable process on multi-kilogram scale would have been possible for this intriguing molecule. Regardless of this setback, relentless synthetic efforts are being deployed with the aim of devising better and better procedures.¹⁰⁹ This level of complexity is, however, not the end, as literature sources indicate commercial development of the macrocyclic lactone apoptolidin is now under way – a molecule with 25 stereocenters displaying potent cytotoxic and tumor-inhibiting effects.^{56,110–113} Not disregarding these stunning achievements, the fact still remains that probably about 50% of enantiomerically pure products on industrial scale are

Figure 10 Structures of (+)-discodermolide and apoptolidin.

prepared via classical diastereomer resolution at least if one takes their value into account. In the future, as more and more robust and reliable ‘competing’ methodologies are developed and validated this figure will inevitably be reduced step by step. It should be noted that the discussion here is restricted to small molecule APIs, that is, the increasingly abundant monoclonal antibodies (MAbs) and protein-based drugs have been excluded. Commercial manufacturing of these products is making use of entirely different technologies such as fermentation or cell line expression.

2.17.6 The Regulatory Environment

Representing the industrial sector that has by far the strictest rules and legislations to adhere to, the pharmaceutical companies must develop a high degree of expertise in the regulatory field. Moreover, the fact that any drug to be marketed has to gain approval from the regulating body in charge before it can be made publicly available demands that forward-looking regulatory strategies are implemented in the very early stages of an R&D project. Also as has been seen in recent years, there is a pronounced mutual trend to engage in an open dialogue between both parties along the timeline – probably pioneered by the US Food and Drug Administration (FDA) who in an attempt to improve on performance measures such as approval rate and efficiency of throughput of new drug applications encourages data to be debated and discussed – to allow dissemination of different types of problems and challenges. As technological breakthroughs such as new therapeutic targets, biomarkers, and pharmacogenomics have not seen a corresponding translation into increased numbers of NCEs (on the contrary there has been a dramatic decline over the past 8 years), something needs to be done.⁸ Furthermore, the burning issue of the reasons for more failures in late stage development (notably in phase III) as well as for market withdrawal has to be taken very seriously.¹⁶ Thus, based on the insight in the FDA that the current drug development process is not operated in an adequately efficient way a strategy needs to be devised, which addresses the shortcomings. In a recently published ‘white paper’¹¹⁴ on the critical path to new medical products three dimensions stand out as being of key importance:

- Assessing safety
- Demonstrating medical utility
- Industrialization.

Each one of these brings its own set of activities, so for example in safety the product has to demonstrate clinical reliability; the utility has to be proven by achieving clinical effectiveness; and in industry there is a demand for the design of a high-quality product and the capacity for mass production under strict quality control. All in all it is strongly advocated in this paper that “a better product development toolkit is urgently needed” and a discussion is conducted on what these tools might be in the specific areas mentioned above as well as devising suitable standards and paths forward.

Focusing on chirality in this context it is interesting to notice the outcome of a recent survey on what kind of compounds have received worldwide approval as new drugs during the period 1983–2002 coupled with similar statistics from the FDA covering the years 1991–2002.¹¹⁵ This clearly shows that drugs using single enantiomers have now surpassed those that have an achiral compound as API, putting racemates as a definite minority. The picture thus presented is further emphasized by the 15 NCEs approved by the FDA in 2003 where 64% are enantiomerically pure, 22% are achiral, and 14% are racemates. In actual fact, the gradually evolving awareness of biological and pharmacological issues connected with chiral drug molecules and their significance that started during the 1970s and accelerated in the 1980s brought about a surprisingly quick response from various stakeholders. Thus, the FDA launched a policy statement addressing the development of new stereoisomeric drugs in May 1992, which was later on complemented by a corrections note early in 1997.¹¹⁶

Furthermore, pharmaceutical industry bodies – both nationwide and on international committee levels – have picked up this urgent and complex question to try and formulate well-thought-through and adequate guidelines.^{117,118} A common theme is the desire to demystify the concept of stereoisomerism¹¹⁹ and instead apply a scientifically sound approach to chirality and the fact that mirror images of chiral compounds often but not always display different properties.²⁷ In general terms the recommendations speak of the necessity that in cases where both antipodes are present, for example in the form of a racemate, it is unambiguously demonstrated that such a drug is safe for the patient. Moreover, when this is not the case and instead one enantiomer has unwanted side effects then this component will be regarded in the same way as any impurity and has to be treated accordingly. This means that it rests upon the sponsor (i.e., the responsible pharmaceutical company) to ensure that the remaining amounts are brought down to residual levels dictated by the findings in toxicological assessments and other studies.¹²⁰ For new drugs branded as enantiopure this will today most likely imply around or below 1% of undesired antipode (indicating a purity of 98% ee or better) and with current manufacturing technology this is entirely feasible on a routine basis in many instances. As quality carries a price it is essential in this context to point out that, when methods and techniques are used to achieve extremely stereomerically pure materials ($\geq 99.9\%$ ee), this will inevitably result in a drastic increase in cost. Therefore, such ultra-high qualities should only be demanded when unambiguous and validated scientific data makes this indisputably necessary.

From a regulatory Chemistry, Manufacturing, and Control perspective the argument is made that the three-dimensional integrity (i.e., the molecular configuration) of the API has to be proven in a stereochemically selective identity test. And, furthermore, a selective assay method is required to accurately determine its stereochemical composition, which means that a reliable low-level quantitation of stereoisomers present should also be possible. Even if this set of criteria is applicable to all stereoisomers – irrespective if in enantiomeric or diastereomeric relationship – the problems that one faces with the latter are considerably smaller as an upgrade of a mixture of diastereomers can, in most cases, be achieved relatively easily due to their differences in physical properties (e.g., solubility, melting and boiling points). In summary, the previous default position for developing and marketing racemic compounds has now been replaced by a situation where the clinically most efficacious and safe enantiomer is taken forward, unless the racemate has some intrinsically beneficial properties.

2.17.7 Drugs at Any Cost?

The pharmaceutical industry has, in general, a reputation of being a very lucrative business offering its owners good if not excellent profit margins. While this might be true in many cases it is important to be mindful of a few facts,^{4,6,7,10,15} some of which are provided below:

- The vast majority of marketed drugs – maybe as many as 90% – earn less than \$180 million per year
- As many as 70% fail to recover their overall R&D expenditures during the entire life cycle
- Only a small proportion ($\approx 12\%$) provide what might be called a satisfactory return on investment
- The total out-of-pocket R&D investment to take an NCE through to registration has seen a truly explosive development in recent years and was reported to be \$403 million in 2003, which translates to the often-cited figure of capitalized pre-approval cost of \$802 million. This number is now probably outdated and we are most likely

rapidly approaching the stunning level of \$1 billion, especially in the light of recent setbacks and failures of some high-profile products

- Cost of drug marketing has accelerated tremendously over a period of years and has reached a level comparable to the R&D component if not higher
- Running clinical trials is becoming increasingly complex as more and more complicated diseases are addressed
- Safety concerns from health authorities demand more and more patients to be enrolled in the trials and when aiming at demonstrating superiority over current therapy (competitor drug) the number of patients needed in outcomes studies could mount to 20 000 or even 30 000
- The ‘classical’ pharmaceutical industry is under severe attack from generic competition and its patent portfolio is aggressively challenged from all angles
- The capability to deliver sustainable annual double-digit growth rates with regard to turnover and profit might be hampered as a consequence of fewer potential mega brand products (sales > \$1 billion per year) coming through the pipeline
- Attrition is maintained at a high level (90% on average) partly because of poorly understood diseases being investigated (e.g., Alzheimer’s, obesity, stroke, severe cancer forms, rheumatoid arthritis, human immunodeficiency virus (HIV)), and the desire to move from symptom relief to disease modification.

In particular the numerical data presented here (originating from the late 1990s and the early years of the new millennium) do not pretend to show a picture that is entirely correct in an absolute sense. This is mostly due to the inaccessibility of industry-wide intelligence that manages to provide real-time ‘as-is’ information, confidentiality and business secrets being main obstacle in this regard. Instead the information intends to highlight some intriguing relationships and globally observed trends. Taken in a broader context, the scenario alluded to above has confronted the drug industry with some unforeseen challenges. And on top of this has been added the sharply increasing resistance from authorities and the market to accept the prices that historically have been regarded as feasible to finance necessary reinvestments in new and continuously risky ventures. Furthermore, several newly introduced products have been aggressively attacked as policy-makers and various pressure groups have questioned their usefulness and safety. Also there is a clear reluctance from the (political) health officials to recommend that doctors should prescribe wider use of new, more expensive and efficacious drugs rather than the old less costly ones with lower efficacy. This has all of a sudden changed the once so prosperous, stable, and highly esteemed pharmaceutical sector into, if not a crisis, certainly one that is grappling with its self-image and severely curtailed public reputation. It is probably not too far-fetched to project drastic changes in our industry that in the end can affect the fundamental principles for operating this kind of business: [Figure 11](#) clearly indicates the sort of challenges that one faces with regard to R&D expenditures, new molecular entity (NME) output, and overall development time lines.

How does the process that is developed in order to produce API at commercial scale come into all of this? Is this component of the multifaceted activities required to successfully take a product to market launch really capable of playing any noticeable role, especially from a cost point of view? The outright answer to this is: previously not to a very

Figure 11 This index-based graph shows accumulated trends from 1994 through 2003 for sales, R&D expenditure, development times, and output of new molecular entities (NMEs). (Source: CMR international and IMS Health.)

Figure 12 Pie chart: relative share of the cost of goods (COGS) components as represented in a large-sized product portfolio. Bar chart: product-wise minimum to maximum distribution of interrelated cost contributing parameters.

great extent, but in today's climate increasingly so. Looking at some recent industry estimates reveals that in a large product portfolio the API represents about one-third of the entire cost of goods (COGS), the other contributors being formulation and packaging. Extending the view to an inspection of product-by-product distribution the spread in API share goes from below 1% up to 40%. Similarly COGS and API, respectively, as share of manufacturing price display a wide variation as is evident from the graphics shown in [Figure 12](#).

In the old regime where COGS rose to $\leq 30\%$ of the manufacturing price the drive for process improvements were not very pronounced:

- Reducing the API cost by 50% (e.g., via improved yields, cheaper starting materials) resulted in a 15% COGS reduction at an API share of 30%
- This outturn brings a payback of a 1.5–4.5% lower manufacturing price.

In future with growing COGS share as dictated by severe downward-directed price pressure the situation is dramatically changed:

- At 50%, API share alone represents 15% of manufacturing price
- Cutting the API cost into half improves profit margin by 7.5%
- This increases the impact of API on manufacturing price by 67%.

These simple and rather generic calculations should suffice to convince even a skeptic that the industry is moving away from a view where the API is considered to be of inferior importance to one where much emphasis is placed on driving its cost down as much as possible. The knockon effect that this has is of course the need to develop more efficient and cost-conscious processes. By the way, in order to keep profits up in an era of severe price pressure all links in the chain – R&D, Operations, Sales & Marketing – contributing to the cost of the labeled drug will be forced to improve on their way of working and the methodologies applied. Only then can the pharmaceutical companies stay in business.

2.17.8 Chiral Switches: From Racemate to Enantiomer

As pointed out previously, the main drivers when contemplating the transformation of an existing drug in racemic form to a single enantiomer are improvement in clinical efficacy, elimination of undesired side effects (better toxicity profile), and eventually the possibility of reducing the chemical load on the body's metabolic system (in theory by 50% given that nothing else is changed).²⁷ In this context the interpretation of what constitutes a significant enough improvement to warrant a switch to be taken forward is up for debate. There are no clear guidelines for how this should be handled, but a general feeling is that in order to demonstrate a high enough innovation over the racemate to ensure IP protection, a prerequisite for wanting to take the inherent financial risk involved in the development of a new drug, an approximately 2:1 activity ratio between antipodes would probably be regarded as necessary. One further aspect of this is perhaps more irrational, namely that a marketing strategy could lie behind a company's decision to replace a

racemic drug with one of its enantiomers as a means of counteracting generic competition (on the racemate). To repeat the words of warning made earlier in this chapter: this is a very complicated area and, therefore, each case has to be treated on its own merits. There is no law of nature that says an enantiopure compound is always the best, nor that we should focus only on the extremes with either 100% stereoisomeric purity or 50% as is the case in racemic mixtures. Instead the optimum from a pharmacological and medicinal point of view could be somewhere in between.

How successful has this transition from racemate to enantiomer been? When this business opportunity emerged around 1990 a rather large number of compounds were of course in use as racemates on the market. Unsurprisingly this raised expectations, and rosy pictures were painted envisioning more or less a switch of the entirely accessible portfolio of products. This has not been achieved. On the contrary, the outturn has been a number that is far from the optimistic target. Thus, available statistics reveals that in the period from 1994 to 2002 only about 10 instances occurred which resulted in the actual launch of a pure enantiomer drug.²⁸ And this is the case in spite of the continuous approval by regulatory authorities of racemic NCEs throughout the 1990s with on the average about 10% of the annually approved drugs worldwide, a trend that has actually proceeded into the new millennium according to statistics from both the FDA and the the UK Medicines Control Agency (MCA). A few pertinent examples from this exclusive list are shown in Figure 13.

Irrespective of the medical success or nonsuccess the chiral switch concept has, no doubt, spurred a lot of attention to scalable methodologies enabling the preparation of the desired antipode of previously manufactured racemates. Thus, one is likely to find all the conceptually different approaches outlined previously (see Section 2.17.2) represented amongst the cases known so far. In that regard this has been helpful in pushing the technology frontier forward and by doing so setting an example for how to deal with challenges of such a kind. A few years into the twenty-first century there is still a fairly well filled pipeline of potential chiral switch candidates around – some in late stage clinical phase, some in earlier, and some even in a state of suspension – but the projection that we are approaching the final act of this play in its original version is not very far-fetched. The reason being, of course, that the likelihood of developing chiral NMEs as racemates will continue to stay at a very low level, if not to virtually disappear, and, therefore, business opportunities are bound to be scarce. However, a new spin on this might be the growing interest to thoroughly investigate not only the natural product as it is found in nature per se,¹²¹ but also the unnatural/low abundance enantiomer of natural or nearly natural products.²⁸ With the increasing knowledge about disease mechanisms and molecular biology it is entirely feasible to discover new and clinically significant pharmacological activities in the antipodes (or quasiantipodes in cases where several stereogenic centers are present and only some of them inverted) of

Figure 13 Molecules that have gone through the transition from racemate to single enantiomer, listed alongside their medical indication and year of launch.

known single enantiomers. One early example illustrating this would be the reputable gossypol case from the 1970s. The lead role here was played by the yellow pigment gossypol present in cotton plants and mainly composed of the (+)-isomer,¹²² which was found to exhibit male contraceptive activity. Later on it was proven that this spectacular property resided almost exclusively in the (–)-form, present only in minute quantities in the natural source. Due to systemic toxicity and incomplete reversibility of action this promising program had to be disbanded,¹²³ but hopefully without entirely disqualifying or compromising the general pros of the concept as such.

2.17.9 Successes and Failures: What Are the Discriminating Factors?

The heading expresses a classical and often debated question: is there a way for us to identify early on those cases that will become successful? Looking at the drug approval statistics of recent years there is, sad to say, little pointing in that direction. As alluded to previously the level of attrition is stubbornly staying at the annoying figure of roughly 90%, in spite of all the knowledge gathered about causes for diseases, mechanistic understanding of biological events,¹²⁴ and, not forgetting the wealth of data generated by unraveling the human genome. Two main bottlenecks often mentioned in this regard where the scientific frontline expertise will rarely give the correct guidance are validation of the biological target and biomarkers, respectively. In fact these ‘components’ stand at the very center of drug R&D with the former accountable for identifying the specific target (enzyme, protein, cell membrane, organ, etc.) responsible for an illness and the latter for what to measure and how to ensure that certain treatments work and others do not. This situation and all the frustrations caused by it have probably forced many pharmaceutical companies to re-evaluate their business strategies in the direction of a more humble and hopefully realistic approach with less emphasis on speed and more on quality. It takes some courage to say that although we know a lot about how to develop drugs, there is still much more that we don’t know!

What we can be certain about, however, is that there will be progress – slowly but steadily. And at every new failure there will be lessons to take in which will improve the likelihood that, ideally speaking, a repeat of the same mistake should not occur. One of the intrinsic properties of computers besides speed of operation is their capacity to handle enormous amounts of data that human beings cannot really cope with any more. This invaluable feature will allow us to analyze the information matrix from various angles and pick out significant areas of similarities or discrepancies. Most importantly it will be a tool for identifying trends, which in turn will provide powerful support to make predictions on expected outcome. Here we have started to move into new territory where the available *in silico* technologies by virtually drawing from all accumulated experience can direct our move into the future. Science fiction perhaps but in areas where these models have been used and at least partly validated, for example predicting absorption, distribution, metabolism, and excretion (ADME) properties, cardiac toxicity, or human oral drug absorption, it is absolutely clear that the concept is standing on firm ground. Also in the more chemistry-oriented parts of the business these methods are being utilized more and more frequently. The by far best example is Lipinski’s¹⁰⁵ rule of five focusing on physicochemical properties, which is now rather rigorously applied in the early discovery phase to select potential candidate compounds. It will most likely not tell you the absolute truth but instead will provide guidance when you have a wide variety of possible selections. Coupling this sort of predictability tool with for example a statistical analysis of the impact of API molecular weight on survival probability is a step toward extracting even more information out of the data. A comprehensive survey¹²⁵ has shown that the mean molecular weight for marketed oral drugs is somewhere in the interval 330 to 350 and that the population rapidly decreases when the value approaches 500 or above. Thus heavier molecules stand a much greater risk of failure than lighter ones, as projected by this study. Another striking result is that compounds featuring a more lipophilic character (measured as $\log P$ or $\log D_{7.4}$) are more frequently being discontinued than the ones with less. All in all, wise use of predictive tools as the ones mentioned here together with other knowledge might offer a good chance that attrition could start to creep down. It is, however, important to stress that, simply speaking, all tools are built up around models describing how the connection between variables can be expressed and translated into mathematical algorithms. And it is the quality of the latter that will decide how successful a prediction in a particular case will turn out. Furthermore, as most of these tools operate in isolation focusing on their respective field and fail to take other ‘external’ parameters into account, it is highly unlikely that they will all point in the same direction – for example to one particular API as being the optimum – when forecasts are compared.

Pharmacological activity alone is not sufficient for the success of a new drug but, moreover, purely molecular features which for convenience can be grouped together as the aforementioned physicochemical properties have to be given a high degree priority. This has brought the question about ‘druglikeness’ of compounds under evaluation to the forefront and their chance of being druggable.¹²⁶ In individual cases this empirical assessment is of course hampered by the far from 100% precision offered by the predictive tools. Nonetheless it has forced a change of the decision process from having been more or less entirely activity-driven to also encompass parameters like solubility, lipophilicity,

molecular weight, number of hydrogen bonds, and oral bioavailability.¹²⁷ That on top of this expanded evaluatory procedure there is a demand for input from a Process R&D^{58,59,97–99,101–104} and biopharmaceutics/preformulation perspective comes as quite a natural extension. The former to make statements about plausible process design, potential risks during scale-up, availability of raw materials in bulk, and estimated cost of API, while the latter focuses on perceived problems when trying to identify a suitable salt, the foreseeable presence of polymorphs, and eventual technical constraints to achieve the desired formulated drug product. Combining all these sets of data with results from in vitro and animal studies is bound to have a beneficial impact on the quality of the compounds selected and their suitability to be developed into novel drugs.

An interesting observation is that in this dissemination of best practice when it comes to weighing in relevant influencing factors to ensure that the most promising molecule is picked as candidate drug the words chirality or stereochemistry have not been mentioned at all. The reason is not ignorance; instead it shows how deeply this property has become embedded and integrated in the discovery process. Stereoisomers of chiral compounds will inevitably be scrutinized and only if they can be judged equivalent, notably from a safety and efficacy standpoint, might it be considered to take them forward as a racemic mixture or even in a nonequimolar composition. So if stereochemistry is seen as a normal parameter to deal with when hunting for new drug molecules it still has the potential to present some really challenging synthetic problems. Therefore, mastering adequate technologies and methods capable of achieving the desired single enantiomer not only in laboratory amounts but also on scale remains a key asset. And with the declared ambition to drive cost of goods down as a consequence of strong price pressure on medicines (*see* Section 2.17.7) it is even more important that best available technology has to be applied when designing synthetic routes and processes. Furthermore, there is and will always be a desire to minimize waste generation in chemical production, that is to move more and more toward a 'green' manufacturing regimen.^{128,129} One industrially validated way to respond to these kinds of demands is to shift from stoichiometric or superstoichiometric (run with excess reactant and/or reagent) chemistry to catalytic procedures, irrespective of whether the task is to conduct asymmetric or nonstereoselective reactions.^{130,131} In particular the latter problem focusing on environmental impact has been successfully addressed and amply demonstrated, but, equally, the cost of APIs and fine chemicals can undergo substantial improvement. The main contributing factors here are the often better yields attainable, a shorter synthetic sequence, higher productivity, and the move away from expensive reagents. Thus the current trend toward catalytic reactions becomes quite obvious and this approach is now evaluated on virtually a routine basis when considering the preparation of pharmaceutical intermediates and actives. The applicability of catalysis is very broad, allowing a wide range of substrates to be used, but the most spectacular achievements have perhaps been documented in the area of stereoselective synthesis. A renown example has already been mentioned ((*S*)-metolachlor in Section 2.17.2) and another one would be esomeprazole (active ingredient in antiulcer drug Nexium),^{132,133} which is produced commercially by a highly efficient asymmetric sulfide oxidation (Figure 14).^{58,59,98,134–136}

The tough challenge when aiming at designing and developing a catalytic process – irrespective of whether in asymmetric or achiral mode (exemplified by the increasingly popular and versatile C–C, C–N, and C–O coupling reactions following the Suzuki and Buchwald–Hartwig protocols) – is to identify which catalyst will be best for a given substrate. So far this has resulted in tedious trial-and-error work but much hope is placed in finding a prediction model that could dramatically narrow down the list of options in analogy to what has been alluded to earlier. Instead of randomly screening catalyst libraries or probing different experimental conditions such a tool would allow fine-tuning and optimization of a system (a metal in conjunction with the appropriate ligand) to quickly establish its performance on scale-up. Superficially the task seems possible to solve but with the multitude of parameters that can be used to describe such systems – electronic, geometric, and even energetic – it will most likely present a formidable challenge to condense multivariate data sets to their most significant linear combinations allowing a rank order to be calculated with the help of principal component analysis (PCA) technique or other statistical tools.¹³⁷ If successful, however, this could revolutionize the way in which chemical processes are designed in the future with a default position to operate as much as possible under catalytic conditions and where traditional stoichiometry-based transformations appear as rare exceptions.

2.17.10 Major Conclusions and Projections for the Future

It is hoped that this account has provided a comprehensive overview of the current situation and challenges perceived in pharmaceutical R&D, both in a general context and more specifically with an emphasis on the issue of chirality and chiral drugs as seen through the eyes of Process R&D. On top of the wide variety of problems faced by the industry there is also a geographical dimension. This can be illustrated by the fact that in the late 1980s 41% of the top 50 list of innovative drugs originated from the USA, a figure which had risen to 62% a decade later. Furthermore, 1992 saw six out of the 10 best-selling medicines worldwide having been developed in Europe and this measure has fallen sharply to

Figure 14 Efficacious production of the (S)-enantiomer sulfoxide esomeprazole on ton scale using titanium catalyzed oxidation.

only two over the succeeding 10 years. Without knowing exactly where the balance should lie, these figures reveal that some rather dramatic changes have taken place over only a short period of time. The root cause for this is open for debate, but will most certainly include socioeconomic factors, political agendas, variation in the organization of healthcare systems, and differences in the innovative climate. In particular the questions about innovation in the drug industry in general and about whether major pharma is still innovating have been the topics for in-depth analyses.^{15,138}

Having devoted a fair number of pages to discussing the current landscape in the pharmaceutical industry¹³⁹ – its problems, challenges, and opportunities – and trying to explain some of the factors responsible for this as well as pointing out a roadmap for the future,¹⁴⁰ it seems best to summarize the key observations and messages in a condensed format with an emphasis on R&D matters:

- Portfolio composition to maintain an optimal balance between early–late and easy–difficult R&D projects
- Application of right level of risk taking along the Discovery–Development timeline
- Drive down the level of attrition or alternatively ensure a higher success rate
- Reach proofs of principle (PoP) or concept (PoC) as rapidly as possible
- Aim at using validated targets and establish biomarkers that enable unequivocal readout of results
- Explore how maximum use of prediction models and other in silico tools can support selection of more successful drug candidates or best technical methods
- Aspire to use cutting-edge technology wherever needed, but especially to overcome hitherto unsurpassed challenges
- Ensure top-class performance in all aspects along the entire value chain
- Keep cost of goods (API and formulated product) in focus with a declared policy of minimization to ensure profit margins are kept up
- Go for quality in all aspects of drug R&D and especially when appointing a new candidate drug
- Maintain time as a strong driving force when bringing the project forward to decision points and milestones
- Identify scientific and technical must-win areas and ensure the necessary competence level is available
- Debottleneck the value chain, particularly the R&D portion, to avoid unnecessary delays or misjudgements
- Apply strict cost control and decision-making
- Foster the skills and abilities to work across disciplinary and cultural boundaries in a global environment.

It would not be impossible to come up with another list of at least as many topics as are included in the one above, but depending on personal priorities and circumstances in individual companies there will always be variations, not to speak of the wide spread of opinions that one would face when asking for a prioritization from most to least important. In all likelihood company A would approach the challenges differently from company B, which however does not mean that their respective solutions are so far apart. It is important to stress that in as complex an environment as represented by the healthcare sector and the pharmaceutical industry it is not sufficient if one or a few areas operate effectively and efficiently. This *modus operandi* has to be adopted throughout the whole arena.

To finish off with a question as food for thought: where will the concept of personalized medicine¹⁴¹ take us in the future? Will this, as it seems, revolutionary therapeutic approach be the dominating medicinal practice 10, 15, or 20 years from now? Impossible to say, but certainly something to speculate about and have your own visions for!

Biography

Hans-Jürgen Federsel, PhD, is a renowned specialist in the field of process R&D where he has spent his entire professional career spanning a period of 30 years. Starting off as bench chemist in former Astra at the major Swedish site in Södertälje he has climbed the ranks occupying positions both as line and project manager as well as being Director of a global project and portfolio management function. After the merger that formed AstraZeneca in 1999 he became Head of Projects Management at Södertälje and was then appointed to a newly created role as Director of Science in Global Process R&D from the beginning of 2004. In connection with this he was also given the prestigious title Senior Principal Scientist. Strong academic links have been further developed throughout the years after obtaining his PhD in organic chemistry in 1980 at the Royal Institute of Technology in Stockholm; his award of an Associate Professorship

there in 1990 recognized this. Furthermore, his long-lasting links to this Institute have recently brought him a seat on the Board of the School of Chemical Science and Engineering. Publishing in peer-reviewed journals and books and frequent lecturing has made Dr Federsel's name well known far beyond the limits of his own company, and he enjoys invitations from all over the world to share learning and experience from his broad knowledge base on process R&D.

2.18.1 Introduction

Virtual and experimental high-throughput screening (HTS) are widely used to identify novel ligands for drug development.^{1–4} Despite their successes, these methods are haunted by false positives, compounds that initially appear to have a desired biological activity but on closer evaluation are found to act by spurious mechanisms. Often, these counterfeit screening hits have peculiar behaviors that cannot be reconciled with canonical modes of inhibition. These compounds are ultimately found to be developmental dead-ends and are discarded, typically after a great deal of time and resources has been devoted to them.

The frustration caused by such molecules is compounded by their prevalence; it has been estimated that in any given experimental HTS, the ratio of false positives to true positives is at best 1:1 and more likely 10:1.⁵ This enrichment of phony inhibitors has led to increased scrutiny of hit lists and an increased interest in developing filters and counterscreens to rapidly recognize and eliminate ‘non-lead-like’ compounds from further consideration.^{6–11}

Toward this end, work over the last decade has been devoted to understanding the origins of false-positive screening hits. Experimental artifact, such as compound impurity¹² or assay interference,^{7,13} is a well-known cause. Inhibitor promiscuity due to reactive groups^{14,15} or privileged scaffolds^{16–22} has also been described. More recently, aggregate formation has emerged as a potential mechanism of promiscuous inhibition.^{23,24} This model proposes that some nonspecific inhibitors form aggregates in solution and that the aggregate species is responsible for enzyme inhibition (Figure 1). Preliminary studies suggest that aggregate-forming promiscuous compounds may be common among screening libraries and hit lists. This chapter will initially focus on nonspecific enzyme inhibition as caused by aggregate-forming molecules and will review experimental methods for the identification of such compounds. Computational algorithms for the prediction of all types of promiscuous inhibitors will then be discussed and outstanding questions regarding promiscuous inhibitors in drug discovery will be considered.

Figure 1 Model of promiscuous enzyme inhibition. The promiscuous compounds form aggregates in solution and enzyme molecules (white arrows) adsorb onto the surface of the aggregate particle, resulting in enzyme inhibition. Although initial microscopy images suggest surface adsorption of enzyme molecules, absorption of enzyme into the aggregate interior cannot be excluded. (Reprinted with permission from McGovern, S. 2.18.2 Promiscuous Inhibition by Aggregate-Forming Compounds

By the late 1990s, experimental and virtual HTS were commonly used to identify new leads for drug design. Although various screening techniques and algorithms had been developed, it became apparent that the output from these large-scale methods was suboptimal. Hit lists were populated, if not dominated, by nonspecific compounds with peculiar properties, such as steep inhibition curves, flat structure–activity relationships (SARs), and complex time-dependent behavior. Despite the use of filters for reactivity,¹⁴ chemical swill,¹¹ and druglikeness,²⁵ problematic molecules continued to appear on screening hit lists. These compounds caused much frustration and were often abandoned after significant effort had been invested in them.

To explore the underlying mechanism responsible for this perplexing behavior, 115 compounds were initially investigated. This included 45 screening hits,^{23,24} 15 leads used as experimental tools,²⁶ and 55 clinically prescribed drugs.²⁷ Of the 115 compounds studied, 53 were found to inhibit diverse model enzymes, including β -lactamase, chymotrypsin, dihydrofolate reductase, and β -galactosidase. These promiscuous compounds showed time-dependent inhibition that was sensitive to enzyme concentration, the presence of bovine serum albumin (BSA), and ionic strength. Based on these observations, it was hypothesized that the nonspecific compounds formed aggregates in solution, and the aggregate particles caused enzyme inhibition (**Figure 1**).²³ Consistent with this hypothesis, dynamic light scattering (DLS) and transmission electron microscopy revealed that the promiscuous compounds formed particles on the order of 30–1000 nm in diameter; these particles were absent from solutions of nonpromiscuous compounds.²³

How did the aggregate particles interact with enzyme molecules to cause inhibition?²⁴ Centrifugation experiments suggested a direct interaction between aggregate-forming inhibitors and enzyme molecules; this interaction was disrupted by the addition of detergent such as Triton X-100.²⁴ Aggregate formation and enzyme inhibition by the promiscuous compounds were also prevented or rapidly reversed by the addition of Triton X-100.²⁴ Additional microscopy studies showed that protein molecules were adsorbed onto the surface of the aggregate particles, although absorption into the aggregate interior could not be excluded. This interaction was also prevented by the addition of detergent such as Triton X-100.²⁴ To account for these observations, it was proposed that some promiscuous compounds form aggregates in solution and enzyme molecules adsorb onto the surface of the aggregate particle, resulting in reversible enzyme inhibition (**Figure 1**).²⁴

Since the first proposal of this model, a growing number of research groups have identified potential aggregate-based inhibitors among their screening hits (**Table 1**). Their observations, in addition to the initial, small-scale evaluation of the prevalence of aggregators suggest that they occur among screening hits,^{23,28–31} small-molecule reagents used in the lab,²⁶ and, surprisingly, even clinically used drugs.^{27,32} A recent study evaluating 1030 random druglike molecules suggests that up to 19% show experimental signatures of aggregate-based promiscuity.³³ Because of the potentially widespread occurrence of aggregate formers, there is much interest in the development of rapid experimental methods for the identification of these promiscuous compounds. There has also been a growing interest in the development of computational models to predict compounds likely to act as aggregate formers because such filters could be used to remove suspect molecules from screening libraries or from hit lists. These experimental and computational efforts are considered in turn in the following sections.

Table 1 Promiscuous compounds from virtual and high-throughput screening

Structure	Type of screen	IC ₅₀ (μM) versus target	Experimental evidence for promiscuity	Reference
	Virtual screen	5 β-Lactamase	<ul style="list-style-type: none"> • Decreased inhibition with detergent • Decreased inhibition with increased enzyme concentration • Inhibition of diverse enzymes • Time-dependent inhibition • Particles observed by DLS 	23,24

2.18.3 Experimental Identification of Promiscuous Inhibitors

The peculiar experimental signature of aggregate-forming compounds can be used to distinguish them from specific, well-behaved inhibitors,^{23,24,28} and several research groups have used these characteristics to triage their screening hits for potential promiscuity.^{12,28–31,34–42} The appropriate experiments range in complexity and intensity from a rapid

biochemical assay to a much more laborious microscopy study. Depending on the purposes of the research effort, these experiments can be tailored appropriately. For most early-stage discovery programs, the following experiments are performed to answer the question: Is this hit likely inhibiting the screening target as an aggregate? If the answer is yes, it is unlikely that the hit will be a favorable starting point for lead design and it should be dropped from further consideration immediately, as the pain of throwing out compounds early in the process pales in comparison to the agony of abandoning leads that have been through several nonproductive development cycles. If the answer to the above question is no, then one element of the hit's potential has been reassuringly established. The necessary experiments and examples of their recent application in drug discovery projects are described below; detailed recipes for performing these assays have been described elsewhere.⁴³

2.18.3.1 Biochemical Assays for Promiscuity

Fortunately for screening programs faced with evaluation of tens to thousands of hits, the most informative experiments are among the easiest to perform and are the most amenable to high-throughput methods. Often, the experimental assay that initially identified the screening hit can be easily modified to accomplish many of the initial tests of promiscuity. Additionally, these protocols can be used to assay for other mechanisms of promiscuity, such as chemical reactivity. If the original assay lacks sufficient dynamic range or is otherwise difficult to alter, it may be simpler to use easily purchased model enzyme systems such as chymotrypsin or β -lactamase. Colorimetric, kinetic assays have proven to be especially robust for these purposes.

The particular components of the assay can affect the outcome. For instance, the ionic strength²³ and pH⁴⁴ of the buffer can alter the aggregation and inhibition properties of the compounds; 50 mM potassium phosphate, pH 7.0, has previously been found useful. Increased enzyme concentration²³ or the presence of excess protein such as albumin^{23,30} can decrease the apparent inhibition by aggregators; a starting enzyme concentration of 1–10 nM is typical. Ideally, solutions of inhibitors and substrate are prepared from fresh buffer or dimethyl sulfoxide (DMSO) stocks and diluted into buffer so that the final DMSO concentration in the assay is as low as possible, preferably less than 5%. Substrate concentrations are typically greater than the K_m for the reaction to allow for maximal velocities.

2.18.3.1.1 Detergent sensitivity

In the presence of detergents such as Triton X-100, inhibition by aggregate-forming inhibitors is markedly attenuated. For instance, the inhibition of β -lactamase by a 3 μ M solution of tetraiodophenolphthalein (I4PTH), a prototypical aggregator, decreases from 78% in the absence of detergent to 3% in the presence of 0.01% Triton X-100.²⁴ Indeed, Triton X-100 rapidly reverses inhibition of β -lactamase by I4PTH without affecting a specific, well-behaved inhibitor of the enzyme (Figure 2).

To date, detergent sensitivity is the easiest way to discriminate between aggregators and nonaggregators.^{24,45} Therefore, the most rapid method of identifying aggregate-based inhibitors is to repeat the screening assay with the addition of 0.01% Triton X-100. A typical protocol consists of incubating fresh detergent, inhibitor at the IC_{50} (concentration of inhibitor that reduces enzyme activity by 50%), and enzyme for 5 min and initiating the reaction with substrate.^{24,43,45} If inhibition is due to aggregation, inhibition should decrease from 50% to less than 40% in the presence of detergent. It may also be useful to consider adding 0.01% Triton X-100 to the baseline assay buffer as a prophylactic measure to prevent aggregate-forming compounds from appearing as inhibitors at all.

The first control for this experiment requires establishing that the addition of Triton X-100 does not significantly affect the reaction rate or any of the other assay components. A negative control experiment will show that a well-behaved inhibitor of the system is not affected by the detergent, and a positive control will show that a known aggregator, such as I4PTH,²³ is attenuated by the detergent.

It is worth noting the discussion in this chapter emphasizes the use of Triton X-100, as it has been shown to reverse enzyme inhibition by aggregators (Figure 2).²⁴ Other detergents have been employed as agents to study promiscuity, such as saponin,^{27,38} Tween-20,⁴⁵ and CHAPS.^{34,45}

Because of its relative simplicity, detergent sensitivity has been used in a growing number of drug discovery projects to triage compounds for promiscuity (Table 1).^{28,34–36,38,39} For instance, using a library of 147 compounds derived from the Cdc25A phosphatase inhibitor dysidiolide, Koch and co-workers found selective inhibitors of three enzymes that were structurally similar to Cdc25A. All of the library compounds were assayed against each target enzyme in the presence and absence of 0.001 or 0.01% Triton X-100 to ultimately identify the specific inhibitors.³⁵ Detergents have also been used to study the inhibition of PTP1b by ertiprotafib, a compound that had reached phase II clinical trials (Table 1).³² The IC_{50} of ertiprotafib against 1 nM PTP1b increased 10-fold with the addition of 0.01% Triton X-100. This observation, in combination with other properties of the compound,³² was consistent with an aggregate-based mechanism of inhibition.

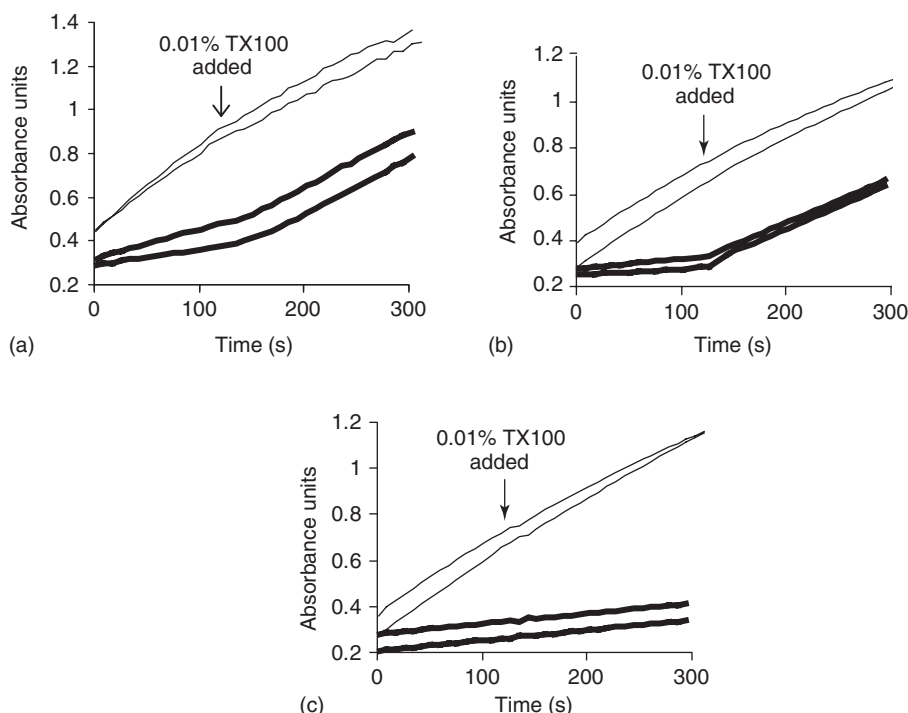

Figure 2 The effect of 0.01% Triton X-100 added during a β -lactamase inhibition assay. (a) Inhibitor is 10 μ M I4PTH. (b) Inhibitor is 5 μ M rottlerin. (c) Inhibitor is 0.6 μ M BZBTH2B, a specific β -lactamase inhibitor.⁵⁹ In all panels, thick lines (—) denote reactions containing inhibitor and thin lines (—) denote reactions containing DMSO control. TX100, Triton X-100. (Reprinted with permission from McGovern, S. L.; Helfand, B. T.; Feng, B.; Shoichet, B. K. *J. Med. Chem.* **2003**, 46, 4265–4272. Copyright (2003) American Chemical Society.)

2.18.3.1.2 Sensitivity to enzyme concentration

The key observation leading to the development of the aggregate hypothesis was that the promiscuous inhibitors were sensitive to the concentration of enzyme. For instance, a 10-fold increase in the concentration of β -lactamase from 1 to 10 nM was sufficient to increase the IC_{50} of 35 aggregate-forming compounds by 3- to over 50-fold, even when the inhibitor was present at micromolar concentrations.²³ The ability of nanomolar enzyme to titrate micromolar inhibitor suggested that the active form of the inhibitor might be an aggregate of many individual inhibitor molecules; although the ratio of individual inhibitor molecules to enzyme molecules might be 1000:1 or greater, the ratio of aggregate particles to enzyme molecules would be much lower.

To evaluate screening hits for this property, the concentration of the target enzyme is increased 10-fold and the assay is repeated with the inhibitor at the IC_{50} obtained at the baseline enzyme concentration. If aggregate formation is involved, inhibition ought to decrease from 50% to less than 40% against the 10-fold greater concentration of enzyme. This assay requires that the ratio of inhibitor to enzyme remains elevated, on the order of 1000:1 or greater, even after the enzyme concentration has been increased. Many assays may not be able to tolerate increases in enzyme concentration due to cost, limited reagent availability, or an increased reaction rate that makes it technically difficult to obtain accurate velocity measurements. In such cases, it may be helpful to decrease the initial assay concentration of the enzyme or to use alternative substrates with slower reaction rates.²³

As in the detergent assay described above, a well-behaved inhibitor should not be affected by the increase in enzyme concentration and can serve as a negative control.²³ A known aggregator that has been shown to be sensitive to enzyme concentration should be used as a positive control.^{23,26,27}

This protocol has also been used by several research groups to evaluate screening hits.^{13,28,36,37} For example, Disperse Blue against 3.3 μ g mL⁻¹ phosphomannomutase/phosphoglucomutase (PMM/PGM) had an IC_{50} of 5 μ M; when the enzyme concentration was increased to 33 μ g mL⁻¹, the compound did not show any detectable inhibition up to 10 μ M.²⁸ Similarly, the IC_{50} of ertiprotafib against PTP1b increased from 1.6 to 9 μ M as the concentration of the enzyme increased from 10 to 100 nM.³²

The inclusion of BSA also decreases the potency of aggregate-based inhibitors through a similar mechanism to increasing the enzyme concentration, except enzyme molecules are displaced from inhibitor particles by inert protein instead of active enzyme.²³ Consequently, addition of BSA to screening assays has been used to accomplish the equivalent purpose; for examples, see ^{30,36} and Table 1.

2.18.3.1.3 Inhibition of diverse model enzymes

One of the earliest warning signs leading to the discovery of aggregators was their ability to inhibit dissimilar targets.²³ For example, rottlerin, a widely used kinase inhibitor,⁴⁶ has an IC_{50} of 3 μ M against PKC δ , 1.2 μ M against β -lactamase, 2.5 μ M against chymotrypsin, and 0.7 μ M against malate dehydrogenase.²⁶ It has since become clear that aggregators can inhibit a variety of enzymes, ranging from β -lactamase (40 kDa monomer) to β -galactosidase (540 kDa tetramer).²³

Ideally, for each screening hit under consideration, at least one counterscreen is performed against an enzyme that is unrelated to the target enzyme in terms of structure, function, and ligand recognition. Depending on the level of certainty required, testing against one dissimilar enzyme may be sufficient; testing against two or more provides additional reassurance. Screening across receptors also allows for investigation of other mechanisms of promiscuity, such as chemical reactivity or privileged scaffolds; nonspecific inhibition from any mechanism may be sufficient to drop the compound from further optimization studies.

For secondary screening to be practical, an experimentally robust system with readily available components and a straightforward assay readout should be used. Beta-lactamase, chymotrypsin, and malate dehydrogenase have been used successfully in the past.^{26,27,29,31,45} It may be more convenient to use enzymes already known to the research group; for instance, Fattorusso and colleagues assayed a novel caspase inhibitor discovered in a combination NMR and computational screening project against a metalloprotease that was also under investigation in their laboratory.³⁷

Control experiments for these assays are straightforward. Specific inhibitors of the target enzyme and the enzymes used for counterscreening should not cross-react. For the positive control experiment, a known aggregator should be shown to inhibit each enzyme under study.

In practice, hits are often tested against related enzymes to evaluate for specificity within a protein class or across species.⁴⁶ For instance, Blanchard and co-workers used HTS of 50 000 compounds to identify novel coronavirus proteinase inhibitors. After a series of filters, the 572 hits yielded five compounds with IC_{50} values of 0.5–7 μ M for the target, and two of those compounds inhibited coronavirus protease but not four other proteases.³⁰ Baldwin and colleagues screened a 220 000 compound library to find novel inhibitors of dihydroorotate dehydrogenase from *Plasmodium falciparum*; follow-up screens identified a competitive inhibitor with an IC_{50} of 16 nM against the parasite enzyme and 200 μ M against the human isozyme.¹² These approaches have been extended by recent technological developments that allow for testing compounds against multiple enzymes in parallel. For instance, proteomics-based methods^{47,48} and enzyme microarrays⁴⁹ have been described. These techniques provide an evaluation of inhibitor specificity against several enzymes simultaneously; future developments along these lines can be expected.

2.18.3.1.4 Time-dependent inhibition

Preincubation of aggregate-based inhibitors with enzyme increases the apparent IC_{50} of the compounds 2- to over 50-fold.^{23,26,27} Several mechanisms could account for this observation, such as slow on-rates or covalent binding. To explore the origin of time-dependent behavior by aggregators, Tipton's group conducted a thorough analysis of the kinetic behavior of Disperse Blue.²⁸ Their results suggested that slow-binding did not occur when this compound interacted with its target enzyme, PMM/PGM. Instead, they found that the compound behaved as a parabolic, noncompetitive inhibitor, and they proposed that the kinetic signature of time-dependent inhibition with a nonlinear dependence on inhibitor concentration may be a marker for aggregation.²⁸ Future studies to evaluate the generalization of this observation are certainly anticipated. In the meantime, it should be noted that time-dependent inhibition is consistent with several modes of enzyme inhibition and is not singularly sufficient to denote a compound as an aggregator.

In a typical test for time dependence, an IC_{50} is determined by incubating enzyme with inhibitor for 5 min and initiating the reaction with substrate. The assay is then repeated, except substrate is first mixed with the inhibitor at the IC_{50} concentration and the reaction is initiated by the addition of enzyme. If inhibition without incubation decreases from 50% to less than 40%, the result is consistent with the time-dependent behavior observed of aggregators. Control experiments include repeating the assay with a specific, nontime-dependent inhibitor of the target enzyme as well as a known aggregator. These protocols are usually performed in conjunction with other assays to evaluate inhibitor behavior (e.g., see ³²).

2.18.3.1.5 Steep inhibition curves

It has been observed that steep inhibition curves are often associated with undesirable screening hits.⁵⁰ This experimental property has been used as a filter to triage compounds; for example, in their search for coronavirus inhibitors, Blanchard and co-workers eliminated 54 of 126 compounds because they did not have a sigmoidal semilogarithmic dose–response curve.³⁰ Aggregate-forming inhibitors have also been shown to have a steep inhibition curve relative to classically behaved inhibitors,²⁶ although mechanistic understanding of this experimental observation awaits further study.

2.18.3.2 Light Scattering

The biochemical experiments described above provide phenomenological support for the identification of an aggregate-based inhibitor, but they do not yield direct evidence for the presence of aggregate particles. To obtain such data, a biophysical method such as DLS is necessary. DLS has a growing number of applications in the biological and material sciences, but this discussion will focus on the use of DLS to determine if particles are present in a solution of a promiscuous inhibitor and, if so, what is their size? In conjunction with the assays previously described, DLS completes the series of experiments typically needed to characterize a promiscuous, aggregate-based inhibitor.

DLS is most commonly used to analyze particles with a diameter of 1–1000 nm. In a standard setup, a sample of the solution under study is placed in a chamber and exposed to a laser. Particles in the sample cause the laser light to scatter. A detector at a fixed angle relative to the chamber records the scattered photons over a period of time, usually tens of seconds to minutes. Because particles in the sample undergo Brownian motion, the intensity of the scattered light measured by the detector will fluctuate, typically on the microsecond timescale. These fluctuations reflect the rate of diffusion by the particle in solution, which in turn depends on the hydrodynamic radius of the particle according to the Stokes–Einstein equation. The necessary calculations are performed by software provided with the DLS instrument, and given certain assumptions about particle shape and distribution, the hydrodynamic radius can be used as a measure of particle size. This is only a brief explanation of the method; for more details on the theory and practice of DLS, see descriptions by Santos⁵¹ and Wyatt.⁵²

For analysis of a promiscuous inhibitor, the first task is to determine if particles are present. Graphically, this can be determined from the shape of the autocorrelation function obtained during the DLS experiment. For instance, rottlerin is a known promiscuous, aggregate-forming inhibitor,²⁶ and it yields an autocorrelation function with well-defined decay on the microsecond timescale as shown in **Figure 3a**. The same is true for K-252c, another promiscuous kinase inhibitor (**Figure 3b**). Surprisingly, suramin, a compound that is known to inhibit multiple targets, produces an autocorrelation function with a poorly defined decay, suggesting that it does not form aggregates in solution (**Figure 3c**).²⁶

Additionally, it is useful to note the average intensity of the scattered light at the detector during the experiment. This is usually reported as counts per second (cps) or kilocounts per second (kps). The absolute value of the intensity will depend on the particular instrument used, but solutions that are known to be particle free, such as filtered water, should yield average intensities at least an order of magnitude less than that of solutions known to contain particles, such as latex beads or albumin. Therefore, it is worthwhile to conduct both positive and negative control experiments to evaluate the signal-to-noise ratio of the instrument.

If particles are present, the next step is to determine their size. Typically, this is calculated by software that accompanies the instrument. Results between different algorithms, even in the same software package, can vary markedly based on assumptions about particle shape. Again, it is worthwhile to test the system using particles of known size, such as latex bead standards or albumin.

More recent developments in DLS technology allow for coupling of DLS with a high-performance liquid chromatography (HPLC) column to provide rapid eluent analysis. Of particular interest for screening purposes, at least two companies (Wyatt Technology Corporation and Precision Detectors, Inc.) have developed high-throughput DLS, increasing the number of compounds that can be studied by this method.

A growing number of research groups have incorporated DLS into their evaluation of hit or lead compounds. For instance, Klebe's group used DLS to rule out aggregation as a contributor to the inhibition of tRNA-guanine transglycosylase by several hits identified in a FlexX-based screen.⁴⁰ Similarly, Wang and co-workers used light scattering to rule out aggregation as contributor to the activity of a novel non-nucleoside reverse transcriptase inhibitor (NNRTI).³⁹ The technique has also been used to confirm the presence of particles in solutions of suspected promiscuous inhibitors. Soelaiman and colleagues used DOCK to identify new inhibitors of edema factor, a toxin secreted by *Bacillus anthracis*. Three active compounds were evaluated by DLS, and one was found to form particles greater than 1000 nm in diameter.²⁹ Tipton's group also used DLS in their analysis of Disperse Blue; at 10 μ M,

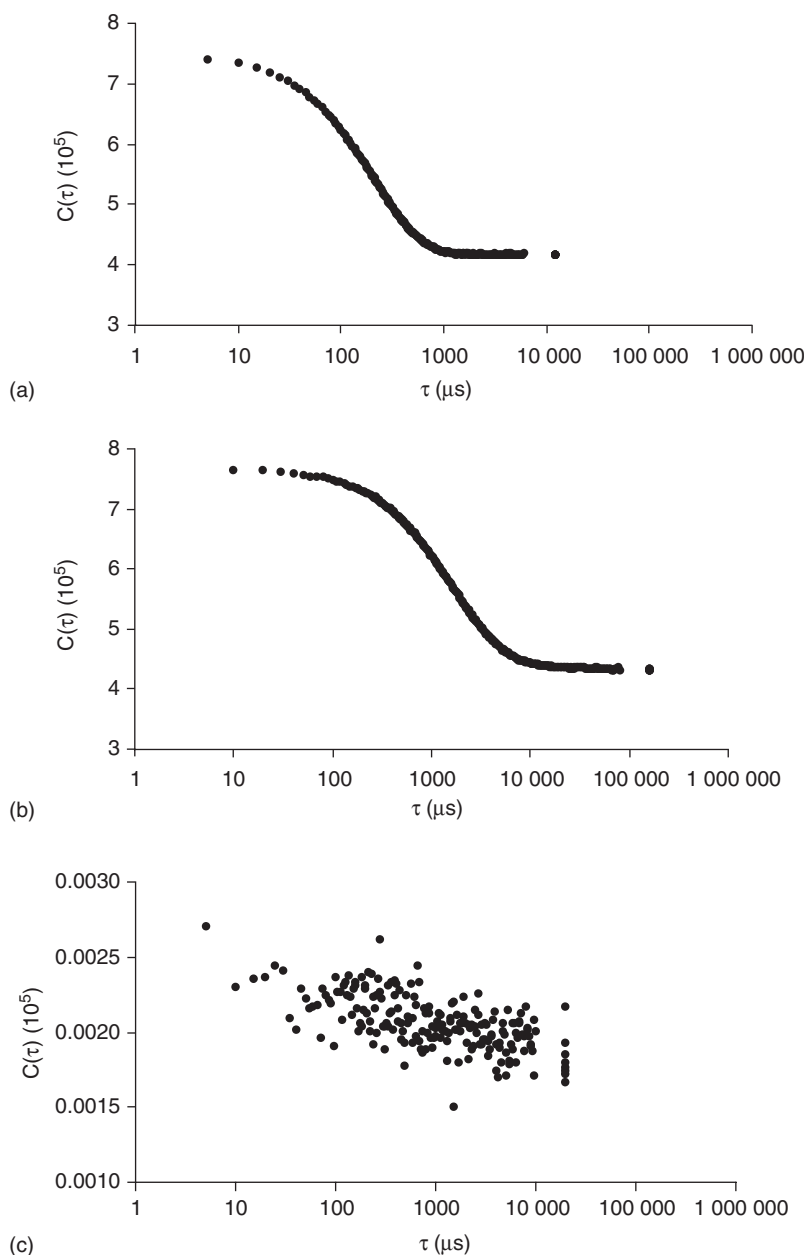

Figure 3 Representative autocorrelation functions from DLS experiments. (a) 15 μM rottlerin, (b) 10 μM K-252c, and (c) 400 μM suramin. (Reprinted with permission from McGovern, S. L.; Shoichet, B. K. *J. Med. Chem.* **2003**, 46, 1478–1483. Copyright (2003) American Chemical Society.)

the compound was observed to form particles with a mean radius of 43.4 nm and average scattering intensity of 92.4 kcps.²⁸

DLS has also been used to explore the factors influencing aggregation by small molecules. In a report from Arnold's group, 15 diaryltriazine and diarylpyrimidine NNRTIs were studied by DLS to evaluate the effect of pH and compound concentration on aggregate size.⁴⁴ All of the compounds were found to form particles in solution. For three compounds studied in detail, aggregate size increased as the pH increased from 1.5 to 6.5. Aggregate size was also found to increase as the inhibitor concentration increased from 0.001 to 10 mM. Intriguingly, compounds with particle radii of 30–110 nm had more favorable absorption than compounds with radii greater than 250 nm, and it was proposed that the systemic adsorption of the drugs depended on the formation of appropriately sized aggregates.⁴⁴

2.18.3.3 Microscopy

Confocal fluorescence and transmission electron microscopy have been used to visualize small molecule aggregates and to explore the interaction of these particles with protein.^{23,24,44} Low-resolution imaging has been obtained by confocal study of green fluorescent protein (GFP) in the presence of I4PTH aggregates.²⁴ Initial images obtained by this method suggest that the inhibitor aggregates cause GFP to accumulate in clusters; these clusters dissolve upon addition of Triton X-100 (**Figure 4**). Notably, GFP retains its fluorescence signal in the presence of I4PTH, suggesting that the protein is not denatured by the aggregates (**Figure 4b**). Higher resolution imaging of similar solutions of β -galactosidase and I4PTH obtained by transmission electron microscopy show that the protein adsorbs onto the surface of the inhibitor aggregate (**Figure 4e**), and with the addition of detergent, this interaction is prevented (**Figure 4f**). These observations, in combination with biochemical and biophysical studies, suggest that enzyme is adsorbed onto the surface of the aggregate particles and thereby inhibited, although absorption into the aggregate interior cannot be excluded.²⁴ Furthermore, the interaction between aggregate and enzyme can be prevented or reversed by the addition of Triton X-100.²⁴

Electron microscopy is an intensive process not typically amenable to screening, although there has been at least one report of a research program using transmission electron microscopy to evaluate a novel drug lead for aggregation.³⁹ The technique was also used to visualize aggregates formed by NNRTIs studied by Arnold's group; although these compounds were not considered promiscuous, aggregate formation was suggested to mediate bioavailability of the drugs.⁴⁴

2.18.3.4 Additional Confirmation Assays

Beyond the experiments described above, there are several tests one could consider performing to evaluate screening hits for peculiar behavior. Most simply, the original assay could be repeated under exactly the same conditions to evaluate for trivial experimental errors.¹³ More rigorously, it has been proposed that when the same compound library is screened against the same target in three different assay protocols, the agreement between assays is only 35%.¹

Figure 4 Visualization of I4PTH aggregates and GFP molecules by confocal fluorescence microscopy (a–c) and TEM (d–f). (a) 0.33 mg mL^{-1} GFP alone. (b) 0.25 mg mL^{-1} GFP with $500 \mu\text{M}$ I4PTH. (c) 0.25 mg mL^{-1} GFP with $500 \mu\text{M}$ I4PTH and 0.0075% Triton X-100. (d) 0.5 mg mL^{-1} GFP alone. (e) 0.1 mg mL^{-1} GFP with $100 \mu\text{M}$ I4PTH. (f) 0.1 mg mL^{-1} GFP with $100 \mu\text{M}$ I4PTH and 0.001% Triton X-100. Representative I4PTH aggregates are marked with black arrows, GFP molecules with white arrows. Bar = $5 \mu\text{m}$ in panels a–c; bar = 200 nm in panels d–f. Consequently, it may be useful to design an alternative assay protocol for the target and then rescreen the entire library or, less laboriously, only the initial hits with the alternative format.¹³

Depending on the particular screening protocol used, it may be informative to test the compound set for interference with the assay readout. For instance, Jenkins and colleagues used a fluorescence-based HTS to identify angiogenin inhibitors.¹³ The initial set of hits was re-plated with activated fluorescent substrate to evaluate the hits for interference with the fluorescent readout; strikingly, 73% of the hits were found to interfere.¹³

Screening for chemical reactivity may also be productive. The ability of the same screening hit to inhibit diverse receptors, as described above, may be the first sign of reactivity. Time-dependent behavior may also suggest an irreversible reaction. More directly, some authors have found it useful to repeat the screening assay in the presence of dithiothreitol (DTT) to evaluate hits for thiol reactivity.^{15,30} Alternatively, mass spectrometry (MS) has been used to evaluate compounds for adduct formation.¹⁵

Less glamorously but no less importantly, it is often useful to evaluate the purity of screening hits because the observed activity may be due to a contaminant. A variety of approaches are possible; most simply, a new solution of the compound can be prepared from fresh powder or with powder from a different lot.¹⁵ Alternatively, the compound can be repurified and then reassayed.¹⁵ For a more rigorous analysis, HPLC or MS can be employed to detect impurities.¹²

2.18.4 Computational Prediction of Promiscuous Compounds

Given the expense of experimental work and the desire to minimize efforts spent on false positives, there is a considerable interest in the development of computational methods to predict compounds likely to behave promiscuously. Since Lipinski's seminal work showed that 90% of drugs share a common set of easily identified properties,²⁵ there has been much effort devoted to predicting druglike behavior based on chemical structure. The following section will review recent computational approaches for identifying various classes of promiscuous compounds.

2.18.4.1 Frequent Hitters

As defined by the Roche group, 'frequent hitters' are compounds that appear as actives in multiple screening projects, across a range of targets.⁵³ These include reactive species, compounds that interfere with the assay, and privileged scaffolds. To predict compounds likely to act as frequent hitters, Roche and colleagues first developed a database of known frequent hitters. These compounds were culled from compounds that had hit in at least eight different HTS assays, compounds from an in-house depository that had been requested by at least six different discovery projects, and additional compounds from various sites within Roche.⁵³ Eleven teams of medicinal chemists voted on the structures to identify molecules that according to their expert opinion and experience were likely to be frequent hitters. To obtain a set of nonfrequent hitters, a diverse set of compounds from the Roche human drug database were selected. The final data set contained 479 frequent hitters and 423 nonfrequent hitters.⁵³

Structural analysis with LeadScope revealed that no single substructure was sufficient to identify a frequent hitter. To extend the analysis, Ghose and Crippen descriptors were calculated for all compounds in the data set and used to define a partial least squares (PLS) multivariate linear regression model. The PLS model correctly predicted 92% of frequent hitters and 88% of nonfrequent hitters. The group then developed a nonlinear model using a neural network, again based on the Ghose and Crippen descriptors. The final model correctly classified 90% of frequent hitters and 91% of nonfrequent hitters.⁵³ As the authors explained, 'frequent hitter' is not synonymous with 'undesired structure;' for instance, ligands that bind a similar set of receptors will cross-react because of common substructures. Therefore, this model was not intended for elimination of compounds but for prioritization of compounds for purchase, library design, or testing.

A subsequent effort to identify frequent hitters was described by Merkwirth and co-workers.⁵⁴ Various single and ensemble methods, including k-nearest neighbors classifiers, support vector machines (SVM), and single ridge regression models, were derived for binary classification of compounds. These models were then trained against the same frequent hitters data set described above. The best models had cross-validated correlation coefficients of up to 0.92 and misclassification rates of 4–5%, an improvement from the 10% misclassification rate produced by the neural network approach.⁵⁴

2.18.4.2 Aggregators

Recent efforts have been directed toward the problem of identifying aggregating promiscuous inhibitors. Seidler and colleagues screened 50 clinically prescribed drugs and found that seven showed aggregate-based inhibition of

β -lactamase, chymotrypsin, and malate dehydrogenase.²⁷ These experimental results were used to develop a data set of 111 compounds containing 48 aggregators and 63 nonaggregators. Simple cutoffs based on solubility or ClogP classified 87% or 81% of the 111 compounds correctly, respectively. To obtain a more precise model, a recursive partitioning algorithm based on 260 physicochemical descriptors was developed (Figure 5). As shown in Table 2, the model correctly classified 43 of 48 aggregators (90%) and 61 of 63 nonaggregators (97%).²⁷

The same neural network⁵³ and SVM method⁵⁴ described in the preceding section were then tested against the 111 compounds in the aggregator test set; the results are described fully in⁵⁴ and briefly here (Table 2). The neural net identified 30 of 48 aggregators (63%) and 53 of 63 nonaggregators (84%) with a Matthew's correlation coefficient of 0.48. The SVM method correctly predicted 32 of 48 aggregators (67%) and 58 of 63 nonaggregators (92%) with a Matthew's correlation coefficient of 0.63. In summary, these methods did not discriminate between aggregators and nonaggregators as well as the recursive partitioning model. One obvious cause is that these models were trained against a data set containing frequent hitters acting by a variety of mechanisms, not simply aggregation. Nonetheless, it

Figure 5 Recursive partitioning analysis of 111 aggregators and nonaggregators. Each branch contains the physicochemical criterion used to split a group of compounds; T indicates compounds that satisfy this criterion, and F indicates compounds that do not. Terminal nodes are green and coded as 'NON' if they consist predominantly or completely of nonaggregators; terminal nodes are red and coded as 'AGG' if they are predominantly or completely aggregators. Nodes with more compounds are identified by larger circles. (Reprinted with permission from Seidler, J.; McGovern, S. L.; Doman, T. N.; Shoichet, B. K. *J. Med. Chem.* **2003**, 46, 4477–4486. Copyright (2003) American Chemical Society.)

Table 2 Classification rates for three different algorithms tested on the same data set of 48 aggregators and 63 nonaggregators

Algorithm	Aggregators correctly classified (total = 48)		Nonaggregators correctly classified (total = 63)		Reference
	No.	%	No.	%	
Recursive partitioning	43	90	61	97	27
Neural network	30	63	53	84	53
Ensemble method (SVM) ^a	32	67	58	92	53

^aSVM, support vector machines.

is remarkable that these algorithms performed as well as they did, given that the molecules on which they were trained were not specifically designated aggregators or nonaggregators. Indeed, it is intriguing to consider that the frequent hitters data set may include (as yet unidentified) aggregators, thereby contributing to the success of these models.

Recently, an additional 1030 compounds have been tested for aggregation³³; the results increase the number of publicly reported compounds studied for this property by an order of magnitude. As the database of compounds explicitly found to be aggregators or nonaggregators grows, it is hoped that these data will provide greater insight into the nature of aggregation and enable the development of more precise models.

2.18.4.3 Privileged Substructures

Certain molecular scaffolds encode for recognition of diverse receptors. These privileged substructures are often starting points for the design of ligands with improved specificity for a particular receptor. This section will review two pharmacophore-based studies describing the use of privileged substructures for designing G protein-coupled receptor (GPCR) targeted compound libraries¹⁷ and for identifying promiscuous kinase inhibitors.¹⁶

Mason and co-workers introduced a method for generating 4-point pharmacophores that could be modified to include a pharmacophore for a particular substructure such as a privileged scaffold.¹⁷ Using Chem-X, atom types were automatically generated and assigned to a feature type used to generate the pharmacophore. Atom types or dummy centroid atoms unique to a privileged substructure were designated as a special 'privileged' feature type. This feature type was designated as one of the four points used to generate the pharmacophore map for the compound. Because all of the subsequent pharmacophore descriptor sets contained the privileged substructure, molecular similarity and diversity could be compared relative to their shared privileged scaffold. The authors proposed that this could be used as an aid for library design, either to imitate features of known active compounds or to explore 'missing diversity' among existing compounds containing the desired scaffold. The latter goal could be accomplished by using molecules containing the privileged substructure as reagents to obtain desired chemically accessible products.¹⁷

In addition, the method was shown to identify pharmacophores enriched among a class of ligands sharing similar biological activity. For instance, structural features shared by GPCR ligands were distinguished from those in a set of small molecule enzyme inhibitors and in a set of random compounds.¹⁷ The method could also be used to address ligand selectivity by comparing pharmacophore keys across sets of ligands for related enzymes, such as trypsin, thrombin, and factor Xa. More recent work has explored the use of pharmacophores for describing related binding sites, for instance see⁵⁵.

In a subsequent report, Aronov and Murcko derived a five-point pharmacophore to describe kinase frequent hitters.¹⁶ In this work, frequent hitters were defined as compounds with K_i values less than 50 nM against two or more of the following diverse kinases: protein kinase A, Src, Cdk2, Erk2, and Gsk3. Selective inhibitors were defined as compounds that had a K_i value less than 50 nM against only one of the five kinases and greater than 50 nM against the other four. Both the promiscuous and selective compounds were known to exhibit ATP-competitive kinase inhibition at nanomolar concentrations. In total, the authors compiled a set of 43 frequent hitters and 209 selective inhibitors.¹⁶

Ligand-bound structures of four of the promiscuous compounds had been solved in-house; these structures were aligned and used to generate a five-point pharmacophore composed of two hydrogen bond donors, two hydrogen bond acceptors, and one aromatic feature.¹⁶ These results were compared against the frequent hitter and selective inhibitor data sets described above; 38 of 43 frequent hitters (88%) but only 10 of 209 selective inhibitors (5%) matched the pharmacophore. Considering only selective inhibitors with a K_i value less than 2 nM for one of the kinases (25-fold greater specificity), 0 of 61 compounds (0%) matched the pharmacophore. Therefore, the pharmacophore captured some of the features that distinguished frequent hitters from specific inhibitors.¹⁶ By placing the pharmacophore features in the ATP binding site, it was possible to identify interactions between conserved kinase residues and the frequent hitters that contributed to the inhibitors' promiscuity. The authors proposed that either by addition of features beyond those five associated with promiscuity or subtraction of at least one of the substructures represented by the pharmacophore, it might be possible to engineer ligands with greater specificity for a given kinase.¹⁶

2.18.4.4 Reactive Species

Chemically reactive groups are a well-known source of false-positive screening hits.¹⁴ Several commercial and in-house filters for identifying and removing reactive species are currently in use.^{50,56} Despite the widespread use of filters, reactive compounds remain a significant challenge for discovery efforts. For example, Blanchard and co-workers

reported that of 69 HTS hits against coronavirus protease, 64 (93%) were discarded after repeat assays with DTT suggested thiol reactivity.³⁰

To address this persistent problem, Hajduk's group at Abbott has proposed the thiol reactivity index (TRI) for estimating the probability that a given compound will be reactive.¹⁵ Their recently developed ALARM NMR method for detecting thiol reactivity found that of 476 lead compounds experimentally shown to be reactive, only 156 (33%) were predicted as such by computational filters. To better define the relevant moieties, structural descriptors were calculated for a series of reactive compounds. The probability of reactivity (P_R) for any given structure was then defined as the sum over all structural descriptors of the number of occurrences of each descriptor in that compound weighted by the TRI for that descriptor. If the P_R for a compound was greater than 0.3, the compound was predicted to be reactive. The TRI for each descriptor was determined by using nonlinear regression to maximize the agreement between observed and predicted reactivity as described by a scoring function.¹⁵

The final set of 75 nonzero TRIs was applied to a data set of 3504 compounds studied by ALARM NMR.¹⁵ Using a P_R of 0.3, 486 of 509 experimentally reactive compounds (95%) were correctly predicted and 2005 of 2995 experimentally nonreactive compounds (67%) were correctly predicted. As described, the method has a high sensitivity and a low number of false negatives, making it a useful flag for identifying compounds for follow-up experimental reactivity testing.¹⁵

2.18.4.5 Experimental Artifact

Interference with the assay readout is another familiar source of screening false positives.^{7,14} Few computational approaches for removing actives due to experimental artifact have been developed, but Jenkins and colleagues proposed that virtual screening can be used as a filter for such compounds.¹³ Their underlying hypothesis was that true positives should be enriched by virtual screening and false positives due to experimental artifact should be de-enriched. To explore this idea, the National Cancer Institute Diversity Set and the ChemBridge DIVERSet were combined to produce a library of 18 111 compounds that was initially docked against angiogenin in a fluorescence-based HTS. To distinguish true hits from false positives, HTS hits were rescreened in a luciferase assay and an HPLC assay. Of 178 initial HTS hits, 12 (6.7%) were confirmed as true hits by the follow-up assays.

The same database of compounds was also tested against angiogenin in two separate virtual screens, one using DockVision for docking and Ludi for scoring, and a second using GOLD for both docking and scoring. The computational methods were then evaluated for their ability to enrich for true hits among the total docked library and also among the HTS hit list. The DockVision/Ludi combination ranked 33% of the true hits in the top 10% of the total database for a 3.3-fold enrichment over random and the GOLD algorithm placed 42% of the true hits in the top 2% to yield a 21-fold enrichment. When only the HTS hits were docked, the highest enrichment was observed by a consensus scoring method that counted compounds ranked in the top 25% by both virtual screening methods. This approach placed four of the true hits among the top 9 (5%) of the 178 HTS hits for an enrichment of 6.6-fold over HTS alone. The authors concluded that virtual screening was best used as a post-HTS filter to prioritize compounds for further testing.

2.18.5 Future Directions

Despite the growing interest in promiscuous compounds, several outstanding questions remain. For instance, what is the prevalence of aggregate-based inhibitors, particularly among small molecules that are most interesting for drug design? Early observations suggest that these compounds may be widespread among druglike compounds^{23,33}; further work to explore the distribution of aggregators is clearly needed.

Even if aggregators are found to occupy substantial regions of relevant chemical space, what is the significance of this behavior? Is aggregation a feature or a bug? Since clinically used drugs have been found capable of inhibiting enzymes by forming aggregates,²⁷ one could make the argument that aggregation is not a significant problem for drug design. Indeed, recent studies have proposed that aggregation may be a necessary step in the systemic uptake of NNRTIs,⁴⁴ suggesting that aggregation may even be a desirable property.

Clearly, it is possible for drugs to show aggregation-based inhibition, as a compound that is specific at nanomolar concentrations for a pharmacologic target may also aggregate at micromolar concentrations. Indeed, it is interesting to speculate on possible consequences of aggregation by drugs. But aggregation at micromolar concentrations leading to inhibition of nontarget receptors does not change the fact that the drug also inhibits its target at nanomolar concentrations. This is the important difference between a drug that inhibits off-pathway

targets via aggregation and a hit that inhibits its screening target via aggregation. The purpose of screening is to find new leads for inhibitor design. A screening hit that is only active because it inhibits its target receptor via aggregation is likely not a good starting point for further design work and should be abandoned. Furthermore, even though the screening hit shares the same pathology (aggregation) as a real drug, it does not necessarily follow that it may also share the same desired feature (classical inhibition of a target). Conversely, aggregation at micromolar concentrations does not exclude the possibility that the compound may also act as a specific inhibitor of a given target at nanomolar concentrations.

Efforts have been made to explore the mechanism of aggregate-mediated inhibition,^{24,28,45} but these experiments have only raised more questions. What is the nature of the physicochemical interaction between enzyme molecules and aggregate particles? Recent studies of nanoparticle-mediated inhibition of chymotrypsin^{57,58} may provide insight. Functionalized amphiphilic nanoparticles have been found to inhibit chymotrypsin via an electrostatic interaction followed by denaturation; up to 50% of enzyme activity was restored by the addition of surfactant.⁵⁷ Depending on the particular functional groups exposed on the surface of the nanoparticle, various modes and degrees of inhibition were observed.⁵⁸ Various biophysical experiments including fluorescence, fluorescence anisotropy, DLS, and circular dichroism were performed to study the conformational changes induced in the enzyme due to nanoparticle binding.^{57,58} Similar experiments to explore the nature of aggregate-mediated enzyme inhibition may be worthwhile.

It is also interesting to consider the scope of receptors that are targets for small molecule aggregates. For instance, some enzymes are more susceptible to inhibition by aggregators than other enzymes. Is this due to variations in protein size, shape, surface charge distribution, or other physicochemical property? Additionally, most work to date has been done with soluble enzymes, but aggregators have also been identified in screens using membrane-bound receptors.²³ Do aggregating compounds generally inhibit surface receptors? If so, how does inhibition compare to that of soluble enzymes? Can aggregators act as agonists as well as antagonists? These questions are active areas of research, and results from these studies are eagerly anticipated.

A final area of interest concerns the SARs among aggregators. What distinguishes aggregators from nonaggregators? What factors determine the size of the particle formed by each aggregator? Preliminary observations have been made by a few groups. For instance, Frenkel and colleagues analyzed SARs among 15 aggregating NNRTIs and found that compounds containing oxygen atoms tended to form larger particles.⁴⁴ The authors proposed that oxygen's ability to serve as a hydrogen bond donor could result in different interactions from a similarly placed carbon or nitrogen atom and consequently lead to different aggregation patterns. In a separate study, Seidler and co-workers studied a series of azole antifungals, four of which were aggregate formers and two of which were not.²⁷ Interestingly, the two nonaggregators are prescribed as orally available medications, but the four aggregators are only administered as topical agents. These compounds could be distinguished from each other based on their ClogP values, with the aggregators having a ClogP greater than 5 and the nonaggregators having a value less than 5.²⁷ In addition to physical properties, potential structural descriptors have been suggested by the various computational models described above. Additionally, pharmacophore-based methods may be a useful approach for studying SARs among these compounds. It is hoped that as more small molecules are explicitly studied for aggregation, the structural influences leading to aggregation will be better defined and the mechanism itself will be better understood.

Biography

Susan L McGovern received her BSc in biochemistry and mathematics from the University of Notre Dame in 1997. Later that year, she joined the NIH-sponsored Medical Scientist Training Program of Northwestern University in Chicago, IL. In 2003, she earned her PhD in Brian Shoichet's laboratory for her work on molecular docking and aggregate-forming promiscuous inhibitors. In 2005, she finished her MD at Northwestern and moved to the University of Texas/MD Anderson Cancer Center to begin residency training in radiation oncology. Her long-term research goals are to use small molecules as tools for exploring the molecular basis of cancer and to develop pharmacologic agents for use in radiation oncology. Her research has been supported by two NIH training grants, a fellowship from the PhRMA Foundation, and a Presidential Fellowship from Northwestern University.

2.19.1 Introduction

The pharmaceutical industry is confronted with several important challenges today, including the need to sustain their pipelines and offset patent expirations and inevitable generic competition. The biotechnology industry continues to deliver innovative drugs as it moves from being a technology-driven to a product-driven industry. Not unexpectedly, the pharmaceutical industry has aggressively partnered with biotechnology companies to fill their pipeline gaps.

The biotechnology industry began the revolution in drug discovery by creating protein biologicals such as human insulin, growth hormone, and erythropoietin. In addition to the biologicals, the biotechnology companies have focused on using many cloned proteins as targets for small-molecule drugs. Throughout the last decade, there has been a dramatic increase in the number of potential molecular targets for potential disease states. Small companies, in general, do not have access to market research data to help guide their selection of disease indications. Therefore, these

companies tend to pursue disease indications based on a perceived market or based on their own experiences. This chapter outlines some of the progress and technologies that are being used by the biotechnology industry that make a vital contribution to the healthcare industry. The industry has grown remarkably since its inception in the early 1980s, and it is a continual driver of both innovation and execution.

2.19.2 Definitions

2.19.2.1 Therapeutic Area Focus versus Target Class Focus

In the past decade, there have been two predominant themes in how to pursue drug discovery. One is to build an organization to pursue a particular disease area (therapeutic area) such as inflammatory or cardiovascular diseases. This permits the company to deeply explore one area of disease biology at the expense of having a cursory knowledge of many different target classes.

Another common theme for building a biotechnology company has been to focus on a particular class of molecular target (such as kinases or proteases). This is a particularly important way to focus an organization that is dealing with protein targets that have been recently discovered. For any new target there is extensive work that needs to be done to decipher the pathway around that target and how it links to a disease state. As with the first theme, there is a significant downside to this approach as well. While the company would have a deep understanding of a particular type of target, they would only have a very cursory understanding of several different therapeutic areas.

2.19.2.2 Therapeutic Target versus Molecular Target

The goal of a molecularly targeted approach to drug discovery is that when a modulator of the protein is developed, it will have an overall effect on the course of the disease in question. This assumes that the chosen molecular target has a pathophysiological link to the disease of interest. Molecular target-based approaches may also have advantages in terms of drug discovery, high-throughput screening (HTS), and preclinical–clinical safety predictions based on a logical extension of the effect of the drug candidate on the selected target. The overall goal of any drug discovery operation is to choose a disease indication (therapeutic target) that currently has no (or suboptimal) drugs in the market to effectively treat that condition, or to have a substantial therapeutic advantage over existing drugs via a new mechanism, even if the established drugs work well. Such advantages may include reduced side effects or greater safety. For example, the kinase bcr-abl is the molecular target for the compound imatinib that is used as a therapeutic to treat chronic myelogenous leukemia (CML).

2.19.2.3 Target ‘Druggability’

There are several phrases that are sometimes used interchangeably when the issues of compounds and molecular targets are discussed. In this chapter, the term ‘drug target’ will be used to mean a biological macromolecule that has the potential to bind a small-molecule organic compound. It needs to be stressed that by this definition it is meant that a compound should be able to bind to the target of interest, but there is no guarantee that this binding will modulate the underlying biology, or that the compound will be selective for that target. Druggability, on the other hand, typically refers to a family of proteins where there are representative therapeutics on the market that modulate a member of this family and are effective therapeutics.

Finally, in the strictest definition, a validated protein target is one for which a drug that modulates the target is already on the market. With this in mind, there are degrees with which new targets have been validated as potential druggable targets. The least validated is one in which only a gene sequence is known and nothing about the role of that particular gene in a biological process. Nearly all of the projects being pursued in the pharmaceutical/biotechnology industry use targets that fall somewhere within these two boundaries.

2.19.3 The Impact of the ‘Genomics Bubble’ on Drug Discovery

The ‘genomics revolution’ has had an enormous impact on the practice of drug discovery, but the impact in terms of new therapeutic agents has yet to be realized to the same degree. The advances in DNA sequencing technology have paved the way for the scientific community to realize that, at last, rapid sequencing was available and that it would be possible to imagine obtaining the complete sequence of a particular organism. With this realization there were several

companies created aimed at identifying, at the level of the DNA sequence, those genes that would be important for the initiation or perpetuation of disease states. The rapidity with which this developed created a naïve expectation that the drug discovery industry would change tomorrow (almost literally). However, the publicity surrounding the Human Genome Project and the genomics revolution did have the benefit of providing an impetus for these various projects and the funding that they required for success. There were variations in the approach, from a direct ‘sequence everything’ in competition with the US government-sponsored effort coordinated through the National Institutes of Health (e.g., Human Genome Sciences and Celera), to more specific disease-oriented sequencing efforts of genes that appeared to be upregulated in specific disease tissues compared with normal tissues (e.g., Incyte and Millennium Pharmaceuticals).

Commercializing the information coming from these massive sequencing projects was aided by the entities involved applying for patents on their sequences. These patents often were filed on the sequence itself (or fragments of the sequence) without any mention being made of the utility of that particular gene sequence. During this period there was significant concern among many companies that a great advantage would be lost by not being part of this ‘genomics revolution,’ either as a direct participant or as a paying customer to obtain rights for the screening of particular gene product. There were efforts by large pharmaceutical companies to participate in well-funded collaborations (such as Bayer with Millennium and Curagen) from which they received a quota of genomically defined ‘targets.’ In some circumstances this interest led to the acquisition of a biotechnology company that appeared to have significant numbers of potential drug targets (e.g., Upjohn (now Pfizer) and Sugen). Through the 1990s, this was a model that sustained many of the genomics companies and simultaneously spurred improvements in the capacity of drug discovery in other areas.

The large number of apparent drug targets being discovered on a daily basis provoked greater interest and emphasis on those efforts focused at improving the rate at which new compounds were discovered. Prior to the advent of the genomics revolution, the drug discovery industry had begun to increase their HTS capacity. Other companies began to pioneer the rapid synthesis of compound libraries utilizing solid phase synthesis approaches (e.g., Alanex, Trega, and Pharmacopeia, *see* [Section 2.19.5.2](#)). However, increased screening capabilities and the development of larger specialized libraries were not the only developments to create a means to capitalize on the genomics revolution. With the enormous amount of sequencing data being produced, there was a tremendous need for robust technology to handle and interpret the data. Improvements in the existing software and development of new programs either within companies or by specific specialty software companies, were necessary. This would allow the raw genome sequencing data to be correlated with functional data mined from the literature. Correlations could then be made between the raw sequence data and the molecular nature of disease and disease processes. These developments allowed the generation of biological databases that induced hypothesis generation in ways that were not possible previously. While the above are enabling technologies and processes, the number of new gene sequences initially identified had very little information that would help the understanding of their biological context either within normal or pathological states. The tools to understand the role of a particular gene product were lagging behind the requirement of having sufficient validation of a protein for it to be considered as a drug target. Whether bioinformatics, systems biology, or bio-information technology approaches are able to accelerate such validation *in silico* remains to be seen.

The translation of genomically defined drug targets into new approved therapeutics developed against those targets has been slow to date. Much of this relates to the difficulty in obtaining validation of many potential targets for a particular disease state and being able to use this information for selecting the best molecular targets to pursue. Recent estimates indicate that novel targets result in a 50% lower success rate than clinically validated targets.^{1,2} Coupled with rising costs and an inherent reticence within the industry for working on unproven targets due to lower success rates, the low number of therapeutics directed against novel targets is perhaps not surprising. Thus, the industry continues to work on targets for which there is substantial preclinical and clinical validation in the literature. Companies are also creating small research groups on an ‘experimental’ basis to work on the validation aspect of ‘novel’ targets that have been identified through genomics (and, more recently, proteomics) efforts. As the understanding of these targets increases through efforts within companies and from academic work, the prevalence of these targets within discovery pipelines will increase.

The use of genetic models has accelerated the target validation process, and companies have been founded on the applications of these models to explore the role of gene products in both developmental and disease states. These companies are using model systems from simple organisms such as yeast and nematodes to gene knockout and transgenic strains in mice. These efforts have been complemented by academic research, which may be smaller on an individual scale, but larger in the aggregate. Also, the academic research groups have an imperative to publish their findings, which yields a larger public database. A significant advance in validating molecular targets has come from small interfering RNA (siRNA or RNAi) technology (*see* [Section 2.19.5.4](#)) that has recently become a widespread technique

for selectively manipulating gene expression. This technology has been used in cellular systems as well as with *in vivo* models, and some companies have started clinical trials based on this technology. Gene expression analysis continues to improve both in speed and in the number of different organisms on which analyses can be performed (due to the availability of the complete genome sequences of other organisms in addition to humans). Coupled with increasingly sophisticated bioinformatics tools, the role of particular molecular targets allows the validation of these targets to be accomplished in far shorter time frames than even a decade past.

2.19.3.1 Payoff – Is it Here Yet or On the Horizon?

There was a serious misconception regarding the immediate benefits of genome sequencing relating to drug discovery. Stratospheric claims were made regarding the benefits and the enormity of riches to be immediately delivered into drug discovery pipelines consequent to the genomics efforts of the 1990s. The naïveté for the genomics pioneers was centered in the real, but not realized, difficulty of determining the biological functionality for these hundreds of gene sequences. Without solid biology relating to a new target, companies are reluctant to make the decision to spend tens of millions of dollars in a drug discovery effort relating to that target. There was an apparent lack of understanding from the leaders of these genomics companies on what it takes to make a drug, beyond identification of the gene product and a rudimentary biochemical assay.

However, as the ‘land rush’ for potential targets has largely ended with the completion of the human genome sequence, many of the companies involved in more specific ‘genomics’ activities have been attempting to transition into biopharmaceutical companies. This means that in order to survive they will have to produce compounds with a demonstrable therapeutic benefit. This has proven to be a significant challenge for these companies, particularly as expectations from the business community have become more exacting. Companies of the genomics era have had to rapidly transform and implement more rigorous drug discovery models as well as regulatory and clinical development functions. The processes associated with these activities are quite different from their previous genomic biotechnology era. Many companies have had to struggle with changes in company skill sets and, internally, with the way their company business operates. While attempting to manage personnel and process changes, these companies have also become aware that drug discovery and development include significant challenges quite apart from what they had previously encountered. Not the least of these challenges is the length of time it takes for a clinical trial – be it for therapeutic benefit or to characterize biomarkers of a response in the clinical population. The toll this has taken in terms of successful transition (and it is an ongoing experiment) can be determined from the listings of those biotechnology companies with genomics as a significant part of their platform technology between 10 years ago and today. There may be one or two companies that survive and continue to be successful following a transition from genomics to biotechnology–pharmaceutical (e.g., HGS and Millennium). The larger impact of genomics on drug discovery and development has not yet been realized in new therapeutics, but will continue to increase its impact for at least the next couple of decades.

2.19.4 Focusing on a Target Class

There are four main types of macromolecule that can be modulated by therapeutic agents: proteins, polysaccharides, lipids, and nucleic acids. However, the vast majority of successful drugs achieve their activity by binding to, and then modulating, the activity of proteins. Thus, proteins have provided the best source for drug targets, and nearly half of these targets fall into seven gene families: G protein-coupled receptors (GPCRs), ion channels, protein kinases, zinc metalloproteases, serine proteases, nuclear hormone receptors, and phosphodiesterases.^{3,4} There has been much speculation as to the number of molecular targets that are ‘druggable.’ The druggable portion of the human genome (~30 000 genes) has been calculated to be between 5000 and 10 000 targets, although this may be even greater.^{5,6} Current drugs bind to approximately 500 targets. While there may be a large number of drug targets, it is unclear how many of these are linked to disease, and the clinical evaluation of modulators of truly novel targets is the only definitive means to establish disease relevance.

In the 1980s, molecular biology technologies allowed the cloning of protein targets for use in biological screens for drug discovery. These new technologies spawned an increase in the number of biotechnology companies targeting either proteins themselves as therapeutics or discovering small-molecule modulators of these protein targets. In order to create a differentiating advantage, many biotechnology companies chose to focus on target classes or even individual targets. This focus has several advantages, including allowing the company to develop a deep understanding of the biological and disease relevance of the targets, to focus medicinal chemistry and structural knowledge of the target(s), and to select from multiple therapeutic areas associated with the target class. [Table 1](#) reflects a partial list of such companies and their target class focus.

Table 1 Biotechnology companies focusing on a specific therapeutic target

2.19.4.1 G Protein-Coupled Receptors

It is estimated that 50% of current drugs and approximately 25% of the top 200 best-selling drugs modulate GPCRs.³⁸ Drugs targeting GPCRs treat numerous diseases, including cardiovascular, CNS, and gastrointestinal diseases, along with asthma/allergies and cancer. There are between 800 and 1000 GPCR genes, but endogenous ligands are only known for approximately 210 of them (see the GPCR database³⁹).^{40,41} Consequently, there is tremendous interest in exploring these orphan receptors and considering their use for future drug discovery efforts. Concomitant with the increase in the number of GPCR targets is recognition that GPCR responses to ligands can be complex, leading to the identification of classic agonists and antagonists, as well as inverse agonists and allosteric modulators.

One strategy that has aided the drug discovery process for GPCRs is the availability of compound libraries tailored to interacting with this class of proteins. These libraries were constructed based on a pharmacophore model for GPCRs, and many companies have their own proprietary focused libraries. There is also direct structural information for rhodopsin and a model for the neurotensin type 1 receptor bound to a peptide agonist that have been used to design libraries.⁴² The latter may represent viable templates for pharmacophore-based searches of chemical libraries for nonpeptide ligands that might be of therapeutic value.

2.19.4.2 Protein Kinases

Kinase-induced phosphorylation of cellular proteins is a universal mechanism to control virtually all cellular processes, including cell growth and differentiation, metabolism, membrane transport and apoptosis. The protein kinase family is comprised of two major subfamilies: the protein tyrosine kinase (PTK) subfamily and the serine–threonine kinase subfamily. Targeting PTKs has already generated important drugs to treat cancer, including imatinib and erlotinib. More than 530 kinase-related sequences have been identified in the human genome, and three-dimensional information is available for many of them.⁴³ This has greatly facilitated the discovery of selective kinase inhibitors, since all protein kinases contain a structurally conserved catalytic domain. ATP binds in a cleft between the two major portions (N- and C-terminal) of the catalytic domain, and the majority of kinase inhibitors are ATP-competitive. The commonality of the ATP binding sites does create selectivity issues for the development of kinase inhibitors. However, there are several ATP site-directed and highly selective inhibitors that are being developed, and a number of kinase inhibitors are also under development in various cancers that modulate multiple kinases.

2.19.4.3 Ion Channels

Ion channels are ubiquitous pore-forming proteins that allow the passive diffusion of ions (such as Na⁺, K⁺, Ca²⁺, and Cl[−]) across cell membranes. Information on some of these proteins is collected in a target-specific database, the Ligand-Gated Ion Channel Database.⁴⁴ Numerous therapies modify ion channel function, and 15 of the top 100 best-selling drugs target ion channels and include antihypertensive Ca²⁺ channel blockers. The list includes amlodipine, nifedipine, and the antiepileptics such as the Na⁺ channel blocker carbamazepine. These ion channel-modulating drugs were discovered serendipitously before the ion channel superfamily was appreciated. In humans, approximately 650 ion channels have been identified to date.

These targets have proved challenging, and have only recently benefited from higher-throughput electrophysiology techniques, as well as advances in structural knowledge of the proteins. Greater numbers of ion channel-targeted drugs are anticipated to enter clinical development as these technologies improve screening campaigns. Also, natural products (especially toxins from the spider, bee, scorpion, snake, puffer fish, and coral) have helped in classifying channel subtypes and probing their functions. A proprietary ion channel ligand design tool called Helical Domain Recognition Analysis has been developed by BioFocus, to facilitate small-molecule library design for this target class.

Additional target focused companies continue to emerge; example, ProScript (targeting the proteasome), in Cambridge, MA (now part of Millennium), Conforma (targeting heat shock protein 90) in San Diego, CA, MethylGene (targeting histone deacetylases) in Montreal, Idun (targeting the caspase cysteine protease family) in San Diego (now part of Pfizer), and the Coley Pharmaceutical Group (targeting toll-like receptors) in Wellesley, MA. These and other biotechnology companies are hoping they have chosen targets that will soon be clinically validated by small-molecule modulators.

2.19.4.4 Intellectual Property (IP) Landscape

In order to work on targets or target classes it is essential to clarify the IP landscape. Gene sequence patents can provide incentives crucial to downstream investment, and have been central to the development of the biotechnology industry. According to a recent review, 20% of human genes are claimed as US IP.⁴⁵

This represents 4382 of the 23 688 genes in the National Center for Biotechnology Information gene database. Major patent assignees include the University of California, ISIS Pharma, Human Genome Sciences, and Incyte Pharmaceuticals/Incyte Genomics. Much of the genome is unpatented, but some genes have numerous patents asserting rights to gene uses, cell lines, and constructs containing the gene.

2.19.5 Companies Built around Compound Classes or Particular Chemistries

2.19.5.1 The Example of IMiDs Compounds

Thalidomide (α -(*N*-phthalimide)glutarimide) was marketed in Germany in the mid-1950s as a safe, nonbarbiturate sedative – a so-called pure hypnotic – that was also an effective antiemetic in pregnancy. Unfortunately, the drug caused birth defects, and it was withdrawn in 1961. The compound was later found to be highly efficacious in patients with erythema nodosum leprosum (ENL), a potentially life-threatening inflammatory complication of leprosy. Thalidomide was only given US Food and Drug Administration (FDA) approval for the treatment of acute ENL in 1998 after additional immunological properties were discovered.

Apart from its approved use in ENL, thalidomide has been evaluated in over 150 clinical trials in the USA for various oncological, dermatological, and inflammatory conditions. In addition to the teratogenic liability, thalidomide treatment is associated with somnolence, constipation, rash, peripheral neuropathy, and deep vein thrombosis.⁴⁶ As a consequence, Celgene has synthesized thalidomide analogs that are structurally similar but functionally different from the parent compound. Lenalidomide has been approved by the FDA for the treatment of transfusion-dependent anemia due to low- and intermediate-risk myelodysplastic syndromes associated with a deletion 5q cytogenetic abnormality with or without additional abnormalities. Two other IMiDs compounds (proprietary compounds having immunomodulatory properties) are CC-4047 and CC-11006, which are in clinical trials for various diseases (Figure 1).

While these compounds have several biological activities (notably lowering tumor necrosis factor α , antiangiogenic and T cell co-stimulatory properties, and direct antitumor activity including pro-apoptotic activity), the precise mechanism of action (MOA) of the IMiDs compounds is not known. Consequently, the development of these compounds is rather unusual in the modern day, since the determination of MOA may be made after the drugs have proven to be safe and effective. However, in much of the history of pharmaceuticals, the MOA was proven after marketing, or even not fully understood to this day (e.g., penicillin, methotrexate, and aspirin).

Clinical activity for the IMiDs compounds has been observed in various hematological and solid tumor cancers, including multiple myeloma, myelodysplastic syndrome, renal cell carcinoma, pancreatic cancer, and androgen-independent prostate cancer. The FDA is currently reviewing an application for the approval of thalidomide for newly diagnosed multiple myeloma. Lenalidomide is also being reviewed by the FDA for the treatment of relapsed or refractory multiple myeloma. Additional clinical studies are being conducted on a variety of other hematological diseases and solid tumor cancers. The resurrection and rehabilitation of thalidomide and the development of other IMiDs compounds has provided Celgene with a drug chemistry and IP platform for major unmet medical conditions.

3-Dimensional Pharma ⁵⁶	Exton, PA	Acquired by J&J (JNJ)
Chembridge Corp ⁵⁷	San Diego, CA	Private

2.19.5.2 Strategies for Chemical Libraries

Combinational chemistry, born in the early 1990s, promised to revolutionize drug discovery, allowing even small biotechnology companies access to chemical libraries from thousands to millions of compounds. Many of the companies listed in [Table 2](#) that originally generated libraries that were licensed to pharmaceutical and biotechnology companies have changed their business models, and now perform their own drug discovery.

There was considerable interest in accessing chemical libraries with large numbers of members in order to increase the likelihood of obtaining a hit against any target screened. These combinational screening libraries, while very large (often in the millions), did not appear to increase successful identification of drug candidates, unfortunately. This may be attributed to their lack of true diversity (or at least pharmaceutically relevant diversity) and the manner in which they were synthesized. It is estimated that the number of theoretically possible small molecules is approximately 10^{60} , which may be lowered to 10^{28} by applying constraints of druglikeness and synthetic capability.⁴⁷ This is vastly greater than the largest compound collections (in the millions) and the largest virtual library (10^{12}). The diversity of many of the early combinatorial libraries was further hampered by having been synthesized on a solid support, or by being too peptide-like (and thus unlikely to be druglike, at least insofar as oral bioavailability and other drug characteristics are concerned). This limited the types of chemistries that could be used to create members of the library, thereby decreasing the diversity of the library. Another problem with the design of these early libraries was that the compounds made were never purified. Once a particular well of a library was identified as a hit, an attempt was made to purify the active component. Typically, the compound that was supposed to have been in the well comprised less than 40% of the material present. Often, the desired compound was not present at all. This model did not turn out to be very effective in most laboratories (with a few notable exceptions, e.g., Affymax, Chiron, and Pharmacopeia), which is why the industry (and the library suppliers) have moved away from libraries synthesized in this manner.

In an effort to increase the hit rate of HTS, and to find better-quality leads, library synthesis efforts have moved to a new model. In this model, libraries are generated based on known pharmacophores to the different target classes. These focused (or targeted libraries) are built around knowledge of target classes or individual hits. For example, as mentioned above, GPCR libraries and kinase libraries have been constructed.⁵⁸

2.19.5.3 Structure-Based Drug Design

Devising new ways to identify chemical leads for specific protein targets has been a constant challenge for the biotechnology and pharmaceutical industries. Since many of the targets are primarily enzymes, x-ray crystallography has been increasingly used to accomplish this goal. Originally a slow and tedious process, several biotechnology companies have embraced the challenge and created HTS-based drug design platforms ([Table 3](#)). These have been particularly useful to identify kinase inhibitors.

Fragment-based lead discovery has also been developed whereby low molecular weight (MW) compounds (typically MW < 200) are screened against a target at high concentrations (~ 1 mM). The initial hits have very low affinities, but

Table 3 Structure-based drug design companies

<i>Company</i>	<i>Location</i>	<i>Status</i>
Agouron ⁶⁷	San Diego, CA	Acquired by WL/PD (now Pfizer)
Syrrx ⁶⁸	San Diego, CA	Acquired by Takeda
SGX Pharmaceuticals ⁶⁹	San Diego, CA	Private
Vertex ⁷⁰	Cambridge, MA	VRTX
Plexxikon ⁷¹	S. San Francisco, CA	Private
Astex ⁷²	Cambridge, UK	Private

with the aid of x-ray crystallography or macromolecular structure determination by nuclear magnetic resonance spectroscopy, these low-affinity hits can be rapidly improved in potency. A typical nonfragment-based screening lead could have a MW > 350. Often, in order to improve the potency of this type of lead, functional groups will have to be removed (causing a decrease in potency) then others added to give the final compound. The fragment approach starts with the low-affinity hit, and a bound structure of the hit (or hits) in the target protein. This approach removes one portion of the synthetic cycle (i.e., having to remove unnecessary functional groups on the screening lead). It is becoming apparent that the speed to a final compound can be quicker with the fragment-based approach due to removal of excess synthetic design cycles.⁵⁹

2.19.5.4 Ribonucleic Acid (RNA)-Based Strategies (ISIS⁶⁰ and Sirna⁶¹)

Since the control of protein expression by antisense RNA was first described,^{62,63} a number of different RNA-based therapeutics have been used in clinical trials. The first and only antisense RNA therapeutic to receive FDA approval and enter the market is fomivirsen (ISIS Pharmaceuticals), which is approved for cytomegalovirus retinitis.^{64,65} There are three different mechanisms by which RNA-based inhibitors work, involving anti-sense RNA, ribozymes, and siRNA. New biotechnology companies have been started around each of these technologies, and a number of modified oligonucleotides have entered clinical trials (see the TriLink Biotechnologies website for an article listing many of the ongoing clinical trials with oligonucleotide-based therapeutics).⁶⁶ Two companies are good examples of the history of the different RNA interference strategies, ISIS Pharmaceuticals and Sirna Therapeutics (formerly Ribozyme Pharmaceuticals).

ISIS was founded to exploit the new field of RNA antisense technology in 1989. Over the years since its founding, ISIS has engaged in collaborations with over two dozen different entities, including academic institutions, biotechnology companies, and large pharmaceutical companies. The first generation of antisense therapeutics encountered physiological problems that included an innate immune response caused by certain dinucleotide sequences in the oligonucleotide.⁶⁵ The first generation of antisense RNA oligonucleotides incorporated phosphorothioate linkages between the bases (Figure 2) to prevent nuclease digestion in vivo.

Fomivirsen falls into the phosphorothioate class of oligonucleotides. ISIS had also been developing a number of other 'first-generation' antisense compounds, and the latest data from the Investigational Drugs database⁷³ indicates that nearly all of them have been discontinued.

The second generation of antisense oligonucleotides focused on increasing the stability of the compound and decreasing the immune response. The new compounds had a mixture of phosphorothioate linkages and ribonucleosides containing 2'-OCH₃ modifications at the 5' and 3' ends. Several of these mixed-backbone oligonucleotides have entered clinical trials, with two of them having advanced as far as Phase II (GEM 231 from Hybridon and MG98 from MethylGene and Hybridon).

Sirna based their early technology on the ability of ribozymes (stretches of oligonucleotide that can catalytically cleave their target messenger (mRNA)) to inactivate mRNAs resulting from gene transcription. Three ribozymes were taken into Phase I clinical trials by Sirna in either cancer indications (RPI-4610, Angiozyme, and Herzyme) or hepatitis B infections (LY 466700). Based on the data from these Phase I trials, Sirna discontinued development of all three compounds and switched their focus to RNAi technologies (see below).

The most recent technology for regulating translation of mRNA to protein is called RNAi. This technology differs from the two previous technologies to silence RNA in that it is a natural process in many eukaryotic species and uses double-stranded oligonucleotides instead of single-stranded oligonucleotides.⁷⁴ The sequence of the RNAi is still

Figure 2 Phosphorothioate oligodeoxynucleotide.

complementary to the target sequence, but since it is double-stranded material it can either be delivered to the cell directly or by the use of viruses encoding the desired sequence.⁷⁵ The RNAi becomes part of a silencing complex that includes several proteins. Once the RNAi finds and binds to its targeted sequence, the mRNA is rapidly degraded.

A number of companies are using RNAi technology to move therapeutics into the clinic. As mentioned previously, Sirna discontinued their work on commercializing ribozyme therapeutics and began working on drugs based on RNAi. They currently have one compound in Phase I clinical trials for macular degeneration (Sirna-027).⁷⁵ Even though the technology is significantly newer than antisense oligonucleotides or ribozymes, there are approximately 10 products in late preclinical/early clinical development. These products come from about eight different biotechnology companies.

To date, there has been very little success with developing therapeutics based on disrupting the translation of mRNA to protein via nucleic acid technologies. Even the latest technology (RNAi) will have to overcome similar hurdles that have been faced by the older technologies (e.g., short in vivo half-lives, dosing directly to affected tissue, and potential immune response). For RNAi that will be delivered virally, there is the added burden of the lack of success with other types of gene therapy trials. What was hoped to be a ‘magic bullet’ for disease modulation has not fulfilled its promise to date, but has encountered similar levels of success as disease modulation with small, organic compounds.

2.19.6 Companies Built with a Therapeutic Focus

Two of the largest biotechnology companies in the world (Genentech⁷⁶ and Amgen⁷⁷) had very similar beginnings. Both companies started out by trying to harness new genetic engineering technologies for making therapeutically important human proteins in other organisms or cells on industrial scales. Genentech was the first biotechnology company to get a product to market when it showed that human insulin could be made via recombinant DNA technology in bacteria. The project was licensed to Eli Lilly, which made the protein on an industrial scale and got it approved for marketing in 1982.⁷⁶

Amgen was started in 1980, also with the goal of making human therapeutic proteins. During the 1980s, Genentech and Amgen pioneered efforts to switch from producing proteins in bacteria to producing them in mammalian cells. This was an important improvement in producing therapeutic proteins. Mammalian cells chemically modify many of the proteins that they make, which can alter their overall three-dimensional structure and/or the activity of the protein. Many of these modification pathways are not available in bacteria.

Both of these early biotechnology companies matured from their focus on applications of new technology to production of human therapeutics. Amgen and Genentech came by their therapeutic foci as a result of their early efforts to produce therapeutic proteins. Amgen’s initial success was with epoetin alfa and filgrastim, two products that have an effect on blood function. Both of these products each had 2004 revenues in excess of US \$2.5 billion. One of

the indications for epoetin alfa is anemia induced by chemotherapy. For filgrastim, the primary indication is to boost white blood cell counts, to prevent infection in patients undergoing chemotherapy treatment. Building on their experience in the area of modulating blood cell function (including white blood cells), Amgen expanded their efforts in targeting immunological diseases with the purchase of Immunex.⁷⁸

Genentech's current focus is on cancer, immunology, and vascular biology.⁷⁹ The company's expertise in producing and marketing proteins such as human growth factor and insulin has allowed it to expand into producing therapeutic antibodies for various cancer indications. Genentech currently either solely or with other companies markets a number of therapeutic proteins, including bevacizumab, trastuzumab, and rituximab in oncology and efalizumab in immunology.

ILEX, on the other hand, started with a focus in oncology. The company grew out of the nonprofit Cancer Therapy and Research Center in San Antonio, TX, and was formerly spun off into a for-profit enterprise in 1994. The founders felt that 'there was a big, unmet medical need' in cancer.⁸⁰ Prior to its acquisition by Genzyme, the company was split into two businesses. One half of the business was devoted to drug development services in oncology while the other subsidiary was devoted to discovering novel drugs for the treatment and prevention of cancer.

ILEX placed into trials and marketed alemtuzumab (a monoclonal antibody for the treatment of chronic lymphocytic leukemia), and was completing trials with clorfarabine for acute leukemia in children⁸¹ when Genzyme bought the company in 2004 in order to strengthen its oncology portfolio.

The examples cited above show two different models by which companies have brought focus to their drug discovery efforts. Two of the oldest biotechnology companies (Amgen and Genentech) matured into a narrow focus in two or three narrow therapeutic areas. ILEX, on the other hand, began with a narrow focus, and continued to guide the company with that focus. There are other companies that have used this model successfully as well, one of which is Esperion, focusing on atherosclerotic diseases (see below).

2.19.7 Challenges to Moving Compounds into the Clinic

There have been a number of reviews written in the past several years indicating that there has been a decline in the number of new chemical entities being approved by the FDA for marketing.⁸²⁻⁸⁴ There have been almost as many suggestions on how the drug discovery process can be fixed.^{82,83,85-89} Drugs for oncology have one of the lowest success rates from first-in-human to registration of any of the therapeutic areas.^{83,90} Many companies launched efforts into the development of oncology drugs, attempting to respond to the great unmet medical need. Additionally, the severity of the disease would require shorter clinical trials, and the tolerance for side effects in this disease is greater than for other therapeutic areas. However, many of these efforts have foundered on lack of sufficient efficacy and unacceptable side effects.

A number of concepts are beginning to mature, facilitated by improving technologies that are predicted to increase the success rate of compounds moving into clinical testing. The concept of biomarkers has become almost universal, and returns to center stage the study of pharmacodynamics. During the drug discovery phase, increased effort and emphasis has been placed on developing assays that will allow the determination of target inhibition in a functional assay. A simple example is to monitor the phosphorylation of a kinase substrate within the cell environment after exposure to the respective kinase inhibitor. Elaboration of this assay to in vivo and then the clinical setting would allow monitoring of target inhibition following dosing. These types of assays will allow the assessment of the magnitude, duration, and consequence of inhibition, leading to a more rapid conclusion of whether inhibition of the target will have therapeutic benefit. However, often with such assays, translation from discovery to development can be difficult, and alternatives need to be considered. The increasing use of gene chip arrays has prompted some to consider global gene expression of some readily sampled tissue in response to treatment as an alternative. Moving to this type of assay should more generally be considered a surrogate of response, rather than a marker of inhibition. Additionally, as diseases are becoming more molecularly defined, both in etiology and progression, the opportunity for more specific therapies is presented. A recent example of this would be imatinib, a compound approved for CML.⁸³ Ninety-five percent of CML patients have a particular chromosomal translocation that creates a mutant tyrosine kinase called bcr-abl. Imatinib was developed to target this particular mutation. Looking to the future, the potential of defining a disease by the molecular pathology and employing specific antagonists to create a 'tailor-made' therapy can be imagined.

The major difficulty with any new technologies introduced into drug discovery is the long time frames before the results are realized by new drugs on the market.⁹¹ There are two facets of drug discovery where improvements in the individual processes would speed the approval process and decrease the amount of money required to bring drugs to market. The first area where improvements need to be made is in the overall attrition rates of compounds from first-in-human to approval. Recent estimates put the overall success rate for new chemical entities at 11%.^{1,83,90} By reducing attrition rates, the expense for the whole process would decrease due to failures in clinical trials, which are the most expensive part of the discovery process.⁹¹

The second area that would improve the overall process is by reducing the time that drugs spend in the R&D process. This would potentially reduce the overall amount spent on any single drug, giving it a longer patent protection period once it entered the market. Some estimates indicate that about 40% of all drugs entering clinical trials fail due to poor pharmacokinetic/pharmacodynamic properties.⁹² Being able to get an early indication if a new chemical entity is being extensively metabolized will decrease the amount spent on further clinical development. Micro-dosing (Phase 0) pharmacokinetic studies could be done in healthy volunteers, at subtherapeutic doses of compound labeled with an appropriate tracer. With the increased sensitivity of mass spectroscopic detection, levels of compound in the blood and even metabolites of the parent compound can be detected.⁹³ This process will also allow comparisons of two pharmacologically similar compounds in humans in order to determine which compound would have the better metabolic profile,⁹² and should lower attrition rates due to poor pharmacokinetic/pharmacodynamic parameters discovered in Phase I safety testing.

An early determination of the efficacy of a drug in clinical testing would be a major benefit in the design of subsequent trials. The ideal test for early efficacy would be minimally invasive and have a high correlation with disease remediation. This desire has spawned the field of biomarker discovery and utilization in the discovery and clinical testing of new therapies. A recent review by Frank and Hargreaves⁹⁴ defines the different types of biomarkers that are used, and covers examples of direct and indirect markers of disease/compound efficacy.

In the most straightforward case, the measurement that identifies patients requiring therapy is the same measurement made to monitor the results of the therapy. An example of this would be plasma cholesterol levels, which indicate which patients should take cholesterol-lowering therapies. This is the same measurement that is made to indicate the success of the drug.⁹⁴ Not all cases are this simplistic, however. Many diseases do not have a biomarker that can be measured directly. This is especially true of diseases such as Alzheimer's disease, where affected tissue in a living patient is not accessible. In these cases, surrogate endpoints are required.⁹³ A surrogate endpoint is a biomarker, but not one that is directly linked to the therapeutic outcome. An example of this would be the effect that a kinase inhibitor has on the phosphorylation status of the protein substrate for that kinase. The hypothesis being tested in the clinic, then, is that inhibition of the particular kinase correlates with inhibition or remission of the disease. An example of this would be imatinib and its efficacy in CML. The surrogate biomarker would then be inhibition of bcr-abl activity in patient blasts.^{89,95}

Whether direct or indirect, the biomarker field could have a positive impact on the speed and course of clinical trials. The power of clinical trials will be enhanced for any particular therapeutic if patients are preselected for the trial based on the presence or absence of a relevant biomarker. Most likely, these biomarkers will be mechanism based and be responsive to the compound being administered. The correlation between the biomarker level and disease response will need to be addressed prior to the beginning of the clinical trial for a particular compound. The regulatory agencies (such as the FDA) will have to accept that the mechanistic biomarker is a surrogate for an effect on the clinical response of the patient. A clinical trial could be ended early if the compound, when dosed in humans, does not modify the biomarker. This will permit less money to be spent on compounds that do not have a chance of succeeding. However, clinical trials may need to enroll fewer patients, since those only likely to respond to the therapy will be selected for inclusion in the trial. This has the potential to reduce the overall cost of bringing a compound to market.

2.19.8 Models for Start-Up Companies

If one were to start a biotechnology/drug discovery company today, there are several different models that could be used. The classical biotechnology model starts with target discovery, and progresses through drug discovery to compounds in the clinic. A second model for a start-up company is one where a project (along with a compound or compounds and the scientists involved in the project) is spun out of a large pharmaceutical company. A third model is a virtual company that is built with the intention of being sold as soon as there is sufficient clinical data to indicate a reasonable chance of success. In the current funding environment, each model has its plusses and minuses.

2.19.8.1 Classical Biotechnology with a Twist

Over the years, many companies have been started based on a molecular target class or a technology. Examples of the former include Exelixis, Plexxicon, and Arena. Examples of the latter include the structural biology companies such as Structural Genomics (now SGX Pharmaceuticals) and Syrrx, and the genome companies such as Millennium, Human Genome Sciences, and Curagen. The company of today would have to have equal emphasis on chemistry as well as on biology. It would be built from the ground up, but instead of spreading itself broadly across a target class, it would go deep into a particular region of biology. An example of this would be a particular cell lineage that is known to be

involved in many different disease states (such as a monocyte/macrophage). Another example is a particular signaling pathway that has been shown clinically to be involved in a particular disease state. This intense focus will allow the company to drive deep into the biology of the target cell/pathway, and create a significant body of knowledge in a relatively confined area of biology.

The second requirement would be to have medicinal chemistry on board at the inception of the company. Many biotechnology companies have been started with a strong biology focus and have added chemistry much later in the game. With the tight funding for start-up companies, the process of drug discovery needs to move more quickly, and bringing trained medicinal chemists on at company inception will promote this speed. The remainder of the organization needs to be built with an eye to products that will be entering the clinic 3–4 years from now. An innovative preclinical pharmacology group that can bring on-line novel animal disease models that utilize specific biomarkers to track compound effectiveness is helpful. A translation medicine group would become involved with the project early on, in order to examine how preclinical biomarkers could be used for first-in-human studies (even Phase 0 work). The speed with which a pharmacokinetic/pharmacodynamic relationship can be established during the development and clinical testing phase of an experimental drug will have a direct impact on stopping work on compounds early in the process and saving money in the long run. Venture capitalists these days are looking for major clinical milestones in order to fund another round for a new company. They also argue for focus, though this can work against a company if the focal area is not successful. Indeed, companies need to diversify their portfolio of projects, much as portfolio managers need to diversify their holdings.

Once proof-of-principle has been determined for a particular compound, collaborating with a company that has the capabilities to move the compound all the way to market is paramount. This will require business development staff who can determine the worth of a particular compound in light of its fit in the marketplace. The business development staff ideally should have experience from working in a company that has taken projects all the way through the clinic and onto the market. They will have a good appreciation of what is entailed in going to the next steps in the process and have sufficient contacts in the industry to open doors. Crafting the deal must be on realistic terms due to the difficulty in getting funding from a larger partner. Realistic expectations on both sides of the negotiating table will go a long way to speed up the process of getting the compound tested and into the market.

2.19.8.2 The Spin Cycle

Over the past decade, large drug discovery operations have been spinning off noncore areas of research. This has led to significant opportunities for starting up new companies that may have projects close to the clinic. One of the examples of this would be Esperion Pharmaceuticals, which was started by a group of scientists from the Atherosclerosis Department (including the former director of the department) at Warner-Lambert/Parke-Davis (WL/PD, now part of Pfizer) in the 1990s. The team that started Esperion had all taken part in the successful discovery program that resulted in the new statin atorvastatin.⁹⁶ As a class, the statins work to lower low-density lipoprotein levels, and hence lower 'bad cholesterol' in the body. The focus of Esperion was on raising the levels of high-density lipoprotein (HDL, or 'good cholesterol'). The team licensed a project from Pharmacia-Upjohn, with Pharmacia-Upjohn retaining an exclusive option for co-development and marketing outside the USA and Canada. The project focused on the development of a protein that had been shown to promote rapid cholesterol removal from atherosclerotic plaques.⁹⁷

The licensed technology (ApoA1-Milano or ETC-216) was not a high priority for Pharmacia-Upjohn. Additionally, the effect of artificially raising HDL levels on atherosclerotic plaques was still speculative. The founders of Esperion, however, had extensive experience in atherosclerosis, and were willing to take a chance on developing a protein therapeutic. ETC-216 was in Esperion's main area of focus (i.e., modulating cholesterol levels and effecting atherosclerotic lesions). Esperion was founded in 1998, and by 2003 was publishing results of a Phase II clinical trial with ETC-216.⁹⁸ Esperion also was developing a pipeline of other therapeutics for atherosclerosis and cardiovascular disease.

The published Phase II results for ETC-216 were very impressive, showing a statistically significant reduction in atherosclerosis after 6 weeks of treatment. The results were impressive enough that it generated interest in Esperion from larger companies. Finally, at the end of 2003, Pfizer agreed to buy Esperion for US \$1.3 billion.⁹⁹ This brought several of the founders full circle, having left WL/PD years before it was acquired by Pfizer, then to have Pfizer bring them back into the company after showing potential success with a new therapeutic protein. The circle was fully closed on Esperion, since Pfizer also bought Pharmacia-Upjohn, from whom they had licensed the technology from in the first place.

The above example illustrates a number of advantages of building a company along this model. There are other examples of companies that have been started with a similar model, such as Barrier Therapeutics (whose founders worked together at Johnson & Johnson) and Actelion (whose founders worked together at Hoffmann-La Roche). The first (and one of the most important) is that these companies were started by groups of scientists that had been

working together already. They did not have to spend as much time integrating the initial personalities, as happens with many start-up companies. Another advantage of this model is that the company was started with a fairly advanced project that had already been of interest to a major pharmaceutical company. The scientists themselves were already familiar with the steps necessary for putting a therapeutic into development, since many of them had been on development teams during their careers.

The model here, then, is one that relies on the current efforts at focusing the research areas at major pharmaceutical companies. This results in significant talent being let go by these large companies, many of whom are well schooled in the drug discovery process. Instead of research teams going their separate ways, however, there could be a big advantage to keeping the team together and starting a new company. The team would have to choose the project to work on with care (the more advanced, the better). The project could be one that the large company does not feel would be significantly profitable for them to pursue but could be profitable for a smaller organization or may not be in the large company's core area of marketing or development expertise.

Since the project that has been licensed will be more advanced than starting with a therapeutic target from the beginning, the infrastructure that needs to be built will be different as well. More effort should be devoted to building up a development organization (late-stage preclinical to first-in-human) than to building up the early discovery organization. Concentration on an advanced project will make raising venture capital easier, at least in today's funding environment, since the investors will be potentially able to realize a quicker exit strategy.

Once a compound or therapeutic is advanced enough to give a strong indication of success (through the end of Phase II), the rest of the organization can be backfilled. This would be done in the opposite way to a company that was starting with a target or technology but no compound. In vivo pharmacology and pharmacokinetic/drug metabolism would be the next departments to be staffed. This would allow the company to begin looking for other indications where the clinical compound may be of use. The focus would still be on the program that is in the clinic, but the thought process of building an early discovery organization would begin. Questions that would need to be addressed would include the therapeutic area for the company to concentrate on (if there is a compelling reason to change from the direction it started with), small-molecule discovery versus biological therapeutics, the target class to pursue, and how many programs should be run at one time. The goal down the road would be to become a fully integrated drug discovery operation, and potentially have a revenue stream with which to build the company.

2.19.8.3 The Virtual Company

In this model, the long-term up-front costs are kept low. Most of the work is outsourced to contract research organizations (CROs), with a few specialists on staff to interpret the data. There is some question as to whether this model is sustainable in the long run, however. The virtual company can be geared to take a candidate compound that has failed in one indication and push it forward in another indication that may have a lower return but could be quicker into the clinic. The second goal would be to give investors a relatively quick return on their investment. The exit strategy would be aimed toward getting sufficient proof of concept for a compound in order to make it interesting to a potential acquirer. By outsourcing most of the research, fixed costs could be kept low. The exchange for this reduction in fixed costs, however, is loss of control of the project. The company is dependent on time-lines from the CROs, and a significant amount of time is spent looking for CROs that can reliably deliver high-quality data.

The advantages of operating a biotechnology company with a small internal staff of experts with most of the data being generated by CROs was beginning to be touted in the early 1990s.¹⁰⁰ In this scenario, projects would be in-licensed, then the company would act as a group of study directors to obtain the necessary data for presentation to the FDA. Taken to the extreme, this type of operation would generate no data internally, but collect and collate the data generated by other organizations. While this may increase an organization's flexibility, there is no a priori reason why it should increase the success rate of bringing drugs to market.

Perhaps a more workable term that encompasses different degrees of outsourcing is the extended enterprise.¹⁰¹ Nearly all current biotechnology companies, as well as large pharmaceutical companies, engage in some form of an extended enterprise arrangement. Specific portions of the process are outsourced, due to either time constraints of building the effort internally or access to technologies/intellectual property that are proprietary to another company. An article by Cavalla¹⁰¹ lists some of the advantages and disadvantages of the extended enterprise model. Major disadvantages of this model would have to be the loss of control of the time-lines of the project, and difficulties in managing external resources. For access to new projects or promising compounds, there is significant competition in the marketplace currently. Large pharmaceutical companies have long had very active licensing operations. With the current downturn in the rate of new chemical entity approvals, the search for quality external programs has increased. This makes it difficult for a small company to compete at in-licensing discovery stage projects/compounds for eventual clinical trials.

An example of this type of company would be Salmedix, located in San Diego, CA (now part of Cephalon). The company has identified several oncology compounds that had been launched overseas but not in the USA or had been in clinical trials previously and failed. They are taking the compounds into trials designed to achieve FDA registration, and are partnering with other organizations to perform the clinical trials.

2.19.8.4 The Bottom Line

If a biotechnology company was being started now, in order for it to be successful it would have to combine portions of all three of the above models. The company should focus its efforts in one particular therapeutic area.¹⁰² This focus will allow the staff of the new company to drill deep into the biology and chemistry of the therapeutic area. Even further focus in one part of the biology of the therapeutic area would be even better (such as focusing only on preventing atherosclerotic plaque build-up instead of all cardiovascular diseases). Instead of looking to license a project or compound from another small biotechnology company, it should look to license in a project from large pharmaceutical company that is outside of its expertise or does not have the potential return on investment for a large company.

Probably the quickest way for the new company to move forward would be to hire a research and development group that has already worked extensively together. Several of the members should have experience bringing compounds through development and into clinical trials. With the recent down-sizing that has happened in large pharmaceutical companies, there are not only compounds/projects available, but also even whole research teams. This process has two advantages. The first is that the project is one that a large company had initially thought worth pursuing, and the second is that the company starts with a seasoned research team. The further along that the licensed project/compound is in the discovery/development process, the potentially shorter time will be required to reach a decision on its feasibility.

Finally, by starting with a later-stage project, the new company will focus on hiring individuals with late-stage preclinical, early clinical experience. Any studies that need to be performed that require expertise in earlier parts of the drug discovery process can initially be farmed out to a CRO. As the company matures (i.e., a potential payoff from a compound making it to market is looming), the discovery stage staff can be brought on-board to begin to build an early pipeline.

With the current mood in the venture capital community of seeking more immediate returns on their investment, the above model has the potential to succeed. The new company must continue to seek more efficient methods to get early reads on clinical compounds. This can be done either through Phase 0 microdosing trials to obtain an early read on pharmacokinetic/drug metabolism issues or early proof-of-principal studies using relevant disease biomarkers to give an early indication if the therapy has a chance to succeed. Work in this area could potentially limit the cash drain of a compound/therapeutic that does not have a reasonable chance of success. This process could also help to raise additional capital for the company if these small-scale trials add data that speak to the chance of the therapeutic succeeding.

Biographies

David A Giegel currently heads the biochemistry department at Celgene, Signal Research Division. Prior to joining Celgene in October of 2003, he was the director of lead discovery at MitoKor, Inc. There, he worked on mitochondrial targets involved in central nervous system diseases and diabetes. From 1991 to 2000, Giegel was in the department of biochemistry at the Parke-Davis Research Division of Warner-Lambert (now Pfizer) in Ann Arbor, MI. He rose to the level of director of high-throughput screening technologies, where he was responsible for introducing several new screening platforms and assay technologies. He has spent considerable time investigating serine and cysteine proteases as drug discovery targets in inflammatory and cardiovascular diseases. He was a project leader of a collaboration team between Parke-Davis and BASF Bioresearch (now Abbott Bioresearch) that examined the role of IL-1b-converting enzyme (caspase 1) in inflammatory disease. Prior to joining Parke-Davis, Giegel worked at the NutraSweet Division of Monsanto in Chicago, IL. Giegel is trained as an enzymologist, and received his PhD in biological chemistry under Dr Vincent Massey and Dr Charles Williams at the University of Michigan. He did his postdoctoral training, also at the University of Michigan, for the same advisors that he worked with for his PhD.

Alan J Lewis, PhD, joined Novocell, Inc. in February 2006 as President and Chief Executive Officer. Novocell is a biotechnology company focused on commercializing cellular therapies to cure intractable diseases. Alan was previously President of Celgene (San Diego), a biopharmaceutical company focused on the discovery, development, and

commercialization of small-molecule drugs for the treatment of cancer and immunological diseases. He served as Chief Executive Officer and Director of Signal Pharmaceuticals since 1996 and as President of the company since 1994. Prior to joining the company, Dr Lewis worked for 15 years at the Wyeth-Ayerst Research division of American Home Products Corporation, where he served as Vice President of Research from 1990 to 1994. At Wyeth-Ayerst, Dr Lewis was responsible for research efforts in CNS, cardiovascular, inflammatory, allergy and bone metabolism diseases. Dr Lewis currently serves as a Director of Discovery Partners International, BioMarin Pharmaceutical, Inc., and Cytochroma, Inc. Dr Lewis holds a PhD in pharmacology from the University of Wales in Cardiff and completed his postdoctoral training at Yale University.

Peter Worland is the executive director of experimental therapeutics at Celgene, responsible for both inflammation and oncology. Worland was previously at Millennium Pharmaceuticals, Inc., where he was the senior director and head of discovery oncology, and the senior director of the cancer pharmacology department. Worland has worked in both biotechnology and large pharmaceutical companies (Celgene, Millennium, Mitotix, and Pharmacia). He has worked on cell cycle and mitotic kinases in the past, leading the CDK inhibitor program at Mitotix and the Aurora program at Pharmacia, and overseeing several discovery oncology programs at Millennium Pharmaceuticals as the head of the discovery oncology effort.

2.20.1 G Protein-Coupled Receptor (GPCR) Therapeutic Relevance, Structure, and Families

2.20.1.1 Therapeutic Potential of G Protein-Coupled Receptors

G protein-coupled receptors (GPCRs) are a large protein superfamily comprising greater than 1% of the total human genome. Recent market analyses indicate that 40–50% of all modern drugs and almost 25% of the top 200 best-selling drugs target GPCRs.^{1–3} GPCR-targeted drugs are used to treat a wide variety of diseases including cardiovascular and gastrointestinal diseases, CNS and immune disorders, diabetes, and cancer. Endogenous ligands have been identified for approximately 210 GPCRs, many of which have been important drug discovery targets. However, evaluation of the human genome suggests that there are between 800 and 1000 genes coding for GPCRs. With the exclusion of olfactory GPCRs, over 100 ‘orphan’ GPCRs remain for which the endogenous ligands have not been identified. Orphan GPCRs undoubtedly represent the future provisional drug discovery targets representing lucrative economic opportunities for the pharmaceutical industry.⁴

2.20.1.2 Prototypic Drugs Targeting G Protein-Coupled Receptors

There are a wide variety of drugs that act directly to activate (agonists) or block (antagonists) GPCRs (Table 1) and most of these drugs target class A GPCRs. The largest number of drugs targeting GPCRs are receptor antagonists and examples include β_1 -adrenergic antagonists used to treat hypertension, angiotensin AT₁ antagonists used to treat hypertension, and histamine H₁ antagonists used to treat allergies. Some of the drugs targeting GPCRs are receptor agonists and include mu-opiate agonists for treatment of pain, β_2 -adrenergic agonists used to treat asthma, and α_2 -adrenergic agonists to treat glaucoma. A common issue with the therapeutic use of GPCR agonists is that they can lose their efficacy with repeated dosing, commonly referred to as tachyphylaxis. There are also a number of drugs not listed in Table 1 that indirectly target GPCRs. For example, serotonin reuptake inhibitors (e.g., Prozac, Paxil, and Zoloft) used to treat depression act indirectly at serotonin GPCRs by increasing synaptic levels of serotonin and facilitating activation of both presynaptic (5HT_{1A}) and postsynaptic (5HT₂) serotonin receptors. The efficacy of most drugs targeting GPCRs is due to a selective interaction with one GPCR whereas the efficacy of some drugs, for example, risperidone or olanzapine, which are used for treatment of schizophrenia, is due to blockade of several different classes of GPCRs at therapeutic doses including select dopamine, serotonin, muscarinic cholinergic, histamine, and adrenergic receptors. Most drugs targeting GPCRs are small molecules that have oral bioavailability. However, there are also recent examples of the therapeutic use of peptides to target GPCRs. An example is the recent approval of the use of the glucagons-like peptide-1 (GLP-1) receptor analog, exenatide, for treatment of type 2 diabetes.

2.20.1.3 Genetic Studies of G Protein-Coupled Receptors and Disease Relevance

There are a number of examples in which naturally occurring mutations of known GPCRs are directly related to human diseases thus providing direct evidence for their therapeutic relevance. It appears that loss-of-function mutations are typically autosomal recessive whereas gain-of-function mutations are autosomal dominant. Furthermore, gain-of-function mutations typically involve mutations that result in ligand-independent activation. Many functionally relevant GPCR polymorphisms result in changes in ligand binding, receptor G protein coupling, or in receptor phosphorylation and desensitization. Evaluation of the literature concerning GPCR polymorphisms indicates that for many, the linkage of the mutation with disease is often not statistically supported. However, considerable evidence now indicates that several adrenergic receptor polymorphisms may confer susceptibility to congestive heart failure. Table 2 lists some examples of human GPCRs for which mutations have been found and may be implicated in human disease. For many of these examples, the evidence is not compelling and further detailed studies are required to firmly establish their connection to disease. Furthermore, some GPCR mutations may affect receptor sequence without promoting a change

Table 1 Top selling drugs targeting GPCRs

<i>Brand name</i>	<i>Generic name</i>	<i>No. prescriptions* (millions)</i>	<i>Target/pharmacology</i>	<i>Primary use</i>
Hydrocodone	Hydrocodone	92.7	μ -agonist	Pain
Atenolol	Atenolol	44.2	β_1 -antagonist	Hypertension
Toprol	Metoprolol	32.8	β_1 -antagonist	Hypertension
Proventil	Albuterol	31.2	β_2 -agonist	Asthma
Zyrtec	Cetirizine	22.4	H ₁ -antagonist	Allergy
Singular	Montelukast	22.0	CysLT ₁ -antagonist	Asthma
Lopressor	Metoprolol tartrate	20.8	β_1 -antagonist	Hypertension
Allegra	Fexofenadine	18.8	H ₁ -antagonist	Allergy
Plavix	Clopidogrel	18.7	P2Y ₁₂ -antagonist	Coronary artery disease, thrombosis
Darvon	Propoxyphene	17.9	μ -agonist	Pain
Zantac	Ranitidine	14.9	H ₂ -antagonist	Ulcers
Desyrel	Trazodone	14.5	5HT _{2/1A} and α -antagonist	Depression
Flexeril	Cyclobenzaprine	13.3	5HT ₂ -antagonist	Muscle relaxant
Diovan	Valsartan	13.1	AT ₁ -antagonist	Hypertension

in phenotype or in disease incidence but may alter the efficacy of drugs used to treat the disease. It is likely that further genotyping of humans with various diseases will reveal additional orphan GPCRs that may directly play a role in human diseases. In addition, screening for various GPCR polymorphisms may enable development of more personalized drug treatments in the future.

2.20.1.4 Conserved Structural Features of G Protein-Coupled Receptor

GPCRs share several conserved structural features even though they are activated by chemically diverse ligands including biogenic amines, purines, nucleotides, amino acids, lipids, phospholipids, peptides, proteins, glycoproteins, ions, and sensory stimuli. First, the N-terminus of all GPCRs is located extracellularly while the C-terminus is located intracellularly (Figure 1). Second, all members possess seven highly conserved antiparallel transmembrane (TM) helices consisting of 20–28 amino acids in length (TM1–7) surrounding a central cleft and connected by three intracellular (IC1, IC2, IC3) and three extracellular (EC1, EC2, and EC3) loops. Other highly conserved regions include a disulfide bond between EC2 and EC3 loops, the presence of a (D/E)RY motif at the junction of TM3 and the IC2 loop, and a NpXXY motif in TM7.^{5,6} GPCRs interact with G proteins via IC3 and IC2 loops and their C-terminal tails.^{7–11} The N-terminus of many GPCRs contains several glycosylation sites and highly conserved C-terminal cysteine residues that can undergo palmitoylation, and these posttranslational modifications can influence both receptor expression and function.^{12–16} It has also been proposed that palmitoylated C-terminal cysteine residues form a hydrophobic attachment to the cell membrane and, thereby, create a fourth IC loop or eighth helix.^{17–19} The IC3 loop and C-terminal tail of GPCRs both undergo phosphorylation by specific kinases called GRKs (G protein-coupled

Table 2 Examples of GPCR polymorphisms that may contribute to human diseases

<i>GPCR</i>	<i>Potential disease relationships</i>
α_{1A} -adrenergic	Alzheimer's disease

receptor kinases), which is important for initiating the process of functional desensitization (*see* Section 2.20.3.8) and also influences G protein coupling.^{20–22} Furthermore, the C-terminal tail of GPCRs serves as an important docking site for GPCR interacting proteins such as scaffold proteins, which play important roles in organizing signaling molecules, and beta-arrestins, which mediate receptor internalization and desensitization.^{23–26}

2.20.1.5 Families of Human G Protein-Coupled Receptors

The GPCR superfamily can be divided into six subfamilies based on endogenous ligand structure, sequence similarity, and/or G protein-coupling characteristics.^{27–32} A regularly updated classification list of all known and orphan GPCRs is currently available for downloading from the International Union of Pharmacology (IUPHAR) database.^{33,666} Members of each GPCR subfamily generally share greater than 20% sequence identity in their TM regions and are considered to have evolved from a common ancestor. The focus of this chapter will be confined to class A, B, and C GPCRs as these are the predominant subfamilies targeted for drug discovery.

Class A GPCRs, represented by rhodopsin and the β_2 -adrenergic receptors, are the largest subfamily of GPCRs and are activated by a wide variety of different ligands including biogenic amines (e.g., norepinephrine, histamine, dopamine, serotonin), purines (e.g., adenosine), nucleotides (e.g., ADP, ATP), eicosanoids (e.g., prostaglandins, leukotrienes), lipids (e.g., lysophosphatidic acid, shingosine-1-phosphate, endocannabinoids), small peptides

(e.g., vasopressin, angiotensin), glycoproteins (e.g., TSH, LH, FSH), and sensory stimuli (e.g., photons). The ligand-binding pocket for class A GPCRs activated by smaller ligands such as biogenic amines is located deep in the TM core formed primarily by TM3, TM4, TM5, TM6, and TM7 (Figure 2).³⁴ In contrast, the ligand-binding pocket for class A GPCRs activated by small peptides is composed of intracellular loops and the N-terminus of the receptor with some contribution by the upper region of the TM core.^{35,36} The ligand-binding pocket of class A GPCRs activated by glycoproteins is located on the large N-terminus of the receptor and is also comprised of regions in extracellular loops ECL1 and ECL3.^{37,38} The class A subfamily of protease-activated GPCRs, represented by the thrombin receptors, is uniquely activated by proteolysis of their N-terminus, which allows the remaining N-terminus to act as a covalently bound ligand. Mutational studies of human thrombin receptors also suggest that the tethered N-terminal peptide interacts with amino acids contained within the ECL2 loop.³⁹ Phylogenetic analyses of the human genome sequence indicate that 79% of the total GPCRs in the genome are class A members and that half of these are orphan GPCRs.⁴⁰

Class B GPCRs, also referred to as the secretin family, typically contain a N-terminal hydrophobic signal peptide, a large N-terminus (100–160 amino acids), and are activated by large peptides (e.g., 30–40 amino acids). Examples of class B GPCRs include the PTH (PTH1R and PTH2R), glucagon-like peptide (GLP-1R and GLP-2R), glucagon, calcitonin, corticotropin-releasing factor (CRFR1 and CRFR2), and vasoactive peptide (VPAC1R, VPAC2R, PAC1R) receptors. Class B GPCRs have overall morphology similar to class A GPCRs activated by glycoproteins but do not share any sequence homology. Furthermore, the overall sequence homology between class B members is relatively low.^{41,42} Mutational studies suggest that the binding pocket of these GPCRs is discontinuous and is comprised of contact points from the extended N-terminus and the three extracellular loops. Class B GPCRs also contain six conserved cysteine residues involved in intradomain disulfide bridges and also contain a conserved region within the N-terminal domain close to TM1, which is involved in ligand binding.^{43,44} A simple low-resolution ‘two domain’ model of the class B GPCR ligand binding pocket suggests that the N-terminal region of the hormone binds to the N-terminal domain and that this initial interaction acts as an affinity trap supporting an additional interaction of the N-terminal region of the ligand with the TM bundle region.⁴⁵

Figure 2 Ligand binding pockets for Class A, B, and C GPCRs.

A novel subclass of class B GPCRs, referred to as large N-terminal GPCRs or EGF-TM7 receptors, shares homology in the TM regions with secretin receptors, but also contains several structural features that are unique for this subclass. These features include a long N-terminus with variable numbers of EGF-like motifs, a mucin-rich stalk region enriched in serine and threonine residues, and a GPCR proteolytic site (called the GPS domain), which, after cleavage, becomes noncovalently associated with the TM regions of the receptor.⁴⁶ These GPCRs can also contain additional N-terminal domains including arginine-glycine-aspartic acid (RGD) motifs, cadherin domains, and immunoglobulin domains. The physiological functions of members of this subclass are still largely unknown but some evidence suggests that they play roles in mammalian development and cellular adhesion. Examples of this subclass include the latrotoxin and CD97 receptors. Within this subfamily, only CD97 has an identified binding partner, membrane protein CD55, and activation of this receptor appears to play a role in leukocyte migration.⁴⁷ Recently, a total of 30 different orphan GPCRs belonging to this subclass have been identified but little is known concerning the function of these new GPCRs.³¹ Since many of these GPCRs most likely bind large proteins, their small molecule 'druggability' remains to be established.

Class C GPCRs, represented by metabotropic glutamate receptors, contain a large N-terminal extracellular domain, followed by a cysteine-rich domain (except the GABA_B receptor), and a C-terminus of variable length; and they have low but significant homology with bacterial periplasmic proteins. Endogenous ligands for class C GPCRs include amino acids (glutamate), γ -amino-butyric acid (GABA), magnesium and calcium ions, putative pheromones, and taste molecules. The metabotropic glutamate and calcium-sensing receptors share approximately 20 conserved cysteine residues in the extracellular region of the TM bundle. Class C GPCRs generally form homodimers (*see* Section 2.20.3.6) and each subunit has a large extracellular domain called a venus flytrap module (VFTM). The ligand binding pocket of class C GPCRs is situated in a cleft between two lobes of the VFTM and x-ray crystallography studies indicate that the VFTM lobes close upon ligand binding leading to activation of the TM core domain.^{48–51} Class C GPCRs make up only a small proportion of mammalian GPCRs (1–2%).

2.20.2 G Protein-Coupled Receptor-Mediated Activation of G Proteins

2.20.2.1 The G Protein Cycle

Ligand binding to the extracellular surface of GPCRs initiates a set of conformational changes culminating in the exposure of receptor IC2 and IC3 loops to participate in G protein coupling and subsequent activation of G proteins. Activated G proteins in turn regulate a variety of specific effector proteins and signal transduction pathways ultimately leading to a variety of cellular responses. G proteins are heterotrimeric proteins containing α -, β -, and γ -subunits and function by a cycle of α - and $\beta\gamma$ -subunit dissociation superimposed by GPCR-mediated guanine nucleotide exchange on the α -subunit (Figure 3). The sequential events occurring in receptor-mediated activation of G-proteins are as follows: (1) agonist binds to the receptor promoting a series of conformational changes favoring receptor coupling to G protein(s); (2) formation of the agonist–receptor–G protein ternary complex induces a G protein conformational change that facilitates the exchange of α -subunit bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP); (3) GTP binding destabilizes the G protein heterotrimer and promotes dissociation into

Figure 3 G protein activation cycle.

GTP bound α -subunit and the $\beta\gamma$ -complex; (4) GTP bound α -subunit and the $\beta\gamma$ -complex regulate the activity of select intracellular effector proteins (enzymes or ion channels) leading to changes in levels of second messengers (e.g., cAMP and calcium) and regulation of select signal transduction pathways; (5) activity of GTP bound α -subunit is terminated by hydrolysis of GTP to GDP, referred to as the GTPase reaction; (6) inactivated GDP bound α -subunit reassociates with the $\beta\gamma$ -complex completing the G protein cycle. The G protein activation/deactivation cycle is generally rapid and ranges from milliseconds to seconds in duration. Some reports in the literature suggest that G proteins can activate effectors without subunit dissociation but this claim currently remains controversial.^{52–55} In addition, GPCRs can also modulate signaling pathways by G protein-independent mechanisms (see Section 2.20.3.8).

2.20.2.2 General Structure of G Proteins

Mammalian G proteins are divided into four subfamilies (G_s , $G_{i/o}$, G_q , and $G_{12/13}$) based on the structural and functional similarities of their α -subunits. There are several isoforms of G protein subunits with over 16 different α -subunits, 5 β -subunits, and 14 γ -subunits expressed in mouse and human genomes.^{56–60} The α -subunits are typically palmitoylated on conserved N-terminal cysteine residues (with the exception of $G\alpha_t$) or myristoylated on N-terminal glycine residues (only $G\alpha_{i/o/z}$)^{61–64} both of which play an important role in membrane localization as well as regulation of interactions with other proteins including $\beta\gamma$ -complexes.^{64–67} Unlike myristoylation, palmitoylation is a reversible process and it appears to be highly regulated. Structural studies including x-ray crystallography of $G\alpha_{i1}$ indicate that G protein α -subunits are composed of two important structural domains, a Ras-like nucleotide-binding domain (called the GTPase domain) that mediates GTP binding and hydrolysis, and an alpha-helical domain that buries GTP within the core of the G protein α -subunit.^{68–71} The α -subunit helical portion is most structurally divergent between G protein families and plays an important role in determining the specificity of receptor- and effector-G protein coupling. The N-terminal region of α -subunits is ordered by their interaction with the β -subunit.^{69–71} Domains of α -subunits involved in GPCR recognition include the α -subunit C-terminus, which contacts receptor IC2 and IC3 loops, the extreme N-terminus, a region between helices α_4 and α_5 , and a region within the loop linking the N-terminal α -helix to the β 1-strand of the Ras-like domain.^{71–73} Unfortunately, several attempts to determine G protein selectivity for various GPCRs empirically based on GPCR sequences have not been successful to date.

The $\beta\gamma$ -complex is made up of two polypeptides, but is functionally a monomer because this complex does not dissociate in cells. All β -subunits contain seven WD40 repeat motifs and a tryptophan-aspartic acid sequence that repeats about every 40 amino acids and forms small antiparallel beta-strands.^{57,70,74} X-ray crystal studies indicate that the seven WD40 repeats fold to form a seven-bladed beta-propeller structure and the N-terminus forms an α -helix.⁷⁴ With the exception of β_5 , which is exclusively expressed in the central nervous system, all β -subunit isoforms display 79–90% sequence identity. In contrast, the γ -subunits are much more heterogeneous suggesting that they have unique functional roles. Structural studies indicate that the γ -subunit folds into two helices: the N-terminal helix forms a coiled-coil with the α -helix of the β -subunit, while the C-terminal helix makes extensive contacts with the base of the β -subunit.^{69,70,74–76} All γ -subunits are alpha-helical and isoprenylated with either farnesyl- or geranylgeranyl-groups that are important for function and facilitate membrane localization of the $\beta\gamma$ -complex.^{77–82} $\beta\gamma$ -complex interacts with a hydrophobic pocket residing in the GDP-bound α -subunit and GTP binding eliminates this pocket promoting a reduction in affinity between the GTP-bound α -subunit and the $\beta\gamma$ -complex resulting in G protein subunit dissociation.⁶⁹ Biochemical approaches have suggested that different $\beta\gamma$ -complex combinations are functionally similar but more recent studies using gene targeting approaches have demonstrated that GPCRs have a preference for certain subunit combinations to link to perspective effectors. For example, it has been reported that dopamine D_1 receptors require $\beta\gamma$ -complexes with the γ_7 to stimulate adenylyl cyclase in discrete brain areas.⁸³

2.20.2.3 Families of G Proteins and Effectors Regulated by α -Subunits

The $G\alpha_s$ G protein subfamily includes the members $G\alpha_s$ and $G\alpha_{olf}$, which primarily act to stimulate adenylyl cyclase, an enzyme responsible for converting ATP to the second messenger, cAMP (Figure 4; Table 3).⁸⁴ Increases in cAMP levels, in turn, promote activation of protein kinase A (PKA) and phosphorylation of specific cellular substrates leading to cellular responses. The activation of PKA is terminated by phosphodiesterase-mediated conversion of cAMP to AMP. Cholera toxin promotes activation of adenylyl cyclase by catalyzing ADP ribosylation of a conserved C-terminal arginine residue of $G\alpha_s$ resulting in an inhibition of its GTPase activity. Although $G\alpha_s$ and $G\alpha_{olf}$ both stimulate adenylyl cyclase, $G\alpha_{olf}$ has been shown to differ from $G\alpha_s$ by having a lower affinity for GDP and a more rapid deactivation

Figure 4 G protein-mediated regulation of adenylyl cyclase. PDE, phosphodiesterase; PKA, protein kinase A.

Table 3 Effectors directly regulated by different G protein α -subunits

Subfamily	Members	Effectors
G_s	$G\alpha_s$	Stimulation of adenylyl cyclase, src activation
	$G\alpha_{olf}$	Stimulation of adenylyl cyclase
$G_{i/o}$	$G\alpha_{i1}$	Inhibition of adenylyl cyclase
	$G\alpha_{i2}$	Inhibition of adenylyl cyclase
	$G\alpha_{i3}$	Inhibition of adenylyl cyclase
	$G\alpha_{oA}$	Inhibition of adenylyl cyclase
	$G\alpha_{oB}$	Inhibition of adenylyl cyclase
	$G\alpha_z$	Inhibition of adenylyl cyclase; GRIN1, Eya2
	$G\alpha_{t1}$	Stimulation of cGMP-phosphodiesterase
	$G\alpha_{t2}$	Stimulation of cGMP-phosphodiesterase
G_q	$G\alpha_q$	Stimulation of PLC β , PLD; activation of RhoGEF
	$G\alpha_{11}$	Stimulation of PLC β ; stimulation of Brunton's tyrosine kinase; activation of RhoGEF
	$G\alpha_{14}$	Stimulation of PLC β
	$G\alpha_{15/16}$	Stimulation of PLC β
$G_{12/13}$	$G\alpha_{12}$	Activation of p115RhoGEF, PDZ-RhoGEF, Ibc-RhoGEF, LARG, interaction with glutamate transporter associated protein GTRAP4, cell adhesion molecules, PLC ϵ activation, A-kinase anchoring protein 110, heat shock protein 90, and protein phosphatase 5
	$G\alpha_{13}$	

cycle.⁸⁵ There are four known splice variants of $G\alpha_s$, two shorter variants and two larger variants, with the latter being predominantly expressed in neuroendocrine cells.⁸⁶ Constitutively activating mutations of $G\alpha_s$ in which GTPase activity is diminished are present in endocrine tumors, fibrous bone dysplasia, and McCune-Albright syndrome, whereas a loss-of-function mutation leads to Albright hereditary osteodystrophy.⁸⁷ Biochemical and genetic evaluations

suggest that $G\alpha_s$ is involved in diverse physiological processes including regulation of bone growth,^{88,89} ion channel function^{90–92} meiotic arrest,⁹³ and insulin sensitivity⁹⁴ as well as recognized roles in regulation of the immune response, adipose metabolism, glycogen synthesis, and cardiac function. $G\alpha_{olf}$ is expressed in olfactory neurons, striatum, and pancreatic beta-cells.^{95–97} Besides playing a fundamental role in olfaction, activation of $G\beta_{olf}$ in beta-cells has been reported to be involved in regulation of insulin status and beta-cell survival and regeneration during development and diabetes.⁹⁸ Striatal dopamine D_1 and adenosine A_{2A} -mediated increases in cAMP are reported to be mediated by $G\alpha_{olf}$ ⁹⁹ and prolonged elevation of $G\alpha_{olf}$ levels in human Parkinson's disease patients may lead to a persistent D_1 receptor hypersensitivity and contribute to the genesis of long-term complications of L-dopa treatment.¹⁰⁰

The larger $G\alpha_{i/o}$ G protein subfamily includes $G\alpha_{i1}$, $G\alpha_{i2}$, $G\alpha_{i3}$, $G\alpha_{oA}$, $G\alpha_{oB}$, $G\alpha_z$, $G\alpha_{t1}$, $G\alpha_{t2}$, and $G\alpha_g$. All family members (except $G\alpha_z$) are substrates for pertussis toxin (PTX) ADP ribosyl transferase and ADP ribosylation of C-terminal arginine residues inhibits receptor-G protein coupling. The cellular focus of activated $G\alpha_i$, $G\alpha_o$, and $G\alpha_z$ subunits is primarily inhibition of adenylyl cyclase¹⁰¹ (Figure 4). Of the nine different isoforms of mammalian adenylyl cyclase identified, the V, VI, and I isoforms are directly inhibited by $G\alpha_{i/o}$ subunits.^{102,103}

$G\alpha_i$ proteins are the most widely expressed G protein subfamily and are hypothesized to serve as an important source of G protein $\beta\gamma$ -complexes. The high structural similarity of $G\alpha_i$ proteins suggests that they may have at least partially redundant physiological functions. $G\alpha_{i1}$ subunits have been reported to play an important role in regulation of calcium currents,¹⁰⁴ platelet activation,¹⁰⁵ and activation of K^+ channels.¹⁰⁶ $G\alpha_{i2}$ subunits have been demonstrated to play physiological roles in regulation of calcium currents,¹⁰⁷ control of hormone release from pancreatic alpha-cells,^{107–109} activation of K^+ channels in pancreatic alpha-cells,¹⁰⁸ control of proliferation of neural progenitor cells,¹¹⁰ facilitation of GLUT4 translocation¹¹¹ and insulin signaling in skeletal muscle and adipose tissue, regulation of platelet activation and adipocyte differentiation,^{112,113} regulation of immune cell development¹¹⁴ and function,^{115–118} and regulation of cardiac cell apoptosis and cardiac hypertrophy.^{119–121} The $G\alpha_{i3}$ subunit plays key roles in regulation of calcium currents¹²² and inflammatory responses of immune cells.¹²³ Interestingly, $G\alpha_{i2}$ is reported to be required for direct inhibition of adenylyl cyclase whereas $G\alpha_{i3}$ is required to inhibit $G\alpha_s$ -activated adenylyl cyclase.¹²⁴ The rate of guanine nucleotide exchange for $G\alpha_i$ is one of the most rapid of all G proteins and the turnover rate for $G\alpha_z$ is one of the slowest.¹²⁵

$G\alpha_o$ is predominantly expressed throughout the nervous system with lower levels expressed in heart, pituitary, and pancreas.¹²⁶ The physiological functions of $G\alpha_o$ isoforms ($G\alpha_{oA}$ and $G\alpha_{oB}$) other than inhibition of adenylyl cyclase, regulation of ion channel activity, and regulation of retinal function remain to be further elucidated. Recent evaluations of this G protein subfamily also suggest that they play roles in modulation of voltage-gated calcium channels and in exocytosis in chromaffin cells, pituitary cells, and melanotrophs. Most of the actions of $G\alpha_o$ are thought to be mediated primarily by $\beta\gamma$ -complexes.

$G\alpha_z$ is predominately expressed in cells exhibiting regulated exocytosis and include hypothalamic neurons, adrenal medulla cells, platelets, and pancreatic beta-cells. $G\alpha_z$ participates in several cellular processes including cellular and neuronal development, survival, proliferation, differentiation, pituitary hormone secretion,^{127–129} apoptosis,¹³⁰ and pancreatic beta-cell signaling.¹³¹ Association of $G\alpha_z$ with a number of different signaling molecules, some of which are neuronal specific proteins, suggests that it may play a role in cellular development, survival, proliferation, differentiation, and apoptosis. These proteins include G protein-regulated inducers of neurite outgrowth (GRIN1, 2, and 3)¹³² and Eya2 transcription factor, both of which are involved in embryonic neuronal development.¹³³ $G\alpha_{t1}$ and $G\alpha_{t2}$, known as transducins, are well-characterized retinal G proteins that interact with specific phosphodiesterases that hydrolyze cGMP.¹³⁴ $G\alpha_g$, also known as gustducin, is highly related to transducin and is primarily expressed in taste tissue and plays a role in taste signal transduction.^{135–137}

The $G\alpha_q$ G protein subfamily includes the members $G\alpha_q$, $G\alpha_{11}$, $G\alpha_{14}$, $G\alpha_{15}$, or $G\alpha_{16}$, all of which stimulate phospholipase C β , an enzyme that catalyzes hydrolysis of membrane-associated phosphatidylinositol species (PI, PIP, and PIP2) to form inositol phosphates (IP, IP₂, and IP₃) and diacylglycerol (DAG)^{138,139} (Figure 5). Elevation of intracellular IP₃ levels in turn leads to activation of an IP₃ receptor located on the endoplasmic reticulum membrane resulting in a transient elevation of intracellular Ca^{2+} and activation of a number of calcium-dependent proteins and enzymes including protein kinase C (PKC). $G\alpha_q$ and $G\alpha_{11}$ are ubiquitously expressed in human tissues while $G\alpha_{14}$ is predominately expressed in spleen, lung, testes, and kidney and $G\alpha_{16}$ expression is restricted to hematopoietic lineages.¹⁴⁰ Although $G\alpha_{14}$ and $G\alpha_{15}$ are expressed in mice, only the $G\alpha_{16}$ subunit is expressed in humans. Receptors activating the G_q family in mammalian systems do not generally distinguish between $G\alpha_q$ and $G\alpha_{11}$.¹⁴¹ Targeted knockout of $G\alpha_q$ and $G\alpha_{11}$ in mice results in impairment of normal hypothalamic functions resulting in somatotroph hypoplasia, dwarfism, and anorexia.¹⁴² Several cardiac G_q -coupled receptors (e.g., angiotensin and endothelin receptors) mediate cardiac inotropy and chronotropy as well as development of hypertrophy.¹¹⁹ Recently, GPCR-mediated

Figure 5 G protein-mediated activation of phospholipase C. PKC, protein kinase C; ER, endoplasmic reticulum.

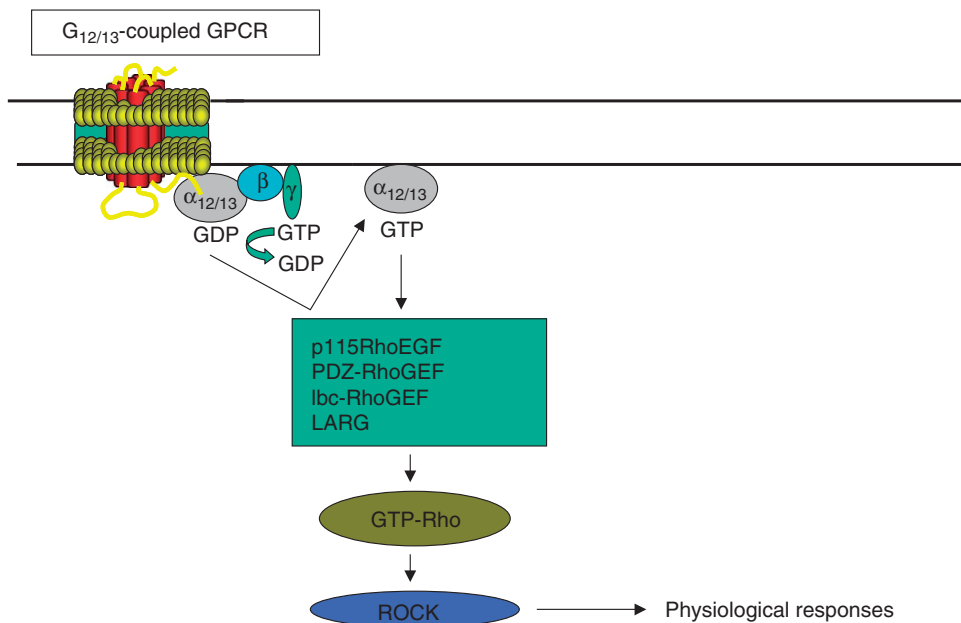

Figure 6 G protein-mediated activation of RhoA.

activation of a K^+ channel by $G\alpha_q$ subunits has been reported.¹⁴³ Stimulation of some G_q -coupled GPCRs has been observed to induce phosphorylation of $G\alpha_{q/11}$ but the significance of this is unclear.¹⁴⁴

The $G\alpha_{12}$ G protein subfamily has two members, $G\alpha_{12}$ and $G\alpha_{13}$.^{145–147} It is currently unclear which signaling pathways are shared between these two subunits and which are controlled more exclusively by one or the other. The effector pathways regulated by $G\alpha_{12}$ and $G\alpha_{13}$ have recently been elucidated and activation of both G protein α -subunits leads to activation of the small G protein RhoA through the guanine nucleotide exchange factor RhoGEF or related proteins (PDZ-RhoGEF, Ibc-RhoGEF, LARG) (Figure 6). Indeed, in cell-free studies, $G\alpha_{13}$ directly stimulates

p115RhoGEF to enhance guanine nucleotide exchange for RhoA and that p115RhoGEF binding with RhoA accelerates the rate of GTP hydrolysis by both $G\alpha_{12}$ and $G\alpha_{13}$.^{148,149} Activated RhoA in turn activates RhoA kinase (ROCK) leading to regulation of a variety of important cellular activities including cell cycle progression, cellular proliferation, cellular adhesion, chemotaxis, cytoskeletal rearrangements (such as stress fiber formation), smooth muscle contraction, and gene expression.^{147–149} Furthermore, $G\alpha_{12}$ and $G\alpha_{13}$ knockout mice deficient in neural crest–cell-derived cardiac cells display significant cardiac malformations.¹⁵⁰ In addition, $G\alpha_{12/13}$ has been shown to possess oncogenic activity.¹⁵¹ The majority of GPCRs coupling to $G\alpha_{12/13}$ also couple to $G\alpha_q$, which has complicated determination of cellular processes selectively regulated by $G\alpha_{12/13}$ (Table 4). $G\alpha_{12}$ and $G\alpha_{13}$ have also been reported to interact directly with other effector proteins besides p115RhoGEF including glutamate transporter EAAT4-associated protein, radixin, cortactin-interacting protein Hax-1, cell adhesion molecules, PLC ϵ , A-kinase anchoring protein 110 (AKAP), heat shock protein 90, Ser/Thr phosphatase type 5, and protein phosphatase 2A.^{152–162} The physiological importance of most of these protein interactions remains to be further elucidated.

2.20.2.4 $\beta\gamma$ -Regulation of Effectors

The original functional roles that G protein $\beta\gamma$ -complexes were thought to play in GPCR signal transduction were to facilitate the attachment of G protein heterotrimers to the plasma membrane as well as to complex with inactive GDP-bound α -subunits. However, it is now well substantiated that $\beta\gamma$ -complexes regulate the activity of a wide variety of effectors. In fact, the list of different effector proteins regulated by $\beta\gamma$ -complexes is now larger than those regulated by α -subunits (Tables 3 and 5).^{58–60,163–166} Many effector proteins regulated by $\beta\gamma$ -complexes contain conserved protein–protein interaction domains called PH domains. However, not all proteins containing PH domains are $\beta\gamma$ -complex effectors. An important factor concerning $\beta\gamma$ -complex-mediated signaling is that the $\beta\gamma$ composition of any given cell will determine the quality and efficiency of effector regulation and will also influence receptor–G protein coupling specificity similar to α -subunits. For any GPCR, activation of one G protein generates not only activated α -subunits but $\beta\gamma$ -complexes as well, which contributes to the potential complexity of GPCR signaling. For example, some $G_{i/o}$ -coupled receptors may not only inhibit adenylyl cyclase activity, but may also mediate stimulation of PLC β -pathway by a $\beta\gamma$ -mediated mechanism.

2.20.2.5 G Protein-Coupled Receptor-Mediated Activation of Mitogen-Activated Protein Kinases

GPCR-mediated control of cellular growth, proliferation, differentiation, and survival in many instances involves activation of a family of cytoplasmic serine/threonine kinases called mitogen activated protein (MAP) kinases (MAPKs). Mammalian cells express three major classes of MAPKs: the extracellular signal-regulated kinases (ERK1 and ERK2); c-Jun terminal kinase/stress-activated protein kinases (JNKs/SAPKs); and p38/HOG1.^{217–222} All MAPKs are activated by a series of parallel kinase phosphorylation cascades, each pathway comprising a collection of three distinct kinases that are successively phosphorylated. For example, activation of the ERK1/2 cascade involves c-Raf-1 kinase and B-Raf kinase-mediated phosphorylation of the dual function threonine/tyrosine kinases, MAP kinase kinase (MEK1 and MEK2), which subsequently phosphorylates and activates ERK1 and ERK2. Ultimately, activated MAPKs then in turn phosphorylate a variety of membrane, cytoplasmic, nuclear, and cytoskeletal substrates leading to a diverse set of cellular responses. One common endpoint of MAPK activation and signaling involves their translocation from the cytosol into the nucleus where they phosphorylate and activate specific nuclear transcription factors that control DNA synthesis and cell division.

GPCR-mediated activation of MAPKs is clearly involved in several different human diseases such as certain forms of cancer, cardiac hypertrophy, neointimal hyperplasia of vascular smooth muscle, and prostate hypertrophy.^{223–226} Activation of MAPK appears to play a role in a number of important physiological processes including smooth muscle relaxation, contraction, and proliferation,^{227,228} control of learning and memory processes,²²⁹ protection against ischemia/reperfusion injury,^{230–232} and control of immune cell function.²³³ GPCRs that couple to G_s , $G_{i/o}$, and $G_{q/11}$ can, depending on the GPCR and the cell type, activate different MAPKs. Although GPCRs are known to activate JNKs and p38 families of MAPKs, the following discussion of GPCR regulation of MAPKs is restricted to activation of ERK1/2 as these pathways are more established than pathways leading to activation of the later two families of MAPKs. However, GPCR-mediated activation of JNK and p38 MAPK families is undoubtedly important both physiologically and pathophysiologically.^{220–222}

GPCR-mediated activation of ERK1/2 generally occurs by three different mechanisms; signals initiated by classical G protein signaling molecules such as PKA and PKC; signals initiated by GPCR-mediated activation

Table 4 Examples of different GPCRs activating $G\alpha_{12/13}$

<i>GPCR</i>	<i>Cells</i>	<i>Assay cellular change</i>
Serotonin 5HT _{2C}	NIH3T3	RhoA activation
Serotonin 5HT _{4A}	NIE-115	Neurite retraction
Serotonin 5HT _{4A}	NIH 3T3	Serum response element activation
Adenosine A ₃	Cardiomyocytes	Phospholipase D activation
α_{1A} -adrenergic	Cardiomyocytes	Hypertrophy
Angiotensin AT ₂	Smooth muscle	Contraction
Bradykinin B ₂	132N1	Phospholipase D activation
Bombesin	Swiss 3T3	Actin polymerization
Complement C5a	Neutrophils	RhoA activation
Cholecystokinin (CCK)	Intestinal smooth muscle	Phospholipase D activation
Chemokine CXCR3	BML	RhoA activation and chemotaxis
Leukotriene CysLT(1)	Epithelial	Stress fiber formation
EDG3	CHO	RhoA activation
EDG5	CHO	RhoA activation
Prostaglandin EP ₃	PC12	RhoA activation and neurite retraction
Endothelin ET _{A/B}	Smooth muscle	Actin polymerization
FMLP	Neutrophils	F-actin polymerization
G2A	Swiss 3T3	Rho A activation, stress fiber formation, SRE activation
Galanin GAL2	Swiss 3T3	Stress fiber formation
Gastrin-releasing peptide	Isrecol	Cellular invasion
Histamine H ₁	1321N1	PLD activation
LPA	Swiss 3T3	Stress fiber formation
LPA	Endothelial	Stimulate calcium current
LPA	Fibroblasts	Membrane depolarization-chloride channel activation
LPA	NEI-115	RhoA activation and neurite retraction
Muscarinic M ₁	Jurkat	Serum response element activation
Muscarinic M ₁	HEK293	Rho activation
Muscarinic M ₃	CHO	Stress fiber formation
Metabotropic mGluR1a	CHO	Phospholipase D activation
Tachykinin NK1	U-373-M6	IL6 and IL8 production
Purinergic P2Y	C6	MAP kinase activation
Purinergic P2Y	Swiss 3T3	RhoA activation, stress fiber formation
Purinergic P2Y2	Swiss 3T3	RhoA activation, stress fiber formation
Purinergic P2Y4	Swiss 3T3	RhoA activation, stress fiber formation
Purinergic P2Y6	Swiss 3T3	RhoA activation, stress fiber formation

<i>Effector</i>	<i>Regulation</i>	<i>References</i>
Adenylyl cyclase I	Inhibition	167, 101, 168–171
Adenylyl cyclase II, IV, and VII	Stimulation	167, 101, 169–171
Akt/protein kinase B	Stimulation	172, 173
Brunton's tyrosine kinase	Stimulation	174
Calcium channels (L, N, P, Q, R type)	Inhibition	175–180
Calmodulin	Inhibition of CAM kinase	181
Dynamin I	Increased GTPase activity	182
GIRK 1, 2, 4 ion channels	Stimulation	183–188
G protein receptor kinases	Membrane recruitment	189–195
KSR-1 (stress responsive kinase)	Sequestration of $\beta\gamma$	196
PI3-kinase	Stimulation	197–200
PLC β	Stimulation	201–205
PLC ϵ	Stimulation	206
P-Rex1	Stimulation	207
Protein kinase D	Stimulation	208
RACK1 (receptor for activated C kinase)	Inhibition of $\beta\gamma$ -mediated stimulation of effectors	209
Raf-1 protein kinase	Sequestration of $\beta\gamma$	210, 211
Sodium channels	Stimulation	212
Src kinase	Stimulation	213, 214
Tsk tyrosine kinase	Stimulation	215
Tubulin	Increased GTPase activity	216

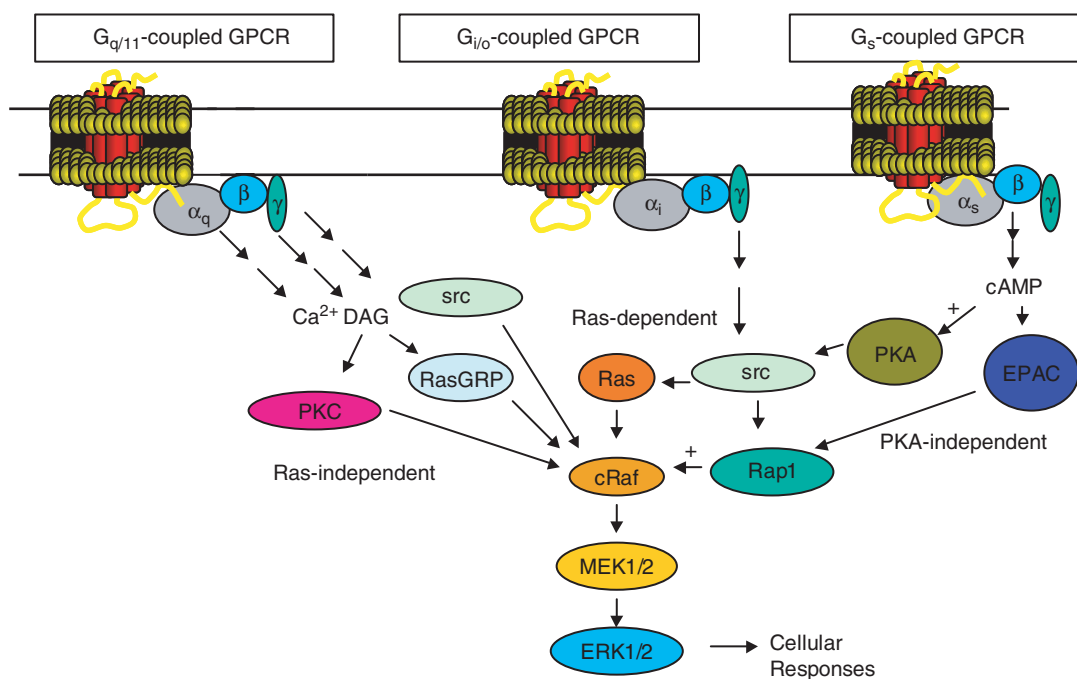

Figure 7 GPCR-mediated regulation of ERKs by classical pathways.

of receptor tyrosine kinases (RTKs) (a process called transactivation); and signals generated by the direct interaction of beta-arrestin and components of the MAPK phosphorylation cascade.^{234–239} The overall mechanism(s) and the different signaling molecules involved in GPCR-mediated activation of ERK1/2 are still poorly defined. Furthermore, the mechanism involved in a given cell will be dictated by the complement and cellular orientation of signaling proteins present, which is regulated by interaction with a number of cellular scaffolding proteins.^{236,238,240}

Classical activation of ERKs by GPCRs involves G protein-mediated activation of PKA or PKC (Figure 7). For example, in neuronal cells, G_s-coupled receptors stimulate ERKs via PKA mediated phosphorylation of the small G proteins, Rap-1 and RapB.^{241–244} In addition, cAMP can act directly to stimulate the guanine nucleotide exchange factor EPAC in some cells, which in turn stimulates the Ras-like GTPase Rap-1 (Figure 7).^{245–248} Activation of PKC by G_q-coupled receptors via PLCβ-mediated increases in intracellular diacylglycerol and Ca²⁺ can also lead to MAPK activation through both Ras-dependent and independent mechanisms.^{249–251} In addition, PKC can directly phosphorylate Raf-1 resulting in MAPK activation.²⁵² G_i-coupled receptors can activate MAPKs via increases in PKC activation or through a mechanism involving βγ-mediated activation of the cytoplasmic tyrosine kinase, c-src. As previously stated, the mechanism of GPCR-mediated activation of ERK1/2 is highly dependent upon the receptor and the cell type that is investigated.

The second mechanism of GPCR-mediated MAPK activation involves activation of the small G protein Ras, via a pathway involving transactivation of specific RTKs such as the epidermal growth factor receptor (EGFR) (Figure 8).^{253–255} The first step in the process of transactivation involves GPCR-mediated G protein heterotrimer dissociation and βγ-complex-mediated activation of c-src, which along with the βγ-complex, activates specific membrane-associated metalloprotease(s) (primarily members of the ADAM (a disintegrin and metalloprotease) family). These metalloproteases in turn act to cleave membrane-associated growth factor precursors to their active form, a process termed ectodomain shedding. The processed growth factor then binds to its receptor leading to receptor autophosphorylation, activation of a series of cytoplasmic adapter proteins culminating in activation of Ras, which in turn triggers activation of ERK1/2.²⁵⁶ The differential involvement of RTKs and downstream signaling molecules activated in response to GPCR-mediated stimulation allows fine-tuning of GPCR signaling.²²³ GPCR-mediated transactivation of other receptor tyrosine kinases, such as PDGF (platelet-derived growth factor), FGF (fibroblast growth factor), and Trk (a neurotrophic growth factor), has been reported, but it is unclear if ADAM proteases are involved as has been established for EGF receptor transactivation. It appears that GPCR-associated cancers involve activation of EGF and Ras signaling pathways.

Figure 8 GPCR-mediated transactivation of RTKs and MAPK activation.

The third mechanism of MAPK activation involves the scaffolding protein, beta-arrestin. Initially, beta-arrestin was thought to primarily play a role in GPCR desensitization and internalization. However, beta-arrestin has clearly been demonstrated to play an important role in GPCR-mediated activation of ERK1/2. Specifically, it is now appreciated that beta-arrestin acts to recruit signaling proteins such as src and MAPK cascade components to the membrane as well as modulate GPCR endocytosis, trigger ERK1/2 activation, and target MAPKs and associated signaling molecules to specific locations in the cell.²²² In some cases, receptor-mediated activation of ERK1/2 via beta-arrestin is G protein independent. The precise mechanism(s) of beta-arrestin-mediated activation of ERKs is currently unclear but appears to require recruitment and interaction with c-src kinase.^{257–258} For certain GPCRs, receptor internalization is a prerequisite for MAPK activation and for others it is not.²⁴³ It appears that for many GPCRs, beta-arrestin-mediated activation of MAPKs results in retention of the kinase in the cytoplasm and results in phosphorylation of predominately cytoplasmic substrates. In contrast, activation of MAPKs through G protein-dependent pathways primarily promotes translocation of MAPKs into the nucleus resulting in activation of nuclear transcription factors.

2.20.2.6 Regulators of G Protein Signaling

Regulators of G protein signaling (RGS proteins) are cytoplasmic proteins that modulate signaling of heterotrimeric G proteins by facilitating the GTPase activity of G protein α -subunits.^{259–262} Currently, there are more than 30 different members of this family divided into five separate subfamilies. All RGS proteins share a conserved RGS domain of 120–130 amino acids flanked by N- and C-terminal domains of variable length. RGS proteins also contain a γ -subunit-like domain important for interaction with the G protein β -subunits.²⁶³ In addition to increasing G protein GTPase activity, RGS proteins can accelerate the kinetics of G protein α -subunit-mediated responses without compromising steady-state signaling strength.^{264–267} One explanation for this latter effect may be that RGS proteins act as important scaffolds facilitating the assembly of signaling complexes between GPCRs and G proteins. Alternatively, RGS proteins may promote entry into the G protein cycle by facilitating dissociation of trimeric G proteins into prospective GTP- α and $\beta\gamma$ subunits, thus serving as 'kinetic' scaffolds.^{268,269} Recently, a novel model for the action of RGS proteins on the G protein cycle has been described in which RGS proteins enhance the kinetic efficiency of the ternary complex between agonist, GPCR, and G protein by a direct association with the G protein α -subunits.²⁷⁰

Evidence now suggests that RGS proteins can directly interact with GPCRs to modulate their activity. For example, RGS2 has been reported to directly interact with the IC3 loop of the α_{1A} -adrenergic receptor and is recruited by the unstimulated receptor to the plasma membrane to inhibit $G_{q/11}$ signaling.²⁷¹

2.20.3 Updated Models of G Protein-Coupled Receptor Activation

2.20.3.1 Constitutively Active G Protein-Coupled Receptors

Many GPCRs are capable of undergoing ligand-independent activation and G protein coupling, commonly referred as constitutive activation. One of the first reports regarding constitutive activity of a GPCR came from a landmark study by Costa and Herz (1998) of delta-opiate receptors naturally expressed in NG108–15 cells.²⁷² They observed that certain delta-opiate antagonists displayed physiological actions that were opposite to those observed with delta-opiate agonists (termed ‘negative intrinsic activity’), while other antagonists displayed no intrinsic activity. Furthermore, these unexpected actions could also be blocked with delta-opiate antagonists lacking negative intrinsic activity. Compounds displaying this novel activity were subsequently called ‘inverse agonists’ and compounds not displaying negative intrinsic activity are now called ‘neutral antagonists.’ There have been a large number of papers describing constitutively activate GPCRs in which ligand-independent signaling was observed in guanine nucleotide exchange assays or assays measuring second messengers such as cAMP or inositol phosphates (Table 6). There are three primary experimental approaches to generating constitutively active GPCRs including overexpression of native receptors in recombinant expression systems, overexpression of select G proteins,^{273–276} or by mutation of amino acids primarily contained within TM regions and IC loops (see Table 6). Pharmacological characterization of a wide variety of previously characterized antagonists for several different GPCRs using constitutively active receptors has revealed that a large proportion of these GPCR ligands (greater than 85%) have now been reclassified as inverse agonists.²⁷⁷ Furthermore, studies of different constitutively activating mutations of GPCRs have helped to elucidate the regions of GPCRs that are important in receptor activation and G protein coupling (see Section 2.20.3.2). An impressive list of different mutations that promote GPCR constitutive activation are available on-line.⁶⁶⁷

The pathophysiological significance of constitutively active GPCRs has been clearly confirmed by the existence of several naturally occurring activating mutations of different GPCRs that are clearly associated with several different human diseases (Table 7). Furthermore, a variety of GPCRs display constitutive activity in cell lines and tissues suggesting that this property is not simply an artifact of GPCR overexpression and that some GPCRs display constitutive activity when expressed at physiological densities (Table 8). Recently, a protein isolated from the CNS called agouti-related protein, has been shown to be an endogenous melanocortin MC3 and MC4 receptor inverse agonist. It is likely that other natural inverse agonists may exist for other constitutively active human GPCRs. One caution in studies of endogenous constitutively active GPCRs is that trace amounts of agonist must be removed from cell suspensions or plasma membrane preparations before constitutive activity can be confirmed. Another requirement for proving the existence of naturally occurring constitutively active GPCRs is the availability of a neutral antagonist to prevent inverse agonist as well as agonist actions. Several excellent reviews addressing agonist-independent activation of GPCRs have appeared in recent years.^{278–289}

Methodologies to promote constitutive activation of GPCRs have enabled development of screens that allow identification of inverse agonists. If constitutively active GPCRs are associated with human disease, inverse agonists should be superior therapeutics to neutral antagonists.²⁸⁸ However, if constitutively active GPCRs are not associated with a particular disease, neutral antagonists would be predicted to be as therapeutically effective as inverse agonists. Thus, the therapeutic importance of inverse agonists will be dependent upon instances in which the basal signaling by the receptor is controlled mainly by its intrinsic activity rather than by the endogenous ligand. A large number of inverse agonists, particularly for biogenic amine receptors, are widely used drugs. However, the clinical importance of their inverse agonist properties remains to be further established. In addition, the question remains as to whether inverse agonists can be designed rather than found in primary screening of small-molecule compound libraries.²⁹⁰

2.20.3.2 Models of G Protein-Coupled Receptor Activation and G Protein Coupling

The original model of GPCR activation and G protein coupling, called the ‘ternary complex model’ (Figure 9a), suggests that GPCR activation and receptor–G protein coupling involves an agonist-induced receptor conformational change that facilitates receptor and G protein coupling leading to formation of an active ternary complex between agonist, receptor, and G protein.^{291,292} In the presence of GDP, agonist binding promotes the formation of a stable ternary complex displaying high affinity for agonists. However, in the presence of GTP, the ternary complex is only transiently formed, resulting in receptor-mediated G protein activation followed by ternary complex dissociation and

Table 7 Human diseases caused by naturally mutated constitutively active GPCRs

<i>GPCR</i>	<i>Disease</i>
Ca ²⁺ sensing	Familial hypocalcemia
LH	Familial male precocious puberty
LH	Sporadic Leydig cell tumors
PTH/PTHrP	Jensen's chondrodysplasia
Rhodopsin	Congenital night blindness
TSH	Familial nonautoimmune hyperthyroidism
TSH	Sporadic hyperfunctional thyroid adenomas

Information taken from ^{278–289}.

conversion of the receptor to a low-affinity conformation. Although this model has been widely accepted for several years, it does not account for constitutively active GPCRs and inverse agonism.

To accommodate these new phenomena, the 'extended ternary complex model' has been recently adopted in place of the ternary complex model²⁹³ (Figure 9b). This new model has incorporated the ability of GPCRs to spontaneously and conformationally isomerize (called the J constant) to an active state. A simplification of the extended ternary complex model, called the 'two-state model,' is shown in Figure 9c. This model suggests that GPCRs exist in an equilibrium between inactive (R) and active (R*) conformations and only the R* state is capable of interacting with G protein to promote a physiological response. Full agonists act to shift this equilibrium from the inactive R state to the active R* state and stabilize the active conformation. Partial agonists promote a similar directional equilibrium shift but are less effective than full agonists. Conversely, inverse agonists are capable of shifting the equilibrium from the active R* state to the inactive R state and stabilize the receptor in its inactive conformation. Similarly, partial inverse agonists promote a similar directional shift but are less effective than full inverse agonists. Inverse agonists also block agonist actions and this explains why many inverse agonists have been initially classified as antagonists. Neutral antagonists do not promote a shift in equilibrium between R and R* but are capable of blocking the actions of either agonists or inverse agonists. Ultimately, this model predicts that the concentration of active receptor G protein complex [R*G] will determine the level of constitutive activation. Several constitutively active mutant GPCRs display enhanced agonist-independent signaling compared to the native wild-type receptor expressed at similar levels. These observations suggest that the mutated receptor is a better representation of the natural active conformation of GPCRs, although this is likely an oversimplification. For example, in some instances, GPCR mutations have been reported that signal at considerably higher levels than agonist-occupied receptor suggesting that some constitutive activating mutations may not represent the agonist-occupied active R* state. Consistent with the two-state model, constitutively active GPCRs will display increased agonist affinity, increased potency for agonists and partial agonists, and, in some cases, increased receptor instability and desensitization.^{294–299} Indeed, several reports regarding constitutively active mutated GPCRs suggest that they also display constitutive phosphorylation and undergo constitutive internalization^{300–308} and, in some cases, the majority of receptor is internalized at steady state. However, there are also reports that inverse agonists can prevent constitutive receptor internalization.^{307,308} Na⁺ ions, similar to inverse agonists, stabilize the inactive R form of GPCRs and the precise molecular locus of the action of Na⁺ ions is presumably a highly conserved aspartate residue in TM2.^{309–313}

The extended ternary complex model adequately addresses most of the molecular pharmacology of GPCRs but it does not account for unproductive receptor and G protein coupling. For example, antagonists for opioid, histamine H₂, pheromone, and CB₁ receptors have been reported to promote formation of a nonsignaling ternary complex.^{314–316} To accommodate these observations, the 'cubic ternary complex model' (Figure 9d) has been formulated. This model incorporates an allowance for the interaction of G protein not only with the active conformation of the receptor (R*) but also with the inactive conformation (R).^{317–319} There are a number of excellent reviews that discuss the detailed theoretical considerations of the different models presented in Figure 9.^{319–325}

Protean agonism is another theoretical prediction of the extended ternary complex model.³²¹ For constitutively active GPCRs, some compounds can display either agonist or inverse agonist activity depending upon the level of receptor constitutive activity. The reversal from agonism to inverse agonism will occur if the agonist-promoted active

Table 8 Examples of constitutively active GPCRs in cell lines and tissues and inverse agonist actions

<i>Receptor</i>	<i>Tissue or cell</i>	<i>Inverse agonist effect</i>
α_1 -adrenergic	Rat aorta	Decreased contraction
α_{2A} -adrenergic	H.E.L.92.1.17	Increased cAMP levels
α_{2D} -adrenergic	Rat RIN5AH cells	Decreased basal GTP γ S binding
β_1 -adrenergic	Human ventricle	Decrease in contraction
$\beta_{1/2}$ -adrenergic	Guinea pig and human cardiomyocytes	Decreased calcium current
$\beta_{1/2}$ -adrenergic	Turkey erythrocyte membranes	Decreased adenylyl cyclase activity
$\beta_{1/2}$ -adrenergic	Rat atria	Reduction in contraction
β_2 -adrenergic	Human mast cells	Opening of iKCa1 ion channel
β_2 -adrenergic	Guinea pig trachea	Increased contraction
β_2 -adrenergic	Bovine tracheal smooth muscle	Increased sensitivity to muscarinic agonists
β_2 -adrenergic	BC3H1 cells	Decrease in basal cAMP levels
Bradykinin B	Human H69 cells	Decrease in basal thymidine incorporation
Bradykinin B ₁	Rat and bovine myometrial membranes	Decreased IP accumulation
CB ₁ cannabinoid	Rat cerebellar granule cells	Increased aspartate release
CB ₁ cannabinoid	Mouse vas deferens	Increased norepinephrine release
CB ₁ cannabinoid	Human neocortex	Increased acetylcholine release
CB ₁ cannabinoid	Rat superior cervical ganglion	Increased calcium current
CB ₁ cannabinoid	Mammalian brain	Increase in cAMP levels
CB ₁ cannabinoid	Rat brain	Increased basal cAMP; decreased basal GTP γ S binding
CB ₁ cannabinoid	Rat hippocampal synaptosomes	Increase in acetylcholine release
Dopamine D ₂	GH4C1 cells	Increases in cAMP levels
GLP-1	Murine betaTC-Tet cells	Decreased basal insulin release
Histamine H ₂	U-937 cells	Decrease in basal cAMP levels
Histamine H ₃	Rat synaptosomes	Increased histamine release
Serotonin 5HT _{2C}	Rat striatum and nucleus accumbens	Increased dopamine release
Serotonin 5HT _{2C}	Rat choroid plexus	Decrease in basal IP accumulation
Melatonin MT ₁	Rat caudal arteries	Decreased GTP γ S binding
Muscarinic	Rat cardiomyocytes	Increase in cAMP levels
Muscarinic	Porcine atrial membranes	Reduction in GTP γ S binding
Muscarinic	Frog/rat cardiac cells	Decreased calcium current
Muscarinic	Rat thoracic aorta strips	Decreased calcium current
Muscarinic M ₂	Pig atrial sarcolemma	Decreased GTPase activity
Muscarinic M ₂	Rat cardiomyocytes	Increase in cAMP levels
δ -opiate	NG-108-15	Decreased GTPase activity; decreased basal GTP γ S binding
δ -opiate	GH3 cells	Reduction in basal GTP γ S binding
κ -opiate	Guinea pig ileum	Reduced contraction
μ -opiate	GH3	Reduction in GTP γ S binding

Figure 9 Models of GPCR and G protein activation. (a) Ternary complex model; (b) extended ternary complex model; (c) simplified two-state model; and (d) the cubic extended ternary complex model (without equilibrium dissociation constants). R, receptor; A, agonist or endogenous ligand; G, G protein; AR, inactive agonist receptor complex; AR*G, active ternary complex between agonist, receptor, and G protein; ARG, inactive ternary complex between agonist, receptor, and G protein; R*G, active receptor-G protein complex; RG, inactive receptor-G protein complex.

conformation has lower efficacy for G protein coupling than the constitutively active receptor. A clear example of protean agonism concerns the histamine H₃ ligand proxyfan, which acts as a protean agonist at recombinant H₃ receptors expressed in Chinese hamster ovary (CHO) cells.³²⁶ The therapeutic value of protean agonists has not been established.

2.20.3.3 The Multistate Model of G Protein-Coupled Receptor Activation

The various forms of the extended ternary complex described above adequately explain the properties of agonism, antagonism, and inverse agonism for GPCRs, but all of these models assume that there are only two functional or active states of GPCRs. However, a considerable amount of experimental evidence now suggests that most GPCRs are not just on/off switches for activating G proteins and that there are at least three or more active conformations of GPCRs. An alternative model of GPCR activation accommodating multiple active GPCR conformations is referred to as the ‘three state’ or ‘multistate’ model.³²⁷

One important observation supporting this model is the simple fact that several GPCRs clearly couple to multiple G proteins and activate multiple signaling pathways.³²⁸ Although, in many cases, this multiplicity of G protein coupling can be an artifact of overexpression of GPCRs in recombinant expression systems, several examples of GPCRs coupling to multiple G proteins and signaling pathways in cell lines and tissues expressing endogenous levels of receptor exist.^{328–335} Another important observation supporting this new model is that mutations in the TM regions of certain GPCRs have been shown to result in a conversion of activation of multiple G proteins and signaling pathways to a single G protein and associated signaling pathway.^{336–339} Since TM regions are not involved in influencing selectivity of receptor and G protein coupling, these specific mutations should not alter receptor G protein interactions. Furthermore, functional G protein reconstitution studies with GPCRs expressed and purified from insect cells and different G protein α -subunits indicate that different agonists can produce different patterns of G protein activation.³⁴⁰

Multiple agonist-induced active GPCR conformations can also be inferred from studies in which different agonists have differential efficacy in activation of different G proteins and signaling pathways,^{341–344} and that certain agonists appear to prefer activation of one G protein signaling pathway over another, a phenomenon referred to as ‘agonist trafficking’.^{320–325} The multistate model thus also provides the theoretical basis for the concept of signaling-selective agonism. There are numerous examples of agonist trafficking for several different GPCRs in the literature. For example, agonist activation of the 5HT_{2C} receptor results in the activation of two signaling pathways, G_q-mediated activation of inositol phosphate accumulation and G_q-independent activation of phospholipase A₂ resulting in cellular arachidonic acid accumulation. Some agonists (e.g., trifluoromethylphenyl-piperazine) were found to be more efficacious in stimulating inositol phosphate accumulation whereas others (e.g., LSD) favored activation of the phospholipase A₂.³⁴¹ Agonist trafficking has been demonstrated for several surrogate ligands, but only a few examples exist with endogenous GPCR ligands. In some cases, agonist trafficking may really occur through a strong signal-type mechanism in which a high-efficacy agonist could activate multiple signaling pathways whereas a weaker efficacy agonist may stimulate only one.³⁴² Other examples of ligand-selective GPCR regulation include ligands that promote coupling to one G protein pool while inhibiting coupling to another. For example, the GnRH receptor antagonist Ant135–25 acts as an agonist in the G_i signaling pathway and as an antagonist in the G_q pathway.³⁴³ Signal-selective antagonism has also been reported for GPCRs including the cholecystokinin CCK_B³⁴⁴ and tachykinin NK1 receptors.³⁴⁵

Dual efficacy ligands have also recently been reported to exist for certain GPCRs and their existence also supports the concept of multiple active conformations of GPCRs. For example, propranolol and ICI118551, two well-established β_2 -adrenergic inverse agonists in the G_s pathway, have been reported to be partial agonists in activating the MAPK pathway in the same cells.^{346,347} Furthermore, the activation of the MAPK pathway was demonstrated to be G protein-independent and required recruitment of the scaffold protein, beta-arrestin. Dual efficacy ligands have also been discovered for delta-opiate receptors that act as inverse agonists in the cAMP pathway (reverse agonist-mediated decreases in cAMP) and agonists in the MAPK pathway. The discovery of dual efficacy ligands adds even more complexity to the molecular pharmacology of GPCRs that already exists with the advent of agonist trafficking.

The most convincing data regarding the existence of multiple agonist-induced conformations of GPCRs comes from several important fluorescence labeling studies performed in Brian Kobilka's laboratory. In an early study, a fluorescent reporter was chemically incorporated into the interface of the IC3 loop and TM3 of the β_2 -adrenergic receptor and fluorescence changes around this reporter were evaluated with exposure to chemically different receptor agonists.³⁴⁸ These studies indicated that agonists promote formation of two different conformations of the β_2 -adrenergic receptor IC3 loop, a receptor domain critical in mediating G protein coupling. In addition, it was observed that receptor conformations promoted by partial agonists were distinguishable from those promoted by full agonists. In another later study, catechol derivatives were designed to mimic the endogenous ligand (epinephrine, norepinephrine) and were observed to induce two kinetically distinguishable active conformations of the β_2 -adrenergic receptor.³⁴⁹ A more recent study from this laboratory has also demonstrated differences in receptor conformations promoted by structurally related agonists and partial agonists for the β_2 -adrenergic receptor.³⁵⁰ Recently, studies of both opiate^{351,352} and β_2 -adrenergic receptors³⁵³ using plasmon resonance spectroscopy, a method used to evaluate ligand–receptor interactions that avoids the requirement of receptor labeling, have also indicated that agonists, partial agonists, and inverse agonists may promote formation of different receptor conformations. Collectively, these studies support the multistate model of GPCR activation.

Several recent studies of GPCR phosphorylation, internalization, and desensitization also indicate that different agonists for a given GPCR can promote different levels of receptor phosphorylation and subsequent internalization supporting the notion that GPCRs can also adopt different deactivated conformations.^{354–361} For example, both enkephalins and morphine stimulate delta- and mu-opiate receptors but only the former promotes receptor desensitization. Similarly, endogenous ligands for the CCR7 receptor including CCL19 and CCL21 display equivalent potency and efficacy in stimulating increases in intracellular calcium but dramatically differ in their ability to promote desensitization of the CCR7 receptor.³⁶² Recent mass spectroscopy studies of the β_2 -adrenergic receptor have shown that selective ligands can determine the degree of phosphorylation of different intracellular regions of the receptor. Phosphorylation of the IC3 loop is increased to a similar degree with the agonists isoproterenol, dopamine, and epinephrine. However, differences in agonist-mediated phosphorylation of the C-terminal tail were detected with dopamine being less capable of promoting phosphorylation than isoproterenol or epinephrine.³⁶³ A recent study of three constitutively active mutants of the C5a receptor also provides evidence for multiple conformations of GPCRs. One receptor mutant exhibited both constitutive activation of G protein and endocytosis, another mutant exhibited constitutive activation of G protein but was found to undergo endocytosis only in the presence of agonist, and a third mutant only activated G protein with agonist present and was found to be constitutively endocytosed.³⁶⁴ Vauquelin and Van Liefde,³²⁷ Perez and Karnik,³⁶⁵ and Maudsley and co-workers³⁴² have recently reviewed the accumulating evidence supporting multiple active conformations of GPCRs and their potential impact on GPCR drug discovery. These reviews suggest the theoretical possibility that each chemically distinct agonist will impart upon the receptor its own unique activated conformation.

The potential existence of multiple GPCR conformations of endogenously expressed GPCRs (possibly several) in disease relevant cells and tissues could have an enormous impact on GPCR drug discovery programs. Their existence suggests that it may be possible to selectively target different receptor conformations with new drugs to increase their efficacy and reduce on-target associated side effects. The case for the multiple active states for several different GPCRs is now quite strong, but the most important question concerns what receptor conformation(s) and associated signaling pathway(s) are related to GPCR-associated diseases. If the signaling pathway associated with a therapeutic target can be linked to the disease of interest or to unwanted side effects, GPCR signaling-biased screens should be developed and implemented for drug discovery efforts. For GPCR drug discovery programs, it is possible that important compounds may be missed in a screening campaign because the appropriate signaling pathway was not captured in the functional screen used. Furthermore, if signaling pathways associated with the therapeutic endpoint are unknown, it may be necessary to perform multiple functional screens relevant to all known GPCR-activated signal transduction pathways activated by the GPCR target. Some GPCR experts have recently suggested that the potential

multiplicity of G protein coupling and signaling may require that GPCR drug discovery should start with a primary emphasis on receptor binding screens followed by a battery of relevant functional assays.³⁶⁶ This is a departure from recent years when the industry embraced predominantly functional cell-based assays over ligand binding assays. The development of fluorescence-based technologies to evaluate different agonist or surrogate ligand-induced conformational states upon ligand binding will become a new component to successful GPCR drug discovery programs in the future.

2.20.3.4 Organization of G Protein-Coupled Receptors and Signaling Molecules

Over the last 4 years, it has become clearly established that many GPCRs, G proteins, and effectors are not randomly distributed in the plasma membrane but form discrete signaling complexes involving a variety of accessory proteins referred to as GPCR interacting proteins (GIPs) (Table 9). Specifically, GIPs act to assemble GPCRs, G proteins, and effectors into prearranged signaling complexes and involve receptor C-terminal tail PDZ domain motifs and SH3 motifs.^{23–26,342,371–375} In general, organization of GPCRs in microdomains and their interaction with GIPs is thought mainly to control the speed and specificity of GPCR signaling.^{240,367} GIPs also play roles in GPCR regulation such as desensitization and internalization. Potential GPCR–protein interactions are typically evaluated using yeast two-hybrid screening and immunoprecipitation methodologies in recombinant cells³⁶⁸ or by using the C-terminal tail GST-fusions as bait to isolate the interacting proteins.³⁶⁹ Once identified, it is important to establish that a putative GPCR–protein interaction be demonstrated *in vivo*. Nowhere has the importance of the organization of GPCRs and associated signaling molecules been more clearly demonstrated than in the spatial and temporal activation of the MAPK pathway.³⁷⁰ Activation of a nuclear pool of ERK1/2 as a consequence of GPCRs transactivation of receptor tyrosine kinases may provide a mitogenic stimulus whereas activation of ERK1/2 localized at the plasma membrane or in endosomal vesicles via scaffolding proteins such as beta-arrestin may spatially restrict ERK1/2 activity favoring phosphorylation of non-nuclear ERK substrates.³⁷⁰ Proteomics approaches should enable identification and quantification of additional GIPs associated with various GPCRs so that a better understanding of macromolecular signaling complexes can be delineated.

Several GIPs reported to interact with GPCRs and their potential effects on GPCR function, signaling, and regulation are listed in Table 9. GIPs may represent a new locus to pharmacologically modulate GPCR function and may not only provide alternative ways to modify receptor activity but also to exploit new chemical space for drug-like molecules.³⁷⁶ The relevance of GIPs to GPCR drug discovery is currently unclear but we anticipate that cellular content and GPCR–GIP interactions will become increasingly more important variables to be considered in developing new GPCR functional screens. Targeting GPCR and protein interactions may be a reasonable therapeutic endpoint, but our ability to selectively block protein–protein interactions with small molecules has been limited up to this point.

2.20.3.5 Models of Class A G Protein-Coupled Receptor Activation and G Protein Coupling Based on Rhodopsin

Elucidation of the structural basis for ligand-mediated activation of GPCRs by x-ray crystallography has been limited because it is difficult to produce and purify large quantities of protein and it is difficult to form suitable crystals of integral membrane proteins. However, the x-ray crystal structure of the light-activated GPCR rhodopsin has been solved primarily as a result of the availability of large quantities of purified receptor from bovine retina and the stabilization of solubilized receptor with the inverse agonist 11-*cis*-retinal resulting in suitable formation of crystals for x-ray.^{417,418} The x-ray crystal structure of rhodopsin confirms the seven TM bundle arrangement of GPCRs proposed many years earlier. Collectively, analyses of x-ray crystallography data, biochemical approaches including cysteine cross-linking, spin labeling and scanning accessibility, and analyses of retinal movement by photoaffinity labeling have been valuable methodologies to determine the mechanism of light activation of the rhodopsin receptor.^{419–421} Current models suggest that photons induce retinal isomerization, which triggers an outward movement of TM helices 3, 4, and 6, and which, in turn, exposes rhodopsin intracellular loops to couple to the G protein transducin.^{422–425} Recent reviews suggest that light activation of rhodopsin involves reorientation of the cytoplasmic end of TMVI and changes in the relative disposition of TMVI and TMIII.^{426,427} Light-induced conformational changes have also been observed in the cytoplasmic domain spanning TM1 and TM2 and the cytoplasmic end of TM7 and helix 8. Since the crystal structure of rhodopsin has been generated for only inverse agonist bound receptor, it has provided only limited information concerning activated conformations of other GPCRs.

Table 9 GPCR interacting proteins

<i>GPCR interacting protein</i>	<i>GPCRs</i>	<i>Functional significance</i>	<i>References</i>
AKAP79/250 (Gravin)	β_2 -adrenergic	Organizes GPCRs, kinases, phosphatases, ion channels, and cytoskeletal elements	377, 378
β -Arrestin	Most GPCRs	Organizes numerous signaling molecules (e.g., src) into receptosomes	379
ATRAP	Angiotensin AT ₁	Promotes receptor downregulation	380
Calmodulin	mGluR ₇	Regulation of receptor phosphorylation and signaling	381, 382
Calnexin	LHR, FSHR, vasopressin V ₂	Regulation of endoplasmic reticulum export	383, 384
Caveolin-1	Serotonin 5HT _{2A}	Regulates G _q signaling	385
CIPP	Serotonin 5HT _{2A}	Regulation of ion channel activity?	386
Clathrin adaptor complex 2	α_{1B} -adrenergic	Role in receptor endocytosis	387
CortBP1	Somatostatin SSTR ₂	Unknown	388
Endophilin	β_1 -adrenergic	Promotes receptor internalization	389
Filamin-A	CaR, dopamine D _{2/3}	Scaffold protein for MAPK components	390–392
GASP-1/2	δ -opiate	May regulate receptor sorting in the golgi	393
GIPC	Dopamine D _{2/3} , LHR	Regulates receptor trafficking, recruits RGS proteins	394, 395
Homer	mGluR _{1, 5}	Regulates receptor interactions with signaling proteins	396
JM4	Chemokine CCR ₅	Regulation of receptor trafficking	397
MAGI-2	β_1 -adrenergic	Regulation of receptor internalization	398
MMP-3	Serotonin 5HT _{2C}	Unknown	386
MRAP	Melanocortin MCR2	May play a role in receptor trafficking to the plasma membrane	399
MUPP1	Serotonin 5HT _{2C}	Assembly of signaling complexes,	400
Muskelin	Prostaglandin EP ₃	Controls cytoskeletal organization	401
NHERF-1/2	β_2 -adrenergic	Role in receptor recycling versus lysosomal degradation	402
NHERF	κ -opiate	Facilitates receptor homodimerization	403
Nm23-H2	Prostanoid TP receptor	Modulates receptor internalization	404
Periplakin	Opiate, MCHR	Limits receptor and G protein interaction	405, 406
PICK	Prolactin-releasing peptide, mGluR ₇	Regulates PKC phosphorylation of receptors, receptor clustering	407, 408
Protein phosphatase 1C, 2C	mGluR _{1a, 5a, 5b, 7b}	Regulates receptor internalization	409
PSD-95	β_1 -adrenergic, serotonin 5HT _{2C} , 5HT _{2A}	Augments signal transduction and inhibits receptor internalization	410
RCP	CGRP	Regulates receptor signal transduction	411
Siah1A	mGluR _{1/5}	Mediates degradation of internalized receptors	412
Spinophilin	$\alpha_{2A/B}$ -adrenergic	Stabilizes receptor expression; regulates calcium signaling via interaction with RGS proteins	413, 414
Tamalin	mGluR _{1,2,3,5}	Regulates receptor signaling	415
Tubulin	mGluR ₇	Regulation of receptor trafficking	416

The mechanism by which the binding of 'diffusible ligands' leads to GPCR activation and G protein coupling has only recently begun to be elucidated. The x-ray crystal structure of rhodopsin has been successfully used as a template to create homology models for several GPCRs including the dopamine D₂, muscarinic M₁, and chemokine CCR5 receptors. However, crystal structures of other GPCRs have been difficult to obtain due to limitations in producing milligram quantities of pure receptor, poor methods of crystallization, and inadequate methods to reconstitute GPCRs into lipid bilayers so that active conformations can be studied. Fluorescence spectroscopic studies of the β_2 -adrenergic receptor using fluorescent probes indicate that activation of the β_2 -adrenergic receptor involves rotation and tilting of TM6 upon agonist binding.^{428–433} The change in conformation of this core domain generally affects the conformation of the IC2 and IC3 intracellular loops that are directly linked to TM3 and TM6 and form one of the principle sites involved in G protein recognition and activation. Other regions of class A GPCRs playing a role in receptor activation include an aspartate residue in TM2 and the DRY region at the interface of TM3 and the IC2 loop. Recently, light-driven activation of β_2 -adrenergic receptor signaling has been demonstrated using a chimeric rhodopsin receptor containing β_2 -adrenergic cytoplasmic loops.⁴³⁴ Site-directed mutational and biochemical studies of dopamine D₂^{435,436} and muscarinic M₁^{437,438} receptors have also supported this model of GPCR activation. However, cysteine cross-linking studies of the muscarinic M₃ receptor also suggest that receptor activation involves both rotation of TM7 and an increase in the proximity of the C-terminal ends of TM1 and TM7.⁴³⁹ Recently, Baneres and colleagues (2005) have purified the serotonin 5-HT_{4a} receptor and evaluated conformational changes associated with receptor activation by both circular dichroism (CD) and steady-state fluorescence measurements.⁴⁴⁰ They reported a specific change in the near UV CD band associated with the disulfide bond connecting TMII to the IC2 loop. New developments in NMR technology should allow further elucidation of ligand-mediated activation of GPCRs and provide information complementary to x-ray crystallography studies. In general, activation of class A GPCRs by biogenic amines is considered to involve a conformational change resulting in release of a constrained inactive conformation resulting in G protein coupling.⁴⁴¹ In addition, numerous GPCR mutational studies resulting in constitutive activation also support this model of activation (*see* Section 2.20.3.1).

Activation of class A GPCRs by peptide-hormone receptors does not appear to involve salt bridge disruption, but displacement of residues in TM3 appears to be involved in activation.^{441–444} In addition to TM3 movements, activation of the angiotensin II receptor has also been reported to involve movement of TM2 and has led to the hypothesis that receptor activation involves an interaction of TM2 and TM7.⁴⁴⁴ The EC3 loop connects TM6 and TM7 and at the cytoplasmic terminus of these two helices are the IC3 loop and helix 8, both of which have been implicated in G protein coupling. The EC3 loop is generally short and, as such, may constrain their motion preserving the inactive state. Substitutions of the EC3 loop relieving this constraint lead to constitutive activation of the delta-opiate receptor suggesting that the EC3 loop is important for receptor activation.⁴⁴⁵ Activation of glycoprotein binding GPCRs such as the TSH and LH receptors appears to involve initial binding to the long N-terminus of the receptor and activation also involves TM helices.^{446,447} For example, mutation of TM6 and TM7 of the LH receptor results in constitutive activation. Thus, conformational changes associated with extracellular loops are also associated with ligand-dependent activation of some GPCRs. Our understanding of GPCR activation and associated conformational changes is still in its infancy and is mostly limited to class A receptors. It will be interesting to see if the x-ray crystal structures of additional GPCRs will be solved, especially class B and class C members.

2.20.3.6 G Protein-Coupled Receptor Oligomerization and Heterodimerization

The view that GPCRs function as monomeric proteins has recently been challenged by numerous recent studies and it is now well established that many, if not most GPCRs, exist as dimers or even higher structure oligomers.^{448–452} A commonly used methodology employed in early studies of GPCR dimerization has been coimmunoprecipitation of epitope-tagged GPCRs after solubilization with appropriate detergents. However, potential issues with this approach include concern that solubilization of hydrophobic proteins with detergents can promote formation of artifactual protein aggregates and the use of antibodies can promote artifactual receptor clustering. A newer methodology used to study GPCR dimerization in living cells is bioluminescence resonance energy transfer (BRET), which is based on the transfer of energy between recombinant expressed GPCR fusion proteins in which, for example, Renilla luciferase and green fluorescent protein (GFP) are recombinantly expressed on the C-terminal tail. Energy transfer can only take place between luciferase-tagged GPCR and GFP-tagged GPCR if both molecules are in close proximity after addition of the luciferase substrate coelenterazine.^{453–455} Another related methodology used to study GPCR dimerization in living cells is fluorescence resonance energy transfer (FRET) and is based on transfer of fluorescence energy between recombinant expressed GPCR fused to cyan fluorescent protein (CFP) and the same or a distinct GPCR fused to yellow fluorescent protein (YFP) when they are in close spatial proximity.⁴⁵⁶

In addition, time resolved FRET^{457,458} using europium chelate technology has also been used to study GPCR dimerization. Furthermore, fluorescent-labeled ligands have been used to study GPCR dimerization as well.^{459,460} One limitation of early BRET and FRET studies was that they were not able to discern whether receptor dimerization occurred at the cell surface or in intracellular compartments. However, the marriage of BRET/FRET technologies with confocal microscopy has helped to resolve the existence of GPCR dimers in the plasma membrane.

Considerable evidence now suggests that many GPCRs undergo dynamic dimerization.^{460–462} A major concern with dimerization studies using recombinant expressed GPCRs is the possibility that artifactual dimerization may take place primarily due to GPCR overexpression and may not be physiologically relevant. In addition, it is often difficult to determine the proportion of receptors existing as monomers and dimers. A study of BRET saturation in which different ratios of Renilla luciferase and GFP-tagged forms of the β_2 -adrenergic receptor were recombinantly coexpressed has indicated that 80% of the total receptor population is present as dimers.⁴⁶³ The percentage of monomers and dimers of any given GPCR may be quite variable and will most likely be different for different cells. Important GPCR domains mediating dimer formation include TM regions and the C-terminal tail.^{464–470} Current evidence suggests that at least for the metabotropic glutamate receptors, GPCR dimers can interact with only one G protein and that, in some cases, only one dimer binds the endogenous ligand.⁴⁷¹

One of the primary cellular effects of GPCR dimerization appears to be regulation of GPCR expression and trafficking. For example, dimerization of the muscarinic M_3 receptor has recently been reported to be required for beta-arrestin recruitment to the plasma membrane during the process of endocytosis.⁴⁷² In addition, GPCR dimerization is important for proper protein folding and for transport of GPCRs from the endoplasmic reticulum and the golgi apparatus to the plasma membrane during biosynthesis.⁴⁷³ A recent report by Cao and co-workers (2005) suggests that dimerization of the β_2 -adrenergic receptor when expressed in human embryonic kidney cell line (HEK293) cells may be important for determining the fate of the receptor upon internalization (recycling to the plasma membrane versus lysosomal degradation).⁴⁷⁴ Currently, it is unclear whether oligomerization is ligand regulated or a general prerequisite for GPCR signaling.⁴⁵⁰

GPCRs also undergo heterodimerization, a process in which different but usually related GPCRs form physical complexes that, in some cases, can result in changes in GPCR ligand binding specificity, trafficking, and signaling.^{448–450,475} Heterodimerization is absolutely required for functional activity for some GPCRs such as GABA_B and taste receptors. As with studies of dimerization in recombinant cells, it is often unclear as to whether heterodimerization represents a physiologically relevant interaction or whether it is an artifact of GPCR overexpression. Unfortunately, there is limited information regarding GPCR heterodimerization in endogenous cells and tissues. That said, there are many reports of GPCR heterodimerization in a number of different cell lines. Putative GPCR domains important for heterodimerization, similar to those mediating homodimerization, include TM regions and the C-terminal tail.^{476–478} One of the most striking examples of heterodimerization involves delta- and mu-opiate receptors. Coexpression of these two receptors results in pharmacology that is distinct from either of the monomers and the delta/mu heterodimer also displays strong positive cooperativity in ligand binding.⁴⁷⁹ Several other reports also suggest that other GPCR heterodimers display a unique pharmacology compared to their constitutive monomers and this property could significantly contribute to the functional diversity of GPCRs.⁴⁸⁰ For example, a study of melatonin MT₁/MT₂ heterodimers suggests that heterodimers have distinct ligand interaction properties compared to monomers.⁴⁸¹ Similarly, heterodimerization of β_1 -adrenergic and β_2 -adrenergic receptors in cardiac myocytes promotes a higher potency of isoproterenol to stimulate cAMP accumulation than with either receptor alone.⁴⁸²

One of the most common functional consequences of GPCR heterodimerization is change in receptor internalization and desensitization. In a study of the functional consequences of heterodimerization of $G_{i/o}$ -coupled opiate receptor and G_s -coupled β_2 -adrenergic receptor, heterodimerization did not affect ligand binding or G protein coupling but did affect receptor internalization as indicated by the ability of the β_2 -agonist isoproterenol to promote delta-opiate receptor internalization and, conversely, the opiate agonist etorphine promotes β_2 -adrenergic receptor internalization.⁴⁸³ There are several other reports also indicating that GPCR heterodimerization can prevent internalization and endocytosis of associated receptor monomer.^{484–450} For example, coexpression of β_1 -adrenergic and β_2 -adrenergic receptors in HEK293 cells results in heterodimer formation and agonist-mediated internalization of β_2 -receptor was inhibited by heterodimerization with the β_1 -receptor. Recently, Uberti and co-workers (2005) have reported that heterodimerization of α_{1D} -adrenergic receptors with β_2 -adrenergic receptors promotes membrane surface expression of α_{1D} -adrenergic receptors as well as their ability to mobilize intracellular calcium and that heterodimerization with β_2 -adrenergic receptors also confers the ability of the α_{1D} -adrenergic receptor to become internalized with the β_2 -adrenergic receptor.⁴⁸⁴

Heterodimerization may also affect G protein coupling and GPCR signaling. For example, heterodimerization of the ORL-1 receptor and mu-opiate receptors when expressed in HEK293 cells results in formation of a heterodimer that selectively cross-desensitizes the mu-opiate receptor leading to impairment of its signaling and may account for ORL-1 receptor-mediated antioxioid effects in the brain.⁴⁸⁵ In addition, formation of cannabinoid CB₁ and dopamine D₂ receptor heterodimers has been reported to result in a shift from CB₁-mediated inhibition of adenylyl cyclase to stimulation of adenylyl cyclase and MAPK cascades.⁴⁸⁶ The question as to whether receptor ligands induce or inhibit GPCR heterodimerization is currently still debated and there are examples of both effects.^{448–450} Overall, the functional and pharmacological consequences of GPCR heterodimerization appear to be diverse and can be highly influenced by what cells are used for expression. Additional studies of GPCR heterodimers in endogenous cells and tissues should help to further elucidate the pharmacological and functional consequences of GPCR heterodimerization.

The relevance of GPCR heterodimerization to GPCR drug discovery remains to be further established. Despite the accumulating *in vitro* data supporting physiological heterodimerization, supporting *in vivo* information from animals is lacking. Furthermore, the role of GPCR heterodimers in human diseases needs to be further established. Limited clinical evidence for a role of GPCR heterodimerization in human disease comes from a study in which hypertension in pre-eclampsia has been found to be associated with an increase in heterodimerization of angiotensin AT₁ and bradykinin B₂ receptors.⁴⁸⁷ The greatest impact of GPCR heterodimerization for drug discovery will be targeting therapeutically relevant constitutive GPCR heterodimers that exhibit novel pharmacology compared to receptor monomers. A recent report indicates that the opiate analgesic agonist 6'GNTI has the unique property of selectively activating only opioid receptor heterodimers (κ/δ) and not monomers.⁴⁸⁸ The therapeutic relevance of heterodimerization of a large number of GPCR pairs in native tissues still needs to be fully elucidated. What complicates this evaluation is that many therapeutically interesting cells or tissues express up to 40–50 different GPCRs making the potential number GPCR monomer combinations enormous.⁴⁸⁹ It will also be interesting to determine which existing orphan GPCRs do not have their own personal endogenous ligand; these might work by endowing novel pharmacological and functional properties on other known GPCRs through heterodimerization.⁴⁹⁰ A combinatorial expression approach, although laborious, may help to establish this possibility. GPCR heterodimerization has also led to the evaluation of novel bivalent ligands that interact with binding pockets of both monomers but their therapeutic utility remains to be established.

2.20.3.7 G Protein-Coupled Receptor Desensitization

Determination of the molecular events and players associated with GPCR desensitization, internalization, recycling, and degradation has been the focus of several laboratories. A major facilitator of these studies has been the marriage of the use of GFP-tagged GPCRs or beta-arrestin proteins, BRET or FRET technologies, and confocal microscopy.^{491,492} GPCR function is generally terminated by three mechanisms: desensitization (defined as a loss of agonist response), endocytosis or internalization, and downregulation or a loss of receptor number due to degradation. A widely accepted canonical model of GPCR desensitization involves the following steps: (1) agonist binding promotes a conformational change in the receptor leading to phosphorylation of serine and threonine residues located within IC2 and IC3 loops and the C-terminal tail by PKA, PKC, or one of a collection of seven G protein-coupled receptor kinases called GRKs; (2) GPCR phosphorylation leads to recruitment of beta-arrestin from the cytosol to the plasma membrane leading to inhibition of receptor–G protein coupling and facilitating targeting of the phosphorylated GPCR to clathrin-coated pits; (3) GPCR is removed from the plasma membrane surface via a dynamin-mediated endocytosis; (4) agonist dissociates from the GPCR within endosomes; and (5) internalized GPCR is either chaperoned back to the plasma membrane subsequent to beta-arrestin dissociation or is degraded by lysosomes⁴⁹³ (Figure 10). Important GPCR domains associated with desensitization and endocytosis include IC2 and IC3 loops and the C-terminal tail, all of which are also important for G protein coupling.^{494–499} Specific C-terminal amino acid motifs present in some GPCRs are important for determining whether the receptor is recycled to the plasma membrane or is degraded⁵⁰⁰ and are also critical for beta-arrestin-independent internalization.⁵⁰¹

Ligand-dependent GPCR internalization and endocytosis occurs primarily by two different mechanisms. The most widely employed mechanism involves GPCR internalization into clathrin-coated pits.⁵⁰² Clathrin-coated pit formation requires recruitment of adapter protein complexes and accessory proteins to the membrane, assembly of clathrin coats, induction of membrane curvature, and fission of the mature endosomal bud.^{503–505} Beta-arrestin-associated delivery of GPCRs to clathrin-coated pits appears to be mediated by its direct interaction with the adapter protein.⁵⁰⁶ An alternative but controversial method of internalization utilized by chemokine, sphingosine-1-phosphate, endothelin, and cannabinoid receptors involves interaction of receptors with lipid rafts enriched in cholesterol, sphingolipids, and

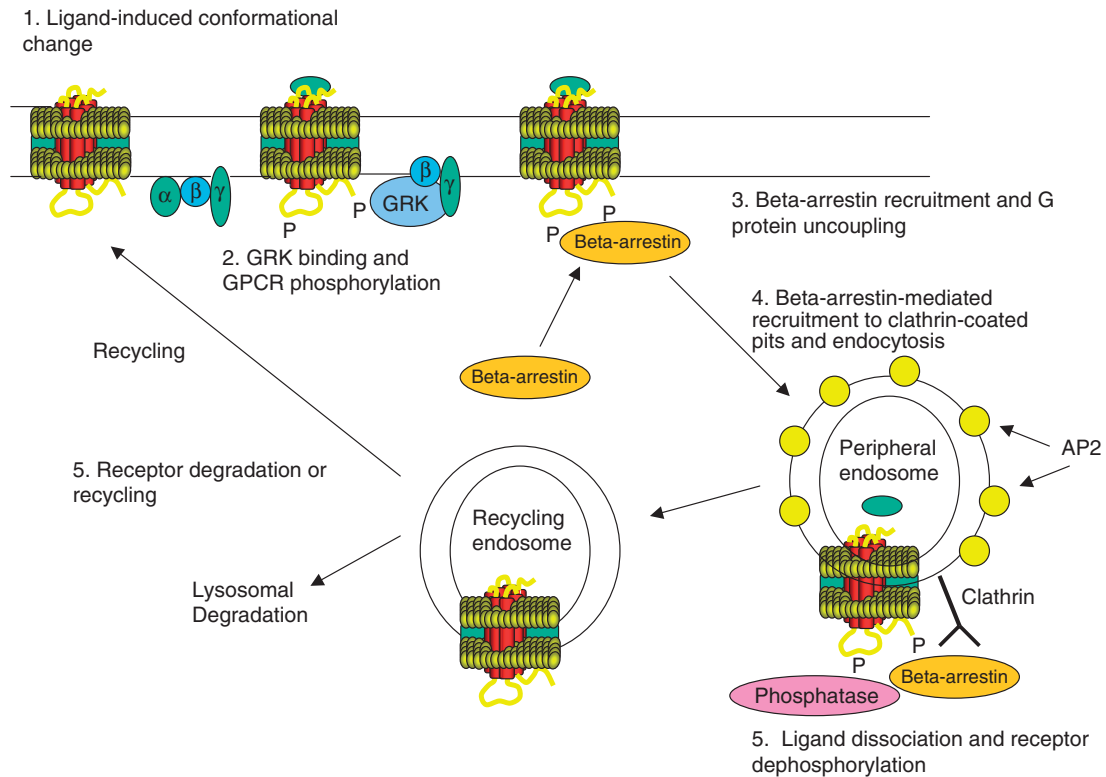

Figure 10 GPCR desensitization, internalization, degradation, and recycling.

caveolin, a protein associated with caveolae.^{507–510} For some GPCRs, a C-terminal Np_xxY motif appears to be essential for internalization.^{511–513}

In most cases, the efficacy of an agonist to promote G protein activation and signaling correlates with its ability to desensitize and internalize the receptor. However, there are some exceptions to this general rule that also lend support to the multistate model of agonist activation and multiple active GPCR conformations. First, several GPCRs including metabotropic glutamate receptor mGluR5, galanin GAL2, and α_{1A} -adrenergic receptors have been reported to undergo beta-arrestin-dependent constitutive internalization in the absence of agonist.^{514–517} Furthermore, internalization and desensitization of some GPCRs has been shown to be independent of receptor phosphorylation^{518–520} or beta-arrestin interaction.^{521–526} Beta-arrestin-independent internalization of certain GPCRs appears to rely on serine residues on the C-terminal tail.⁵²⁷ Angiotensin AT₂ receptors with mutations of their DRY sequence leading to reduced coupling to G protein have been reported to internalize normally in the presence of AngII indicating that G protein-independent internalization can occur.⁵²⁸ In addition, certain β_2 -adrenergic ligands that do not activate G proteins are able to recruit beta-arrestin to the plasma membrane.³⁴⁷ Similarly, truncated forms of apelin activate the apelin receptor and subsequent signaling but only the full-length version of the peptide is capable of efficiently inducing receptor internalization.⁵²⁹ Furthermore, the hypotensive effects of apelin have been reported to correlate with their propensity to promote receptor internalization. Comparison of various peptide and nonpeptide somatostatin receptor agonists ability to promote inhibition of adenylyl cyclase and receptor endocytosis has indicated that peptides promote similar potencies for both events, but nonpeptide agonists are more potent in inhibiting adenylyl cyclase than promoting receptor internalization.⁵³⁰ Thus, for some GPCRs, the process of desensitization and internalization deviates from the canonical model that generally applies to many GPCRs.

Beta-arrestins are ubiquitously expressed in cells and the recruitment of this protein to the plasma membrane can be visualized using confocal microscopy and GFP-tagged beta-arrestins. There are two forms of nonvisual beta-arrestins (beta-arrestin2 and beta-arrestin3) that mediate GPCR responses and endocytosis. The x-ray crystal structure of bovine arrestin2 in its resting state has been published and indicates that the protein has N- and C-terminal domains flanked by a polar core.^{531,532} As previously stated, beta-arrestins are major players in the process of receptor desensitization and internalization as well as activation of MAPK cascades. The interaction of beta-arrestin with

phosphorylated GPCRs results in inhibition of receptor and G protein coupling as well as the initiation of recruitment of the receptor into clathrin-coated pits.^{533,534} There are a number of adapter proteins that facilitate the endocytosis of the receptor–beta-arrestin complex with clathrin and adapter protein-2 plays a paramount role.⁵³⁵ In some cases, c-src interaction with beta-arrestin is also important for clathrin-coated pit-mediated receptor endocytosis.⁵³⁶ Important GPCR contact sites involved in beta-arrestin recruitment include IC2 and IC3 loops as well as the C-terminal tail.⁵³⁷ Based on differences in the stability and trafficking of receptor–beta-arrestin complexes, there are two primary classes of receptors: one in which this interaction is transient resulting in beta-arrestin dissociation and rapid recycling of GPCR back to the membrane (class A, e.g., β_2 -adrenergic receptor); and another (class B, e.g., vasopressin V_2 receptor) in which the receptor and beta-arrestin complex are stable and receptors either recycle more slowly or are degraded in lysosomes. Introduction of serine and threonine residues in the C-terminal tail from class B receptors into class A receptors results in prolonged retention of the receptor and reduces the rate of recycling.⁵³⁸ In some cases, disruption of receptor and beta-arrestin interactions does not alter receptor desensitization, endocytosis, and G protein-dependent signaling.⁵³⁹ For certain GPCRs, beta-arrestin-mediated receptor endocytosis requires homodimerization,⁵⁴⁰ and several reports suggest that GPCR heterodimerization can influence receptor internalization.^{541,542} Dissociation of beta-arrestin from GPCRs such as the bradykinin B_2 receptor during endocytosis has been reported to be necessary for receptor cycling back to the plasma membrane.⁵⁴³ Whether this is a general requirement for GPCR recycling remains to be determined.

GRKs have been widely studied and there are a total of seven different isoforms of this kinase. The main GRKs associated with phosphorylation and desensitization of GPCRs are GRK2, GRK3, GRK4, GRK5, and GRK6. Some GRKs appear to shuttle between the cytoplasm and the plasma membrane while others such as GRK5 appear to associate exclusively with the plasma membrane. GRKs contain three important functional domains, an RGS homology domain, a protein kinase domain, and a PH domain that mediates interaction with $\beta\gamma$ -complex.^{544,545} GRK-mediated phosphorylation is initiated when, upon receptor activation, a conformational change in the receptor causes exposure of IC3 loop and C-terminal tail phosphorylation sites become exposed, which facilitates GPCR and GRK interaction.^{546–550} For example, agonist occupation of the α_{2A} -adrenergic receptor leads to phosphorylation of four sites on the IC3 loop, and peptide-blocking studies indicate that GRK2 interacts with basic residues in both IC2 and IC3 loops.⁵⁵⁰ There is considerable evidence that PKA and PKC also initiate and mediate GPCR internalization. GRK2 and GRK3 have been shown to interact with $G\alpha_q$ via its RGS homology domain and it appears that GRKs in addition to beta-arrestin act to prevent receptor and G protein coupling. This may explain how GPCRs may uncouple from G protein activation via phosphorylation-independent mechanisms.⁵⁵¹ The interaction of the human oxytocin receptor with GRK2 and beta-arrestin has been measured in real time in living cells using BRET, indicating that receptor and GRK interaction takes place temporally prior to beta-arrestin-mediated desensitization.⁵⁵² Furthermore, FRET studies have indicated that the kinetics of β_2 -adrenergic receptor and beta-arrestin interaction are limited by the kinetics of GRK-mediated phosphorylation of the receptor and that repeated agonist stimulation results in the accumulation of phosphorylated receptor that can interact rapidly with beta-arrestin upon reactivation.⁵⁵³

Subsequent to receptor endocytosis, the events associated with receptor degradation or recycling to the plasma membrane are not well understood. Endocytic sorting of several different internalized GPCRs has been shown to be dependent upon a signal residing on the GPCR C-terminal tail.⁵⁵⁴ Different C-terminal GPCR sorting motifs include PDZ ligands, tyrosine-based motifs, and lysine residues that can become ubiquitinated.⁵⁵⁵ A recent report also suggests that palmitoylation of the LH receptor may regulate recycling of the receptor back to the plasma membrane.⁵⁵⁶ Furthermore, Mialet-Perez and co-workers (2004) report that N-terminal glycosylation of the β_2 -adrenergic receptor is important for promoting lysosomal degradation of the receptor.⁵⁵⁷ Conjugation of GPCRs such as the β_2 -adrenergic receptor with ubiquitin appears also to play a role in sorting internalized receptors to lysosomes for degradation,⁵⁵⁸ but not all GPCRs require this modification for lysosomal degradation.⁵⁵⁹

2.20.3.8 Allosteric Modulation of G Protein-Coupled Receptors

Historically, the majority of GPCR drug discovery has been focused on drugs that bind to the same site as the endogenous ligand, commonly referred to as the 'orthosteric site'. As such, most of the drugs on the market are orthosteric agonists, neutral antagonists, or inverse agonists. With the recent shift in GPCR screens from competitive radioligand binding assays to functional screens, an increasing number of new compounds has been discovered from screening small molecule libraries that do not interact with orthosteric sites but rather interact with distinct allosteric sites. Allosteric modulators have now been discovered for a variety of different GPCRs including adenosine, adrenergic, chemokine, dopamine, endothelin, glutamate, muscarinic, neurokinin, purinergic, and serotonin receptors^{560–563} (Table 10).

Table 10 Examples of allosteric modulators of GPCRs

<i>Receptor</i>	<i>Modulator</i>	<i>Actions</i>
α_{2A} -adrenergic	SCH-202676	Negative modulator, reduces the density of orthosteric agonist and antagonist binding sites
Adenosine A ₁	LUF5484	Positive modulator, enhances orthosteric agonist binding
Adenosine A ₁	SCH-202676	Negative modulator, reduces orthosteric ligand binding and accelerates dissociation
Adenosine A ₁	PD81723	Positive modulator, increases binding and function of orthosteric agonists and inhibits binding of antagonists and inverse agonists
Adenosine A _{2A}	Amiloride	Negative modulator, accelerates orthosteric agonist dissociation kinetics
Adenosine A _{2A}	SCH-202676	Negative modulator, reduces orthosteric ligand binding and accelerates dissociation
Adenosine A ₃	DU124183	Positive modulator, increases orthosteric agonist efficacy
Adenosine A ₃	SCH-202676	Negative modulator, inhibits orthosteric ligand binding and increases dissociation kinetics
Adenosine A ₃	VUF5455	Positive modulator, decreases orthosteric agonist dissociation kinetics
β_2 -adrenergic	Zn(II)	Positive modulator, increases orthosteric ligand affinity
Ca ²⁺ sensing GPCR	Calcindol	Positive modulator, increases calcium signaling (IP accumulation)
Ca ²⁺ sensing GPCR	Calhex 231	Negative modulator, decreases calcium-induced signaling (IP accumulation)
Ca ²⁺ sensing GPCR	Cinacalcet (AMG073)	Positive modulator, increases orthosteric agonist signaling (IP accumulation)
Ca ²⁺ sensing GPCR	NPS R-568	Positive modulator
Ca ²⁺ sensing GPCR	NPS 2143	Negative modulator, decreases calcium-mediated signaling (calcium)
CXCR1/2	Repertaxin	Negative modulator, prevents orthosteric ligand signaling
CRF ₁	NBI35965	Negative modulator, inhibits orthosteric agonist binding
CRF ₁	DMP696; DMP904	Negative modulator, blocks CRF signaling and decreases CRF binding
Endothelin ET _A	Aspirin, sodium salicylate	Negative modulator, decreases endothelin signaling and accelerates ET-1 dissociation kinetics
GABA _B	CGP7930	Positive modulator, enhances orthosteric agonist functional potency
GABA _B	GS39783	Positive modulator, increases functional potency and efficacy of GABA (GTP-S binding), increases agonist affinity, promotes G protein coupling
mGluR1	EM-TBPC	Negative modulator, decreases orthosteric ligand efficacy (calcium)
mGluR1	BAY36-7620	Negative modulator, decreases efficacy of glutamate
mGluR1	R214127	Negative modulator, decreases glutamate signaling
mGluR2	LY487379	Positive modulator, enhances potency and efficacy of glutamate
mGluR4	PHCC	Positive modulator, enhances glutamate potency and efficacy
mGluR5	CDPPB	Positive modulator, increases efficacy and potency of glutamate
mGluR5	CPPHA	Positive modulator, increases efficacy and potency of glutamate
mGluR5	DFB	Positive modulator, increases glutamate potency (calcium assay)

continued

Table 10 Continued

<i>Receptor</i>	<i>Modulator</i>	<i>Actions</i>
mGluR5	DMeOB	Negative modulator, decreases orthosteric ligand potency (calcium assay)
mGluR5	MPEP	Negative modulator, inhibits orthosteric ligand binding
Serotonin 5HT _{1B/D}	Moduline (Leu-Ser-Ala-Leu)	Negative modulator, decreases orthosteric agonist binding sites, reduces function (GTP-S binding)
Serotonin 5HT _{2C}	PNU-69176E	Positive modulator, increases serotonin binding sites (no effect on antagonist sites) and increases G protein coupling (GTP-S binding assay)
Serotonin 5HT ₇	Oleamide	Positive modulator, increases 5HT binding signaling (cAMP)
Muscarinic M ₁	AF-DX 384	Positive modulator, increases orthosteric ligand binding
Muscarinic M ₁	Anandamide	Negative modulator, reduces orthosteric ligand antagonist binding sites
Muscarinic M ₁	Brucine	Negative modulator, decreases ACh binding, enhanced binding of other agonists
Muscarinic M ₁	N-desmethylozapine	Allosteric partial agonist, no requirement for orthosteric ligand
Muscarinic M ₁	Mamba toxin MT-7	Negative modulator, slows orthosteric antagonist and accelerates orthosteric agonist dissociation kinetics
Muscarinic M ₁	SCH-202676	Negative, inhibits orthosteric antagonist binding
Muscarinic M ₁	Tacrine	Negative modulator, decreases orthosteric agonist binding
Muscarinic M ₁	W84	Negative modulator, decreases orthosteric agonist binding
Muscarinic M ₁	Xanomeline	Negative modulator, inhibits orthosteric antagonist binding
Muscarinic M ₂	Allcuronim	
Muscarinic M ₂	Heptane-1,7-bis (dimethyl-3'-phthalimidopropyl)-ammonium bromide	Negative modulator, decreased orthosteric antagonist binding
Muscarinic M ₂	(-)-Eburamonine	Negative modulator, decreases acetylcholine binding but increases binding of other agonists
Muscarinic M ₂	Gallamine	Negative modulator, decreases orthosteric antagonist affinity
Muscarinic M ₂	W84	Negative modulator, decreases orthosteric antagonist binding
Muscarinic M ₃	Brucine	Negative modulator, decreases ACh binding, enhanced binding of other agonists
Muscarinic M ₃	Gallamine	Negative modulator, decreases orthosteric antagonist affinity
Muscarinic M ₃	PG987	Negative modulator, accelerates orthosteric antagonist dissociation kinetics
Muscarinic M ₃	WIN 62577	Positive modulator, increases acetylcholine and antagonist affinity
Muscarinic M ₄	(-)-Eburamonine	Negative modulator, decreases orthosteric agonist
Muscarinic M ₄	Thiochrome	Positive modulator, increases orthosteric ligand affinity

The majority of these examples are taken from ^{560–568}.

The simplest and most common type of allosteric modulation occurs when the binding of an allosteric modulator results in changes in the affinity (positively or negatively) of the orthosteric ligand for its binding site. For example, synthetic small molecule allosteric modulators of the cannabinoid CB₁ have been discovered that increase affinity of the orthosteric ligand by reducing its dissociation kinetics.⁵⁶⁴ Another type of allosteric modulator is one that modifies GPCR signaling properties in addition to, or instead of, affecting the affinity of the orthosteric ligand. This type of allosteric modulator can act to alter the efficacy of the orthosteric ligand or activate the receptor in the absence of the orthosteric ligand.^{560–563} A third type of GPCR allosteric modulator is one that acts to either increase or decrease the

number of orthosteric sites. For example, SCH-202676 is a compound that acts to decrease the number of orthosteric ligand binding sites of α_{2A} -receptors as well as other GPCRs.⁵⁶⁵ In contrast, PNU-69176E, a positive allosteric modulator of the 5HT_{2C} receptor, acts to increase the number of 5HT_{2C} agonist binding sites and also promotes constitutive activation of the receptor.⁵⁶⁶ Allosteric modulators have been discovered for most families of GPCRs. Interestingly, a relatively large number have been discovered for class C GPCRs, presumably because they possess a very long N-terminal tail that is linked by a spacer region to TM domains. For example, a family of small molecule allosteric modulators acting at mGluR5 receptors has been discovered, which act as either positive or negative allosteric modulators.^{567,568} Both radioligand binding studies (kinetic and equilibrium) as well as functional assays have been used to characterize the mechanisms of GPCR allosteric modulation. These studies can be complicated and several good reviews describe the theoretical basis of GPCR allosteric modulation well and how it is experimentally evaluated.^{560–563}

Allosteric modulators may possess certain properties that may make them superior drugs compared to those interacting with orthosteric sites. One of the largest benefits would be that allosteric modulators may confer better receptor selectivity within a related family of GPCRs (e.g., muscarinic M₁, M₂, M₃, M₄, M₅) than orthosteric ligands resulting in better efficacy and fewer side effects.^{560–563} Orthosteric binding pockets are highly conserved for receptors activated by the same endogenous ligand and allosteric modulators would interact with potentially less conserved regions of GPCRs. Second, allosteric modulators displaying limited cooperativity with the orthosteric ligand may be safer than orthosteric ligands because they have the potential for a ‘ceiling effect’ resulting in less potential for patient overdosing.^{560–563} This property can be capitalized upon to provide an increased duration of action by increasing drug doses without producing unwanted side effects. Third, a majority of allosteric modulators discovered to date act directly to influence orthosteric binding and/or signaling properties.^{560–563} Thus, they will only possess pharmacological activity in the presence of the endogenous ligand and thus are likely to mimic more closely the pharmacological effects of the orthosteric agonist. Another potential benefit of screening for allosteric modulators is that there is potentially a greater probability of discovering allosteric modulators acting at GPCRs activated by large peptides, for many of which it has been difficult to discover small molecules acting at orthosteric sites. We anticipate that the pharmaceutical industry will focus more on discovery of selective allosteric modulators in known and orphan GPCR drug discovery programs.

2.20.4 Screening G Protein-Coupled Receptors in Functional Assays

To have an appropriate appreciation of GPCRs as drug discovery targets, the following sections describe commonly used functional assays used to screen small molecule libraries to identify novel pharmacophores as well as to direct GPCR structure–activity relationship (SAR) programs. There are a number of choices for GPCR functional assays and several companies sell assay kits that can be utilized for rapid screen development and validation. However, each of these different assays can differ in price, assay throughput, and reliability, and different assay platforms can sometimes give significantly different experimental results. In the first part of this section, the impact of several new paradigms concerning GPCR function and regulation on assay development and screening outcomes are discussed. Several functional assay platforms are then described that are widely applied to GPCR drug discovery. An understanding of these assays will benefit medicinal chemists and facilitate a better understanding of functional screening data generated for a GPCR drug discovery program.

2.20.4.1 Impacts of Multiplicity of G Protein-Coupled Receptor Signaling, Agonist Trafficking, and G Protein-Coupled Receptor Homodimerization and Heterodimerization on G Protein-Coupled Receptor Drug Discovery and Screen Development

GPCR functional assays have greatly facilitated GPCR drug discovery. Traditionally, drug discovery was initiated by screening small molecule libraries for competition for binding of a trace radioligand to the GPCR of interest. Although binding assays are still employed in drug discovery, they have largely been replaced by functional assays designed to detect agonists, antagonists, inverse agonists, and allosteric modulators up front. GPCR functional assays are generally membrane- or cell-based assays. Membrane-based assays are operationally useful as large preparations of cells can be scaled up intermittently and large membrane preparations can be made and stored at -80°C before use. Cell-based assays are currently more popular but require continual cell culture activity to supply adequate quantities of cells. Recombinant expressed GPCRs are commonly used for development of functional screens and generally allow the expression of high levels of GPCRs to increase assay signal and provide a homogeneous population of cells expressing the GPCR of interest.

However, there are several important considerations regarding the use of recombinant expressed GPCRs for functional screen development. First, the levels of receptor expression in recombinant expression systems should be measured using N-terminally epitope-tagged GPCRs and commercially available antibodies. This is important for several reasons. First, a threshold of receptor expression is required for generation of a suitable assay signal that is dependent upon expression of sufficient levels of receptor. Second, G protein coupling can vary as the density of receptor is increased and nonphysiological coupling to multiple G proteins can occur. Third, the level of constitutive activity may be important for optimizing the assay signal. For example, constitutive activity may need to be minimized for development of agonist-biased screens and may need to be maximized for optimizing inverse agonist screens. In addition, as the levels of constitutive activity increase, the ability to detect partial agonists is reduced and these will actually appear as full agonists.

Another important consideration for developing GPCR functional assays is that the GPCR-mediated signal event chosen for measurement should be as proximal to receptor activation as possible. This is because ligand efficacies and potencies measured at the level of G proteins or effector proteins can often be quite different. Although GPCR functional assays involving downstream signaling events have the potential for favorable signal amplification, they can also become mechanistically very complicated and assay 'hits' can be difficult to interpret. Furthermore, the more signal transduction steps captured subsequent to receptor activation, the higher the probability of obtaining false-positive hits in which the activity of the test compound is not due to an effect at the level of the receptor but at a locus downstream from the receptor. However, this type of assay hit can simply be re-evaluated in the same assay using cells that do not express the receptor of interest to determine if the hit is receptor mediated.

The choice of cells used for developing functional GPCR screens is also an important consideration. Commonly used mammalian cells for recombinant expression of GPCRs for assay development (e.g., CHO, HEK293, COS7, HeLa) may not have the relevant signaling molecules required or their concentrations may be different from those in endogenous cells or tissues, both of which can influence receptor pharmacology. In addition, functionally and pharmacologically important GIPs may not be present in recombinant expression systems. The possibility of therapeutically relevant heterodimerization partners being absent in these systems is generally not considered. Furthermore, the posttranslational machinery required for functionally significant posttranslational modification of the receptor (e.g., glycosylation, palmitoylation) may not be present. If therapeutically relevant cells endogenously expressing the GPCR target of interest exist, their use for screen development should be considered. Many investigators suggest that expression of physiological levels of GPCRs in a therapeutically relevant cell line or use of cells that express the GPCR of interest endogenously is most desirable for a relevant cell-based screen.

Development of functional screens for GPCRs has demonstrated that coupling to multiple G proteins and activating multiple signaling pathways can be a challenge for a drug discovery program. If the disease-relevant GPCR signaling pathway is known, then it should be captured in the relevant signaling-biased screen. Furthermore, activation of certain signaling pathways associated with a particular GPCR target may also be associated with undesired side effects and these may need to be captured in secondary assay evaluations of primary assay hits. If therapeutically relevant signaling pathways for a given GPCR target are unknown and multiple signaling pathways are activated in therapeutically relevant cells or tissues, then it may be important to develop and utilize multiple screens in GPCR drug discovery programs. This can be an essential consideration for agonist screens for receptors in which agonist trafficking is a possibility. G protein activation by a given GPCR target can be established experimentally by immunoprecipitation of G proteins in a relevant cell line after labeling activated G protein with [³⁵S]GTPγS or using photoactive guanine nucleotide analogs followed by Western blotting.^{569–577} Definition of therapeutically important signaling pathways for GPCR targets and the use of appropriate signaling-biased screens will hopefully lead to the future development of drugs that possess desired downstream effects while minimizing unwanted side effects. Furthermore, if different agonists promote different rates and extent of receptor internalization and desensitization, one may be therapeutically more valuable because it will be less apt to promote tachyphylaxis. Signal-biased screens can in theory be designed by coexpression of a desired G protein with constitutively active GPCRs to selectively enrich the system for the desired pathway for assay development and screening.

2.20.4.2 Functional Assays for G Protein-Coupled Receptors

Before describing different screening assays, there are several general considerations that should be made in designing functional screens. Cost-effective high-throughput functional screening platforms capable of efficiently evaluating large compound libraries (and SAR compounds) are critical for development of a successful GPCR drug discovery program.⁵⁷⁸ An ideal GPCR screen should be simple and robust (high signal to noise), should not involve separations,

should contain a minimum of assay additions or steps, and should be amenable to an automation-compatible microtiter plate format (96-, 384-, or 1536-well). Radiometric assays are less desirable currently because of safety issues and significant expenses associated with radioactive waste disposal.

2.20.4.3 GTP γ S Binding Assays

GPCR-mediated guanine nucleotide exchange is a proximal step in GPCR signaling (see [Figure 3](#)). This event can be captured in an assay in which binding of the nonhydrolyzable GTP analog, radiolabeled GTP γ S ($[^{35}\text{S}]\text{GTP}\gamma\text{S}$), is measured by using crude plasma membranes prepared from cells expressing the GPCR of interest.^{579–581} Typically, membranes are incubated for 30–60 min with test compound, $[^{35}\text{S}]\text{GTP}\gamma\text{S}$, and an assay buffer containing NaCl, MgCl_2 , and GDP. Then free and bound $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ are separated by a filtration step followed by scintillation counting. Unfortunately, this assay has been generally limited to use for $\text{G}_{i/o}$ -coupled GPCRs because $\text{G}_{i/o}$ is the most abundant G protein in most cells and has faster kinetics of GDP-GTP exchange rate compared to other G proteins. In addition, filtration significantly limits assay throughput and generally these assays are performed in a 96-well microtiter format. Owing to the slow turnover of $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ for G_s - and G_q -coupled receptors, assay backgrounds are generally high but can be reduced by immunoprecipitation of select G proteins using G-protein α -subunit selective antibodies. The SPA (scintillation proximity assay, GE Healthcare) technology has been used to develop homogeneous $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding assays to increase assay throughput. With a combination of these approaches, $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding assays have been developed for G_q - and G_s -coupled GPCRs.^{582–585} In addition, $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding assays have been widely used to demonstrate constitutive activity of several different $\text{G}_{i/o}$ -coupled GPCRs (see [Table 6](#)). Commonly, a comparison of K_d values for agonists derived from radioligand binding evaluations are lower than EC_{50} values obtained in $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding assays because of the requirement for NaCl and GDP in the latter assay, both of which will reduce agonist potency. Another consideration for these assays is that high NaCl concentrations are required for optimization of agonist assay windows and low concentrations of NaCl are required for maximizing windows for inverse agonist screens.

Perkin Elmer has recently released a nonradioactive time-resolved fluorescence (TRF) GTP binding assay that measures GPCR-mediated binding of europium-labeled GTP rather than $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ to G proteins. TRF is a sensitive platform because it allows excitation and a delay in emission reading to allow deletion of short-lived background fluorescence contributed by test compounds and membranes because the europium chelate has a slow rate of fluorescence emission decay. Optimization and validation of this assay involves evaluation of similar variables as required for $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding assays ([Table 11](#)). The throughput of this assay is still limited because it requires both filtration and washing steps, which at a cost, can be automated. This new assay has been validated using membranes expressing recombinant α_{2A} -adrenergic,⁵⁸⁶ motilin, serotonin 5HT $5a$, neurotensin, muscarinic M1 receptors,⁶⁶⁸ and NPFF2⁵⁸⁷ receptors. Agonist EC_{50} values obtained with the TRF and $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ binding assays are reported to be comparable. [Figure 11](#) lists the assay steps associated with the different guanine nucleotide binding assays used in GPCR drug discovery.

2.20.4.4 cAMP Assays

Several commercially available cAMP kits can be used to conveniently develop whole cell-based cAMP or membrane-based adenylyl cyclase assays for screening either G_s - or G_i -coupled GPCRs.^{588,589} Cell-based assays are easy to develop

Table 11 Important variables for optimizing nonhomogeneous membrane $[^{35}\text{S}]\text{GTP}\gamma\text{S}$ or Eu-GTP binding assays

<i>Variable</i>	<i>Test range</i>	<i>Reason</i>
Membrane	1–20 $\mu\text{g}/\text{well}$	Optimize S/N, reduce background, limited capacity due to filtration unless antibody capture is used
$[^{35}\text{S}]\text{GTPs}$ or Eu-GTP	0.1–1 nM for $[^{35}\text{S}]\text{GTP}\gamma\text{S}$; 0.1–10 nM for Eu-GTP	Optimize S/N, reduce background
MgCl_2	0.1 μM –10 mM	Important variable because different G proteins have different MgCl_2 requirements
NaCl	0–300 mM	Has an influence on assay background, agonist screens optimal at high NaCl, inverse agonist screens optimal with low NaCl
GDP	0.1 M–100 μM	Has an influence on assay background by enhancing inactive G protein state

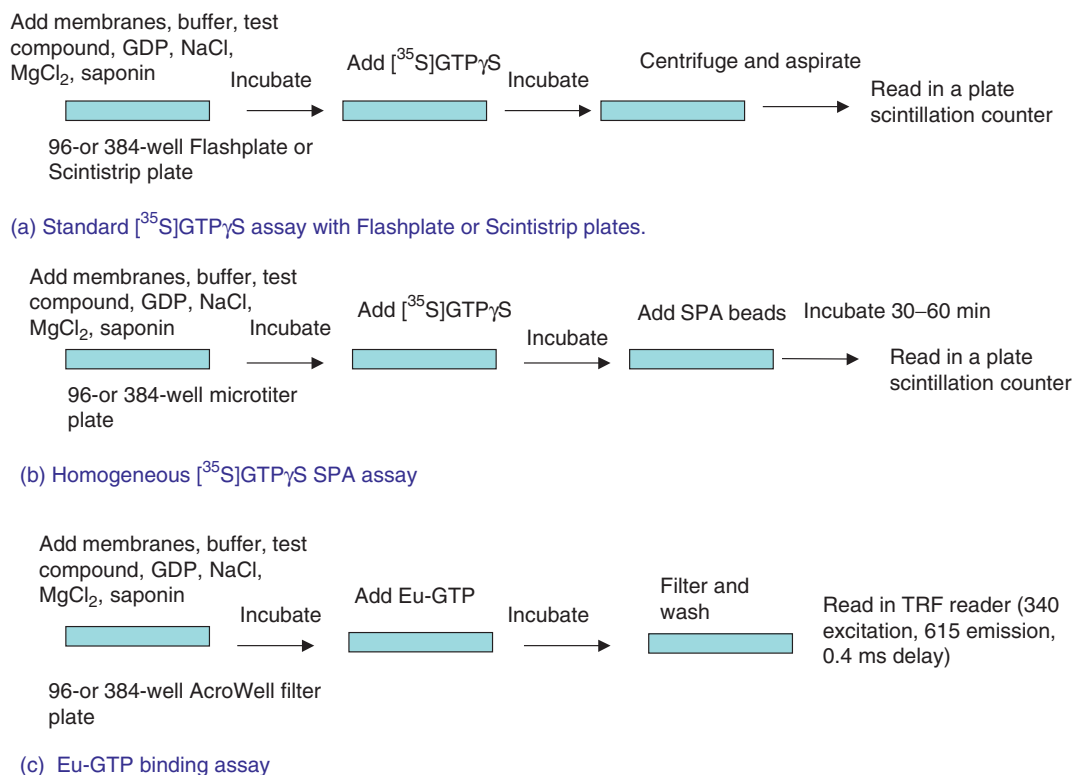

Figure 11 Steps associated with guanine nucleotide binding assays. Eu-GTP, europium-labeled GTP.

and optimize because the only assay variables are number of cells, the incubation conditions, and the concentration of phosphodiesterase inhibitor (usually IBMX or rolipram) to include. Membrane-based adenylyl cyclase assays are also widely used in screening GPCRs, but require addition and optimization of additional assay reagents such as GTP, MgCl₂, ATP, a regenerating system for ATP, and phosphodiesterase inhibitors. Screening small molecule libraries against G_s-coupled receptors in cAMP assays is generally straightforward. However, screening G_{i/o}-coupled receptors in cAMP assays is more complicated because activation of adenylyl cyclase with the direct adenylyl cyclase activator forskolin is required to optimize the window of GPCR-mediated inhibition. In addition, use of cells in which the GPCR is transiently transfected rather than stably expressed can result in a low signal to noise. This is because adenylyl cyclase in all cells added to the assay will be stimulated by forskolin, but not all cells will express receptor unless high transfection efficiency is obtained. For this reason, cells stably expressing the GPCR of interest are more commonly used to develop cAMP assays for G_{i/o}-coupled receptors. Another important consideration for cAMP assays is that levels generated in the assay need to be in the linear portion of standard curves used to extrapolate cAMP levels.

2.20.4.4.1 Radiometric cAMP assays

The first commercially available homogeneous assay kits used for measurement of cAMP consist of radiometric ELISA-based assays and include the GE Healthcare SPA⁵⁹⁰ and the Perkin Elmer FlashPlate⁵⁹¹ assays. The SPA assay is based on the competition of endogenously produced cAMP and trace radiolabeled [¹²⁵I]cAMP for binding to a scintillant-containing bead conjugated to a cAMP antibody. Only [¹²⁵I]cAMP in close proximity with the SPA bead can activate scintillant contained within the beads leading to an assay signal. Conversely, the FlashPlate assay utilizes microtiter plates coated with scintillant to which a cAMP antibody is attached. Endogenously generated cAMP competes for binding of trace labeled [¹²⁵I]cAMP to the immobilized cAMP antibody. Both of these assay platforms are sensitive, can be configured into 96- and 384-well formats, are compatible for use in both membrane- and cell-based assays, and cAMP increases result in a decreased assay signal. However, safety considerations and the high expense associated with radioactive waste disposal have led to their replacement with nonradioactive assay alternatives.

2.20.4.4.2 Fluorescence-based cAMP assays

2.20.4.4.2.1 Time-resolved fluorescence resonance energy transfer cAMP assay

A high-throughput cAMP assay kit based on time-resolved fluorescence energy transfer technology is available from Cisbio (HTRF). The basis of this assay consists of a reduction in assay signal as endogenous cAMP acts to inhibit the interaction of cAMP labeled with the acceptor allophycocyanin (XL665) and an anti-cAMP antibody labeled with europium cryptate resulting in a decrease in energy transfer.^{574,575} Laser light is used to excite at Eu-cryptate 337 nm and energy transfer occurs to the allophycocyanin acceptor and emission is read at 665 nm. This assay platform is amenable to assay miniaturization (96-, 384, and 1536-well formats available), has low test-compound endpoint detection interference, and is sensitive. Furthermore, both whole cells as well as membranes can be used in this assay. This assay has been validated for both G_s-coupled (β_2 -adrenergic, histamine H₂, melanocortin MC₄, CGRP, dopamine D₁) and G_i-coupled histamine H₃ receptors.⁶⁶⁹ With high assay sensitivity, this assay is suitable for use in cells expressing lower densities of GPCR.

2.20.4.4.2.2 Fluorescence polarization cAMP assay

Fluorescence polarization (FP)-based cAMP measurement kits are now commercially available from Perkin Elmer,^{592,593} Molecular Devices,⁵⁹⁴ and Amersham (GE Healthcare). In this assay, as endogenous cAMP increases, it competes for trace fluorescent-labeled cAMP binding to a cAMP antibody. As endogenous levels of cAMP increase, the polarization of light becomes less because it competes for binding of the larger fluorescent-labeled cAMP to the cAMP antibody.⁵⁹⁵ This assay platform has been successfully miniaturized to a 1536-well format and it has been used for both membrane and whole cell assays. The FP cAMP assay has been reported to have a lower signal-to-noise ratio and sensitivity than other platforms, and a potential for endpoint detection interference. The release of new red-shifted fluorescent dye-labeled cAMP analogs has been reported to reduce compound interference and increase assay sensitivity.⁵⁸⁹ This assay platform is more compatible for assays in which high densities of recombinant GPCRs are expressed.

2.20.4.4.3 Chemiluminescent cAMP assays

2.20.4.4.3.1 AlphaScreen cAMP assay

AlphaScreen (amplified luminescent proximity homogeneous assay) is another homogeneous high-throughput cAMP measurement assay platform developed by Packard Bioscience/Perkin Elmer that has been widely used in the pharmaceutical industry for functional screening of GPCRs.^{578,588,589} The assay is based on competition of endogenous cAMP with biotin-conjugated cAMP for binding to high-affinity streptavidin-coated donor beads and a decrease in assay signal due to reduced donor bead and acceptor bead proximity. Following excitation of donor beads by laser at 680 nm, singlet oxygen is generated, which in turn reacts with a chemiluminescent compound contained in the acceptor bead if it is in close proximity to the donor bead. Activation of the acceptor beads then leads to generation of a chemiluminescent signal at 320 nm. The AlphaScreen assay has been successfully configured into 96-, 384-, and 1536-well formats, is sensitive, and is cost effective. It is most widely used for cell-based cAMP measurement. Potential issues with this assay format include acceptor bead light and temperature sensitivity and the potential for color quenching by test compounds.

2.20.4.4.3.2 HitHunter cAMP assay

DiscoverX offers a homogeneous high-throughput cAMP assay kit called HitHunter that is based on a patented enzyme complementation technology.^{596–598} This technology is based upon an engineered beta-galactosidase enzyme consisting of two subunits which, when joined, display enzymatic activity. Specifically, the assay utilizes a small complementation peptide conjugated with cAMP that is recognized by a cAMP antibody and a complementation peptide recognized by an acceptor fragment of the engineered beta-galactosidase enzyme. As endogenously produced cAMP increases, it binds to the cAMP antibody and displaces the small complementation peptide cAMP conjugate resulting in an increase in assay signal with increased endogenous cAMP levels. This assay can be performed using either a chemiluminescent or a fluorescent beta-galactosidase substrate. This assay kit can be purchased and performed in a 96-, 384-, or 1536-well format⁵⁹⁹ and kits can be purchased for either adherent or nonadherent cells.

2.20.4.5 Inositol Phosphate Accumulation-IP₃ Assays

Cell-based radiometric inositol phosphate accumulation assays have been widely used to develop reliable functional screens for G_q-coupled GPCRs (see [Figures 5 and 12](#)). The basis of this assay is to initially incorporate [³H]inositol

into membrane-associated inositol phospholipids and measure GPCR-mediated PLC β activation by the measurement of generated [^3H]inositol phosphates (IP $_1$, IP $_2$, and IP $_3$). Typical assays first consist of overnight loading of cells with [^3H]inositol, which becomes incorporated into membrane-associated phospholipids to form phosphatidyl inositol species (PI, PIP, PIP $_2$). The next day, cells are washed and then test compounds are added followed by cell lysis and an ion exchange step to resolve [^3H]inositol and [^3H]inositol phosphates. This step can be accomplished in a 96-well microtiter plate containing ion exchange resin and elutions are performed under vacuum pressure.^{600,601} However, the ion exchange step still significantly limits assay throughput and disposal costs associated with radioactivity add considerable expense to the assay. The SPA technology has also been applied to develop higher throughput homogeneous assays for inositol phosphate that avoid the separation step.⁶⁰² One approach utilizes metal ions immobilized to the SPA bead to bind [^3H]inositol phosphates via their phosphate groups and has been validated using the neurokinin NK $_1$ receptor.⁶⁰³ Another approach utilizes yttrium silicate immobilized to SPA beads that bind inositol phosphates but not inositol.⁶⁰⁴ Although IP accumulation assays are not widely used for primary screening of G $_q$ -coupled GPCRs and have generated excellent pharmacological data, they are commonly used as secondary assays to confirm results obtained using higher throughput assays such as intracellular calcium assays.

Assay kits designed to measure IP $_3$ instead of total inositol phosphate species have been commercially available for some time and are based on the use of a crude IP $_3$ receptor preparation and competition of endogenous IP $_3$ with trace-labeled IP $_3$ (typically radiolabeled). These assays are difficult to automate because IP $_3$ generated becomes rapidly dephosphorylated to form IP $_2$ and IP $_1$ and assay incubations need to be very short (15–30s). A nonradioactive assay method using the AlphaScreen platform has been developed in which donor and acceptor beads are brought into close proximity with biotinylated IP $_3$ and signal declines as IP $_3$ is formed.⁵⁹⁶ Echelon has also developed an AlphaScreen-compatible assay using a different IP binding protein that binds both IP $_2$ and IP $_4$.⁵⁹⁶ In addition, DiscoverX has also developed and released a nonradioactive IP $_3$ assay that is based on fluorescence polarization.⁵⁹⁶ This assay is based on the competition of in assay endogenous IP $_3$ and trace fluorescence labeled IP $_3$ molecule binding to an IP $_3$ antibody. Compound interference or quenching is minimized by use of a series of novel ‘red’ tracers in the assay. Validation of this assay for high-throughput screening of G $_q$ -coupled GPCRs has not appeared in the literature to date.

Cisbio has recently released a new homogeneous time-resolved fluorescence assay for measuring inositol phosphate accumulation, called the IP-One assay.⁶⁶⁹ The basis of this assay platform is competition of endogenous inositol phosphate for trace acceptor-labeled inositol phosphate binding to europium-conjugated inositol phosphate antibody (Figure 12). This assay has been configured into a 384-well microtiter plate format and has been validated with muscarinic M1, vasopressin V1A, oxytocin, histamine H $_2$, purinergic P2Y $_1$, chemokine CCR5, metabotropic mGluR1, and metabotropic mGluR5 receptors.⁶⁶⁹ Since intracellular calcium assays are not suitable for screening for inverse

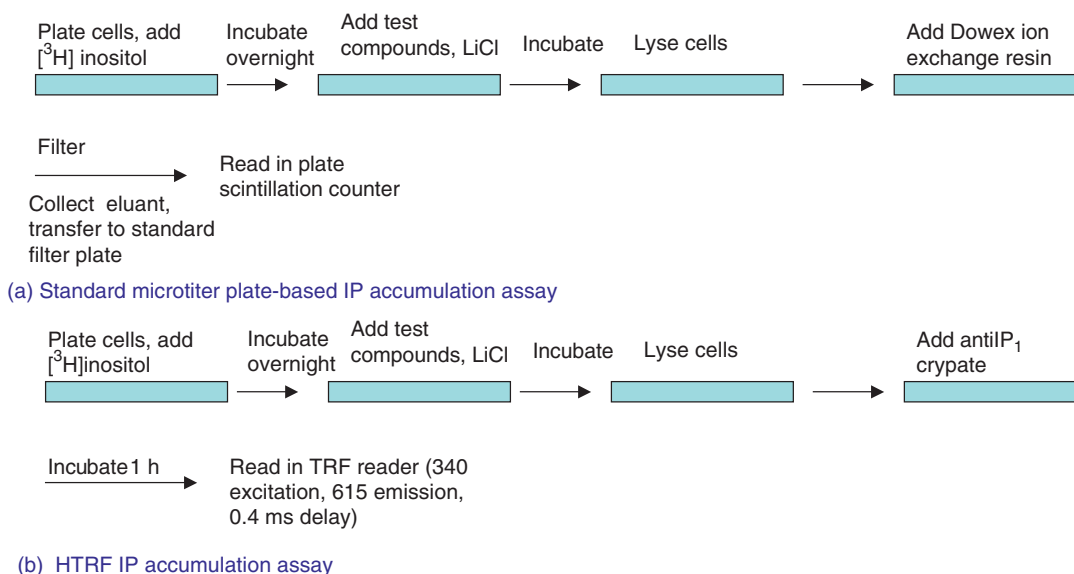

Figure 12 Steps associated with radiometric and TRF IP accumulation assays.

agonists, the IP-One assay will be a very useful alternative to traditional assays that require separation of total [^3H] inositol phosphates from unincorporated [^3H]inositol. There have been no reports in the literature concerning the use of the IP-One assay for screening G_q -coupled GPCR targets and industrial validation of this platform remains to be published.

2.20.4.6 Intracellular Calcium Assays

A popular homogeneous high-throughput functional assay applicable for screening G_q -coupled GPCRs is the measurement of receptor-mediated increases in intracellular calcium ($[\text{Ca}^{2+}]_i$) (see [Figure 5](#)) using calcium-sensitive fluorescent dyes such as Fura-2, Fluo-3, Fluo-4, and Calcium Green-1. GPCR-mediated increases in $[\text{Ca}^{2+}]_i$ are typically transient and return to basal levels in less than 1 min. Thus, typical fluorescence plate readers that read one row of wells at a time could not be used to capture this signal for a whole assay plate. Fortunately, the availability of automated real-time CCD-based fluorescence plate readers such as fluorometric imaging plate reader (FLIPR) (Molecular Devices), Cell Lux (Perkin Elmer), or the FDSS6000 (Hamamatsu), allowing real-time fluorescence reading of all wells simultaneously on a subsecond time scale, has dramatically increased the throughput of this assay platform. These instruments also contain automated liquid handling capacity allowing simultaneous addition of reagents into all microtiter plate wells. For typical assays, cells expressing the GPCR of interest (adherent or nonadherent) are initially loaded with a fluorescent dye that becomes trapped intracellularly because of cellular esterase activity and unincorporated dye is removed by washing the cells. Cells are then loaded into special microtiter plates, test compounds are added by automated liquid handling, and changes in $[\text{Ca}^{2+}]_i$ are measured over a period of a few minutes. Measurement of $[\text{Ca}^{2+}]_i$ is now the method of choice for the functional screening of G_q -coupled receptors and is a sensitive, cost-effective format.^{605–607} One consideration when using this assay platform is that increases in $[\text{Ca}^{2+}]_i$ are not only a function of IP_3 -mediated release from the endoplasmic reticulum but are a reflection of several homeostatic mechanisms that act to control $[\text{Ca}^{2+}]_i$, including calcium influx through calcium-permeable ion channels such as the L-type calcium channels, and by cellular processes involved in restoring calcium levels to resting levels such as cellular Ca^{2+} ATPases and $\text{Na}^+/\text{Ca}^{2+}$ antiporter activities. It is not uncommon to observe right-shifts in dose–response curves obtained in $[\text{Ca}^{2+}]_i$ assays compared to IP accumulation assays, which is likely to be due to these other factors regulating $[\text{Ca}^{2+}]_i$. One potential disadvantage of fluorescence-based assays is that test compounds can either autofluoresce or quench the assay signal resulting in false-negative or positive hits.

Two recent advances have further increased the capacity of $[\text{Ca}^{2+}]_i$ assays for high-throughput screening. First, a new fluorescent dye kit called Calcium 3 has been developed by Molecular Devices that allows fluorescent dye loading of cells without the requirement for removal of unincorporated dye by repeated cell washing.⁶⁰⁸ Elimination of the cell washing step not only saves time but also reduces several potential problems associated with cell washing such as cell lifting and lowered cell competency, and incomplete dye washing leading to assay variability. A comparison of agonist potency data for serotonin 5HT_{2C} and mGluR5 glutamate receptors obtained using a conventional fluorescent calcium dye and the Calcium 3 assay kit suggests that both methods give comparable results.⁶⁰⁸ However, the contents of this kit are proprietary making it difficult to determine any potential pharmacological effects of the assay ingredients.

The second advance is that the FLIPR instrument can now be configured using 96-well, 384-well, and 1536-well pipetting heads, thus enabling considerable assay miniaturization.^{609,610} Issues with the 1536-well format include concerns regarding assay mixing and evaporation of reagents. Although the measurement of changes in intracellular calcium has been used for high-throughput agonist and antagonist screening, this method cannot be used to screen for inverse agonists because increases in basal intracellular calcium are not observed for constitutively active G_q -coupled GPCRs. One possible explanation for this observation is that the endoplasmic reticulum IP_3 receptor becomes desensitized due to increased basal IP_3 levels.

A related high-throughput platform for measuring GPCR-mediated changes in intracellular calcium utilizes recombinant expressed jellyfish photoprotein aequorin instead of calcium-sensitive dyes.^{611–617} This assay platform is based on the use of aequorin, a calcium-sensitive reporter protein that generates a luminescent signal when a coelenterazine derivative is added. Euroscreen (Brussels) offers cell lines that express receptors, G proteins, and apoaequorin (AequoScreen) that can be utilized for efficient development of high-throughput $[\text{Ca}^{2+}]_i$ assays for GPCRs.⁶¹⁸ The Hamamatsu Photonics FDSS600 plate reader is commonly used to measure the bioluminescent signal.

A variant of the intracellular calcium assay has been developed recently for screening G_s - and G_i -coupled GPCRs. This assay is based on increases in live cell intracellular cAMP, which act to open a recombinant expressed (HEK293 cells) modified (lacks the calmodulin regulatory site involved in channel closing) olfactory cyclic nucleotide-gated (CNG) calcium channel leading to increases in $[\text{Ca}^{2+}]_i$, which can be measured using FLIPR.⁶¹⁹ This assay platform

has been validated in a 96-well format for G_s-coupled GPCRs including β_2 -adrenergic, adenosine A_{2B}, dopamine D₁, and trace amine TA1 receptors and G_i-coupled ORL-1 and kappa-opiate receptors and yields results similar to those obtained in cAMP platforms. BD Biosciences is offering this technology to the screening community.

2.20.4.7 Reporter Gene Assays

Cell-based reporter gene assays are a widely used high-throughput functional homogeneous assay platform for screening GPCRs and are based on the ability of GPCR-mediated second messenger molecules such as cAMP or $[Ca^{2+}]_i$ to activate or inhibit a responsive element placed upstream of a minimal promoter, which, in turn, regulates the expression of a selected reporter protein.⁵⁸⁹ For G_s- and G_i-coupled receptors, the cAMP responsive element (CRE) is commonly used to develop reporter assays. For G_q-coupled receptors, activating protein-1 (AP-1) or nuclear factor of activated cells (NFAT) promoters are employed. Performing these assays is very simple and consists of adding assay reagents, incubating for 8–24 h, lysing cells, and reading plates on an endpoint detector. Specific protocols for these assays may differ in the number of response elements and the reporter gene chosen.⁵⁸⁹ GFP and beta-galactosidase reporters have been widely used but have the disadvantage of being less sensitive than other reporters due to high background noise.⁵⁸⁹ The luciferase reporter, which has a much shorter half-life, allows greater assay sensitivity. However, automation of luciferase assays is difficult unless newer commercially available long-lived luciferase substrates are employed (glow versus flash substrates).⁵⁸⁹ Primary advantages of this assay platform include successful miniaturization to a 1536-well format, which is primarily due to signal amplification and full robotic automation, and it is relatively inexpensive to perform. Potential disadvantages of reporter gene assays include long incubation periods (8–24 h) and the requirement for a cell lysis step. The lengthy incubation times required can promote compound degradation and cytotoxicity can lead to false-positive or negative hits.

The beta-lactamase reporter gene assay has become very popular in recent years and has been successfully configured into a 3456-well microtiter plate format. Use of cell-permeable fluorescent substrates has also allowed omission of cell lysis prior to endpoint reading. Furthermore, the beta-lactamase reporter provides high sensitivity due to the absence of endogenous beta-lactamase activity in mammalian cells.^{620–625} Another live-cell reporter assay has been described in which GFP was used as a reporter gene under transcriptional control of the CREs, which also does not require cell lysis.⁶²⁶

2.20.4.8 Promiscuous and Chimeric G Proteins and Design of Universal Screens for G Protein-Coupled Receptors

Several attempts have been made to design a ‘universal’ GPCR screen that utilizes a common assay endpoint. This would allow better comparison of the activity of screening compounds across a set of GPCRs. In addition, this would reduce costs of running different assays utilizing different assay reagents and endpoint readers. One approach to accomplish this goal has been to utilize promiscuous G proteins such as G α_{14} , G α_{15} , or G α_{16} to force signaling of G_s- and G_i-coupled GPCRs to changes in IP accumulation and, more importantly, to changes in $[Ca^{2+}]_i$.^{627–631} This has been successfully accomplished for several GPCRs, but these promiscuous G proteins do not couple to all GPCRs. Additional engineering of promiscuous G proteins has improved the coupling efficiency of these G proteins. For example, coupling of both G_s- and G_{i/o}-coupled receptors to G $\alpha_{15/16}$ can be further improved by production of a G protein α -subunit chimera (G α_{16z25}) of G α_{16} is combined with the C-terminal tail of G α_z .^{632–634} Stable cell lines expressing these modified promiscuous G proteins can be generated and coexpression of GPCR and G α_{16z25} does not interfere with the receptor’s ability to activate endogenous signaling pathways. The increases in GPCR coupling observed with these new chimeric G proteins is presumably due to greater association of the G α_{16} backbone with the plasma membrane. Similarly, chimeric G proteins in which the last five amino acids of G α_{16} are replaced with various lengths of G α_s have also been reported to increase the promiscuity of G α_{16} toward G_s-coupled receptors.⁶³⁵

Several studies have indicated that the C-terminus of G proteins is an important molecular determinant conferring selectivity for GPCR coupling to G proteins. Indeed, Coward *et al.* reported that replacement of the last five amino acids of G α_q with the three C-terminal amino acid residues of G α_i could switch coupling of G_i-coupled receptors to stimulation of phospholipase C and increases in intracellular calcium.⁶³⁶ The nomenclature of this chimera is G $\alpha_{q/i3}$, which denotes that the backbone of G α_q is combined with the three C-terminal amino acids of G α_i . Based on these results, it was suggested that a C-terminal turn, centered around a glycine residue, plays an important part in specifying receptor interactions with G proteins. Several G protein chimeras have been produced by a number of groups and have been extensively used to evaluate GPCR–G protein coupling specificity. Typically, maximally effective chimeras are ones in which between four and five C-terminal amino acids are replaced to alter G protein specificity. Molecular

Devices offers expression vectors or cells stably expressing $G_{q/11}$, $G_{q/12}$, $G_{q/13}$, and $G_{q/14}$ chimeras for easy assay development. Although a significant number of G_i - and G_s -coupled receptors have been configured to couple to these chimeric G proteins, this approach does not work for all GPCRs. Chimeric G proteins have been widely used for development of drug discovery screens for GPCRs^{637–641} as well as endogenous ligand identification for orphan GPCRs.^{607,617,631,639} One caution concerning the use of chimeric G proteins in GPCR functional assays is that the efficiency of coupling of GPCRs for chimeric G proteins may be less than that for the G protein(s) to which it couples physiologically.

At Arena Pharmaceuticals, we utilize the Melanophore platform for screening known and orphan GPCR targets. This assay platform is suitable for G_s -, G_i -, and G_q -coupled GPCRs, and is based on the ability of transiently expressed GPCRs to alter the distribution of melanin-containing melanosomes in *Xenopus* melanophores. Specifically, transfected melanophores will either aggregate (absorb less light) or disperse (absorb more light) the melanosomes depending on whether the GPCR is $G_{i/o}$ - or $G_{s/q/11}$ -coupled, respectively. This assay allows a simple readout based on light absorption, is robust and cheap (5 cents/well), does not require cell lysis before absorbance reading, has been fully automated, and is adapted to 384- and 1536-microtiter plate formats as well as open lawns.^{642–647} One advantage of this platform is that expression of native as well as mutated GPCRs in melanophores consistently results in constitutive activity that can often be titrated by altering the level of GPCR expression.

2.20.4.9 G Protein-Coupled Receptor Biosensors

There are several recent reports concerning the construction and use of GPCR ‘biosensors’ to study GPCR function and regulation in real time and in live cells. These new tools have helped to further progress our understanding of GPCR activation, protein interactions, and signal transduction in a ‘natural’ environment. GPCR biosensors have initially been developed by academic groups and may find an application for development of new functional screening platforms for GPCR drug discovery.

BRET (bioluminescence resonance energy transfer) has been used for several years to study GPCR protein interactions such as homodimerization, heterodimerization, and beta-arrestin interactions. BRET studies of beta-arrestin-mediated GPCR internalization typically utilize recombinant expressed GPCRs in which green fluorescent protein (GFP) is fused to the C-terminus and recombinant expressed beta-arrestin2 is fused with Renilla luciferase in living cells.⁶⁴⁸ For example, this approach was used to demonstrate the important functional role of vasopressin V_2 receptor C-terminal palmitoylation on beta-arrestin2 membrane recruitment, receptor-mediated ERK1/2 activation, and receptor endocytosis. Recently, this technology has been used to develop high-throughput homogeneous GPCR screens but early applications were limited by low signal-to-noise ratios. However, Vrecl and co-workers (2004) have reported using BRET and GFP-tagged beta-arrestin2 mutants that are either phosphorylation-independent in their interaction with GPCRs or lack sites important for interaction with clathrin-coated pits.^{649,650} By introduction of these mutations, a reasonable signal-to-noise ratio has been obtained allowing the assay to be configured into a microtiter-plate format. Similarly, Hamdan and colleagues (2005) have reported development of a BRET-based screening assay using a stable cell line expressing both beta-arrestin-Renilla luciferase and GPCR with a C-terminal fused acceptor EYFP (VENUS).⁶⁵¹ BRET has also been used to evaluate the kinetics of the interaction of the oxytocin receptor with the G protein kinase GRK2 and this assay could possibly be configured as a potential screen depending upon the level of the assay signal compared to background.⁵⁵² BRET has also been utilized recently to study the interaction of GPCRs and G proteins in living cells and this assay could be potentially used as a functional screen for GPCRs.⁶⁵² Validation of this assay consisted of screening a small molecule compound library for novel antagonists of the chemokine receptor CCR5.

FRET has also been used to measure GPCR and beta-arrestin interactions^{653–655} or GPCR and G protein interaction in real time with live cells.⁶⁵⁶ These assays typically utilize two variants of GFP, cyan (CFP) and yellow (YFP) fluorescent proteins. For example, live cell studies of G protein subunit dissociation typically utilize CFP-tagged $G\alpha$ -subunit and YFP-tagged $G\beta$ -subunits. Using a different approach, Hoffman and co-workers have introduced both CFP and a small membrane-permeable fluorescein derivative called FIAH, tagged into a short tetracysteine sequence of the human adenosine A_{2A} receptor, and report that they can monitor receptor activation in live cells by FRET.⁶⁵⁷ Although FRET biosensors have not been used for screening GPCRs, they may become more popular if the assay signal-to-noise ratio is sufficient and the assay can be automated.

2.20.4.10 G Protein-Coupled Receptors and High-Content Imaging

High-content imaging is a new assay technology that has continued to mature in recent years and is almost ripe for application in high-throughput screening for GPCR targets. High-content GPCR assays are defined as assays in which pieces of information about the behavior of GPCRs can be gathered in parallel because they offer a method to

multiplex several assay endpoints into one assay (usually up to five colors).^{658–660} High-content screening platforms generally combine confocal microscopy and charge coupled device (CCD) camera imaging systems to analyze multiple cells in a microtiter plate. High-content assays designed specifically for GPCRs generally rely on fluorescence measurement of protein translocation within cells (e.g., cytosol to the plasma membrane or cytosol to the nucleus) or receptor internalization and trafficking.^{661–664} One of the first GPCR functional assays based on high content imaging was developed by Norak and is called the TransfluoR technology (now owned by Molecular Devices). This assay platform is based on the redistribution of fluorescent-labeled beta-arrestin (GFP-tagged) from the cytosol to the plasma membrane and subsequent internalization of the GPCR–beta-arrestin–GFP complex into clathrin-coated pits to measure receptor agonist activation or inactivation.^{664,665} This platform has been used to screen small molecule libraries to discover vasopressin V2 agonists.⁶⁶² To date, the TransfluoR technology has been validated for over 85 different GPCRs (G_s -, $G_{i/o}$ -, and $G_{q/11}$ -coupled) and is currently available by license from Molecular Devices (Sunnyvale, CA). Several high-content imaging instruments including the IN Cell Analyzer (GE Healthcare), ArrayScan (Cellomics), Explorer (Accumen), Opera (Evotec), and MetaXpress (Molecular Devices) have been shown to be compatible for use with the TransfluoR technology. Alternatively, BioImage has developed a GPCR translocation assay utilizing GPCRs in which EGFP (enhanced green fluorescent protein) is fused to the C-terminus of the receptor of interest, such as the chemokine CXCR4 receptor, and a granularity algorithm is used to quantify receptor internalization using the IN Cell Analyzer.⁶⁶¹ This platform may have some advantage over the TransfluoR platform in that beta-arrestin-independent internalization of GPCRs can be measured using the latter methodology. Important assay variables for development of high-content GPCR internalization assays include plate type used, cell plating conditions, number of cells used, kinetics of GPCR internalization, and dimethyl sulfoxide (DMSO) sensitivity.

Assay throughput continues to be an issue that limits the use of high-content imaging for larger primary screening campaigns. However, throughputs of around 100 plates per day are now claimed by some instrument companies, allowing consideration as a primary screening tool for carefully selected targets such as orphan GPCRs with poorly defined G protein signaling properties and 7-TM proteins more distantly related to traditional GPCRs. For example, Borchert and co-workers recently reported the development of a high-content assay for activators of the Wnt-Frizzled pathway based on translocation of beta-Catenin.⁶⁶⁵ This assay has been used to screen a library of 51 000 compounds and produced a reasonable 0.6% hit rate. High-content screening will undoubtedly be used to a greater extent for screening GPCRs in the future.

2.20.5 Target Validation of G Protein-Coupled Receptors

The pharmaceutical industry is now focusing on mining the human genome sequence to identify new GPCR drug discovery targets. Analyses of the human genome suggest that there are currently over 100 human orphan GPCRs (oGPCRs) for which the endogenous ligand remains to be identified. Thus, oGPCRs represent a vast opportunity for development of new therapeutics. The current challenge facing the pharmaceutical industry concerns rapid implementation of new strategies to enable efficient target validation of oGPCRs. An integrated approach in which well-established strategies (such as reverse pharmacology as well as gene knockdown) are combined in parallel with newer strategies (such as chemical genomic and microarray analysis) should help to achieve this goal. We have recently published a review on target validation of oGPCRs that describes such an integrated approach.⁴

Biographies

William J Thomsen is currently Director of Molecular Pharmacology at Arena Pharmaceuticals, Inc., and has also served as Research Fellow (2003–04), Associate Director of Assay Development and Screening (2001–03), and Manager of Assay Development and Screening (1998–2001). Prior to joining Arena Pharmaceuticals, Dr Thomsen was Director of Research at CellPath, Inc. (1997–98) and Director of Research at Lasure and Crawford, Inc. (1994–97), both in Seattle. From 1992 to 1994, Dr Thomsen served as a Senior Project Manager in Drug Discovery at Panlabs, Inc. in Seattle. Prior to entering industry, Dr Thomsen was a Postdoctoral Fellow in the Department of Pharmacology at the University of Washington between 1988 and 1991 (William Catterall's laboratory) and he received his PhD in Pharmacology from the University of Michigan (Rick Neubig's laboratory) in 1988. Dr Thomsen also received an MS degree in Biochemistry and a BSc in Chemistry from the University of South Dakota.

Dominic P Behan is a cofounder of Arena Pharmaceuticals, Inc. and has served as a director since April 2000, and as Senior Vice President and Chief Scientific Officer since June 2004. Dr Behan served as Vice President of Research from April 1997 to June 2004. From 1993 to January 1997, Dr Behan directed various research programs at Neurocrine Biosciences, Inc., a public biopharmaceutical company. From 1990 to 1993, Dr Behan was engaged in research at the Salk Institute. Dr Behan holds a BSc in Biochemistry from Leeds University, England and a PhD in Biochemistry from Reading University, England.

2.21.1 Introduction

Ion channels form a large superfamily of integral membrane proteins that are expressed almost ubiquitously in excitable and nonexcitable cells.¹ They take advantage of transmembrane potential and ionic concentration differences to regulate the passive and rapid exchange of ions across cell membranes. Consequently, ion channels control electrical and biochemical signaling, and regulate a multitude of diverse physiological processes, including modulation of neuronal excitability, muscle contraction, neurotransmitter and hormone release, cell proliferation, and cell volume. An ion channel is minimally defined as an integral membrane protein that provides a regulated ion-permeable route through the cell membrane. Most ion channels are in fact multisubunit protein complexes, and several key features are critical for their proper operation. To form a functional ion channel, at least one of the subunits must be anchored in the

Figure 1 (a) The structure of the $K_v1.2$ homotetramer, as viewed from the extracellular side of the membrane. The crystallographic coordinates of $K_v1.2$ were taken from the Protein Data Bank entry 2A79⁴⁹ and visualized with PyMol. Each of the four monomers, which are colored differently, contributes to the formation of the central pore. There is a striking degree of interdigitation between the monomers. (b) This view differs from (a) by a 90° rotation of the axis that goes through the pore. In this view, only the S5–S6 segments from each monomer are displayed for clarity. It shows again the high degree of interdigitation between the monomers, and illustrates in more detail the interactions that create the minimum functional unit. (The assistance of Carlos Faerman of Vertex Pharmaceuticals Inc. is gratefully acknowledged in generating Figure 1.)

cell membrane by two or more membrane-spanning segments (S1, S2, through S n), and must contain the necessary pore-forming elements. Typically, the subunits containing the pore-forming elements will be positioned in a circular arrangement with the pore located in the center (Figure 1). The pore must be capable of opening and closing in response to physiological stimuli, such as a change in the transmembrane potential or the binding and unbinding of extracellular (e.g., neurotransmitters) or intracellular (e.g., calcium) ligands (*see* 2.22 Ion Channels – Ligand Gated). Ion selectivity is a key attribute, and is provided by a theoretical filter that may form the narrowest part of the pore. The direction of ion flux across the cell membrane is governed by the electrochemical driving force on the permeant ion. Ion channels are often categorized by their physiological regulators of gating and by their permeant ionic species. Thus, there are the large families of voltage-gated sodium (Na^+), calcium (Ca^{2+}), and potassium (K^+) ion channels as well as the diverse families of ligand-gated anion and cation channels. Isoforms representing each of the voltage-gated ion channel families are often co-expressed in excitable cells, where they work in concert as initiators and effectors of electrical and biochemical signaling.

Most voltage-gated ion channel subunits are characterized by the presence of multiple positively charged amino acids in one of the transmembrane segments. This part of the ion channel is capable of moving in response to changes in the transmembrane potential of the cell, and effectively functions as its voltage sensor. Voltage-gated ion channels can exist in a variety of different states, which may either be conducting (open) or nonconducting (closed), and may switch between these different states by theoretical voltage-dependent gating processes. The properties of gating underlie the complex behavior of individual ion channel subtypes. Importantly, there are two major closed states, namely resting and inactivated, a crucial difference being that resting channels can open, whereas most inactivated channels do not have the ability to open until they have returned to a resting state. In quiescent excitable cells, the membrane potential normally sits at a relatively hyperpolarized level of -60 mV to -90 mV (cell type-dependent), and the majority of the ion channels will be in a resting state. Membrane depolarization increases the probability that resting channels will open or activate. The membrane potential at which a channel first opens is its threshold potential, and often this is a defining parameter. With maintained depolarization, open channels will eventually close or inactivate. Other key biophysical parameters that can be used to differentiate the members of an ion channel family are the duration of the open state, the rate and type of inactivation, and the rate at which inactivated channels recover to the resting state.

Voltage-gated ion channels are key regulators of cellular function, and are widely considered to be viable and attractive targets for therapeutic modulation in the treatment of human diseases, particularly those diseases that affect excitable cells. Several drugs that target voltage-gated ion channels are currently marketed for the treatment of a variety of cardiovascular and neurological diseases (Table 1). Together, these ion channel drugs have been estimated to

Table 1 Ion channel drugs used to treat cardiovascular and neurological diseases

<i>Primary mechanism of action</i>	<i>Drug name</i>	<i>Molecular structure</i>	<i>Primary indications</i>
Cardiovascular diseases			
L-type Ca^{2+} channel blockade	Nitrendipine		Hypertension
	Nimodipine		Subarachnoid hemorrhage
	Nicardipine		Hypertension and angina pectoris
	Diltiazem		Hypertension, angina pectoris and cardiac arrhythmia
	Verapamil		Hypertension, angina pectoris and cardiac arrhythmia
Mixed Na^{+} and L-type Ca^{2+} channel blockade	Amiodarone		Cardiac arrhythmia
Na^{+} channel blockade	Disopyramide		Cardiac arrhythmia
	Flecainide		Cardiac arrhythmia

N- and/or P-type Ca ²⁺ channel modulation(?)	Gabapentin		Epilepsy and pain

generate US \$6–15 billion in total annual sales. The majority of these marketed drugs were discovered and developed many years ago using traditional pharmacological approaches. However, it is widely believed that the ion channel family remains underexploited because all of these drugs target only a handful of distinct ion channel subtypes. Thus, the ion channel drug class is likely to grow in the future as a direct consequence of recent advances in our understanding of ion channel structure–function relationships, the role of ion channels in disease, and the development of new technologies, such as automated electrophysiology platforms. Together, these biological and technological advances are expected to have a major impact on the discovery of new chemical entities that modulate ion channels.

The large families of ion channels that selectively pass Na⁺, Ca²⁺, or K⁺ and which share the common property of being gated by changes in the transmembrane potential are the subjects of this chapter. This chapter will review our current understanding of the many genes that encode voltage-gated ion channel subunits, addressing important topics such as the physiological and pathological roles that are associated with these subunits in normal and diseased states, their prototypical pharmacology, and therapeutic opportunities of subtype-selective drugs.

2.21.2 Sodium Channels

2.21.2.1 Current Nomenclature

Voltage-gated Na⁺-permeable ion channels are members of the diverse ion channel superfamily that also comprises Ca²⁺- and K⁺-permeable channels.² Native voltage-gated Na⁺ channels are composed of a large pore-forming

Figure 2 Pore-forming (α) and auxiliary subunits of a voltage-gated Na^+ channel. The α subunit consists of four highly homologous domains (DI through DIV), each containing six transmembrane segments (S1 through S6). The pore loop between S5 and S6 determines ion selectivity, S5 and S6 line the pore, and positively charged amino acids in S4 confer voltage dependence on the protein. The β subunits have a single transmembrane segment, with an extracellular N-terminus and an intracellular C-terminus. The β_1 and β_3 subunits are noncovalently linked to the α subunit, whereas the β_2 and β_4 subunits are capable of forming a covalent disulfide linkage (not shown).

α subunit that is associated with one or two smaller auxiliary β subunits (Figure 2). It is the α subunit that provides the ion permeation pathway, although the β subunits may modulate its function, pharmacology, and membrane expression. Voltage-gated Na^+ channels in different cell types are functionally quite similar, yet, with good reason, various groups of researchers have used their own classification systems for categorizing them. As with all ion channels, the nomenclature of Na^+ channels has evolved in parallel with the development of new technologies that could be applied to their study. Typically, physiological, biophysical, pharmacological, and/or tissue distribution properties were measured, and distinct putative subtypes were often characterized according to differences in these properties. More recently, genomic approaches have led to the identification of the pore-forming α and auxiliary subunits of Na^+ channels as well as orphan Na^+ channel-like proteins, which have not been functionally expressed but that have been classified solely on the basis of sequence similarity to known subunits. By the end of the 1990s, the varied nomenclature coupled with the fact that most excitable cells express multiple subtypes of Na^+ channels had produced an apparently confusing state of affairs and so a new, International Union of Pharmacology (IUPHAR)-approved naming system was proposed.^{3,518} The new naming system takes advantage of knowledge gained from recent advances in the identification and sequencing of several genes that encode Na^+ channel subunits. Consequently, the current Na^+ channel nomenclature reflects an integrated numerical-based system that parallels those used for Ca^{2+} and K^+ channels.

For the family of Na^+ channel α subunits, the current terminology (Table 2) indicates the permeant ionic species (Na) along with the physiological regulator, voltage (subscripted V), to yield Na_V . Currently, there is only one subfamily of Na^+ channel α subunits, and this is denoted as Na_V1 . The Na_V1 subfamily contains nine subtypes (i.e., $\text{Na}_V1.1$ through $\text{Na}_V1.9$), each displaying varying levels of amino acid similarity. Na^+ channel α subunits are subject to extensive splice variation, and, where appropriate, these are indicated by a letter after the subtype number (e.g., $\text{Na}_V1.1a$). In the future, it is possible that additional Na^+ channel subtypes and/or subfamilies will be identified among those orphan Na^+ channel-like genes that make up the Na_X group. There is a parallel naming system for the genes that encode the various Na^+ channel α subunits, although the gene number is not always the same as the isoform number (see Table 2). Consistent with their common evolutionary origins, several Na^+ channel α subunit genes are proximally located on the same chromosomes. Most of the genes encoding tetrodotoxin-sensitive (TTX_S) Na^+ channel α subunits are found on human chromosome 2. The exceptions are the $\text{Na}_V1.6$ gene (*SCN8A*), which is found on chromosome 12 and the skeletal muscle $\text{Na}_V1.4$ gene (*SCN4A*), which is found on chromosome 17 in close proximity to the skeletal muscle Ca^{2+} channel γ_1 subunit (see Table 4). The TTX -insensitive (TTX_I) and TTX -resistant (TTX_R) Na^+ channel genes are found on chromosome 3.

For the Na^+ channel auxiliary β subunits, the current nomenclature distinguishes different subtypes by using a subscripted number (e.g., β_1 – see Table 2). Currently, four distinct Na^+ channel β subunit isoforms have been identified,⁴⁻⁹ with at least one isoform subject to splice variation.¹⁰ The Na^+ channel β subunits are not related to the auxiliary subunits (β or other) of Ca^{2+} and K^+ channels, but they are related to certain cell adhesion molecules. Similar to the Na^+ channel α subunit genes, there is a parallel naming system for the β subunit genes (see Table 2). The gene encoding the β_1 subunit is located on chromosome 19, whereas the three other β subunit genes are located on chromosome 11.

Table 2 Voltage-gated Na⁺ channel subunit classification

<i>Subunit type and name</i>	<i>Human gene symbol name</i>	<i>Human chromosome</i>	<i>General description</i>
Pore-forming α subunit

β_3	<i>SCN3B</i>	11q23	This subunit is noncovalently linked to the α subunit and is found mainly in central neurons and skeletal muscle
β_4	<i>SCN4B</i>	11q23	This subunit forms a covalent linkage with the α subunit and is found mainly in neurons

2.21.2.2 Molecular Biology

Each of the nine Na⁺ channel α subunit isoforms has a distinct pattern of tissue and subcellular distribution. In general, they are expressed highly in excitable cells that generate fast action potentials. Na⁺ channel α and β subunit expression patterns are developmentally regulated, and may also become altered in complex ways in pathological conditions. The changes in expression can be causative in diseases that are associated with genetic mutations in Na⁺ channel genes (*see Section 2.21.2.8*) or they can represent a component of the compensatory response of the cell to an ongoing pathological state.

The TTX_S subtypes, Nav1.1, Nav1.2, Nav1.3, and Nav1.6, are expressed predominantly in neurons of the central nervous system (CNS),^{11–13} whereas the Nav1.7, Nav1.8, and Nav1.9 subtypes are expressed primarily in neurons of the peripheral nervous system (PNS).^{14–17} At the subcellular level, neuronal Na⁺ channel subtypes may be distributed differentially on dendrites, soma, and/or axons, suggesting that each isoform serves distinct yet complementary functions in integrating input signals and controlling the output responses of the neuron.^{18,19} In addition, Na⁺ channel density varies significantly across the neuronal cell membrane, and, generally speaking, this reflects the localized membrane excitability. Na⁺ channel density is highest at specialized regions, such as the axon initial segment,²⁰ where action potential initiation occurs, and also at nodes of Ranvier in myelinated axons to support saltatory (jumping) conduction. Saltatory conduction is a rapid process that requires both Na⁺ and K⁺ channels to be concentrated at axonal nodes of Ranvier, which are breaks in the insulating myelin sheath provided by oligodendrocytes in the CNS or Schwann cells in the PNS. Neurological diseases that induce axonal demyelination, such as multiple sclerosis, will permit Na⁺ and K⁺ channel redistribution away from the nodes of Ranvier, leading ultimately to impairment or even complete blockade of

action potential conduction.²¹ In contrast, ectopic action potential generation and overexcitability of peripheral and central neurons in response to nerve injury involves up- and downregulation of certain Na⁺ channel α and β subunits as well as their redistribution at the subcellular level.^{22–25} The preferential targeting of individual isoforms to specific subdomains under normal and diseased conditions suggests that isoform-specific signaling may guide these processes. The protein trafficking and compartmentalization processes that govern the precise distribution of Na⁺ channels in neuronal cell membrane subdomains are far from being completely understood. Protein–protein interactions between Na⁺ channel α and β subunits and other molecules, either within the neuron itself or in supporting cells such as astrocytes and oligodendrocytes, are sure to be involved, and several mechanisms have been proposed recently.^{26–31}

The TTX_S subtype Nav1.4 is found primarily in innervated skeletal muscle cells,³² with its highest density being at the motor end-plate.³³ Interestingly, Na⁺ channel expression in mammalian skeletal muscle undergoes several well-documented phenotypic changes upon tissue denervation. The first change of note is a reorganization of Na⁺ channel expression away from the end-plate to a more uniform distribution pattern.³⁴ The other major changes are a transient downregulation of the Nav1.4 transcript coupled with a parallel upregulation of the Nav1.5 transcript (TTX_I subtype).³⁵ In addition to their differences in TTX sensitivity, these two Na⁺ channel subtypes have distinct biophysical properties.³⁶ Consequently, the changes in transcript levels can explain earlier electrophysiological studies on the contrasting biophysical properties and TTX sensitivity of Na⁺ currents in innervated and denervated skeletal muscle fibers.³⁷

Studies on Na⁺ channel expression in cardiac myocytes have revealed that Nav1.5³⁸ is the predominant subtype and that several TTX_S subtypes such as Nav1.1, Nav1.2, Nav1.3, and Nav1.6 are also present at lower levels.^{13,39} Subcellularly, Na⁺ channels are found in high density in the plasma and transverse tubule membranes of atria and ventricles. The Nav1.5 isoform is preferentially localized, along with the β_2 auxiliary subunit, in the plasma membrane and intercalated disks at the ends of adjacent ventricular myocytes.^{40,41} In contrast, the brain-type Na⁺ channel isoforms appear to be preferentially localized, along with the β_1 and β_3 auxiliary subunits, in the transverse tubule membrane of ventricular myocytes⁴¹ and in the sinoatrial (SA) node and atrial myocytes.⁴² The mechanisms underlying the expression and subcellular distribution patterns of Na⁺ channels in the heart have not been fully elucidated. Ubiquitin–protein ligases, such as Nedd4-2, which is expressed in heart, can downregulate the expression of Nav1.5.⁴³ Many additional factors that control Na⁺ channel trafficking in the heart have been reviewed recently.⁴⁴ Following myocardial infarction, tissue remodeling takes place in the heart. This is associated with ventricular hypertrophy and altered Na⁺ channel expression. In particular, upregulation of Nav1.1 appears to alter electrical activity in remodeled myocytes, perhaps leading to arrhythmogenicity.⁴⁵ In contrast, there appears to be a downregulation of Na⁺ channel expression in end-stage heart failure.⁴⁶

Regarding the general expression of the auxiliary subunits, the β_1 subunit exhibits a widespread distribution, and has been identified in the neurons of brain, spinal cord, and dorsal root ganglia (DRG) as well as skeletal muscle and cardiac myocytes.⁴⁷ In contrast, expression of the β_2 , β_3 , and β_4 subunits is restricted mainly to neurons of the CNS and PNS,^{6,8,9} although some evidence suggests that β_3 may also be found in skeletal muscle.⁴⁸

2.21.2.3 Protein Structure

Since the Na⁺ channel α subunit has not yet been crystallized, very little is known about its tertiary structure. However, given the similarity in primary and predicted secondary structures of voltage-gated Na⁺, Ca²⁺, and K⁺ channels, it is likely that the overall tertiary structure of the Na⁺ channel α subunit resembles that of the tetrameric K⁺ channel Kv1.2, which was crystallized recently in its open state (see [Figure 1](#)).^{49,50} Therefore, the mechanisms that are involved in activation and inactivation of the various voltage-gated ion channels are likely to be variations on a common functional theme, and the recent ground-breaking work toward understanding the structure of K⁺ channels can be developed to provide models for other subtypes of voltage-gated ion channels.

The Na⁺ channel α subunit is an integral membrane protein (approximately 2000 amino acid residues and 260 kDa) with intracellular N and C termini (see [Figure 2](#)). The α subunit is comprised of four highly homologous domains (DI through DIV) that are linked sequentially by intracellular loops, some of which contain multiple sites for phosphorylation by protein kinase A (PKA) and protein kinase C (PKC).⁵¹ Several portions of the α subunit contain key structural elements that are involved in determining its localization as well as its functional and pharmacological properties. The first and second intracellular loops are relatively long, whereas the third intracellular loop is short. The second intracellular loop contains a motif that directs axonal clustering of Na⁺ channels.⁵² The third intracellular loop is of particular importance because it contains a hydrophobic IFM motif. This motif is believed to represent the Na⁺ channel fast inactivation gate that binds within the inner mouth of the pore to block ion permeation.⁵³ Within each homologous domain, there are six transmembrane segments (S1 through S6) that are linked by short intracellular and extracellular loops. In addition, there are four short segments, or pore loops (P-loops), which are positioned between S5

and S6 of each domain. These short segments re-enter (but do not span) the membrane from its extracellular side, and line the outer entrance to the ion permeation pathway.⁵⁴ The S5 and S6 segments appear to line the inner entrance to the Na⁺ channel pore. The S4 segments are believed to represent the voltage sensor of the Na⁺ channel. According to some ion channel gating models, coordinated outward movement of the S4 segments in a helical screw-like motion within the plane of the membrane changes the position of the activation gate in S5 and S6, leading to Na⁺ channel opening. The S4 segments contain regularly spaced positively charged amino acid residues such as arginine or lysine at every third position. Mutagenesis experiments have confirmed that these amino acid residues determine the voltage-dependence of Na⁺ channel activation, and are essential for the channel to sense and then open in response to small changes in the local electric field within the cell membrane.^{55,56} The ion selectivity and permeation characteristics of the Na⁺ channel are determined by EEDD and DEKA motifs, with one amino acid residue in each motif being contributed by each of the four P-loops.^{57–59} The negatively charged amino acid residues that make up these motifs are believed to create two rings that are located adjacent to the outer and inner entrances of the pore, respectively.

The Na⁺ channel β subunits are smaller but heavily glycosylated proteins, containing around 200 amino acid residues (approximately 33–36 kDa). Each β subunit contains a large extracellular N-terminal domain, a single transmembrane α helical segment, and a short cytoplasmic C terminus (see [Figure 2](#)). The extracellular domains of the four known β subunits have multiple cysteine residues, some of which pair to form an immunoglobulin (Ig)-like fold, similar to that found in cell adhesion molecules. The β_1 and β_3 subunits are noncovalently linked to the α subunit. In contrast, the extracellular domains of the β_2 and β_4 subunits have an unpaired cysteine residue that is capable of forming a covalent disulfide linkage with the Na⁺ channel α subunit.

2.21.2.4 Physiological Functions

Voltage-gated Na⁺ channels are critical regulators of electrical activity in excitable cells such as neurons as well as skeletal muscle, cardiac muscle, and neuroendocrine cells. They are found in the plasma membrane of these cells, where their major function is to regulate the flux of positively charged Na⁺ ions along their electrochemical gradient. Under physiological conditions, the direction of Na⁺ flux is from the extracellular milieu into the cell. The physiological roles of Na⁺ channels are to integrate postsynaptic potentials, influence subthreshold electrical activity, and amplify small depolarizing changes in membrane potential into larger events called action potentials. Regardless of the particular combination of α and β subunits in an excitable cell, all voltage-gated Na⁺ channels serve basically this same physiological role. Nevertheless, subtle differences in the voltage-dependent behavior and kinetic properties of each subtype, coupled to specific subcellular distribution patterns, can conspire to impact cell responsiveness and action potential firing rates in profound ways. This is particularly relevant in disease states, such as epilepsy, cardiac arrhythmias, and chronic neuropathic pain, which may involve phenotypic switches in expression, altered membrane insertion, and subcellular redistribution of certain Na⁺ channel subunits.

At negative membrane potentials, most Na⁺ channels exist in resting states, and can open in response to depolarization of the cell membrane. Under physiological conditions, the excitatory input that drives the membrane depolarization normally originates from the opening of other cation-permeable ion channels. In neurons, these cation channels may include neurotransmitter-gated ionotropic receptors such as the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and *N*-methyl-D-aspartate (NMDA) subtypes of the glutamatergic receptor, which are localized postsynaptically on dendritic spines. In addition, low-voltage-activated (LVA) Ca²⁺ channels may cause complex Na⁺ channel activation patterns under conditions that promote neuronal burst firing (see [Section 2.21.3.4](#)). In cardiac myocytes, the excitatory drive may be provided by hyperpolarization-activated, cyclic nucleotide-gated (HCN) cation channels, which serve a pacemaker function in the SA node. In skeletal muscle cells, it is acetylcholine-gated nicotinic receptors that excite the membrane at the neuromuscular junction, leading to Na⁺ channel activation. Once open, Na⁺ channels cause further depolarization of the cell membrane by permitting an influx of positively charged Na⁺ ions. In this way, voltage-gated Na⁺ channels amplify the initial excitatory input in a voltage-dependent, nonlinear fashion. When the local depolarizing currents spread to activate adjacent Na⁺ channels, the membrane depolarizes even further, and may reach its threshold level, at which point an all-or-nothing Na⁺-dependent action potential will be generated and then propagated throughout all electrically excitable regions of the cell membrane. In muscle cells and unmyelinated axons, action potentials are conducted relatively slowly in a smooth wave-like manner, whereas in myelinated axons, they travel more rapidly by saltatory conduction. Normally, after a short period of time (typically a few milliseconds), Na⁺ channels inactivate. This terminates the Na⁺ influx and allows K⁺ channel-dependent membrane repolarization to proceed, signifying the end of the action potential. More complex Na⁺ channel gating modes are apparent in cerebellar Purkinje neurons, where resurgent Na⁺ currents may be generated upon membrane repolarization, reflecting the reopening of inactivated Na_v1.6 channels.⁶⁰

Na^+ channels play a central role in the generation of cardiac action potentials and in the propagation of electrical impulses throughout the heart. Consistent with the isoform-specific distribution patterns, the TTX_i subtype $\text{Nav}1.5$ appears to be the critical determinant of action potential initiation and propagation throughout the heart. Indeed, $\text{Nav}1.5$ heterozygous knockout mice display reduced Na^+ channel expression in SA node and atrial tissue along with a correspondingly depressed heart rate, slowed conduction, and frequent conduction block.⁶¹ Given their relatively low abundance in heart, some TTX_s Na^+ channels appear to play only a supporting role in the control of nodal pacemaker rate⁴² and excitation–contraction coupling in the ventricles.⁶² Certain subpopulations of TTX_s Na^+ channels may fail to inactivate after activation in nodal and ventricular tissue. This gives rise to persistent Na^+ currents that may contribute to the pacemaker current in nodal tissue, thereby influencing the heart rate.⁶³ In addition, persistent Na^+ currents may contribute to the plateau phase of the action potential in ventricular myocytes,⁶⁴ thereby influencing the effective refractory period.

The β subunits differentially influence several characteristics of the Na^+ channel.⁶⁵ In general, when they associate with the α subunit, they modify its functional properties, probably through an allosteric effect on the gating machinery. As a result, the voltage dependence of channel inactivation can be shifted to more negative membrane potentials, and the Na^+ current kinetics accelerated. Courtesy of their extracellular Ig-like fold, the β subunits also function as cell adhesion molecules, and they have been shown to interact with other cell adhesion molecules such as contactin²⁹ and neurofascin⁶⁶ as well as the extracellular matrix molecules tenascin-C and tenascin-R.²⁷ In this way, the β subunits modulate insertion of the α subunit into the cell membrane and contribute to subcellular localization of the Na^+ channel (e.g., at nodes of Ranvier in myelinated axons). Interestingly, the α subunit is also modulated indirectly by contactin^{29,30,67} and the glycoprotein tenascin-R,⁶⁸ possibly through their respective interactions with the β subunits. The protein–protein interactions between the α subunit and the β subunits and cell adhesion molecules may represent a novel point for therapeutic intervention in order to control Na^+ channel function, membrane excitability, and cellular response characteristics in diseases that affect excitable cells.

In addition to their direct effects on membrane potential, Na^+ ions are an effective physiological second messenger, and are involved in the opening of large conductance, Na^+ -activated K^+ channels in cardiac myocytes and neurons.^{69–71} These channels require high concentrations of intracellular Na^+ for activation, and may be functionally important under conditions of rapid, perhaps pathological, firing as well as ischemia.^{72,73} Two candidate genes have been identified (*KCNT1* (*Slack* or *Slo2.2*) and *KCNT2* (*Slick* or *Slo2.1*)) that, when expressed in mammalian cells, produce Na^+ -activated K^+ currents.^{74,75} Both genes display differential tissue expression, with *Slick* being expressed in brain, heart, and skeletal muscle, and *Slack* being found predominantly in neurons. These channels are related to the large conductance Ca^{2+} -activated K^+ channel commonly referred to as Slo1 , BK_{Ca} , or maxi-K (*KCNMA1*).

2.21.2.5 Regulation

Regulation of Na^+ channel function by intracellular second messenger-dependent signaling cascades is a fundamental process that is implicated in the control of input-output relationships in excitable cells. Modulation of Na^+ channel function produces a flexible system for the fine tuning of electrical excitability in neurons and cardiac muscle cells. Several Na^+ channel α subunits have multiple intracellularly accessible serine, threonine, and tyrosine residues that are subject to phosphorylation by PKC and PKA. Electrophysiological studies have been critical in determining how phosphorylation affects the properties of the channel. PKA and PKC typically exert inhibitory effects on TTX_s Na^+ currents in central neurons. Neurotransmitters that activate the PKC pathway induce phosphorylation of residues in the DI–DII (S554, S573, and S576) and the DII–DIII (S1506) intracellular linkers of the Na^+ channel α subunit. Phosphorylation of S1506 appears to be necessary for PKC to induce all of its effects, including reduced peak Na^+ current amplitude and slowed channel inactivation.⁷⁶ Both of these effects have been observed following activation of muscarinic acetylcholine receptors in hippocampal neurons.⁷⁷ In addition, neurotransmitters that activate the cAMP-dependent protein kinase pathway also reduce Na^+ current amplitudes by inducing phosphorylation of amino acids (probably S687) in the DI–DII linker.^{78,79} This effect has been observed following activation of D_1 -like dopaminergic receptors in hippocampal neurons.⁸⁰ Interestingly, it seems that phosphorylation of the S576 residue by PKC is required before phosphorylation of S687 by PKA can inhibit the Na^+ currents.⁷⁹ In rat striatal neurons, phosphatase-1 inhibition leads to reduced Na^+ current amplitudes, probably as a result of enhanced α subunit phosphorylation.⁸¹ Thus, the function of neuronal Na^+ channels appears to be regulated through dynamic control of their phosphorylation state. Indeed, the appearance of the resurgent Na^+ current in repolarizing cerebellar Purkinje neurons seems to depend on the phosphorylation state of the $\text{Nav}1.6$ TTX_s Na^+ channel.⁸²

A change in the phosphorylation state of Na^+ channels is an important mechanism of neuromodulation in both peripheral and central neurons. Inflammatory mediators such as prostaglandin E_2 (PGE_2) can induce hyperalgesia in

humans and animals, and this is associated with increased primary sensory neuron excitability. Mechanistically, the effect of PGE₂ appears to involve activation of E-prostanoid subtypes of G protein-coupled receptors (GPCRs) with downstream activation of cAMP-dependent PKA. Subsequently, PKA-mediated phosphorylation of the TTX_R Na⁺ channel induces an enhancement of the TTX_R Na⁺ current amplitude in sensory neurons, and this is associated with more rapid current inactivation and a negative shift in the voltage-dependence of activation (reduces the threshold for action potential firing).⁸³ Studies with heterologously expressed Nav1.8 have suggested that PKA-dependent phosphorylation occurs at sites that are located in the DI–DII linker.⁸⁴ Interestingly, the PKA-dependent phosphorylation of the TTX_R Na⁺ channel seems to require prior phosphorylation by PKC at a different site.⁸⁵

The synchronized propagation of Na⁺ channel-dependent cardiac action potentials is critical for coordinated atrial and ventricular contraction. Cardiac Na⁺ channels are regulated differentially by both PKC- and PKA-mediated phosphorylation in response to GPCR activation. In the heart, β-adrenergic receptor activation speeds up action potential conduction and induces a faster heart rate. Consistent with this, voltage clamp experiments on cardiac myocytes have shown that β-adrenergic receptor activation by agonists, such as isoproterenol, enhances Na⁺ current amplitudes and induces faster Na⁺ channel inactivation.⁸⁶ Studies with heterologously expressed Nav1.5 have suggested that the effects of PKA on the cardiac Na⁺ channel involve amino acid residues that are located in the large cytoplasmic DI–DII (S526 and S529) linker.^{87,88} In contrast, PKC-mediated phosphorylation of Nav1.5 (S1505) inhibits the Na⁺ current amplitude, stabilizes inactivation, and induces a negative shift in the steady state inactivation relationship.⁸⁹ In summary, both neuronal and cardiac Na⁺ channels are subject to protein kinase-mediated phosphorylation, although the pattern of modulation is isoform-specific in each tissue.

2.21.2.6 Prototypical Pharmacology

Ion permeation through the Na⁺ channel can be modulated by a variety of pharmacologically active substances, including animal and plant toxins (peptides and alkaloids) as well as synthetic therapeutically useful small molecules (Table 3). All of these substances exert their effects on Na⁺ channel function by binding directly to the α subunit. Some of them bind within or close to the pore and block ion permeation whereas others bind to regions that are coupled to the voltage-gating machinery, and can allosterically activate or inactivate the channel in the absence of membrane potential changes. So far, seven pharmacologically relevant receptor sites have been described on the Na⁺ channel, although not all α subunits contain all sites.

Within the Na⁺ channel pore loops, the amino acids forming the EEDD and DEKA selectivity motifs are important for defining neurotoxin receptor site 1.^{57,59} This is where TTX (from the puffer fish *Fugu*), saxitoxin (STX, from the algae *Alexandrium catenella*), and μ-conotoxins (e.g., μ-PIIIA from the marine cone snail *Conus geographus*) all bind. Site 1 toxins have served as valuable research tools to identify and describe native and recombinant Na⁺ channels. These toxins occlude the pore and directly interfere with Na⁺ permeation. They do not exhibit any preference for open or inactivated states of the channel, and so their mechanism of action displays little or no use- or voltage-dependence. Na⁺ currents are often characterized and described in terms of their sensitivities to inhibition by TTX and STX, which are extremely potent and selective blockers of many mammalian Na⁺ channels. Most native Na⁺ currents in the CNS, PNS, and skeletal muscle are blocked by very low concentrations of TTX (single-to-double-digit nanomolar IC₅₀ values), and, consistent with these data, the Na⁺ channel subtypes that predominate in these tissues (Nav1.1–1.4, Nav1.6, and Nav1.7) also have high sensitivity to TTX. In contrast, the predominant native cardiac Na⁺ channel, Nav1.5, has been classified as TTX_I (single-digit micromolar IC₅₀ value). A number of kinetically distinct Na⁺ currents with low sensitivity to TTX (single-to-double-digit micromolar IC₅₀ values) have been described in isolated primary sensory neurons. Consistent with these findings, the Na⁺ channel subtypes Nav1.8 and Nav1.9 are expressed in DRG neurons, and display correspondingly low sensitivities to TTX.^{14,17,90} While the EEDD and DEKA motifs are important for the binding of site 1 toxins, the distinct TTX sensitivities of the different Na⁺ channel subtypes are determined primarily by the identity of a specific amino acid in the P-loop of domain I.^{14,91} In TTX_S Na⁺ channels, the amino acid residue that is located two positions before the first E residue of the EEDD motif is a tyrosine, which contains an aromatic ring. In contrast, the equivalent residue in Nav1.5 is a cysteine, and in Nav1.8 it is a serine. Mutagenesis studies have confirmed that an aromatic ring at this location is essential for the high-affinity binding of TTX.⁹²

As already mentioned, there are many natural peptide and alkaloid toxins that interfere with the activation and inactivation processes of the Na⁺ channel by binding to neurotoxin receptor sites 2–6, which are located in close proximity or are allosterically coupled to the gating machinery. Toxins such as veratridine (from the seed of the lily *Schoenocaulon officinale*), aconitine (from the root of monkshood, *Aconitum napellus*), batrachotoxin (from the poison dart frog *Phylllobates terribilis*) (all site 2), α scorpion toxins (e.g., Lqh II from *Leiurus quinquestriatus hebraeus*) (site 3),

β scorpion toxins (e.g., toxin IV from *Centruroides suffusus suffusus*) (site 4), brevetoxins (from the algae *Ptychodiscus brevis*), ciguatoxin (from the dinoflagellate *Gambierdiscus toxicus*) (both site 5), and δ -conotoxins (e.g., δ -EVIA from the marine cone snail *Conus ermineus*) (site 6) may directly activate Na^+ channels and may slow or prevent their inactivation. Depending on the extent and time-course of their effects on gating processes, these toxins may enhance Na^+ influx, depolarize cell membranes, prolong action potential durations, induce repetitive firing, reduce membrane excitability, and modulate neurotransmitter release. Paralysis of skeletal muscle, tachycardia in the heart, and convulsions in the brain are commonly observed toxicities. Since neurotoxin sites 2–6 are not found in all Na^+ channel subtypes,^{93,94} several of the site 2–6 toxins can be used as research tools to discriminate between the various native neuronal, skeletal muscle, and cardiac channels.

Voltage-gated Na^+ channels have been established as the molecular target for several classes of clinically useful drugs, including local anesthetics as well as certain antiepileptic, antiarrhythmic, and analgesic agents. This includes older drugs such as lidocaine, phenytoin, and mexiletine as well as newer ones such as ropivacaine, lamotrigine, and ralfnimide (NW-1029). Many of these small-molecule drugs block ion permeation through the Na^+ channel, and inhibit electrical activity in excitable cells by binding to the local anesthetic (LA) receptor site (site 7), which is thought to be located on the cytoplasmic side of the Na^+ channel α subunit. Several amino acid residues in the S6 segments of the four homologous domains have been implicated in forming the LA receptor site,^{95,96} although only two residues appear to be critical (i.e., F1764 and Y1771). Since the amino acid residues that define site 7 are highly conserved between the nine different TTX_S, TTX_I, and TTX_R Na^+ channel α subunit isoforms, the majority of these drugs display little or no subtype selectivity, and so the challenge for the discovery novel subtype-selective drugs is huge. Most clinically useful local anesthetics and antiarrhythmics inhibit action potential conduction in a frequency-dependent manner (i.e., the extent of block varies in direct proportion to the firing rate). This is because local anesthetic-like drugs block Na^+ channels by binding preferentially to open and/or inactivated states and then stabilizing the channels in drug-bound, nonconducting states. The mechanism by which this occurs can be explained in terms of the modulated receptor hypothesis (MRH)⁹⁷ or the guarded receptor hypothesis (GRH).⁹⁸ Simply stated, the MRH proposes that the affinity of drugs for the LA receptor site varies with the conformational state of the Na^+ channel, whereas the GRH proposes that the affinity of drugs for the LA receptor site is constant, but that access of the drug to the site is controlled or guarded by a Na^+ channel gate. According to these hypotheses, circumstances that increase the probability of the channel being in open and/or inactivated states will enhance Na^+ channel block and will therefore cause greater inhibition of action potential conduction. Frequency-dependent block of Na^+ channels is particularly relevant in diseases that involve abnormal action potential firing, such as may be observed in the heart during arrhythmias and in neurons during epilepsy and neuropathic pain. Interestingly, the pharmacological sensitivity of the Na^+ channel may be impacted by the particular β subunit that is present, possibly due to the effect of the latter on inactivation behavior of the channel.⁹⁹

2.21.2.7 Prototypical Therapeutics

Voltage-gated Na^+ channels represent well-validated targets for local anesthesia as well as a number of disease states that are associated with overactivity of excitable cells. Changes in the expression levels, distribution patterns, or functional properties of Na^+ channels are observed in many diseases that affect excitable cells. Thus, Na^+ channel blockers will have therapeutic utility in situations where there is a need to interfere with action potential generation or conduction in normal or pathological cells. Na^+ channel inhibition represents an attractive therapeutic approach to the treatment of cardiac arrhythmias and certain forms of epilepsy, as well as neuropathic pain and chronic inflammatory pain.

Conduction anesthesia comprises a variety of local and regional anesthetic techniques that are often applied to peripheral or spinal nerves during surgery. Local anesthesia is restricted to a small part of the body such as a tooth or an area of skin, whereas regional anesthesia affects a larger part of the body such as a leg or an arm. Application of local anesthetic drugs to specific nerve pathways may lead to loss of all sensation, including pain, as well as paralysis. Conduction anesthesia involves the inhibition of spontaneous and evoked electrical activity in normal nerves, and is a clinically important and frequently used procedure in minor surgical settings. In addition, due to superior pain relief and fewer side effects, conduction anesthesia is sometimes used to relieve nonsurgical pain.¹⁰⁰ Most amide- and ester-based local anesthetics are weak bases, and both protonated and unprotonated forms exist in equilibrium at normal pH. While it is the unprotonated form that easily crosses the cell membrane, only the protonated form is able to block Na^+ channels. Thus, local anesthetic potency is impacted by pH changes, and local acidosis caused by infection may reduce the effectiveness of these drugs in the dental surgery setting.

A variety of evidence has linked voltage-gated Na^+ channels to the development and maintenance of various epilepsies. First, electrophysiological studies in brain slices have demonstrated that experimental manipulations that

increase Na^+ channel activity can induce epileptiform-like discharging.^{101,102} Second, the levels of Na^+ channel α and β subunit mRNA and protein as well as Na^+ current amplitudes may be differentially altered in an isoform-specific manner in the brains of epileptic patients^{103,104} and epilepsy-prone animals.^{105–108} Finally, many CNS-penetrant antiepileptic drugs such as carbamazepine, phenytoin, and lamotrigine appear to act by modifying Na^+ channels in neurons. The mechanism of action of these drugs is use-dependent, as a result of inactivated state-dependent interactions with the Na^+ channel α subunit. Therefore, they are capable of reducing late Na^+ channel openings¹⁰⁹ and limiting sustained high-frequency neuronal discharges.

Physiological, pharmacological, and gene knock-down approaches have also implicated voltage-gated Na^+ channels in the development and maintenance of chronic pain states associated with tissue inflammation and nerve injury. In particular, subcellular changes in Na^+ channel expression can induce repetitive spontaneous and evoked action potential firing patterns, which may underlie the abnormal sensory phenomena in affected patients. The symptoms of chronic pain include abnormal sensory disturbances such as spontaneous pain, allodynia, and hyperalgesia, all of which reflect the increased excitability of peripheral and spinal neurons.^{110,111} Neuronal hyperexcitability may be explained by increased Na^+ current levels, either as a result of altered expression per se,^{112,113} or as a result of G protein modulation of function.¹¹⁴ Electrophysiological and molecular biology approaches have revealed that both TTX_S and TTX_R Na^+ channels are affected, and, at a molecular level, the neuronal hyperexcitability may also involve phenotypic switches whereby Na^+ channel α and β subunits that are normally expressed at lower levels become upregulated either in direct response to the nerve injury or in response to ongoing neuronal overactivity.^{25,115–122} Moreover, gene deletion of $\text{Nav}1.7$, $\text{Nav}1.8$, or $\text{Nav}1.9$ in mice has predictable effects on Na^+ currents in DRG neurons, and can alleviate the behavioral symptoms of neuropathic pain in nerve-injured animals.^{123–128} In addition, there may be changes in the subcellular distribution pattern of neuronal Na^+ channels in primary sensory neurons, including redistribution and accumulation at ectopic sites in the membrane, leading to aberrant action potential firing.^{22,129} Importantly, nonselective use-dependent Na^+ channel blockers, including some local anesthetics, antiepileptics, and tricyclic antidepressants, can reduce neuronal hyperexcitability, and this may explain their proven efficacy in the alleviation of neuropathic pain symptoms in humans.¹³⁰

With the recent identification of the molecular components of voltage-gated Na^+ channels, there has been a surge of research to better understand and describe the tissue-specific distribution of Na^+ channel isoforms as well as the subtype-specific changes in expression that occur in disease. For instance, individual Na^+ channel subtypes that are selectively expressed in sensory neurons suggest opportunities for the development of potent and safer alternatives to currently available analgesics, although targeting of the LA receptor site will probably not be a fruitful approach. Rather, success may come in the form of novel Na^+ channel gating modifiers (e.g., inactivation gate mimetics that bind to the gate receptor, or molecules that bind to the voltage sensor and cause positive shifts in the voltage dependence of activation). An understanding of these areas will underpin efforts to discover novel molecules displaying improved Na^+ channel subtype selectivity in addition to well-understood frequency-dependent mechanisms of action. It is anticipated that these novel molecules will be developed as more efficacious and safer drugs for the treatment of diseases associated with membrane hyperexcitability.

2.21.2.8 Genetic Diseases

The cell surface density and functional properties of voltage-gated Na^+ channels are key determinants regulating neuronal and myocyte activity. It has long been known that certain diseases involving electrically excitable cells have strong genetic predispositions. Perhaps not surprisingly, analysis of DNA samples taken from affected individuals has revealed that mutations in certain ion channel genes are associated with several of these inherited diseases. Relevant mutations may cause amino acid exchanges, amino acid deletions, or protein truncations that induce abnormal operation of certain key components of the ion channel, including the voltage sensor and inactivation gate. Mutations in multiple ion channel genes have been associated with various monogenic epilepsy disorders. However, many of these diseases no doubt are heterogeneous in origin (i.e., multiple genes and possibly environmental factors are likely involved). Collectively, ion channel-associated diseases are referred to as channelopathies.¹³¹

Cell membrane overexcitability is a feature of epilepsy and cardiac arrhythmias, and is consistent with genetic mutations that might produce a Na^+ channel gain of function phenotype. In particular, mutations in Na^+ channel α and β subunit genes have been reported, and often these are associated with either subtle or obvious abnormalities of Na^+ channel function, including altered biophysical properties or overexpression in the cell membrane.¹⁰⁶ Mutations in the Na^+ channel genes *SCN1A* and *SCN1B* have been implicated in at least two forms of familial childhood epilepsy (i.e., generalized epilepsy with febrile seizures plus (GEFS+) and severe myoclonic epilepsy of infancy (SMEI)). More than 100 single-point mutations have been documented in *SCN1A*, making it the most

clinically relevant epilepsy gene identified to date. Yet, electrophysiological studies show no consistent relationship between alterations in Na^+ channel properties and clinical phenotype, suggesting heterogeneity of underlying causes. Nevertheless, functional analysis of $\text{Na}_v1.1$ subunits that have been engineered to include specific epilepsy relevant mutations has revealed several gain of function phenotypes that may contribute to epileptiform activity in affected patients. Typically, these mutations affect the Na^+ channel gating processes and promote neuronal hyperexcitability. The mutation D188V endows the Na^+ channel with an increased ability to sustain high-frequency activity.¹³² The mutation R1648C produces a persistent or noninactivating (window) current, which would tend to increase Na^+ influx at negative membrane potentials and exert a continuous depolarizing influence on the cell.¹³³ Furthermore, the D1866Y amino acid exchange in $\text{Na}_v1.1$ weakens the ability of the α subunit to interact with β subunits, perhaps leading to increased Na^+ channel availability at hyperpolarized membrane potentials.¹³⁴ Conversely, several of these effects on Na^+ channel gating are replicated by the GEFS + -associated mutation C121W in *SCN1B*.¹³⁵ This mutation affects the extracellular Ig-like fold of the Na^+ channel auxiliary β_1 subunit, interfering with its ability to bond noncovalently with the α subunit. Therefore, mutations either in α or β subunit genes can lead to the gain of function phenotype that may underlie neuronal overexcitability and seizure activity. Of significant clinical importance, even though these mutations may not be located at the LA site, is the fact that they may indirectly alter the pharmacological sensitivities of the Na^+ channel by altering the gating kinetics or the voltage-dependent equilibrium that exists between the different states of the channel.¹³⁶

Primary erythralgia is an autosomal-dominant painful neuropathy that is characterized by intermittent burning pain with redness and heat in the extremities.¹³⁷ This condition has been associated with mutations in the α subunit gene *SCN9A*,^{138,139} which encodes a TTX_S Na^+ channel that is expressed primarily in primary sensory and sympathetic neurons.¹⁵ Several mutations have been detected, including I848T, L858H, and F1449V (close to the IFM motif in the loop connecting domains III and IV).^{140,141} These mutations alter the activation characteristics of $\text{Na}_v1.7$, lowering the threshold for action potential generation and promoting neuronal burst firing in the DRG.

Several cardiac arrhythmias, including the LQT3 form of congenital long-QT syndrome, Brugada syndrome, and conduction system disease, have been associated with more than 100 mutations in the cardiac Na^+ channel α subunit gene *SCN5A*. Interestingly, mutations in the TTX_S Na^+ channel genes do not appear to be associated with cardiac conduction abnormalities, underscoring the dominant role that $\text{Na}_v1.5$ plays in controlling heart function. The majority of the *SCN5A* mutations are missense, but deletions, insertions, frameshifts, nonsense, and splice donor errors have also been observed with distinct cellular and clinical electrophysiological phenotypes. In congenital long-QT syndrome, prolongation of the cardiac action potential predisposes individuals to syncope and sudden death as a result of ventricular arrhythmias. The LQT3 syndrome is associated with a gain of function mutations in *SCN5A*, and typically, the mutant channels flicker abnormally between open and closed states, producing sustained inward Na^+ current during ventricular myocyte depolarization. This serves to prolong the cardiac action potential, and provides a molecular mechanism for LQT3 syndrome. Brugada syndrome is an inherited cardiac disorder that involves ventricular fibrillation that may lead to sudden death. Brugada syndrome appears to be associated with mutations in the *SCN5A* gene, including R282H¹⁴² and the double-mutant R1232W/T1620M.¹⁴³ Electrophysiological investigation of mutant channels reveals a large reduction in Na^+ current density and a shift of Na^+ channel activation to more positive membrane potentials. The phenotypes are closely related to the clinical observations in Brugada syndrome, which includes conduction block at the atrioventricular (AV) node.

Mutations in the skeletal muscle voltage-gated Na^+ channel α subunit gene (*SCN4A*) have been associated with a variety of inherited nondystrophic myotonias and periodic paralyses, including paramyotonia congenita (PC)^{144,145} and hyperkalemic periodic paralysis (HYPP).¹⁴⁶ Both conditions are autosomal-dominant disorders that are associated with muscle weakness. In PC the weakness may be induced by low muscle temperature, whereas in HYPP the weakness is associated with high levels of serum K^+ . Many of the disease-associated alleles include missense mutations in *SCN4A* that result in amino acid substitutions in transmembrane regions of the $\text{Na}_v1.4$ channel, including S4. Electrophysiological methods have demonstrated that many of these mutations delay Na^+ channel inactivation and induce a persistent Na^+ current. Open- and inactivated-state Na^+ channel blockers (e.g., phenytoin and tocainide) may have therapeutic benefit in patients suffering from PC and/or HYPP.^{147,148}

2.21.3 Calcium Channels

2.21.3.1 Current Nomenclature

In common with other members of the voltage-gated ion channel superfamily, Ca^{2+} channels are integral membrane protein multisubunit complexes.² Native Ca^{2+} channels are composed of a large α_1 subunit that is commonly

Figure 3 The large pore-forming α_1 subunit has four homologous domains (DI through DIV), each with six transmembrane segments. The $\alpha_2\delta$ subunit is the product of a single gene, but the α_2 and δ portions are post-translationally cleaved and then linked by disulfide bonds. The α_2 portion is located extracellularly, and is essential for modifying the function of the α_1 subunit. The δ portion contains a transmembrane segment that serves to anchor the subunit in the cell membrane. The γ subunit has four transmembrane segments. The β subunit is located in the cytosol, where it interacts with the intracellular loop connecting DI to DII in the α_1 subunit.

associated with auxiliary $\alpha_2\delta$, β , and γ subunits (Figure 3). The α_1 subunit provides the ion permeation pathway, and contains most of the regulatory and pharmacologically relevant binding sites. The roles of the auxiliary subunits include modulation of Ca^{2+} channel kinetics, pharmacology, and membrane expression.¹⁴⁹

Voltage-gated Ca^{2+} channels are highly diverse, and the terminologies that have been used to categorize them over the years are correspondingly complex. Ca^{2+} channels in native tissues were originally classified alphabetically on the basis of qualitative descriptors of their biophysical and pharmacological properties. Thus, the term L-type has been assigned to high-threshold Ca^{2+} channels that underlie high-voltage-activated (HVA), dihydropyridine-sensitive Ca^{2+} currents in neurons and muscle cells. Similarly, the name T-type has been applied to those low-threshold Ca^{2+} channels that produce LVA Ca^{2+} currents in neurons as well as cardiac and smooth muscle cells. For both L-type and T-type Ca^{2+} channels, evidence was apparent for the existence of distinct subtypes of each channel, often within the same cell. Neuronal N-type channels were defined as those that generate ω -conotoxin GVIA-sensitive HVA Ca^{2+} currents. Additional Ca^{2+} channels underlying neuronal HVA Ca^{2+} currents include the ω -agatoxin IVA-sensitive P-type channel, which was first identified in cerebellar Purkinje neurons, and the ω -conotoxin MVIIC-sensitive Q-type channel, which is in fact an ω -agatoxin IVA-insensitive variant of the P-type channel. Finally, the R-type channel was named because of its pharmacological resistance to all known Ca^{2+} channel blockers, although it was recently shown to be sensitive to the peptide SNX-482.¹⁵⁰ Individual cells in many native tissues often display multiple Ca^{2+} currents (e.g., some neurons have five distinct Ca^{2+} current components).¹⁵¹ This alphabetical terminology remains in widespread use today because it helps to classify Ca^{2+} currents in native tissue where the exact genetic composition of expressed channels is unknown.

With the advent of the gene-cloning era, a letter-based naming system was proposed for the α_1 subunits.¹⁵² This sequential naming system began at α_{1A} , has been extended through to α_{1I} and also includes α_{1S} , for a total of 10 separate gene products (Table 4). Ca^{2+} currents that result from the expression of cloned α_1 subunits in heterologous systems can be defined using the same functional and pharmacological descriptors that are used for native Ca^{2+} currents. The α_{1A} subunit gives rise to the P/Q-type Ca^{2+} current, the α_{1B} subunit to the N-type current, and the α_{1E} subunit to the R-type current. Also, it is universally accepted that the α_{1C} , α_{1D} , α_{1F} and α_{1S} subunits correspond to the predominant L-type Ca^{2+} currents in neurons, cardiac muscle, retinal cells, and skeletal muscle, respectively. Finally, there is little dispute that the α_{1G} , α_{1H} , and α_{1I} subunits underlie T-type Ca^{2+} currents in neurons, muscle, and endocrine cells.

More recently, a number-based IUPHAR-approved naming convention was proposed to better coordinate the α_1 subunit classification and also pre-empt the confusing scenario that a future α_{1L} subunit may not encode an L-type Ca^{2+} channel.^{153,154,518} The new numerical nomenclature for Ca^{2+} channel α_1 subunits mirrors that of the voltage-gated Na^+ and K^+ channel families, by systematically grouping Ca^{2+} channel α_1 subunits into subfamilies according to their structural relationships (see Table 4). The permeant ionic species is denoted (Ca) along with the physiological activator (subscripted V for voltage), to yield Ca_V . Currently, three subfamilies have been described. Subfamily 1

<i>Subunit type and name</i>	<i>Human gene symbol name</i>	<i>Human chromosome</i>	<i>General description</i>
Pore-forming α_1 subunits			
$\text{Ca}_v1.1$	<i>CACNA1S</i>	1q32	Skeletal muscle L-type Ca^{2+} channel/voltage sensor
$\text{Ca}_v1.2$	<i>CACNA1C</i>	12p13	Cardiac L-type Ca^{2+} channel
$\text{Ca}_v1.3$	<i>CACNA1D</i>	3p14	Neuronal L-type Ca^{2+} channel
$\text{Ca}_v1.4$	<i>CACNA1F</i>	Xp11	Retinal L-type Ca^{2+} channel
$\text{Ca}_v2.1$	<i>CACNA1A</i>	19p13	Neuronal P/Q-type Ca^{2+} channel
$\text{Ca}_v2.2$	<i>CACNA1B</i>	9q34	Neuronal N-type Ca^{2+} channel
$\text{Ca}_v2.3$	<i>CACNA1E</i>	1q25	Neuronal R-type Ca^{2+} channel
$\text{Ca}_v3.1$	<i>CACNA1G</i>	17q22	Neuronal and cardiac T-type Ca^{2+} channel
$\text{Ca}_v3.2$	<i>CACNA1H</i>	16p13	Neuronal and cardiac T-type Ca^{2+} channel
$\text{Ca}_v3.3$	<i>CACNA1I</i>	22q12	Neuronal T-type Ca^{2+} channel
High-threshold Ca^{2+} channel auxiliary subunits			
$\alpha_2\delta_1$	<i>CACNA2D1</i>	7q21	The auxiliary subunits regulate the membrane insertion of the α_1 subunits and modulate the functional properties, including biophysical and pharmacological properties, of the assembled Ca^{2+} channels
$\alpha_2\delta_2$	<i>CACNA2D2</i>	3p21	
$\alpha_2\delta_3$	<i>CACNA2D3</i>	3p21	
$\alpha_2\delta_4$	<i>CACNA2D4</i>	12p13	
β_1	<i>CACNB1</i>	17q11	
β_2	<i>CACNB2</i>	10p12	
β_3	<i>CACNB3</i>	12q13	
β_4	<i>CACNB4</i>	2q22	
γ_1	<i>CACNG1</i>	17q24	
γ_2	<i>CACNG2</i>	22q13	
γ_3	<i>CACNG3</i>	16p12	
γ_4	<i>CACNG4</i>	17q24	
γ_5	<i>CACNG5</i>	17q24	
γ_6	<i>CACNG6</i>	19q13	
γ_7	<i>CACNG7</i>	19q13	
γ_8	<i>CACNG8</i>	19q13	

comprises $\text{Ca}_v1.1$ – 1.4 (corresponding to α_{1C} , α_{1D} , α_{1F} , and α_{1S}), and represents the L-type Ca^{2+} channels. Subfamily 2 contains the toxin-sensitive subunits $\text{Ca}_v2.1$ (α_{1A} ; P/Q-type), $\text{Ca}_v2.2$ (α_{1B} ; N-type), and $\text{Ca}_v2.3$ (α_{1E} ; R-type). Subfamily 3 contains three members (i.e., $\text{Ca}_v3.1$ – 3.3 – corresponding to α_{1G} , α_{1H} , and α_{1I} , respectively), and represents the T-type channels. Ca^{2+} channel α_1 subunits are subject to extensive splice variation, and, where

necessary, lowercase letters are used to distinguish unique variants. A parallel gene symbol nomenclature exists where *CACNA1* forms the root of the name and the letters A through I plus S denote the 10 members of the three subfamilies. (Caution: this gene naming system still reflects the old letter-based α_1 subunit naming convention, and so the possibility of a future *CACNA1L* being non-L-type still exists.)

The naming of the Ca^{2+} channel auxiliary subunits utilizes numbers to distinguish different isoforms and letters to distinguish splice variants (see Table 4). The $\alpha_2\delta$ subunit family (denoted by the gene symbol *CACNA2D*) has four members ($\alpha_2\delta_{1-4}$) that display 30–60% amino acid similarity with each other. The β subunit family (denoted by the gene symbol *CACNB*) has four members (β_{1-4}), whereas the γ subunit family (denoted by the gene symbol *CACNG*) has eight members (γ_{1-8}). As with the α_1 subunits, these auxiliary subunits are subject to extensive splice variation.

2.21.3.2 Molecular Biology

Voltage-gated Ca^{2+} channels exhibit significant molecular and functional diversity, and often an individual cell will express multiple subtypes. The expression of Ca^{2+} channels in neurons as well as in endocrine, cardiac muscle, smooth muscle, skeletal muscle, fibroblasts, photoreceptor, and kidney cells has been supported by a combination of electrophysiological and pharmacological studies. However, molecular biology approaches, including immunohistochemical and in situ hybridization methods, have proven most useful in the localization of individual Ca^{2+} channel subunits to different tissues. At the molecular level, the primary source of Ca^{2+} channel diversity is that 26 genes are known to encode the pore-forming and auxiliary subunits. Further molecular diversity exists because most of these Ca^{2+} channel subunits are subject to splice variation. Theoretically, the array of potential subunit combinations could therefore extend to several hundred distinct possibilities. The subunit composition of the Ca^{2+} channels underlying neuronal HVA Ca^{2+} currents likely includes two or more auxiliary subunits (i.e., $\alpha_2\delta$, β , and, possibly, γ). Some Ca^{2+} channel auxiliary subunits have been shown to affect the function of recombinant Ca_v3 subunits,^{155,156} although anti- β subunit antisense strategies failed to reveal any consequence of β subunit depletion on T-type Ca^{2+} channel function in neuroblastoma cells.¹⁵⁷ Therefore, the exact subunit composition of neuronal T-type Ca^{2+} channels remains a matter of speculation. At the functional level, each α_1 subunit displays unique biophysical and pharmacological properties that have enabled them to be correlated with native Ca^{2+} currents in various tissues. However, this is not a conclusive exercise because the functional properties of pore-forming subunits can be modulated in an isoform-specific manner by association with auxiliary subunits, indicating that functional diversity may also reflect heterogeneity of subunit combinations.^{158,159} Additional complexity of function arises from the fact that many Ca^{2+} channels are subject to regulation by intracellular second messengers and enzymes.

In various types of muscle cells, excitation–contraction coupling is dependent on the L-type (Ca_v1) subfamily of Ca^{2+} channels, although T-type (Ca_v3) Ca^{2+} channels also play a role. The molecular composition of L-type Ca^{2+} channels has been widely studied in skeletal muscle because of their high density in this tissue. The $\text{Ca}_v1.1$ subtype is expressed almost exclusively in skeletal muscle, where it is associated with the Ca^{2+} channel $\alpha_2\delta_1$, β_{1a} , and γ_1 auxiliary subunits¹⁶⁰ as well as the large (> 5000 amino acids) ryanodine receptor type 1 (RyR_1).¹⁶¹ The $\text{Ca}_v1.2$ subtype is found in contractile cells of the cardiovascular system,¹⁶² and several $\alpha_2\delta$ and β subunits are also expressed, raising the possibility that multiple molecularly distinct L-type Ca^{2+} channels may be expressed in atrial and ventricular cells.^{163,164} The cardiac $\text{Ca}_v1.2$ -containing L-type Ca^{2+} channels are localized in both the plasma and transverse tubule membranes, where they are functionally coupled to the ryanodine receptor type 2 (RyR_2).¹⁶¹ Interestingly, the $\text{Ca}_v1.2$ splice variant in cardiac muscle cells appears to be different from that in vascular smooth muscle cells.¹⁶⁵ The $\text{Ca}_v1.3$ subtype is also present in heart, being expressed in SA node cells, where, due to its relatively low activation threshold, it may play a pacemaking role.¹⁶⁶ The $\text{Ca}_v1.4$ subtype was originally thought to be retinal-specific, but is now known to have a broader distribution, including certain cells of the immune system.¹⁶⁷ This L-type Ca^{2+} channel controls neurotransmitter release in retinal bipolar cells, and appears to be the only physiologically active Ca^{2+} channel present.¹⁶⁸ Gene deletion studies in mice have shown that the β_2 subunit forms an essential component of the retinal L-type Ca^{2+} channel.¹⁶⁹ At a molecular level, the $\text{Ca}_v3.1$ and $\text{Ca}_v3.2$ subunits are expressed widely but at relatively low levels in the cardiovascular system, and their relative expression changes with development.¹⁷⁰ The molecular composition of cardiac T-type Ca^{2+} channels has not been determined biochemically, so it remains unclear if they resemble the L-type channels in being multisubunit complexes or whether they consist only of the α_1 subunit. In vascular smooth muscle, the high sensitivity of the T-type Ca^{2+} current to nickel is consistent with expression of $\text{Ca}_v3.2$,¹⁷¹ although its functional role is unclear.¹⁷²

Almost all of the known Ca^{2+} channel α_1 subunits appear to be expressed in neurons. Neuronal L-type Ca^{2+} channels likely contain either $\text{Ca}_v1.2$ or $\text{Ca}_v1.3$, and are localized mainly on neuronal cell bodies and proximal

dendrites.^{173,174} Ca^{2+} influx through neuronal L-type Ca^{2+} channels appears to be involved in the regulation of gene expression¹⁷⁵ as well as the activation of Ca^{2+} -dependent K^{+} channels^{176,177} and enzymes.¹⁷⁸ Immunohistochemical studies with P/Q-type ($\text{Ca}_v2.1$ -containing)¹⁷⁹ and N-type ($\text{Ca}_v2.2$ -containing)¹⁸⁰ selective antibodies have demonstrated that these channels are present at high levels in the presynaptic terminals of central and peripheral neurons, where they may be complexed with a variety of proteins that are involved in neurotransmitter secretion, including syntaxin, synaptotagmin, and SNAP-25.¹⁸¹ The P-type Ca^{2+} channel is also found on cell bodies and dendrites of cerebellar Purkinje neurons as well as cell bodies of pyramidal neurons in CA1–CA4 of the hippocampus.¹⁸² The $\text{Ca}_v2.3$ subunit is a likely candidate to explain the neuronal SNX-482-sensitive R-type Ca^{2+} current,¹⁸³ which has a somatic, proximal dendritic, and presynaptic distribution in certain neurons of the brain,^{174,184} and may play a role in controlling neurotransmitter release.¹⁸⁵ Consistent with the widespread distribution of LVA Ca^{2+} currents throughout the nervous system, the protein and mRNA for the Ca_v3 α_1 subunits have been found throughout the brain, spinal cord, and peripheral sensory ganglia.^{186–188}

2.21.3.3 Protein Structure

As with voltage-gated Na^{+} channels, the Ca^{2+} channel α_1 subunit has not yet been crystallized, and therefore its overall tertiary structure remains a matter of speculation. Nevertheless, it is very probable that the tertiary structure of the Ca^{2+} channel α_1 subunit is grossly similar to that of the tetrameric K^{+} channel $\text{K}_v1.2$, which has been crystallized in its open state (see [Figure 1](#)).^{49,50} Regardless of whether they underlie HVA or LVA Ca^{2+} currents, all of the Ca_v α_1 subunits exhibit highly similar primary and predicted secondary structures. Each α_1 subunit contains approximately 2000 amino acid residues (190–250 kDa). Within each Ca^{2+} channel subfamily, the primary amino acid sequences are approximately 70% identical, whereas between subfamilies the similarity is typically 40% or less. Each α_1 subunit has intracellular N and C termini, and four sets of transmembrane α -helical segments (S1 through S6), which are grouped in four homologous domains (DI through DIV). These domains are linked sequentially by intracellular loops, the first of which (DI–DII) contains a so-called α -interaction domain (AID) that is required for the cytosolic β subunit to bind and exert its modulatory effects on activation and inactivation rates, G protein modulation, pharmacological sensitivity, and cell surface expression.^{189,190} Several amino acid residues that are involved in or are critical for this interaction have been defined in both the α_1 and β subunit.^{191,192} The fourth transmembrane segment (S4) in each domain of the α_1 subunit contains several positively charged amino acid residues, and is believed to represent the voltage sensor of the channel. Surprisingly, the amino acid sequences of the S4 segments do not appear to explain the different voltage sensitivities of high- and low-threshold channels.¹⁹³

The cation selectivity of voltage-gated Ca^{2+} channels is controlled by a putative ring structure that is formed by four negatively charged amino acids contributed by the pore loops of each domain. In high-threshold Ca^{2+} channels, each pore loop contributes a glutamate residue, to form an EEEE motif,¹⁹⁴ whereas in low-threshold Ca^{2+} channels the third and fourth pore loops each contribute an aspartate residue, to form an EEDD motif.^{195–197} These motifs are analogous to the DEKA motif of the voltage-gated Na^{+} channels. The exact spatial arrangement of these four amino acid residues in the pore is responsible for determining the divalent cation selectivity and permeation mechanism of the channel. That the motifs differ between the high- and low-threshold Ca^{2+} channels may explain their distinct selectivity profiles: high-threshold channels typically display a higher permeability to Ba^{2+} while low-threshold channels are equally permeable to both cations.

Voltage-dependent inactivation of Ca^{2+} channels appears to proceed via a hinged lid mechanism. In this model of Ca^{2+} channel gating, the DI–DII connecting loop acts as an inactivation gate, and appears to occlude the pore by physically docking at the intracellular ends of the S6 segments in DII and DIII.¹⁹⁸ The hinged lid model provides a mechanism for auxiliary β subunits to influence the inactivation process by altering the mobility of the DI–DII inactivation gate. A Ca^{2+} -dependent inactivation process has also been described for Ca^{2+} channels in cardiac cells, and this represents a negative-feedback mechanism for regulating L-type Ca^{2+} channel activity.¹⁹⁹ It appears that a Ca^{2+} -binding EF-hand motif in the C terminus of the α_1 subunit contributes to the Ca^{2+} -dependent inactivation process.

The $\alpha_2\delta$ subunit is a medium-sized (140–170 kDa) and heavily glycosylated protein that regulates the trafficking, function, and pharmacology of voltage-gated Ca^{2+} channels.²⁰⁰ This subunit is composed of two domains, α_2 and δ , which are in fact products of the same gene. After translation, the $\alpha_2\delta$ protein is cleaved to produce the larger α_2 and the smaller δ domains that then become linked by disulfide bonds. The $\alpha_2\delta$ subunit is anchored in the membrane by the δ domain, which has one transmembrane segment and contains the intracellular C terminus of the protein.²⁰¹ In contrast, the α_2 domain is located extracellularly, and it is this part of the protein that interacts with the α_1 subunit to modulate membrane insertion and functional properties of the resultant Ca^{2+} channel. Interestingly, both α_2 and δ domains are required for gabapentin binding.²⁰²

Unlike the Na^+ channel β subunits, which are anchored in the cell membrane, the Ca^{2+} channel β subunits are soluble proteins (52–78 kDa) that are found in the cytosol.²⁰³ Crystallization studies with recombinant protein revealed that Ca^{2+} channel β subunits exhibit a high-affinity interaction with the AID in the DI–DII linker of the α_1 subunit by virtue of multiple protein-interacting modules.²⁰⁴ Homology modeling of the β subunits has identified Src homology 3 (SH3) and guanylate kinase (GK) motifs, both of which are essential for producing normal Ca^{2+} currents.²⁰⁵ An additional role of the β subunit is to mask an endoplasmic retention signal in the DI–DII loop of the α_1 subunit, thereby facilitating cell surface expression of the channel.²⁰⁶ The AID region of the α_1 subunit does not appear to mediate the functional effects of the β subunit directly. Rather, its purpose appears to be to ensure correct orientation of the β subunit. For instance, when the β subunit interacts with the AID, it is positioned close to the intracellular end of S6 in DI, and may influence its ability to move, resulting in altered channel inactivation kinetics.²⁰⁷ Furthermore, isoform-specific effects of β subunits on the function of the channel occur through contacts in the α_1 subunit that reside outside of the AID,²⁰⁸ including the N terminus.²⁰⁹ The distinct regulatory properties of the β_{2a} subunit appear to be controlled by its state of palmitoylation, and so this mechanism contributes to the functional diversity within the Ca^{2+} channel family.²¹⁰

The γ subunit is an integral component of some voltage-gated Ca^{2+} channels.²¹¹ Ca^{2+} channel γ subunits are glycosylated proteins (25 kDa) that contain four transmembrane segments with intracellular N and C termini, as well as a conserved N-linked glycosylation site and a signature GLWXXC motif in the first extracellular loop. The γ subunits typically have an inhibitory effect on Ca^{2+} channel function, but do not modulate channel insertion into the membrane.

2.21.3.4 Physiological Functions

Ca^{2+} is a ubiquitous intracellular second messenger that activates a multitude of effector molecules and downstream processes in excitable cells, including neurons, myocytes, and neuroendocrine cells, as well as nonexcitable cells such as osteoblasts, lymphocytes, mast cells, and endothelial cells. Normally, the cytoplasmic concentration of free Ca^{2+} is kept low (0.1 μM) by Ca^{2+} -binding proteins and Ca^{2+} pumps that transport Ca^{2+} ions across the plasma membrane or the membranes of intracellular organelles.²¹² However, the cytoplasmic Ca^{2+} level may become elevated 10-fold or more during cellular activity. While voltage-gated Na^+ and K^+ channels govern action potential initiation and propagation, it is the voltage-gated Ca^{2+} channels that represent the most significant and obvious signal transduction mechanism that links membrane electrical activity to intracellular events. Voltage-gated Ca^{2+} channels are important dynamic regulators of intracellular Ca^{2+} levels because when they are open, positively charged Ca^{2+} ions can move passively into the cell according to the driving force provided by their electrochemical gradient. The elevation of intracellular Ca^{2+} that accompanies Ca^{2+} channel opening contributes to many physiologically significant events such as excitation–secretion coupling in neurons and endocrine cells, excitation–contraction coupling in muscle cells, as well as regulation of cell growth, proliferation, and differentiation.

Ca^{2+} channels operate by undergoing voltage-dependent gating transitions between conducting and nonconducting states in response to changes in the transmembrane voltage of the cell. The voltage dependencies and rates of these transitions are defining characteristics of different Ca^{2+} channel subtypes, and, ultimately, voltage-dependent Ca^{2+} influx will be shaped by the kinetics of channel activation, inactivation, and deactivation processes. The T-type Ca^{2+} channels are low-threshold in nature (i.e., they begin to open when the membrane potential depolarizes from -90 mV to beyond -70 mV) and their currents are transient in nature as a result of relatively fast activation and inactivation processes. However, their deactivation process is slow, and, consequently, in excitable cells they permit most Ca^{2+} entry during the action potential repolarization phase.²¹³ In contrast, most L-, N-, and P/Q-type channels are high-threshold in nature, and do not begin to open until the membrane depolarizes beyond -30 mV. Compared with T-type Ca^{2+} channels, their activation and inactivation processes are relatively slow, whereas their deactivation process tends to be more rapid. Therefore, most of their Ca^{2+} influx occurs during depolarization, and longer action potentials will evoke more Ca^{2+} influx.²¹³ Many Ca^{2+} channels display pronounced overlap in the voltage dependence of activation and inactivation, and, consequently, a small percentage of channels may fail to inactivate at certain membrane potentials, leading to the appearance of a so-called window current.^{167,214} The window current is important because it permits physiologically relevant Ca^{2+} entry even under depolarized conditions in vascular smooth muscle cells²¹⁵ and neurons.²¹⁶ Ca^{2+} influx generally exerts a depolarizing influence on the cell membrane, and also acts as a second messenger for the initiation of downstream processes. In electrically excitable cells, the direct depolarizing influence of Ca^{2+} entering the cell can result in the activation of other voltage-gated ion channels, such as Na^+ channels, and these may serve to amplify and accelerate the response of the membrane to depolarization. The second messenger effects of Ca^{2+} include activation of Ca^{2+} -activated K^+ channels, which may exert counteracting inhibitory effects on

membrane excitation through hyperpolarizing and/or current-shunting actions. Therefore, a consequence of Ca^{2+} channel activation in excitable cells may be an increased complexity of membrane electrical responsiveness. The extensive diversity in the molecular composition, tissue distribution, and functional properties of Ca^{2+} channels is consistent with the diversity in the physiological roles that they play in different cells.

Skeletal muscle contracts in response to acetylcholine release from the terminals of motor neurons at the neuromuscular junction. Acetylcholine activates nicotinic cholinergic receptors on the membrane of the skeletal muscle, leading to the generation of an endplate potential that may be large enough to induce a Na^+ channel-dependent action potential. This action potential pervades the muscle cell membrane, including the transverse tubule system that projects deeply into the cell. Although the skeletal muscle L-type Ca^{2+} channel complex is localized to both the plasma and transverse tubule membranes, Ca^{2+} influx through this channel is not required for skeletal muscle contraction. Rather, the L-type Ca^{2+} channel is tightly associated with RyR_1 , which is localized on the membrane of internal Ca^{2+} stores, where it functions as a Ca^{2+} release channel. The L-type Ca^{2+} channel acts as a voltage-sensor, and effectively couples membrane depolarization to activation of RyR_1 . Functional coupling of L-type Ca^{2+} channel activation to RyR_1 activation in skeletal muscle provides a mechanism by which plasma membrane depolarization can evoke rapid release of Ca^{2+} from the sarcoplasmic reticulum. This causes the large increase in intracellular Ca^{2+} concentration that is required for the contraction of skeletal muscle fibers.

In contrast to skeletal muscle, the contraction of cardiac muscle is not initiated by the release of a neurotransmitter from nerve terminals, and does not rely solely on the L-type Ca^{2+} channel acting as a voltage sensor. Instead, cardiac muscle contraction is initiated by the spread of spontaneous, regularly spaced single action potentials that originate in the pacemaker tissue of the SA node. Cardiac action potentials spread from the SA node to the AV node, and then to the working cells of the heart via specialized cells that constitute the conduction system. While these action potentials are Na^+ -dependent, gene knockout and pharmacological studies have suggested that $\text{Ca}_v1.3$ -containing L-type¹⁶⁶ and $\text{Ca}_v3.2$ -containing T-type²¹⁷ Ca^{2+} channels contribute to the control of heart rate. Although no T-type Ca^{2+} current has ever been recorded from human atrial cells, the biophysical properties of T-type channels and the clinical effects of mibefradil, a moderately selective T-type Ca^{2+} channel blocker, are also consistent with a role in pacemaking. When action potentials invade the plasma membrane and transverse tubule membrane of cardiac myocytes, the ensuing activation of $\text{Ca}_v1.2$ -containing L-type channels is critical for cardiac contractility. L-type channels are functionally coupled to RyR_2 , which unlike RyR_1 is activated by Ca^{2+} . Therefore, Ca^{2+} influx through L-type Ca^{2+} channels represents a crucial step in the excitation-contraction process in cardiac myocytes. Intracellular Ca^{2+} serves as a second messenger to activate RyR_2 , which in turn causes the release of Ca^{2+} from the sarcoplasmic reticulum. The influx of positively charged Ca^{2+} ions, coordinated with sustained Na^+ influx through persistent Na^+ channels and delayed K^+ efflux through voltage-gated K^+ channels, supports the generation of a relatively long cardiac action potential. Prolonged membrane depolarization is significant in the heart because it drives further Ca^{2+} influx to maintain the ventricles in a contracted state for long enough to eject most of the blood during systole. Furthermore, the prolonged membrane depolarization sets the effective refractory period by maintaining most of the voltage-gated Na^+ channels in inactivated states, thereby reducing membrane excitability. Unlike skeletal muscle, the ventricle cannot usually respond to premature action potentials, and can therefore avoid entering a dangerous state of fibrillation. As a consequence of the multiple roles that the various L-type channels play in cardiac function, certain Ca^{2+} channel blockers may exert both negative chronotropic and negative inotropic effects on the heart. Furthermore, neurons of the autonomic nervous system release neurotransmitters that act through adrenergic and cholinergic receptors to modulate the function of cardiac ion channels, thereby regulating the rate of depolarization in the SA node, action potential conduction velocity, as well as the force of cardiac muscle contraction.

Vascular smooth muscle cells in resistance arteries and arterioles express L- and T-type Ca^{2+} channels.²¹⁸ Both subtypes of channel permit physiologically significant Ca^{2+} influx that leads to activation of calmodulin and myosin light chain kinase. In turn, this leads to enhanced myosin light chain phosphorylation and smooth muscle contraction.²¹⁹ Both types of Ca^{2+} channel are involved not only in maintaining basal myogenic tone but also in regulating the reactivity of vascular smooth muscle cells to increased intraluminal tension and the presence of vasoactive substances. The expression of voltage-gated Ca^{2+} channels in vascular smooth muscle also correlates with cell proliferation rates. In particular, neointima formation, which occurs in response to vascular injury and hypertension, involves excessive smooth muscle cell proliferation and Ca^{2+} influx through T-type channels has been implicated in this pathological process.²²⁰

All three subfamilies of voltage-gated Ca^{2+} channel are well-represented in central and peripheral neurons.²²¹ At the subcellular level, both high- and low-threshold Ca^{2+} channels are found at postsynaptic and somatic sites, where they control the integration of synaptic inputs and the responsiveness of the neuron.²²² High-threshold Ca^{2+} channels are also found at presynaptic sites, where they regulate neurotransmitter release in response to action potential invasion of the nerve terminal. The N-type Ca^{2+} channels are of special interest because of their exclusive presynaptic

localization at many central synapses.¹⁸⁰ This includes the central terminals of primary afferent neurons in the superficial laminae of the dorsal horn in the spinal cord,¹⁷⁴ where they control the release of nociceptive neurotransmitters.²²³ In contrast, P-type Ca^{2+} channels provide the Ca^{2+} influx that is necessary to trigger acetylcholine release at the neuromuscular junction.^{224,225} P-type channels also contribute to the control of neurotransmitter release at multiple synapses throughout the CNS and PNS.^{226–228} Interestingly, N- and P-type Ca^{2+} channels may coexist at certain synapses, where the distinct functional properties of both subtypes enable them to modulate differentially the pattern of action potential-evoked neurotransmitter release.²²⁹ Furthermore, circumstances that alter the expression level of one subtype often cause compensatory changes in the expression level of other Ca^{2+} channels.^{230,231} While $\text{Ca}_v2.2$ knockout mice are viable, disruption of $\text{Ca}_v2.1$ expression leads to a severe neurological deficit and, ultimately, death. Therefore, P-type Ca^{2+} channels appear to be more important than N-type Ca^{2+} channels in the control of critical neurological and life functions. Interestingly, the so-called stargazer mouse is an ataxic and epileptic mutant mouse that is associated with an abnormal neuronal Ca^{2+} channel auxiliary subunit. The affected protein in stargazer is a homolog of the γ_1 auxiliary subunit of the skeletal muscle L-type Ca^{2+} channel, and is called stargazin or γ_2 .²³² Stargazin is enriched in synaptic plasma membranes, and has been shown to interact not only with voltage-gated Ca^{2+} channel α_1 subunits, including $\text{Ca}_v2.1$,^{233,234} but also with AMPA glutamatergic receptors and the synaptic scaffolding protein, PSD-95.²³⁵ Stargazin clearly represents a multifunctional protein that, despite its relatively small size, plays an exceptionally important role in the normal functioning of the brain.

The biophysical properties and distribution patterns of T-type Ca^{2+} channels allow them to exert profound influences on action potential firing patterns in both peripheral and central neurons. Depending on the membrane potential, some neurons may respond to excitation by firing action potentials either in a tonic or a phasic manner.^{236–238} This switch is dependent on the presence and availability of T-type Ca^{2+} channels. At relatively depolarized resting membrane potentials (e.g., -50 mV), T-type channels are inactivated, and membrane excitation typically leads to the generation of a single Na^+ -dependent action potential (tonic firing). In contrast, at more negative resting membrane potentials (e.g., -90 mV), T-type Ca^{2+} channels are resting, and, in this case, membrane excitation can activate the T-type channels. This leads to the generation of a low-threshold spike (LTS) that briefly maintains the membrane potential in a depolarized state and allows the repetitive activation of voltage-gated Na^+ and K^+ channels. Thus, the T-type channel-dependent LTS promotes the generation of high-frequency action potential bursts (phasic firing). The action potential burst terminates partly as a consequence of time-dependent inactivation of the T-type channels and also because of the opening of Ca^{2+} -activated K^+ channels. Burst firing is an important electrophysiological phenomenon because it is intimately involved in the promotion of rhythmic/oscillatory behavior in neuronal circuits and also in the generation of sleep patterns, epileptiform activity, and nociception.²³⁹

2.21.3.5 Regulation

The function of voltage-gated Ca^{2+} channels is subject to complex modulation by several mechanisms, including GPCR-activated pathways.²⁴⁰ Ca^{2+} channel modulation may occur via direct influences on the biophysical properties of the α_1 subunit or via influences on its ability to associate with Ca^{2+} channel auxiliary subunits and other regulatory proteins.²⁴¹ Furthermore, through their modulatory actions on G_{α} , regulators of G protein signaling (RGS) molecules add an additional level of complexity to Ca^{2+} channel modulation.²⁴² Activation of phospholipase C-coupled G_{α_q} leads to the production of inositol triphosphate (IP_3) and diacylglycerol (DAG). In turn, DAG activates PKC, which can enhance L- and N-type Ca^{2+} channel function.^{243,244} In addition, activation of adenylate cyclase-coupled G_{α_s} and G_{α_i} can regulate (in opposite directions) the intracellular level of cAMP. Manipulations that increase intracellular cAMP cause activation of PKA, which can enhance L-type Ca^{2+} channel function in the heart and vascular smooth muscle.^{245,246} In contrast, and apparently in a G protein isoform-specific manner,²⁴⁷ $G_{\beta\gamma}$ exerts inhibitory effects on both HVA and LVA Ca^{2+} currents. The $\text{Ca}_v3.2$ subunit is subject to $G_{\beta\gamma}$ modulation via a site that is located on the DII–DIII linker,²⁴⁸ whereas multiple loci have been identified where $G_{\beta\gamma}$ may interact with $\text{Ca}_v2.1$ and $\text{Ca}_v2.2$, including the DI–DII intracellular linker and portions of the N- and C-terminal domains.^{249,250} Biochemical studies suggest that $G_{\beta\gamma}$ competes with the Ca^{2+} channel auxiliary β subunit for binding to the DI–DII linker. Therefore, it is possible that some of the inhibitory effects of $G_{\beta\gamma}$ on N-type Ca^{2+} channel function may be mediated by displacement of the auxiliary β subunit.²⁵¹ In the cases of N- and P/Q-type Ca^{2+} channels, $G_{\beta\gamma}$ appears to stabilize the channels in a reluctant gating mode, thereby inhibiting the Ca^{2+} influx required for neurotransmitter release.²⁵² This is a key mechanism in the spinal analgesic actions of opioid receptor agonists. The voltage-gated Ca^{2+} channel α_1 subunit may serve as an integrator of multiple signals, since both strong membrane depolarization and PKC activation stabilize the channels in a willing gating mode, and therefore can prevent inhibition of the channel by $G_{\beta\gamma}$.²⁵³ In conclusion, voltage-gated Ca^{2+} channels are subject to complex regulation by intracellular second-messenger signaling pathways.

2.21.3.6 Prototypical Pharmacology

The pharmacology of Ca^{2+} channels has been studied extensively in native cells and heterologous expression systems. While potency and selectivity determinations at recombinant channels are important, it is the pharmacology of native channels that is of prime importance in elucidating the mechanism of action of a drug. Ion permeation through Ca^{2+} channels can be modulated by a wide variety of substances, suggesting that these channels contain multiple ligand-binding sites. The three main types of blockers that will be discussed are inorganic metal cations, invertebrate-derived peptide toxins, and organic small molecules (see [Table 3](#)). With the exception of the small-molecule drugs gabapentin and pregabalin, both of which bind with high affinity to the Ca^{2+} channel $\alpha_2\delta$ subunit, most Ca^{2+} channel modulators bind to the α_1 subunit to modulate channel function. While selective blockers of N-, P/Q-, and L-type Ca^{2+} channels exist, no ligand that is truly specific for T-type channels has been discovered. Inorganic divalent (e.g., cadmium, nickel, and zinc) and trivalent (e.g., yttrium and holmium) metal cations are potent blockers of voltage-gated Ca^{2+} channels, and are used routinely to probe the functional roles of Ca^{2+} channels in various isolated tissues. For example, they are capable of interfering with Ca^{2+} channel-dependent physiological processes such as neuronal synaptic transmission,²⁵⁴ hormone secretion,²⁵⁵ and cardiac pacemaking.²⁵⁶ Due to their generally poor selectivity profiles, metal cations have limited application in defining the subunit composition of native Ca^{2+} channels, although nickel is interesting because it is relatively selective for T-type Ca^{2+} channels. Furthermore, within the Ca_v3 family, it displays moderate selectivity for the $\text{Ca}_v3.2$ subtype, and can therefore be used as a tool to dissect certain components of complex native LVA Ca^{2+} currents.²⁵⁷ Mechanistically, the metal cations appear to compete with Ca^{2+} for its binding site in the pore of the channel, and so increasing the concentration of Ca^{2+} can overcome metal cation-induced block. A multitude of ion channel-modulating peptide toxins have been purified from the venoms of several invertebrate species. Many of these toxins display great selectivity for certain voltage-gated Ca^{2+} channels, particularly the N and P/Q types, and, as such, they have proven to be extremely useful in investigating the expression and functional roles of Ca^{2+} channels in a variety of neuronal tissues. Of particular interest are the N-type channel-selective ω -conotoxins GVIA,²⁵⁸ MVIIA,²⁵⁹ and CVID,²⁶⁰ which were isolated from the venoms of the marine snails *Conus geographus*, *Conus magus*, and *Conus catus*, respectively. These ω -conotoxins selectively block ion permeation through N-type Ca^{2+} channels by binding with high affinity to the S5–S6 region of DIII, and thereby occluding the pore. They inhibit the presynaptic Ca^{2+} influx that is necessary to trigger exocytotic vesicle fusion, and have been instrumental in substantiating the role of N-type Ca^{2+} channels in controlling neurotransmitter release at many central and peripheral synapses. The toxin MVIIA is of immense therapeutic interest because a synthetic version (SNX-111 or ziconotide (Prialt)) has been approved by regulatory organizations in several countries for the symptomatic treatment of intractable severe pain. This drug likely alleviates pain by inhibiting nociceptive signal transmission in the spinal cord.²⁶¹ Invertebrate-derived peptide toxins have also proven useful in the investigation of neuronal P/Q-type Ca^{2+} channels. Even though these channels are products of the same gene (i.e., $\text{Ca}_v2.1$),²⁶² they actually exhibit defining differences in their pharmacological profiles. While both subtypes are blocked by ω -conotoxin *MVIIIC*, the Q-type channel is distinguished from the P-type channel by its lower sensitivity to block by the funnel-web spider (*Agelenopsis aperta*) peptide ω -agatoxin IVA.¹⁵¹ Together, all of these marine snail and spider toxins have been used to determine the relative contributions of N-, P-, and Q-type Ca^{2+} channels to the control of neurotransmission at mammalian neuronal and neuromuscular synapses. In contrast to the plethora of peptides that selectively target high-threshold Ca^{2+} channels, less progress has been made toward the discovery of T-type channel-selective peptides. Kurtoxin, which was isolated from scorpion venom (*Parabuthus transvaalicus*),²⁶³ reduces T-type Ca^{2+} currents in thalamic neurons²⁶⁴ and spermatogenic cells.²⁶⁵ Electrophysiological studies with multiple recombinant Ca^{2+} channels have demonstrated that it is somewhat selective for Ca_v3 -containing channels. Within the T-type Ca^{2+} channel family, the $\text{Ca}_v3.1$ and $\text{Ca}_v3.2$ subtypes are more sensitive to block than $\text{Ca}_v3.3$, and so kurtoxin may help define the molecular identity of complex T-type Ca^{2+} currents in native tissue. In contrast to the high-threshold Ca^{2+} channel pore-blocking toxins, kurtoxin appears to reduce Ca^{2+} currents by interfering with the channel activation mechanism. Other toxins that inhibit LVA Ca^{2+} currents by interfering with gating include the tarantula venom (*Thrixopelma pruriens*) peptides ProTx-I and ProTx-II.²⁶⁶

A diverse collection of small molecules, belonging to several distinct chemical classes, displays Ca^{2+} channel-modulating abilities. The classical Ca^{2+} channel blockers are represented by the dihydropyridines (e.g., nifedipine), phenylalkylamines (e.g., verapamil), and benzothiazepines (e.g., diltiazem) (see [Table 3](#)). These drugs are normally considered to be selective for L-type Ca^{2+} channels, although there are examples of dihydropyridines that also block T-type channels. The binding sites for these Ca^{2+} channel modulators have been localized to various regions of the α_1 subunit, and at least some of the amino acid residues that are involved in these interactions have been described. Most of their binding sites are in close proximity to or are allosterically coupled to the channel pore and gating machinery. In particular, the S5, S6, and pore regions of DIII and DIV are critically involved in the interaction between

the L-type Ca^{2+} channel and the dihydropyridines,^{267,268} phenylalkylamines,^{269,270} and benzothiazepines,^{271,272} although distinct groups of amino acids appear to be involved in the binding of each class. Even though they share a common molecular target, there are important mechanistic differences in these drugs. Many of the newer dihydropyridines display higher affinity for the inactivated states of the Ca^{2+} channel,²⁷³ and, so, in accordance with the MRH and GRH, their blocking potency is predicted to be greater under depolarized conditions. In contrast, the phenylalkylamines appear to target the open state preferentially.²⁷⁴

The tetralol derivative, mibefradil is differentiated from these classical Ca^{2+} channel blockers on the basis of its novel antihypertensive mechanism of action. Mibefradil is a potent inhibitor of LVA Ca^{2+} currents in a variety of cell types, including vascular smooth muscle cells²⁷⁵ and cardiac pacemaking cells,²⁷⁶ as well as peripheral²⁷⁷ and central^{278,279} neurons. Mibefradil also potently inhibits Ca^{2+} currents in mammalian cells expressing recombinant Ca_v3 subunits, although it displays no subtype selectivity.^{214,280,281} Mibefradil has high affinity for inactivated states of the T-type Ca^{2+} channel, and therefore its apparent potency increases under depolarized conditions, possibly explaining the favorable vascular to cardiac tissue selectivity ratio of this drug. Despite its widespread acceptance as a selective blocker of T-type Ca^{2+} channels, mibefradil also interacts with L-type Ca^{2+} channels at a site that is distinct from the classical Ca^{2+} channel blocker-binding sites. Mibefradil displays approximately 10-fold selectivity for Ca_v3 over $\text{Ca}_v1.2$, although analogs with improved potency and selectivity profiles have also been described.²⁸²

Modulation of neuronal Ca^{2+} channels appears to be at least a component of the mechanism of action of a large number of diverse drugs that are used to treat nervous system disorders. This includes antiepileptic drugs such as phenytoin, gabapentin, pregabalin, ethosuximide, and zonisamide as well as diphenylbutylpiperidine derivatives such as pimozone and penfluridol that, owing to their high-affinity antagonism at dopamine D_2 receptors, are commonly used as neuroleptic drugs. Also included are the diphenylmethylpiperazines such as flunarizine and cinnarizine that are neuroprotective and may be used to treat a variety of conditions, including migraine, vertigo, and epilepsy. Most of the antiepileptic drugs are relatively nonselective Ca^{2+} channel blockers, although ethosuximide and zonisamide appear to work by a distinct molecular mechanism involving a reduction in membrane responsiveness through preferential block of neuronal T-type Ca^{2+} channels.^{283,284} Neither drug discriminates between the three different T-type Ca^{2+} channel α_1 subunits,²⁸⁵ and, like the other antiepileptic drugs mentioned, the interaction of ethosuximide and zonisamide with T-type Ca^{2+} channels is state-dependent, although differences exist. Whereas ethosuximide behaves as an open-state blocker,²⁸⁵ zonisamide interacts preferentially with inactivated states.²⁸⁶ Both classes of diphenyl-containing drugs are noteworthy because several representatives are potent Ca^{2+} channel blockers that display moderate selectivity for T-type and N-type channels.^{287,288} In general, these drugs preferentially interact with and stabilize inactivated states of the channel. Substitution at the diphenyl group, to produce 4-arylpiperidine or 4-arylpiperidinol compounds, is an effective method for reducing the affinity of binding at the dopamine D_2 receptor while at the same time maintaining potency at neuronal T-type Ca^{2+} channels.^{289,290} Compounds with this profile remain active in models of neuroprotection and epilepsy, and, if they were to be developed clinically, they could potentially be devoid of adverse extrapyramidal side effects that are associated with D_2 receptor antagonism. As with mibefradil, it has been proposed that the diphenyl-containing drugs bind to a site that is distinct from those of the classical Ca^{2+} channel blockers. The precise amino acid residues that comprise this unique site have not yet been fully defined, but the site seems to be located intracellularly and may include the DI–DII linker.²⁹¹ This happens to be where both the auxiliary β subunit and G protein $\beta\gamma$ subunits bind to regulate Ca^{2+} channel function. Consequently, the diphenyl pharmacology of the Ca^{2+} channel may be modulated by the β subunit isoform contained in the channel complex and by the extent of G protein activation in the cell.

2.21.3.7 Prototypical Therapeutics

Dysregulation of Ca^{2+} handling underlies a variety of pathological conditions that may be associated with abnormal gene transcription, uncontrolled cell proliferation, and aberrant electrical activity. Therefore, ion channels that contribute to the regulation of intracellular Ca^{2+} levels represent an attractive group of targets for potentially treating disorders that are characterized by abnormal regulation of Ca^{2+} -dependent signaling. In particular, voltage-gated Ca^{2+} channels represent well-validated targets for a number of diseases that involve overactivity of excitable cells. Indeed, a large number of commonly prescribed drugs that block Ca^{2+} channels have significant beneficial impact in the treatment of cardiovascular and nervous system disorders, although clearly there is room for improvement. An increased understanding of the specific voltage-gated Ca^{2+} channels that are functionally important in relevant cell types is expected to aid not only in the discovery and development of new drugs for treating cardiovascular and nervous system diseases but also in the identification of novel disease opportunities.

Ca^{2+} channel blockers have been used successfully for many years in the clinical management of cardiovascular diseases such as hypertension, angina pectoris, and cardiac arrhythmias.²⁹² This therapeutic profile is consistent with the physiological roles that voltage-gated Ca^{2+} channels play in the blood vessels and heart, including initiation of the muscle contraction process in both tissues and generation of the prolonged action potential in the heart. The dihydropyridine drugs exert their therapeutic effects primarily through blockade of L-type Ca^{2+} channels in vascular smooth muscle cells. This promotes arterial dilation and leads to a reduction in the resistance to circulation of the blood. Arterial relaxation in the peripheral vasculature is therapeutically beneficial in conditions of hypertension, whereas relaxation of coronary arteries is a successful approach to the treatment of angina pectoris. Even though L-type Ca^{2+} channels are also expressed in the heart, some dihydropyridine drugs display a favorable vascular to cardiac tissue selectivity ratio,²⁹³ and this may help them to avoid negative inotropism. The molecular basis of the vascular selectivity is twofold. First, the membrane potential tends to be more depolarized in vascular smooth muscle cells than in cardiac muscle cells. Therefore, drugs that interact preferentially with inactivated states of the channel will tend to be more potent at relaxing vascular smooth muscle. Second, different splice variants of $\text{Ca}_v1.2$ are expressed in the cardiovascular system, and the smooth muscle specific variant appears to have a higher sensitivity than the cardiac variant to inhibition by certain dihydropyridines.²⁹⁴ Thus, differences in membrane potential coupled with the tissue-specific expression of splice variants displaying different drug sensitivities represent a plausible explanation for the favorable vascular selectivity displayed by novel dihydropyridines. In addition, it is fortuitous that the $\text{Ca}_v1.3$ ²⁹⁵ and $\text{Ca}_v1.4$ ^{296,297} subtypes also appear to be less sensitive to inhibition by many commonly used Ca^{2+} channel blockers, and so the potential side effects of bradycardia and vision impairment are not expected with these drugs.

Some L-type Ca^{2+} channel blockers have proven to be useful in the treatment of cardiac arrhythmias of supraventricular origin, including those associated with AV node re-entry.²⁹⁸ Open-state blockers of L-type Ca^{2+} channels, such as the phenylalkylamine verapamil, are particularly effective. The antiarrhythmic effect of verapamil occurs largely as a result of its actions on the SA and AV nodes, where impulse conduction is Ca^{2+} channel-dependent. Verapamil shortens the duration of nodal action potentials, depresses AV node conduction, and prolongs the effective refractory period, without altering normal atrial or ventricular conduction time.

Selective T-type Ca^{2+} channel blockers represent a novel and potentially improved approach to the treatment of cardiovascular disease.²⁹⁹ Mibefradil was marketed briefly as an antihypertensive drug (Posicor), and, as exemplified by its clinical utility, selective T-type Ca^{2+} channel blockers are expected to be useful in the treatment of hypertension and angina pectoris, as well as in reducing cardiac ischemia-induced infarct damage. If mibefradil is indicative, then selective T-type Ca^{2+} channel blockers may also protect against the tachycardia-induced atrial remodeling that plays a role in maintenance and recurrence of atrial fibrillation. Unlike dihydropyridine drugs, selective T-type channel blockers have the desirable potential of lowering blood pressure without unwanted negative inotropic effects on the heart.

Ca^{2+} channels contribute to the appearance of diseases associated with neuronal hyperexcitability, such as epilepsy and certain sensory abnormalities. Neuronal hyperexcitability may occur due to extrinsic mechanisms such as enhanced excitatory synaptic input or reduced inhibitory input, as well as intrinsic mechanisms such as changes in the electrical properties of the neuronal membrane. Perhaps indicative of similarities in the underlying molecular mechanisms of such diseases, many Ca^{2+} channel modulators (e.g., phenytoin, gabapentin, pregabalin, ethosuximide, and zonisamide) are used successfully to treat certain forms of epilepsy and chronic pain in humans. These drugs have in common an ability to decrease neuronal excitability by inhibiting the function of Ca^{2+} channels that are involved either in increasing neuronal membrane responsiveness (e.g., T-type channels) or in promoting neurotransmitter release (e.g., N- and P/Q-type channels). Open- and inactivated-state interactions are common among the Ca^{2+} channel-blocking antiepileptic drugs, and this state dependence permits the preferential targeting of pathological neurons. The mechanism of action of the T-type channel blockers likely involves inhibition of Ca^{2+} -dependent LTS, interruption of neuronal burst firing, and abolition of rhythmic electrical behavior in affected neuronal circuits. The mechanism of action of the N-type Ca^{2+} channel blockers likely involves the reduction of excitatory and, possibly, inhibitory neurotransmitter release in the CNS. Interestingly, α_{1B} and $\alpha_2\delta$ subunits are upregulated in peripheral sensory neurons following nerve injury or tissue inflammation, suggesting that N-type Ca^{2+} channels continue to play a dominant role in controlling nociceptive signal transmission under pathological conditions.^{300–305} Indeed, blockade of N-type Ca^{2+} channels that control the release of excitatory neurotransmitters involved in the processing of nociceptive information at the level of the spinal cord is a clinically proven mechanism for the management of pain in humans. Ziconotide, which contains the active ingredient ω -conotoxin MVIIA (SNX-111), is effective at treating a wide range of intractable pain conditions in humans,^{306–308} and has been approved in several countries worldwide for the treatment of intractable severe chronic pain.

As indicated already, most Ca^{2+} channel-modulating drugs bind directly to the pore-forming α_1 subunits to inhibit ion permeation. Gabapentin (Neurontin) and pregabalin (Lyrica) are two structurally related drugs that display similar but not identical antiepileptic and analgesic properties in a wide range of clinical settings. While their mechanism of

action remains to be fully clarified, these drugs are unique in that they bind with high affinity to the Ca^{2+} channel $\alpha_2\delta$ subunit.^{309,310} In particular, the $\alpha_2\delta_1$ subtype appears to be essential for the analgesic actions of pregabalin.³¹¹ Gabapentin and pregabalin have been reported to inhibit HVA Ca^{2+} currents in central and peripheral neurons,^{312–316} although there are some reports to the contrary.^{317,318} A possible explanation for the discrepancies could be the precise subunit composition of native Ca^{2+} channels in different neuronal populations.³¹⁹ It has been postulated that the mechanism of action of these drugs actually involves binding to the Ca^{2+} channel $\alpha_2\delta$ subunit, blockade of presynaptic Ca^{2+} influx, with inhibition of neurotransmitter release in brain^{320–322} and in the spinal cord.^{323–326} Given the non-pore-forming role of the $\alpha_2\delta$ subunit and the small physical size of gabapentin and pregabalin, it may be the case that these drugs modulate ion permeation through a subtle mechanism, perhaps by modifying Ca^{2+} channel gating processes and/or the kinetics of resting–open–inactivated state transitions.^{327,328} Interestingly, mutations in the gene encoding $\alpha_2\delta_2$ have been found to underlie the mouse *ducky* phenotype, which is characterized by spike wave seizures and cerebellar ataxia, and is considered to be a model for absence epilepsy.

2.21.3.8 Genetic Diseases

Many diseases have strong genetic predispositions. Not surprisingly, given their integral role in the control of cellular function, mutations in Ca^{2+} channel pore forming and auxiliary subunits have been implicated in certain diseases involving electrically excitable cells. Most Ca^{2+} channelopathies are associated with mutations in the *CACNA1A* gene, leading to abnormalities of the P/Q-type channel, although mutations in L-type Ca^{2+} channel genes are also known.

CACNA1A-associated disorders include familial hemiplegic migraine (FHM), spinocerebellar ataxia type 6 (SCA6), episodic ataxia type 2 (EA2), and absence epilepsy.³²⁹ FHM is an autosomal-dominant disorder that is sometimes associated with a mild permanent cerebellar ataxia. FHM is associated with more than 10 different missense mutations in the *CACNA1A* gene, and these induce a variety of functional changes in $\text{Ca}_v2.1$ -containing channels. Most of these mutations affect the biophysical properties of P/Q-type currents, and a common mechanism appears to be the alteration of channel gating. The genetic mutations that are associated with FHM sometimes affect voltage-sensing regions of the channel,³³⁰ leading to gain of function phenotypes where Ca^{2+} influx is enhanced at negative membrane potentials.³³¹ In addition, the inactivation process may be affected,³³² and some mutations appear to relieve G protein $\beta\gamma$ subunit-mediated inhibition of channel activity.³³³ The P/Q-type Ca^{2+} channel phenotypes appear to favor a persistent state of neuronal membrane hyperexcitability, potentially leading to an increase in action potential-triggered vasoactive neurotransmitter release from neurons in the trigeminal ganglia. Consequently, Ca^{2+} channel blockers such as verapamil may represent effective therapies for the treatment of this inherited form of migraine.³³⁴ SCA6 is a dominantly inherited degenerative disorder of the cerebellum, characterized by progressive death of Purkinje cells. SCA6 is associated with an expansion of a trinucleotide CAG repeat in the 3' region of the *CACNA1A* gene, leading to an expanded tract of glutamine residues in $\text{Ca}_v2.1$ subunits that are expressed in cerebellar Purkinje cell bodies and dendrites. This results in a gain of function phenotype, leading to excessive Ca^{2+} entry and Purkinje cell degeneration.³³⁵ EA2 is an autosomal-dominant channelopathy. A few EA2-associated genetic mutations have been described, and these tend to affect regions of the $\text{Ca}_v2.1$ α_1 subunit that are important for the normal permeation and gating of the channel.³³⁶ Often, these mutations lead to $\text{Ca}_v2.1$ protein truncation, and they have similar functional consequences in that they cause a complete loss of P/Q-type Ca^{2+} current.^{337–339}

A couple of inherited diseases are associated with dysfunction of the L-type Ca^{2+} channel-RyR₁ complex in skeletal muscle. Hypokalemic periodic paralysis is an autosomal-dominant skeletal muscle disorder manifested by episodes of weakness under conditions of reduced serum K^+ concentrations. Hypokalemic periodic paralysis seems to be caused by mutations in *CACNA1S* that result in loss of function of the skeletal muscle L-type Ca^{2+} channel. This channel acts as a voltage sensor in skeletal muscle, coupling membrane depolarization to the release of intracellular Ca^{2+} . Mutations have been identified that affect positively charged amino acids in the voltage-sensing S4 of DII and DIV.^{340,341} Although not very well understood, the loss of function in the voltage sensor may be associated with muscle weakness, because the skeletal muscle would be unable to respond normally to membrane depolarization. Malignant hyperthermia is an autosomal-dominant disorder of skeletal muscle. It is manifested as a potentially fatal hypermetabolic condition that is triggered by commonly used volatile anesthetics, such as halothane. During exposure to such agents, an increase in intracellular Ca^{2+} concentration leads to sustained muscle contractions with increased muscle metabolism and heat production, triggering hyperthermia. Malignant hyperthermia appears to be caused by mutations in the gene encoding the RyR₁ Ca^{2+} release channel of the sarcoplasmic reticulum.³⁴² The dysfunctional RyR₁ has mutations in the cytosolic part of the protein (i.e., the foot), and is sensitive to activation by volatile anesthetics, resulting in unwanted muscle contractures. Dantrolene, an allosteric inhibitor of Ca^{2+} release from the sarcoplasmic reticulum, has been used successfully to abort fulminant crises and reduce the mortality rate.

Electroretinogram abnormalities and visual impairments such as congenital X-linked stationary night blindness, abnormal color vision, and hyperopia are all symptoms that may be associated with mutations in *CACNA1F*, which is the gene that encodes the slowly inactivating α_1 subunit $\text{Ca}_v1.4$.^{343,344} Synaptic transmission in the retina depends on graded changes in the membrane potential of retinal photoreceptor cells. These cells become depolarized in the absence of light stimuli, and tonically secrete the neurotransmitter glutamate in response to Ca^{2+} entry, mainly through L-type Ca^{2+} channels. Normally, light stimuli hyperpolarize the photoreceptor cell membrane, which closes the retinal L-type Ca^{2+} channels, inhibiting further Ca^{2+} influx and reducing glutamate release from the photoreceptors. Single point mutations leading to an amino acid change in DII–S6 leads to a gain of function phenotype that is characterized by profound effects on the voltage-dependence of L-type Ca^{2+} channel activation and the kinetics of inactivation.³⁴⁵ Consequently, mutated $\text{Ca}_v1.4$ subunits may fail to close in response to the membrane hyperpolarization that normally accompanies light stimuli, and so neurotransmitter release continues unabated, leading to vision impairment.

2.21.4 Potassium Channels

2.21.4.1 Current Nomenclature

K^+ channels are members of a large family of transmembrane proteins that allow K^+ to cross biological membranes selectively. Like Ca^{2+} and Na^+ channels, voltage-gated K^+ channels undergo conformational changes to open and close a gate in response to membrane depolarization.¹ The K^+ channel family is formed by a complex and diverse group of proteins that is known to exist in all three domains of organisms, eubacteria, archaeobacteria, and eukaryotes, and this continues to stimulate discussions on ion channel evolution. K^+ channels have a wide range of functions that includes setting the resting membrane potential, modulating electrical excitability, and regulating cell volume. It has become increasingly apparent that a greater understanding of the impact of K^+ channels on cellular function will come from insightful integration of molecular biology, cell biology, physiology, and pharmacology data (Figure 4). The following sections will attempt to summarize and provide highlights of a very broad and complex body of literature. Several detailed reviews have addressed specific attributes of voltage-gated K^+ channels, and will be referenced to guide further clarification and understanding of this complex ion channel family.

K^+ channels are a large and diverse family of membrane proteins that provide a selective pore for K^+ to cross the lipid bilayer. This attribute of selective K^+ ion permeation is the central feature classifying an ion channel as belonging to the K^+ channel family, and is easily recognized by a highly conserved amino acid motif called the K^+ channel pore signature sequence.^{346,347} This signature sequence forms the structural element commonly referred to as the selectivity filter, and contains the amino acid residues TTVGYG (TMxTVYG), with some variations. In 2003, a collaboration between IUPHAR and the American Society for Pharmacology and Experimental Therapeutics (ASPET) provided the current standard classification for K^+ channels.^{348,349,517,518}

The nomenclature of K^+ channel families primarily reflects two broad groups: the 6TM voltage-gated and the 2TM inward rectifier.^{1,350} For the most part, these are referred to as the α subunits because, in common with the Na^+ and

Figure 4 Voltage-gated K^+ channels are the most diverse group of voltage-gated ion channels. The K_v subunits represent the archetypal K^+ channel, and the other families appear to have evolved from them through acquisition of C-terminal sensor domains for various intracellular molecules (e.g., Ca^{2+} , Na^+ , Cl^- , pH, and cyclic nucleotides). In terms of membrane topology and structural features, K^+ channel α subunits resemble each of the four homologous domains of the Na^+ and Ca^{2+} channels: the K_v , CNG, HCN, and most K_{Ca} subunits have six transmembrane segments (S1 through S6), whereas $\text{K}_{Ca1.1}$ has seven transmembrane segments (S0–S6). A functional and properly localized K^+ channel is formed by the co-assembly of four α subunits along with appropriate auxiliary subunits and accessory proteins (not shown). Furthermore, within each subfamily, heteromultimeric K^+ channels can be formed by mixing and matching appropriate α subunits.

Ca^{2+} channels, they contain the pore-forming elements of the channel. As more information has been forthcoming in relation to the structural and functional diversity of K^+ channels, the underpinnings of these classifications have been challenged, and this has contributed to the seemingly confusing historical nomenclature for these channels. For voltage-gated K^+ channels, there are three families that we will address in this chapter: the delayed rectifier K^+ channel family (K_V); the Ca^{2+} -activated K^+ channel family (K_{Ca}); and the hyperpolarization-activated, cyclic nucleotide-gated cation channel family (HCN), covered here because of their relative selectivity for K^+ .^{351–356} Other members of the K^+ channel family, such as K_{IR} and certain subtypes of K_{Ca} , will not be discussed in this chapter because these K^+ channels are not regulated by transmembrane voltage changes.

The K_V family of K^+ channels represents the delayed rectifier channels, as first described by Hodgkin and Huxley.³⁵⁷ These channels allow excitable cells to repolarize efficiently after an action potential, returning Na^+ and Ca^{2+} channels to their resting state. Hodgkin and Huxley first used the term ‘delayed rectifier’ to describe the voltage-dependent K^+ current that developed after the Na^+ current in response to depolarization of squid giant axon. Since then, the term has remained in use to describe K^+ channels that exhibit a delayed onset of activation followed by little or slow inactivation. The original nomenclature of the K_V family was based on pioneering studies in *Drosophila melanogaster*, where four related K^+ channel genes were identified (i.e., *Shaker*, *Shab*, *Shaw*, and *Shal*).¹ Since then, mammalian homologs have been identified for each one of these genes, and, furthermore, the K_V family has expanded greatly as novel genes have been discovered.³⁴⁸ All K_V channels comprise 6TM subunits that contain the pore signature sequence between S5 and S6 (see Figure 4). The homo- or heteromultimeric assembly of four 6TM K_V subunits forms a functional K^+ channel. As masterfully summarized by Gutman and colleagues,³⁴⁸ the subfamilies are numbered 1–12, and most subfamilies contain several members. This is a very diverse group of K^+ channels with a variety of common names, such as *Shaker*, *Shab*, *Shaw*, *Shal*, KCNQ, human ether-a-go-go related gene (hERG), erg, elk, etc. (Table 5).

Numerous cytosolic and membrane-spanning auxiliary and accessory subunits for K_V channels exist. In common with the Na^+ and Ca^{2+} channel auxiliary subunits, association of the $\text{K}_V \alpha$ subunit with auxiliary or accessory proteins often leads to changes in protein trafficking and/or function. For the most part, these proteins differentially co-assemble in tetramers, producing a channel complex that consists of four α subunits and four auxiliary subunits.^{358,359} Some K_V family members such as K_V5 , K_V6 , K_V8 , and K_V9 appear to function only as auxiliary subunits that modulate the activity of other K_V family members.^{358,359} While these proteins display the 6TM topology, they are silent and do not generate functional channels when expressed alone, possibly due to their retention in the endoplasmic reticulum. A number of K_V accessory or auxiliary subunits that are not 6TM in nature may play a role in the generation of functional delayed rectifier K^+ channels (Table 6). These subunits include IsK,³⁶⁰ $\text{K}_V\beta$,^{361–363} K^+ channel-associated protein (KChAP),^{364,365} K^+ channel-interacting proteins (KChIP),^{366–368} and dipeptidyl aminopeptidase-like (DPPL) proteins, such as dipeptidyl aminopeptidase-X (DPPX)³⁶⁹ and DPP10.³⁷⁰ The IsK-related (*KCNE*) gene family encodes single transmembrane proteins, such as minK and MiRP1–4, which are essential for the formation of delayed rectifier K^+ channels in heart. The $\text{K}_V\beta$ subunits are cytoplasmic proteins that share sequence similarity with aldo-keto reductases. There are three known members of this gene family (*KCNAB1–3*), and the proteins they encode appear to interact only with K_V1 channels. KChAP is a cytoplasmic protein that belongs to a class of transcription factor interacting proteins, although its effects on specific K^+ channels (i.e., $\text{K}_V1.3$, K_V2 , and $\text{K}_V4.3$) are transcription-independent. Interestingly, KChAP is not required for proper functioning of K_V -containing channels. Rather, it interacts with the N terminus, and enhances K^+ channel density, suggesting a pure chaperone function. KChIP auxiliary subunits are members of a class of multiple EF-hand-containing neuronal Ca^{2+} -sensor proteins that appear to bind to an intracellular domain of K_V4 subunits. DPPL proteins are transmembrane proteins that also interact with K_V4 subunits. Both KChIP and DPPL proteins appear to be critical components in controlling the trafficking and operation of K_V4 subunits that underlie transient outward currents in neurons (I_A)^{368,371,372} and heart (I_{to}).^{367,373} This is a burgeoning area, and regrettably we have provided only a brief summary, but it is necessary to highlight that these auxiliary and accessory proteins appear to endow cloned K_V subunits with many of the properties ascribed to native K^+ channels.

The family of so-called K_{Ca} channels is divided into three groups that may be differentiated on the basis of their single-channel conductance (small (SK_{Ca}), intermediate (IK_{Ca}), or large (BK_{Ca})). There are five subfamilies of K_{Ca} channels that can be distinguished on the basis of sequence similarity, but, surprisingly, not all of them are Ca^{2+} -sensitive. It would appear that the K_{Ca} family evolved from the 6TM K_V channels through acquisition of sensors for a variety of intracellular factors, including Ca^{2+} ,³⁷⁴ Na^+ ,⁷⁵ chloride (Cl^-),⁷⁴ or pH (see Figure 4).³⁷⁵ Even among the Ca^{2+} -sensitive members, different mechanisms appear to have evolved for the sensing of intracellular Ca^{2+} .^{376,377} Despite the putative common ancestral origins of these channels, only two members of this family appear to be voltage-gated (i.e., $\text{K}_{Ca}1.1$ ³⁷⁴ and $\text{K}_{Ca}5.1$).³⁷⁵ $\text{K}_{Ca}1.1$ underlies the large-conductance Ca^{2+} -activated K^+ channel, which is commonly referred to as Slo1, BK_{Ca} , or maxi-K.³⁷⁸ This channel is interesting because it is sensitive to allosteric

Table 5 K⁺ channel α subunit classification

<i>α subunit name</i>	<i>Human gene symbol name</i>	<i>Human chromosome</i>	<i>General description</i>
K _v 1.1	<i>KCNA1</i>	12p13.3	<i>Shaker</i> -related, delayed-rectifier K ⁺ channel family

activation by both voltage and physiological Ca²⁺.³⁷⁹ BK_{Ca} is a multisubunit K⁺ channel that contains four K_{Ca}1.1 α subunits (KCNMA1) in combination with four β subunits, of which there are four subtypes (KCNMB1–4).^{380,381}

The family of cyclic nucleotide-modulated K⁺ channels comprise two groups: cyclic nucleotide-gated (CNG) and HCN channels.^{352,382,383} These channels are characterized by K_v-like 6TM topology, and are believed to have

originated through evolution from K_V channels through acquisition of a cyclic nucleotide-binding domain (CNBD) near the C terminus. There are four known members of this class (HCN1–4), and there are no known auxiliary or accessory subunits.³⁵⁵ Like K_V and K_{Ca} subunits, CNG and HCN subunits form tetramers, and their activity is influenced by transmembrane potential, with HCN subunits demonstrating a greater dependence on voltage for activation. However, HCN channels open in response to membrane hyperpolarization and close upon depolarization.^{355,384} Like K_{Ca} channels, CNG and HCN opening can also be influenced by intracellular signaling events. In the case of CNG and HCN, cyclic nucleotides may interact directly with the α subunit. In comparison with K_V and K_{Ca} channels, HCN channels are less selective for K^+ , and hence they can be referred to as cation-selective channels. Due to their structural and functional similarities to K_V and K_{Ca} channels, we have included the HCN channels in this chapter.

2.21.4.2 Molecular Biology Classification

Voltage-gated K^+ channels display significant molecular diversity as a result of the expression of a multitude of pore-forming and auxiliary subunit genes. The first *Drosophila melanogaster* K^+ channel genes were characterized in 1987^{385,386} and 1988,³⁸⁷ and, since then, almost 100 different mammalian K^+ channel subunit genes have been identified.^{348,349,518,519} However, there still exists only a basic understanding of the molecular biology aspects of these genes.^{348,350,358,388} K^+ channel genes are similar to Na^+ and Ca^{2+} channel genes in that they encode for proteins with presumed 6–7TM configurations. In contrast to Na^+ and Ca^{2+} channel genes, K^+ channel genes encode only one homologous domain, supporting the widely held view that functional K^+ channels are tetrameric in nature.^{49,50} K_V , K_{Ca} , and HCN K^+ channels are protein complexes, often composed of several cytosolic and polytopic membrane subunits. Many mammalian voltage-gated K^+ channel α subunits are encoded in a single exon, whereas others are segmented into multiple exons. An additional factor determining the molecular diversity of K^+ channels is the alternative splicing of gene transcripts.³⁸⁹ In the case of K_{Ca} -containing channels, alternatively spliced variants can differ in their sensitivity to Ca^{2+} and/or voltage. Auxiliary subunits also arise from separate genes that display alternative splicing.

Voltage-gated K^+ channels are especially diverse proteins that determine patterns of cellular excitability.¹ In general, the voltage-gated K_V , K_{Ca} , and HCN channels are abundantly expressed in mammalian cells. Functional channels can either be homo- or heteromultimeric, and this increases the apparent diversity of K^+ channels in native tissues. Due to the ubiquitous distribution patterns of the multitude of K_V and K_{Ca} subunits and the complexity of subunit associations, it is difficult to summarize adequately their distribution and localization patterns in this chapter, and, therefore, only a few salient features will be highlighted. As one can imagine, the use of genetic tools, such as transgenic and gene knockout animals, as well as delivery of small interfering RNA (siRNA) and gene regulatory agents has led to a very mixed understanding of K^+ channel distribution and contribution to cell function, but this will not be reviewed here.

K^+ channels are found ubiquitously in cell membranes, but evidence is accumulating to suggest that they are not randomly distributed. The precise subcellular localization of K^+ channels is certainly a necessary feature of cells to ensure rapid and efficient integration of intracellular and extracellular signaling events. Indeed, specific subcellular distribution patterns of voltage-gated K^+ channel subunits have been documented, but little is known about the mechanisms responsible, although significant gene regulation clearly occurs. Most of the proposed mechanisms have fallen under the umbrella of protein trafficking; however, other factors have recently been examined.^{390,391} Knowledge of the processes that direct the specific placement of ion channel pore-forming and auxiliary subunits in subcellular compartments is necessary for a complete understanding of the role of ion channels in normal physiology and pathophysiology.

Distinct cellular distribution patterns can occur through protein–protein interactions such as between K^+ channel α and auxiliary subunits.^{391–393} An excellent example of the complex patterns of voltage-gated K^+ channel distribution and the influence of this on cell function is illustrated in a recent review by Misonou and Trimmer.³⁹⁰ Neurons are morphologically complex cells, and the precise control of electrical activity underpins neurological function. K_V , K_{Ca} , and HCN channels are very important contributors to the control of membrane excitability. For the K_V subunits, K_V1 are mostly localized on axons, whereas K_V2 and K_V4 are mostly somatodendritic. The K_V3 family is expressed more ubiquitously in subcellular compartments of neurons. Other excitable cell types, such as cardiac and smooth muscle, demonstrate equally complex expression patterns of K_V ,³⁹⁴ K_{Ca} ,³⁹⁵ and HCN subunits.^{383,396} The differential cell surface expression of K^+ channels in polarized and nonpolarized cells as well as morphologically complex cells suggests isoform-specific mechanisms exist to direct subcellular localization.³⁵⁸ For example, K_V1 channel trafficking can be regulated by chaperone proteins such as calnexin.³⁹⁷ The oxidoreductase activity of K^+ channel β subunits may also play a role in K_V subunit trafficking, potentially linking cellular metabolic states to channel function.³⁹⁸

In addition to the role of accessory proteins in controlling the distribution of K^+ channels, there is also increasing information that supports the involvement of membrane lipids.³⁹⁹ The existence of plasma membrane microdomains has extended interest in lipid interactions of a variety of proteins, including ion channels. Lipid rafts represent specialized microdomains within the plasma membrane. They are rich in cholesterol and sphingolipids, and can be associated with cellular enzymes and cytoskeletal proteins. Lipid rafts have been shown to assist in the localization of various subtypes of K^+ channels⁴⁰⁰ while excluding others.^{392,399} In addition, their lipid components, such as cholesterol, have been shown to modulate K_V channel function.⁴⁰¹ Moreover, these and other specialized lipid domains have been shown to organize other cellular proteins, suggesting that lipid rafts in excitable and nonexcitable cell membranes form a scaffold where selected proteins can be brought in close proximity with others in order to achieve specific functions.

2.21.4.3 Protein Structure

Structural perspectives on ion channels have been of great interest since the first descriptions of their function more than 60 years ago. However, information about the molecular architecture of K^+ channels has advanced significantly only over the last several years as higher resolution structural information has accumulated. As discussed above, the proteins produced by the K_V , K_{Ca} , and HCN genes have provided an early topological map of the 6–7TM ion channel subunits. More recently, a variety of elegant studies have focused on increasing our understanding of the relationship of protein structure to the three main functions of voltage-gated channels, namely subunit assembly, ion permeation/selectivity, and gating. These efforts have generated much excitement and debate as structural information has been applied to gain an understanding of functional measurements of voltage-gated ion channels.^{350,402,403}

In voltage-gated K^+ channels, the intracellular region from the N terminus to S1 is an important determinant of K_V subunit assembly. This region is called the T1 domain, and it contains signals that promote tetramerization of α subunits within the same subfamily.⁴⁰⁴ One interesting aspect of the T1 domain is that it appears to be positioned directly over the intracellular mouth of the pore, suggesting that ions moving through the pore must pass close to it.⁵⁰ During the process of N-type inactivation, the T1 domain has been shown to interact with another polypeptide region of the channel to occlude the pore.^{405,406} There is also evidence that the T1 domain may interact with the $K_V\beta$ subunits.⁵⁰ The T1 domain appears to be multifunctional, since it can also serve to dock auxiliary subunits, modulate gating of the channel, and guide the channel to preferred subcellular locations such as axons. Undoubtedly, the T1 domain will be the subject of more studies to elucidate its roles in controlling K^+ channel structure–function relationships.

For the permeation pathway, K^+ channels exhibit the properties of high conduction rates and high selectivity. The first high-resolution crystal structure of the permeation pathway came from the prokaryotic K^+ channel, KcsA, through the ground-breaking work of MacKinnon and associates.³⁴⁷ This bacterial channel differs from the mammalian K_V channels in that its topology is 2TM, with the pore loop residing between S1 and S2. In this study, the permeation pathway was best represented by an inverted tepee structure, with the pore lined by the elements of signature sequence described earlier. Crystal structures have now been determined for four different prokaryotic channels as well as the mammalian $K_V1.2$ channel (see [Figure 1](#)).^{49,50} Collectively, these studies demonstrate a growing consensus view of the common architecture of the pore domain as well as the basic principles underlying permeation and selectivity for K^+ ions. The channel uses the pore signature sequence to present electronegative oxygen moieties that are arranged to interact strongly with a dehydrated permeating K^+ ion. This structure varies with conformational changes as the pore opens and the T1 domain communicates with the pore. Selectivity for K^+ ions has been described as a matter of fit. Compared with K^+ , Na^+ and other ions are presented in energetically unfavorable states with respect to their fit in the pore, and this underpins the preference of the channels for K^+ ions.³⁴⁷ High permeation rates while maintaining high selectivity is believed to arise from three ion-binding sites that are arranged sequentially and in close proximity along the axis of the pore so that ions will electrostatically repel each other.^{50,407}

The structural view of ion channel gating has been more challenging, and has stimulated much debate.^{403,408–410} Since the studies of gating charge movements in *Shaker* K_V channels, it has been known that some 13 electron equivalent charges are moved through the lipid membrane environment.¹ These observations have stimulated many other crystallographic, computational, and amino acid charge-mapping studies aimed at understanding how the subunits are positioned in the membrane and how they move to expose the pore to permeating ions. In addition, they have addressed the role of lipids and the membrane environment in controlling these ion channel functions. Much attention has been focused on S4, which is a common structural feature among all voltage-gated ion channels. One common principle for understanding the voltage-sensing role of S4 domain is its helical structure with regularly spaced positively charged amino acid residues. The positive charges of S4 lie within the transmembrane electric field, and are capable of sensing changes in the transmembrane voltage. These charges respond by moving within the lipid

environment, and this movement causes the ion channel pore to open, although it is clear that other parts of the channel are also necessary. The first high-resolution picture that provided a working model came from the prokaryotic channels MthK⁴¹¹ and K_VAP.^{412,413} Comparison of the closed-pore structure of KcsA and the open-pore structure of MthK provided evidence that S5 and S6 are involved in channel opening. The structure of K_VAP provided evidence that S4 may be highly mobile, although this was in disagreement with other studies suggesting smaller S4 movements.^{414–418} Recent studies with rat K_V1.2^{49,50} have confirmed the importance of S3, S4, the S4–S5 linker, and the T1 domain in modulating ion channel gating. As more studies are now focused on examining structural movements within ion channels, the expectation of the ion channel community is that our understanding of how channels gate will progress rapidly, adding an important structural dimension to ion channel knowledge.

The Ca²⁺-activated K⁺ channel subunit K_{Ca}1.1 has an extracellular N terminus, and comprises a core, which contains the voltage-sensing and pore-forming elements, a linker, and an intracellular C-terminal tail, which contains the Ca²⁺-sensing elements.^{419–422} The linker joins the core to the tail, although covalent linkage is not essential for the tail to regulate the function of the core.⁴²³ The core has nine hydrophobic segments, seven of which are believed to be membrane-spanning (S0–S6) and the other two to be intracellular (see [Figure 4](#)). The segments S1 through S6 are analogous to the corresponding regions of the K_V subunits, and, in common with most voltage-gated ion channels, S4 serves as the primary voltage sensor. Ion selectivity is determined by signature residues in the pore loop, and the ion conduction pathway is lined by S5 and S6. The tail appears to contain two hydrophobic segments and a so-called Ca²⁺ bowl. The Ca²⁺ bowl contains multiple aspartate residues, and appears to be critically involved in Ca²⁺ sensing.^{424,425} Nevertheless, there remains some controversy over how many domains actually participate in Ca²⁺ sensing.^{426,427} Interestingly, both the core and the tail are required to produce functioning K⁺ channels,⁴²³ suggesting that the tail not only senses Ca²⁺ but that somehow it also regulates the voltage sensitivity of the core. Therefore, a gating model has been proposed in which the tail acts as a negative regulator of K_{Ca}1.1, and, in the absence of Ca²⁺-binding, exerts a tonic inhibitory effect on voltage-dependent channel gating. In this model, Ca²⁺ binding induces conformational changes in the protein that reduce the association of the tail with the core. In this way, Ca²⁺ binding relieves the tonic inhibition, resets the voltage sensitivity of the core, and permits the channel to open in response to membrane potential changes.⁴²⁸

HCN channels have many structural features in common with K_V and K_{Ca} channels, yet they function differently. Like K_V channels, HCN channels contain positively charged amino acid residues in the voltage-sensing S4. However unlike K_V channels, HCN channels are activated by membrane hyperpolarization, and are not as sensitive to changes in membrane potential.^{355,429} In order to open, HCN channels require only 4–6 equivalent charges to move across the electric field, compared with 13 charges for K_V channels. Other differences are that HCN channels open quite slowly compared with K_V channels, and the gate that controls channel activation and inactivation is located on the intracellular side of the channel.⁴³⁰ Together, these data strongly suggest that voltage-dependent gating of HCN channels involves novel mechanisms of transmembrane segment movements.^{355,429} Perhaps hyperpolarization may remove HCN channel inactivation, leading to channel opening, or the linkage mechanism by which the voltage sensor is coupled to the activation gate is reversed. Ion selectivity of HCN channels also remains a puzzle. They are selective for K⁺ over Na⁺ (ratio of about 4:1), possibly due to a CYG motif in the pore structure,^{355,429} yet they can also conduct inward Na⁺ and Ca²⁺ currents under physiological conditions.³⁵⁶ Another interesting feature of HCN channels is the intracellular CNBD, which is located in the C terminus. The CNBD is functionally analogous to the Ca²⁺-binding regions of K_{Ca}1.1. Deletion of the CNBD mimics the effect of cAMP (i.e., it enhances channel activity). This suggests that the CNBD tonically inhibits HCN channels and that cyclic nucleotide binding enhances gating by relieving the inhibitory action of the CNBD. Recently, a model for ligand-dependent channel modulation was proposed based on the crystal structure of a C-terminal fragment of HCN2 that was obtained in the presence of cyclic nucleotides.⁴³¹ Comparisons of the HCN channel structure–function relationship to K_V and K_{Ca} channels and the CNBD of other proteins will undoubtedly be of great interest in the coming years.

2.21.4.4 Physiological Functions

K⁺ channels are ubiquitously expressed. They are most notable for their role in buffering cell membrane excitability and in setting the resting membrane potential in all cells.^{432,433} Voltage-gated K⁺ channels have an intracellular gate that serves to control the flow of ions through the pore. Upon membrane depolarization, these K⁺ channels transition through multiple closed states before finally opening. Thus, K⁺ channels undergo voltage-dependent gating that involves resting, activated-not-open, open, and inactivated states. As a general principle, K⁺ channel opening promotes K⁺ efflux and causes cell membrane hyperpolarization. Conversely, K⁺ channel closing reduces K⁺ efflux and promotes cell membrane depolarization.

To accomplish their physiological roles, K^+ channels must be expressed in relevant regions of the cell at a density that is appropriate to supply the required K^+ conductance. The proper functioning of K^+ channels is determined by the biochemical and biophysical properties of the component subunits. K^+ channel operation must be tightly coordinated in time with the activity of other ion channels, most notably the faster activating Na^+ and Ca^{2+} channels. Despite the plethora of work concerning the cellular expression of K^+ channel genes, considerable uncertainty remains in correlating K^+ channel genes to native K^+ currents. As described earlier, several auxiliary and accessory subunits can associate with K^+ channel α subunits, thereby increasing the molecular and functional diversity within the K^+ channel family. Indeed, some of these auxiliary and accessory subunits are required in order to reconstitute certain properties of native channels. In terms of the impact of voltage-gated K^+ channels on cellular function, it must be appreciated that various physiological stimuli and pathophysiological conditions can regulate K^+ channel expression and function. To illustrate this, several studies have demonstrated that metabolic conditions^{434,435} and changes in lipid composition⁴³⁶ can regulate K^+ channel activity. Moreover, diseases such as hypertension can impact K_V and K_{Ca} channel subunits.^{437,438} The translation from gene function to native currents will clearly continue to be approached using a variety of research tools and the blending of several scientific disciplines.

Native voltage-gated K^+ channels in excitable cells are normally activated by membrane depolarization. Voltage-gated K^+ channels open typically in response to Na^+ - or Ca^{2+} -dependent action potentials that are generated in neurons, skeletal muscle, and secretory cells.¹ This reactive behavior represents a common feature of K^+ channels. When activated, K^+ channels control not only the generation and propagation of action potentials but also their duration and frequency. Consequently, K^+ channels participate in the control of excitation–secretion coupling in neurons and endocrine cells and excitation–contraction coupling in muscle cells.⁴³⁹ Neuronal M channels are characterized as low-threshold, noninactivating, voltage-gated K^+ channels, and are defined by their physiological regulation by muscarinic receptors.⁴⁴⁰ M channels have slow opening and closing kinetics, and are thought to limit repetitive firing of action potentials. Notable K^+ channels that control cardiac function are I_{To} , I_{Kur} , I_{Ks} , and I_{Kr} , which are distributed in specific regions of the heart where they contribute to complex and carefully orchestrated cardiac excitability.⁴⁴¹ To accomplish their functions in excitable cells such as neurons, different K^+ channels tend to be localized in specific subcellular compartments (e.g., axonal or somatodendritic regions).³⁹⁰ Due to their delayed activation kinetics, the K_V subunits are believed to underlie the delayed rectifier K^+ currents. Like Na^+ and Ca^{2+} channels, some K^+ channels inactivate during maintained depolarization. The kinetics of inactivation can either be rapid or slow, and often they are voltage-dependent, with inactivation being speeded up by stronger membrane depolarization. Still other K_V channels inactivate little during maintained depolarization. Thus, as a class, K_V channels demonstrate a wide range of functional properties, and defy a universal and general characterization as illustrated for Na^+ and Ca^{2+} channels.

Activity of BK_{Ca} channels is dependent not only on membrane depolarization but also on increased intracellular Ca^{2+} . Overall, these channels have been implicated in the control of neuronal excitability, muscle contractility, and secretory events.^{442–444} BK_{Ca} channels require $>1\ \mu M$ intracellular Ca^{2+} to be activated,^{442,443} and studies have suggested that this can in fact occur under physiological conditions as a result of localized concentration changes.⁴⁴⁵ In neurons, BK_{Ca} channels have been implicated in action potential repolarization and generation of after-hyperpolarizations. BK_{Ca} activity can alter the duration and frequency of action potential firing in secretory cells, and thus they participate in excitation–secretion coupling. In smooth muscle cells, increases in intracellular Ca^{2+} occur at specific intracellular sites independent of membrane depolarization. This may cause BK_{Ca} activation, thereby dampening membrane electrical activity and limiting myocyte contraction.^{395,446,447}

The K^+ current produced by HCN channels has been termed I_h , I_f , or I_q , and is found in a variety of neurons, pacemaker cells, and photoreceptors.^{353,354,448} The best understood function of HCN is as the pacemaker current (I_h) in cardiac SA node cells.^{355,356} When the cardiac action potential terminates, the membrane potential hyperpolarizes, and HCN channels open. By virtue of their cation selectivity, HCN channels exert a depolarizing influence on the cell. As the membrane depolarizes, Na^+ and Ca^{2+} channels activate, and this leads to the initiation and propagation of another action potential. Subsequently, the Na^+ and Ca^{2+} channels begin to inactivate, and then delayed rectifier K^+ channels open, allowing the repolarization phase to proceed. As the action potential terminates and additional K^+ channels become activated, the membrane potential returns to a hyperpolarized level again, and the process repeats. The pacemaker function of HCN channels can also be observed in neurons,^{449,450} as well as in signal transduction cells, such as taste receptors, photoreceptors, and auditory receptors.

K^+ channels are functional in nonexcitable cells, such as lymphocytes and epithelial cells, where they provide an electrochemical gradient to support many cell functions. An essential signaling step following T cell receptor activation in lymphocytes is Ca^{2+} entry through the Ca^{2+} release-activated Ca^{2+} channel, which underlies the native current, I_{crac} , the molecular identity of which is incompletely understood. This Ca^{2+} influx depends on a hyperpolarized

membrane potential, and is essential for driving downstream signaling cascades that ultimately lead to increased T cell proliferation and cytokine production. The voltage-gated K^+ channel $K_V1.3$ (along with the voltage-insensitive channel IK_{Ca}) regulates the membrane potential and indirectly controls Ca^{2+} entry. In renal and other epithelial cell types, various K^+ channels have specialized functions in the apical and/or basolateral membranes.⁴⁵¹ In the apical membrane of renal epithelial cells, K_V channels are responsible for stabilizing the membrane potential, whereas in the basolateral membrane, Ca^{2+} -activated K^+ channels play a role in flow-dependent K^+ secretion. $K_V1.1$ and $K_V1.3$ channels have been identified in epithelial cells of the choroid plexus, where they contribute to secretion of cerebral spinal fluid.⁴⁵² As has been discussed, K^+ channels exhibit diverse functions, and these are determined not only by their biophysical properties but also by their subcellular placement.

2.21.4.5 Regulation

Central to their physiological roles, voltage-gated K^+ channels are both initiators and effectors of cell signaling. In common with Na^+ and Ca^{2+} channels, K_V , K_{Ca} , and HCN channels can interact with a variety of other cellular molecules, and are subject to complex modulation by multiple mechanisms (e.g., enzymes, membrane lipids, scaffolding proteins, and intracellular second messengers can regulate the expression and function of these channels). There are numerous articles in the literature that provide a wealth of information about the regulation of K_V , K_{Ca} , and HCN channels as well as auxiliary subunits. Many reports address the modulation of both native and cloned channels, and provide a clear demonstration of direct interactions between ion channel subunits and other cellular signaling molecules within a multicomponent protein complex.

Modulation of K^+ channels by second messengers is a dynamic way to fine-tune the excitability of neurons and muscle cells.¹ In particular, K^+ channel modulation influences the ability of neurons to encode information, and is exemplified by the following examples. $K_V1.3$ is a substrate for multiple tyrosine kinases, which can regulate its activity and impact cell function. This channel is highly expressed in rodent olfactory bulb, where it is localized in mitral and granule neurons.⁴⁵³ It has been shown that $K_V1.3$ phosphorylation modulates not only the K^+ current amplitude but also the voltage-dependence and kinetics of inactivation.⁴⁵³ Two adaptor proteins, Grb10 and n-Shc, differentially modulate the degree of $K_V1.3$ phosphorylation and the biophysical properties of the channel.⁴⁵⁴ Regulation of $K_V1.3$ phosphorylation by adaptor proteins is most likely via protein–protein interactions, suggesting a protein complex comprising K^+ channel, kinase, and adaptor molecules. Regulation of $K_V1.3$ by molecules involved in intracellular signaling has also shown to be an important regulator of its role in T cell function. $K_V2.1$ localization has been shown to depend on the phosphorylation state of the channel. $K_V2.1$ is often found in large clusters on the cell bodies and dendrites of hippocampal pyramidal neurons. However, neuronal activity enhances dephosphorylation of $K_V2.1$, which induces its translocation from clusters to a more uniform distribution pattern.⁴⁵⁵ This effect is regulated by the Ca^{2+} -dependent phosphatase calcineurin, and appears to involve serine and threonine residues in the cytoplasmic tail of $K_V2.1$. Interestingly, $K_V2.1$ translocation can be mimicked by glutamatergic receptor activation and induced in vivo by motor seizures, suggesting a link between neurotransmission and intrinsic neuronal excitability. $K_V2.1$ phosphorylation can also induce a hyperpolarizing shift in the voltage dependence of activation, suggesting that this mechanism could dynamically regulate dendritic excitability.⁴⁵⁶ In contrast, $K_V2.1$ can be downregulated by protein-tyrosine phosphatase ϵ and upregulated by Src, with both effects occurring through the T1 domain.⁴⁵⁷ Similarly, the functional modulation of $K_V1.5$ currents is complex and may involve multiple mechanisms, including SH3 domain binding-dependent and binding-independent phosphorylation, both of which lead to suppression of $K_V1.5$.⁴⁵⁸ Many reports have suggested modulation of native K^+ channels by physiological agents. For instance, activation of pancreatic β cell glucagon-like peptide-1 receptors by exendin-4 causes a hyperpolarizing shift in the voltage dependence of steady state inactivation, effectively suppressing the K^+ current. This effect is dependent on phosphorylation by PKA and phosphatidylinositol 3-kinase.⁴⁵⁹ Enzymatic modulation K_{Ca} channels have been studied extensively. PKA-dependent phosphorylation of residue S899 in all four α subunits of the BK_{Ca} channel is required to increase channel activity.⁴⁶⁰ In addition, specific PKC isozymes can increase BK_{Ca} currents in vascular smooth muscle cells through a cyclic guanosine monophosphate (cGMP)-dependent protein kinase.⁴⁶¹

2.21.4.6 Prototypical Pharmacology

The pharmacological characterization of voltage-gated K^+ channels has benefited from the availability of a broad collection of relatively selective modulators, and these have fueled a large body of literature, some of which was reviewed recently.⁴³² Thus, native and cloned K^+ channels have been characterized according to the effects of inorganic ions (e.g., cesium), toxins, and antiarrhythmic drugs (see [Table 3](#)). However, lack of specificity of many

of these agents continues to spark debate in the literature, as attempts are made to deduce the subunit composition of native K^+ channel by comparison with the pharmacological characteristics of cloned channels. Nevertheless, pharmacological modulators of K^+ channels have proven to be valuable tools in elucidating the physiological roles of K^+ channels in many cells and tissues. Here, we will present only a brief overview of K^+ channel pharmacology.

As with Na^+ and Ca^{2+} channel modulators, most K^+ channel modulators either act through a pore-blocking mechanism or via an allosteric effect on channel gating processes. Nonpeptide K^+ channel pore blockers including 4-aminopyridine (4-AP) and quaternary ammonium ion derivatives such as tetraethylammonium (TEA) appear to bind competitively to open K^+ channels. Despite the conserved sequences in the pores of most K^+ channel subtypes, blockers such as TEA often display a wide range of potencies ($IC_{50} < 1$ mM to > 20 mM). 4-AP enters the K^+ channel pore after the channel has opened, and appears to promote closure of the intracellular gate, thereby stabilizing the activated-not-open state. In addition, various peptide toxins, including charybdotoxin, dendrotoxin, margatoxin, noxiustoxin, agatoxin, and kaliotoxin,^{462–464} have been isolated from the venoms of species such as scorpions, snakes, spiders, and snails. Like 4-AP, many of these toxins block the channel by direct occlusion of the pore, yet at the same time they often exhibit significant selectivity for certain K^+ channel subtypes. In general, the selectivity of the K^+ channel-blocking toxins derives from tight interactions not just with the pore but also with adjacent domains. Charybdotoxin (from the scorpion *Leiurus quinquestriatus hebraeus*) is a potent but relatively nonselective blocker of some K_V and K_{Ca} channels, whereas the dendrotoxins, which are a group of proteins that are found in the venom of various green mamba snakes (e.g., *Dendroaspis angusticeps* and *Dendroaspis viridis*), appear to be very selective for some K_V1 channels. Still other toxins from tarantula venom appear to display remarkable specificity for individual K^+ channel subtypes. For instance, hanatoxin (from *Grammostola spatulata*) is a potent blocker of $K_V2.1$,⁴⁴⁹ while phrixotoxin-1, phrixotoxin-2 (from *Phrixotrichus auratus*),^{465,466} and *Theraphosa leblondi* toxin 1⁴⁶⁷ appear to inhibit K_V4 channels specifically.

Small-molecule modulators of voltage-gated K^+ channels appear to act by allosterically interfering with the gating processes, but, unfortunately, most of these agents are not selective among the different K_V channels. Thus, while small molecules have been good starting points to characterize K_V currents, proper caution must be exercised when dissecting complex native voltage-activated K^+ currents. Due to the therapeutic interests of pharmaceutical and biotechnology companies, the most novel compounds tend to be those that target K_V and K_{Ca} channels in cardiac myocytes, smooth muscle cells, and neurons, although $K_V1.3$ blockers for the treatment of immune disorders are also attractive. Antiarrhythmic drugs are a heterogeneous group that includes molecules with actions on voltage-gated Na^+ (class I), K^+ (class III), and Ca^{2+} (class IV) channels. These classifications are not mutually exclusive (i.e., some Na^+ channel blockers also block Ca^{2+} and/or K^+ channels). Consistent with the wide repertoire of K^+ channels expressed in the heart, class III antiarrhythmic drugs are a structurally and mechanistically diverse group that includes tedisamil, dofetilide, ibutilide, clofilium, flecainide, quinidine, and sotalol. Few of these drugs display selectivity for individual K_V channels, or indeed other ion channel subtypes. Courtesy of its key role in the repolarization phase of the cardiac action potential and its propensity to block by many drugs, the hERG ($K_V11.1$) K^+ channel has gained notoriety, and has been classified by the US Food and Drug Administration and other regulatory bodies worldwide as a safety hurdle in drug development. Many class III antiarrhythmics as well as other (noncardiac) drugs, such as cisapride, astemizole, terfenadine, and sertindole, have been shown to block hERG, and are associated with significant adverse consequences for cardiac function.⁴⁴¹ In addition to blocking hERG, many class III antiarrhythmic drugs also inhibit K_V4 channels.⁴⁶⁸ Diverse voltage-gated K^+ channels are also sensitive to block by many Na^+ and Ca^{2+} channel modulators, including local anesthetics (e.g., lidocaine and tetracaine), phenylalkylamines (e.g., verapamil), and diarylaminoalkylamines (e.g., bepridil). The only K_V channels that appear to enjoy a distinguishing pharmacology are the K_V7 (KCNQ) subtypes. These pore-forming α subunits associate with minK-related auxiliary subunits, and are believed to underlie the K^+ current, I_{Ks} ($K_V7.1$) in cardiac cells and the so-called M current ($K_V7.2$, $K_V7.3$, and $K_V7.5$) in neurons. Channels containing these subunits have distinct sensitivities to TEA (e.g., $K_V7.2$ is more sensitive than $K_V7.3$), and can also be blocked by the cognition enhancers XE991 and linopirdine.^{469,470} Interestingly, the pharmacology of K_V7 may be altered significantly in the presence of auxiliary subunits. Finally, neuronal K_V7 -containing K^+ channels are activated by the antiepileptic drug retigabine⁴⁷¹ and the antiischemic drug BMS-204352.⁴⁷²

A number of pharmacological agents that either open or block BK_{Ca} channels have been described. The prototypical pharmacology for $K_{Ca}1.1$ channels is block by toxins (iberiotoxin, charybdotoxin, and noxiustoxin) and indole-diterpenes (penitrem-A and paxilline).^{432,444} Unlike most K_V channels, $K_{Ca}1.1$ channels are quite sensitive to low concentrations of TEA. Like the K_V7 channels, openers of $K_{Ca}1.1$ have been identified, and these are of great therapeutic importance. The first opener of this channel that was identified was the glycosylated triterpene, dehydrososyosaponin-1.⁴⁷³ Subsequently, several small molecule activators (e.g., NS1608⁴⁷⁴ and NS1619⁴⁷⁵) have been described, although these agents are not selective. It has been difficult to separate the effects of these agents on the voltage and Ca^{2+} dependence of the channel, underscoring the close working relationship of these mechanisms in channel activation.

Although HCN channels play a key role in pacemaking activity of neurons and heart cells, there are few reports of specific modulation by pharmacological agents. The most extensively studied blocker of HCN channels is ZD7288,^{449,476} which specifically blocks native I_h and cloned HCN channels in a voltage-dependent manner. Other agents that block HCN channels are the bradycardic agents ivabradine, zatebradine, and alinidine, although these are less selective than ZD7288.^{355,356,477}

2.21.4.7 Prototypical Therapeutics

Many pharmacological agents that target voltage-gated K^+ channels are of proven therapeutic utility or are in various stages of clinical development. The rationale for targeting specific voltage-gated K^+ channel subtypes for disease management arises from several forms of target validation. Data from genetic and molecular biology studies, including knockout or overexpression of various pore-forming and auxiliary subunits and accessory proteins, have revealed novel roles for K^+ channels in animal physiology. Moreover, pharmacological characterization of K^+ channels in normal and pathological cells has been essential in supporting the validation of K^+ channels in disease. Consequently, agents that modulate various voltage-gated or Ca^{2+} -activated K^+ channels are displaying potential in many phases of drug discovery and early clinical development.

As a class, most voltage-gated K^+ channel modulators are primarily focused on the management of cardiac and airway disorders,⁴⁷⁸ although additional therapeutic indications are becoming apparent. Disruptions of normal cardiac rhythm are the leading cause of serious illness and premature death. The key to developing treatments for these conditions is an understanding of the molecular basis of electrical activity in the heart. The heart is a highly specialized organ that maintains a closely choreographed sequence of depolarization, repolarization, and muscle contraction.⁴⁴¹ There are multiple K^+ channels that contribute to membrane repolarization and hyperpolarization during the cardiac action potential, and, consequently, several potential drug targets have been suggested for the treatment of cardiac electrical or contractile abnormalities. In particular, $K_v1.5$ subunits are believed to underlie the ultra-rapid delayed rectifier K^+ current (I_{Kur}) in atrial myocytes.⁴⁷⁹ Moreover, many class III antiarrhythmic drugs inhibit this channel, and so it has emerged as an attractive drug target for the management of atrial arrhythmias.⁴⁸⁰ Consequently, several novel inhibitors of $K_v1.5$ are currently being investigated in the clinic as potential antiarrhythmics. Adding to the pharmacological complexity, it has been shown that the association of $K_v\beta1.3$ subunits with $K_v1.5$ can modulate drug block.⁴⁸¹ Other studies have established the importance of the transient outward K^+ current (I_{to}) on cardiac function.⁴⁸² This current is relatively large in atrial cells, and its blockade by antiarrhythmic drugs causes a significant increase in the duration of atrial depolarization. The proteins that underlie I_{to} have been the focus of many studies, and the channel identity is highly species-dependent. In most mammals, I_{to} appears to be a protein complex containing $K_v4.2$ and/or $K_v4.3$, KChIP,⁴⁸³ and, perhaps, additional proteins.^{373,484} However in the rabbit, I_{to} appears to result primarily from $K_v1.4$ expression.⁴⁸⁵ Adding to the difficulty of validating I_{to} is the observation that phrixotoxin, which inhibits $K_v4.2$ and $K_v4.3$ channels, affects mainly AV node and ventricular function but does not appear to affect atrial repolarization significantly.⁴⁶⁵ Other important delayed rectifier currents in the heart are I_{Kr} and I_{Ks} . I_{Kr} results from hERG association with MiRP1, whereas I_{Ks} results from $K_v7.1$ association with minK. However, again there are considerable species differences, and so there is uncertainty surrounding the identity of the actual subunits underlying these native channels. In addition to the complexities of composition and function of native voltage-gated K^+ channel in heart cells,^{486,487} the additional problem of species differences underscores the challenges that are faced in the preclinical development K^+ channel-modulating antiarrhythmic drugs. Perhaps as a result of these difficulties, many drugs that target voltage-gated K^+ channels have had limited success in the clinical setting, and this has enhanced the desire to invoke novel strategies and technologies in the search for new class III antiarrhythmic drugs.^{394,478}

T cells of the immune system express $K_v1.3$, and blockade of this channel may be a possible treatment in autoimmune diseases such as multiple sclerosis. Due to the critical role of $K_v1.3$ -containing channels in controlling the membrane potential of T cells, blockade of $K_v1.3$ has been shown to be effective in suppressing Ca^{2+} influx and T cell activation. Moreover, expression of $K_v1.3$ is upregulated in T cells derived from rodent models of autoimmune diseases as well as from multiple sclerosis patients.⁴⁸⁸ Several pharmacological agents have been identified that can block $K_v1.3$ and impact T cell activation.^{489–491} Currently, agents that block $K_v1.3$ are in various stages of clinical development, and may represent a new treatment paradigm for immunosuppression. $K_v1.3$ has also gained interest as an interesting therapeutic target for the management of insulin resistance and type II diabetes.⁴⁹² Recent data indicate that $K_v1.3$ inhibition increases insulin sensitivity, suggesting that this channel may be an important regulator of glucose metabolism.⁴⁹³ It has been proposed that $K_v1.3$ may increase translocation of the glucose transporter GLUT4 to the plasma membrane by decreasing inflammatory cytokines.

Voltage-gated K^+ channel modulators are also relevant in other areas, including oncology, neurology, the circulatory system, and the genitourinary system. K^+ channel genes are amplified and protein subunits are upregulated in many cancerous conditions. Consistent with a role for this upregulation, K^+ channel blockers have been shown to suppress the proliferation of uterine cancer cells⁴⁹⁴ and hepatocarcinoma cells,⁴⁹⁵ presumably through inhibition of Ca^{2+} influx and effects on Ca^{2+} -dependent gene expression. Voltage-gated K^+ channels are well established as critical for determining the resting membrane potential, action potential firing frequency, and neurotransmitter release in neurons. Both activators and inhibitors are in various preclinical and clinical phases of development as antiepileptics^{496,497} and analgesics.⁴⁹⁸ In airway,^{499,500} vascular,^{501–503} and bladder⁴³⁹ smooth muscle cells, voltage-gated K^+ channels (K_V and K_{Ca}) are important for setting basal myogenic tone, suggesting opportunities to develop novel pharmacological therapies for treating the symptoms of asthma, hypertension, and incontinence.^{395,432}

Due to the role of HCN channels in controlling pacemaker potentials in heart and neurons, there has been a growing interest to identify pharmacological agents. Although the focus of HCN channels has been in the heart,^{355,356} two recent studies have reported that the HCN blocker ZD7288 can modulate pain responses in several animal models of pain.^{450,504} As a result of perineural administration of ZD7288, mechanical allodynia was reduced, presumably through nerve block. Similarly, intraperitoneal administration of ZD7288 reduced paw withdrawal thresholds in a test of mechanical allodynia. While ZD7288 inhibited neuronal action potential firing, it also caused a marked bradycardia.⁴⁷⁶ In order to overcome the inherent safety concerns, identification of HCN subtype-selective agents will be essential.

2.21.4.8 Genetic Diseases

Complex genetic factors contribute to the pathogenesis of many types of diseases. For those genetic mutations related to voltage-gated K^+ channelopathies, many appear to be due to gain or loss of function, and are primarily determined by surface expression abnormalities.^{131,505–510} K^+ channelopathies are primarily implicated in diseases of cardiac, skeletal muscle, and neuronal systems. For cardiac diseases, over 200 mutations have been characterized in the seven so-called long QT (LQT) genes, and these account for 50–60% of the clinically manifested LQT syndromes.⁵⁰⁷ In nervous system disorders, K^+ channel mutations have been associated with various forms of epilepsy as well as neuromuscular ataxia and deafness. However, in each disease, the relationship between genetic mutations and the clinical presentation in patients is extremely complex and only partially understood.

The best known yet least understood cardiac K^+ channel genetic mutations inhibit the current I_{K_r} ⁴⁴¹ which is believed to provide the main repolarizing influence on the action potential. It is believed that the *KCNH2* gene encodes the α subunit (hERG; $K_V11.1$), and the *KCNE2* gene encodes the auxiliary subunit (MiRP1), of the channel that underlies this current. Loss of function mutations in both genes may cause a variety of inherited LQT syndromes. These mutations may delay action potential repolarization and induce the electrical abnormality torsade de pointes, which in turn may lead to cardiac fibrillation. In addition, a variety of drugs can prolong the cardiac action potential and induce LQT, apparently by inhibiting the function of I_{K_r} through blockade of hERG-containing K^+ channels. This has forced most drug development initiatives to include hERG pharmacology measurements in their integrated safety evaluations.⁵¹¹ The misunderstood component of I_{K_r} -related LQT channelopathies arises from the fact that the cardiac action potential is the result of a delicate balance and close coordination between depolarizing and repolarizing ionic currents. Therefore, it is not surprising that not all mutations in *KCNH2* and *KCNE2* lead to LQT and not all drugs that inhibit I_{K_r} (or block hERG) cause QT prolongation.⁵¹²

There are other forms of cardiac disease associated with K^+ channel genetic mutations. Some forms of LQT have been associated with loss of function of other subtypes of voltage-gated K^+ channels.^{478,512} The implicated proteins include the pore-forming α subunit of $K_V7.1$ (*KCNQ1*) and the auxiliary subunit *KCNE1* (minK/IsK). $K_V7.1$ associates with minK, to form the channel that underlies the slowly activating I_{K_s} in heart. I_{K_s} plays a role in action potential repolarization as well as rate-dependent shortening of the action potential. There are also genetic mutations in K^+ channels that lead to short QT syndromes.⁵¹³ These include gain of function mutations in hERG and $K_V7.1$. These syndromes are associated with sudden cardiac death, syncope, palpitations, and paroxysmal atrial fibrillation. In addition, loss of function mutations in *HCN2* and *HCN4* has been related to sick sinus syndrome, familial atrial fibrillation, and sudden cardiac death.^{514,515}

Several nervous system disorders have been associated with loss of function of voltage-gated K^+ channels. Epilepsy has been defined as an imbalance in the electrical harmony of neuronal circuits, and, as such, it has much in common with cardiac arrhythmias. This imbalance has been associated with the abnormal functioning of several subtypes of voltage-gated K^+ channels. Of these, the loss of function mutation in the pore-forming $K_V7.2$ (*KCNQ2*) and $K_V7.3$ (*KCNQ3*) subunits have been linked to various forms of epilepsy.⁵⁰⁸ Episodic ataxia type 1 is a rare disabling condition

that begins in early childhood and is associated with uncoordinated movement of the head, arms, and legs. Attacks are provoked by sudden postural change or emotional stimulus, and have been associated with $K_v1.1$ (KCNA1) mutations. $K_v7.1$ and $K_v7.4$ subunits are expressed in the ear, and mutations in both have been associated with deafness.^{516,517} Loss of function mutations in $K_v7.1$ is associated with aberrant endolymph secretion, whereas mutations in $K_v7.4$ are associated with abnormal electrical signaling.

2.21.5 Challenges and New Directions for Ion Channel Drug Discovery

In recent years, ion channel biology has developed into one of the most challenging, exciting, and rewarding fields in life science and drug discovery. As discussed above, Na^+ , K^+ , and Ca^{2+} channels represent key components of the cellular machinery that controls diverse physiological functions. However, despite years of intensive research there are many levels on which our understanding of ion channel biology remains rudimentary. Several hundred genes encoding ion channel subunits have been identified, yet there remains a large gap in our understanding not only of the molecular composition of individual ion channel subtypes but also of how the properties of individual subunits relate to the physiological functions of native ion channels in different highly specialized systems such as the brain, kidney, and heart. The challenge has been to correlate sometimes incomplete information about ion channel subunit expression and function in certain populations of cells with ion channel properties that have been studied in most detail in heterologous

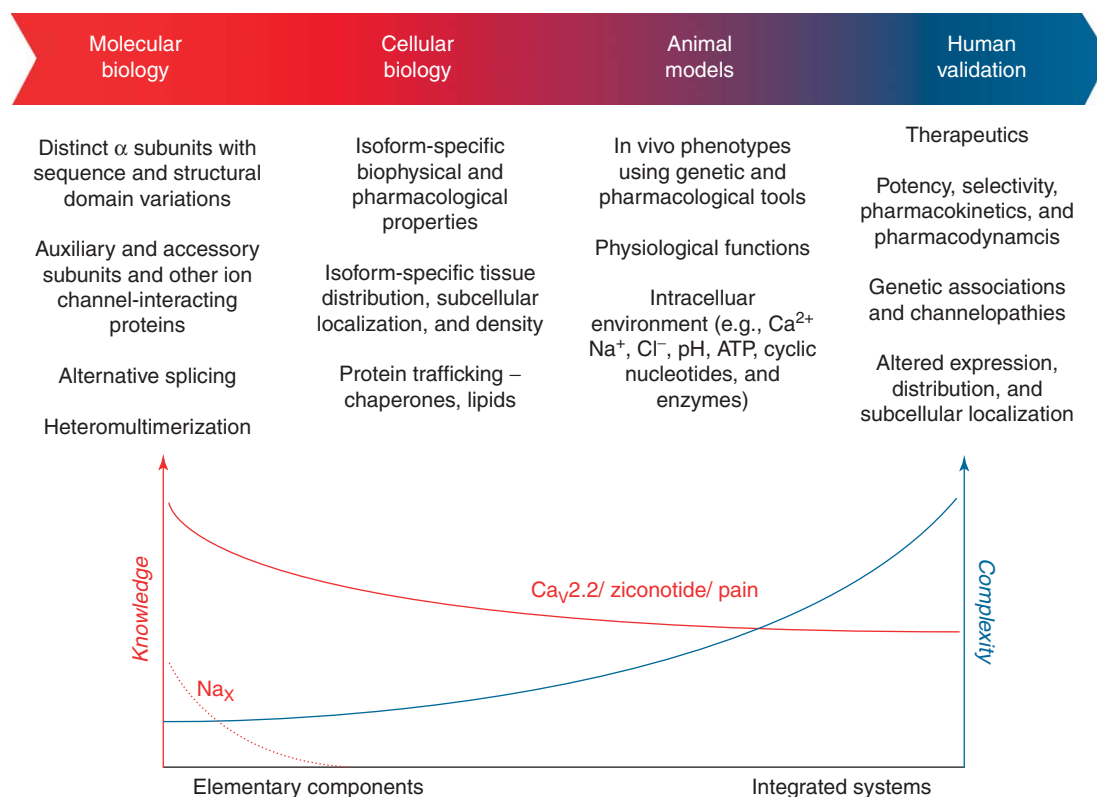

Figure 5 Schematic representation of the multidisciplinary challenges that are faced in ion channel basic research and in drug discovery and development. The inherent level of complexity tends to increase (the blue line) as one moves from describing the elementary molecular basis of ion channels toward elucidating their functional roles in complicated systems such as the human body. However, sufficient knowledge and understanding (the red lines) may permit the complexities to be addressed. For instance, the N-type ($Ca_v2.2$ -containing) Ca^{2+} channel represents a target where a wealth of molecular and cellular data exist and significant knowledge has been obtained about its role in human physiology and disease. Furthermore, validation of this target has been achieved in clinical trials of the N-type Ca^{2+} channel-specific drug ziconotide, which has been approved for the treatment of chronic pain in humans. In contrast, the orphan Na^+ channel-like genes (Na_x) have been categorized solely on the basis of sequence similarity, since their functional properties have not been determined in native cells or in heterologous expression systems. Perhaps through development and implementation of new technologies, the frontiers of knowledge about Na_x genes might advance, and eventually a more complete understanding of their role in human physiology and disease may emerge.

expression systems. Furthermore, the ways in which ion channel expression and function are modified in response to changing physiological environments present many barriers to translating ion channel gene functions to whole-animal physiology and pathology. Pharmacological and genetic approaches have proven to be invaluable in the study of ion channel function in native cells and in promoting our understanding of the role of ion channels as potential therapeutic targets. Nevertheless, it is becoming increasingly evident that an integrated approach is required in order to correlate information and knowledge obtained from *in vitro* cell biology and *in vivo* physiology approaches (Figure 5).

Looking to the future of drug discovery for voltage-gated ion channel targets, the development of automated planar chip-based electrophysiology systems will have an impact on success. Despite their current limitations, these systems have enabled a paradigm shift in ion channel research, and expectations are high for them to promote a better understanding of structure–activity relationships within multiple series of novel compounds. Over the next few years, it will be exciting to observe these new technologies improve and advance to enable true high-throughput, parallel, electrophysiology-based screening of ion channels. Of significance, automated electrophysiology-based screening systems offer a high-content advantage over other screening systems because multiple measurements can be made on each cell. At the macroscopic current level, the impact of an ion channel modulator on important parameters, such as peak current amplitude, as well as the kinetics of activation and inactivation, may be examined. These electrophysiology-based systems are also able to provide an additional level of information aimed at the early elucidation of the mechanism of action of an increased number of compounds than previously possible. Careful design of voltage clamp protocols enables several characteristics of the interaction of a compound with voltage-gated ion channels to be described (e.g., tonic versus phasic inhibition of ionic currents reflecting use dependence, as well as variable channel block at different holding potentials, reflecting state dependence). These valuable mechanistic data will enhance the ion channel drug discovery process and will be useful for prioritizing series of compounds that may appear similarly behaved when considered solely from a potency and selectivity perspective.

Biographies

Joseph G McGivern is the associate director of research in the HTS-Molecular Pharmacology Department at Amgen Inc., Thousand Oaks, CA. He obtained his PhD in physiology from the School of Medicine at the Queen's University of Belfast, UK, in 1992. Following the award of his PhD, he held research positions at Syntex Pharmaceuticals in Edinburgh (1991–95) and Roche Bioscience in Palo Alto, CA (1995–2000), before moving to Amgen in 2000. During his career in industry, McGivern has been involved in many aspects of ion channel drug discovery, including target validation, assay development, high-throughput screening, and technology development.

Jennings F Worley is the associate director of discovery operations at Vertex Pharmaceuticals Inc., San Diego, CA. He has been involved in ion channel research and drug discovery throughout his career. He received his PhD from the University of Maryland, School of Medicine in 1985 from the Department of Physiology. He then held postdoctoral positions at the University of Miami, Department of Pharmacology, and the University of Vermont, Department of Pharmacology. As a faculty member at the West Virginia University Department of Pharmacology and Toxicology, he continued his work on the relationship between ion channel structure and function and the role of ion channels in controlling cell function. Since 1990, Worley has been contributing to drug discovery, first at GlaxoSmithKline for over 12 years, then at Amphora Discovery Corporation and, more recently, at Vertex. During this time he has been involved in many phases of drug discovery, including target identification and validation, high-throughput screening methodology and technology development, as well as advancing compounds through preclinical studies for candidate selection.

2.22.1 Introduction

Ion channels expressed in the plasma membrane have been classified broadly as voltage-gated ion channels (VGICs; *see* 2.21 Ion Channels – Voltage Gated) and ligand-gated ion channels (LGICs). In case of the latter, the ligand is generally considered to be an extracellular messenger such as a neurotransmitter. Often, the same transmitter acts upon an array of G protein-coupled receptors (GPCRs) as well as LGIC, for example, acetylcholine acting via the muscarinic GPCR as well as nicotinic acetylcholine receptor (nAChR) LGIC. A few notable exceptions include glycine which, to date, is known to act on LGIC only and neuropeptides and histamine which appear to act exclusively via GPCRs. The boundaries between LGIC and VGIC become less marked when one considers intracellular ligands, for example Ca^{2+} /calmodulin or G protein-regulated channels, or the fact that some channels may be regulated by both ligand and voltage. In this chapter, however, we will consider the term ‘ligand’ to refer to extracellular messengers that are meant, physiologically, to exert predominant control over the opening or closing of the ion channel. Typically, this would comprise neurotransmitter receptor-associated LGIC hosting an ion channel

domain that is integral to the transmembrane region and an extracellular ligand binding domain. The chemical signal to which an LGIC responds depends on the specificity of ligand binding whereas the nature of the electrical signal generated depends on both selectivity of the ion channel and the electrochemical gradient across the membrane. Generally, cation-selective channels generate a net depolarizing or excitatory signal and anion-selective channels generate a net hyperpolarizing or inhibitory signal.

LGIC activated by extracellular ligands may be divided into five families. Three LGIC families that have initially been recognized based upon protein sequence and predicted receptor structure are (1) the Cys-loop superfamily (nAChRs, 5-hydroxytryptamine 5HT₃ receptors, γ -amino-butyric acid (GABA_{A/C}) receptors, glycine receptor (GlyR), and a newly discovered Zn²⁺-gated channel, (2) the glutamate (Glu)-gated family, and (3) the ATP (purinergic)-gated family. Two additional LGIC that are increasingly being recognized and whose better-known roles lie outside the synapse are (1) the transient receptor potential (TRP) channel family where members have been shown to respond to specific extracellular messengers, and (2) the acid-sensitive ion channel (ASIC) family whose members are gated by proton interaction. TRP and ASIC generally appear to function as sensory channels, but some family members are also expressed in central neural pathways, including brain, where the roles remain to be further elucidated. Many LGIC are expressed not only in neurons and muscle, but also in nonneuronal, ‘nonexcitable’ cells such as glia, lymphocytes, keratinocytes, endothelial cells, pancreatic cells, sperm, and others. Thus, LGIC undoubtedly serve many roles apart from neurotransmission, but these roles are only beginning to be elucidated. This chapter will present an overview of the properties of various LGIC. For more detailed information and discussion, the reader is referred to recent review articles cited in the following topical sections. Topography models of LGIC are depicted in [Figure 1](#), and a general summary of functional and pharmacological properties are presented in [Table 1](#).

2.22.2 Cys-Loop Superfamily

All members of the Cys-loop superfamily are thought to possess a similar architecture. These LGICs are pentameric, comprising five membrane-spanning subunits arrayed pseudosymmetrically around a central ion-conducting channel that is opened and closed depending upon agonist binding and allosteric transitions associated with activation and desensitization. Each subunit has four putative transmembrane (TM) regions. Functional Cys-loop LGIC require subunits with a large N-terminal domain, wherein agonist is bound, and at least one (usually two) subunits must contain the signature vicinal cysteine pair that defines one of the peptide loops important for ligand binding and/or channel gating. Typically, a subunit containing the Cys-loop signature sequence is given the α appellation, whether or not it has been demonstrated to participate directly in channel gating.

The Cys-loop superfamily contains both cationic and anionic LGIC. Cation-conducting LGIC are excitatory – depolarizing the cell membrane to activate voltage-dependent channels and, in many but not all instances, gating Ca²⁺ to activate intracellular Ca²⁺-dependent signaling pathways. Other LGIC are anion-conducting and generally inhibit neuronal firing in adult mammals (depending upon the Cl[−] ion gradient that differs among cells and with development). Within the Cys-loop superfamily, nAChR and 5HT₃ receptor channels are cationic and excitatory whereas GABA_A and Gly receptor channels are anionic and generally inhibitory. Although structure–function studies of LGIC have revealed a great deal about the molecular determinants critical to agonist binding and ion selectivity, a comprehensive understanding of how LGIC function is limited; high-resolution positioning and dynamics to designate these determinants in a three-dimensional context is an increasingly active area of research.^{1–5} The more recent discovery and structural resolution of a soluble acetylcholine binding protein (AChBP) by Sixma and colleagues has provided a framework to model the extracellular domain of all Cys-loop LGIC in three-dimensional terms, and chimeric constructs of AChBP with Cys-loop LGIC (e.g., 5HT₃) have begun to determine how agonist binding is converted to channel opening in this family.^{1,6}

2.22.2.1 Nicotinic Acetylcholine Receptors

nAChRs are widely characterized transmembrane allosteric proteins involved in the physiological responses to acetylcholine. These receptors are composed of homologous subunits encoded by a large multigene family, and are expressed in muscle, nerve, and sensory cells where they play critical roles in neuronal transmission and modulation. Several excellent reviews describing biophysical, physiological, and pharmacological properties of nAChR subtypes have appeared recently.^{7–11}

2.22.2.1.1 Current nomenclature

nAChRs comprise the ionotropic side of acetylcholine receptors, with muscarinic acetylcholine receptors (mAChRs) comprising the GPCR side. Classically, GPCR is the metabotropic receptor. However, nAChR and other LGIC also can

Figure 1 Topography models of ligand-gated ion channels (LGICs). Schematic representation of transmembrane topology of LGIC – Cys-loop (nAChR, 5HT₃R, GABA_A, and GlyR), glutamate (NMDA, AMPA, and kainate), ATP (P2X), ASIC, and TRP members. N and C indicate the N- and C-terminus, respectively. The heterooligomeric (trimeric, tetrameric, or pentameric) organization is also depicted.

influence metabotropic processes through Ca^{2+} influx mediated directly through the LGIC pore and indirectly through depolarization and activation of voltage-gated Ca^{2+} channels. Classically, nAChRs were categorized as ‘muscle-type’ (skeletal muscle and the related electroplaque of *Torpedo* and other electric fish) and ganglionic (sympathetic, parasympathetic, and enteric ganglia) based upon pharmacologic distinctions such as selective blockade of ganglionic receptors with hexamethonium and selective neuromuscular desensitization by decamethonium.¹² In the past 15 years, however, molecular biology studies have made it clear that nAChRs are widespread in brain as well as ganglia and skeletal muscle. The term neuronal nAChRs is meant to include those found in the central nervous system (CNS – brain and spinal cord) and in the peripheral nervous system (PNS – sensory as well as autonomic and enteric), but not skeletal muscle/electroplaque. Indeed, no muscle nAChR subunit has yet been found to be expressed in brain or ganglion. However, neuronal nAChRs are not exclusively neuronal; several of these subunits are found in various nonneuronal cells such as endothelial cells, keratinocytes, macrophage, and lymphocytes where their roles remain to be determined.

nAChR subunits containing the Cys-loop signature vicinal cysteines in the appropriate position are designated as α . In skeletal muscle, the other subunits were named β , δ , ϵ (embryonic), and γ (adult substitute for ϵ). Since the cloning of neuronal nAChR, muscle α has become $\alpha 1$ and neuronal α are numbered in sequence of discovery. Neuronal nAChR subunits that did not contain the signature vicinal cysteines were designated as non- α in the earlier literature. Today, all neuronal non- α are designated as β and numbered in order of discovery with the muscle subunit being $\beta 1$. These

Table 1 Ligand-gated ion channels: functional and pharmacological distinctions

<i>Transmitter class</i>	<i>Receptor subtype</i>	<i>Ion selectivity^a</i>	<i>Agonists</i>	<i>Antagonists</i>	<i>Modulators</i>
ACh nicotinic	$\alpha 1\beta 1\gamma\delta$ / muscle, <i>Torpedo</i>	Cation; low PCa^{2+}	Nicotine, decamethonium, succinylcholine	Pancuronium, vecuronium, α -bungarotoxin, α -conotoxin MI	Physostigmine, galantamine, proadifen, steroids, e.g., promgestone, cholesterol
	$\alpha 3\beta 4$ / ganglionic nAChR		Nicotine, lobeline, DMPP	Hexamethonium, trimetaphan	
	$\alpha 4\beta 2$	Cation; moderate PCa^{2+}	Nicotine, cytosine, isproniline, ABT-418, SIB-1508Y	Dihydro- β -erythroidine	
	$\alpha 6$		Epibatidine, A-85380, cytosine	α -Conotoxin MII	
	$\alpha 7$		Choline, PNU-282987	Methyllycaconitine	PNU-120596, 5-hydroxy indole
	$\alpha 9, \alpha 9\alpha 10$	Cation; high PCa^{2+}	ACh	α -Conotoxin PeIA, nicotine, strychnine	
Serotonin	5HT _{3A}	Cation; moderate PCa^{2+}	2-methyl-5-hydroxytryptamine, phenylbiguanide, <i>m</i> -chlorophenylbiguanide, SR 57227A	Ondansetron; Granisetron; MDL72222	Ethanol, anesthetics (volatile)
GABA GABA _A	GABA _A $\alpha 1\beta 2\gamma 2$		Muscimol > GABA, THIP (selective for GABA _A versus GABA _C)	Bicuculline	Benzodiazepines, barbiturates, neuroactive steroids, ethanol
	GABA _A $\alpha 4, \alpha 6$	Anion (Cl^-)			Relatively insensitive to benzodiazepines
GABA GABA _C	$\rho 1, \rho 2, \rho 3$		GABA > muscimol, (+)-CAMP	TPMPA, CGP36742, 3-ACPBuPA	Glycine potentiates, Zn^{2+} inhibits, loreclezole and (+)-ROD188 potentiate GABA _A , inhibit GABA _C ; μM neurosteroids potentiate GABA _C versus nM for GABA _A
Glycine		Anion	Glycine, β -alanine, taurine	Strychnine, nipecotic acid, ginkgolide B, tropisetron	Positive ivermectin, ethanol and volatile anesthetics Negative progesterone, pregnenolone (inhibition)
Zn^{2+}	ZAC	Cation	Zn^{2+}	<i>d</i> -Tubocurarine	
Glutamate ^b	GluR1	Cation, moderate PCa^{2+}	(<i>S</i>)-AMPA, (<i>S</i>)-ACPA, (<i>S</i>)-5-fluorowillardiine	ATPO, GYKI 53655, GYKI 52466, SYM-2206, Spider toxins (iGluR subunit and	Cyclothiazide, PEPA, AMPAkines

Table 1 Continued

<i>Transmitter class</i>	<i>Receptor subtype</i>	<i>Ion selectivity^a</i>	<i>Agonists</i>	<i>Antagonists</i>	<i>Modulators</i>
AMPA-sensitive	GluR2	Cation and low Cl^- (0.1 $\text{PCl}^-/\text{PNa}^+$) Q/R RNA editing reduces conductance and $\text{PCa}^{2+}/\text{PNa}^{+c}$		Q/R editing dependent), CNQX, DNQX	
Glutamate kainate- sensitive	Generic GluR5- GluR6			Spider toxins (Q/R dependent), CNQX/ DNQX (also block AMPA-sensitive iGluR)	Concanavalin A
	GluR5	Cation	(<i>S</i>)-5-iodowillardiine, (<i>S</i>)-ATPA, LY339434	LY382884, LY294486, NS-102, SYM-2081 (desensitizer)	
	GluR6	Cation, Q/R RNA editing reduces $\text{PCa}^{2+}/\text{PNa}^+$ and increases $\text{PCl}^-/\text{PNa}^+$		NS-102, SYM-2081 (desensitizer)	
	GluR6/KA		5-Iodowillardiine (weak)		
Glutamate NMDA- sensitive	NR1 (glycine coagonist site)			Kynurenic acid derivatives, quinoxalinediones, phthalazinediones, benzazepinediones	
	NR1/NR2 generic	Cation; high PCa^{2+}	NMDA, aspartate Coagonist: glycine	Mg^{2+} , AP5, AP7; MK801	Positive: arachidonic acid, PACAP Negative: dynorphin, H^+ , Zn^{2+}
	NR1/NR2A	Cation; moderate–high PCa^{2+} , low PCl^-		10-fold less sensitive to glycine site antagonists	High Zn^{2+} and dynorphin sensitivity
	NR1/NR2B	Cation; high PCa^{2+}		CGP 61594 glycine site antagonist, Ifenprodil, Ro 25-6981, CP 101,606	
	NR1/NR2C	Cation; moderate PCa^{2+}			Low Zn^{2+} sensitivity
	NR1/NR2D				
Unknown	NR3A	Cation	Glycine alone is agonist		
	NR3B				
ATP (purines)	P2X1	Cation, high PCa^{2+} , ($\text{PCa}^{2+}/\text{Na}^+ \sim 3.9$)	BzATP, α,β -MeATP	Ip5I, TNP-ATP, suramin analogs, PPADS analogs	
	P2X1/5	Cation, moderate PCa^{2+}	α -MeSATP, α,β -MeATP	Weak sensitivity to TNP- ATP	

Sensory stimuli	P2X2	Cation, moderate PCa^{2+} , large pore formation	2-MeSATP, ATP γ S (insensitive to α,β -MeATP)	PPADS	Zn^{2+} potentiates, H^+ potentiates
	P2X2/3	Cation, moderate PCa^{2+}	BzATP, α,β -MeATP, little response to Ap5A	TNP-ATP, A-317491	H^+ potentiates
	P2X3	Cation, moderate PCa^{2+}	BzATP, α,β -MeATP, Ap5A	TNP-ATP, A-317491, suramin, PPADS	Zn^{2+} potentiates, H^+ inhibits
	P2X4	Cation, large pore formation	BzATP	(Insensitive to suramin, PPADS)	Zn^{2+} ; ivermectin
	P2X5	Cation	ATP (insensitive to α,β -MeATP)	(Insensitive to suramin, PPADS)	
	P2X6		α,β -MeATP		
	P2X7	Cation, large pore formation		Calmidazolium; KN-62	
	TRPA1		Mustard oil, cinnamon oil		
	TRPM8	Cation, moderate PCa^{2+} ($\text{PCa}^{2+}/\text{Na}^+ 1-3$)	Menthol, Icilin		
	TRPV1	Cation, high PCa^{2+} ($\text{PCa}^{2+}/\text{Na}^+ \sim 10$), PMg^{2+} ($\text{PMg}^{2+}/\text{Na}^+ \sim 5$)	Capsaicin, resiniferatoxin, anandamide, olvanil, SDZ-249665 Endogenous: anandamide, 12-HPETE, leukotriene B4, <i>N</i> -arachidonoyl dopamine	Capsazepine, Iodo-resiniferatoxin, NDT-9525276, ruthenium red	'Agonists', protons, temperature, may act in concert as modulators
Proton	TRPV3		Camphor		
	ASIC1a	Cation; Ca^{2+}	Proton	PcTx1	Zn^{2+} (nM inhibition), FMRFamide (potentiation)
	ASIC1b	Cation	Proton		FMRFamide (potentiation)
	ASIC2a	Cation, low PCa^{2+}	Proton		Zn^{2+} (μM potentiation)
	ASIC2b	Cation	Proton		
	ASIC3	Cation	Proton	APETx2; Gd^{3+}	FMRFamide, neuropeptide SF, neuropeptide FF ²⁷
	ASIC4		Proton		

^a Calcium permeability (PCa^{2+}): low PCa^{2+} : $\text{PCa}^{2+}/\text{Na}^+ \leq 1$; moderate PCa^{2+} : $\text{PCa}^{2+}/\text{Na}^+ 1-3$; high PCa^{2+} : $\text{PCa}^{2+}/\text{Na}^+ 3-20$.

^b Glutamate LGIC are subject to RNA editing and alternative splicing at sites in or near the channel region.¹⁴⁵

^c RNA-edited forms tend to be predominant in the adult (for further discussion, see text).

^d Lower concentrations of neuropeptide FF appear selective for ASIC2a/3 heteromeric receptors.²²⁸

numeric designations are not sub- or superscripted. Subscripted numbers are meant to refer specifically to the number of like subunits present in the pentameric nAChR. Thus, for example, the adult muscle nAChR is $(\alpha 1)_2\beta 1\delta\gamma$, meaning two $\alpha 1$, one $\beta 1$, one δ , and one γ subunit. However, one should be cautious in that the same muscle nAChR might also be called $\alpha 2\beta\delta\gamma$ or $\alpha_2\beta\delta\gamma$, especially before additional nAChR α became known. Muscle nAChRs do not contain $\alpha 2$ or any α other than $\alpha 1$, nor any β other than $\beta 1$. Likewise, muscle nAChR subunits are not known to be expressed in neurons nor any other cell type. The lone exception is that ‘neuronal’ $\alpha 7$ nAChR, which in fact is found in many nonneuronal cells, can be transiently expressed in embryonic or denervated skeletal muscle, in addition to the classical $\alpha 1$ -containing muscle nAChR.^{13–15}

Lastly, use of the asterisk (*) wild card should be noted. In most instances outside the neuromuscular junction, the exact composition and stoichiometry of nAChR is not known with certainty. Characteristics of the physiologic response may be similar to a recombinant nAChR expressed, for example, in *Xenopus* oocytes or transfected HEK293 cells, but often differences also can be found and it is not clear whether the differences are due to assay, expression context, or receptor structure. The asterisk wild card is used to indicate the possibility that other subunits may also contribute to the nAChR, or may be read to indicate that the response is similar but not necessarily identical to the nAChR designated. Thus, for example, $\alpha 4\beta 2^*$ would mean $\alpha 4\beta 2$ -like nAChR that may contain other subunits.

2.22.2.1.2 Molecular biology

To date, 17 nAChR subunits have been cloned. Of these, five ($\alpha 1$, $\beta 1$, δ , ϵ , and γ) are expressed in skeletal muscle or the related fish electroplaque, and apparently only in those tissues. The other 12 subunits are found in neurons, in endocrine cells (adrenal chromaffin cells), and to some extent, also in classically nonexcitable cells such as endothelial, epithelial, and immune system cells. These are the $\alpha 2$ through $\alpha 10$ and $\beta 2$ through $\beta 4$ subunits. Among these, $\alpha 7$ nAChR subunits appear to be one of the most widespread throughout the body, including brain, autonomic ganglia, adrenal chromaffin cells, nonneuronal cells, and even skeletal muscle during development or following denervation. The roles of $\alpha 7$ nAChR are not well understood, but are of considerable interest because of implications in diseases with large unmet medical need.

The nAChRs principally responsible for autonomic synaptic transmission, including sympathetic/adrenal transmission, are the $\alpha 3^*$ nAChRs. These include $\alpha 3\beta 2^*$ as well as $\alpha 3\beta 4^*$ nAChR. In recombinant expression systems the $\alpha 3\beta 4$ nAChR correlates more closely with ganglionic receptors expressed by neuroblastoma IMR-32 or pheochromocytoma PC-12 cells assayed in the same system. Other nAChR subunits expressed in autonomic neurons and endocrine cells are $\alpha 5$ and $\alpha 7$. There are many possible combinations for these five subunits in a pentameric complex, but exactly what combinations are formed and whether they differ in any disease or pathological state is not clear. The $\alpha 5$ subunit does not function alone or with any known β subunit, but $\alpha 5$ may combine with other subunits to modify their function biophysically or pharmacologically, for example, in $\alpha 3\alpha 5\beta 4$. The $\alpha 7$ subunit, in contrast to $\alpha 5$, can form functional homomeric nAChR in recombinant systems, and it is believed that native $\alpha 7$ nAChRs also are homomeric, at least, in part. There is some evidence that $\alpha 7$ may combine with $\beta 2$ or other subunits, but further research is needed. Ganglionic $\alpha 3^*$ nAChRs also are expressed in CNS and other areas of pharmaceutical interest. However, potential adverse effect liability resulting from interaction with autonomic and endocrine nAChR may be an obvious problem.

CNS receptors of particular interest are $\alpha 4\beta 2^*$, $\alpha 7^*$, and $\alpha 6^*$. The $\alpha 4\beta 2$ nAChR comprises 90% of the high-affinity nicotine-binding sites in rodent brain and may be involved in attentional and cognitive functions as well as mediating the nicotine cue (reward). In recombinant systems, $\alpha 4\beta 4$ also can be expressed and are particularly sensitive to many agonists, but there is little evidence for physiological expression of $\alpha 4\beta 4$ except perhaps in retina.^{16,17} The $\alpha 7^*$ nAChRs have among the lowest affinity to nicotine, but also may contribute to cognition and $\alpha 7$ deficits have been implicated in schizophrenia and Alzheimer’s disease (AD). While $\alpha 7$ expression is widespread, its roles are largely unknown and knockout mice have shown surprisingly subtle deficits.^{18,19} The $\alpha 6^*$ nAChRs have been difficult to express functionally in recombinant systems and therefore development of $\alpha 6^*$ pharmacology has been slow. However, recent studies in mice have made it clear that $\alpha 6^*$ nAChR is expressed in brain and can stimulate dopamine release.^{20–25} Unlike many other nAChR subunits, $\alpha 6$ and $\alpha 4$ appear to be selectively expressed in CNS and are thereby an enticing target if highly selective ligands can be identified.

The $\alpha 9$ subunit has a restricted distribution, being found primarily in the inner ear,^{26–31} keratinocytes,³² and lymphocytes.³³ Additionally there is some evidence for $\alpha 9$ expression in sensory dorsal root ganglia.³⁴ In recombinant systems, $\alpha 10$ increases the functional expression of $\alpha 9$ without marked influence on the unique $\alpha 9$ pharmacology.^{32,35} Whether $\alpha 10$ can combine with other subunits is not clear.

The $\alpha 2$ subunit forms functional nAChR when combined with $\beta 2$ or $\beta 4$, and $\alpha 2$ is expressed in brain, particularly monkey.^{36–38} However, at present, there are few tools available to address $\alpha 2^*$ nAChR and its roles are unclear.

Two subunits, $\alpha 5$ and $\beta 3$, have been enigmatic in expression systems. The $\alpha 5$ subunit clearly is expressed throughout the nervous system and likely plays a role in nAChR expression and function. In recombinant systems, however, it does not form functional nAChR either by itself or when combined with any known β subunit. There are reports that $\alpha 5$ may modify the function of other nAChR, particularly as a third party in $\alpha 4\beta 2^*$ and $\alpha 3\beta 4^*$. However, functional effects are subtle and further work is needed.

Likewise, the $\beta 3$ subunit does not form a functional nAChR when combined with any known α subunit in a mixture limited to two subunit types. However, $\beta 3$ again may modify expression or function of other nAChR. In brain, elegant recent studies using gene deletion and selective ligands including *Conus* toxins indicate that $\beta 3$ may be particularly important in $\alpha 6^*$ nAChR.^{21,23,39,40}

The $\alpha 8$ subunit is known to be expressed only in avian brain and retina, not in mammals. Pharmacologically and biophysically it is similar to $\alpha 7$.

2.22.2.1.3 Protein structure

All nAChRs, like other members of the Cys-loop superfamily, are believed to be pentameric (assembled from exactly five homologous subunits). The $\alpha 7$, $\alpha 8$, and $\alpha 9$ nAChR subunits each are able to form functional homomeric LGIC (comprising one and only one subunit type) in recombinant expression systems. Among these, $\alpha 9$ functional expression is boosted markedly by $\alpha 10$ making it seem likely that $\alpha 9\alpha 10$ is a prominent heteromer, $\alpha 8$ has been found in chick only, and thus $\alpha 7$ appears to be the predominant homomeric nAChR in mammals. However, conceivably $\alpha 7$ could also participate in heteromeric assemblies and some evidence suggests expression of $\alpha 7\beta 2$ by some neurons.⁴¹

Other nAChRs are heteromeric and assembled from at least two different subunits including at least one from the α group and at least one from the non- α group. The binding site for ACh lies at the interface(s) between α and non- α subunit, and peptide loops from both subunits contribute to binding and allosteric channel activation. While the α subunit may have the more prominent influence, the non- α subunit also contributes to nAChR pharmacology. The existence of transcripts for a range of α and β subunits in neurons raises the potential for a wide array of receptor combinations, although one would expect that a smaller subset of combinations would be preferred in vivo. Accordingly, the analysis of native nAChR composition is an area of intense research guided by both pharmacologic studies with subtype selective ligands and evaluation of gene knockout animals. For example, it has been determined that a variety of α/β subunit combinations underlie α -conotoxin MII-sensitive and -insensitive nAChRs modulating dopamine release in the striatum²² whereas a unique combination has been elucidated in retinal afferents.²¹

Initial evidence that nAChRs are pentamers is derived from electron microscopy of tubular crystals prepared from *Torpedo* electric organ postsynaptic membranes.⁴ More recently, additional insight into nAChR structure has emerged from x-ray diffraction studies with an invertebrate soluble ACh binding protein (AChBP).^{1,2,42–45} AChBP also is a pentamer and shows considerable similarity to the extracellular N-terminal ligand binding domain of nAChR, with conservation of amino acid residues involved in the formation of agonist binding site.

The muscle-type nAChR, derived from assembly of two $\alpha 1$ subunits and one each $\beta 1$, δ , and γ (ϵ in fetus), is organized in a clockwise $\alpha 1\gamma\alpha 1\beta 1\delta$ arrangement. ACh binds to two orthosteric sites located at the interfaces of $\alpha 1-\gamma$ and $\alpha 1-\delta$. The segments hosting the ligand binding domain are organized around two sets of beta-sheets and joined via disulfide bridges forming the Cys-loop, as demonstrated by the structure of AChBP.⁴⁶ The subunits in the membrane-spanning domains are made from four alpha-helical segments TM1–TM4 that are arranged symmetrically, forming an inner ring of helices (TM2) which shapes the pore and an outer shell of helices (TM1, TM3, and TM4), which coil around to shield the inner ring from lipids.⁴ The ion-conducting channel makes a narrow water-filled path across the membrane and contains the ion gate, which opens when ACh occupies both binding sites. Utilizing the structural model of the *Torpedo* ACh receptor, a series of molecular links that couple the neurotransmitter binding to channel gating has been identified.⁴⁷ A pair of arginine and glutamate residues in each α subunit electrostatically links peripheral and inner beta-sheets from the binding domain and positions them to engage with the channel. The glutamate, along with the flanking valine residues, energetically couples to conserved proline and serine residues in the pore-forming alpha-helix. These series of interresidue couplings serve as a primary pathway for linking ligand binding to channel gating. Mutual interactions between residues in the extracellular agonist binding domain and the TM2–TM3 loop has also been shown to be critical for fast gating properties.⁴⁸

The TM3–TM4 intracellular loop in nAChR and other Cys-loop members is relatively long, exhibits relatively low homology among subunits, and contains a number of potential phosphorylation sites. It is thought that this loop may be important for receptor assembly, trafficking, and/or modulation by kinase signaling cascades. However, this is an active

research area with much remaining to be learned. The extracellular C-terminus beyond TM4 is short, for example, only eight amino acids in rat and human $\alpha 4$. Nevertheless, it remains a region that may participate in LGIC pharmacology, and for example has been implicated in the potentiation of $\alpha 4\beta 2$ nAChR by estradiol.⁴⁹

Neuronal nAChRs are believed to have a similar pentameric structure. Most are thought to comprise at least two functional α subunits (five in the case of homomeric nAChR) and three β or combination of β plus $\alpha 5$ ($\alpha 7\alpha 8$ in chick and $\alpha 9\alpha 10$ in mammal would be exceptions lacking β but not homomeric). Thus, $\alpha 4\beta 2^*$, thought to comprise 90% of the high-affinity nicotine binding sites in rodent brain, would be expected to be $(\alpha 4)_2(\beta 2)_3$ or possibly $(\alpha 4)_2\alpha 5(\beta 2)_3$. However, more complex combinations can be envisioned and even with just $\alpha 4$ and $\beta 2$, at least two pharmacologically distinct nAChR can be expressed in recombinant systems.⁵⁰ The composition of muscle nAChR is fairly well known, those of neuronal nAChRs are beginning to come to light, and those of other nAChR are not known but generally thought to follow the neuronal pattern. Pharmacologically, one may think of nAChR in six categories: (1) skeletal muscle ($\alpha 1^*$); (2) $\alpha 3\beta 4^*$ (correlating with the more prominent ganglionic nAChR pharmacology although other nAChR also are expressed in autonomic ganglia); (3) $\alpha 3\beta 2^*$ and $\alpha 6\beta 2^*$ (these likely will be subdivided in the near future, but there are few pharmacologic tools at present); (4) $\alpha 4\beta 2^*$; (5) $\alpha 7^*$; and (6) $\alpha 9^*$. Other receptors likely are expressed, for example $\alpha 4\beta 4^*$ in retina¹⁶ but are yet to attract as much therapeutic interest as others.

In addition to primary subunits, a number of accessory proteins that coassociate or interact with nAChRs continue to emerge. A family of genes encoded by the neuregulin-1 gene can modulate the expression of both muscle and neuronal-type nAChRs. In addition to their well-described roles at the neuromuscular junction, neuregulins can also increase expression of nAChRs in neurons such as those from interpeduncular nucleus and hippocampal interneurons.⁵¹ In interaction of rapsyn with muscle, but not neuronal, nAChRs appear to be important for clustering nAChRs at the neuromuscular junction. RIC-3, originally identified in *Caenorhabditis elegans* as a protein encoded by the gene resistance to inhibitors of cholinesterase, can enhance the expression of multiple nAChRs including both homomeric and heteromeric receptors in transfected mammalian cells, possibly by enhancing subunit folding and assembly.⁵² Other novel proteins have been identified by tandem affinity purification of the levamisole-sensitive nAChRs from *C. elegans*.⁵³

2.22.2.1.4 Physiological functions

nAChRs are involved in a range of synaptic and extra synaptic functions.^{9,54,55} The muscle-type nAChR is a key mediator of electrical transmission at the neuromuscular junction. In the PNS, nAChRs mediate ganglionic neurotransmission whereas in the CNS, nicotinic cholinergic innervation mediates synaptic transmission and regulates processes such as transmitter release, synaptic plasticity, and neuronal network integration by providing modulatory input to a range of other neurotransmitter systems. Thus, nAChR subtypes are implicated in a range of physiological and pathophysiological functions related to cognitive functions, learning and memory, reward, motor control, arousal, and analgesia. For example, the central $\alpha 4\beta 2$ containing nAChRs are strongly implicated in the analgesic effects as revealed by knockout mice where antinociceptive effects to nicotine are reduced in both $\alpha 4$ and $\beta 2$ null mutant mice.⁵⁶ Results from the gain-of-function $\alpha 4$ -nAChR knockin mice suggest that this nAChR subunit is also important for nicotine-induced reward, tolerance, and sensitization.⁵⁷ On the other hand, $\alpha 7$ nAChRs are more implicated in cognitive and psychotic disorders. There is also growing evidence that nAChRs can modulate cellular functions beyond synaptic transmission in CNS and PNS. Acetylcholine can inhibit the release of macrophage tumor necrosis factor (TNF- α) and high mobility group box 1 (HMGB1) principally via the $\alpha 7$ nAChRs.⁵⁸

2.22.2.1.5 Regulation

Upregulation of nAChRs, particularly the $\alpha 4\beta 2$ subtype in the CNS, is a notable feature of chronic nicotine exposure, both in vitro and in vivo including in smokers.⁵⁹ This phenomenon has been studied in a number of heterologous expression systems. At least with $\alpha 4\beta 2$ nAChRs, the extent, magnitude, and functional consequences have been attributed to factors such as ratio of heteromeric subunits, ligand-induced chaperon activity that accelerates pentamer assembly, and stabilization of receptors in a predominantly high-affinity state.^{60,61} Upregulation of nAChRs derived from other subunits including $\alpha 7$, $\alpha 3$, and $\alpha 6$ has been reported, albeit to a lesser extent compared to $\alpha 4\beta 2$ nAChRs.^{62,63} nAChR regulation by kinases and phosphatases also is known, with a major role for tyrosine phosphorylation. The density and functional properties of $\alpha 7$ nAChRs are influenced by tyrosine phosphorylation status, where the net effects may be the result of balance between SRC family kinases and tyrosine phosphatases.^{64,65} $\alpha 7$ nAChRs on chick ganglion neurons undergo calcium-dependent trafficking that requires functional soluble

N-ethylmaleimide-sensitive factor attachment protein receptors (SNARE) without which these receptors lose their ability to activate the transcription factor cAMP response element binding protein (CREB) when re-exposed to agonist.⁶⁶

2.22.2.1.6 Prototypical pharmacology

In addition to the endogenous transmitter acetylcholine and the prototypical agonist nicotine, a range of selective agonists, competitive antagonists, and allosteric modulators of nAChRs are known to exist (Figure 2). Many systematic reviews of published nAChR agonists and antagonists of nAChRs are available.^{7,8,11} In the area of agonists, medicinal chemistry efforts have focused mostly on analogs of nicotine, epibatidine, anabaseine, and cytosine. Analogs of nicotine and metanictine analogs, cytosine (e.g., varenicline), epibatidine, and various classes of diamines and pyridyl ethers (e.g., A-85380, ABT-594) have been described with varying degrees of agonist efficacy and selectivity. A major objective in the optimization of these analogs is to enhance selectivity to specific heteromeric nAChR combinations ($\alpha 4^*$, $\alpha 6^*$, etc.) versus ganglionic nAChRs. At the $\alpha 7$ nAChR, a variety of quinuclidine analogs have been described as selective agonists with little activity at $\alpha 4\beta 2$ and other heteromeric receptors whereas hydroxyindole, urea, and tetrahydroquinoline derivatives have been claimed as positive allosteric modulators. Like agonists, most of the reference antagonists are also obtained from natural sources. These include α -bungarotoxin, methyllycaconitine, dihydro- β -erythroidine, and D-tubocurarine with varying levels of discrimination among different nAChR subtypes. Conus peptides targeted to three different families of ligand-gated ion channels including nAChRs also are described, of which the most widely examined are the alpha-conotoxins exemplified by alpha-conotoxin ImI and alpha-conotoxin MII.⁶⁷

2.22.2.1.7 Prototypical therapeutics

Neuromuscular nAChR antagonists have been marketed as muscle relaxants (antispasmodics) including surgical adjuncts, and in some instances, these compounds may reduce headache or muscle pain by reducing muscle spasm. Examples include afloqualone, atracurium, cisatracurium, doxacurium, eperisone, mivacurium, oxantel, pipecuronium, rocuronium, and vecuronium. Mecamylamine, a CNS-penetrating nAChR antagonist, was once marketed for

Figure 2 Agonists, antagonists, and modulators of nAChR.

hypertension, and currently may be of interest for neuropsychiatric disorders such as Tourette's syndrome, attention deficit hyperactivity disorder (ADHD), and depression. Other nAChR-related compounds in the market include ondansetron for emesis and galanthamine for AD/cognitive impairment. However, neither of these compounds was targeted toward nAChR initially. Ondansetron is a 5HT₃ antagonist, which undoubtedly could explain its antiemetic action, but it also acts as an antagonist at muscle and neuronal nAChRs.^{68–70} The alkaloid galanthamine is an acetylcholinesterase inhibitor, but some laboratories have argued that it may also act as an allosteric modulator of certain nAChRs.^{71–77} However, the latter remains somewhat controversial since the modulatory effects are rather modest compared to more recently discovered compounds.

Compounds with varying degrees of nAChR subtype selectivity have more recently entered clinical trials. These include varenicline, an $\alpha 4\beta 2$ partial agonist for smoking cessation; ABT-089 and ispronicline (TC-1734), $\alpha 4\beta 2$ partial agonists for ADHD, AD, and other cognitive deficits; GTS-21, an $\alpha 7/\alpha 4\beta 2$ ligand for cognitive deficits in schizophrenia; MEM-3454 and TC-1698, $\alpha 7$ selective ligands for cognitive impairment and schizophrenia. Other agents that have been or continue to be investigated clinically include gantacurium, a neuromuscular nicotinic antagonist as anesthesia adjunct for muscle relaxation; rivanicline, an nAChR agonist for ulcerative colitis; ACV-1, an nAChR antagonist isolated from *Conus victoriae*, for neuropathic pain; CGX-1007, a *Conus* peptide, as an nAChR antagonist for epilepsy; and the alkaloid lobeline, an inhibitor of nicotine-evoked dopamine release for ADHD and methamphetamine abuse. Finally, another approach under study is the use of nicotine immunization to aid smoking cessation. Substances in clinical trials include NicQb (CYT-002) in phase II, Nic Vax, and TA-NIC (IPC-1020).

2.22.2.1.8 Diseases

The importance of nAChRs in pathology is illustrated by the findings that muscle nAChR is a target for autoimmunity in myasthenia gravis. Myasthenia gravis is caused by antibodies against the muscle nAChR, which compromise the end-plate potential reducing effective synaptic transmission.⁷⁸ Neuronal nAChR mutations are associated with a rare form of genetically transmissible epilepsy, the autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE).⁷⁹ Mutations in the $\alpha 4$ and $\beta 2$ genes in individuals suffering from ADNFLE give rise to single nucleotide polymorphisms, which cause single amino acid mutations or insertions. Heteromeric expression of the mutant subunit with its wild-type α or β counterpart demonstrated increased sensitivity to ACh and reduced Ca²⁺ potentiation response.⁸⁰ Another $\beta 2$ mutation in the TM3 segment, outside the known ADNFLE cluster, also resulted in increased sensitivity to ACh.⁸¹ This mutation is associated not only with epilepsy, but also with defects in cognitive tasks such as nAChR verbal memory tasks. The $\alpha 7$ nAChR has been implicated in schizophrenia, in particular for the auditory sensory processing deficit (P50 deficit) through genetic linkage findings in chromosome 15q14 locus, which corresponds to the locus of the gene encoding $\alpha 7$ subunit.⁸²

2.22.2.2 5HT₃ Receptors

Serotonergic signaling plays key roles in the generation and modulation of various cognitive and behavioral functions such as pain, mood, sleep, addiction, depression, anxiety, and learning, and disruption of serotonergic systems has been implicated in the etiology of various psychiatric disorders.

2.22.2.2.1 Current nomenclature

Serotonin (5-hydroxytryptamine, 5HT) exerts its diverse actions by binding to receptors that are classed based on sequence similarity, second messenger signaling pathways, and pharmacological properties. The wide range of biological functions of 5HT is reflected in the existence of a large family of receptor subtypes for this neurotransmitter.⁸³ The majority of 5HT receptors couple to effector molecules through GPCRs.^{84,85} However, the 5HT₃ receptor functions as a rapidly activating LGIC with a nonselective cation channel.^{86–88}

2.22.2.2.2 Molecular biology

The human genome contains five genes (*5HT3A–E*) of which two subunits, *5HT3A* and *5HT3B*, have been well described and shown to be involved in the formation of functional ion channels. The first to be cloned, *5HT3A*, expresses as a functional homomer, whereas the second, *5HT3B*, does not express alone, but expresses in the presence of 5HT_{3A} subunit. The genes for these two subunits are located in close proximity on chromosome 11. Although the exact subunit composition of receptors *in vivo* is not fully known, there does appear to be region-specific expression of the different subunits.⁸⁹ Long and short splice variants of 5HT_{3A} receptors are known. In the case of the short splice variant, five or six amino acid residues located within the putative large intracellular loop between the TM3 and TM4

domains are deleted. The shorter form is the most abundant in the CNS. Cloned human forms correspond to the shorter form. In neuroblastoma cells and rodents, the proportions of short and long forms are regulated by development and/or differentiation. Studies in rat hippocampal CA1 interneurons demonstrate that the primary 5HT₃ receptor is the short subunit with 5HT_{3B} and 5HT_{3A} long variants undetected.⁹⁰

2.22.2.2.3 Protein structure

Like other members of this superfamily, the 5HT₃ receptor is pentameric in nature, with the five subunits surrounding a central ion channel. Purified 5HT₃ receptor from NIE-115 neuroblastoma reveals a protein band of ~55 kDa. The receptor shares structural features common to Cys-loop LGIC, such as a large extracellular N-terminus region, four transmembrane domains (TM1–TM4), and a relatively long intracellular loop between TM3 and TM4. Studies of epitope-tagged 5HT₃ subunits using atomic force microscopy show that the subunit stoichiometry is 2A:3B and that the arrangement around the receptor rosette is B-B-A-B-A.⁹¹ Like other LGIC, the agonist-binding site is located in the N-terminal region. A conserved proline residue at the apex of the TM2–TM3 loop of 5HT₃ has been shown to be critical for gating and mutation of this residue yielded receptors that could bind radiolabeled ligands, but were nonfunctional.⁹² Recent studies of 5HT₃ in conjunction with other members of the Cys-loop family have helped identify key determinants in TM2 and the intracellular TM2–TM3 loop that affect channel conductance and ion selectivity.⁹³

2.22.2.2.4 Physiological functions

5HT₃ receptors are expressed in native central and peripheral neurons where they are thought to play important roles in sensory processing and control of autonomic reflexes. Activation of the presynaptic 5HT₃ receptors is associated with modulation in the release of neurotransmitters and neuropeptides such as acetylcholine, GABA, dopamine, glutamate, and vasoactive intestinal peptide (VIP). 5HT₃ receptors play a role in nociceptive processing consistent with their expression on primary sensory afferents in the dorsal root ganglion and in the dorsal horn of the spinal cord. Overexpression of 5HT₃ receptors in mouse resulted in enhanced hippocampal-dependent learning and attention.⁹⁴ 5HT₃ receptors on vagal sensory afferents modulate visceral afferent and efferent pathways in the gastrointestinal and cardiovascular systems. In the enteric nervous system, 5HT₃ receptors also regulate gut motility and peristalsis whereas within the lower urinary tract, presynaptic 5HT₃ receptors have been implicated in parasympathetic transmission to the bladder.⁹⁵

Native and cloned receptors evoke current responses to 5HT that reverse close to 0 mV, and desensitize in the continued presence of the agonist. Under physiological conditions, the response to 5HT is carried by inward movement predominantly of Na⁺ ions, and divalent cations such as Ca²⁺ and Mg²⁺ suppress 5HT₃-mediated inward currents. The biophysical properties of the cloned 5HT_{3A} and 5HT_{3A-B} heteromers exhibit significant differences. Coexpression with the 5HT_{3B} subunit results in about 10-fold higher single-channel conductance receptors derived from the 5HT_{3A} homomer alone. By constructing chimeric 5HT_{3A} and 5HT_{3B} subunits, the ‘HA-stretch’ region within the large cytoplasmic loop of the receptor was identified as markedly influencing the single-channel conductance.⁹⁶ Although evidence for 5HT_{3A/3B} heteromeric combinations cannot be ruled out in vivo, single-cell reverse-transcriptase polymerase chain reaction (RT-PCR) and whole-cell patch-clamp recording studies of rat hippocampal neurons suggest that the 5HT_{3A} short subunit is most likely the primary 5HT₃ subunit contributing to the formation of functional 5HT₃ receptors in vivo.⁹⁰

2.22.2.2.5 Regulation

In addition to the observation that coexpression with the 5HT_{3B} subunit contributes to tissue-specific functional and pharmacological differences in 5HT₃ mediated signaling,⁹⁷ there is also evidence that the nicotinic α_4 subunit can coassemble with the 5HT_{3A} subunit to form a native heteromeric ion channel in CA1 hippocampal neurons in vivo.⁹⁰ Biochemical studies and site-directed mutagenesis to selectively eliminate N-linked glycosylation showed that all three sites on the N-terminal of the murine 5HT_{3A} receptor are critical for maximal plasma membrane targeting, ligand binding, and calcium influx.⁹⁸ The human homolog of the *ric-3* gene, *hRIC-3*, which enhances expression of $\alpha 7$ and possibly other nAChRs in heterologous expression systems, reportedly abolishes the expression of 5HT₃ receptors.⁹⁹

2.22.2.2.6 Prototypical pharmacology

5HT₃ receptor antagonists are clinically utilized for preventing nausea and vomiting that commonly occur during cytotoxic cancer chemotherapy and radiation therapy.¹⁰⁰ These agents, also known as ‘setrons’, are regarded as one of the most efficacious antiemetics available and serve as agents of first choice to control nausea and vomiting. These

Figure 3 Agonists and antagonists of 5HT₃.

agents inhibit 5HT activity in the small intestine, vagus nerve, and the chemoreceptor trigger zone of the medulla-vomiting center. Examples of 5HT₃ antagonists include ondansetron, dolasetron, tropisetron, palonosetron, and granisetron (Figure 3). Currently approved ‘setrons’ are all effective antiemetics, but differ in terms of pharmacodynamic and pharmacokinetic profiles influencing dosing regimens, cardiovascular safety, and potential drug–drug interactions. Notable differences in the pharmacological profiles for some 5HT₃ antagonists also exist. For example, granisetron is a potent and highly selective 5HT₃ receptor antagonist and has little or no affinity for other 5HT receptors whereas ondansetron, palonosetron, and tropisetron display affinity for other neurotransmitter receptors and LGIC, although the relative contributions of these interactions to the efficacy and/or adverse event profile are unclear.

The plant alkaloid picrotoxin, known as an antagonist of GABA_A and glycine receptors, also inhibits 5HT₃ receptors. Picrotoxin displays notable selectivity between homomeric and heteromeric 5HT₃ receptors, with reduced sensitivity following coexpression with 5HT_{3B} subunit. The TM2 segment is a major determinant in picrotoxin sensitivity.¹⁰¹ Halogenated volatile anesthetics such as chloroform, isoflurane, and sevoflurane and *n*-alcohols such as octanol can modulate heteromeric human 5HT_{3A/B} and 5HT_{3A} receptors, albeit differentially. The effects (increase or decrease) on 5HT_{3A/B} currents are dependent on the molecular volume of the anesthetic agent.¹⁰² An allosteric interaction of certain cannabinoids at 5HT_{3A} receptor was suggested on the basis that compounds such as tetrahydrocannabinol (Δ^9 -THC) and anandamide inhibited currents through recombinant 5HT_{3A} receptors independently of cannabinoid receptors.¹⁰³

Besides 5HT, other known agonists include 2-methyl-5-hydroxytryptamine, phenylbiguanide, *m*-chlorophenylbiguanide, and SR-57227A. More recently, 5HT₃ receptor partial agonists also have been interrogated as agents with potential utility in the control of gastrointestinal motility without completely blocking 5HT₃ sensitized nerve function. No potent positive allosteric agents have yet been developed for 5HT₃ receptors.¹⁰⁴ Anesthetic alcohols such as trichloroethanol potentiate 5HT₃ function at millimolar concentrations whereas ifenprodil, a ligand of the *N*-methyl-D-aspartate (NMDA) sensitive NR2B N-terminal domain, and certain L-type calcium channel blockers such as verapamil, inhibit 5HT₃ binding in a noncompetitive manner.

2.22.2.2.7 Prototypical therapeutics

5HT₃ antagonists are routinely used as antiemetics postoperatively and during chemotherapy. These include numerous launched products – azasetron, granisetron, indisetron, ondansetron, palonosetron, dolasetron, ramosetron, and tropisetron. Some of the 5HT₃ antagonists reportedly are in clinical trials for other disorders such as arrhythmias (tropisetron), irritable bowel syndrome (ramosetron), and schizophrenia (dolasetron). Alosetron has been launched for irritable bowel syndrome but its use is restricted because of side effects. Mosapride is a 5HT₄ agonist and a 5HT₃ antagonist launched as a prokinetic for gastritis. Additional compounds reportedly in development for irritable bowel syndrome include AGI-003, DDP-22, pumosetrag, and cilansetron. Clearly 5HT₃ receptors are present in the CNS, but besides dolasetron there appear to be no 5HT₃ targeted therapeutics in clinical trials for neuropsychiatric disorders. The potential and limitations for CNS indications were recently reviewed.⁸⁸

2.22.2.2.8 Diseases

Serotonergic dysfunction has been implicated in a variety of neuropsychiatric disorders, largely in relation to metabotropic (GPCR) 5HT systems. 5HT₃ LGIC have been examined to a more limited extent. In patients with bipolar disorders, polymorphism and missense mutations were observed in the upstream open reading frame of the *HTR3A* gene. However, no significant association was found between the C195T polymorphism and bipolar affective disorder. In contrast, a C178T (Pro16Ser) variant showed functional differences versus wild-type alleles and it was suggested that this might affect susceptibility to bipolar disorders.^{105,106} Although polymorphisms were detected in 5HT_{3A} and 5HT_{3B} receptors in patients with Tourette's syndrome, these do not appear to be directly disease-related.¹⁰⁷ A valine to serine mutation in the TM2 domain of the 5HT_{3A} receptor subunit was previously shown to produce a homomeric receptor ~70-fold more sensitive to 5HT than the wild-type receptor when expressed in oocytes.¹⁰⁸ Characterization of gene knockin mice expressing this mutation showed morphologic, pharmacologic, and cystometric changes in the urinary bladder and urethral outlet tissues, characteristic of urinary bladder outlet obstruction as seen in patients with benign prostatic hyperplasia (BPH) or neuropathic lesions.⁹⁵

2.22.2.3 GABA_A and GABA_C Receptors

GABA_A receptors are widely distributed in the mammalian CNS where they are typically thought to mediate fast synaptic inhibition. This inhibition is generally via enhancement of GABA_A-mediated Cl[−] conductance that leads to postsynaptic hyperpolarization and additional dampening of excitatory inputs due to the electrical shunt. The net overall effect depends upon a number of variable factors, including resting membrane potential, subcellular localization of the receptors, and synaptic drive. In addition to distribution at inhibitory synapses on dendrites and cell bodies of neurons, evidence for GABA_A receptor mediated tonic transmission at extrasynaptic locations has also been documented.¹⁰⁹ Of the diverse LGIC, GABA_A receptors have received heightened attention as they serve as targets for clinically important drugs such as sedatives, hypnotics, anticonvulsants, anxiolytics, muscle relaxants, and anesthetics. For recent reviews, see ^{110–113}.

2.22.2.3.1 Current nomenclature

Being the major inhibitory neurotransmitter in the CNS, GABA plays a key role in modulating neuronal activity via distinct receptor systems – the ionotropic GABA_A and GABA_C and metabotropic GABA_B receptors. Unlike GABA_B receptors that act via the binding and activation of guanine nucleotide-binding proteins,¹¹⁴ GABA_A and GABA_C receptors directly gate chloride conductance and mediate majority of the rapid inhibitory synaptic transmission.^{109,115}

2.22.2.3.2 Molecular biology

Multiple subunit associations underlie the pharmacological and biochemical diversity of GABA_A receptors. At least 19 different mammalian GABA_{A/C} receptor subunit genes have been identified and divided into subfamilies. These include GABA_A receptor subunits – alpha (α1–α6), beta (β1–β3), gamma (γ1–γ3), delta (δ), epsilon (ε), theta (θ), and pi (π) and GABA_C receptor subunits – rho (ρ1–ρ3). Although a multitude of combinations in theory is possible, it appears that an α, β, and one other subunit type such as γ, δ, or ε are required for fully functional GABA_A receptor. Coexpression of α and β subunits produces GABA-gated channels, but inclusion of a γ subunit provides sensitivity to benzodiazepine modulation. Although the exact subunit composition of GABA_A receptor subtype in the CNS remains to be determined and complex patterns of subunit distribution in different brain regions have been observed, studies with recombinant receptors indicate a likely subunit ratio of 2α:2β:1γ. In brain, the predominant GABA_A is α1β2γ2, comprising about one-third of the receptors.¹¹⁶ Another third is α2β3γ2 and α3β3γ2 together, and other less well-defined combinations make up the remainder.

GABA_C receptors, highly enriched in the vertebrate retina, are biochemically and pharmacologically distinct from GABA_A receptors.^{117–119} GABA_C receptors have a simpler organization derived from three different ρ subunits, and are insensitive to bicuculline and baclofen, unlike GABA_A receptors.

2.22.2.3.3 Protein structure

GABA_A receptors are heteropentameric proteins with a total molecular mass of 230–270 kDa. All of the GABA_A subunits are predicted to have a similar overall domain structure. This includes a signal sequence, a large N-terminal region, four transmembrane domains (TM1–TM4), and a relatively large and variable intracellular loop between TM3 and TM4. Models of the extracellular and transmembrane domains of GABA_A receptor based on AChBP and *Torpedo* nAChR along with putative drug binding pockets within and between subunits have been described. By overlaying the α and γ subunits onto the model of AChBP, the pockets involved in benzodiazepine binding sites have been modeled with previously identified amino acids.^{120,121}

2.22.2.3.4 Physiological functions

GABA_A receptors are critical for diverse physiological processes including the regulation of vigilance, anxiety, epileptogenic activity, and memory functions. Activation of GABA_A receptors increases inward chloride currents, which hyperpolarizes the postsynaptic cell and inhibits synaptic activity. Activation of GABA_A receptors underlies fast synaptic inhibitory postsynaptic potentials (IPSPs) and thus influences impulse initiation, duration and amplitude of the excitatory postsynaptic potentials (EPSPs). However, the frequency of synaptic transmission is a critically important determinant of neural communication, as one may appreciate in considering the difference between a thump and a symphony. GABAergic transmission does not simply turn the system on or off, but is critical for controlling the frequency, as in electroencephalogram (EEG) rhythms associated with learning and memory, and for preventing excessive activity as observed in seizures.^{122,123} Enhancement of GABA_A receptor mediated fast synaptic inhibition is the basis for pharmacotherapy of various neurological and psychiatric disorders. Both GABA_A and GABA_C receptors have high Cl⁻ sensitivity, with permeability ratios of K⁺ to Cl⁻ of <0.05. However, GABA_C receptors are pharmacologically and biophysically distinct from GABA_A receptors. Major differences include about 10-fold higher sensitivity to GABA, steeper Hill slopes for the agonist concentration response, weaker desensitization even in presence of high agonist concentration, and low single-channel conductance, relative to GABA_A receptor. Studies on GABA_A receptor subunit knockout and knockin mice have provided valuable insights into the physiological, pharmacological, and behavioral role for the various subunits.¹²⁴ Knockin mice where specific GABA_A receptor mutations are insensitive to diazepam and general anesthetics have related specific roles of individual subunits to pharmacology.

2.22.2.3.5 Regulation

GABA_A receptors are regulated by neurosteroids and by ethanol, and under pathological conditions such as neurodegenerative diseases and epilepsy. The regulated expression of the GABA_A receptor subunit can be influenced by conditions that alter subunit mRNA levels, promoters that control such levels, and multiple transcription response elements.¹²⁵ Other proteins such as gephyrin can also modulate expression of GABA_A receptors. Gephyrin, a 93 kDa membrane protein, is a major component of the postsynaptic apparatus that is involved in the stabilization of GABA_A and glycine receptor clusters at the synapse. In several brain regions, gephyrin is selectively associated with GABAergic synapses, whereas in brainstem and spinal cord, it appears to be localized at glycinergic synapses.¹²⁶ Intracellular domains of GABA_A receptor subunits can be phosphorylated by a variety of kinases at serine, threonine, and tyrosine residues. GABA_A receptors are associated with both protein kinase C β II and RACK1 (receptor for activated C kinase) that together mediates phosphorylation of β receptor subunits, thereby facilitating trafficking and functional modulation of GABA_A receptors. GABA_A receptors also undergo dynamin-dependent, clathrin-mediated endocytosis.¹²⁷

2.22.2.3.6 Prototypical pharmacology

A variety of agonists, competitive and noncompetitive antagonists, and a wide array of allosteric modulators are known. GABA site ligands include muscimol, 3-aminopropane sulfonate, imidazole acetic acid, and piperidine-4-sulfonate, whereas antagonists include bicuculline and gabazine (Figure 4). Subunit-selective fine-tuning of pharmacological activity of GABA_A receptors can be achieved via allosteric rather than orthosteric ligands. This has been realized with several classes of clinically important drugs acting in a positive allosteric manner at the GABA_A receptors such as benzodiazepines, barbiturates, neurosteroids, and anesthetic compounds. GABA is about 10 times less potent at GABA_A than GABA_C receptors. Whereas GABA_A receptors are selectively blocked by the alkaloid bicuculline and modulated by benzodiazepines, steroids, and barbiturates, these compounds are much weaker at GABA_C receptors. The conformationally restricted GABA analog *cis*-amino crotonic acid (CACA) is an early, moderately selective GABA_C partial agonist, but the compound does inhibit GABA transporters, potentially producing indirect effects through alteration of GABA levels, and CACA can activate $\alpha 6$ -containing GABA_A LGIC. Another conformationally restricted analog, (+)-CAMP [(1*S*,2*R*)-2-aminomethylcyclopropanecarboxylic acid] appears to be more selective and is more efficacious (full agonist) at $\rho 1$ and $\rho 2$ GABA_C. TPMPA is a selective antagonist. Muscimol is commonly used as a GABA_A agonist in physiological studies, but it is important to note that muscimol also activates GABA_C LGIC. Thus, THIP (gabaxadol; 4,5,6,7-tetrahydroisoxazolo[5,4-*c*]pyridin-3-ol), which also activates GABA_A but inhibits GABA_C, and TPMPA, the GABA_C-selective antagonist, are important additional tools. Among modulators, GABA_C receptors are insensitive to barbiturates and benzodiazepines, compounds well known to potentiate common GABA_A LGIC. Neurosteroids also differentiate, potentiating GABA_C at micromolar concentrations and GABA_A at nanomolar concentrations. Two other modulators – loreclezole and (+)-ROD188 – inhibit GABA_C while potentiating GABA_A, or at least those GABA_A containing $\beta 2$ or $\beta 3$ subunits. The differential pharmacology of GABA_C and GABA_A receptors has been reviewed.¹¹⁷

Figure 4 Agonists, antagonists, and modulators of GABA_A and GABA_C.

2.22.2.3.7 Prototypical therapeutics

Benzodiazepines are well-known CNS therapeutics whose sedative/hypnotic, antiepileptic, and anxiolytic activities are primarily due to positive allosteric modulation of GABA_A LGIC. Examples of clinically available compounds include clonazepam, prazepam, tofisopam, clobazam, pinazepam, estazolam, flunitrazepam, camazepam, temazepam, nimetazepam, delorazepam, clobazam, ketazolam, lorazepam, alprazolam, halazepam, oxazolam, doxepazepam, flutazolam, mexazolam, quazepam, flutoprazepam, metaclazepam, and cinolazepam. Many were launched in the mid 1970s to mid 1980s. Flumazenil is a benzodiazepine antagonist marketed for benzodiazepine or alcohol overdose. Nonbenzodiazepines that appear to act through the benzodiazepine GABA_A modulatory site include thiazoles such as clomethiazole, thienodiazepines like clotiazepam, etizolam, and brotizolam, benzoxazines like etifoxine, the benzothienodiazepine bentazepam, the piperazinecarboxylic acid zopiclone, the pyrazolopyrimidine zaleplon, and the cyclopyrrolone pagoclone.

Another approach to potentiation of GABA_A LGIC takes advantage of the neurosteroid example, as exemplified with alphadalone and ganaxolone. Other compounds thought to exert a component of their actions at GABA_A LGIC include: pregabalin (diabetic neuropathy, epilepsy), a GABA analog that acts as a GABA_A LGIC agonist (also $\alpha 2\delta$ Ca²⁺ channel ligand); substituted thiophenes (e.g., Merck's 6,6-dimethyl-3-(2-hydroxyethyl)thio-1-(thiazol-2-yl)-6,7-dihydro-2-benzothiophen-4(5H)-one) and naphthyridenes (AC-3933) that are GABA_A inverse agonists for cognitive impairment; TP-003 that is a GABA_A $\alpha 3$ selective modulator for cognitive impairment, anxiety, and epilepsy; ELB-139, a GABA_A $\alpha 3$ selective modulator/inverse agonist for anxiety, psychoses, and epilepsy; THIP, a muscimol analog and GABA_A agonist sedative-hypnotic. Other GABA_A agonist anxiolytic molecules include ocinaplon, SL 651498, and PNU 101017. Agents launched primarily for the treatment of epilepsy include tiagabine, a GABA reuptake inhibitor that acts indirectly by increasing extracellular GABA levels, and vigabatrin, a compound that acts as both a GABA aminotransferase inhibitor, which would increase GABA levels, and a dopamine receptor antagonist.

2.22.2.3.8 Diseases

Mutations in GABA_A receptor α 1, γ 2, and δ subunits have been associated with different idiopathic generalized epilepsy syndromes.¹²⁸ These mutations could result in altered receptor gating, expression, or trafficking and contribute to neuronal disinhibition, thereby predisposing affected individuals to epilepsy. For example, in a family with juvenile myoclonic epilepsy, a mutation in the *GABRA1* gene predicting a single amino acid substitution A322D results in loss of receptor function attributed to reduced surface expression, reduced GABA sensitivity, and accelerated deactivation.¹²⁹ Association studies implicate an involvement of the *GABRA4* gene in the etiology of autism and a potential increase in autism risk through interaction with another clustering *GABRB1* gene.¹³⁰ Another linkage analysis in families with migraine identified a susceptibility locus in the 15q11–q13 genomic region, which harbors genes encoding three GABA_A receptor subunits.¹³¹

2.22.2.4 Glycine Receptors

2.22.2.4.1 Current nomenclature

Glycine receptors are responsible for fast inhibitory neurotransmission in the CNS, predominantly in the spinal cord and brainstem. Similar to GABA, glycine also activates anion channels (Cl[−] and HCO₃[−] conducting) that lead to hyperpolarization, thereby suppressing neuronal firing. These receptors share structural homology with the nAChRs, GABA_{A/C}, and 5HT₃ receptors. Several reviews^{132–135} have dealt in detail with the structure–function, physiology, and pharmacology of glycine receptors.

2.22.2.4.2 Molecular biology

Four ligand binding glycine receptor α subunits (α 1– α 4) and one β subunit have been identified. The α subunits can form functional homomeric LGIC in recombinant expression systems, but the β subunit can not.¹³⁶ Studies on native and recombinant receptors demonstrate that glycine receptors in the adult CNS are probably composed of α and β subunits, and a subunit stoichiometry of 2 α 1:3 β , as per nAChR, has been proposed.¹³⁷ Coexpression of β subunit with α 1 subunits does not appear to influence macroscopic properties such as whole-cell current amplitudes or kinetics, but results in lower single-channel conductance properties. Alternative splicing within the intracellular loop between TM3 and TM4 has been observed with α 1 and α 3 subunits, the latter resulting in differences in channel desensitization.

2.22.2.4.3 Protein structure

The glycine receptor was one of the first neurotransmitter receptors to be isolated from mammalian CNS, exploiting its high affinity to the convulsant alkaloid, strychnine. Like other Cys-loop receptors, the glycine subunits are regarded as pentameric oligomers, composed of five subunits, each consisting of a large extracellular N-terminus, four TM domains, and a large intracellular domain between TM3 and TM4. The extracellular N-terminus comprises approximately 50% of the total protein and contains regions that are critical for ligand binding and associated steps leading to channel gating, as well as for subunit assembly. Because the sequence of AChBP is about 20–24% identical to the extracellular domain of nAChR and some 15–18% identical to the aligned extracellular domain sequences of glycine, GABA_{A/C}, and 5HT₃ subunits, the AChBP structure provides a structural template for the extracellular domain of Cys-loop receptors. By a combination of electrophysiological and molecular modeling approaches, two conserved, oppositely charged residues located on adjacent subunit interfaces were identified as crucial for agonist binding. A ring of threonine residues from each of the five α subunits is critical for picrotoxin sensitivity; the presence of β subunits reduces sensitivity of the glycine receptor to picrotoxin. With regard to transmembrane architecture, a high-resolution structure of the 61-residue TM2–TM3 segment of GlyR α 1 subunit was reported.¹³⁸ Well-defined domain structures were identified for TM2, TM3, and interconnecting extracellular loop regions. Contrary to the popular model of alpha-helical structure for the pore-lining TM2 domain for the Cys-loop receptor family, the last three residues of the TM2 domain and the first eight residues of the loop appear to be intrinsically nonhelical and highly flexible. The six remaining residues of the TM2–TM3 loop and most of the TM3 domain exhibit helical structures.

2.22.2.4.4 Physiological functions

Functional glycinergic synapses have been characterized in various brainstem nuclei, spinal cord motor reflex pathways and pain sensory pathways, and in the retina. The glycine receptor plays a fundamental role in mediating inhibitory neurotransmission in the spinal cord and brainstem, although recent evidence suggests it may also have other physiological roles, including excitatory neurotransmission in embryonic neurons.¹³⁴ Additionally, activation of glycine

receptors together with GABA_A receptors in the sperm plasma membrane appears to be essential for acrosome reaction, an important step in the fertilization process. Glycine binding to the receptors opens anion channels, mostly leading to Cl⁻ influx, which hyperpolarizes the neuron and thereby inhibits neuronal activity. In general, glycine receptors have permeability and conductance properties similar to GABA_A receptors – both being anion selective with a $PK^+/PCI^- < 0.05$. The $\alpha 1$ subunit exhibits five conductance states ranging from 20 to 90 pS, with the 90 pS state occurring with the greatest frequency. Coexpression with the β subunit eliminates the highest conducting levels leaving a 45 pS state as the most frequently occurring. Substitution of two to three residues of the glycine receptor can switch the $\alpha 7$ nAChR pore from cation selective to anion selective suggesting that these residues in TM2 sequences are important determinants of the selectivity filter.⁴⁸

2.2.2.4.5 Regulation

As with GABA_A receptors, gephyrin also plays a key role in regulating the postsynaptic clustering of the glycine receptor. Gephyrin mediates synaptic clustering by binding to glycine receptor β subunits, and receptor activation is required for initiation of the anchoring process. In rats, a developmental switch from $\alpha 2$ to predominantly $\alpha 1\beta$ heteromers is observed around postnatal day 20, an event that may be important for, or reflective of, the β subunit dependent receptor anchoring via gephyrin. Glycine receptor subunits also carry consensus motifs for phosphorylation, glycosylation, and ubiquitination.

2.2.2.4.6 Prototypical pharmacology

In addition to glycine, taurine and beta-alanine have been proposed as endogenous glycine receptor agonists in early development (Figure 5). Native and recombinant glycine receptors are activated by amino acid agonists with a rank order of potency: glycine > beta-alanine > taurine > GABA. When $\alpha 1$ receptors are expressed in HEK-293 cells, glycine, beta-alanine, and taurine all behave as full agonists, with glycine exhibiting an EC₅₀ value of 20–50 μ M.

Figure 5 Agonists, antagonists, and modulators of glycine receptors.

Glycine receptors derived from $\alpha 2$, $\alpha 3$, and $\alpha 4$ subunits are thought to have similar agonist sensitivities to that derived from the $\alpha 1$ subunit. The plant alkaloid strychnine is a selective and potent competitive antagonist versus glycine, beta-alanine, and taurine with a K_D value of 5–10 nM. Strychnine also inhibits $\alpha 9$ nAChR, but GlyR currents (anionic) are readily distinguished from $\alpha 9$ nAChR currents (cationic) by other means. Thus, strychnine sensitivity is one of the most definitive means of discriminating glycinergic from GABAergic anionic synaptic currents. Radioligand binding and electrophysiological studies suggest that glycine and strychnine bind to partially overlapping, but not identical, sites on the receptor. The proconvulsant alkaloid picrotoxin also inhibits glycine receptors albeit with lower potency than at GABA_A receptors. The GlyR α/β heteromers are much less sensitive to inhibition by picrotoxin than α homomers, independently of the type of α subunit ($\alpha 1$, $\alpha 2$, or $\alpha 3$). The picrotoxin components picrotin and picrotoxinin show similar potencies in inhibiting $\alpha 1$ glycine receptors. Tropicisetron, known as a 5HT₃ antagonist, also interacts with GlyR. At low concentrations (0.01–1 μ M), tropisetron potentiates GlyR $\alpha 1$ and $\alpha 1\beta$ whereas it suppresses currents at high (>10 μ M) concentrations. The antiparasitic agent ivermectin is a potentiator of GlyR currents, by interaction with a site distinct from the glycine and strychnine binding site. Several volatile anesthetics such as isoflurane, halothane, and enflurane can potentiate $\alpha 1$ GlyR, inducing a leftward shift in the EC₅₀ value of glycine.

2.22.2.4.7 Prototypical therapeutics

A number of agents that have other primary targets have been reported to interact with the glycine receptor. Besides 5HT₃ antagonists, calcium channel antagonists such as nitrendipine, the neuroprotective agent riluzole, and the microtubule-depolymerizing agent colchicine all antagonize glycine-induced currents in the micromolar range. Clinically relevant concentrations of riluzole have been found to accelerate the desensitization of the $\alpha 1/\beta$ glycine receptor while having no effect on maximal current amplitude. The estrogen receptor modulator tamoxifen potentiates effects of submaximal glycine responses. Development of therapeutic agents that potentiate glycine receptor responses could have significant utility as muscle relaxants and analgesic agents, as these receptors are involved in motor reflex circuits and nociceptive sensory pathways.¹³⁵

2.22.2.4.8 Diseases

Inherited disorders that have been ascribed to mutations in GlyR subunits include the familiar startle disease (hyperekplexia) in humans, spastic, spasmodic, and oscillator phenotypes in mouse, and myoclonus in bovine TM1. Aberrant splicing leading to >90% loss of functional β subunits underlies the murine phenotype *spastic*. In human startle disease, many of the mutations reduce glycine sensitivity and/or GlyR channel gating and most occur in GlyR $\alpha 1$ TM1, TM2 the intracellular loop between TM1 and TM2, and the α helical region of the extracellular TM2–TM3 loop near TM2.¹³⁴ Additionally, a startle mutation inserts a stop codon prior to TM1, and one other substitutes an arginine for a serine in TM1 to alter receptor insertion into the plasma membrane.

2.22.2.5 Zinc-Gated Ion Channel

A distinct member of the Cys-loop LGIC family, designated as a Zn²⁺-activated ion channel, was uncovered using searches of expressed sequence tag (EST) databases using a consensus peptide sequence of 5HT₃ and nAChRs.¹³⁹ The subunit (ZAC, also called L2 protein) encodes a polypeptide of 411 amino acids, has a signal sequence, cys–cys motif, four predicted transmembrane domains, and several invariant residues that underpin the conserved secondary structure of the Cys-loop LGIC superfamily. Sequence analysis reveals that a common ancestral gene gave rise to the ZAC, nAChR, and 5HT₃ receptor subunit genes. Expression studies indicate that ZAC subunit genes are absent in mouse and rat, but present in dog, chimpanzee, cow, opossum, and human.¹⁴⁰ Messenger RNA (mRNA) levels have been detected in various tissues including pancreas, brain, liver, lung, heart, and kidney. In the brain, immunoreactivity was dominantly detected in the hippocampal CA3 pyramidal cells and in the polymorphic layer of the dentate gyrus, an area of the brain where neuronal Zn²⁺ is particularly high. The ZAC subunit, expressed in HEK-293 cells, formed homomeric channels that were activated by application of Zn²⁺ (1 mM) but not by agonists of other LGIC. Zn²⁺-activated currents are inhibited by relatively high concentrations of tubocurarine, but not by any of the other LGIC antagonists. These effects are of interest because at ZAC Zn²⁺ behaves as an agonist, unlike its modulatory effects at other LGIC, and because it adds to the evidence that endogenous Zn²⁺ may act like a neurotransmitter in an area where Zn²⁺ is present at high concentrations in synaptic vesicles and may be released synaptically. These effects remain to be further investigated using tissues from nonrodent species.

2.22.3 Glutamate-Gated Family

Glutamatergic transmission is the predominant form of excitatory, rapid synaptic transmission in the CNS. Other excitatory amino acids that may act as neurotransmitters include aspartate and *N*-acetylaspartylglutamate (NAAG), but it is not clear that these substances act upon receptors distinct from those known as glutamate receptors. Aspartate can activate NMDA-sensitive glutamate receptors selectively, and NAAG can activate metabotropic glutamate receptors.¹⁴¹ For recent reviews, see ^{142–151}.

2.22.3.1 Current Nomenclature

Glutamate receptors (GluR) refer to both metabotropic GPCR and ionotropic LGIC and are often termed mGluR and iGluR, respectively, to make the distinction. However, this terminology has not been applied universally, and in many reports the LGIC may be referred to as simply GluR. Among the iGluR, there are three broad families that share a common structure but are differentiated according to their subunit composition, functional properties, and pharmacology. The three main families are the AMPA (α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid)-sensitive receptors, the kainate-sensitive receptors, and the NMDA-sensitive receptors. These often are referred to simply as AMPA receptors, kainate receptors, and NMDA receptors, although this is not strictly accurate because AMPA, kainate, and NMDA are not the physiological ligands. Additionally, a misconception that arises from this terminology is that AMPA and kainate themselves define distinct iGluR. In fact, kainate can also activate AMPA-sensitive receptors and AMPA can activate kainate-sensitive receptors. The term ‘AMPA/kainate receptor’ often is used in physiological research addressing native receptors, in recognition of the difficulty in distinguishing kainate-sensitive from AMPA-sensitive receptors. In addition, the $\delta 1/\delta 2$ and NR3A/NR3B subunits may be considered to identify subfamilies within the NMDA-sensitive iGluR, but a clear nomenclature on this aspect has not arisen.

2.22.3.2 Molecular Biology

Eighteen iGluR subunits or homologous proteins have been cloned, not including splice variants and other edited products. The iGluR share a common structure and subunit composition, but there is a degree of specificity to the subunit assembly. AMPA-sensitive iGluR comprise iGluR1, iGluR2, iGluR3, and iGluR4 subunits. Kainate-sensitive iGluR comprise iGluR5, iGluR6, iGluR7, KA-1, and KA-2 subunits. NMDA-sensitive iGluR comprise NR1, NR2A, NR2B, NR2C, and NR2D (all separate gene products despite the nomenclature).

Additionally, NR3A and NR3B can combine with other subunits to modify the properties of NMDA-sensitive iGluR in heterologous expression systems.^{152–154} Indeed, it has been reported that NR3A and NR3B combined with the glycine-binding subunit NR1 can form a novel cationic LGIC gated by glycine, but expression of such a construct is yet to be confirmed *in situ*. Nevertheless, NR3A and NR3B are expressed in CNS where they may alter the properties of native NMDA-sensitive iGluR,^{155–158} and there is some evidence that altered NR3A expression may be involved in schizophrenia and bipolar disorders.¹⁵⁹

Two ‘orphan’ gene products have been identified by homology cloning: $\delta 1$ and $\delta 2$.^{160–162} These proteins are $\leq 25\%$ homologous to other iGluR subunits and it appears that $\delta 1$ and $\delta 2$ do not combine with other iGluR *in situ*.¹⁶³ With or without other known iGluR subunits, however, it does appear that the δ subunits play important roles in CNS physiology, as $\delta 2$ is selectively expressed in cerebellar Purkinje neurons where it appears to play key roles in synaptic plasticity and motor control.^{164–168}

2.22.3.3 Protein Structure

While the iGluR families share a similar structure overall, they may display significantly different functional properties owing to differences in subunit composition. Each iGluR comprises four subunits arranged around the central ion channel pore. The AMPA- and kainate-sensitive iGluR subunits are approximately 900 amino acids or 100 kDa in size. The NMDA-sensitive iGluR subunits tend to be somewhat larger with approximately 1000–1200 amino acids, although NR3B is about 900 amino acids. The N-terminal region is extracellular, the C-terminus is intracellular, and there are three transmembrane segments. Additionally, between TM1 and TM2 in the intracellular membrane face (as opposed to the extracellular face in VGIC) there is a re-entrant ‘P-loop’ that contributes to the channel and is at least partly intramembraneous, but does not completely traverse the membrane. It was initially thought that the P-loop was another transmembrane segment, making a total of four transmembranes per subunit. This would place both N- and C-terminal regions on the same (extracellular) side of the membrane with the N-terminal and TM3–TM4 loop on opposite sides of the membrane. However, a number of structure–function studies

and the application of membrane-impermeant antibodies selective for various regions of the iGluR subunit have clarified that the C-terminal region is intracellular, the N-terminal region and the intertransmembrane loop are extracellular, and the region initially defined as TM2 is, in fact, a 'P-loop' that lines the ion channel, but does not traverse the membrane.

The ligand binding domain is formed as an interface between a portion of the N-terminal region closer to the membrane and the extracellular loop between TM2 and TM3. To some extent, this may be considered similar to ligand binding at the interface between subunits in the Cys-loop LGIC family, but the iGluR ligand binding domain is formed within a subunit, not between subunits. Further toward the N-terminus is a large N-terminal domain or N-terminal domain that is fairly well conserved among subunits. The function of the N-terminal domain is not entirely clear for many of the iGluR, but it may be involved in modulatory interactions and/or receptor assembly.

2.22.3.3.1 α -Amino-3-hydroxy-5-methylisoxazole-4-propionic acid-sensitive receptors

Four of the iGluR subunits (iGluR1, iGluR2, iGluR3, and iGluR4) combine to form AMPA-sensitive iGluR. Receptors are formed as pairs of dimers with like subunits facing one another across the central channel. The AMPA-sensitive receptor agonist binding site is relatively well characterized since it has been possible to separately express and crystallize individual receptor subunits and the ligand binding core with and without ligands bound. The binding site is made from two domains of the subunit, one being an ~ 150 amino acid segment between the N-terminal domain and TM1, and the other being the extracellular domain between TM2 and TM3. The alpha-carboxyl of glutamate binds to the first domain (D1 or S1, that preceding TM1) and the gamma-carboxyl binds to the second domain (D2 or S2). However, the amino acid residues involved are not necessarily the same for every ligand. Among the ligands glutamate, AMPA, and kainate (which is also an AMPA agonist), the alpha-carboxyl of each binds to the same residue in D1 but at the other end of the ligand, the isoxazole of AMPA does not bind to the same residue in D2 as do the gamma-carboxyls of glutamate and kainate. In the NMDA-sensitive NR1 subunit, which binds glycine but not glutamate, the binding pocket is particularly small, about one-fourth the size of iGluR pockets, and binding of the glutamate gamma-carboxyl is blocked by a tryptophan residue.

How ligand binding is coupled to channel gating is less clear, although important clues have been derived from crystallization studies. The interactions of partial agonists remain somewhat enigmatic. Some of the data seem to fit the induced-fit model, which predicts a variable degree of conformational transition according to agonist efficacy, i.e., a partial agonist produces a smaller transition than does a full agonist. Other data fit the Monod-Wyman-Changeux model, which assumes discrete conformation states (i.e., either closed, open, or desensitized) and variable population of these states according to relative ligand affinity.

2.22.3.3.2 Kainate-sensitive receptors

Kainate-sensitive LGIC are structurally similar to AMPA-sensitive receptors, but are formed from different combinations among the five known subunits. In expression systems, recombinant iGluR5, iGluR6, and iGluR7 can form functional homomeric or heteromeric assemblies. Two other subunits – KA1 and KA2 – bind ligands, but do not themselves form functional LGIC. However, KA1 and KA2 can be coexpressed with iGluR5, iGluR6, or iGluR7 to form functional LGIC with properties that can be differentiated from the respective iGluR without KA. Often, one is not clear whether the complex created in recombinant expression systems is physiological, but in brain there is evidence for iGluR6 coassembly with KA1 and KA2.

2.22.3.3.3 N-methyl-D-aspartate-sensitive receptors

NMDA-sensitive LGICs are believed to be tetrameric, like the AMPA- and kainate-sensitive counterparts, but formed from a different set of subunits: NR1 (which has eight splice variants), NR2A, NR2B, NR2C, NR2D (these NR2s are four different gene products, not splice variants of one another), and NR3. Unlike the iGluR subunits, which can form functional homomeric assemblies in expression systems, NMDA-sensitive receptors require at least two different types of subunit – NR1 together with either NR2 or NR3. Recently the ligand binding core of the NMDA-sensitive receptor, like that of the AMPA-sensitive receptor, was crystallized and the structures determined with glutamate and glycine bound.¹⁶⁹

NR1 is not a glutamate receptor per se. NR1 binds the coagonist glycine, but does not itself form a functional LGIC in heterologous expression systems. NR2 subunits bind glutamate and coassemble with NR1 to form NMDA-sensitive receptors that require both glycine and glutamate for activation. However, in physiological saline and at normal neuronal resting potentials (example at ~ -70 mV), the NMDA-sensitive receptor channel is blocked by extracellular

Mg^{2+} and little current flows through the channel despite the binding of glutamate and glycine. The Mg^{2+} blockade is voltage dependent and if the cell is depolarized by glutamatergic or other types of inputs, then the NMDA-sensitive channel block by Mg^{2+} is relieved, allowing ion flux consequent to receptor activation by agonist. Thus, NMDA-sensitive LGICs are considered 'coincidence detectors' because full activity requires appropriately timed coincident signals – depolarization plus agonist and coagonist. Although prevailing levels of glycine in cerebrospinal fluid may be sufficient for coagonist activity when glutamate is released as transmitter, nevertheless the chemical signal also requires an electrical signal in order to gate ion flux through the channel.

NR3A and NR3B subunits^{170,171} also require NR1 coexpression and do not combine functionally with NR2, but also do not generate the typical NMDA-sensitive glutamate receptor. LGIC composed of NR1 and NR3 are gated by glycine alone, not glutamate. The NR1/NR2 glycine site coagonists D-alanine, D-cycloserine, and 1-aminocyclopropanecarboxylic acid (ACPC) are weak inhibitors of NR1/NR3 activation by glycine, while the NR1/NR2 coagonist D-serine is an NR1/NR3 weak partial agonist that can block the response to glycine. These glycine-sensitive LGIC are cation permeable and excitatory, unlike GlyR in the Cys-loop family, but the NR1/NR3 channel is not blocked by Mg^{2+} as is the NR1/NR2 NMDA-sensitive LGIC.

2.22.3.4 Regulation

Glutamate LGICs are subject to a remarkable degree of physiological regulation, and various subunit isoforms could create a wide array of receptors.^{145,150} Some of this includes RNA editing, a function not known to occur with other classes of LGIC. In AMPA- and kainate-sensitive LGIC, iGluR2, iGluR5, and iGluR6 are subject to glutamine/arginine (Q/R) editing at a specific site in the P-loop that affects channel gating and ion selectivity. Q is specified genomically, but after the rat 'second trimester' (E14), almost all iGluR2 is found to have R in this position, thereby reducing single-channel conductance, inward rectification, and relative Mg^{2+} permeability. This is accomplished by conversion of adenosine to inosine (deamination) at the mRNA level, thus changing the relevant codon to one specifying arginine instead of glutamine. Similar effects are seen in the kainate-sensitive iGluR5 and iGluR6 subunits, although the overall degree of editing may be lower. Another site, near the flip/flop region (below) in AMPA-sensitive iGluR2, iGluR3, and iGluR4 can be edited from arginine to glycine (R/G), reducing desensitization and increasing resensitization. Additionally, in TM1 of kainate-sensitive subunits iGluR5 and iGluR6, isoleucine can be edited to valine (I/V) and tyrosine to cysteine (Y/C). The effect depends upon the subunit assembled, but has been found to affect ion permeability when iGluR6 is assembled with an iGluR containing Q in the edited P-loop site. In adult, 50–100% of the Q/R and R/G sites are edited in iGluR, depending upon site, subunit, and in the case of iGluR4 whether it is flip (50% edited) or flop (80–90% edited). However, the degree of editing can be altered under pathological conditions such as ischemia.

Flip and flop are alternative splicing variants found in AMPA-sensitive subunits iGluR1, iGluR2, iGluR3, and iGluR4. The site is in the TM3–TM4 extracellular loop just prior to TM4. This tends to affect desensitization, with intrinsic rates and/or extent of desensitization being moderately slower/lesser in the flip forms. Additionally, effects of desensitization modulators may be flip/flop dependent, e.g., cyclothiazide has greater effect on flip and 4-[2(phenylsulfonylamino)ethylthio]-2,6-difluorophenoxyacetamide (PEPA) has greater effect on flop. Additional alternative splicing variants are found in the C-terminal region of iGluR2-7 and NR1 and in the N-terminal region of iGluR5 and NR1.

Expression of AMPA-sensitive receptors in the synaptic region can be upregulated through increased surface expression, synaptic trafficking, and stabilization of turnover. Ca^{2+} /calmodulin regulated processes and PDZ [postsynaptic density-95 (PSD-95)/Discs large (Dlg)/zona occludens-1 (ZO-1)] protein domain interactions are involved. Kainate-sensitive receptor expression does not appear to be as immediately upregulated as are AMPA-sensitive receptors but the PDZ domain in the C-terminal region of kainate-sensitive subunits may be involved in receptor localization and does appear to affect synaptic efficacy.

2.22.3.5 Physiological Functions

AMPA-, kainate-, and NMDA-sensitive LGIC, like the metabotropic glutamate receptors, respond to glutamate, the most broadly expressed excitatory neurotransmitter in the vertebrate CNS. AMPA-sensitive receptors mediate rapid high-amplitude synaptic transmission. Kainate-sensitive receptors also mediate fast synaptic transmission in hippocampus, but these synaptic events tend to be smaller and relatively slower than those mediated by the AMPA-sensitive receptors. NMDA-sensitive receptors tend to play important modulatory roles as opposed to immediate signal transfer. NMDA-sensitive LGIC are about two orders of magnitude more sensitive to glutamate than are AMPA- or kainate-sensitive receptors, are about two orders of magnitude slower to desensitize, and are about one to three orders of magnitude slower to deactivate upon agonist removal. Thus, NMDA-sensitive LGIC can respond to glutamate over a

longer period of time and/or distance (e.g., extrasynaptic) than can AMPA- and kainate-sensitive LGIC. These kinetics together with the voltage-dependent Mg^{2+} block allows NMDA-sensitive LGIC to integrate glutamate, glycine, and electrical signals over specific time domains. With multiple signals occurring in the appropriate frequency, or timing coincidence, the channel is opened and can partially depolarize the cell and, more importantly, allow sufficient Ca^{2+} inflow to trigger a host of Ca^{2+} -dependent signaling processes. Such processes may include positive modulation of other LGIC through kinase cascades, increased synaptic expression of AMPA-sensitive receptors, activation of nuclear transcription factors such as CREB ultimately to augment synaptic function or morphology, or adverse consequences including cytotoxicity with excess stimulation.

NMDA-sensitive LGIC containing NR2B have been considered as a target of interest for pain, in part due to their dominant expression in spinal dorsal horn relative to other NR2 subunits and upregulation of NR2B in pain states. NMDA-sensitive receptors are involved in nociceptive sensitization, a process like memory, thought to be dependent upon long-term potentiation (LTP) in central synapses. However, NR2B subunits also are expressed in brain. During maturation of the rodent CNS, NR2B is downregulated while NR2A is upregulated. Nevertheless, NR2B is not eliminated and synaptic receptors are thought to comprise NR1/NR2A/NR2B while extrasynaptic receptors, which still could be activated by transmitters, are derived from NR1/NR2B. Thus, NR2B-selective antagonists may inhibit brain as well as spinal NMDA-sensitive receptors with potential adverse effects on memory formation, cognitive performance, and psychoses.

2.22.3.6 Prototypical Pharmacology

The initial and still commonly used prototypic agonists for AMPA-sensitive, kainate-sensitive, and NMDA-sensitive LGIC are AMPA, kainate, and NMDA themselves. However, historically it has been difficult to distinguish AMPA from kainate responses in tissues. Kainate, for example, has only moderate selectivity for kainate- compared to AMPA-sensitive receptors.

Structure–activity relationship (SAR) studies based upon the isoxazole moiety of AMPA led to a series of compounds useful in cocrystallization studies of the AMPA-sensitive iGluR subunits.^{172,173} (*S*)-ACPA was identified as one of the most potent agonists in the series. For both ACPA and AMPA, stereoselectivity favors the (*S*) configuration by >100-fold. (*S*)-5-Fluorowillardiine is a nonisoxazole selective agonist for AMPA-sensitive iGluR.¹⁷³ Within AMPA-sensitive subtypes, (*S*)-5-fluorowillardiine exhibits an order of magnitude selectivity for iGluR1 and iGluR2 relative to iGluR4. Ibotenic acid, a naturally occurring isoxazole, is an agonist at mGluR and NMDA-sensitive iGluR. However, derivatives of homoibotenic acid (HIBO) display interesting selectivity for iGluR1 and iGluR2 relative to iGluR3, iGluR4, and iGluR6 while selectivity against iGluR5 varies.^{173,174} Representative structures are depicted in [Figure 6](#).

At the kainate-sensitive receptors, SYM-2081 ((2*S*,4*R*)-4-methylglutamate) shows two to three orders of magnitude selectivity relative to AMPA-sensitive receptors.¹⁴⁵ The isoxazole derivatives (*S*)-ATPA and (*S*)-5-iodowillardiine also are selective agonists, particularly for iGluR5.¹⁷³ The nonisoxazole LY 339434, in contrast, shows three orders of magnitude selectivity for iGluR6 ([Figure 7](#)).

The competitive antagonists CNQX and DNQX often are used as AMPA/kainate-sensitive blockers, but they have little selectivity between the two subtypes. AMPA-selective antagonists include NBQX (competitive), GYKI 52466 and GYKI 53655 (noncompetitive), and joro spider toxin (channel blocker). At kainate-sensitive receptors, LY 294486 is selective for kainate-sensitive iGluR5 relative to iGluR6 or iGluR7. LY 294486 also inhibits AMPA-sensitive iGluR, although with less potency than at iGluR5. NS-102, on the other hand, is an iGluR6 selective antagonist.

Modulation of AMPA-sensitive receptors has been another direction of interest with respect to positive allosteric modulators ('AMPAkines') such as CX-516 and LY 395153 for treatment of cognitive disorders such as in AD, and with respect to negative allosteric modulators such as talampanel for treatment of disorders such as epilepsy and Parkinson's disease.¹⁷³

For NMDA-sensitive receptors, prototypic selective agonists include NMDA itself, aspartate (which may function as a signaling molecule in some areas of the CNS), and quinolinic acid ([Figure 8](#)). Additionally, glycine or D-serine is required for the glycine coagonist NR1 site, but in *in vivo* or in tissue studies, sufficient glycine is generally present. Commonly used competitive selective antagonists are AP5 (also known as APV), AP7, CPP, and CGS19755. 7-Chlorokynurenate, 5,7-dichlorokynurenate, L-701,324, and MNQX are selective glycine-site inhibitors. NMDA-sensitive iGluR channel blockers include (+)-MK-801 (dizocilpine), ketamine, PCP (phencyclidine), dextromethorphan, and memantine. MK-801 is a very selective, potent, and long-lasting inhibitor owing in part to entrapment in the NMDA-sensitive iGluR channel. It is a widely used research tool to identify NMDA-sensitive iGluR *in vitro*. *In vivo*, the ability of MK-801 and other NMDA-sensitive iGluR channel blockers to induce psychosis or psychosis-like behavior is both a limitation and a research tool. Memantine also inhibits NMDA-sensitive iGluR, but it is less potent

Figure 6 Agonists, antagonists, and modulators of AMPA-sensitive iGluR.

Figure 7 Agonists and antagonists of kainate-sensitive iGluR.

Figure 8 Agonists, antagonists, and modulators of NMDA-sensitive iGluR.

and reversible, and this is thought to be advantageous in allowing the compound to inhibit a low level of NMDA-sensitive iGluR activation while not blocking phasic synaptic transmission. Other NMDA-sensitive iGluR inhibitors of interest, particularly for neuropathic pain, are the NR2B-selective compounds such as ifenprodil, Ro 25-6981, Ro 8-4304, and CP 101,606.¹⁵¹

2.22.3.7 Prototypical Therapeutics

NMDA-sensitive LGIC has been of considerable therapeutic interest in light of its role in cognition (memory/LTP), ischemia/stroke (excitotoxicity), and pain/hyperalgesia. MK-801 is potent and selective NMDA-sensitive LGIC antagonist, but it induces psychosis-like behavior indicating a potential antipsychotic-role of NMDA-sensitive LGIC. On the other hand, excess NMDA-sensitive LGIC activation may be neurotoxic. Modulation of the glycine coagonist site has been of interest as a means of regulating NMDA-sensitive LGIC activity without excessive activation or blockade. Recently, memantine has emerged as an NMDA-sensitive LGIC antagonist, paradoxically, for the treatment of AD.^{175–177} The paradox is that NMDA-sensitive LGIC blockade should, in principle, inhibit LTP induction and thereby inhibit memory formation and aggravate the disease. The rationale with memantine, however, is that in the aged population there is excess glutamatergic transmission and/or increased neuronal depolarization and diminished intracellular Ca^{2+} buffering such that the excitotoxic capacity of NMDA-sensitive LGIC is enhanced. Memantine, as a weak competitive inhibitor, could reduce excess Ca^{2+} influx through NMDA-sensitive LGIC while having less impact on synaptic transmission where the agonist (glutamate) is present at higher concentration. However, memantine is certainly a weak antagonist (micromolar IC_{50}) and is not entirely selective for NMDA-sensitive receptors. For example, it has been reported to inhibit $\alpha 7$ nAChR with potency better than at NMDA-sensitive LGIC.¹⁷⁸ Memantine appears

to offer some benefit in a CNS disorder still starved for effective therapy, but the true target of the drug may be not yet known. In addition to AD, memantine also is of clinical interest for diabetic neuropathy and glaucoma.

AMPA/kainate-sensitive receptors may be involved in epilepsy and neurodegeneration, and antagonists have been found to be anticonvulsant in animal models.^{179–182} However, these receptors also are involved in physiological transmission throughout the brain and an antiepileptic therapy based upon AMPA/kainate-sensitive blockade has not emerged. As LTP is thought to be a principal neural mechanism underlying memory, and enhancement of AMPA-sensitive receptor transmission is thought to underlie LTP, then a positive allosteric modulator of AMPA-sensitive receptors could be an effective approach for cognitive enhancement (e.g., mild cognitive impairment, AD). The nootropic aniracetam potentiates AMPA-sensitive iGluR and is effective in tissue models.^{183–185} A metabolite of aniracetam has been found to potentiate $\alpha 7$ nAChR.¹⁸⁶ Aniracetam was launched for cognitive impairment in Japan, Italy, and Greece (1993), but subsequently withdrawn in Japan due to insufficient efficacy. Nefiracetam, a structurally similar nootropic, potentiates NMDA-sensitive iGluR and nAChR.^{187,188} Ampakines represent another class of AMPA-sensitive iGluR modulator.^{189–191} Examples include CX516 and CX717 for AD and ORG-24448 for schizophrenia. In addition to memantine, launched products include budipine, an NMDA-sensitive receptor antagonist for Parkinson's dyskinesia, also of interest for cluster headache and migraine, premarin for menopausal syndrome and postmenopausal osteoporosis, and ifenprodil, an NMDA-sensitive receptor antagonist/ α -adrenergic receptor antagonist vasodilator.

Numerous other iGluR-based compounds have been evaluated clinically. These include: NMDA-sensitive receptor antagonists BIO-176 (a ketamine formulation) for restless leg syndrome; CHF-3381 for neuropathic pain, epilepsy, and cognitive impairment; CNS 5161 for neuropathic pain; dimebon, which also may have cholinergic agonist and histaminergic antagonist properties, for cognitive impairment; perzinfotel for neuropathic pain and stroke; PMI-150 (another ketamine formulation) for pain; traxoprodil (NR2B selective) for pain and stroke; delucemine for depression, epilepsy, neuroprotection, and pain; neramexane for cognitive impairment, ischemia, alcohol dependence, pain, and osteoarthritis; dexanabinol for stroke and other forms of CNS injury; and neurodex, which also has sigma-1 receptor agonist and CYP2D6 inhibitor properties, for emotional lability in amyotrophic lateral sclerosis and multiple sclerosis, neuropathic pain, and cough. D-Serine and neoglutamine are glycine site coagonists of interest for schizophrenia, while GW 468816 is a glycine site antagonist of interest for smoking cessation. SYM-1010, a conantokin-G analog, is an NMDA-sensitive receptor partial agonist that was of interest for epilepsy, although intrathecal administration is required. AMPA/kainate-sensitive receptor inhibitors include NGX-424 for pain and migraine; LY 293558 for epilepsy/seizures, neuroprotection, pain, and migraine; AMP-397 for epilepsy; E-2007 for Parkinson's disease, multiple sclerosis, and epilepsy; NS 1209 for epilepsy and stroke; and talampanel for epilepsy, Parkinson's disease, and neuroprotection.

2.22.3.8 Diseases

In mouse, the *lurcher* and *hotfoot* mutations in iGluR- $\delta 2$ cause disruption in cerebellar Purkinje synaptic transmission.^{192,193} The *lurcher* mutation can cause iGluR- $\delta 2$ to be constitutively open when expressed in *Xenopus* oocytes, but this probably is influenced by association with an endogenous *Xenopus* iGluR subunit in oocytes and does not explain the *lurcher* mechanism in the mammalian Purkinje neuron where $\delta 2$ appears to function independently of LGIC.

2.22.4 Adenosine Triphosphate-Gated Family

There is now abundant evidence that ATP functions as a neurotransmitter and/or cotransmitter in addition to being a critical player in kinase signaling pathways and energy metabolism. Purinergic transmission is that which utilizes a purine nucleotide (typically ATP) or its metabolite as the extracellular messenger. ATP is rapidly degraded to ADP, AMP, and adenosine by ectonucleotidases, and therefore these substances may serve as messengers consequent to ATP release and metabolism as well as being released directly. Indeed, adenosine acts as an extracellular messenger through P1 GPCR. The purinergic LGIC are termed P2X and are selective for ATP. For reviews see ^{194–202}.

2.22.4.1 Current Nomenclature

Extracellular nucleotides such as ATP and UTP modulate cellular function by activation of membrane-bound P2-receptors, which are divided into two families of P2 receptors: ionotropic P2X LGIC and metabotropic P2Y GPCR. The idea that ATP is a neurotransmitter was controversial for many years, but was supported by pioneering research

principally in Burnstock's laboratory and ultimately widely accepted following the cloning of ATP receptors. Initially, the P2X family was subclassified and members named according to the cell type in which the receptor was first found and according to the pharmacology of the receptor. This nomenclature became cumbersome and confusing, and present nomenclature is based primarily upon amino acid sequence. Up to now seven mammalian P2X receptor subtypes (P2X₁₋₇) and eight mammalian P2Y receptor subtypes (P2Y_{1,2,4,6,11,12,13,14}) have been cloned and functionally defined as P2 receptors.^{198,203}

2.22.4.2 Molecular Biology

The seven P2X receptor subunits cloned to date, P2X₁₋₇, form a new structural family of ligand-gated cation channels.^{196,201} The P2X₁ to P2X₆ receptors have 379–472 amino acids, with a predicted tertiary structure of two TM segments, a large extracellular loop with 10 conserved cysteine residues, and intracellular N and C termini. The P2X₇ receptor (595 amino acids) is similar, but with a much larger intracellular C terminus. This is different from that of the other known ligand-gated ionotropic receptors, such as the nicotinic, glutamate, glycine, GABA_A, or 5HT₃ receptors.

2.22.4.3 Protein Structure

Currently known P2X subunits can combine to form homomeric or heteromeric LGIC channels in a trimeric arrangement. Like other LGIC, the P2X subunits are thought to span the membrane and to assemble in such a way as to form a centrally located gated ion channel. However, the trimeric structure, relatively short N- and C-termini in many of the subunits, and presence of only two putative transmembrane regions are departures from the Cys-loop and iGluR LGIC noted above. Each subunit has a large extracellular domain (~280 amino acids) between the two TM segments. In the extracellular domain are 10 conserved cysteine residues thought to be important for proper folding or loop formation via disulfide bonds. Within two of these loops are conserved histidine, proline, and glycine residues associated with modulation by metal binding and with receptor flexibility. The ATP-binding motifs found in other ATP-sensitive proteins are not found in P2X. Rather, the phosphate portion of ATP appears to interact with basic residues near the channel mouth – a lysine near TM1, and a lysine and slightly upstream asparagine-phenylalanine-arginine near TM2 – while the adenine portion of ATP interacts with asparagine-phenylalanine-threonine in a separate loop approximately in the middle of the extracellular sequence. Additionally, near the phosphate-binding loop are two conserved histidine residues that appear to be involved in modulation by protons. Intracellularly, the N-terminal region is short but includes a protein kinase C consensus site, and the C-terminal region varies considerably in length among subtypes (27–239 residues) but includes a trafficking motif near the intracellular portion of TM2.

Known P2X receptors are trimeric assemblies comprising one or two of the seven subunits. Combined pharmacological and electrophysiological evaluation has provided evidence that heteromeric assemblies exist natively, as well as interesting clues related to channel function. For example, P2X₃ homomeric receptors are sensitive to α,β -methylene-ATP (α,β -meATP) and desensitize rapidly upon continued agonist application, while P2X₂ homomers are insensitive to α,β -meATP and desensitize slowly to ATP or other agonists. Heteromeric P2X_{2/3} receptors can be clearly observed as LGIC that are activated by α,β -meATP but desensitize slowly. Similar currents are observed in sensory ganglia, suggesting that the native LGIC are P2X_{2/3} heteromers. This also suggests that ligand binding occurs within the subunit, as in glutamate-gated channels rather than at the subunit interfaces, as in nAChR. P2X₇ is the subunit with the longest intracellular C-terminal region, and is the only subunit that appears not to form functional heteromeric assemblies. P2X₆, in contrast, appears to function only in heteromeric assemblies.

P2X members are nonselective cation channels, permeable to Ca²⁺ as well as monovalent cations. Some homomeric LGIC, notably P2X₁ and P2X₃, desensitize rapidly while others display slower desensitization kinetics. Yet others – P2X₂, P2X₄, and P2X₇ – display a remarkable, and unusual, macromolecular pore formation in which agonist initially gates cation channel opening, but after minutes of continued agonist application, the channel is opened sufficiently wide to be permeable to dyes such as YO-PRO-1. This has been of particular interest in P2X₇ (P2Z in older literature) function where it is thought that pore formation may mediate apoptotic or anti-infection processes. The answer is not resolved, but this remains an active area of research.

2.22.4.4 Physiological Functions

Purinergic receptors and responses are found throughout nervous system and in smooth muscle of various types. Characterization of the subtypes involved has been hampered by a lack of highly selective agonists and antagonists, but

has, to some extent, benefited from gene knockout studies and from unique properties of certain heteromeric combinations. P2X₁ is found in smooth muscle and platelets as well as sensory ganglia, sympathetic nervous system, and CNS. It functions in purinergic transmission in arterial, bladder, gut, and vas deferens smooth muscle. One of its roles is exemplified by the finding that male P2X₁ knockout mice are infertile owing to the lack of P2X₁ mediated contraction in vas deferens. P2X₁ also is found in platelets and may play a role in platelet aggregation. On the other hand, P2X₂ and P2X₃ are expressed in sensory neurons (e.g., dorsal root ganglia) and appear to function in a heteromeric (P2X_{2/3}) complex. Given the predominant localization of P2X₃ in sensory neurons and upregulation of P2X₂ and P2X₃ expression with inflammation, P2X₃ has been a target of interest for pain and urological disorders. The effects of P2X₃ agonists, antagonists, and intrathecal antisense treatment are consistent with a role for P2X₃ in pain, although results with P2X₃ knockout mice have been modest. Interestingly, capsaicin can induce a Ca²⁺-dependent cross-desensitization of the P2X_{2/3} response in dorsal root ganglia, suggesting the possibility that efficacy of capsaicin or other TRPV1 agonists could, in part, be due to desensitization of P2X as well as TRPV1 receptors. P2X_{1/5} and P2X_{4/6} also may be expressed in spinal cord, along with P2X₇. Disruption of P2X₇ receptors abolished chronic inflammatory and neuropathic pain and it has been hypothesized that the P2X₇ receptor, via regulation of mature interleukin-1 β (IL-1 β) production, has a common upstream transductional role in the development of neuropathic and inflammatory pain.²⁰⁴

P2X subunits of all types also are expressed in the sympathetic nervous system, where in fact evidence for purinergic transmission was initially developed.²⁰⁵ ATP and ACh are copackaged in cholinergic synaptic vesicles (as are ATP and catecholamines in secretory granules) and might function as cotransmitters, although the physiological/pathological role for this remains unclear. Interestingly, there is evidence that P2X receptors and Cys-loop receptors (e.g., nAChR) may inhibit one another apparently through protein–protein interaction. P2X₇ has attracted attention for its potential role in mycobacterial killing and other potential functions in lymphocytes (mitogenesis) and microglia where P2X₇ is highly expressed. However, expression of P2X₇ is widespread, including airway epithelium, vascular and other smooth muscle, pancreas, pituitary, spinal cord, retina, mast cells, skin, bone, and salivary glands.

2.22.4.5 Regulation

P2X receptors have the potential to activate Ca²⁺-dependent intracellular signaling by admitting Ca²⁺ through the P2X channel and by activating voltage-dependent Ca²⁺ channels through depolarization of the cell. In turn, P2X receptors may be modulated through the conserved protein kinase C consensus site in the N-terminal region. The role of this process is not clearly understood, but regulation of desensitization kinetics is suspected.

2.22.4.6 Prototypical Pharmacology

Prototypic P2X agonists are ATP derivatives,^{195,201,206} such as α,β -MeATP (P2X₁ and P2X₃ selective), BzATP (P2X₁, P2X₂, and P2X₇), and 2-Me-thioATP (active at all but most potent at P2X₃ and P2X₁). The dyes suramin and PPADS are commonly used antagonists, which are not selective among P2X₁, P2X₂, P2X₃, and P2X₅ but are selective for these P2X (micromolar IC₅₀) relative to P2X₄, P2X₆, and P2X₇ where they have little activity. P2X₇, on the other hand, is selectively blocked by calmidazolium. TNP-ATP is a potent (nanomolar) antagonist selective for P2X₁ and P2X₃, but does display micromolar IC₅₀ for P2X₂ and P2X₄. Most compounds do little to distinguish P2X₁ and P2X₃. However, the antagonist IP₅I is three orders of magnitude selective for P2X₁ versus P2X₃ (~ 3 nM versus ~ 3 μ M IC₅₀). A-317491, on the other hand, selectively inhibits P2X₂, P2X₃, and P2X_{2/3} receptors and exhibits analgesic-like effects in animal models (see [Figure 9](#) for representative structures).^{199,200,207}

2.22.4.7 Prototypical Therapeutics

P2X receptors appear to be involved in numerous physiological systems, and recently P2X₃ and P2X₇ have been of particular interest for pain and infection, respectively. However, development of a successful therapeutic, as well as verification of the suspected role in vivo, has been hampered by issues such as selectivity and suitable pharmacokinetic/physicochemical properties. Pyridoxal phosphate (MC-1) is a naturally occurring substance evaluated as a cytoprotectant in myocardial infarction, ischemia, and stroke.^{208,209} MC-1 combined with other substances such as an angiotensin receptor antagonist (MC-4262) or lisinopril as an angiotensin converting enzyme inhibitor (MC-4232) are of interest in hypertension. However, pyridoxal phosphate may have a variety of actions and its specificity for any particular P2X receptor is not clear. YM-529 is a novel bisphosphonate investigated as a potential therapeutic in

Figure 9 Agonists, antagonists, and modulators for P2X receptors.

osteoporosis, various types of cancer, and pain. It has been reported to inhibit P2X_{2/3} responses in an expression system, but in that regard it is not particularly potent nor is its selectivity for P2X_{2/3} clear. AZD 9056 is a P2X₇ antagonist with potential for the treatment of rheumatoid arthritis and chronic obstructive pulmonary disease.

2.22.4.8 Diseases

Although a P2X₁ dominant negative mutation has been reported, the role of that mutation in the patient's bleeding disorder remains uncertain. Nevertheless, P2X₁ as well as certain P2Y receptors may be of interest in platelet disorders such as thrombosis.

2.22.5 Transient Receptor Potential Family

There are seven transient receptor potential (TRP) channel families playing a variety of roles from *Drosophila* to human: TRPC (canonical), TRPV (vanilloid), TRPM (melastatin), TRPP (polycystin), TRPML (mucolipin), and TRPA (ankyrin). Many roles appear to be in the sensory system, and various channels are activated by diverse stimuli, including temperature and possibly other physical parameters such as mechanical stimuli. However, some of the TRP also appear to be affected by exogenous and endogenous ligands, and therefore may be considered LGIC. For reviews, see ^{210–220}.

2.22.5.1 Current Nomenclature

TRP ion channels are so named because *Drosophila* photoreceptors lacking TRP exhibit a transient voltage response to light stimulation. Unlike other ion channels, TRP channels are not named according to ligand, function, and/or selectivity. TRP channel mechanistic functions are disparate and sequence homology among family members may be as low as 20%. Nevertheless, TRP channels share overall structural similarity, and are named and grouped into subfamilies based upon structure. The nomenclature also reflects a mix of structure, mechanism, and pharmacology. TRPC are the classical or canonical subfamily with structure similar to *Drosophila* photoreceptor proteins where TRP channels were first identified.²¹⁰ TRPV are named for sensitivity of TRPV1 (formerly known as VR1 or vanilloid receptor 1) to vanilloid compounds such as capsaicin found in chili peppers. TRPM1 is named for melastatin, found in metastatic melanoma cells. However, this should not be taken to indicate that TRPM channels are involved in cancer induction or metastasis. TRPM8, for example, is distributed in sensory neurons and responds to cold and to menthol. TRPP are related to the polycystic kidney disease proteins PKD2 (TRPP2), PKD2L1 (TRPP3), and PKD2L2 (TRPP5). TRPML are related to the founding mucolipins, intracellular vesicular membrane proteins identified through mutation of TRPML1 (MCOLN1) in mucopolipidosis. TRPA1 (formerly ANKTM1) is named for its large number of ankyrin repeats (≥ 14) and thus far is the only TRPA subfamily member. TRPA1 responds to temperature (cold in mammals, warmth in *Drosophila*). TRPN1 (formerly NompC) also has a large number of ankyrin repeats but nevertheless constitutes a subfamily different from TRPA1.^{213,215} TRPN1 and TRPA1 appear to be required for mechanotransduction in hair cells, perhaps explaining the high content of ankyrin repeats.

2.22.5.2 Molecular Biology

The primary structure of TRP channels predicts six TM-spanning domains with a channel-forming pore domain (P-loop) between the TM5 and TM6 segments. Both the C- and the N-termini are located intracellularly. This architecture is a common theme for ion channels such as voltage-gated K⁺ channels present in life forms ranging from bacteria to mammals. The mammalian TRP channel family is united primarily by structural homology within the TM-spanning domains. Other features include a 25-amino acid motif (TRP domain) containing TRP box (EWKFAR) just C-terminal to the sixth TM segment. The TRP domain and box are present in all other TRPC channel genes but not in all other TRP channel genes. The N-terminal cytoplasmic domain of TRPA1, TRPC, TRPN1, and TRPV contain ankyrin repeats, whereas the TRPC and TRPM contain proline-rich regions just C-terminal to the predicted sixth TM segment. At present, no one feature other than overall six-TM architecture and homology defines the TRP family. Thus, we expect that the definition of TRP channels will evolve as functions and structures are clarified. Updated summary tables of the molecular and biophysical properties of various TRP channels including tissue distribution can be found elsewhere.²²¹

2.22.5.3 Protein Structure

Functional TRP assemblies are derived from four subunits. While the subunit and quaternary structure bears an overall similarity to voltage-gated K⁺ channels, TRP channels are not K⁺-selective but rather are cation channels permeable

to Ca^{2+} as well as Na^{+} and K^{+} . The Ca^{2+} permeability is significant with $\text{PCa}^{2+}/\text{PNa}^{+}$ typically up to 10 with a few exceptions: TRPM4 and TRPM5 are not permeable to Ca^{2+} (monovalent cation selective) while TRPV6 is Ca^{2+} selective. Studies have focused upon homomeric assemblies, but heteromers may be formed within each family. The N- and C-termini of TRP channels demonstrate a variety of regulatory sites including potential sites of protein–protein interaction PDZ domain in C-terminal region (TRPV), and ankyrin repeats in the N-terminal region (3–4 in TRPV, 14 in TRPA1).

2.22.5.4 Physiological Functions

The gating of TRP channels is not well understood and is an active area of research. Although TRPV1 is activated by ligands such as capsaicin applied extracellularly, the binding site is thought to be intracellular. Mutagenesis studies have suggested that TM3 and the N- and C-termini are important to vanilloid binding, with the hydrophobic area of the ligand interacting with TM3 and the hydrophilic area interacting with N- and C-termini. TRPV1–4 are polymodal sensory receptors responsive to elevated temperature, and acid and endogenous substances such as arachidonate lipoxygenase products as well as exogenous substances such as capsaicin or camphor. Protons appear to act as modulators, increasing thermal and ligand sensitivity. TRPV1–4 appear to function as temperature sensors and cover specific temperature ranges according to receptor subtype. Additionally, extracellular messengers and low pH associated with inflammation can activate TRPV1 and produce burning pain. TRPV1 knockout mice show reduced thermal sensitivity in inflammation models, although there appears to be less effect on mechanical hyperalgesia.

Most studies of recombinant TRP subunits have used homomeric receptors, but some may function as heteromers in vivo and this could alter the pharmacology of the receptors with important impact on therapeutic development. TRPV3 and TRPV1, for example, share some elements of function and of neuronal distribution, but it is not clear whether they coassemble and how that might influence their response to ligands. TRPV5 and TRPV6, on the other hand, are found in renal and intestinal epithelia and have an exceptionally high Ca^{2+} permeability ($\text{PCa}^{2+}/\text{PNa}^{+} > 100$). It has been proposed that these TRPV may function in Ca^{2+} transport.

TRPM5 seems to be a taste transducer although it is not clear whether these responses reflect direct or modulatory interactions. TRPM8 responds to cold, menthol, and icilin and is thought to function as cold sensor in C-fiber neurons, but is not localized specifically to sensory ganglia and may have additional functions.

TRPA1, characterized by 14 ankyrin repeats in the N-terminal region, is coexpressed with TRPV1 but not with TRPM8 in mammalian sensory neurons. The role of TRPA1 in mammals is not clear. Activation of TRPA1 by cold is controversial, but it apparently is effectively activated by mustard oil and cinnamaldehyde. THC also has been reported to activate the channel. It has been suggested that TRPA1 may be involved in mammalian hearing, in analogy with related TRP in zebrafish and *Drosophila*.

2.22.5.5 Regulation

TRPV and other TRP channels are clearly regulated by protein kinase A and C, and some responses to exogenous substances and extracellular messengers may in fact be indirect. However, TRPV1 responses to vanilloids and arachidonate derivatives do appear to be mediated by ligand interaction. Principal intracellular activators of TRP channels include calcium and diacylglycerol, products from the phospholipase C pathway.²¹⁶

2.22.5.6 Prototypical Pharmacology

The majority of the ligand pharmacology currently available pertains to TRPV1. Many of the ligands are based upon vanilloid- or anandamide-like structures. The potent antagonist NDT-9525276 and other similar compounds are a departure. Other recently disclosed selective antagonists that block diverse modes of TRPV1 activation (by protons, heat, capsaicin, anandamide, etc.) with nanomolar affinities include isoquinoline urea (A-425619), pyridinylpiperazine ureas, biarylcarboxybenzamides, and phenylacrylamide (AMG9810) analogs (Figure 10).

2.22.5.7 Prototypical Therapeutics

Therapeutic interest has focused largely upon TRPV1 in the sensory system, particularly in pain and inflammation (including airway inflammation) and bladder control. Capsaicin activates and desensitizes TRPV1. In neonates, capsaicin can kill sensory neurons, but in adults it is limited to receptor desensitization. Capsaicin is used in some

Figure 10 Agonists, antagonists, and modulators of TRP channels.

topical treatments to alleviate burning pain and itch, but its efficacy has not been impressive. However, capsaicin and another TRPV1 agonist, resiniferatoxin, have been reported to be more effective in bladder hyperreflexia when administered by bladder installation.^{222,223}

Launched capsaicin-derived products include Capsidol and GenDerm as analgesic topicals. Other modifications evaluated in clinical trials include NasoCap, as an intranasal capsaicin for cluster headache and migraine; Transdolor, a dermal patch for neuralgia and neuropathy; Civamide, a capsaicin isomer for neuralgia/osteoarthritis or cluster headache/migraine; ALGRX-4975, an injectable capsaicin for pain and osteoarthritis; and resiniferatoxin for overactive bladder. Clearly, an antagonist rather than a desensitizing agonist would be preferred for indications such as pain. The antagonist capsazepine has been a useful tool in vitro, but has not been effective as an analgesic, presumably because of low potency and limited utility against activation by protons. However, I-resiniferatoxin is potent but not effective in vivo.²²⁴ AMG-517 and GlaxoSmithKline 705498 are TRPV1 antagonists reportedly in clinic trials for inflammatory pain. With the emerging roles of TRP channels as intrinsic cellular sensors in a variety of processes including vision, pain, taste, temperature sensation, and hearing along with links to cancer and apoptosis, selective molecules targeting other TRP channels are expected to advance into clinical proof of concept studies in the not too distant future.

2.22.5.8 Diseases

TRP channels play key roles as receptors for irritants, inflammation products, and xenobiotic toxins, and their involvement in various diseases is an area of active investigation. At least four channelopathies are known at present and the list continues to grow. TRPP containing ion channels play important roles in epithelial cells and tubule formation, and mutations in TRPPs, particularly TRPP1 and TRPP2, are responsible for polycystic kidney disease. Loss-of-function mutations in TRPM6 cause the rare autosomal recessive disorder hypomagnesemia with secondary hypocalcemia manifested as a multitude of neurological symptoms including seizures and muscle spasms during infancy. Mutations in the TRPML1 gene cause mucopolipidosis type IV, a neurodegenerative lysosomal storage disorder characterized by severe psychomotor retardation and other abnormalities. Defective TRPML1 alters endocytotic transport of membrane components by attenuating the fusion between late endosome–lysosome hybrid vesicles. As reviewed recently,²²⁵ other indications of the involvement of TRPs in diseases have emerged from correlations between the levels of TRP channel

expression and disease symptoms or from the mapping of TRP-encoding genes to susceptible chromosome regions. Changes in TRPV1 levels and regulation are implicated in dysfunctional pain sensations such as allodynia and hyperalgesia, gastrointestinal diseases such as inflammatory bowel disease and Crohn's disease, and urinary bladder diseases such as overactive bladder. TRPV4 is widely expressed in airways, and may be involved in bronchial hyperresponsiveness, as in chronic asthma. It has been suggested that TRPV4 provides the calcium influx pathway for regulatory volume decrease in response to hypotonic stress, a process that is defective in airway epithelia of individuals with cystic fibrosis.²²⁶ A role in hearing impairment also is implicated, as one of the gene loci associated with autosomal dominant nonsyndromic hearing loss has been mapped to a region in chromosome 12q21–24 where the TRPV4 gene is located. Although precise involvement remains to be determined, TRPM genes such as the TRPM2 and TRPM3 gene locus has been linked to bipolar disorders, amyotrophic lateral sclerosis, and retinal diseases.

2.22.6 Acid-Sensitive Ion Channel Family

To the extent that protons may be considered ligands, then acid-sensitive ion channels (ASICs) are LGIC. Protons can act as extracellular messengers. Tissue acidifies to pH level <6 under conditions of ischemia and inflammation, and these conditions are detected by the sensory nervous system. Additionally, transmitters are packaged in a low-pH environment in synaptic vesicles and secretory granules and, therefore, protons may be co-released during exocytosis. Furthermore, catabolic hydrolysis of some neurotransmitters increases acid content (ACh to choline and acetic acid, ATP to ADP, AMP, and phosphoric acid). Indeed, there is direct evidence for localized acidification during synaptic activity.²²⁷ Thus, protons may signal pathologic conditions (ischemia, inflammation) and may be released as cotransmitters during physiologic activity. ASICs are highly expressed in sensory neurons and in brain and apparently serve as receptors for these proton messengers. The present challenge, however, is to define the binding site SAR to develop competitive ligands, or to identify selective channel blockers. For recent reviews see ^{228,229}.

2.22.6.1 Current Nomenclature

ASICs are one of the seven subfamilies in the ENaC (epithelial sodium channel)/DEG (degenerin) family of cation channels. Earlier nomenclature labeled these channels in analogy to ENaC or DEG and in recognition of the source tissue, for example BNaC for brain (acid-sensitive) sodium channel, DRASIC for dorsal root acid-sensitive channel, etc. These nomenclatures have now been consolidated as ASIC1, which exists as two isoforms, ASIC1a (formerly ASIC α or BNaC2 α) and ASIC1b (formerly ASIC β or BNaC2 β), ASIC2 along with its two isoforms, ASIC2a (MDEG1, BNaC1 α , or BNC1) and ASIC2b (MDEG2 or BNaC1 β), ASIC3 (DRASIC), and ASIC4 (SPASIC).

2.22.6.2 Molecular Biology

The three principal genes, *ASIC1*, *ASIC2*, and *ASIC3*, and their alternatively spliced transcripts (ASIC1a, ASIC1b, ASIC2a, and ASIC2b) produce subunits that combine to form multimeric channels activated by protons. Neurons express ASIC subunits in variable and overlapping distributions. ASICs are localized principally to neurons in central and peripheral systems, or their target organs. ASIC1a, ASIC2a, and ASIC2b are found in CNS with widespread distribution and particularly high levels in hippocampus, cortex, cerebellum, amygdala, olfactory bulb, and habenula. ASIC1b and particularly ASIC3 are highly expressed in sensory ganglia. ASIC4 also is found in brain and in pituitary, but its function remains to be clarified. As discussed below, much of the current understanding of the functional roles of ASIC subunits is derived from gene knockout experiments.

2.22.6.3 Protein Structure

Each ASIC subunit has two transmembrane domains with relatively short intracellular N- and C-termini, and a large extracellular region between TM1 and TM2. While that is vaguely reminiscent of P2X subunits, functional ASICs are thought to be comprised of four subunits rather than three in the case of P2X. ASIC1–3 can form homomeric or heteromeric LGIC in the typical expression systems, but ASIC4 has not yet been shown to participate in either homomeric or heteromeric assemblies. The site and mechanism of proton gating remain areas of investigation, and may differ among ASIC subtypes. In ASIC3, it appears that gating is due to proton displacement of Ca²⁺, apparently bound to the receptor so as to block the channel²³⁰ – a 'dechelation'. However, the amino acid residues contributing to this interaction have yet to be identified.²³¹ The intracellular N-terminal region is short but contributes to channel function by regulating Mg²⁺ ion selectivity.²³²

2.22.6.4 Physiological Functions

Elucidation of the physiological roles of ASICs is hampered by the limited availability of pharmacological tools. However, gene knockout studies are consistent with the ideas that ASIC3 is involved in pain,^{233,234} and that ASIC2 functions in retinal activity.²³⁵ An early study suggested that ASIC2a participates in touch mechanosensory transmission, but there is some uncertainty.^{236–238} In any case, it does not appear to be involved in pain. The Welsh laboratory has used gene knockout approach to study ASIC subunit function in behavior as well as in *in vitro* CNS tissue physiology. ASIC1 was found to mediate amygdala acid responses and amygdalar behavior such as fear conditioning,^{239,240} and ASIC1a/2a heteromer was implicated in hippocampal function including induction of LTP as well as the adverse effects of ischemia.^{241–243} The hippocampal studies in particular suggest that ASIC may be involved in synaptic transmission or in modulating synaptic transmission.

ASIC1 enjoys a neuronal distribution, including Zn^{2+} -rich areas of hippocampus.²⁴⁴ While ASIC1a and ASIC2a may modulate synaptic function in hippocampus, these LGIC themselves (above) are modulated in a complex manner by Zn^{2+} ,^{245–247} which is concentrated in specific hippocampal and spinal dorsal horn neurons. At micromolar concentrations, Zn^{2+} selectively potentiates ASIC2a-containing LGIC.²⁴⁷ However, at nanomolar concentrations, Zn^{2+} inhibits ASIC1a-containing LGIC.²⁴⁵ Low, nanomolar concentrations of Zn^{2+} are maintained *in vivo*, but in artificial ‘physiological’ saline Zn^{2+} contamination may be sufficiently high to block ASIC1a unless selective chelators are added, raising questions as to the extent to which ASIC1a and other Zn^{2+} -blocked channels have been underappreciated in *in vitro* studies. In ASIC1a/ASIC2a heteromers, as expressed in the hippocampus, it has been suggested that while nanomolar concentrations of Zn^{2+} may block by interacting with the LGIC complex at one site, micromolar Zn^{2+} may interact at another site to relieve the block.²⁴⁵ Thus, the roles of ASIC in hippocampus may be a complex interplay between Zn^{2+} , potentially released from dentate gyrus/CA3 mossy fibers upon specific neuronal input, and protons.

2.22.6.5 Regulation

There is considerable heterogeneity in the nature of pH-evoked currents within and between individual neurons attributable to differences in ASIC subunit make-up, and it is to be expected that channels derived from diverse ASIC subunits could be regulated under normal physiologic and pathologic conditions. For example, transient global ischemia upregulates ASIC2a expression in hippocampal and cortical neurons that survive ischemia.²⁴⁸ Complete Freund’s adjuvant-induced inflammation resulted in increased expression of both ASIC1a and ASIC2a in the dorsal horn, and this may play important roles in inflammation-related persistent pain.²⁴⁹

2.22.6.6 Prototypical Pharmacology

As has often been the case, nature leads the way. By far the most potent and specific ASIC blockers are toxins – the ASIC3 blocker APETx2 from sea anemone^{250,251} and the ASIC1a inhibitor psalmotoxin-1 from spider.^{252–254} Structures of these toxins are known, and perhaps this will lead to better understanding of the LGIC structure and pathways to synthetic ASIC blockers. Amiloride has been typically used to demonstrate that acid-induced effects are receptor-mediated and not via nonspecific interactions. At submicromolar concentrations, amiloride does inhibit ENaC. However, ASIC sensitivity to amiloride is much lower (mid micromolar), and the inhibition is not selective. At such high concentrations, amiloride may inhibit a number of ion channels apart from ENaC and ASIC. More recently, a nonamiloride blocker A-317567 was reported to inhibit ASIC responses in dorsal root ganglion neurons,²⁵⁵ with modest potency and selectivity among the dorsal root ganglion ASIC – perhaps an order of magnitude better than amiloride. As noted above, Zn^{2+} inhibits or potentiates specific ASIC. Gadolinium in micromolar concentrations inhibits ASIC3 homomeric and ASIC2a/ASIC3 heteromeric LGIC.²⁵⁶

ASIC3 is modulated by three related neuropeptides: FMRFamide, which is expressed in invertebrates and neuropeptides FF and SF, which are expressed in mammals including human.^{257–260} This may represent another avenue for pain therapeutics, either by inhibiting the LGIC potentiation or by controlling expression and/or release of the endogenous modulator. Potentiation of ASIC3 appears to involve reduced desensitization. The LGIC site of action is not known.²⁶¹

2.22.6.7 Prototypical Therapeutics

No ASIC-based therapeutics are known. However, interest in ASIC blockers for the treatment of ischemia (cardiac and CNS) and pain is growing. A collaboration between PainCeptor (Canada) and NeuroSearch (Denmark) claims to have identified potent ASIC3 and ASIC1a antagonists from a screening approach and is interested in optimizing these leads for treatment of pain associated with cardiac ischemia, muscle, and bone pain.

2.22.6.8 Diseases

Detailed functions of ASICs in both peripheral and central nervous systems remain to be fully elucidated. In peripheral sensory neurons, ASICs have been implicated in mechanosensation and perception of pain particularly during tissue acidosis as in ischemic myocardium where ASICs transduce anginal pain. The presence of ASICs in the brain suggests that these channels have other functions as well and studies have indicated that ASIC1a is involved in synaptic plasticity, learning/memory, and fear conditioning. Gain-of-function mutations of ASIC1 and ASIC2 have been proposed to participate in neurodegenerative diseases. Additionally, increased ASIC3 expression in inflamed human intestine has been reported.²⁶²

2.22.7 Future Directions

The fundamental ‘specialties’ of the nervous system are spatial and temporal resolution. Neurons use a variety of extracellular messengers, as do the endocrine and immune systems, but further deliver those messengers to a spatially defined volume (synapse) with diffusion-limited catabolic and reuptake processes. Additionally, the messenger is delivered rapidly and in a discrete time window measured in milliseconds to seconds. Thus, the nervous system achieves a high degree of specificity with relatively few transmitters compared to the variety of signals processed. In principle, a systemic therapeutic agent cannot approach this degree of resolution with present technology, and thus the term ‘neurotransmitter mimic’, which has sometimes been applied to LGIC agonists, may be a misnomer. Nevertheless, some LGIC agonists, such as those for nAChR and GABA_A receptors, have appeared in clinical trials with demonstrated proof of concept. In theory, however, one might expect an LGIC antagonist or a modulator to have a better chance of success. For an antagonist, the issue of temporal resolution is reduced since the antagonist would have its effect principally when transmitter is released, but spatial resolution remains a potential problem and a source of adverse effects. The utility is limited to disorders where transmission is excessive, and where blockade of transmission at targeted synapses and pharmacologically similar synapses can be tolerated. Such restrictions can be problematic and may limit therapeutic utility. Furthermore, a number of important CNS disorders, for example, neurodegenerative disorders such as AD and Parkinson’s disease, are due to deficits in transmission, at least in part.

Thus, modulation of transmission would seem a favorable path for neuronal therapeutics, and perhaps LGIC therapeutics in general. Positive modulators could increase the gain on what remains of the physiological signal without causing an inappropriate tonic signal. Negative modulators may be able to reduce the gain without completely blocking transmission. Therapeutic examples of transmission modulators may include biogenic amine reuptake inhibitors (antidepressants), acetylcholinesterase inhibitors (AD), and L-dopa (Parkinson’s disease); all of which, by reduced catabolism or increased synthesis, boost synaptic levels of transmitter contingent upon physiological release of the transmitter. One might also achieve success by modulating the receptor, and perhaps improve selectivity by specifically targeting the receptor compromised in the disorder. Benzodiazepines and related ‘benzodiazepine receptor agonists’ are examples of LGIC (GABA_A) modulator therapeutics. Presumably modulators for other LGIC, particularly homologous LGIC from the Cys-loop family, could be found and developed into successful therapeutics. Indeed, some LGIC modulators may already be in clinical or advanced preclinical phases, for example AMPA-sensitive iGluR and $\alpha 7$ nAChR positive allosteric modulators. However, the binding sites and molecular mechanisms behind these modulators are not clear. Some immediate challenges will be to clarify modulator sites so as to aid rational drug design, to optimize modulator efficacy and selectivity, to identify lead modulators for other LGIC involved in disease processes or disorders, and to identify those LGIC that are appropriate targets.

A pitfall is that our high-throughput, best-identified approaches utilize predefined hetero- or homomeric subunit combinations that may not be strictly reflective of native receptors under physiological and/or pathological conditions. Molecular biology has provided a means of isolating specific LGIC through cloning and functional expression. But, largely unknown are the exact subunit composition of the native LGIC, whether that composition may vary among cells or between health and disease, or whether the expression system provides posttranslational processing and cytoskeletal coupling similar to that of the native LGIC. Clearly, molecular cloning and heterologous expression techniques have provided keys to significant advances in pharmacology and physiology and accelerated initial stages of drug discovery efforts. However, novel compounds discovered with these tools need to be further verified and understood in native systems. LGIC need to be understood in their contextual roles. For example in neuroscience, there is a particularly wide gulf between recombinant LGIC and behavioral readout, and a considerable challenge is to bridge that divide with physiologically relevant systems. Likewise, as new compounds advance through clinical trials, it becomes important to relate efficacy and adverse effects for further target validation by establishing predictability and correlations with preclinical parameters such as receptor occupancy, behavioral measures, and therapeutic window.

Finally, we must better understand the roles of LGIC outside classical synaptic transmission. In the past two decades, it has become increasingly apparent that neuronal LGIC are involved not only in synaptic depolarization/hyperpolarization, but also in mediating signaling processes, particularly Ca^{2+} -mediated processes, important to neuronal regulation. Further, we are beginning to better appreciate that many LGIC are present and functional not only in neuron, muscle, and endocrine cells but also in so-called nonexcitable cells such as endothelial cells, epithelial cells, and immunocompetent cells. A challenge will be to better elucidate the expression and roles of LGIC in such tissues as well as in nervous system in order to better anticipate potential adverse effects of CNS-targeted therapeutics as well as to expand the opportunity to identify novel therapeutics through nonneuronal LGIC.

Biographies

Clark Briggs is a neuropharmacologist/electrophysiologist in the Neuroscience Research Area within the Global Pharmaceutical Research and Development Division of Abbott. Dr Briggs received his ScB (Chemistry) from Brown University and PhD (Pharmacology) from Yale University. Following a postdoctoral fellowship and Research Scientist position at the Beckman Research Institute at the City of Hope Medical Center (Duarte, CA), he joined Abbott in 1986 where he has been engaged in drug discovery programs pertaining to G protein-coupled receptors and ligand- and voltage-gated ion channel targets for neuropsychiatric, analgesic, and urologic indications. Currently, Dr Briggs is engaged in nicotinic acetylcholine receptor research as an Associate Volwiler Research Fellow at Abbott.

Murali Gopalakrishnan is currently working in the Neuroscience Research Area within the Global Pharmaceutical Research and Development Division of Abbott. Dr Gopalakrishnan received his BPharm degree from Banaras Hindu University and PhD degree in Biochemical Pharmacology at the State University of New York at Buffalo. Following a postdoctoral fellowship at the Department of Physiology at Baylor College of Medicine, he joined the Neuroscience Research Area at Abbott. Over the past 13 years, he has been engaged in drug discovery programs in the areas of central nervous system, urology, and pain, focusing on voltage- and ligand-gated ion channels. Currently, Dr Gopalakrishnan is Project Leader and Associate Volwiler Research Fellow at Abbott.

2.23.1 Current Nomenclature

Phosphodiesterase enzymes (PDEs) are so named because of the nature of the reaction they catalyze, as shown in [eqn \[1\]](#). The enzyme activates a molecule of water to hydrolyze the phosphorus–oxygen bond in the substrate, a cyclic phosphate ester nucleotide to produce a nucleoside monophosphate. The first PDE enzymes, and their substrates, were identified in 1972.¹

This family of intracellular enzymes modulates levels of the essential second messengers, cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), which are produced in response to various stimuli. Inhibition of enzymatic activity raises the level of the cyclic nucleotide, and results in maintained or enhanced physiological response to the stimulus. For example, it has been reported that a two- to fourfold increase in cGMP concentration results in a maximal biological response.² The acyclic nucleotide product of eqn [1] is generally inactive as a second messenger, and, as a result, the physiological response associated with stimulus of the signaling pathway is terminated.

A total of 11 different types of mammalian PDEs have been identified to date (PDE1–PDE11) in class I of the phosphodiesterase superfamily. Class II phosphodiesterases have no recognizable sequence similarity to enzymes in class I. Each of the subfamilies in class I have between one and four distinct gene product(s) (designated by a capital letter (A–D)), and in some cases there are also splice variants of these gene products (designated by a roman numeral). Enzymes in the family have individual and distinct degrees of substrate specificity (based on K_m (Michaelis–Menten affinity) values), as shown in [Table 1](#). As noted in [Section 2.23.4](#), V_{max} (maximal velocity) values for the two cyclic nucleotides can differ substantially, rendering differences in K_m values insignificant. The cAMP-specific PDEs include PDE4, PDE7, and PDE8, and the cGMP-specific enzymes are PDE5, PDE6, and PDE9. The remaining family members can process both cyclic nucleotides, although they prefer one or the other to varying degrees.

2.23.2 Gene/Molecular Biology Classification

[Table 2](#) lists the human chromosome location for each of the known PDE enzymes.

2.23.3 Protein Structure

The structural organization of the mammalian PDE superfamily shows a common theme. Each enzyme has a C-terminal catalytic domain and an N-terminal regulatory domain. Most commonly, splice variants occur in the N-terminal region, and regulate the subcellular localization of the enzyme. In the catalytic domain, there is a consensus sequence, HD(X₂)H(X₄)N, which includes binding domains for divalent cations (e.g., Zn²⁺ and Mg²⁺), needed for structural or catalytic functions. The mechanism by which the cyclic phosphate ester is cleaved involves nucleophilic activation of a water molecule and S_N2 displacement at the phosphorus atom, with inversion of configuration.^{3,4} A representation of the structural organization for the 11 PDEs is shown in [Figure 1](#).

The C-terminal catalytic domain of all 11 mammalian family members displays the closest similarities in terms of amino acid sequence (up to 45%). An early prediction by Beavo and co-workers that the catalytic domain resided in this region of the enzyme⁵ was subsequently shown to be correct when PDE1, PDE2, and PDE3 were subjected to partial proteolytic cleavage (to remove regions of the protein outside the C-terminal domain), and these protein

Figure 1 Structural organization of the 11 PDEs.

fragments demonstrated PDE activity. In addition, expression of mutant PDE3, PDE4, and PDE5, engineered to delete N-terminal sequences, also displayed PDE activity *in vitro*.^{6–13} These structural modifications did not significantly influence the binding affinity of cGMP or inhibition by compounds in the case of PDE5, while effects using PDE4 depended on the specific changes in the protein outside of the catalytic domain.

Mutagenesis and hydropathic analysis of PDE5, in an attempt to understand the substrate selectivity of cGMP-specific enzymes, was carried out by Turko *et al.*¹⁴ Substitution of Tyr602, or Glu775 in PDE5 substantially reduced substrate binding, and other amino acid mutations in the sequence around Glu775, including Ala769, Trp762, Gln765, and Leu771, increased the K_m value of cGMP and decreased the K_m value of cAMP, without influencing the K_D (dissociation constant) value of cGMP, or the respective IC_{50} (50% inhibitory concentration) values for the standard inhibitors zaprinast and rolipram. The alanine and leucine mutations employed in this experiment substituted more polar residues, while tryptophan and glutamine were replaced by leucine and tyrosine, respectively. Hydropathic analysis of a 30-amino-acid sequence surrounding the putative catalytic site of PDE1–PDE7 revealed that the cAMP-selective enzymes are uniformly more hydrophilic in a short sequence of residues on the N-terminal side of a key glutamic acid residue that is conserved in all known mammalian PDEs. In the cGMP-selective enzymes, this same sequence is always hydrophobic. Enzymes that can process both cyclic nucleotides show intermediate hydrophobicity in this region of the catalytic site. These differences in amino acid characteristics may be associated with the distinct hydrogen bond donor/acceptor characteristics of purine and pyrimidine bases. This study did not attempt to separate the structural effects of amino acid mutations (on the shape or size of the substrate binding site) from electronic effects that may be associated with substrate binding.

There are much more substantial variations in the N-terminal domains of PDEs, in terms of size, amino acid composition, and organization. Differences in this region of the molecule may be associated with specific subcellular localization requirements for individual PDEs that are associated with distinct cell types and physiological functions for

the enzyme in a particular type of cell. As an example, the N-terminal domain of PDE1 has evolved with a Ca^{2+} /calmodulin-binding domain, while PDE3 has evolved with a distinct transmembrane region, and PDE7 and PDE9 have simple, low-molecular-weight N-terminal domains.

2.23.4 Physiological Function

Phosphodiesterases are highly regulated enzymes as a result of their critical role in second-messenger metabolism. At least three different means have been identified by which enzymatic activity can be controlled or influenced in cells: (1) regulation of substrate availability that can occur by alteration of the rate of cyclic nucleotide hydrolysis in response to competition by other phosphodiesterases, or by elevation of substrate levels; (2) extracellular stimuli that influence intracellular signaling, such as nitric oxide, insulin, or calcium ions; (3) feedback regulation by allosteric binding of a cyclic nucleotide or phosphorylation in response to elevation of the cyclic nucleotide substrate of the PDE. Phosphorylation can occur by a variety of protein kinases, including protein kinase A (PKA), protein kinase B (PKB), mitogen-activated protein kinase, and calmodulin kinase.^{15,16} It is important to keep in mind that all of these processes can also be influenced by the specific subcellular localization of the PDE of interest, because this can limit substrate availability, or influence protein–protein interactions.²

2.23.4.1 PDE1

There are three known genes that encode for PDE1, five different splice variants of PDE1C, and two splice variants of PDE1A. The molecular weight range for enzymes in this family is 60–75 kDa. The PDE1 family hydrolyzes both cAMP and cGMP, and is stimulated by the calcium/calmodulin system. The degree of stimulation depends on the specific isoform. The PDE1A family prefers cGMP (twofold, based on K_m), while the B and C gene products have comparable K_m values for both cyclic nucleotides. Two different types of activity are known: one is a so-called ‘low-affinity’ form, which has been extensively studied.¹⁶ A second, less well studied, ‘high-affinity’ form appears to be localized in the brain and peripheral nervous system.¹⁷ PDE1A is highly expressed in the cortex and hippocampus in the brain. However, a specific physiological role has not yet been conclusively established. PDE1B is found predominantly in the striatal region of the brain and in the granule layer of the dentate gyrus.¹⁸ PDE1C can be found in olfactory epithelial cells, and plays a role in signaling.¹⁹ PDE1C is also found in proliferating cells in smooth muscle vasculature, where it may contribute to vascular tone.^{20–21} Antisense inhibition of the enzyme in cell culture results in decreased cell proliferation.

In addition to these roles, PDE1 may be involved in the integration and cross-talk of signaling pathways associated with insulin secretion. In the pancreas, β cells respond to an increase in Ca^{2+} concentration associated with glycolysis by secreting insulin. This results in an increase in the ATP/ADP ratio that activates PDE1. The resulting increase in cAMP levels leads to a decrease in insulin secretion.²²

In intact cells, Ca^{2+} levels serve as the primary means of activation of PDE1. There are a variety of means by which calcium ion levels are modulated in cells, including ion channels (voltage gated, as well as channels activated by a variety of intra- and extracellular second messengers), and second messengers, such as inositol phosphate, that are themselves activated by other systems.²³ Given the complexity of this system, it is not completely understood if the enzyme can be regulated differently by calcium ions derived from these distinct sources. This could lead to a dynamic and variable degree of cAMP levels in different subcellular compartments.

2.23.4.2 PDE2

This phosphodiesterase subfamily consists of a single known gene product, with three known splice variants. The enzymes are homodimers, with molecular weights of approximately 240 kDa. PDE2 is known to be both a cytosolic as well as membrane-bound enzyme. The subcellular localization is thought to be determined by the hydrophobicity of the N-terminal domain. Both cyclic nucleotides are cleaved, with an approximately twofold difference in K_m values. The V_{\max} values for cGMP and cAMP are similar. Each substrate can substantially stimulate (up to 50-fold) the hydrolysis of the other. Hill values range from 1.2 to 1.6 for cGMP, and 1.6–1.9 for cAMP.^{24–27} Stimulation of catalysis is due to an increase in affinity, rather than an increase in V_{\max} . Occupation of the allosteric nucleotide binding site induces a conformational change in the protein that in addition to enhancing activity also increases susceptibility to proteolytic degradation. From a practical perspective, in cells, the activation constant for cGMP is much lower than that for cAMP (as low as 0.2 μM), meaning that the preferred substrate is most likely cAMP. PDE2 is most highly expressed in the central nervous system (CNS) and in the adrenal cortex, and is also found in the liver and in platelets. In the

adrenal glands, ACTH acts via its cell surface receptor to elevate levels of cAMP, which leads to the increased synthesis of aldosterone. In addition, the peptide hormone atrial natriuretic peptide (ANP), which is involved in maintenance of plasma volume, also acts on cells in the adrenal glands, where activation of its receptors lead to an increase in cGMP synthesis. The binding of cGMP to allosteric sites on PDE2 activates the enzyme toward cAMP hydrolysis.²⁸ In addition, PDE2 also plays a role in platelet aggregation²⁹ and in olfactory signaling pathways.³⁰ More recently, it has been reported that PDE2 can play a role in learning and memory, and that inhibition of PDE2 can lead to increased levels of cGMP in cell culture and in test animals. In addition, improved performances in T maze and social and object recognition assays was observed following administration of a PDE2 inhibitor to rats and mice.³¹

2.23.4.3 PDE3

This PDE exists as two known gene products, each of which is expressed in different tissues. The molecular weights of the enzymes are estimated to be approximately 122–125 kDa.¹⁶ The K_m value for cyclic nucleotides is comparable (ranging from 100 to 800 nM); however, the V_{max} for cAMP is up to 10-fold higher than that observed for cGMP. This substantial rate difference results in selective hydrolysis of cAMP.^{32,33} Some have hypothesized that because cGMP binds tightly to PDE3, but is not cleaved efficiently by the enzyme, it may function as an endogenous inhibitor, and thereby act as a key regulator of cAMP signaling mediated by PDE3.³⁴ Interestingly, the competition between these two substrates can play an important role in mediating the biological actions by enhancing signaling through one pathway at the expense of the other.

PDE3A is present in cardiac tissues, platelets, and smooth muscle, and one of the first physiological actions associated with PDE3 was a link with platelet function. It is known that both cyclic nucleotides inhibit platelet aggregation, and because elevated levels of cGMP will result in inhibition of cAMP hydrolysis by PDE3A, elevation of these cyclic nucleotides can result in an 'antiplatelet' effect on blood coagulation.^{35–36} A recent study suggests a role for PDE3A in cardiomyocyte apoptosis.³⁷ Using primary cultured human myocytes derived from patients with congestive heart failure, decreased expression and activity of PDE3A was measured. Similar data were obtained from cardiac tissue of mice in which chronic pressure overload was experimentally induced. Chronic inhibition of PDE3A by adenovirus-delivered antisense and the PDE3 inhibitor milrinone led to the same result in cell culture.

PDE3B is highly expressed in adipocytes and the liver. The protein appears to be membrane associated.³⁸ This localization has stimulated research into the role the enzyme plays in metabolism and glucose homeostasis. Corbin and co-workers have demonstrated that PDE3-selective inhibitors can effectively eliminate the lipolytic response of adipocytes in cell culture when stimulated by insulin.^{39,40} There is recent evidence for species-specific regulation of lipolysis. Murine 3T3-L1 and rat adipocytes in culture, when exposed to cilostamide, showed moderate levels of stimulation of lipolysis, while human adipocytes gave a much more substantial increase in lipolysis under similar circumstances. Interestingly, this same study demonstrated that a selective PDE1 inhibitor suppressed lipolysis in murine cells, and had no effect on human cells, while a selective PDE2 inhibitor had no effect on lipolysis in either human or murine cell culture. Rolipram, a PDE4 inhibitor, had no effect on lipolysis by human adipocytes, but did stimulate the process in the murine cell lines. A synergistic effect between cilostamide and rolipram was demonstrated only in the murine cell lines.⁴¹ This study illustrates the need to make certain that cellular effects of PDEs and their inhibitors are similar in both animal models and human target tissues.

The regulation of insulin secretion by PDE3B involves both insulin-like growth factor 1 (IGF-1) and leptin. The role of the latter hormone was established with cell-permeable cAMP analogs, one of which was a substrate for PDE3B, and one that was not.^{42,43} Leptin signaling requires activation of phosphoinositide-3-kinase, which activates PDE3B. In pancreatic β cells, leptin causes activation of PDE3B, leading to substantial inhibition of glucagon-like peptide 1 (GLP-1)-mediated insulin secretion.⁴⁴ The role of IGF-1 was established by Beavo and co-workers, who elucidated the signaling mechanism involved.⁴⁵ Using both pancreatic islet cells and insulin-secreting HIT-T15 cells, it was shown that the addition of IGF-1 administration decreased cAMP levels in parallel with a reduction in insulin secretion. Milrinone, a PDE3-subtype selective inhibitor, reversed the effects of IGF-1 in cell culture.

Both PDE3 isoforms are activated by phosphorylation. A variety of different protein kinases are known to have PDE3 as a substrate including PKA.^{16,34}

2.23.4.4 PDE4

This family of cAMP-specific PDE enzymes is the largest in the class I PDE superfamily. There are four distinct gene products, A–D, and a variety of splice variants in each gene product. The K_m value for cAMP ranges from 0.6 μ M to 4 μ M. These values were obtained using isoforms that were transiently expressed in COS7 cells that had been

transfected with the appropriate genes.⁴⁶ The molecular weight of enzymes in the PDE4 family ranges from 68 to 75 kDa for the so-called 'short' form, to 85–110 kDa for the 'long' form. The distinction is based on the presence of one or two upstream conserved regions (UCRs, see below). Molecular weight variability in each of these groups is associated with the particular isoform and splice variant. It is interesting to note that there is a great deal of similarity between human, rat, and mouse forms of each of these gene products. This homology extends beyond amino acid sequence and function to include the genomic organization.^{46,47} The catalytic domain of each PDE4 gene product is very similar, with greater than 80% sequence homology. However, it is possible to achieve selective inhibition of some of these isoforms with small molecules.

PDE4 enzymes exist as both soluble and membrane-bound forms. This feature is associated primarily with the nature of the regulatory N-terminal domain of the protein. The specific N-terminal domain of each PDE4 is also involved in determining specific subcellular localization, catalytic activity, response to other ligands, and temperature stability.^{48–51} As one example, Houslay and co-workers investigated a variety of rat PDE4A isoforms.^{52–54} They have shown that a 25-amino-acid peptide in the N-terminal domain is responsible for membrane localization, and that the structure of this domain contains an amphipathic α helix located adjacent to a tryptophan-rich region.⁵⁵ Distinct functional properties of the cytosolic and membrane-bound forms of PDE4B and PDE4D have also been elucidated.^{56,57} The long form of rat PDE4A5 has been shown to interact with the v-Src SH3 domain in the N-terminal region, while the short-form splice variant of the same enzyme does not.^{58,59}

PDE4 has been hypothesized to exist in different conformations that have different affinity for rolipram (see below).⁶⁰ As a part of this hypothesis, distinct functional activity has been associated with the so-called 'high-affinity'- and 'low-affinity'-rolipram-binding conformers. Emesis and nausea have been proposed to be due to interaction with the former, and anti-inflammatory activity has been proposed by binding to the latter. Detailed characterization of a specific PDE4 isoform, PDE4B2B, was carried out in an attempt to better characterize these potential sites.⁶¹ A nonequilibrium filter binding assay showed a binding site for (*R*)-rolipram with a K_d value of 1.5 nM. Equilibrium binding dialysis gave a binding constant of 140 nM. This enantiomer of rolipram had a K_i value of 600 nM for this enzyme. Proteolysis experiments allowed characterization of a 43 kDa fragment of the enzyme that retained catalytic activity and was inhibited by rolipram. This work suggests that these two binding sites are located in distinct regions of the enzyme. A second report described the preparation of recombinant PDE4B (a truncated form similar to that described by Rocque *et al.*⁶¹) that could be efficiently assayed using a microtiter plate scintillation proximity protocol. This assay was claimed to be useful to identify compounds that preferentially inhibit the low-affinity conformer.⁶² Others have developed a recombinant cell-based system that allows for evaluation of a variety of PDE4 isoforms. Chinese hamster ovary cells (CHO) endogenously express low levels of PDE4 activity, and do not have β_2 -adrenergic receptors, and were transfected with this receptor and various PDE4 isoforms. It was shown that PDE4A4, PDE4B2, PDE4C2, PDE4D2, and PDE4D3 all could exist in a form that contained the high-affinity rolipram-binding site, while PDE4₃₃₀ demonstrated a low-affinity binding conformation in this cell system.⁶³ Using human monocytes and the PDE4 inhibitor RP73401 (piclamilast, **1**, see below), it was shown that tumor necrosis factor α (TNF- α) generation could be suppressed by binding to the low-affinity binding conformation of PDE4.⁶⁴ In recent years, it has become more commonly accepted that the description 'low-affinity binding conformation' refers more specifically to inhibition of the catalytic activity of the enzyme, and the term 'high-affinity binding conformation' refers to a distinct rolipram-binding site on PDE4.

There is another unique structural feature of PDE4 enzymes in their respective regulatory domain that also influences enzyme function. All PDE4 enzymes (long and short) contain one or two conserved regions, UCR1 and UCR2. These regions differ in their amino acid composition and length. UCR1 is shorter (55 amino acids), and is located further away from the catalytic domain. A short linker connects this region to UCR2, which is made up of 75 amino acids, and is connected to the catalytic domain by a hydrophobic linker that varies in length.^{65,66} While the direct functional relevance of these regions has not yet been conclusively established, there is some evidence to suggest that the UCR regions can influence the nature of regulation by small molecules such as rolipram.⁶⁷ In addition, the UCR1 region of PDE4D contains a serine residue (Ser54) that can be phosphorylated by PKA, resulting in a rapid activation of the enzyme. Mutagenesis experiments suggest that hydrogen bonding in the sequence surrounding this serine residue is an important structural feature associated with enzyme regulation. Replacement of Glu53 with an alanine did not affect phosphorylation of Ser54, but did influence enzyme activation.⁶⁸

Phosphorylation provides a short term means by which PDE4 activity can be regulated. PDE4 enzyme activity can also be regulated by transcription. It has been shown that prolonged exposure of rat Sertoli cells to cAMP can result in a substantial increase in PDE4D2, and a smaller increase in PDE4B activity.^{69,70}

Because PDE4 has been the subject of intense interest as a potential target for the treatment of a variety of inflammatory and CNS disorders, structural features in the protein necessary for catalytic activity and inhibition by

small molecules have been heavily investigated. Point mutation of selected histidine residues in PDE4D2 (His278 and His311) to either alanine or proline, or substitution of alanine or proline for Thr349 completely eliminates catalytic activity.⁷¹ Similarly, individual replacement of histidines at position 433, 437, 473, or 477 in a truncated version of human PDE4A4B resulted in either complete or substantial loss of enzymatic activity.⁷² Binding of the prototypical PDE4 inhibitor rolipram (**2**) was also reduced by these mutations. There was a parallel change in rolipram affinity and catalytic activity of the enzyme. Mutant versions of PDE4B1 have been isolated with single amino acid replacements at residues 457, 625, and 667 that are no longer sensitive to rolipram inhibition.⁷³ When serine replaced histidines at residue 505 or 506 (PDE4B numbering), catalytic activity was reduced by 90%, without affecting rolipram binding or IC₅₀. The IC₅₀ of another prototypical PDE inhibitor, IBMX (**3**) was reduced. This information suggests that these histidines are important for cAMP binding. Furthermore, it indicates that IBMX binds at the same site, or in a closely related one, while rolipram does not. Circumstantial support for this hypothesis follows from inspection of the structures of these two compounds.⁴⁶

PDE4 enzymes have also been shown to be associated with β -arrestins, and to play a role in cytoplasmic signaling via protein complexes associated with the arrestins.^{74,75} In this system, the arrestins modulate signaling of β_2 -adrenergic receptors by recruiting PDE4D family members to the plasma membrane where the receptor is located. The phosphodiesterase is available to cleave cAMP in this specific subcellular location, and thereby attenuate the signal that is produced by activation of the β_2 receptor in response to an extracellular stimulus. It was shown that in HEK 293 cells that overexpressed the β_2 -adrenergic receptors, administration of isoproterenol led to a time-dependent recruitment of PDE4D3 and PDE4D5 to the cell membrane. This corresponded to an increase in PDE4 enzyme activity in this region. Recent evidence, gained by use of siRNA technology, provided additional information to indicate that PDE4D5 is the functionally most relevant isoform associated with this process.⁷⁶

The intracellular and tissue-specific distribution of the various family members of PDE4 has been studied in some detail.⁴⁶ Most of this work has been carried out using rodent sources of enzyme. For example, different splice variants of PDE4A have been found to localize to particulate fractions. The specific N-termini in these isoforms determines the precise subcellular location of the protein. Selected PDE4D forms are found in the cytosolic compartment, while others can be found in membrane fractions. The distribution of PDE4B and PDE4C has been less extensively studied. PDE4B, like PDE4D, exists in both cytosolic and membrane fractions. It has been shown that PDE4B2 plays an important role in T cell activation, and this role involves distribution of the enzyme to the immunological synapse during the early stages of T cell signaling.⁷⁷ This complex distribution of PDE4 within cells must have evolved to permit precise control of cAMP in specific regions of the cell in order to control or result in specific signaling pathways and biological response to distinct stimuli.

PDE4 enzymes are expressed in the CNS and other nervous system tissues, smooth muscle, inflammatory and endothelial cells, and in the heart. The expression of PDE4A in the cerebellum suggested a role in neurotransmitter release.^{78,79} More recently, it has been shown that PDE4D knockout mice showed better long-term memory in spatial memory tests, compared with wild-type counterparts, and mice lacking PDE4B did not show similar improvements.⁸⁰ All four PDE4 isoforms have been localized and identified in human brains,⁸¹ and rolipram has been shown to demonstrate efficacy in a variety of cognition and antidepressant animal models.^{82,83} The relative potency in these screens of racemic, (*S*)- and (*R*)-rolipram correspond to their respective potency in vitro as PDE4 inhibitors, and to their affinity for the high-affinity rolipram-binding site.⁸⁰ PDE4 is widely distributed in tissues associated with immunologic and inflammatory responses, including T cells as noted above, macrophages, eosinophils, monocytes, and lymphocytes.⁸⁴ A variety of isoforms have been identified, with the specific enzymes dependent on the source of the cells or tissue used in the experiment. cAMP is well known to play a role in maintaining vascular tone in smooth muscle tissue, and, in humans and rats, PDE4D is the primary isoform present.^{85,86} It has been recently shown that specific short-form versions of PDE4D, PDE4D1, and PDE4D2 play a key role in regulating the cAMP-mediated desensitization of activated vascular smooth muscle cells, leading to the suggestion that isoform-selective inhibitors

of this PDE4 variant might be useful in the treatment of atherosclerosis, and/or vascular inflammation associated with cardiac procedures such as stent installation.⁸⁷ PDE4 activity has also been measured in osteoblasts,^{88,89} in mouse skeletal muscle,⁹⁰ human articular chondrocytes,⁹¹ adipocytes,⁴¹ and olfactory tissue.⁹²

2.23.4.5 PDE5

The emergence of PDE5 as a validated drug target based on the commercial success of sildenafil (4), vardenafil (5), and tadalafil (6) has stimulated substantial interest in this particular PDE in the last 10 years. More details on these and many other PDE5 inhibitors can be found in [Section 2.23.6](#).

PDE5 is cGMP-specific, and only a single gene product is known. Three splice variants have been identified that differ in their tissue distribution.^{93,94} The catalytic properties ($K_m \approx 0.6\text{--}5\text{ }\mu\text{M}$, $V_{\max} < 2.6\text{ }\mu\text{mol min}^{-1}$ per milligram of protein) and inhibitor sensitivity of these different forms are equivalent.^{95–97} The molecular weight of these enzymes ranges from 95 to 100 kDa. PDE5 is found in vascular and tracheal smooth muscle, platelets, gastrointestinal epithelial cells, spleen, kidney, prostate gland, and in the Purkinje cells of the cerebellum,^{98–100} and it exists as a homodimer, where each monomeric unit is composed of a catalytic domain and a regulatory domain.

The regulatory domain contains allosteric binding sites for cGMP, and cGMP binding at these sites increases the rate of cGMP hydrolysis.^{101,102} These sites are kinetically distinct, and occupation of both is required for activation of the enzyme by phosphorylation at Ser92 by either PKA or protein kinase G (PKG).^{103–105} It has been demonstrated that there appears to be a positive correlation between the level of phosphorylation and the catalytic activity of PDE5 in cultured vascular smooth muscle cells.¹⁰⁶ The affinity of these allosteric sites for cGMP is comparatively high (K_m as low as 200 nM), and the high selectivity of the site for cGMP has been attributed to the ionization state of Asp289.¹⁰⁷

Phosphorylation of the isolated PDE5 regulatory domain causes a conformational change in this portion of the protein, and this conformational change contributes to the increased binding affinity of the cyclic nucleotide (about 10-fold).¹⁰⁸ Addition of cGMP has been shown to enhance the affinity of tritiated tadalafil and vardenafil. This interesting observation suggests the possibility that PDE5 inhibitors may potentiate their own binding to the enzyme as cyclic nucleotide levels increase as a result of inhibition.¹⁰⁹ The physiological relevance of this information was supported by experiments using rabbit corpus cavernosum tissue, where binding of cGMP to PDE5 and PKG was found to greatly exceed the free concentration of the cyclic nucleotide in the tissue.¹¹⁰

The regulatory subunit of PDE5 also contains two GAF domains. These regions are contributors to cGMP binding, monomer dimerization, and enzyme regulation.¹¹¹ Structural analysis of the portions of the regulatory domain that contribute to each of these features was carried out by Corbin and Francis.¹¹² It was shown that the GAF α modules can homodimerize with high affinity ($K_D < 30\text{ nM}$), while the GAF β modules have even higher affinity ($\sim 20\text{ pM}$). Dimer stability is controlled by the amino acid sequence linking the two regions. GAF α has higher affinity for cGMP ($K_D < 40\text{ nM}$), and a 176-amino-acid portion of the sequence in this region is sufficient for cyclic nucleotide binding. The sequence containing GAF β and the amino acids immediately flanking it are critical for cGMP-mediated stimulation of Ser102 phosphorylation by PKA and PKG. As noted above, PDE5 phosphorylation is an important activating step for enzymatic activity.

[Section 2.23.3](#) describes some of the work that has been carried out to identify key residues for cGMP binding and catalysis. As noted, a divalent cation, particularly zinc, is important for both of these functions. Point mutations in the enzyme indicate that two key histidine residues, His607 and His643, are critical for metal cation binding. Substitution of these amino acids with alanine resulted in a substantial drop in enzyme activity, and a decrease in binding by Mg^{2+} or Mn^{2+} . It was interesting to note that mutation of several other highly conserved residues within the putative metal binding motif present in PDE5 (e.g., Asn604, His675, or aspartic acids at positions 644, 714, or 754) did not have a substantial influence on catalysis.¹¹³

PDE5 is widely known as a key regulator of vascular tone. In this role, it controls blood flow in the corpus cavernosum tissue of the penis, where it is the primary cGMP-hydrolyzing activity present. Inhibition of enzymatic activity reduces the outflow of blood, leading to engorgement and, ultimately, an erection following sexual stimulation. Recent work using knockout mice lacking in endothelial nitric oxide synthase illustrated that PDE5 expression and activity were downregulated, resulting in priapism in the knockout mice.¹¹⁴ Increased PDE5 activity in the inner medullary collecting duct in the kidney has been demonstrated in pregnant rats. This leads to excessive sodium retention, and resistance to the effects of ANP. ANP signals via cGMP, and resistance to the diuretic effects of the peptide hormone are directly related to enzymatic activity.¹¹⁵ In pulmonary endothelial cells, PDE5 has been recently shown to regulate growth and apoptosis. This process is regulated in part by ANP, as administration of the peptide to pulmonary microvasculature endothelial cells in culture leads to an increase in cGMP concentration, and results in growth inhibition and apoptosis.¹¹⁶

2.23.4.6 PDE6

This PDE is a highly cGMP-specific enzyme that, unlike most other members of the mammalian PDE family, is found essentially in a single tissue, the eye. Some expression can be detected in the pineal gland as well. There are three distinct gene products that encode the catalytic domain of the enzyme (A–C), and three corresponding regulatory domain gene products (D, G, and H). These regulatory domains are composed largely of two distinct GAF binding domains for cGMP binding. PDE6 is localized in the rod and cone cells in the retina, where the enzyme plays a key role in the response to light. Rod PDE6 is organized as a tetramer consisting of two catalytic subunits and two corresponding regulatory subunits (which incorporate the GAF domains mentioned above). Cone PDE6 differs in that the catalytic subunits are identical, rather than homologous. The regulatory subunits are cone-specific and distinct from the rod regulatory subunits. The molecular weight of these various complexes is approximately 200 kDa.¹¹⁷

Specific posttranslational modifications (farnesylation or geranylgeranylation at a CAAX sequence) of the regulatory subunit direct the enzyme to the membrane fraction of the cell. PDE6 activity also exists in the cytosolic fraction of cells. The biological basis for the evolution of these different mixtures of subunits, and their (potential) for distinct function and regulation is not well understood.¹¹⁸ PDE6 has moderate affinity for cGMP ($K_m = 20\text{--}25\text{ }\mu\text{M}$).^{119,120} The enzyme has a substantial degree of sequence homology to PDE5 in the catalytic subunit¹²¹; however, PDE6 operates at a near-diffusion-controlled rate to hydrolyze cGMP, unlike PDE5, which processes substrate at a rate approximately 1000-fold less rapidly.^{122–124}

The extremely high catalytic rate of the enzyme is thought to be evolutionarily driven, in response to its role in light transduction associated with vision. PDE6 is activated by displacement of the inhibitory/regulatory subunit by activated transducin as a part of the visual photoreceptor system in the eye. In the dark, the cellular concentration of cGMP is very high (estimated to be up to $60\text{ }\mu\text{M}$), most of which is bound to allosteric cGMP-binding sites on PDE6. Unbound cyclic nucleotide concentrations are sufficient to maintain the cGMP-gated ion channel in an open conformation. Absorption of a single photon of light initiates a highly amplified process whereby transducin is activated by photoexcitation of rhodopsin. Transducin interacts with the inhibitory subunits of the PDE6 tetramer, resulting in their dissociation. This results in a very rapid increase in enzyme activity. As cGMP is cleaved locally by PDE6, this reduces the concentration of the cyclic nucleotide, and ultimately leads to closure of cGMP-gated ion channels, resulting in membrane hyperpolarization and termination of the light signal.¹²⁵

PDE6 also contains allosteric binding sites for cGMP. These sites contribute to substrate binding at the active site of the enzyme. In the heterotetramer there are two cGMP-binding sites per complex, one on each regulatory subunit. Cyclic nucleotide binding at each allosteric site appears to be coupled. The binding affinity at these allosteric sites is influenced by a variety of factors, including the relative activity state of the tetramer, protein–protein interactions that are in play locally, as well as the presence or absence of the inhibitory $P\gamma$ subunit, which may be associated with the tetramer.

There are a number of visual defects, including retinitis pigmentosa, associated with mutations in PDE6.¹²⁶ Because there is high sequence homology between PDE5 and PDE6 in the active site, enzyme selectivity is an important feature that must be assessed when evaluating novel PDE5 inhibitors. Isolation of native human PDE6 is known to be difficult, and as a potential substitute, recombinant human enzyme has been used in some cases. A recent study suggests that native and recombinant versions of catalytically active PDE6 exhibit differential sensitivity to PDE5 inhibitors, and as a result may provide potentially incorrect information on PDE selectivity. For example, sildenafil demonstrated comparable K_i values for both rod and cone forms ($\sim 95\text{ nM}$) of the recombinant enzyme, and a K_i of 25 nM when the native human preparation was used. In contrast, zaprinast and E4021 demonstrated 30–80-fold lower affinity for the recombinant enzyme.¹²⁷ As an alternative, bovine PDE6 has been used to assess selectivity. However, a similar detailed comparison of inhibitor sensitivity between the native human and bovine forms has not yet been reported.

2.23.4.7 PDE7

Two different gene products are known for this cAMP-specific PDE. The enzyme has high affinity for cAMP ($K_m \approx 200$ nM), and is most closely related to PDE4, although the sequence similarity is not high. Enzymatic activity is not affected by calcium ions, calmodulin, or cGMP. Three distinct splice variants of the PDE7A isoform have been identified with molecular weights in the range of 50–57 kDa.¹²⁸ These isoforms differ only in their N-terminal sequences, which may influence their subcellular localization.¹²⁹ PDE7A1 mRNA has been reported to be associated with both particulate and cytosolic fractions of skeletal muscle and cardiac tissue, and enzymatic activity has been detected in adult skeletal muscle. More abundant protein levels have been measured in T lymphocyte cell lines. PDE7A2 mRNA has been localized to only the particulate portions derived from these tissues, and, as of this writing, no active PDE7A2 enzymatic activity in adult tissues has been detected. The physiological basis for these observations is not yet clear. In lymphocytes that have been activated by both CD3 and CD28, PDE7 activity is markedly stimulated, and inhibition of PDE7 by antisense reduces T cell proliferation.^{130,131}

However, later work suggested that T cell proliferation, using a series of small-molecule PDE7 inhibitors, was equally inhibited in T cells derived from wild type and PDE7A knockout mice.¹³² Further work regarding the influence of PDE7A on T cells was reported using a different and less potent compound, BRL 50481. In three different cell types implicated in the pathogenesis of chronic obstructive lung disease (CD8⁺ T lymphocytes, monocytes, and lung macrophages), PDE7A1 and PDE7A2 could be readily detected by Western blotting. BRL 50481, at concentrations of up to 30 μ M, had little effect on the biosynthesis of TNF- α , and had no effect on the proliferation of CD8⁺ lymphocytes. However, when the compound was tested, along with either rolipram or ORG 9935 (a PDE3 inhibitor using 'aged' monocytes in vitro), the addition of BRL 50481 had an additive and concentration-dependent effect on TNF- α levels.¹³³ The potential role of PDE7 in human T cell function was assessed in a third paper that employed two compounds that were very potent PDE4 inhibitors, with IC₅₀ values less than 1 nM, but with very different activities against PDE7 (~ 2 μ M and greater than 10 μ M). The former, T-2585, inhibited cytokine synthesis, proliferation, and CD25 expression over a concentration range where PDE7A activity was suppressed (1–10 μ M). The latter, RP73401, had little or no effect at 10 μ M, leading the authors to conclude that PDE7 may play a role in the biosynthesis of these inflammatory cytokines.¹³⁴ However, in view of the other papers cited, the very potent PDE4 inhibition associated with these compounds may be the primary feature responsible for the observed activity.

PDE7A expression has been measured by Western blot analysis in normal human B lymphocytes, as well as in primary chronic lymphocytic leukemia (CLL) cells and in a CLL-derived cell line in culture. Protein expression was upregulated in these lines by elevation of cAMP, and also by a PDE inhibitor, IC242. The PKA inhibitor H-89 blocked the IC242-mediated upregulation of PDE7 expression in these cell lines in culture.¹³⁵ In addition to the aforementioned tissues, PDE7A1 and PDE7A2 mRNA has also been measured in rat brain extracts by in situ hybridization histochemistry. The highest levels of expression were observed in the olfactory bulb and tubercle, hippocampus, cerebellum, medial habenula nucleus, pineal gland, area postrema, and choroid plexus.¹³⁶

PDE7B has approximately 70% identity to PDE7A at the amino acid level in the catalytic domain of the protein.^{137–139} The enzyme has a mass of approximately 50 kDa, and a K_m value of 30 nM for cAMP, nearly an order of magnitude lower than lowest reported value for PDE7A, and, like PDE7A, cGMP did not affect the activity of the 7B isoform. Northern blot analysis of mRNA expression of the enzyme revealed the highest expression in the pancreas, followed by brain, heart, skeletal muscle, eye, thyroid, ovary, testis, submaxillary gland, epididymus, and liver. When compared with the 7A isoform, PDE7B shows a similar pattern of inhibitor sensitivity. IBMX, papaverine, dipyridamole, and SCH51866 show broadly similar inhibition. It may be possible that isoform-selective inhibitors could be identified, based on this preliminary data, because IBMX and dipyridamole give lower IC₅₀ values for PDE7B compared with PDE7A (2.1 versus 4.5 μ M and 9 versus 42 μ M, respectively). Papaverine shows somewhat greater inhibition of PDE7A compared with PDE7B (IC₅₀: 12.5 μ M for PDE7A, 22 μ M for PDE7B). However, more potent compounds will be required to establish the validity and potential utility of this possibility.^{140,141}

2.23.4.8 PDE8

This cAMP-selective ($K_m \approx 70$ nM) PDE exists as two gene products. Five different splice variants of the 8A isoform have been identified to date.¹⁴² At the amino acid level, the proteins vary in length from 449 amino acids (PDE8A3) to 829 amino acids (PDE8A1). The enzyme requires comparatively high concentrations of Mn²⁺ or Mg²⁺ (1 mM) for maximal in vitro activity, while calcium ions have little effect on enzymatic activity. When compared with PDE4, the PDE8A enzyme expressed in a baculovirus system processes cAMP with a V_{max} approximately an order of magnitude lower than PDE4.¹⁴³ Expression of PDE8A, measured by Northern blot analysis, in mice appears to be highest in the

testis, followed by the eye, liver, skeletal muscle, and heart. Lower levels can be found in the kidney, ovary and brain.¹⁴⁴ Tissue distribution is similar in humans.¹⁴⁵ This tissue distribution has led to the hypothesis that the enzyme plays a role (as yet undefined) in germ cell development.¹⁴⁶ Among the commonly used PDE inhibitors, only dipyridamole shows significant activity as a PDE8A inhibitor, with an IC_{50} value of 4.5 μ M. The presence of a PAS domain in the protein suggests that this domain may control specific protein–protein interactions that are associated with subcellular localization, as well as provide a binding site for small-molecule or peptide/protein ligand binding.

The PDE8B isoform is very highly expressed in the thyroid gland,¹⁴⁷ with lower levels in the brain. Dipyridamole inhibits this isoform weakly (50% at 40 μ M).

When the enzymatic properties of the 8A and 8B isoforms were compared, PDE8B had a slightly higher K_m value for cAMP (100 nM, versus 40 nM for PDE8A), but a higher V_{max} .¹⁴⁸

2.23.4.9 PDE9

PDE9 exists as a single, known gene product, is highly cGMP-specific, and has been cloned and expressed from both human and murine sources.^{149,150} Four different splice variants have been identified, based on Northern blot analysis, encoding proteins with between 465 and 593 amino acids.¹⁵¹ The K_m value for cGMP has been reported to be as low as 70 nM, and the V_{max} value of 4.9 nmol min^{−1} per microgram of protein is twofold faster than the rate at which PDE4 processes cAMP. When the recombinant protein is assayed in vitro, the activity is strongest in the presence of Mn^{2+} (1–10 mM), compared to Mg^{2+} or Ca^{2+} . Unlike other cGMP-specific PDEs, PDE9 lacks an allosteric binding site for cGMP. When the amino acid sequence is compared with other PDEs, greatest homology (34%) is observed with the cAMP-selective enzyme PDE8A, while the cGMP-specific PDE5 has the lowest (28%) amino acid identity. It has been proposed that because this PDE has very high affinity for cGMP, it functions to maintain basal levels of the cyclic nucleotide in cells.¹⁵² PDE9 is more broadly expressed than other cGMP-specific PDEs, and this observation has been cited as supporting circumstantial evidence of this hypothesis. The enzyme is particularly abundantly expressed in the brain, heart, spleen, kidney, and intestine. Because of its presence in the kidney, a potential role in ANP-mediated diuresis has been proposed.¹⁵³ More recently, Hendrix has shown evidence that PDE9 plays a role in memory acquisition, consolidation, and retrieval in rats, and restoring memory deficits induced by MK801 in mice, based on the activity of a PDE9 inhibitor.¹⁵⁴ The inhibitor sensitivity of PDE9 is distinct from other cGMP-selective enzymes. For example, sildenafil and zaprinast are comparatively weak inhibitors, with IC_{50} values of 7 and 29 μ M, respectively, while rolipram, dipyridamole, IBMX, and *erythro*-9-(2-hydroxy-3-nonyl)adenine (EHNA) do not inhibit enzymatic activity at concentrations as high as 200 μ M. SCH-51866 has better affinity for PDE9, with an IC_{50} value of approximately 1.5 μ M.

2.23.4.10 PDE10

This PDE acts on both cGMP and cAMP, and exists as a single gene product with three known splice variants. The A1 and A2 variants are derived from human sources, while the A3 variety was identified in rats. The enzyme has been cloned and expressed from mouse, rat, and human cDNA libraries.^{155–158} The protein has between 779 and 794 amino acids, and although it has a higher affinity for cAMP (K_m = 50–280 nM) than cGMP (K_m = 3–14 μ M), PDE10A more efficiently hydrolyzes cGMP (two- to fourfold). Each cyclic nucleotide serves as an inhibitor of the binding and hydrolysis of the other. The N-terminus of the enzyme has a GAF binding domain, like PDE2, PDE5, and PDE6, where cGMP may bind and regulate enzymatic activity. The catalytic domain has low to moderate sequence homology (~16–47%) with other known PDEs.

The enzyme is highly expressed in specific regions of the CNS in both humans and rats. In particular, it is found in the putamen and caudate nucleus. More detailed studies to investigate the subcellular localization revealed that PDE10A2 is associated with membrane fractions derived from rat striatum, and immunocytochemical analysis further localized the enzyme to the Golgi apparatus. PDE10A1 and PDE10A3 were found primarily in the cytosolic fractions in the same preparation.¹⁵⁹ It was also shown that PDE10A2 was phosphorylated by PKA at a particular threonine residue. This posttranslational modification was hypothesized to guide the localization of the enzyme to the Golgi membrane. Lower levels of expression were detected in the thyroid gland and testes.¹⁶⁰ The inhibitor sensitivity of PDE10A is unique, compared with other PDEs. Dipyridamole and SCH51866 are comparatively potent (IC_{50} \approx 1 μ M) inhibitors of the enzyme, while sildenafil, rolipram, zaprinast, enoximone, and vinpocetine are much less potent (IC_{50} > 10 μ M, or inactive). IBMX has moderate activity as an inhibitor of PDE10A (IC_{50} \approx 3–10 μ M).

The primary physiological relevance of PDE10A to date appears to be in CNS diseases, specifically in Huntington's disease and in schizophrenia. The potential for a role in the former was suggested by monitoring the rate of reduction of PDE10A mRNA in transgenic mice. It was shown that levels decrease with time, but before the onset of symptoms, suggesting a cause-and-effect relationship in Huntington's disease.¹⁶¹ Papaverine has demonstrated dose-dependent

inhibition of hyperactivity induced by phencyclidine and amphetamine in rats, without affecting dopamine release.^{162,163} PDE10A knockout mice treated with the compound do not show the same activity. Papaverine has been reported to be a 40 nM inhibitor of PDE10A in vitro, and elevate cAMP levels in both brain slices and in cell culture.¹⁶⁴

2.23.4.11 PDE11

The most recently identified member of the superfamily processes both cyclic nucleotides, and only a single gene product has been identified to date. PDE11A has been cloned and expressed from both human and murine cDNA, and a total of four different splice variants have been identified.^{165–168} The molecular weight range for these enzymes was reported to be 56–105 kDa. The N-terminus of the protein includes up to two complete GAF domains, depending on the specific variant. Their affinity for cAMP and cGMP is similar; however, one publication cites very different V_{\max} values for each isoform.¹⁶⁸ Tissue-selective expression of the A3 (testes) and A4 isozymes (prostate) has been shown. Other tissues in which PDE11A mRNA has been detected include skeletal muscle, kidney, liver, and pituitary glands. A recent publication attempted to establish PDE11A protein expression in human tissues. The enzyme (the A4 isoform) was found only in the glandular epithelium of the prostate and, to a much lesser extent, in neuronal cells in the parasympathetic ganglia in the heart. No active protein was found by immunohistochemistry in skeletal muscle, testis, or penis.¹⁶⁹ Dipyridamole and zaprinast are comparatively potent inhibitors of PDE11A, with IC_{50} values of 379 nM and 5 μ M, respectively. In an attempt to establish a physiological role for PDE11, mice lacking the enzyme were produced and evaluated.¹⁷⁰ It was found that ejaculated sperm from knockout animals had a reduced rate of forward progression, and a lower percentage and concentration of live sperm. Pre-ejaculated sperm displayed increased spontaneous and premature capacitation. This study also states that these observations are consistent with human data. However, another recent paper suggests that PDE11 inhibition by tadalafil does not alter semen parameters.¹⁷¹ At the time of this writing, the issue remains unresolved. Another recent paper examined the expression of PDE11A in a range of normal and malignant human tissues using a polyclonal antibody that recognizes all four splice variants.¹⁷² The protein was detected to varying degrees in a wide range of epithelial, endothelial, and smooth muscles cells. Interestingly, this paper reports expression in spermatogenic cells of human testes. Expression of the protein in different human carcinoma cell lines was also measured.

2.23.5 Second Messengers

As noted, the phosphodiesterase enzymes act to regulate levels of the key intracellular second messengers, cAMP and cGMP. These cyclic nucleotides are produced in response to a variety of cellular stimuli, such as release of nitric oxide, activation of G-protein-coupled receptors (GPCRs), and other receptors on the cell surface. Intracellular levels of these second messengers initiate and control a wide range of processes, such as cell growth and differentiation, tissue function, and ion channels. Some receptors (e.g., the vasopressin receptor) signal by elevating levels of the cyclic nucleotide,¹¹⁵ while others signal by negatively affecting the activity of the nucleotide cyclase that generates the cyclic nucleotide (e.g., the CB1 receptor for cannabinoids).¹⁷³

2.23.6 Prototypical Pharmacology

2.23.6.1 PDE1 Inhibitors

Comparatively little work has been carried out in an attempt to prepare PDE1 inhibitors. The alkaloid vinpocetine (**7**) is a very weak inhibitor in vitro, with an IC_{50} value of approximately 20 μ M.¹⁷⁴ Most of the published work has described preparation of combination PDE1/PDE5 inhibitors. Structurally, many compounds in this group are tetracyclic guanine derivatives, and researchers at Schering Plough have exemplified it with a variety of derivatives, such as compounds **8–11** that have in vitro IC_{50} values less than 20 nM.^{174,175} A less potent derivative in this family, SCH51866 (**12**), had an IC_{50} value of 70 nM, and demonstrated antihypertensive activity and platelet antiaggregatory effects in vivo.¹⁷⁶

10

11

12

Another example of guanine-based inhibitors with good potency (PDE1 IC_{50} = 38 nM) was disclosed in a patent application (**13**).¹⁷⁷

13

Older work has summarized the activity of early PDE1 inhibitors, including HA-558 (**14**), ICI 74917 (**15**), and MY 5445 (**16**). These compounds have low micromolar activity against PDE1.¹⁷⁸

Another series of dual PDE1/PDE5 inhibitors was reported by Dan and co-workers (e.g., **17** and **18**). This series is structurally distinct from other PDE1 inhibitors, and is based on the presence of a hydroxamic acid moiety. The most potent compounds in this group had in vitro IC_{50} values between 40 and 90 nM. Selected compounds in this group demonstrated ex vivo vasodilatory activity, with an EC_{50} of 900 nM.¹⁷⁹

14

15

16

17

18

Another distinct series that demonstrated good selectivity for PDE1 was derived from known PDE inhibitors such as milrinone and zaprinast. This group of imidazotriazinones, exemplified by compound **19**, had in vitro IC_{50} values as low as 85 nM.¹⁸⁰

19

2.23.6.2 PDE2 Inhibitors

Interest in developing inhibitors of this phosphodiesterase is growing, based in part on indications that this may lead to novel treatments for CNS disorders such as cognitive deficits.^{31,181} There are a variety of different chemotypes with demonstrated PDE2 activity. Among the least potent are a series of morpholinochromones (**20**) related to a PI3 kinase inhibitor, LY294002 (**21**). Activity in this group of compounds was measured as the percentage inhibition at 50 μ M, and ranged from 0% to 93%.¹⁸²

As noted in Section 2.23.4.2, a PDE2 inhibitor has demonstrated good selectivity and potency, as well as in vivo activity in animal models of cognition. This compound, BAY 60-7550 (**22**), is an imidazotriazinone derivative, and inhibits human PDE2A with an IC₅₀ value of 4.7 nM. Selectivity against other PDEs ranges from 50-fold (PDE1) to 800-fold (PDE3B, PDE7B, PDE8A, PDE9A, and PDE11A).³¹

Pyrido[2,3-*d*]pyrimidine derivatives (e.g., **23**) were claimed in a patent application where the IC₅₀ value was reported to be less than 50 nM for this compound.¹⁸³ Tricyclic oxindoles such as **24** were claimed in another patent application, and the activity of one example was cited as less than 200 nM (IC₅₀).¹⁸⁴ Benzodiazepinone compounds such as **25** also show PDE2 inhibition; however, no detailed description of activity is given.¹⁸⁵

An x-ray crystal structure of the catalytic domain of PDE2 has recently been reported. In this same work, a unique cell-free system was employed to rapidly produce and evaluate active site mutant versions of human PDE2 in order to more rapidly identify key residues in the active site associated with substrate and inhibitor binding.¹⁸⁶ Four key amino acids were identified (Asp811, Gln812, Ile826, and Tyr827); each of these participates in key interactions with the substrate, and potentially with inhibitors.

The adenosine deaminase inhibitor EHNA (**26**) has been used as a selective PDE2 inhibitor in experiments to determine the role of phosphodiesterases in tissues, or to attempt to understand the sensitivity of a newly discovered PDE to inhibitors.^{187,187a}

2.23.6.3 PDE3 Inhibitors

Unlike other phosphodiesterases, the structural variety of compounds that are reported to be 'potent' and 'selective' inhibitors of PDE3 is comparatively limited. Many PDE3 inhibitors contain a substituted pyridinone or valerolactam ring to which a substituted aromatic ring is attached. Examples of prototypical compounds are **27–37**.

The potency of these compounds as PDE3 inhibitors varies widely. In this group, the most potent compound is cilostamide (**32**), with an IC_{50} of 5 nM, and the least potent is amrinone (**29**), with an IC_{50} of 17 μ M.^{188–191} Edmondson and co-workers have reported the preparation of a very potent PDE3B inhibitor that was investigated for potential use in vivo.¹⁹² This compound (**37**) proved to be moderately selective for PDE3B (10-fold) versus PDE3A. Other compounds in this series lacking the phenyl moiety on the cyclohexenone ring were approximately 10-fold less potent, without improved selectivity for PDE3B.

Fossa and co-workers carried out a modeling study in an attempt to understand structural requirements for potent PDE3 inhibition using available PDE4 crystal structure data, as well as PDE3 site-directed mutagenesis and computational methods. This analysis revealed four residues that were essential for inhibitor binding: Thr908, Lys947, Gln1001, and Phe1004. A variety of interactions occur between inhibitors and these residues, including π stacking and

hydrogen bond formation. In addition to these amino acids, Phe989 occupies a potentially important position in the inhibitor-binding site in a hydrophobic region of pocket A on the enzyme. PDE3 has a serine residue at position 1003, and at a similar position in PDE4, a glycine residue is most commonly found. This creates the possibility of a hydrogen bond between the inhibitor and a serine hydroxyl group that is not present in PDE4.¹⁹³

In addition to this work, Scapin *et al.* have reported the crystal structure of the PDE3B catalytic domain complexed with a derivative of **37**.¹⁹⁴ This showed that the modest level of subtype specificity obtained with **37** cannot be readily explained by an examination of the structure. This issue may be resolved if a crystal structure of the full-length protein can be obtained. The structure did reveal features that were important for the high affinity of the inhibitor, including hydrophobic interactions of the aryl substituent on the cyclohexenone ring. The excellent degree of PDE3 selectivity can be attributed to a hydrogen bond interaction between the carbonyl group of the pyridazinone ring and the side chain of His948.

2.23.6.4 PDE4 Inhibitors

The prototypical PDE4 inhibitor is rolipram (**2**).⁴⁶ It is widely used to investigate the potential role of the enzyme in a given cell or tissue preparation because it inhibits all known PDE4 isozymes (although to varying degrees). The structure of rolipram has been used as a template for the discovery of a number of other PDE4 inhibitors. Examples of these structures are **38–45**.

ONO 6126
45

Rolipram and several related compounds have undergone extensive clinical evaluation for a variety of applications, including asthma, chronic obstructive pulmonary disease (COPD), psoriasis, memory impairment, ulcerative colitis, and multiple sclerosis. None of these compounds have been fully cleared for use, although cilomilast has received an approvable letter in the USA.¹⁹⁵ None of these compounds have demonstrated substantial PDE4 subtype selectivity. Other chemotypes have been discovered with good PDE4 potency. Examples of some of these structures are **46–50**. In this group, both AWD 12-281 and YM976 have undergone clinical evaluation. The former is a potent ($IC_{50} \approx 10$ nM) inhibitor

of PDE4 with low affinity for the so-called high-affinity rolipram-binding site. AWD 12-281 was specifically designed for topical/inhalation use in the treatment of asthma, topical rhinitis, and COPD.¹⁹⁶ YM976 is a potent PDE4 inhibitor, with an IC_{50} of 2.2 nM against PDE4 purified from human peripheral leukocytes. When studied in animal models of inflammation, it was possible to establish a window between the beneficial effect and emesis in rats and ferrets. In rats, the oral ED_{30} in a carrageenan-induced pleurisy model was 9.1 mg kg^{-1} , and no emesis was noted at doses up to 10 mg kg^{-1} . In ferrets, there was a dose-dependent effect at 1, 3, and 10 mg kg^{-1} in a similar model without emesis. In contrast, both rolipram and cilomilast induced vomiting at doses comparable to, or less than, their respective efficacious doses.¹⁹⁷

Other noncatechol-based PDE4 inhibitors that have been evaluated in clinical trials include SCH-351591 (**49**) and lirimilast (BAY 19-8004, **50**). SCH-351591 was shown in a ferret emesis model to not lead to vomiting at doses up to 5 mg kg^{-1} , in spite of very high plasma concentration (up to $3.5 \mu\text{M}$). This compound is highly selective for PDE4 compared with PDE1–PDE3 and PDE5–PDE7, and inhibits PDE4 with an IC_{50} of approximately 60 nM.¹⁹⁸

A catechol derivative discovered by workers at Merck, L791943 (**51**), was shown in a similar ferret model to be nonemetic at doses up to 30 mg kg^{-1} , where the compound achieved plasma concentrations of $14 \mu\text{M}$. L791943 was derived from CDP840 (**38**), and was designed to be metabolically more stable than the parent compound.¹⁹⁹ This required substantial changes in chemical structure in order to achieve and maintain good potency against PDE4 ($IC_{50} = 4 \text{ nM}$), and acceptable activity in whole-cell screens and pharmacokinetic parameters. Additional optimization was required to eliminate the affinity of this chemotype for the hERG channel. This led to the identification of L869298 (**52**), a compound with potent PDE4 activity ($IC_{50} = 0.5 \text{ nM}$), excellent whole-cell activity ($EC_{50} = 90 \text{ nM}$), and low emetic potential in squirrel monkeys.²⁰⁰

The development of PDE4 inhibitors is continuing, and recent publications have shown that a wide variety of chemical structures are tolerated by the enzyme. For example, Whitehead and co-workers have identified a series of substituted catechol derivatives that incorporate a substituted adenine ring system with good activity against PDE4 isozymes.²⁰¹ One of the most potent compounds in this series (**53**) has a reported IC_{50} of 6 nM against human PDE4D5, and shows some subtype specificity (e.g., IC_{50} = 2.6 μ M for hPDE4D2).²⁰¹ The structure–activity relationships associated with the discovery of ONO-6126 (**45**) were reported recently.²⁰² The objective was to identify a more hydrophilic compound compared with rolipram to explore the hypothesis that such a compound would penetrate the CNS to a lesser extent and thereby reduce the emetic potential. This work illustrated that the hydroxamic acid moiety found in **45** resulted in a substantial increase in PDE4 affinity (IC_{50} = 0.05 nM), compared with the corresponding carboxylic acid (IC_{50} = 65 nM). ONO-6126 was tested in a ferret emesis model at doses of 3 and 10 mg kg^{−1}, and did not cause any animals in these dose groups to vomit. Pyridylisoquinolines, such as **54**, were reported by Ukita and co-workers to be potent PDE4 inhibitors with similarly high affinity for the HARBS site.²⁰³ A naphthyridine derivative, NVP-ABE171 (**55**), is a PDE4 inhibitor that demonstrates some subtype specificity. The IC_{50} values against PDE4A, PDE4B, PDE4C, and PDE4D are, respectively, 600, 34, 1230, and 1.5 nM. The compound is active in a variety of preclinical models of inflammation, but no information on the emetic potential of **55** is available.²⁰⁴ The pteridine derivative **56** (DC-TA-46) was shown to inhibit PDE4, to elevate cAMP levels in cells, and inhibit the growth of tumor cells in culture.²⁰⁵ Phthalazinone derivatives such as **57** have been reported by Van der May and co-workers to be yet another series of potent PDE4 inhibitors with in vivo activity in animal models of inflammation.²⁰⁶ In this group of compounds, only the *cis* isomers were active, and it was found that a lipophilic substituent on the phthalazinone ring, such as the adamantyl derivative shown, was more potent than an analog with either a benzoic acid or benzoic ester at the same position.²⁰⁶ The amino diazepinoindole CI-1044 (**58**) was discovered by Burnouf and co-workers.²⁰⁷ The compound had good selectivity for PDE1–PDE3 and PDE5, and moderate potency for PDE4 (IC_{50} = 270 nM) obtained from human U937 cells. In spite of this modest potency, the compound demonstrated good activity in vivo (ED_{50} < 3 mg kg^{−1}) in animal models of inflammation, and no emesis in ferrets following intravenous administration, and low affinity for the HARBS PDE4 site. No subtype specificity was observed in this series of compounds. More potent derivatives of the compound were identified, but these analogs led to emesis in ferrets.

57

58

Very recently, two papers reported distinct approaches to the discovery of novel PDE4 chemotypes. One method, reported by Card and co-workers, utilizes high-throughput x-ray crystallography in combination with a scaffold-based approach to convert fragments with low affinity into molecules with high affinity for a given target.²⁰⁸ The N-1 substituents on the pyrazole ring that were evaluated in this work included isoxazoles, quinoline, phenyl, and tetrahydrobenzothienopyrimidine. Of these, the phenyl-based derivatives proved to be the most potent. Analysis of the structural features that are thought to influence association of the small molecule with the enzyme allowed for the rapid optimization of a series of pyrazole-based compounds, the most potent of which (**59**) had IC₅₀ values of 19 and 56 nM for PDE4B and PDE4D, respectively. Card and co-workers have also published a more comprehensive review of the structural basis underlying their scaffold-based approach to PDE inhibitor discovery.²⁰⁹ In the second approach, a particular scaffold with known, but modest, PDE4 activity was chosen as a starting point.²¹⁰ This example used zardavarine, a PDE3/PDE4 inhibitor with a PDE4 IC₅₀ of 800 nM. Using a carefully designed set of linkers and functional groups (selected based on a set of rules derived from physicochemical properties), docking of candidates into PDE4 was scored using three different protocols. Three different points of attachment to zardavarine were considered, along with five simple alkyl linkers and 15 different functional groups chosen with a variety of physical properties. This small library produced a compound (**60**) with a PDE4 IC₅₀ value of 0.9 nM, a 4-log increase from the starting point.

59

60

There have been several crystal structures of PDE4 enzymes reported complexed with inhibitors.²¹¹ Analysis of these structures shows that compounds bind to the enzyme in a variety of ways. A combination of hydrophobic and hydrogen bond interactions are important. None of the crystal structures to date reveal significant interactions between the inhibitor and the essential cations bound within the active site. However, as noted above with **45**, the presence of a hydroxamic acid moiety, which is known to coordinate strongly with certain divalent cations such as zinc, significantly improves potency, possibly by interacting with the bound cation.

Two recent reviews give additional examples of PDE4 inhibitors.^{212,213}

2.23.6.5 PDE5 Inhibitors

The commercial success of sildenafil (Viagra) stimulated a great deal of interest in the pharmaceutical industry in an attempt to develop additional compounds that might be efficacious for the treatment of PDE5-related conditions. The discovery of sildenafil²¹⁴ (**4**) was based on the optimization of zaprinast (**61**). The second PDE5 inhibitor to be approved for use, vardenafil (Levitra **5**), is structurally related to sildenafil.²¹⁵ Interestingly, the rearrangement of nitrogen atoms in the bicyclic core of vardenafil leads to a substantial increase in PDE5 potency, as exemplified by the activity of **62** (IC₅₀ = 40 nM) and **63** (IC₅₀ = 5 nM). The other structural differences between the two compounds do not contribute to the difference in potency between sildenafil and vardenafil.²¹⁶ Haning and co-workers carried out a more detailed investigation of heterocyclic scaffolds as PDE5 inhibitors, where their research showed that the enzyme does bind certain scaffolds more tightly than others, and that a number of other core structures give single-digit nanomolar PDE5 inhibitors.²¹⁷

Tadalafil (Cialis, **6**) is a carbazole analog that clearly is structurally distinct from the other approved PDE5 inhibitors.²¹⁸ It was developed from a distinct carbazole starting point. The structural difference contributes to a distinct binding mode (see the discussion of the x-ray crystal structures below), which contributes to the substantial difference in PDE6 selectivity between tadalafil and the other approved PDE5 inhibitors.²¹⁹

Much of the initial research that led to the discovery of PDE5 inhibitors focused on chemotypes that resembled the guanine template upon which sildenafil and vardenafil were based. Previous reviews have summarized this work very well, and readers are referred to these citations for a thorough discussion and description of this portion of the effort invested in PDE5 inhibitor discovery.^{220–222} This section will focus on developments in the field since 2000.

The quinazoline derivative E4021 (**64**) is a well-known, potent PDE5 inhibitor with an IC_{50} value of 3.5 nM. Just as was done with vardenafil and sildenafil, changes to the bicyclic core of this compound were investigated. This showed that the quinazoline nucleus could be replaced by a phthalazine structure, such as **65**, which, like vardenafil, provided even more potent PDE5 inhibition (IC_{50} = 0.56 nM) compared with E4021. Interestingly, the structure–activity relationships of the quinazoline and phthalazine cores are distinct, and substituents on the respective nuclei lead to compounds with distinct rank order potency as PDE5 inhibitors. The PDE6 potency of this compound was not described in this paper.²²³

A series of pyrazolopyridines was described by Yu *et al.*,²²⁴ who used parallel synthesis techniques to rapidly optimize this series of compounds. Like Watanabe and co-workers, Yu found that the 3-chloro-4-methoxybenzylamino substituent was optimal for PDE5 activity. The preferred compound in this series (**66**) was a subnanomolar PDE5 inhibitor (IC_{50} = 0.8 nM, sildenafil IC_{50} = 1.6 nM) with superior PDE6 selectivity compared with sildenafil. This compound demonstrated equivalent activity to sildenafil in a rabbit corpus cavernosum strip assay, which measures the functional activity of PDE5 inhibitors, and also showed good oral bioavailability in rats and dogs.²²⁴ A series of naphthyridines related to T-1032²²⁵ (**67**, IC_{50} = 1 nM) was investigated in an effort to improve upon the oral pharmacokinetic properties of the original compound. It was hypothesized that by adding a nitrogen atom in the benzene ring of **67**, the resulting significantly lower the log *P* value would improve these properties. In this case, the optimal compound in the series (**68**) was more potent than both sildenafil and T-1032 in vitro (IC_{50} = 0.23 nM), and equally efficacious in a secondary functional assay. Oral bioavailability was not discussed in this paper. In this series, it was noted that 1,7-naphthyridine isomers were equipotent PDE5 inhibitors compared with the 2,7-naphthyridines such as **68**, but did not have an improved PDE6 selectivity profile, and were less efficacious in functional assays.²²⁶ A third compound in this series, T-0156 (**69**) was extensively characterized. Like **68**, T-0156 was a potent (IC_{50} = 0.23 nM) PDE5 inhibitor with good selectivity for PDE6. It increased cGMP levels in corpus cavernosum tissue in a dose–response manner, and relaxed the tissue in a functional assay. In a dog model of erectile dysfunction, **69** potentiated the pelvic nerve stimulation-induced tumescence in the penis.²²⁷

Using the basic bicyclic guanine ring system of cGMP as a template, addition of a third ring to the system has been investigated by a number of groups. One approach inserted a benzene ring between the two heterocycles, leading to two distinct series of PDE5 inhibitors, exemplified by carboxamide (**70**, $IC_{50} = 0.48$ nM) and **71** ($IC_{50} = 0.62$ nM). Both series of compounds demonstrated excellent selectivity for PDE5 over PDE1–PDE4, and both showed superior PDE6 selectivity compared with sildenafil. Activity in a functional assay proved difficult to achieve in the sulfonamide series based on **71**, as this was the sole analog in the series that demonstrated efficacy in this screen. It was hypothesized that molecular weight was a contributing factor, as this series had molecular weights greater than 550. Carboxamide (**70**) proved to be as efficacious as sildenafil in the corpus cavernosum functional assay, but had poor oral bioavailability. PDE6 selectivity in both of these series was dictated by the N-3 benzyl moiety. The respective carboxamide and sulfonamides also showed distinct structure activity relationships with regard to their respective amine substituents.^{228,229}

In place of a linear tricyclic core, the imidazoquinazoline could be converted to an angular one. This furnished a group of pyrazolopyridopyrimidines, such as **72**. These compounds, like the linear analogs **70** and **71**, proved to be potent ($IC_{50} < 1$ nM) and highly selective (> 150 -fold) for PDE5 over PDE6, with a benzylamino moiety added as indicated on the pyridine ring. The activity of this series in functional assays was not described.²³⁰ Another version of this approach was exemplified by Feixas and co-workers, who prepared a series of pyrazolopyrimidopyridazines, such as **73**.²³¹ In this case, two changes to the angular nucleus of **72** were made: the pyrimidine ring was converted to a pyridazine, and the pyrazolopyridine was isomerized to a pyrimidinylpyrazole. The result was a compound that was approximately twofold less potent than sildenafil, with improved PDE6 specificity. A variety of substituents on the pyrimidine ring were investigated, and these had significant effects on both potency and selectivity, with *n*-alkyl substituents furnishing optimal effects.

An alternative to these strategies was described by Xia and co-workers.²³² In this instance, the angular system fused a six membered ring to the pyrimidine core. Structure–activity studies showed that the optimal substituent on the

added fused ring was a methyl group. Other moieties that were investigated included halogens, the cyano group, hydrogen, and aminoalkyl groups. This optimal derivative, **74**, had an IC_{50} of 9 nM and an activity comparable to sildenafil in a corpus cavernosum functional assay. Selectivity for PDE6 was approximately 20-fold.²³²

In yet another example of this line of PDE5 inhibitor design, Yu and colleagues described the pyrazolopyridopyridazine **75**. This compound was designed as a second-generation version of pyrazolopyridine **66**. In the x-ray crystal structure of **66**, a hydrogen bond between the benzylamino NH and amide carbonyl substituents formed a pseudo-six-membered ring. In **75**, the pyridazine formalized this conformation. In many ways, structure–activity studies of the amino substituents on the pyridazine ring mirrored those seen with the phthalazine **65**, and with **66**. The imidazocarboxamide moiety proved to be superior to other substituents, giving a compound with an IC_{50} of 0.3 nM against PDE5, excellent selectivity for PDE5 over PDE1–PDE4, and 150-fold selectivity for PDE5 over PDE6, good functional activity, and good oral bioavailability. In healthy human volunteers, **75** showed no evidence of visual disturbances.²³³

At least one group has reported the synthesis of analogs of tadalafil, where the methyl substituent of the diketopiperazine ring was replaced by a wide variety of other substituents such as cyclic amines, alkyl, alkylcarboxamides, aryl/heteroaryl, and benzyl/heterobenzyl moieties. Some of these, such as benzyl, imidazolylmethyl, and carboxamido groups, furnished potent (IC_{50} as low as 0.7 nM (e.g., **76**), compared with tadalafil with an IC_{50} of 6.7 nM), but somewhat less PDE6-selective, derivatives. One objective of this study was to also investigate PDE11 selectivity in the series. None of the compounds reported in this work demonstrated a significant difference from tadalafil.²³⁴

Researchers at Johnson and Johnson have extensively investigated a group of pyrroloquinolines as PDE5 inhibitors. In the first paper in the series, structure–activity relationships in the rings pendant on the pyrroloquinoline nucleus were investigated. It was found that the number and nature of oxygenated positions played an important role in providing both PDE5 potency, and in one case (**77**) excellent (>300-fold) selectivity for PDE6. This series demonstrated the ability to increase cGMP levels in cells more potently than sildenafil, and efficacy in dogs, as measured by an increase in mean arterial pressure, when administered intravenously.²³⁵ This was followed by an investigation of amide derivatives (**78**) that demonstrated similar PDE5 potency, variable levels of PDE6 selectivity, with less efficacy in the dog model of erectile dysfunction.²³⁶ Substitution of a carbamate for the amide in **78** produced another potent series (**79**) with lower selectivity for PDE5 than for PDE6, and similar results in functional and animal models of efficacy compared with **78**.²³⁷ In a series of pyrroloquinoline analogs, such as **80**, that resembled tadalafil and those reported by Maw and co-workers, markedly lower potency in vitro and in vivo was observed.²³⁸ The final paper in this series resulted in the identification of a compound with properties suitable for clinical evaluation. This was accomplished by converting the pyrimidine ring of **77** to a pyridine, and separation of the enantiomers to furnish the preferred (*R*)-isomer (**81**), leading to a PDE5 inhibitor with good potency (K_i = 0.12 nM), sufficient aqueous solubility, efficacy in erectile dysfunction models, and oral bioavailability in animals.²³⁹

79

80

81

An alternative tricyclic template was reported by Boyle and co-workers. In this case, a five-membered ring was fused to the six-membered heterocycle of the guanine nucleus. This allowed for more expedient exploration of structure–activity relationships in the series previously reported by Ahn.¹⁷⁴ It was found that an ethyl moiety at N-5 of the guanine was preferred with respect to both potency and PDE6 selectivity. Further, a benzyl group at C-7 was superior to other groups in conferring potency and selectivity for PDE5 over PDE1. As observed by others,²²⁸ N-3 benzyl substitution gave more potent and selective PDE5 inhibitors. The optimal compound in the series (**82**) showed an IC_{50} of 2.5 nM against PDE5, 90-fold selectivity for PDE6, and 200-fold selectivity for PDE11. This compound also demonstrated oral bioavailability comparable with sildenafil (**4**) in rats and dogs, and efficacy in a dog model of erectile dysfunction.²⁴⁰

The pyrazole ring in **66** could be replaced by a substituted benzene ring, as shown by Bi and co-workers.²⁴¹ Interestingly, it was necessary to also replace the carboxamide in **66** with a simple hydroxymethyl group to retain potent PDE5 inhibition. The ethyl moiety at C-8 of the quinoline core was an important contributor to both potency and PDE6 selectivity, and the cyano group at C-6 was preferred. The optimal compound in this series (**83**) was shown to be highly potent ($IC_{50} = 0.05$ nM) as a PDE5 inhibitor with excellent (~ 8000 -fold) PDE6 selectivity.²⁴¹

82

83

At least two crystal structures of the catalytic domain of PDE5 with inhibitors bound have been reported. One employed IBMX, and it was shown that it bound in a pocket composed of hydrophobic residues including Val782, Phe786, Phe820, and the previously mentioned key glutamine at position 817. The so-called H and M loops of the enzyme are important structural features for selective inhibitor binding, and differences in this region in PDE5 help to account for subtype specificity compared with PDE4.²⁴² The second structure showed how sildenafil, vardenafil, and tadalafil bound within the active site of PDE5.²⁴³ It showed that sildenafil and vardenafil bound in the same pocket (Q pocket) as IBMX. The sulfonamide moiety in both compounds does not participate in key attractive interactions with the enzyme. Other groups, such as the piperazine ring, alkoxy substituents, and the heterocyclic core, do make important contacts and undergo hydrophobic, as well as hydrogen bonding and π -stacking, interactions with neighboring amino acids on the protein. Tadalafil fills other pockets on the enzyme, in particular the hydrophobic H pocket, and does not interact, like the other two compounds, with the L region of the enzyme.

2.23.6.6 PDE6 Inhibitors

No selective inhibitors of PDE6 have been reported. However, as a part of the development of selective PDE5 inhibitors, this enzyme is often part of the panel of PDEs to be screened, given the high degree of sequence homology

and observation that sildenafil, as a prototypical PDE5 inhibitor, does inhibit PDE6 with an IC_{50} of 37 nM.²¹⁹ This level of in vitro activity is sufficient to result in inhibition of the enzyme at therapeutically relevant doses in humans and produce transient visual disturbances. Vardenafil is also a potent PDE6 inhibitor, with an IC_{50} value of 3.5 nM, and tadalafil has a reported IC_{50} value of 1.2 μ M.²¹⁹ Clinical evidence gained to date indicates a lower incidence of visual changes with vardenafil and tadalafil.

2.23.6.7 PDE7 Inhibitors

The first inhibitors of PDE7 were a group of benzothieno[3,2-*a*]thiadiazine 2,2-dioxides. These compounds (e.g., **84**) proved to be weak inhibitors of the enzyme ($IC_{50} \approx 20 \mu$ M, little selectivity for PDE7 over PDE3 or PDE4).²⁴⁴ A comparative molecular field analysis of this series of compounds was carried out in an attempt to improve the potency. This analysis suggested that hydrogen-bonding interactions between the inhibitor and enzyme were important determinants of activity. Based on this suggestion, an analog was prepared that had improved activity as a PDE7 inhibitor (**85**). This change also improved the selectivity of the series for PDE7 over PDE3 and PDE4.²⁴⁵ More potent guanine-based compounds were described by Barnes and co-workers, where the sugar moiety of the cyclic nucleotide was replaced with hydrophobic bicyclic substituents.²⁴⁶ This furnished compounds (e.g., **86**) with low single-digit micromolar potency, and good selectivity for PDE7 over PDE3 and PDE4.²⁴⁶ Another series of purine-based compounds was described where instead of a lipophilic substituent at N-3 of the purine ring system, an amino thiazole was added at C-2. Along with a substituted benzylamine at C-6, this furnished compounds with IC_{50} values as low as 10 nM. The most potent analogs in this series (**87**) also proved to be potent PDE5 inhibitors.²⁴⁷ Further modification of the C-6 substituent in this series, coupled with alteration of the purine heterocycle, significantly improved the PDE selectivity profile and maintained good PDE7 potency (e.g., **88**).²⁴⁸

A series of spiroquinazolinones was found to give potent PDE7 inhibitors. A high-throughput screen identified a simple spiroquinazolinone lead with good potency that was optimized to provide a compound (**89**) with an order of magnitude increase in activity.²⁴⁹ This was further improved to yield the oxadiazole analog **90**, which had an IC_{50} of 3.5 nM, and good to excellent (at least 100-fold) selectivity against PDE1–PDE6. Selected derivatives in this group had measurable oral bioavailability.²⁵⁰

The same group identified and optimized a series of thiadiazoles that were discovered by high-throughput screening. Once again, the potency of the initial lead was significantly improved, to furnish a compound (**91**) with an IC_{50} of 30 nM for PDE7. Selectivity against PDE4D3 was excellent, as this compound had an IC_{50} of over 8 μ M.²⁵¹ Further improvements in this series focused on oral pharmacokinetic characteristics, and this yielded a compound (**92**) with slightly lower potency (IC_{50} = 60 nM), but with excellent oral bioavailability.²⁵²

A simple sulfonamide derivative, BRL 50481 (**93**) was reported to be a moderately potent PDE7 inhibitor (K_i = 180 nM), with good selectivity against PDE3, and moderate selectivity against PDE4.¹³³

Several patents have described other chemotypes that have claimed activity as PDE7 inhibitors. In some cases, IC_{50} values were reported, and in other cases ranges of IC_{50} values were reported. Representative examples from these patents are shown below. Pyrazolopyrimidinones (**94**) were claimed by Daiichi. These compounds had excellent PDE7 potency, with IC_{50} values as low as 3.5 nM.²⁵³ A series of isoquinolines was claimed by workers at Ono. PDE7 activity was specified for a dihydroisoindole derivative (**95**), with an IC_{50} of 23 nM.²⁵⁴ Phthalazinones (**96**) were claimed by Altana as a series of dual PDE4/PDE7 inhibitors with respective $-\log IC_{50}$ values of 8.64 and 7.64,²⁵⁵ and dihydroisoquinolines (**97**) were claimed by Byk Gulden with a $-\log IC_{50}$ value of 7.49.²⁵⁶ Sulfonamides **98** were claimed by Celltech, with an IC_{50} range reported as less than 1 μ M.²⁵⁷

In a recently reported x-ray crystal structure of the catalytic domain of PDE7, it was found that multiple elements of the structure contribute to selectivity between PDE7 and PDE4.²⁵⁸ The nonselective PDE inhibitor IBMX was employed as the ligand in these studies. Analysis of the binding revealed that the conformation and position of an invariant glutamine residue (Gln413 in PDE7) formed a critical hydrogen bond with IBMX, but clashed sterically with rolipram. A serine residue in PDE7 (Ser377) interacts with this key glutamine to control its orientation and conformation in the active site, and Ile412 occupies a key site that influences the size and shape of the IBMX-binding pocket in PDE7.

2.23.6.8 PDE8 Inhibitors

No selective inhibitors of this enzyme have been reported. Dipyridamole (**99**) is reported to be a weak inhibitor of the enzyme *in vitro*, with an IC_{50} as low as $4.5\ \mu\text{M}$.²⁵⁹ Other standard PDE inhibitors such as rolipram, zaprinast, IBMX, and vinpocetine do not inhibit PDE8.

2.23.6.9 PDE9 Inhibitors

All activity reported to date in the discovery of PDE9 inhibitors has been in the patent literature. Pfizer has been active in the field, with three applications that have published in the last few years. Examples of compounds and chemotypes claimed as PDE9 inhibitors are **100–102**.^{260–262} Compound **102** was reported to lower blood glucose in a mouse model.²⁶²

Another related active series of PDE9 inhibitors was reported by Hendrix. This compound (**103**) had moderate activity ($IC_{50} = 50\ \text{nM}$) against PDE9, and excellent selectivity against all other PDEs except PDE11, against which it demonstrated 50-fold selectivity.²⁶³

The x-ray crystal structure of the catalytic domain of PDE9A2 has been solved using the inhibitor IBMX. Analysis of the structure showed that IBMX binds in a pocket similar to that found in the active sites of PDE4 and PDE5, but with a substantially different orientation. Common binding features include stacking of the xanthine ring of IBMX with

conserved phenylalanine residues, and a hydrogen bond between the N-7 NH of IBMX and a conserved glutamine residue. However, the xanthine ring of IBMX is rotated considerably in the PDE9A2 active site, compared with the other enzymes. This may be due to the larger volume of the PDE9A2 active site compared with the other enzymes, or to more subtle conformational differences in the structure of the H and M loops of the PDE9A2.²⁶⁴

2.23.6.10 PDE10 Inhibitors

There is increasing interest in the discovery of PDE10 inhibitors, as reflected by some recent patent applications claiming a variety of chemotypes for CNS and metabolic disease applications. Examples of dihydroisoquinolines are given in a patent application from Bayer Pharmaceuticals (**104–107**). These compounds were reported to have IC_{50} values of approximately 30 nM in a scintillation proximity assay.²⁶⁵ Structurally related compounds have also been disclosed by others.²⁶⁶ Imidazotriazines such as **107** were claimed for the treatment of neurodegenerative disorders. The compound was stated to have an IC_{50} value of 410 nM.²⁶⁷

The isoquinoline alkaloid papaverine **108** has also been reported to be a PDE10A inhibitor, with an IC_{50} of 40 nM. The compound was used in a mouse model of schizophrenia, where, at oral doses of 3 and 10 mg kg⁻¹ daily, it demonstrated activity comparable with haloperidol. When added to brain tissue slices and striatal spiny neurons in cell culture, papaverine was shown to increase the level of cAMP in the cells. When papaverine was administered to PDE10A knockout mice and examined in the same model, no evidence for efficacy was seen. This suggests that the enzyme may play a role in the disease.²⁶⁸

2.23.6.11 PDE11 Inhibitors

No selective inhibitors of PDE11 have been disclosed at this time. Tadalafil, sildenafil, and vardenafil have been reported to inhibit the enzyme in vitro. In this group, tadalafil is the most potent inhibitor, with an IC_{50} value of 37 nM.²¹⁹ Dipyridamole (**99**) and E4021 (**64**) have also been reported to be a moderately potent PDE11 inhibitors using both cAMP and cGMP as substrates, with IC_{50} values of 0.35–1.8 μ M, when studied with PDE11A3 and PDE11A4.¹⁶⁶

2.23.7 Prototypical Therapeutics

Table 3 lists the generic names of PDE inhibitors approved for use, along with the PDE(s) targeted and the primary indication(s) for use of the compound.

2.23.7.1 PDE1

At the present time, there are no specific therapeutic applications for which a PDE1 inhibitor is indicated. There are, however, different lines of evidence to suggest a role for PDE1 in a number of physiological processes. The issue in these cases is whether or not the enzyme plays a critical part in controlling the signaling pathway. One example can be found in the investigation of combined PDE1/PDE5 inhibitors for vascular injury. SCH51866 (**12**) at a dose of $17 \text{ mg kg}^{-1} \text{ day}^{-1}$ for 1 month has been shown to reduce by approximately 50% the degree of vascular injury in a porcine model.²⁶⁹ Compounds related to the combined PDE1/PDE5 inhibitor **11** showed good antihypertensive activity in a spontaneously hypertensive rat model.¹⁷⁵ As noted in [Section 2.23.4.1](#), PDE1 is a part of a multicomponent signaling pathway that can influence insulin secretion from.

The PDE1 inhibitor vinpocetine **7** was reported to be in clinical trials for the management of urinary urgency and incontinence.^{270,271} This was based on the demonstration that PDE1 plays a key role in maintaining tone in the detrusor muscle.

2.23.7.2 PDE2

Like PDE1, there are no approved therapeutic applications for a PDE2 inhibitor. Unlike PDE1, the availability of highly potent and PDE-subtype selective inhibitors has made it easier to identify and understand the benefits associated with inhibition of this enzyme. As noted in [Section 2.23.4.2](#), a PDE2 inhibitor (**22**) has shown activity in animal models of cognition.³¹ Furthermore, because PDE2 is closely associated with signaling by the ANP receptor, it is conceivable that PDE2 may play a role in maintaining plasma volume. The enzyme has also been shown to have a role in platelet aggregation.²⁹

2.23.7.3 PDE3

PDE3 inhibitors such as milrinone have been used for acute treatment of heart failure. However, the safety of their long-term use in treatment of this disease has been questioned.²⁷² Cardiac arrhythmias have occurred, possibly as a result of cAMP accumulation in the heart. Cilostazol is approved for use as a platelet antiaggregatory agent. Like milrinone, it is not widely used because of safety concerns. The association in vitro between PDE3 inhibition and platelet antiaggregatory action has been studied in detail, and it was shown that more potent cilostazol analogs, such as OPC-33540, were more potent as inhibitors of platelet aggregation.²⁷³ When combined with β -adrenoreceptor antagonists, there is some recent clinical evidence to suggest the use of PDE3 inhibitors as an adjunct in the treatment

Table 3 PDE inhibitors approved for use

<i>Generic name</i>	<i>Target PDE(s)</i>	<i>Primary indication(s)</i>
Theophylline	PDE3, PDE4	Asthma, emphysema, bronchitis
Aminophylline	PDE3, PDE4	Asthma, emphysema, bronchitis
Olprinone	PDE3	Acute cardiac insufficiency
Milrinone	PDE3	Acute cardiac failure
Amrinone	PDE3	Hypertension, acute cardiac failure
Cilostazol	PDE3	Intermittent claudication
Sildenafil	PDE5	Erectile dysfunction, pulmonary hypertension
Vardenafil	PDE5	Erectile dysfunction
Tadalafil	PDE5	Erectile dysfunction
Dipyridamole	PDE1, PDE5	Platelet aggregation

of dilated cardiomyopathy.²⁷⁴ Cilostamide (**32**) has been shown to inhibit cell proliferation in a KB squamous cell carcinoma cell line.²⁷⁵ Other investigations into the potential role of PDE3 for use in the treatment of other types of cancer (e.g., malignant melanoma) showed little role for the enzyme.²⁷⁶ PDE3B has been shown in multiple laboratories to play a key role in insulin release, and, because it is expressed primarily in the liver, it has been hypothesized to be a target for control of metabolism.^{194,277,278} However, the lack of subtype-selective (3A versus 3B) agents has limited the investigation to largely model studies. Cilostamide has also shown activity in a rat balloon injury model, suggesting that PDE3 inhibitors could find use in preventing intimal hyperplasia following angioplasty.²⁷⁹ Olprinone has shown in vivo efficacy in humans with mild, stable asthma when infused intravenously. It does not act additively or synergistically with aminophylline, a standard drug for the treatment of asthma.²⁸⁰

2.23.7.4 PDE4

PDE4 inhibitors have been widely investigated for the treatment of asthma and COPD because of their well-established anti-inflammatory activity in a variety of cellular and animal models. No PDE4 inhibitors have been approved for clinical use; however, cilomilast (Ariflo, **39**) has received an approvable letter from the US Food and Drugs Administration. The potential value of PDE4 inhibitors for these conditions is associated with the expression of the enzyme in the cell types involved, including neutrophils, eosinophils, mast cells, and macrophages. In both cellular and animal models, it is possible to correlate PDE4 inhibition with decreased production of inflammatory cytokines such as TNF- α .⁴⁶ Several PDE4 inhibitors are in clinical development¹⁹⁵ for a variety of conditions, as outlined in [Section 2.23.6.4](#). More recently, PDE4 inhibitors have begun to be investigated for CNS diseases, including anxiety, depression, and cognition disorders.^{80,195} At this point in time, one of the issues that continues to plague PDE4 inhibitor clinical development is the separation between the dose required for the desired therapeutic effect and the dose at which nausea and emesis become intolerable.

In addition to these applications, various PDE4 inhibitors have shown activity in animals for other conditions. For example, rolipram has shown the capacity to reduce aspirin-induced gastric mucosal injury in rats when administered before aspirin.²⁸¹ Rolipram in combination with prostacyclin analogs works synergistically to attenuate acute hypoxic vasoconstriction in the lungs.²⁸² It has been shown that PDE4B2 is overexpressed in human myometrium at the end of pregnancy, and inhibition of the enzyme in cell culture reduces the production of inflammatory cytokines. Thus, PDE4 may be a potential mechanism by which preterm labor can be avoided.²⁸³ Because of the well-established utility of PDE4 inhibitors in inflammatory diseases, they have also been proposed for use in the treatment of inflammatory bowel disease.²⁸⁴ It has been known for several years that high levels of cAMP are cytotoxic. Investigation of the potential for PDE4 inhibitors to act as potential anticancer agents has been reported. It has been shown, for example, that the general PDE inhibitors aminophylline and theophylline can reduce the cytotoxic doses of cisplatin and gemcitabine in cell culture, when tested against lines derived from human lung, ovarian, and prostate tumors. The PDE inhibitors themselves are mildly cytotoxic when used alone. It appears that the PDE inhibitors exert their actions by inducing apoptosis in the tumor cells.²⁸⁵ Rolipram has shown the ability to synergize with glucocorticoids, to cause apoptosis in human B cell chronic lymphocytic leukemia cells. There is no synergistic effect on T cell apoptosis. Based on this activity, clinical investigation of the potential for use in chronic lymphocytic leukemia has been proposed.²⁸⁶

2.23.7.5 PDE5

PDE5 inhibitors have been approved for use for the treatment of erectile dysfunction since 1998. More recently, sildenafil has also been approved for use in the treatment of pulmonary hypertension. Clinical studies are underway for the potential use of PDE5 inhibitors in benign prostatic hypertrophy, based on the high level of expression of the enzyme in the prostate, and the demonstration of the functional relevance of the enzyme in the tissue.²⁸⁷ As noted in [Section 2.23.4.5](#), PDE5 is widely expressed in a number of different smooth muscle tissue types. Because of this, PDE5 inhibitors have been investigated for functional applications in these tissues. For example, in rats, it has been shown that sildenafil dilates fetal and neonatal ductus. It was effective at lower doses in preterm rat pups, and at much higher doses in newborn rats.²⁸⁸ In spontaneously hypertensive rats, a PDE5 inhibitor in combination with the angiotensin-converting enzyme inhibitor enalapril produces a synergistic effect on renal, mesenteric, and hindquarter vascular beds. When given alone, the PDE5 inhibitor produced a smaller effect on the renal vasculature.²⁸⁹ In guinea pig models of airway disease, sildenafil has shown the ability to inhibit inflammation in response to both lipopolysaccharide- and ovalbumin-induced stimuli.²⁹⁰

PDE5 is also expressed in endothelial tissues. For this reason, PDE5 inhibitors have been studied in male smokers for their ability to reverse smoking-induced pulmonary endothelial dysfunction. At a dose of 50 mg, sildenafil completely eliminated the decrease in flow-mediated dilatation of the brachial artery that was acutely induced by smoking.²⁹¹

In patients with congestive heart failure, sildenafil at a dose of 50 mg, in combination with 10 mg of ramipril, an angiotensin-converting enzyme inhibitor, increased flow-mediated dilation. Each drug alone was also able to improve this measure of endothelial function.²⁹² Additional clinical studies have shown a beneficial effect of sildenafil on pulmonary hemodynamics, diffusion capacity, oxygen uptake kinetics, and exercise ventilatory efficiency in patients with chronic heart failure. It has been proposed that these effects are due to the effect of the compound on endothelial function.²⁹³

As noted above, PDE4 inhibitors have been shown to reduce aspirin-induced gastric damage. Sildenafil has shown that it too can prevent indomethacin-induced gastropathy in rats. Acting via nitric oxide-dependent mechanisms, sildenafil decreased leukocyte adhesion, prevented the decrease in gastric blood flow induced by the nonsteroidal anti-inflammatory agent, and also reduced the direct gastric damage caused by indomethacin.²⁹⁴ Delayed gastric emptying, associated with diabetes-induced gastroparesis, can be reversed by sildenafil in mice. Two different murine models of the disease, using nonobese genetically diabetic mice, and in mice where diabetes was caused by streptozotocin administration, were studied, and the compound was efficacious in both cases.²⁹⁵ Animal studies suggested that sildenafil could limit damage to the heart, induced by prolonged ischemia. This was investigated in humans, and in a double-blind, placebo-controlled cross-over study, 50 mg of sildenafil was administered to healthy male volunteers. Flow-mediated dilatation of the radial artery was measured following 15 min of ischemia/reperfusion. It was found that patients given sildenafil were effectively protected against damage. More detailed study of the mechanism using a blocker of K_{ATP} channels, glibenclamide, showed that this ion channel was involved in the process, as glibenclamide reversed the beneficial effects of sildenafil.²⁹⁶ This beneficial effect on cardiac tissue was shown in mice to contribute to attenuation of doxorubicin-induced left ventricular function, and to reduce cardiomyocyte apoptosis.²⁹⁷ Very recently, clinical studies with tadalafil have been reported to show that it too improves endothelial function in men with increased cardiovascular risk.²⁹⁸ In a murine model of cardiac hypertrophy, sildenafil deactivated multiple hypertrophy signaling pathways, and reversed pre-established hypertrophy induced by chronic pressure overload, and also restored chamber function to normal.²⁹⁹

In cases of nephrogenic diabetes insipidus, sildenafil has shown the ability to stimulate insertion of the AQP2 membrane into renal epithelial cells in rats. This suggests that PDE5 inhibitors may be useful in the treatment of this condition in humans.³⁰⁰

In addition to these potential peripheral applications, there is increasing evidence to suggest that PDE5 inhibitors may be useful in cognitive disorders as well. It is well known that nitric oxide–cGMP pathways are involved in memory and learning, and that elevated levels of cGMP in the hippocampus contribute to improved performance of rats in object recognition and passive avoidance learning. Addition of sildenafil to rat hippocampal brain slices elevated cGMP levels in this tissue, and in vivo the compound improved the memory performance of rats.^{301,302} Sildenafil has also been shown to attenuate the learning impairment induced by cholinergic blockade in rats.³⁰³

Sildenafil and vardenafil induce caspase-dependent apoptosis in B-cell-derived chronic lymphocytic leukemia cells in vitro. In this study, the less potent PDE5 inhibitor zaprinast had no effect on apoptosis inducement.³⁰⁴ Thus, similar to PDE4 inhibitors, PDE5 inhibitors may find a use in certain types of cancer chemotherapy. This effect has also been demonstrated in a human colon tumor cell line.³⁰⁵

2.23.7.6 PDE6

No beneficial therapeutic indications have been associated with inhibition of PDE6. However, as noted above, inhibition of this enzyme by selected PDE5 inhibitors leads to reversible changes in color perception.

2.23.7.7 PDE7

Inhibition of PDE7 was originally hypothesized to be useful for the treatment of immunological/inflammatory diseases because the enzyme is substantially upregulated in activated T cells. However, the report that PDE7A knockout mice have functionally competent T cells calls this potential application into question. At the time of this writing, the issue remains unresolved. There is no substantive evidence published on small-molecule inhibitors of the enzyme that beneficial actions are associated with this activity.

2.23.7.8 PDE8

The lack of potent PDE8 inhibitors has limited investigations of the role of enzyme inhibitors for therapeutic benefit. Perez-Torres and co-workers have shown that in the brains of patients with Alzheimer's disease, PDE8B mRNA levels in the hippocampus were significantly higher than in the brains of age-matched controls, and was higher still in patients with advanced disease.³⁰⁶

2.23.7.9 PDE9

As noted in [Section 2.23.6.9](#), PDE9 may play a role in the regulation of glucose homeostasis in type 2 diabetes, based on the ability of a compound (**102**) to lower plasma glucose in an *ob/ob* mouse model of the disease at a dose of 10 mg kg⁻¹.

In addition, there is evidence to indicate that PDE9 plays a role in memory in mice and rats.¹⁵⁴

2.23.7.10 PDE10

In the patents cited in [Section 2.23.6.10](#), PDE10 inhibitors are claimed to be useful for the management of glucose homeostasis by stimulating insulin release from pancreatic β cells. It was possible, using compounds **104–106**, to demonstrate increases in insulin secretion from β cells derived from lean Sprague–Dawley rats in cell culture. Furthermore, PDE10 inhibitors may be useful in the treatment of CNS disorders such as schizophrenia, anxiety, and/or depression, based on the activity of papaverine in animal models, as noted in [Section 2.23.6.10](#).

2.23.7.11 PDE11

No specific applications have been demonstrated for PDE11 inhibitors. However, as outlined in [Section 2.23.6.11](#), it is possible the enzyme plays a role in sperm function and motility, and a recent report identified a distinct pattern of enzyme expression in a variety of normal and malignant human tissues.³⁰⁷

2.23.8 Genetic Diseases

Mutations in the PDE6 gene are known to be associated with retinitis pigmentosum and other retinal dystrophies.^{126,308–310} These mutations are rare.

2.23.9 New Directions in Phosphodiesterase Enzyme Biology and Inhibition

From a therapeutic (enzyme inhibitor) perspective, advances in the field of PDEs will be dependent in part on the discovery of novel role(s) for the enzymes. With the sequence of the human genome in hand, the discovery of new enzymes in the class I family may occur, although no new PDEs have been reported since PDE11 was cloned in the late 1990s. From a purely enzymologic perspective, the enzymes about which the most information is available are those that have attracted the most interest as therapeutic targets: PDE4 and PDE5. Researchers in the field can expect the same to hold true as roles for the more recently discovered PDEs become better defined. The availability of high-resolution x-ray structures for many of the PDEs should prove useful for the discovery of novel inhibitors. Comparison of the structures with inhibitors bound may provide insights for the discovery of highly selective agents, as well as for molecules that can potently inhibit two or more PDEs. The existence of a range of distinct binding modes and subtle differences in the primary sequence in the active sites of the PDEs, along with the wide structural variety of the inhibitors shown in [Section 2.23.6](#), should help to ensure that chemical diversity will allow for the discovery of a range of inhibitors with distinct chemical and physical properties.

Whenever there is more than one family member in a group of enzymes, the question of selectivity arises and must be addressed. This is necessary to first understand the role the enzyme plays in the potential target tissue and disease model, and second to allow researchers to clarify safety issues that may emerge during preclinical and clinical evaluation of a given compound. In the case of PDEs, the fact that within a family, different members may be responsible for distinct physiological responses (as noted, it is possible that this is true for the PDE4 family) creates yet another level of complexity that can complicate the interpretation of *in vivo* results. A PDE3B-selective compound has not yet been reported, making detailed evaluation of the potential of this enzyme as a target for obesity and type 2 diabetes problematic because of the potential safety issues associated with chronic inhibition of PDE3A.

One area that has not been extensively explored is the development of compounds that potently inhibit two or more PDEs. Given that these enzymes are widely distributed, but also often subcellularly localized and therefore probably tightly regulated, the availability of dual/multiple PDE inhibitors could allow better understanding of the role the enzyme(s) play in cell biology and the signaling pathways they influence. These efforts can go hand in hand with gene knockout technology to rapidly advance our understanding of the role PDEs play in signal transduction and regulation.

Among the currently known PDEs, interest in PDE2, PDE9, and PDE10 is slowly increasing because of reports that these enzymes may play a role in CNS disorders such as anxiety, depression, and cognition. PDE7 has been a target of interest for immunologic disorders. However, this interest has waned in recent years, perhaps because (as noted in

Section 2.23.4.7) there is some controversy surrounding the role the enzyme plays in activated T cells. The use of gene knockout and siRNA technology should allow researchers to better understand the role(s) an individual PDE can play in whole animals, and in disease models.

The possibility that two or more PDEs can play a role in modulating cell biology is particularly intriguing. In endocrine biology, for example, glucose homeostasis in response to certain stimuli appears to involve both PDE3 and PDE1. It is possible that other PDEs have similar 'cross-talk' roles. The observation that PDE4 plays a key role in arrestin-mediated signaling raises the possibility that other PDEs might be components of similar or other distinct multicomponent pathways.

The study of PDEs is a complex and very active field of research. Even for those enzymes that have been comparatively heavily studied, new information on structure, function, and inhibition is being generated on a regular basis. The field can look ahead to sustained interest and continued significant developments in the future.

253. Inoue, H.; Murafuji, H.; Hayashi, Y. Preparation of (Pyridinyl)pyrazolopyrimidinone Derivatives as PDE7 Inhibitors. International Patent WO 2004111054, December 23, 2004.
254. Ohhata, A.; Takaoka, Y.; Ogawa, M.; Nakai, H.; Yamamoto, S.; Ochiai, H. Preparation of Isoquinoline Derivatives as Phosphodiesterase (PDE) 7 Inhibitors. International Patent WO 2003064389, August 7, 2003.

255. Hatzelman, A.; Marx, D.; Steinhilber, W.; Sterk, G. J. Preparation of Phthalazinones as Phosphodiesterase 4/7 Inhibitors. International Patent WO 2002085906, October 31, 2002.
256. Bundschuh, D.; Kley, H.-P.; Steinhilber, W.; Grundler, G.; Gutterer, B.; Natzelmann, A.; Stadwieser, J.; Sterk, G. J. Preparation of (Dihydro)isoquinolines as Phosphodiesterase Inhibitors. International Patent WO 2002040450, May 23, 2002.
257. Haughan, A. F.; Lowe, C.; Buckley, G. M.; Dyke, H. J.; Glavin F. C. A.; Mack, S. R.; Meissner, J. W. G.; Morgan, T.; Watson, R. J.; Picken, C. L. et al. A. Preparation of Sulfonamides as Potent Inhibitors of PDE7. International Patent WO 2001098274, December 27, 2001.
258. Wang, H.; Liu, Y.; Chen, Y.; Robinson, H.; Ke, H. *J. Biol. Chem.* **2005**, *280*, 30949–30955.
259. Soderling, S. H.; Bayuga, S. J.; Beavo, J. A. *Proc. Natl. Acad. Sci. USA* **1998**, *95*, 8991–8996.
260. Bell, A. S.; Deninno, M. P.; Palmer, M. J.; Visser, M. S. Preparation of Pyrazolopyrimidinones as Phosphodiesterase 9 (PDE9) Inhibitors for Treating Type 2 Diabetes. US Patent 2004220186, November 4, 2004.
261. Deninno, M. P.; Hughes, B.; Kemp, M. I.; Palmer, M. J.; Wood, A. Preparation of Pyrazolo[4,3-*d*]pyrimidin-7-ones as PDE9 Inhibitors for Treating Cardiovascular Disorders. International Patent WO 2003037899, October 16, 2003.
262. Fryburg, D. A.; Gibbs, E. M. Treatment of Insulin Resistance Syndrome and Type 2 Diabetes with PDE9 Inhibitors. International Patent WO 03037432, May 8, 2003.
263. Hendrix, M. PDE Inhibitors for AD: Influencing Learning and Memory via the cGMP-PDE Pathway. 2nd Annual Phosphodiesterases in Drug Discovery and Development, Philadelphia, PA, November 8–9, 2004.
264. Huai, Q.; Wang, H.; Zhang, W.; Colman, R. W.; Robinson, H.; Ke, H. *Proc. Natl. Acad. Sci. USA* **2004**, *101*, 9624–9629.
265. Sweet, L. Methods for Treating Diabetes and Related Disorders using PDE10A Inhibitors. International Patent WO 2005012485, February 10, 2005.
266. Maier, T.; Graedler, U.; Gimmlich, P.; Quintini, G.; Ciapetti, P.; Contreras, J.-M.; Wermuth, C. G.; Vennemann, M.; Baier, T.; Braunger, J. Preparation of Pyrrolodihydroisoquinolines as Cyclic 3',5'-Nucleotide Phosphodiesterase (PDE10) Inhibitors International Patent WO 2005003129, January 13, 2005.
267. Ergueden, J. K.; Bauser, M.; Burkhardt, N.; Flubacher, D.; Friedl, A.; Gerlach, I.; Hinz, V.; Jork, R.; Naab, P.; Niewoehner, U. et al. Preparation of Imidazotriazines as Phosphodiesterase 10A Inhibitors for the Treatment of Neurodegenerative Diseases. International Patent WO 2003000693, October 3, 2003.
268. Kleinman, R. PDE10: A Potential Target for CNS Diseases. 2nd Annual Phosphodiesterases in Drug Discovery and Development, Philadelphia, PA, November 8–9, 2004.
269. Czarniecki, M.; Ahn, H.-S.; Sybertz, E. J. *Annu. Rep. Med. Chem.* **1996**, *31*, 61–70.

Biography

David P Rotella earned his BS degree (*magna cum laude*) in pharmacy at the University of Pittsburgh, PA, in 1981, and a PhD in 1985 in medicinal chemistry at The Ohio State University College of Pharmacy under the direction of Donald T Witiak. The topic for his dissertation research was the synthesis and evaluation of novel platinum antitumor complexes and potential antimetastatic agents. He was a postdoctoral scholar from 1985 to 1987 in the Department of Chemistry at the Pennsylvania State University under the tutelage of Ken S Feldman, where he was engaged in the development of a novel [6 + 2] photocycloaddition reaction for the synthesis of cyclooctane rings.

His first independent position (1987–91) was as an assistant professor of pharmacognosy at the University of Mississippi School of Pharmacy, where his research interests included synthetic methods and the development of novel enzyme inhibitors. In 1991, he moved to Cephalon, Inc., where he led drug discovery programs for the discovery of potential neuroprotective agents. After accepting a position at Bristol-Myers Squibb in 1997, he became involved in the discovery of phosphodiesterase 5 inhibitors, and while at Lexicon Pharmaceuticals (2003–05), he directed drug discovery programs with metabolic disease applications. At Wyeth Research (2005 to the present) he is a team leader for the discovery of agents that may be useful for the treatment of schizophrenia and depression.

Rotella has authored approximately 25 peer-reviewed articles, is a co-inventor on seven patents or patent applications, and has been invited to speak at a variety of meetings on the topic of phosphodiesterase enzyme medicinal chemistry.

2.24.1 Introduction

Protein phosphorylation has become a central focus of drug discovery as the result of the identification and validation of promising therapeutic targets such as protein kinases, protein phosphatases, and phosphoprotein binding domains.^{1–24} With respect to such protein phosphorylation therapeutic targets, significant progress has been made in mapping the signal transduction pathways involved in disease, including in particular the molecular genesis and/or sustainment of various cancers, and several inflammatory, immune, metabolic, and bone diseases. Protein phosphorylation is an extraordinarily important component of life processes, including various signal transduction pathways underlying cellular proliferation, differentiation, metabolism, survival, motility, and gene transcription. Protein phosphorylation is a complex phenomenon, with molecular triggering, compensatory mechanisms, and both spatial and temporal factors contributing to the biological specificity and functional endpoints within the cellular milieu. The global phosphorylation state of proteins in cells is fundamentally impossible to decipher at high resolution, even though sophisticated methods (e.g., mass spectrometry, functional interaction traps, affinity chromatography) are emerging that can be used to analyze the so-called phosphoproteome. In this chapter, protein phosphorylation is described relative to our current understanding of the biology of protein kinase, protein phosphatase, and the phosphoprotein-interacting domain containing intracellular proteins. In addition a few noteworthy examples of drug discovery focused on developing small-molecule inhibitors of such therapeutic targets are described.

2.24.2 Molecular, Cellular, and Structural Biology of Protein Phosphorylation

Protein phosphorylation is controlled by superfamilies of protein kinases (e.g., tyrosine and serine/threonine protein kinases), protein phosphatases (e.g., tyrosine and serine/threonine protein phosphatases), and phosphoprotein-interacting domains (e.g., SH2, PTB, WW, FHA, and 14–3–3) of various catalytic/noncatalytic intracellular proteins to provide a multidimensional, dynamic and reversible orchestration of the phosphoprotein formation, hydrolysis, and molecular recognition at specific sites involving Tyr, Ser, and/or Thr residues (**Figure 1**).

A significant part (approximately 30%) of proteins encoded by the human genome are probably phosphorylated by ATP as the phosphoryl donor. Relative to Tyr phosphorylation, it is noted that pTyr represents only approximately 0.05% of total phosphorylated protein in normal cells (the remaining 99.95% being pSer and pThr), whereas oncogenic constitutively activated tyrosine kinases (see below) may increase this percentage to 0.5% within transformed cells.²⁵ Since the first observations of protein kinase activity about 50 years ago, there have been significant advances in basic research and, in recent years, drug development.²⁶ Key milestones in basic research into protein phosphorylation include the discovery of Src^{27,28} and epidermal growth factor receptor (EGFR),²⁸ as the first determined nonreceptor and growth factor receptors and tyrosine kinases, respectively, the discovery of PTP1B²⁹ as the first determined protein tyrosine phosphatase, and the discovery of the Src SH2 domain,³⁰ as the first determined phosphoprotein-interacting motif conferring molecular recognition to pTyr-containing cellular proteins. Such studies have led to a plethora of knowledge about a large and diverse superfamily of protein kinases, protein phosphatases, and phosphoprotein-interacting domains containing cellular proteins (**Table 1**).

2.24.2.1 Functional Genomics and Signal Transduction Pathways

Functional genomics and signal transduction pathway studies^{1,7,10,12–17,31–33} have correlated the possible relationships between gene deletion, fusion, mutation and/or overexpression of several known protein kinases, protein phosphatases, and phosphoprotein-interacting domains containing cellular proteins with aberrant cellular activities and in vivo phenotypes correlating to known cancers or other diseases (**Table 2**).

Cancer is one of the most complex diseases, and it is becoming increasingly well understood due to progress in deciphering several of its causative factors, including imbalances in cell-cycle progression, cell growth, and programmed cell death (apoptosis). Of the nearly 300 cancer genes that have been reported to date, protein kinases represent the largest group (nearly 10%) having structural homology. Furthermore, many cancers have been correlated with somatic

mutations of protein kinases, of which both receptor and nonreceptor tyrosine kinases have emerged as particularly significant therapeutic targets for cancer drug discovery. In humans, oncogenic transformation of protein kinases may arise from the fusion products of genomic rearrangements (e.g., chromosomal translocations), mutations (e.g., gain-of-function), deletions, and overexpression resulting from gene amplification. Typically, such transformations result in enhanced or constitutive kinase activity, which then effects subsequent altered downstream signal transduction. Some examples of oncogenic protein tyrosine kinases (see below) are EGFR, HER-2, HER-3, VEGFR-1 (Flt-1), VEGFR-2 (Flk-1/KDR), Flt-3, Flt-4, PDGFR- α , PDGFR- $\beta\beta$, KIT, RET, MET, IGF-1R, Abl, Src and the Src family, FAK, Pyk2, and the JAK family. Some examples of protein serine/threonine kinases that have been identified as key therapeutic targets with respect to oncogenic signaling (see below) are TGF $\beta\beta$ R, the CDK family, Raf, MEK, Erk, MAPK, PKC, PI3K, Akt/PKB, mTOR, and aurora kinases.

Functional genomics and signal transduction pathway studies have also correlated possible relationships between key protein phosphatases and the phosphoprotein-interacting domain containing cellular proteins and certain diseases (Table 2).^{12–17} Some examples of protein phosphatase therapeutic targets (see below) are PTP1B, CD45, and

Table 2 Some functional genomic relationships of protein kinases, protein phosphatases, and phosphoprotein-interacting domain containing cellular proteins with disease phenotypes

<i>Therapeutic target</i>	<i>Gene modification</i>	<i>Cancer (or other disease)</i>
Protein kinase		
EGFR/ErbB1	Overexpression, point mutations	Breast, NSCL, ovarian, glioblastoma
ErbB2/HER2/Neu	Overexpression, point mutations	Breast, ovarian, gastric, NSCL, colon
ErbB3/HER3	Overexpression	Breast
IGF-1R	Overexpression	Cervical, sarcomas
PDGFR- α	Overexpression	Glioma, glioblastoma, ovarian, GIST
PDGFR- β	Fusions (Tel-PDGFR- β)	Leukemias
	Overexpression	Glioma
Flt-3, Flt-4	Point mutation	Leukemias, angiosarcoma
KIT	Point mutations, overexpression	GIST, AML, myelodysplastic syndromes
MET	Point mutations, overexpression	Renal, hepatocellular
RET	Point mutations, fusions	Thyroid, parathyroid, adrenal
VEGFR1/Flt1	Expression	Tumor angiogenesis
VEGFR2/Flk1	Expression	Tumor angiogenesis
Src	C-terminal truncation, point mutations, overexpression	Colon, breast, pancreatic; metastasis
	Deletion (KO)	Osteopetrosis
Yes	Overexpression	Colon, melanoma
FAK	Overexpression	Metastases, adhesion, invasion
Pyk2	Overexpression	Metastases, adhesion, invasion
Abl	Fusions (Bcr-Abl), point mutations	CML, ALL
JAK1, JAK3	Overexpression	Leukemias
JAK2	Translocation	Leukemias
Protein phosphatase		
PTP1B	Deletion (KO)	Increased sensitivity to insulin, resistance to weight gain
Phosphoprotein-interacting domain (cellular protein)		
SH2 (SAP)	Point mutations	X-linked lymphoproliferative disease
SH2 (Btk)	Point mutation	X-linked agammaglobulinemia
SH2 (SHP-2)	Point mutations	Noonan's syndrome
PTB (IRS-1/2)	Point mutations	Type-2 diabetes mellitus
PTB (ARH)	Point mutations	Autosomal recessive hypercholesterolemia

CDC25A for diabetes (and obesity), immune and inflammatory disease, and cancer, respectively. Some examples of phosphoprotein-interacting domains containing cellular protein therapeutic targets (see below) are SH2 (e.g., Grb2, Shc, Src, and ZAP-70) and PTB (e.g., Shc and IRS-1), which are related to cancer, autoimmune disease, osteoporosis, type-2 diabetes mellitus, and autosomal recessive hypercholesterolemia.

2.24.2.2 Structural Genomics and Signal Transduction Pathways

Structural genomics has also provided insight into the molecular architecture and mechanistic properties of protein kinases, protein phosphatases, and phosphoprotein-interacting domains containing cellular proteins intimately involved in signal transduction pathways. Several hundred x-ray crystallographic structures have been determined for this collective group of signal transduction therapeutic targets.^{4-6,13-17,19,34-39}

In the case of protein kinases, both structural biology and drug design studies of small-molecule inhibitors has led to the determination of various modes of enzyme inhibition (i.e., both active and inactive conformations of the catalytic domain), and opportunities to exploit binding interactions beyond those existing for ATP and peptide substrates.^{5,6,9,34-50} Such findings have had an extraordinary impact both on understanding and on overcoming the challenges of resistance to small-molecule inhibitors resulting from mutations of the protein kinase (e.g., imatinib-resistant Bcr-Abl mutants).⁵¹ The number of x-ray crystallographic structures deposited in the Protein Data Bank for protein kinases and inhibitor complexes thereof has continued to increase at an extraordinary rate over the past decade (Table 3). Such three-dimensional structural information provides the incentive for the development of high-powered *in silico* drug design technologies to analyze computationally, visualize, and compare the binding sites of such protein kinases relative to their complexes with chemically diverse ligands, including ATP derivatives (e.g., nonhydrolyzable ATP analogs, ADP, AMP, and adenosine), small-molecule ATP mimetics (e.g., substituted purines, pyrrolopyrimidines, pyrazolopyrimidines, indolinones, pyridopyrimidinones, quinazolines, and quinolines), natural products (e.g., staurosporine), and an emerging class of kinase inactive conformation binding ligands (e.g., phenylaminopyrimidines and diarylureas).

Structural genomics provides the opportunity to exploit high-resolution x-ray structures as well as three-dimensional molecular models of protein kinases, protein phosphatases, and phosphoprotein-binding domains to guide and support drug discovery efforts focused on inhibitors. *In silico* drug design technologies may further be used to identify candidate inhibitors through virtual screening and *de novo* construction with respect to various templates and functional group elaborations thereof. As shown in a simplified perspective of the prototypic protein kinase Src complexed with ATP and substrate (Figure 2), key hydrogen-bonding and hydrophobic and ionic (e.g., Mg^{2+} coordination) interactions confer molecular recognition between the protein and ligands. Furthermore, an auxiliary binding site, which is often referred to as the 'specificity pocket', exists proximate to the purine ring of ATP, and this site has become a key focus of novel small-molecule inhibitor drug discovery for oncogenic protein kinases. The size, shape, and functional group composition of the specificity pocket varies between the different protein kinase gene families. Similar drug design approaches have been used to advance potent inhibitors of other protein kinases as well as inhibitors of protein phosphatases and phosphoprotein-binding domains.

2.24.3 Protein Kinase Therapeutic Targets and Drug Discovery

More than 500 protein kinase genes (excluding additional protein kinase pseudogenes) have been identified from the human genome and constitute nearly 2% of all human genes. Furthermore, chromosomal mapping studies have revealed that 244 protein kinases map to disease loci or cancer amplicons.² It is interesting to note that there may exist several times more proteins (in human) that utilize ATP than the estimated number of protein kinases. However, protein kinases are the largest family of structurally homologous proteins in the human genome that are critical components of the protein phosphorylation in cells. The catalytic domains of most protein kinases contain approximately 250–300 amino acids and have defined binding pockets for ATP (and typically complexed Mg^{2+} or Mn^{2+}) and substrate proteins. The classification of protein kinases by virtue of the alignment of catalytic domain sequences includes several major groups, as exemplified by AGC (e.g., PKA, PKG, and PKC family protein kinases), CaMK (e.g., calcium/calmodulin-regulated protein kinases), CMGC (e.g., CDK family kinases, MAPK, GSK, and CKII protein kinase), TK (e.g., EGFR and Src tyrosine kinases), and OPK (e.g., other protein kinases). There is a website devoted to protein kinase genomic analysis.^{2,2a}

Since the identification of the nonreceptor tyrosine kinase, Src, about 25 years ago,^{26a} a plethora of biological studies have steadily unraveled the complex orchestration of signal transduction pathways involving protein kinases of varying structural architecture and functional properties.^{1,7-10} The superfamily of protein kinases is exemplified by growth factor receptor tyrosine kinases (e.g., the EGFR family, VEGFR family, PDGFR family, and FGFR family), nonreceptor tyrosine kinases (e.g., Abl, the Src family, and FAK), growth factor receptor serine/threonine kinases (e.g., TGF β R), and nonreceptor serine/threonine as well as dual specificity kinases (e.g., CDK family, Raf, MEK, MAPK, PI3K, PKC, PKB/Akt, and mTOR). A number of such protein kinases have proven to be particularly significant as therapeutic targets for cancer drug discovery (see below).

2.24.3.1 Receptor and Nonreceptor Tyrosine Kinases

The seminal identifications of Src and EGFR as oncogenic protein tyrosine kinases launched a campaign in both basic research and drug discovery that has resulted in the creation of first-generation therapies, including small-molecule inhibitors and monoclonal antibodies. Of the approximately 60 receptor tyrosine kinases presently known, each has cell membrane-spanning sequences with extracellular ligand-binding domains and intracellular catalytic (kinase) domains (Figure 2). Ligand (e.g., growth factor) binding induces dimerization or an increased association of already dimerized subunits and subsequent autophosphorylation or cross-phosphorylation of proximate receptors at specific tyrosine residues on the intracellular carboxyl terminal sequences. With respect to signal transduction regulation, the resultant phosphotyrosine (pTyr) sequences of such activated receptor tyrosine kinases may then interact with various intracellular proteins by virtue of pTyr molecular recognition by SH2 domains (e.g., Src, phospholipase-C γ , and phosphatidylinositol-3-kinase, Grb2) or PTB domains (e.g., IRS-1) to modulate various downstream biological pathways. As representatives of nonreceptor tyrosine kinases, Src and Abl each illustrate multiple domain architectures, which include noncatalytic SH2 and SH3 domains (Figure 3).

Some noteworthy examples of receptor and nonreceptor protein tyrosine kinases described further below.

2.24.3.1.1 Epidermal growth factor receptor family kinases

The EGFR family of growth factor receptor tyrosine kinases has been the major focus of drug discovery efforts over the past decade to advance new therapies for the treatment of several cancers (e.g., lung, breast, colon, prostate, ovarian, head and neck, and gliomas). Extracellular-mediated triggering of EGFR by EGF (or other cognate ligands) results in the activation of a network of signal transduction pathways that modulate cell division, apoptosis, motility, and adhesion.^{52–55} EGFR (HER-1/erbB), HER-2 (Neu/erbB-2), HER-3 (erbB-3), and HER-4 (erbB-4) constitute four members of the EGFR family. Dysregulation of EGFR family signaling can result from gene amplification and/or mutations, effecting overexpression and, in some cases, constitutive activity correlating with certain cancers (e.g., lung, gliomas, breast, and ovarian). Recently, two small-molecule inhibitors have advanced clinically to become the first approved EGFR kinase inhibitors for the treatment of specific cancers. These first-generation EGFR tyrosine kinase inhibitors are ZD1839 (Iressa, gefitinib) and OSI-774 (Tarceva, erlotinib, CP-358774); they represent noteworthy ATP-competitive, small molecules based on a quinazoline template (Figure 4).

ZD1839^{56–61} is a potent EGFR tyrosine kinase inhibitor ($IC_{50} = 23$ nM) with high selectivity relative to other protein tyrosine kinases (e.g., HER-2, and VEGFR-1 and VEGFR-2) and serine/threonine kinases. ZD1839 inhibits the proliferation of several cancer cell lines (e.g., NSCLC, breast, ovarian, and colon), shows synergistic enhancement of the inhibitory action of single-agent cytotoxic drugs, and effects dose-dependent antitumor activity in vivo in nude

Figure 3 Schematic representation of the molecular architecture of receptor tyrosine kinases (e.g., the IRK, IGFR, EGFR, FGFR, PDGFR, and VEGFR families) and nonreceptor tyrosine kinases (e.g., the Src family and Abl) showing the catalytic tyrosine kinase (TK) as well as noncatalytic (SH2 and SH3) domains.

Figure 4 Some EGFR family tyrosine kinase inhibitors that have advanced to clinical testing.

mice bearing several human cancer cell xenografts. Very recently, a proteomics study identified cellular targets (beyond EGFR) for ZD1839, and showed that several other protein tyrosine kinases (e.g., Brk, Met, Yes, Hck, and EphB4) as well as protein serine/threonine kinases (e.g., RICK, GAK, Aurora-B, and p38 MAPK) were inhibited.⁶² ZD1839 has been clinically tested and was first approved (in Japan) for the treatment of nonsmall cell lung cancer (NSCLC) as related to inoperable or recurrent disease; it has gained further approvals for previously treated NSCLC in the USA and other countries.

OSI-774^{63–66} is also a potent inhibitor of EGFR tyrosine kinase ($IC_{50} = 20$ nM). It has high selectivity for other protein tyrosine kinases and high efficacy in vivo in nude mice bearing human cancer cell xenografts. Recently determined x-ray crystal structures of the EGFR tyrosine kinase domain, including both apoprotein and a complex with OSI-774, have provided the first experimental analysis of the EGFR family. OSI-774 effects a long-lasting inhibition of EGFR autophosphorylation in tumor xenografts (ex vivo analysis) following high-dose single administration. In combination with cisplatin, OSI-774 showed additive antitumor activity and enhanced apoptosis via suppression of the PKB/Akt survival pathway. Tarceva has been clinically tested and it has just been approved in the USA for the treatment of patients with locally advanced or metastatic NSCLC after failure of at least one prior chemotherapy.

Significant clinical attention has recently been focused on identifying the activating mutations in EGFR tyrosine kinase that underlie the responsiveness of NSCLC (primary tumors from patients) to Iressa.^{67,68} In brief, this study indicated a correlation with NSCLC patients having marked response to Iressa, with a preponderance of somatic mutations in the ATP-binding domain of the EGFR gene. In this particular scenario, such EGFR mutations may stabilize the binding of some ATP-competitive inhibitors, such as ZD-1839, to afford greater sensitivity relative to

wild-type EGFR. Recent clinical studies have also shown that acquired resistance to either Iressa or Tarceva may be correlated with a specific mutation of EGFR at the ATP binding site, namely Thr-790 substitution by Met (T790 M).⁶⁹ Overall, the above clinical results have a significant impact on drug discovery related to EGFR kinase inhibitors within the scope of profiling both wild-type and mutant EGFR kinases.

Relative to ZD1839 and OSI-774, some other noteworthy second-generation EGFR kinase inhibitors that have advanced to clinical testing include GW-572016, PKI-166, PD183805 (CI-1033, canertinib), and EKB-569 (Figure 4). These compounds have different biological profiles and mechanisms of action versus ZD-1839 and OSI-774. GW-572016^{70–73} is a potent quinazoline-based inhibitor of EGFR (IC_{50} = 11 nM) and HER-2 (IC_{50} = 9.2 nM); it is able to block signaling from either receptor, which may be overexpressed in certain cancers (e.g., breast). GW-572016 inhibits proliferation in EGFR/HER-2 overexpressing cancer cells and was effective in vivo at high dose to suppress tumor growth in breast as well as head and neck cancer xenograft mice. PKI-166^{74–77} illustrates a potent pyrrolopyrimidine-based dual inhibition of EGFR (IC_{50} = 1 nM) and HER-2 (IC_{50} = 11 nM), with additional inhibitor selectivity against Abl, Src, and VEGFR-2 tyrosine kinases (IC_{50} = 26, 103, and 327 nM, respectively). CI-1033^{78–80} is a potent quinazoline-based inhibitor of EGFR (IC_{50} = 1.5 nM) and other EGFR family members. In contrast to the aforementioned quinazoline-based compounds, CI-1033 is chemically novel due to its incorporation of an acrylamide electrophilic moiety that was designed to interact covalently (as a Michael acceptor) with a proximate cysteine residue to the ATP binding pocket. This hypothesis was confirmed experimentally, and the uniqueness of this cysteine relative to other receptor or nonreceptor tyrosine kinases may account for the extraordinary selectivity properties of CI-1033 to inhibit EGFR. CI-1033 was a potent inhibitor in vitro and in vivo, including in several EGFR/HER-2-dependent cancer xenograft models, and it has been found to synergize with various cytotoxic agents and radiation. Like CI-1033, EKB-569^{81–84} is also an acrylamide-containing molecule; however, EKB-569 is a cyanoquinoline template-based compound that has been shown to be a potent inhibitor of both EGFR (IC_{50} = 1.3 nM) and HER-2 (IC_{50} = 15 nM). EKB-569 inhibits EGFR and HER-2 expressing cell proliferation in vitro, and it is also found to be effective in vivo in human squamous cancer xenografts in mice. Furthermore, EKB-569, alone or in combination with a nonsteroidal, anti-inflammatory agent was determined to be effective in vivo in a mouse model of human colon cancer.

2.24.3.1.2 Vascular endothelial growth factor receptor, Flt-3, and KIT family kinases

In addition to the EGFR family kinases there are many other promising growth factor receptor kinase therapeutic targets for drug discovery efforts focused on cancer.^{34–50} These include VEGFR family kinases (e.g., VEGFR1 to VEGFR3), PDGFR family kinases (e.g., PDGFR- α , PDGFR- β , CSF-1R, KIT, and Flt-3), insulin family kinases (e.g., IGF-1R and IRK), FGFR family kinases (e.g., FGFR-1 to FGFR-4), NGFR family kinases (e.g., TrkA, TrkB, and TrkC), HGFR family kinases (e.g., Met and Ron), EPHR family kinases (e.g., EPHA1 to EPHA8 and EPHB1 to EPHB6) and TIE family kinases (e.g., TIE, TEK, RYK, DDR, RET, and ROS).

Furthermore, there has emerged an increasing effort to understand the biology of tumors with respect to angiogenesis and lymphangiogenesis in order to identify therapeutic targets critical for the recruitment and formation of blood vessels and lymphatics.^{85–87} One of the major pathways involved in both processes is the VEGF family of ligands and receptors (VEGFR-1/Flt-1 and VEGFR-2/Flk-1/KDR for angiogenesis, and VEGFR-3/Flt-4 for lymphangiogenesis). Overexpression of VEGF ligands has been associated with various cancers (e.g., colorectal, gastric, pancreatic, breast, prostate, lung, and melanoma). Upregulation of VEGFR expression occurs in activated endothelium and is high in blood vessels surrounding tumor tissue that is growing and invading. Some examples of first-generation VEGFR tyrosine kinase inhibitors that are noteworthy ATP-competitive, small-molecules based on a variety of different templates include SU-5416 (semaxanib), SU-6668, SU-11248, PTK-787 (CGP79787, vatalanib), ZD-6474, CEP-7055, and CP-547632 (Figure 5).

SU-5416,^{88–91} a prototype lead compound of a series of indolinone template-based small-molecule inhibitors of VEGFR, was the first to advance to clinical testing with a focus on metastatic colorectal cancer in combination with chemotherapy. Unfortunately, the Phase II/III clinical studies showed no survival advantage for SU-5416, and thus further drug development was discontinued. A second indolinone analog, SU-6668,^{91–93} was determined to be a very potent inhibitor of PDGFR (IC_{50} = 8 nM) relative to VEGFR-2 (IC_{50} = 2.1 μ M) and it was quite effective in inhibiting VEGF-driven mitogenesis in cells. SU-6668 effected significant inhibition of a panel of human tumor xenografts by oral administration in nude mice, and it was further shown to exhibit in vivo antiangiogenic and antimetastatic activities in colon-cancer-cell injected mice. SU-6668 is in Phase II clinical trials for solid tumors. A third indolinone analog, SU-11248,^{94–97} was determined to be a highly potent inhibitor of VEGFR-2 (IC_{50} = 9 nM) and PDGFR- β (IC_{50} = 8 nM) as well as relatively potent inhibitor of other receptor tyrosine kinases (FGFR-1, Flt-3, and KIT). SU-11248 effects potent inhibition of cell proliferation as driven by VEGF, PDGF- β , and FGF. SU-11248 was determined to be orally effective and showed potent in vivo antitumor activity in mice relative to several human xenografts. SU-11248 has also shown

Figure 5 Some VEGFR family tyrosine kinase inhibitors that have advanced to clinical testing.

in vivo antiangiogenic activity in a lung cancer metastasis model. SU-11248 is undergoing Phase III clinical trials for various cancers. PTK-787,^{98–101} a novel phthalazine-based small-molecule inhibitor, is a potent inhibitor of VEGFR-1 ($IC_{50} = 77$ nM) and VEGFR-2 ($IC_{50} = 37$ nM). PTK-787 effects antiangiogenic activity in vitro, including inhibition of VEGF-driven cell proliferation, survival, and cell migration. PTK-787 demonstrates effective in vivo antiangiogenic and antitumor activity in several animal models, and it has further shown in vivo antimetastatic activity, in both orthotopic renal cell carcinoma and human pancreatic xenograft models. ZD-6474^{102–106} is an inhibitor of VEGFR-2 ($IC_{50} = 40$ nM), VEGFR-3 ($IC_{50} = 110$ nM), EGFR ($IC_{50} = 500$ nM), and RET ($IC_{50} = 100$ nM). ZD-6474 effectively inhibits endothelial cell proliferation driven by VEGF, EGF, and FGF. ZD-6474 has been shown to inhibit the growth of various human tumor xenografts in a dose-dependent manner, and it was found also to inhibit primary tumor growth in a spontaneous metastasis model of breast cancer at high dose. ZD-6474 is in Phase II clinical trials for solid tumors. CEP-7055,^{107,108} a water-soluble prodrug of an indenopyrrolocarbazole template-based parent molecule (CEP-5214), is a potent inhibitor of VEGFR-1, VEGFR-2, and VEGFR-3 (IC_{50} in the range 12–18 nM). CEP-7055 is a potent inhibitor of tumor growth in several subcutaneous tumor xenografts, including decreasing the number of metastases. CEP-7055 is in Phase I clinical trials, with indications for solid tumors. CP-547632,¹⁰⁹ an isothiazole template-based molecule, is a potent inhibitor of VEGFR-2 ($IC_{50} = 11$ nM) and FGFR-2 ($IC_{50} = 9$ nM). CP-547632 was found to be an orally active inhibitor of VEGF-induced corneal angiogenesis in mice, and it was also effective in significantly inhibiting human xenograft in nude mice. CP-547632 is in Phase I clinical trials, with indications for solid tumors.

The functional relationship between Flt-3 receptor tyrosine kinase and acute myeloid leukemia (AML) has been implied by the fact that about 30% of AML patients have constitutively activating internal tandem duplications of the juxtamembrane domain or mutations in the activation loop of the Flt-3 receptor kinase.^{110–112} First-generation Flt-3 kinase inhibitors, PKC-412 (CGP41251, midostaurin), CEP-701 (KT-5555), SU-11248 (see above), and MLN-518 (CT-53518), are particularly noteworthy in terms of their chemical diversity (Figure 6) as well as the fact that they have each advanced to clinical testing in patients with AML harboring Flt-3 activating mutations.

PKC-412,^{113,114} a derivative of the natural product staurosporine, is an inhibitor of Flt-3 and several other protein kinases, including VEGFR-2, PDGFR, KIT, and Syk. CEP-701,¹¹⁵ an indolocarbazole derivative, is a potent inhibitor of

Figure 6 Some Flt-3 and KIT tyrosine kinase inhibitors that have advanced to clinical testing.

Flt-3 and Trk tyrosine kinases. SU-11248 (see above) is also a potent inhibitor of Flt-3 tyrosine kinase. MLN-518,¹¹⁶ a quinazoline template-based molecule, is a potent inhibitor of Flt-3, PDGFR, and KIT tyrosine kinases. Several studies have been described^{113–119} that show the effectiveness of these compounds in vitro and in vivo, including the induction of apoptosis in cell lines with Flt-3 activating mutations and prolonging the survival of mice expressing mutant Flt-3 in their bone marrow cells. Prediction of resistance to some of the above small-molecule Flt-3 tyrosine kinase inhibitors using an in vitro screen designed to identify mutations of the ATP-binding pocket has shown several key amino acid mutations, including G697R, that confer resistance and potential clinical problems with a single-agent Flt-3 drug therapy.¹²⁰ In this regard, mutations and translocations involving both receptor (e.g., Flt-3 and KIT) and nonreceptor tyrosine kinases (e.g., Abl, see below) are now well recognized within the scope of transformed hematopoietic cells and underlying myeloid and acute leukemias.¹²¹ Like the aforementioned clinical outcomes from studies on EGFR kinase inhibitors, such mutations enhance the complexity of small-molecule drug discovery relative to lead optimization as well as both in vitro and in vivo testing in disease models, which must reflect the inclusion of known mutant tyrosine kinase therapeutic targets.

KIT is a member of a family of growth factor receptor tyrosine kinases that includes RET and PDGFR. KIT is known to contribute to the growth and survival of cancers, especially those such as gastrointestinal stromal tumors (GISTs) in which it is frequently mutated and activated.¹²² Co-expression of KIT and its ligand, stem cell factor (SCF), are known to exist in breast cancer, small-cell lung carcinoma, gynecological tumors, and malignant glioma cells. More than 30 gain-of-function mutations of KIT have been identified.¹⁰ Juxtamembrane domain mutations of KIT are common in GISTs, while kinase activation loop mutations (e.g., D816V) are common in both systemic mastocytosis and acute myelogenous leukemia (AML). First-generation KIT tyrosine kinase inhibitors STI-571 (CGP57148, Gleevec/Glivec, imatinib), SU-6668 (see above), SU-11248 (see above), PTK-787 (see above), ZD-6474¹¹ (see above), PKC-412 (see above), MLN-518 (see above), PD180970, and AP23848, are particularly noteworthy small molecules based on a variety of different templates (Figure 6) as well as the fact that several compounds, including MLN518 and PKC-412 (each also being Flt-3 tyrosine kinase inhibitors, see above), are in clinical testing for AML.

Initial studies to investigate a KIT tyrosine kinase inhibitor with respect to KIT-driven cell lines, including both wild-type and mutant KIT, which provided proof-of-concept were achieved with STI-571.^{123–125} Consistent with preclinical data showing that KIT wild-type and juxta domain mutants were highly sensitive to STI-571, clinical testing of imatinib revealed that GIST patients having these mutations had a 30–70% response rate to drug therapy.¹²⁶ However, cells expressing KIT activation loop mutant D816V are resistant to imatinib, and patients with systemic mastocytosis involving this mutant are completely resistant to imatinib therapy.^{123,127–129} With regard to identifying small-molecule inhibitors of such KIT tyrosine kinase mutants (i.e., imatinib-resistant), some progress has been achieved with several compounds, including SU-11652, MLN-518, PD180979, and AP23848.^{130–132} For example, AP23848 has very recently been shown to be a highly potent inhibitor of KIT D816V mutant-expressing cell proliferation as well as to induce cell cycle arrest and apoptosis in vitro, and it was further effective in vivo in inhibiting KIT D816V mutant expressing tumor growth at high dose.

2.24.3.1.3 Bcr-Abl kinases

Of the nonreceptor tyrosine kinases that have emerged as highly promising therapeutic targets for cancer therapy, Bcr-Abl provides a fascinating story of mechanistic and structural biology involving mutations and the discovery of small-molecule inhibitors binding to either the so-called ‘active’ or ‘inactive’ conformations of the catalytic domain. Bcr-Abl is encoded by the Bcr-Abl oncogene, a translocation gene product found on the Philadelphia (Ph) chromosome in hematopoietic stem cells, and is a causative factor in chronic myelogenous leukemia (CML) and Ph + acute lymphoblastic leukemia (ALL).¹³³ The chimeric Bcr-Abl protein is expressed with a constitutively active tyrosine kinase, and it has been found to be essential for Bcr-Abl driven transformation and excessive proliferation of Ph + cells of myeloid and lymphoid lineage.

STI-571 (Figure 6, see above)^{134,135} illustrates the first successful development of small-molecule inhibitor of Bcr-Abl kinase to advance into clinical testing and the first-in-class compound approved in the USA for the treatment of CML (and an increasing number of other cancer indications, including GIST, see above). STI-571 is a relatively potent inhibitor of Bcr-Abl ($IC_{50} = 250$ nM) and several other protein kinases, including KIT ($IC_{50} = 100$ nM) and PDGFR ($IC_{50} = 100$ nM). STI-571 has a novel chemical structure relative to previously known ATP-mimetic templates and it has a novel mechanism of inhibition (binding to an inactive conformation of the enzyme), as revealed by recent x-ray structures of STI-571 and analogs complexed with the Abl tyrosine kinase.^{136,137} STI-571 was determined to bind to an inactive conformation of Abl kinase in which the active loop mimics bound peptide substrate. The potency of STI-571 against activated forms of Bcr-Abl probably results from the dynamic nature of protein kinases relative to switching

between active and inactive conformations, thus allowing STI-571 to gain entry and effect inhibition. STI-571 was first determined to be effective *in vivo* with respect to the inhibition of tumor growth in a model developed using syngeneic mice injected with Bcr-Abl transformed cells,¹³⁸ and a plethora of both *in vitro* and *in vivo* studies have further examined in cellular mechanisms of action and pharmacological properties relative to Bcr-Abl as well as other therapeutic targets.¹³⁴ However, despite the successful drug development of imatinib, the issue of Bcr-Abl mutations effecting resistance in CML and ALL patients has confounded the overall effectiveness of STI-571, and this situation has provided an opportunity for second-generation, small-molecule inhibitors having superior potency to Bcr-Abl wild-type and many of the known clinically relevant mutants of Bcr-Abl tyrosine kinase.

Some second-generation Bcr-Abl kinase inhibitors that exemplify advances in potency and/or selectivity toward Bcr-Abl mutants relative to STI-571 include AMN-107, BMS-354825, ON012380, SKI-606, PD180970 (see above), PP1, CGP-76030, and AP23464 (Figure 7). Several compounds, including SKI-606, AZM-475271, PD-180970, PP1, CGP-76030, and AP23464, have been initially described as Src or Src family kinase inhibitors (see below). Both AMN-107 and BMS-354825 are in clinical trials for Bcr-Abl-dependent leukemias.

AMN-107,¹³⁹ a second-generation analog of STI-571, is a more potent inhibitor of Bcr-Abl kinase ($IC_{50} < 30$ nM) as well as being active against several STI-571-resistant mutants (e.g., E255 K, E255 V, F317L, and M351 T) except T315I. AMN-107 inhibits the proliferation of STI-571-resistant Bcr-Abl-expressing cells (except the T315I mutant). An x-ray structure of AMN-107 complexed with Abl kinase mutant M351 T showed that it binds in a similar mode as STI-571; however, the protein α -helix containing M351 T shifts slightly to accommodate binding of AMN-107 relative to its unique disubstituted aniline moiety, reflecting the chemical modification relative to STI-571. In contrast, the Bcr-Abl T315I mutant presumably blocks interaction of AMN-107 by sterically preventing the ability of the inhibitor to penetrate into the so-called 'hydrophobic specificity pocket' that exists proximate to the ATP binding site. AMN-107 is in Phase I clinical trials with indications for CML and ALL. BMS-354825,^{140–142} a novel pyrimidinylaminothiazole template-based molecule, is a highly potent inhibitor of Bcr-Abl ($IC_{50} < 1$ nM), Src ($IC_{50} = 0.5$ nM), and KIT ($IC_{50} = 5$ nM), and it was determined to be further effective in inhibiting both PDGFR- β ($IC_{50} = 28$ nM) and EGFR ($IC_{50} = 180$ nM). An x-ray structure of BMS-354825 revealed its binding to the ATP pocket relative to a number of hydrogen-bonding interactions between the inhibitor and protein, with the disubstituted benzamide moiety fitting well into the hydrophobic specificity pocket (and further implicating the lack of potency against the T315I mutant). BMS-354825 has been described to be an effective inhibitor of several Bcr-Abl mutants (except for T315I) *in vitro*, and *in vivo* studies have shown that it prolonged survival of mice infused with Bcr-Abl wild-type or M351 T mutants. Further comparative analysis of BMS-354825 and STI-571 using saturation mutagenesis experiments showed that each molecule gave rise to an overlapping but different population of mutants, and that combination of the two inhibitors significantly reduced recovery of drug-resistant clones. BMS-354825 is in Phase II clinical trials for CML.

ON012380,¹⁴³ a novel small molecule that is not ATP competitive, is a highly potent inhibitor of Bcr-Abl ($IC_{50} = 1.5$ nM). Preliminary biochemical analysis indicates that ON012380 is substrate-competitive, and if further supported by structural studies, ON012380 would constitute an important breakthrough in small-molecule inhibitor drug discovery for protein kinases. ON012380 induces apoptosis of cells expressing Bcr-Abl as well as a number of mutants (including T315I) at low nanomolar concentrations. ON012380, at high dose, was effective *in vivo* in causing regression of leukemias induced by Bcr-Abl T315I mutant expressing cells injected into mice. SKI-606,^{144,145} a novel quinoline-carbonitrile template-based molecule, is a highly potent inhibitor of Abl kinase ($IC_{50} = 1$ nM) as well as Src ($IC_{50} = 1.1$ nM). SKI-606 effects potent antiproliferative activity against CML cells *in vitro*, and *in vivo* studies further showed SKI-606, at high dose, to cause complete regression of CML xenografts in nude mice. PD180970^{146–148} is a highly potent inhibitor of Abl ($IC_{50} = 2.2$ nM). PD180970 induces apoptosis in CML cells *in vitro*, and it was further shown to block Stat5 signaling and induce apoptosis in a Bcr-Abl high-expressing cell line that is resistant to STI-571. PD180970 was also determined to inhibit several STI-571-resistant Bcr-Abl mutants *in vitro*, with the exception of T315I. A related pyridopyrimidine, PD166326,^{149,150} has been shown to be highly potent against Bcr-Abl kinase and several Bcr-Abl mutants *in vitro*. PP1^{151,152} and a related pyrazolopyrimidine template-based analog, PP2,¹⁵³ were found to be effective inhibitors of Bcr-Abl kinase *in vitro*. CGP76030,¹⁵³ a pyrrolopyrimidine template-based molecule, has been shown to be an effective inhibitor of Bcr-Abl kinase and STI-571-resistant Bcr-Abl mutants (except for T315I) *in vitro*. AP23464,¹⁵⁴ a purine template-based compound, has been determined to be a highly potent inhibitor of Abl kinase ($IC_{50} = 1$ nM) and to be effective in inhibiting Bcr-Abl and STI-571-resistant Bcr-Abl cell lines (except for T315I) *in vitro*. AP23464 effectively ablated Bcr-Abl tyrosine phosphorylation, blocked cell cycle progression, and promoted apoptosis in Bcr-Abl-expressing cells.

Beyond the development of Bcr-Abl kinase inhibitors capable of inhibiting essentially all clinically relevant Bcr-Abl mutants, including the challenging T315I mutant, a combination of Bcr-Abl tyrosine kinase inhibitors may provide a strategy to provide a potentially fail-safe therapy for CML or Ph + ALL patients. Furthermore, combination strategies

Figure 7 Some Bcr-Abl and dual Src and Bcr-Abl tyrosine kinase inhibitors, including several that have advanced to clinical testing.

may include imatinib (or other Bcr-Abl kinase inhibitor) together with another drug that acts on a different, but mechanistically related, signal transduction pathway therapeutic target to overcome STI-571 resistance.¹⁵⁵ In this regard, the farnesyl protein transferase inhibitor SCH66336^{156,157} and PI3K inhibitor OSU-013012¹⁵⁸ have recently been shown to enhance the antiproliferative properties of imatinib in both Bcr-Abl- and STI-571-resistant Bcr-Abl-expressing cells (including T3151) *in vitro*.

2.24.3.1.4 Src family kinases

As a prototype of the superfamily of protein tyrosine kinases to be identified and characterized, Src tyrosine kinase has been the focus of a great many molecular, cellular, and structural biology studies designed to understand its role in signal transduction pathways as well as in disease processes, including cancer, osteoporosis, and both tumor- and inflammation-mediated bone loss.^{10,36,158–167} Such pioneering studies on Src have provided some of the first evidence correlating protein kinase activity and substrate protein phosphorylation in the regulation of various signal transduction pathways critical to cell growth, cell cycle, cell migration, cell survival, and malignant transformation of mammalian cells. Src family kinases include Fyn, Yes, Yrk, Blk, Fgr, Hck, Lyn, and the Frk subfamily members Frk/Rak and Iyk/Bsk. These Src family kinases exhibit a broad spectrum of functional properties, including cell growth, differentiation, survival, cytoskeletal alterations, adhesion, and migration. As the result of many landmark studies,^{168–190} the molecular mechanisms of Src-dependent cancer cell biology (e.g., cell–cell and cell–matrix adhesion, cell motility, and invasion), including cancer metastasis and angiogenesis, have been revealed (Figure 8), as described below. Studies using Src-specific antisense DNA have shown that elevated Src expression and/or activity is correlated with tumor growth in specific cancers having HER2 or c-Met receptors. Elevated Src expression and/or activity has been found in breast cancer cell lines and malignant breast tumors. Src has been implicated in metastatic colon cancer, head and neck cancers, and pancreatic cancer. Activating Src mutations in advanced human colon cancer have also been identified. Src has been implicated in malignant transformations for certain cancers, such as breast cancer and multiple myeloma, via EGF-R or interleukin-6 receptor (IL6-R) signaling pathways, respectively, which commonly activate the transcription factor known as ‘signal transducing activators of transcription-3’ (STAT3). Aberrant activation of STAT signaling pathways have been linked to oncogenesis with respect to the prevention of apoptosis. Relative to integrin receptors and the dynamic relationship between cell–cell and cell–matrix interactions, Src-induced deregulation of E-cadherin in colon cancer cells has been determined to require integrin signaling, and Src kinase activity is required for adhesion

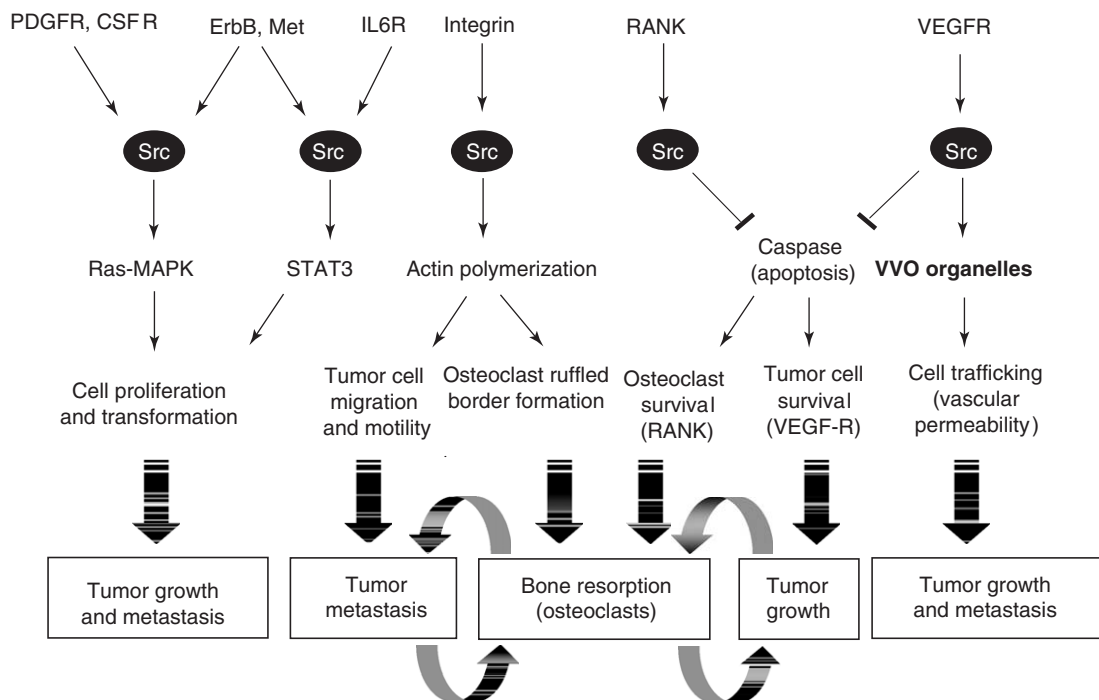

Figure 8 Some Src-dependent signal transduction pathways related to cancer cell growth and metastasis, and osteoclast-driven bone resorption. (Adapted from Sawyer, T.; Boyce, B.; Dalgarno, D.; Iulucci, J. *Expert Opin. Investig. Drugs* **2001**, *10*, 1327–1344.)

turnover associated with cancer cell migration. Collectively, such findings are consistent with the correlation of Src kinase activity (via overexpression of CSK and/or dominant-negative mutants of Src) with cellular and *in vivo* metastasis. With respect to VEGFR, Src is intimately involved in VEGF-mediated angiogenesis and vascular permeability. In particular, the ability of VEGF to disrupt endothelial barrier function, which has been correlated with tumor cell extravasation and metastasis, is mediated through Src kinase. In recent years, gene expression fingerprinting and RNA interference-based analysis of Src-transformed in cancer cells have provided insight to explore further the Src-induced signal transduction and gene activation pathways.

With respect to its structural architecture, Src possesses both catalytic and noncatalytic regulatory motifs (i.e., SH3 and SH2 domains; see below), and these are functionally important in signal transduction processes. The molecular basis of Src activation has been revealed further by structural biology studies, including x-ray structures of near full-length Src (i.e., SH3-SH2-tyrosine kinase).^{191–193} From such investigations, it has been shown that Src can exist in an assembled, inactive conformation (Figure 9) involving intramolecular binding of the SH2 domain with the carboxyl terminal tail (phosphorylated at Tyr-527), as well as intramolecular binding of the SH3 domain with a linker sequence between the SH2 domain and the amino terminal lobe of the tyrosine kinase. Src activation is believed to involve displacement of the imperfect intramolecular SH3 and SH2 interactions within the inactive conformation by intermolecular binding with SH3 and/or SH2 cognate proteins, and subsequent phosphorylation at Tyr-416 (kinase domain) and dephosphorylation at Tyr-527.

Of relevance to Src family kinases, an x-ray structures of Lck have been determined¹⁹⁴ as complexes of the tyrosine kinase domain with AMP-PNP, staurosporine, and PP2. The Lck tyrosine kinase–PP2 complex revealed the detailed molecular interactions of the ATP-mimetic pyrazolopyrimidine template with respect to conserved hydrogen bonding (experimentally comparable with the AMP–PNP complex). The inhibitor PP2 binds into the large, hydrophobic, specificity pocket that is proximate, but not accessed by, AMP–PNP (or ATP). It is noteworthy with respect to the entire superfamily of protein kinases, that this hydrophobic specificity pocket varies in size, shape, and amino acid composition with further relationship to the conformation (active or inactive) of the enzyme and, therefore, provides insight for future drug discovery. Src kinase has been exploited as a prototype model for protein engineering approaches to mutate the ATP-binding pockets of protein kinase, with the objective of enhancing selectivity for synthetic ATP analogs or inhibitors.^{195–197} In brief, mutation of a conserved amino acid in the ATP binding pocket was made to create a unique new site that would accommodate a synthetic ATP substrate analogue, namely, [γ -³²P]-N⁶-(benzyl)-ATP, which then provides a matched set of enzyme–substrate to explore signal transduction pathways with respect to the identification of cellular substrates under varying experimental conditions. The design of Src kinase inhibitors has focused on a number of strategies,^{5,35,36,81,162,163,198,199} including ATP template-related mimetics, novel heterocyclic leads (from screening corporate chemical collections and/or combinatorial libraries), natural products, and peptide substrate-based compounds.

Some first- and second-generation Src (and Src family) kinase inhibitors that exemplify a variety of different templates include BMS-354825 (see above), SKI-606 (see above), PD180970 (see above), PP1 (see above),

Figure 9 X-ray structure of Src SH3-SH2-tyrosine kinase complexed with AMP-PNP, showing a downregulated, inactive conformation of the protein. (Adapted from Xu, W.; Harrison, S. C.; Eck, M. J. *Nature* **1997**, 285, 595–602.)

CGP-76030 (see above), AP23464 (see above), AZM-475271, SU-6656, and AP23451 (Figure 10). BMS-354825 and AZD-530 (an analog of AZM-475271 with unpublished chemical structure) are in clinical trials for Src-dependent cancers. BMS-354825¹⁴⁰ is a highly potent inhibitor of Src kinase as well as Bcr-Abl kinase (see above). There are as yet no reports that describe the biological properties of BMS-35825 or AZD-530 with respect to Src-dependent disease models in vitro or in vivo.

SKI-606,^{144,145,200–202} is a highly potent inhibitor of Src kinase ($IC_{50} = 1.1$ nM). SKI-606 exhibits antiproliferative efficacy against Src-transformed fibroblasts in vitro and in vivo in a xenograft model. PD180970 and related pyridopyrimidine analogs^{146–148,203–205} have been advanced as potent inhibitors of Src kinase with varying selectivities to PDGFR, FGFR, and EGFR tyrosine kinases. PP1 and the related pyrazolopyrimidine analog PP2 were first described²⁰⁶ as potent inhibitors of Src-family kinases with marked selectivity versus ZAP-70, JAK2, EGF-R, and PKA kinases. PP1 has provided a key Src kinase inhibitor to determine the role of Src in VEGF-mediated angiogenesis and vascular permeability.^{186,187} PP1 is an effective inhibitor of Src-driven human breast cancer cells with respect to heregulin-dependent or independent growth.²⁰⁷ pp1 has also been reported²⁰⁸ to inhibit collagen type-I-induced E-cadherin downregulation and the consequent effects on cell proliferation and metastatic properties. CGP-76030 and related pyrrolopyrimidine analogs have been described as potent and selective inhibitors of Src kinase in vitro and in vivo in animal models of osteoporosis.^{209,210} CGP-76030 has been determined to reduce growth, adhesion, motility, and invasion of prostrate cancer cells.²¹¹ AP23464,³⁵ a purine template-based compound, is a highly potent inhibitor of Src tyrosine kinase ($IC_{50} < 1$ nM), and it has recently been utilized²¹² to examine the functional relationship of Src and FAK in adhesion turnover associated with migration of colon cancer cells. AZM-475271,²¹³ a quinazoline template-based compound, is a potent inhibitor of Src kinase and has been determined to be effective in inhibiting tumor growth in Src-transformed cell xenograft mice as well as in orthotopically implanted pancreatic cancer cells in nude mice. Such studies on AZM-475271 have supported the concept of the therapeutic potential of a Src kinase inhibitor for cancer invasion and metastasis. The combination of AZM-475271 and gemcitabin has also been shown to be particularly effective in the pancreatic cancer model. SU-6656²¹⁴ has been described as a potent inhibitor of Src tyrosine kinase (as well as Lck, Fyn, and Yes tyrosine kinases) and to inhibit PDGF-stimulated DNA synthesis and Myc induction in a fibroblast cell line. AP23451,^{36,185,215} a purine template-based compound, is a potent inhibitor of Src kinase ($K_i = 8$ nM) and incorporates a bone-targeting moiety that confers to it a unique property to bind to bone surface (hydroxyapatite) and inhibit Src-dependent osteoclast activity. AP23451 analogs have been described²¹⁶ that detail the structure–activity properties of various bone-targeting substituents, and other templates (e.g., pyridopyrimidine, pyrrolopyrimidine, and pyrazolopyrimidine) have also been elaborated with bone-targeting groups to advance novel Src inhibitors for use in osteolytic bone metastasis and bone diseases.^{217,218} A recent determination²¹⁹ of the x-ray structures of Src kinase complexed with AP23464 and AP23451 provides the first detailed molecular mapping of this therapeutic target with small-molecule inhibitors. Such three-dimensional information also provides insight to understand the various modes of binding and the comparative similarities and differences in molecular recognition amongst the aforementioned Src kinase inhibitors and other chemically novel molecules, including natural products, combinatorial library-based compounds, and substrate-based analogs.^{220–223}

2.24.3.2 Receptor and Nonreceptor Serine/Threonine Kinases

Protein serine/threonine and dual specificity protein kinases are represented by both receptor types (e.g., TGF β R) and nonreceptor types (e.g., the CDK family, Raf, MEK, MAPK, PI3K, PKB/Akt, and mTOR). Due to the fact that, to an extraordinary degree, the primary type of protein phosphorylation in cells is at serine/threonine, there have been identified numerous promising cancer therapeutic targets from this major subfamily of protein kinases. A few examples of receptor and nonreceptor serine/threonine kinase inhibitors are highlighted below to illustrate recent advances in basic research and drug discovery.

2.24.3.2.1 TGF β R kinases

The transforming growth factor ligand TGF β is critically involved in the progression of fibrosis as well as tumor invasiveness and metastasis^{224,225} through binding to the receptor serine kinase TGF β R, of which two subtypes (TGF β R1 and TGF β R2) exist. TGF β R1 activation subsequently leads to the phosphorylation of transcription factors (e.g., SMADs). Uncontrolled cell growth due to decreased growth-inhibiting activity is a major feature of a defect in TGF β function, and evidence is emerging that common variants of the TGF β pathway (ligand and receptors) that alter TGF β signaling may modify cancer risk. For example, a variant of the TGF β R1 gene known as *TGF β R1*6A* has been correlated with decreased TGF β -mediated growth inhibition and increased cancer risk. Interestingly, while decreased TGF β signaling increases cancer risk, TGF β secretion and activated TGF β signaling enhances the aggressiveness of

Figure 10 Some Src and Src family tyrosine kinase inhibitors, highlighting the structural groups that are predicted to bind to the hydrophobic specificity pocket.

Figure 11 Some TGF β R1, CDK, PKC, Raf, and MEK kinase inhibitors, including several that have advanced to clinical testing.

several types of tumors. Noteworthy in this respect are the first-generation TGF β R1 serine kinase inhibitors SB-203580, SKF-104365, and LY-364947/HTS-466284, which exemplify small molecules based on substituted imidazole or pyrazole templates (Figure 11). SB-203580,²²⁶ a trisubstituted imidazole template-based compound, moderately inhibits TGF β R1 serine kinase autophosphorylation ($IC_{50} = 20 \mu M$) and was discovered by cross-screening small-molecule inhibitors of p38 MAPK. SKF-104365²²⁷ was found to be a relatively potent inhibitor of TGF β R1 phosphorylation of SMAD3 ($IC_{50} = 1.6 \mu M$) and was selective relative to p38 MAPK. LY-364947/HTS-466284^{228,229} was independently discovered by screening- and structure-based strategies and is a highly potent inhibitor of TGF β R1 autophosphorylation ($IC_{50} = 51 nM$). Finally, an x-ray structure of LY-36494/HTS-466284 complexed with TGF β R1 serine kinase was also independently determined in these studies.

2.24.3.2.2 Cyclin-dependent kinase family kinases

In a majority of cancers there are aberrations in cell cycle progression, and it has been determined that the tumor suppressor retinoblastoma (Rb) family of proteins act as a master switch to regulate cell cycling. Cell proliferation is driven by Rb proteins via their phosphorylation by cyclin-dependent kinases (CDKs).^{230–233} The CDK family of serine kinases include those activated by D-type cyclins (D1, D2, and D3) and cyclin-E, and are inhibited by two families of CDK inhibitors (CKIs), which include Ink and the Cip/Kip subfamilies. Rb is an important regulator of G1/S transition, and its function is abnormal in most cancers. Loss in Rb function occurs by CDK hyperactivation, hence implicating CDK inhibition as a promising strategy for drug discovery. CKIs have further been shown to have additional functions such as the regulation of Rho signaling and the control of cytoskeletal organization and cell migration. In addition, upregulated cytoplasmic CKIs appear to be involved in tumor invasion and metastasis.²³⁴ With respect to the CDK

family, the prominent therapeutic targets for small-molecule inhibitor drug discovery have been CDK1, CDK2, CDK4, and CDK5. The first- and second-generation CDK serine kinase inhibitors flavopiridol (L86-8275/HMR1275), UCN-01, CYC202 (roscovitine), and BMS-387032 are particularly noteworthy small molecules that have advanced to clinical testing (Figure 11, see above).

Flavopiridol^{231,235–238} is a semisynthetic flavonoid natural product derivative that is a potent inhibitor of CDKs (IC₅₀ values ~100 nM). Flavopiridol effects G1/S and G2/M arrest by inhibition of CDK1 and CDK2. Furthermore, it has been shown to induce apoptosis and to effect antiangiogenesis properties. An x-ray structure of a flavopiridol analog complexed with CDK2 has revealed its binding to the ATP pocket. UCN-01,^{239–241} a staurosporine analogue initially developed as a protein kinase C (PKC) inhibitor, is a potent inhibitor of CDK1 (IC₅₀ = 31 nM) and CDK2 (IC₅₀ = 30 nM), as well as PKC (IC₅₀ = 6.8 nM). UCN-01 inhibits the production of phosphorylated Rb, and induces apoptosis in cancer cells. Recently, UCN-01 has been shown to be a potent inhibitor of Pdk1 serine/threonine kinase, which then results in the inactivation of Akt/PKB, thus modulating the PI3K survival pathway. UCN-01 effects antitumor activities in xenograft mice models of breast cancer, renal cancer, and leukemias. CYC202,^{242,243} a purine template-based compound, is a potent inhibitor of CDK2/cyclin E kinase (IC₅₀ = 100 nM), and it effects cytotoxicity against many human cancer cell lines (IC₅₀ ~10 μM range). CYC202 induces cell death from all compartments of the cell cycle, as was shown in colorectal cancer cells in vitro; in vivo studies in nude mice bearing this cancer showed that CYC202 effected significant antitumor activity at high dose. BMS-387032,²⁴⁴ a substituted aminothiazole-template-based molecule, is a potent and selective inhibitor of CDK2/cyclin-E (IC₅₀ = 48 nM). BMS-387032 effects potent antiproliferative activity in cancer cells in vitro, and in vivo it produced significant antitumor activity in a human ovarian carcinoma xenograft model. Collectively, such CDK serine kinase inhibitors have been shown to be quite effective, and combination studies with either conventional cytotoxic drugs or other novel signal transduction modulatory drugs are expected to be useful in the clinical treatment of certain cancers.

2.24.3.2.3 Raf-MEK-MAPK pathway kinases

The well-established functional relationship between Ras signal transduction and cancer^{245,246} was hallmarked by the first identification of oncogenic and mutationally activated forms of *Ras* genes more than two decades ago. Mutated *Ras* alleles are known to exist in about 30% of human cancers, especially those with poor survival indications (e.g., lung and pancreatic carcinomas). *Ras* can also be abnormally activated by other mechanisms, such as overexpressed or mutationally activated EGFR. Among the therapeutic targets intimately involved in the *Ras* signal transduction are those intimately related to the Raf-MEK-MAPK pathway, including *Ras* farnesyl protein transferase, Raf,²⁴⁷ and MEK kinase inhibitors.²⁴⁸ EGFR inhibitors (both small-molecule tyrosine kinase inhibitors and monoclonal antibodies to the extracellular receptor) and inhibitors of gene expression (i.e., *H-Ras* and *Raf*) provide additional upstream and downstream drug discovery strategies for the Raf-MEK-MAPK pathway. First-generation Raf serine kinase and MEK dual specificity kinase inhibitors BAY43-9006 and PD184352 (CI-1040) are particularly noteworthy small molecules that have advanced to clinical testing (Figure 11; see above). BAY43-9006,^{249,250} a novel biaryl-urea template-based molecule, is a potent inhibitor of Raf-1 serine kinase as well as several receptor tyrosine kinases, including VEGFR-2, PDGFR-β, Flt-3, and KIT. BAY 43-9006 effectively inhibits the MAPK pathway in cancer cell lines (e.g., colon, pancreatic, and breast) expressing mutant K-RAS or wild-type or mutant BRAF. BAY 43-9006 was effective in vivo against a broad-spectrum antitumor activity in colon, breast, and NSCLC xenograft models, and additional evidence showing its inhibition of neovascularization in these xenograft models implicates BAY43-9006 as an in vivo dual inhibitor of both Raf and VEGFR. PD184352,^{251,252} a novel substituted anthranilic acid template-based molecule, is a potent and highly specific inhibitor of MEK (IC₅₀ = 1 nM), blocking the phosphorylation of ERK and downstream signal transduction thereof. PD184352 is not ATP-competitive, but is an allosteric inhibitor of MEK. PD184352 effects significant antitumor activity in vitro and in vivo (e.g., pancreas, colon, and breast cancers), and a correlation with the inhibition of ERK phosphorylation has been determined.

2.24.3.2.4 PI3K-Akt/PKB-mTOR pathway kinases

Like the *Ras* signal transduction and its biological relevance to cancer, the relationship between the PI3K-Akt/PKB-mTOR pathway and cancer has been investigated intensively,^{253–260} and significant evidence exists that dysregulation of the PI3K-Akt/PKB-mTOR pathway may include loss of the PI3K suppressor protein PTEN, PI3K mutations (constitutive activating), and/or other downstream complications involving Akt and mTOR, of which the latter integrates signal transduction from both growth factors and nutrients. Activation of the PI3K-Akt/PKB-mTOR pathway potentiates cell survival and proliferation as well as cytoskeletal function and motility to impact on tumor invasion. Furthermore, the PI3K-Akt/PKB-mTOR pathway is implicated in angiogenesis, including upregulation of angiogenic

Figure 12 mTOR inhibitors that have advanced to clinical testing.

cytokines. The first-generation mTOR inhibitor rapamycin (**39**, sirolimus) and the second-generation rapamycin analog AP23573 (**40**) are noteworthy natural product-based molecules that have advanced to clinical testing (Figure 12). The antiproliferative properties of rapamycin were identified more than two decades ago, and rapamycin has been developed as an immunosuppressive and antifungal agent. Rapamycin has provided a powerful proof-of-concept lead compound in terms of exploiting its potent and specific inhibitory properties against mTOR^{253–255,258,259} in both in vitro and in vivo cancer models.

AP23573^{253–255} exemplifies a highly potent analog of rapamycin, which incorporates a novel modification of the macrolide template with a dimethylphosphoryl moiety. AP23573 and other rapamycin analogs (e.g., CCI-779 and RAD-001)^{253–255} have advanced to clinical testing for the treatment of many cancers.

2.24.4 Protein Phosphatase Therapeutic Targets and Drug Discovery

More than 100 protein phosphatases have been identified^{11–14} from the human genome, and these constitute a superfamily including protein tyrosine phosphatases (e.g., PTP1B, SHP2, PEST, PTPH1, PTP α , and CD45), dual-specificity protein phosphatases (e.g., VHR, CDC25, PTEN, and MKP-4), and protein serine/threonine phosphatases (e.g., PP1, PP2A, and PP2B/calcineurin). Both receptor and nonreceptor tyrosine phosphatases have vital roles in signal-transduction pathways to regulate cell growth and proliferation, cell-cycle progression, cytoskeletal integrity, differentiation, and metabolism. In particular, there is intense interest in the tyrosine phosphatase PTP1B, which dephosphorylates activated insulin receptor kinase, as a result of PTP1B gene knockout. Other studies have shown its functional role as a negative regulator of insulin receptor signaling.^{261–263} Such work suggests that novel small-molecule inhibitors might improve insulin sensitivity in type II diabetes and/or be effective in the treatment of obesity.^{264–266} Dual-specificity phosphatases are generally categorized as a subclass of protein tyrosine phosphatases, and they are uniquely able to hydrolyze a phosphate ester bond on either a tyrosine, serine, or threonine residue of a substrate phosphoprotein. Dual-specificity phosphatases have crucial roles in intracellular signal-transduction pathways, and are most prominently known for regulating the mitogen activated protein kinase (MAPK) signal transduction pathways and cell-cycle progression. Key dual-specificity phosphatases include the MAPK phosphatase VHR and the CDK phosphatase cell-division cycle 25 (CDC25). Protein tyrosine phosphatases differ both in terms of substrate structural recognition and the catalytic mechanism of substrate hydrolysis from protein serine/threonine phosphatases. Protein serine/threonine phosphatases are metalloenzymes, whereas protein tyrosine phosphatases hydrolyze phosphotyrosine substrates in a two-step mechanism involving a conserved cysteine residue to form a thiol–phosphate intermediate, followed by water-mediated hydrolysis assisted by key active site residues in the enzyme.

2.24.4.1 Receptor and Nonreceptor Tyrosine Phosphatases

Some noteworthy first-generation PTP1B tyrosine phosphatase inhibitors include compounds 1–3 (Figure 13). Compound 1,²⁶⁷ which was generated using a combinatorial library strategy, is a potent inhibitor of PTP1B ($K_i = 2.4$ nM)

Figure 13 Some PTP1B, PP1, PP2A, and PP2B phosphatase inhibitors.

and is selective relative to other protein phosphatases (e.g., *Yersinia* PTPase, SHP1, SHP2, LAR, HePTP, PTP α CD45, VHR, MKP3, Cdc25A, Stp1, and PP2C). Compound 2,^{268,269} designed from a lead tripeptide (Ac-Asp-Tyr[SO₃H]-Nle-NH₂), is a moderately potent inhibitor of PTP1B tyrosine phosphatase ($K_i = 220$ nM) and is selective relative to other protein phosphatases (e.g., SHP-2, LAR, CDC25b, and calcineurin). Prodrug modifications provided cellular activity as measured in terms enhanced 2-deoxyglucose uptake in cells (relative to the parent molecule) with concomitant augmentation of the tyrosine phosphorylation levels of insulin-signaling molecules. Compound 3,^{270,271} a tetrahydrothienopyridine template-based molecule, is a less potent inhibitor of PTP1B ($K_i = 5.1$ μ M), but provided a key lead compound for further optimization to achieve oral bioavailability. It is noted that significant efforts to develop PTP1B tyrosine phosphatase inhibitors are ongoing, and the aforementioned small-molecule lead compounds are only representative of such progress in the field of protein phosphatase inhibitor drug discovery.

2.24.4.2 Receptor and Nonreceptor Serine/Threonine Phosphatases

Some noteworthy first-generation PP1, PP2A, and PP2B phosphatase inhibitors include FK506, cyclosporin, and cantharidin (Figure 13, see above). These exemplify both natural-product and small-molecule lead compounds for therapeutic treatment of several diseases, including neurological and metabolic disorders, respiratory disease, immunosuppression, and cancer (e.g., cell-cycle modulation).²⁷² FK506, a macrolide isolated from bacteria, is a highly potent inhibitor of PP2B ($IC_{50} = 0.5$ nM). Cyclosporin-A, a cyclic peptide isolated from fungus, is also a highly potent inhibitor of PP2B ($IC_{50} = 5$ nM). Cantharidin, a natural product isolated from insects, is a highly potent inhibitor of PP1 and PP2A ($IC_{50} = 500$ and 200 nM, respectively).

2.24.5 Phosphoprotein-Interacting Domain Containing Cellular Protein Therapeutic Targets and Drug Discovery

The complex orchestration of signal transduction and related cellular activities that have been unraveled with respect to both protein kinases and protein phosphatases also includes the intimate participation of a relatively large number of cellular proteins that contain phosphoprotein-interacting domains,^{3,4,15–20} including those recognizing phosphotyrosine, such as SH2 (e.g., Grb2, Shc, Src, and ZAP-70) and PTB (e.g., IRS-1 and ARH), as well as others that recognize

phosphoserine/phosphothreonine, such as WW, FHA, and 14-3-3. Collectively, such phosphoprotein-interacting domains underlie cellular mechanisms that have been related to cancer, autoimmune disease, osteoporosis, autoimmune disease, type-2 diabetes mellitus, and autosomal recessive hypercholesterolemia.

2.24.5.1 Phosphotyrosine-Interacting Domains

With respect to small-molecule-drug discovery, the overwhelming focus on such phosphoprotein-interacting motifs has been on the SH2 domain.^{5,15,36,273–277} SH2 domains are noncatalytic motifs of approximately 100 amino acids, and have been determined to be one of the top 25 most frequently occurring protein structural types that have been identified from the human genome. Numerous x-ray and/or nuclear magnetic resonance (NMR) structures have been determined for SH2 domains (e.g., Src, Grb2, and Zap70) and complexes thereof with phosphopeptide, peptidomimetic, or nonpeptide inhibitors. As the prototype SH2 domain, the Src SH2 domain and phosphopeptide (e.g., pTyr-Glu-Glu-Ile sequences) complexes were first determined by x-ray structural studies to provide detailed molecular maps, especially of the pTyr moiety.

A major challenge of SH2 inhibitor drug design was the pTyr moiety, in terms of developing metabolically stable pTyr mimics that exhibit high affinity to a SH2 domain. Another major challenge was the transformation of the peptide ligand scaffold to peptidomimetic or nonpeptide templates that would afford more drug-like properties with respect to cellular and in vivo activity. Two successful drug design campaigns that have advanced key proof-of-concept lead compounds against Src SH2 and Grb2 SH2 domains illustrate endeavors to overcome such pTyr and peptide scaffold challenges. First-generation nonpeptide Src SH2 inhibitors PD-157934, AP22161 and AP22408 are particularly noteworthy small-molecules that have advanced the first proof-of-concept in vivo effective lead compound (Figure 14).

PD-157934,²⁷⁸ a benzamide template-based molecule, was created using de novo drug design strategies and was determined to be a moderately potent inhibitor of the Src SH2 domain ($IC_{50} = 6.6 \mu M$). AP22161,²⁷⁹ a bicyclic benzamide template-based molecule incorporating a novel pTyr mimic and having an electrophilic aldehyde designed to interact with a cysteine residue in the pTyr binding pocket of Src SH2, was determined to be a potent inhibitor of Src SH2 ($IC_{50} = 240 nM$) and to be effective in cell-based assays to block Src-dependent activities in vitro. AP22408,²⁸⁰ a bicyclic benzamide template-based molecule incorporating a novel pTyr mimetic designed to increase binding affinity and confer bone-targeting properties, is a potent inhibitor of the Src SH2 domain ($IC_{50} = 300 nM$) and is effective in inhibiting osteoclast-dependent bone resorption in vitro and in vivo. It is noteworthy that the overall structure-based design of AP22408, with respect to both the pTyr and peptide scaffold replacement strategies, and further studies²⁸¹ have extended the scope of other pTyr mimetics by a strategy of multiple functional group replacement. Other drug

Table 4 Summary of clinically investigated small-molecule protein kinase inhibitors^a

<i>Compound</i>	<i>Protein kinase(s)</i>	<i>Clinical status (cancer indications)</i>	<i>Company</i>
STI-571 (Imatinib)	Bcr-Abl, PDGFR, Kit	Approved (chronic myelogenous leukemia/CML) Approved (gastrointestinal stromal cell tumors/GIST)	Novartis
AMN-107	Bcr-Abl, PDGFR, Kit	Phase I (CML, acute lymphocytic leukemia/ALL)	Novartis
BMS-354825	Bcr-Abl, SFK	Phase II (CML)	Bristol-Myers Squibb
SKI-166	Bcr-Abl, SFK	Phase II (CML, solid tumors)	Wyeth
AZD-530	SFK, Bcr-Abl	Phase I (solid tumors)	AstraZeneca
ZD-1839 (Iressa)	EGFR	Approved (NSCLC)	AstraZeneca
OSI-774 (Tarceva)	EGFR	Approved (NSCLC)	OSI Pharmaceuticals
CI-1033	EGFR, HER2	Phase II (various solid tumors)	Pfizer
PKI-166	EGFR, HER2	Phase III (solid tumors)	Novartis
EKB-569	EGFR, HER2	Phase II (NSCLC, colorectal)	Wyeth
GW-572016	EGFR, HER2	Phase III (NSCLC, solid tumors)	GlaxoSmithKline
PTK787/ZK222584	VEGFR, PDGFR, Kit	Phase III (colorectal, solid tumors)	Novartis/Schering AG
AMG-706	VEGFR, PDGFR, Kit, RET	Phase II (NSCLC, colorectal, GIST)	Amgen
SU-6668	VEGFR, PDGFR, Kit	Phase II (solid tumors)	Pfizer (Sugen)
SU-11248	VEGFR, PDGFR, Kit, Flt-3	Phase III (GIST, solid tumors, acute myeloid leukemia/AML)	Pfizer (Sugen)
CGP53716	PDGFR	Phase III (brain tumors)	Novartis
ZD-6474	VEGFR, Kit	Phase II (solid tumors)	AstraZeneca
CEP-7055	VEGFR	Phase I (solid tumors)	Cephalon/Sanofi
CP-547632	VEGFR, FGFR	Phase I/II (ovarian, NSCLC)	OSI Pharmaceuticals/Pfizer
MLN-518	Flt-3, PDGFR, Kit	Phase II (AML)	Millennium Pharmaceuticals
PKC-412	Flt-3, VEGFR, PDGFR, Kit	Phase II (AML, myelodysplastic syndrome)	Novartis
CEP-701	VEGFR, Flt-3, Trk	Phase II (AML)	Cephalon/Kyowa Hakko Kogyo
BAY-43-9006	Raf	Phase II/III (kidney, breast, lung)	Onyx Pharmaceuticals/Bayer
PD-184352	MEK	Phase II (pancreatic, breast)	Pfizer
Flavopiridol	CDK	Phase II (head and neck cancer, solid tumors)	Aventis
CYC202	CDK	Phase II (NSCLC, lymphoma)	Cyclacel
BMS-387032	CDK	Phase I (metastatic refractory solid tumors)	Bristol-Myers Squibb
UCN-01	PKC, CDK	Phase I/II (refractory solid tumors and lymphomas)	Kyowa Hakko Kogyo
AP23573	mTOR	Phase II (hematologic malignancies, various solid tumors)	ARIAD Pharmaceuticals
CCI-779	mTOR	Phase III (renal cell carcinoma, breast, prostate)	Wyeth
RAD001	mTOR	Phase II (GIST, relapsed/refractory CML or AML)	Novartis

^aAdapted from Garcia-Echevaria and Fabbro,⁵⁴ Laird and Cherrington,⁴¹ Sawyer,³⁵ and other sources of information available as of July 2005.

discovery efforts have advanced Src SH2 inhibitors having nonpeptide templates.^{282–284} First-generation nonpeptide Grb2 SH2 inhibitors 4–6 are particularly noteworthy small molecules that have advanced the first proof-of-concept cellularly effective lead compound (Figure 14). Compounds 4 and 5^{285–287} are peptidomimetics that exploit a β -turn conformation as determined from x-ray structural studies of cognate ligand phosphopeptides complexed with Grb2 SH2, and each is a potent inhibitor of Grb2 SH2 (IC_{50} = 43 nM and 1.6 μ M, respectively). Compound 5 was effective in cells, and provided the first proof-of-concept lead compound relative to disrupting the Ras-Grb2 pathway by the inhibition of Grb2 SH2. Compound 6²⁸⁸ is a novel nonpeptide molecule that is a moderately potent Grb SH2 inhibitor (IC_{50} = 6.2 μ M) and provides a template for further lead compound optimization.

2.24.5.2 Phosphoserine/Phosphothreonine-Interacting Domains

More recently, the identification and characterization of phosphoserine/phosphothreonine (pSer/pThr)-interacting domains has provided new insights into the modulation of signal transduction pathways and cellular activities in terms of the integration of protein serine/threonine kinases and protein serine/threonine phosphatases.^{19, 20].} The 14-3-3 proteins were the first shown to possess pSer/pThr molecular recognition properties, and there are more than 100 known phosphoprotein ligands identified to bind to 14-3-3 domains. Such phosphoprotein ligands include a vast number of protein kinases, protein phosphatases, cell surface receptors, ion channels, and a number of proteins involved in cell-cycle control as well as transcriptional control of gene expression, metabolism, and apoptosis. The WW domain containing cellular proteins includes examples (e.g., proline isomerase Pin1) that specifically recognize pSer-Pro and Thr-Pro motifs in their phosphoprotein ligands. Forkhead-associated (FHA) domains have been found in a number of transcriptional control proteins, DNA-damage-activated protein kinases, cell-cycle checkpoint proteins, and phosphatases. FHA domains bind to pThr sites on phosphoprotein ligands, and there are no known examples of FHA domains that bind to pSer motifs. Small-molecule drug discovery for such pSer/pThr-interacting domains has not risen to the level that has existed for SH2 proteins. However, some noteworthy progress has been achieved relative to probing 14-3-3, WW, and FHA domains with phosphopeptide libraries to provide optimal pSer/pThr-containing sequences recognized as ligands as well as enabling structural biology studies.

2.24.6 Concluding Remarks

Protein kinases and protein phosphatases are key superfamilies of enzymes that modulate protein phosphorylation and signal transduction pathways critical to various cellular functions. The functional relationship of protein kinases to cancer has translated to significant advances in basic research and drug discovery over the past several decades, especially within the last few years. Highlighting such progress in protein kinase drug discovery is an emerging armamentarium of powerful molecular probes, proof-of-concept lead compounds, and clinical candidates (Table 4). Significant progress in drug discovery has also been made for both protein phosphatase and phosphoprotein-interacting domain containing proteins, albeit relatively less than that for protein kinases.

From a medicinal chemistry perspective, the chemical and mechanistic diversity of small-molecule inhibitors for such therapeutic targets is extraordinary. Key concepts and technologies related to structure-based drug design, chemoinformatics, combinatorial libraries, and high-throughput screening have impacted drug discovery efforts with respect to the generation, optimization, and development of lead compounds. Nevertheless, a major challenge for this multidisciplinary field of signal transduction research is biological selectivity (molecular and cellular). As exemplified by some protein kinase inhibitors, multiple inhibition of key therapeutic targets that may synergize with respect to signal transduction pathways converging in a particular disease, may have advantages relative to the modulation of a single therapeutic target. Biological selectivity has also transcended to include an ever-increasing number of mutations of signal transduction therapeutic targets, especially protein kinases (e.g., EGFR, Bcr-Abl, KIT, and Flt-3). Combination drug therapy is an option to overcome resistance due to mutations that select against a particular small-molecule inhibitor. Finally, biological selectivity at the cellular level provides new opportunities to advance novel cancer therapies focused on metastasis and angiogenesis (see above). Future advances in the discovery of small-molecule drugs involving protein phosphorylation in signal transduction pathways will probably address a wider range of diseases and take advantage of progress that has been highlighted in this review.

Biography

Tomi K Sawyer received a BSc degree in Chemistry at Moorhead State University (now Minnesota State University-Moorhead) and PhD in Organic Chemistry at the University of Arizona. His research has integrated synthetic chemistry, drug design, structural biology, chemoinformatics, biochemistry, cell biology and in vivo disease models with a focus on cancer. Tomi's drug discovery track record includes contributions to clinical candidates and/or noteworthy molecular tools for several therapeutic targets, including GPCR receptors (melanocortin), aspartyl proteases (renin and HIV protease), and protein kinases (Src and Abl). He has published more than 200 scientific articles, reviews, commentaries, monographs and books. Tomi is an inventor of more than 50 issued patents and patent filings. He worked at Upjohn Company and Parke-Davis/Warner-Lambert (now both Pfizer Global Research & Development), and is currently Senior-Vice President, Drug Discovery, at ARIAD Pharmaceuticals. He is concurrently adjunct professor, Chemistry as well as Biochemistry & Molecular Biology, University of Massachusetts and also adjunct professor, Cancer

Biology, at University of Massachusetts School of Medicine. Tomi has served on the highlights advisory panel of Nature Reviews Drug Discovery and the editorial advisory boards of Trends in the Pharmacological Sciences, Expert Reviews in Molecular Medicine, Expert Opinion on Investigational Drugs, Journal of Medicinal Chemistry, Chemistry and Biology, Current Medicinal Chemistry (Anti-Cancer Agents), Current Organic Synthesis, Expert Reviews in Molecular Medicine, Expert Opinion on Therapeutic Patents (Oncology), Drug Design and Discovery, Pharmaceutical Research, Molecular Biotechnology, and Biopolymers (Peptide Science). Most recently, Tomi was appointed Editor-in-Chief, Chemical Biology & Drug Design.

2.25.1 Introduction

Nuclear receptors (NRs) are one of the largest known superfamilies of eukaryotic transcription factors that regulate the expression of genes involved in critical processes such as embryonic development, metabolism, and inflammation.¹⁻³ These receptors, upon binding a range of lipophilic extracellular ligands, control the transcription of target genes. Some well-known NR ligands include hormones such as steroids, retinoids, thyroid hormone, and vitamin D3. The NRs are now recognized as playing a pivotal role in critical physiologic and metabolic functions, and dysfunction of NR signaling has been implicated in major disease states such as cancer, infertility, diabetes, obesity, and hypercholesterolemia. As a result, NRs are major targets for drug discovery in several therapeutic areas. Indeed, 8 of the top 100 prescription drugs target an NR, including well-known drugs such as rosiglitazone (Avandia), a PPAR γ ligand; pioglitazone (Actos), also a PPAR γ ligand; raloxifene (Evista), an ER α ligand; and fluticasone (Flonase), a glucocorticoid receptor ligand.

2.25.2 Current Classification and Nomenclature

Genome sequence analysis has identified 49 NR sequences in the human genome, whereas 21 NRs have been found in *Drosophila melanogaster* and about 270 NRs in the *Caenorhabditis elegans* genome.⁴⁻⁶ Through phylogenetic analysis and sequence matching of the identified NR sequences, six subfamilies have been defined among the NR superfamily.⁷

2.25.2.1 Classification of Human Nuclear Receptors

The human NR family is loosely grouped into three classes based on their ligand- and DNA-binding properties.³ Class I NRs are the classic steroid hormone receptors and include the estrogen receptor (ER), androgen receptor (AR), progesterone receptor (PR), glucocorticoid receptor (GR), and the mineralocorticoid receptor (MR). In the absence of ligand, these NRs are sequestered in nonfunctional complexes with heat-shock proteins and are transcriptionally inactive. On ligand activation, Class I NRs bind, as homodimers, to palindromic (head-to-head arrangement) DNA sequences called NR response elements (NREs) (Figure 1). Class II receptors include thyroid hormone receptor (TR), vitamin D receptor (VDR), retinoid receptor (RAR), peroxisome proliferator-activated receptor (PPAR), liver X receptor (LXR), and the farnesoid X receptor (FXR). These receptors bind head-to-tail DNA repeat sequences as heterodimers with the retinoid X receptor (RXR), even in the absence of ligand, and exert a repressive silencing effect on basal promoter activity that is reversed on ligand binding. Class III NRs comprise the orphan nuclear receptors (oNRs) that have been identified using genomic methods. These oNRs are structurally related to the NRs, but they lacked known physiological ligands at the time the receptors were identified. As shown in Figure 1 and Table 1, the oNRs are subclassified as those that are known to bind their DNA sequences as homodimers (e.g., the chicken ovalbumin upstream promoter transcription factor (COUP-TF) and the hepatocyte nuclear factor 4 (HNF-4)), as monomers (e.g., steroidogenic factor (SF-1)), and those that lack DNA-binding domains (DBDs) (e.g., small heterodimeric partner (SHP)).

oNRs present a huge opportunity to uncover new physiological regulatory systems that may be involved in human health and disease and, thus, have potential as future therapeutic targets. Several pharmaceutical companies have undertaken research programs to identify ligands for these oNRs. A combination of targeted screening of small, biased compound collections and high-throughput screening of large random libraries have successfully led to the identification of naturally occurring as well as synthetic ligands for a number of oNRs. Such oNRs have been termed ‘adopted orphan receptors,’ and include the pregnane X receptor (PXR), the constitutive androstane receptor (CAR), and the oxysterol-binding liver X receptor (LXR). Identification of naturally occurring ligands for these oNRs has proved to be one of the most powerful ways to identify the physiological function of the NR; this process is a classic example of reverse endocrinology.⁸

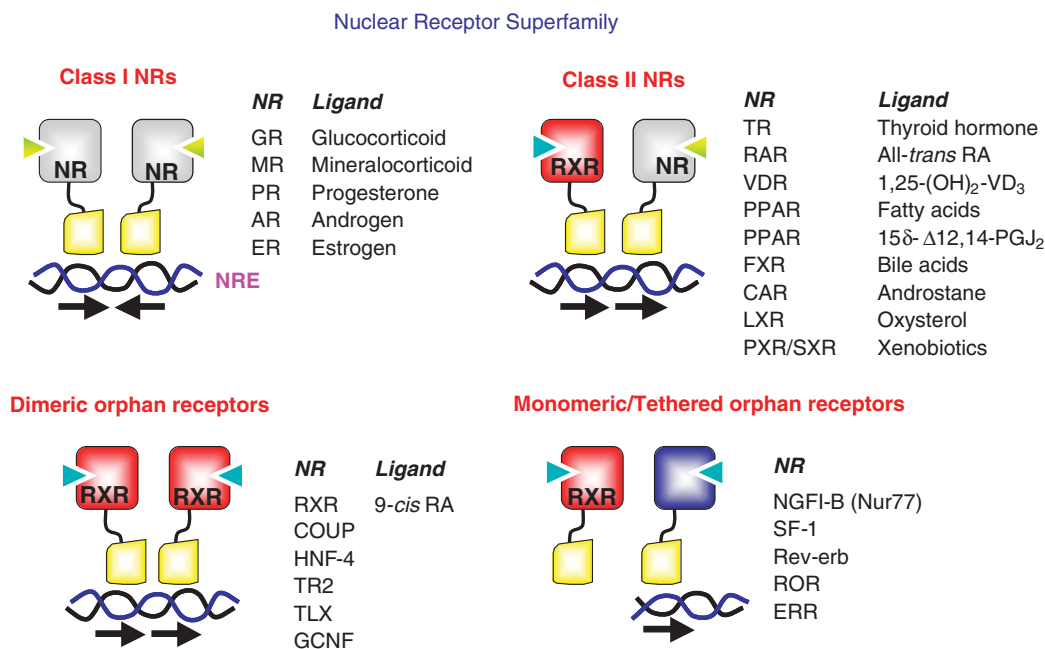

Figure 1 Nuclear receptor classification.

2.25.2.2 Nomenclature of Nuclear Receptors

The genomic revolution of the last decade resulted in the identification in various species of over 300 genes belonging to the NR superfamily. This necessitated the development of a logical and useful classification and nomenclature system that would not only integrate NR genes already identified, but also be flexible enough to allow inclusion of newly identified sequences for which no biological data is yet known. The new nomenclature, proposed in 1999, is based on the evolution of the two well-conserved domains of NRs (the DNA-binding C domain and the ligand-binding E domain, discussed below) and uses molecular phylogeny to connect and classify all known NR sequences.⁹ This system divides the superfamily into six subfamilies and 26 groups of receptors. Each receptor/gene name is described by the letters 'NR' and a three-digit identifier containing an Arabic numeral for the subfamily, a capital letter for the group, and another Arabic numeral for the individual gene. Splice variants (isoforms) are designated by a final lowercase letter. Table 1 shows the designated nomenclature for the known human NRs. For example, the estrogen receptor ERα which belongs to subfamily 3, group A, and is the first gene identified in that group, is named NR3A1. Detailed information about the evolution of this nomenclature can be found on the Nuclear Receptor Nomenclature Homepage.³⁷⁷

2.25.3 Nuclear Receptor Protein Structure

NRs are modular proteins containing three major functional domains,¹⁰ composed of six regions labeled A through F (Figure 2). Each domain has a separate and crucial function in NR-mediated transactivation and signal transduction. The N-terminal domain (known as the A/B region) is highly variable in length and sequence among NRs, and contains an intrinsic transactivation domain, called activation function (AF-1) domain, that is involved in ligand-independent transcriptional activity. The central domain (C/D region) is the DBD. It is the most highly conserved region among the receptors. Although the DBD–DNA interactions vary from receptor to receptor, all DBDs contain two type II zinc-finger motifs that are common to the entire superfamily. These zinc fingers fold into a single structural domain with an α-helical reading head containing three amino acids (the P box) responsible for DNA sequence recognition in the hormone response elements (NREs).¹¹ The C-terminal domain is the ligand-binding domain (LBD) or E/F region, which contains regions for receptor dimerization, heat-shock protein interaction, transcriptional regulation, and, most importantly, ligand binding. LBDs have a conserved overall α-helical architecture, with sufficient sequence diversity to allow for selective ligand recognition among the various NRs. The LBD contains the second activation function (AF-2),

which is critical for ligand-induced transcriptional regulation. The multistep process of gene transcription is orchestrated by the LBD through a complex interplay of other coregulatory proteins (coactivators and corepressors) that couple ligand-induced conformational changes to the regulation of gene transcription. The LBD contains the binding site for synthetic ligands as well as natural hormonal NR ligands, and has been the target for major drug discovery efforts in the pharmaceutical industry (see [12–15](#) for excellent in-depth reviews).

2.25.3.1 Three-Dimensional Nuclear Receptor Protein Structure

Three-dimensional (3D) structures of proteins are usually obtained through a combination of techniques, such as x-ray crystal structure and nuclear magnetic resonance (NMR) spectroscopy, and confirmed by site-directed mutagenesis of the proteins under study. Although structural studies have been carried out on isolated NR domains, no crystal structure of a full-length NR has yet been reported. The Gustafsson and Yamamoto laboratories¹⁶ published the first 3D structure of an NR domain, the GR DBD, as determined by solution NMR spectroscopy. This landmark work set the stage for subsequent determinations of the 3D structures of NRs that have provided remarkable insights into the mechanism of NR action and the design of synthetic NR ligands to modulate these actions. The 3D structures of LBDs have been determined for a few unliganded (apo) receptors and many liganded (holo) NRs ([Table 2](#)),¹⁷ and these structures provide a good understanding of the molecular dynamics of ligand binding, coregulator interaction, and transactivation (reviewed in [18](#)).

2.25.3.1.1 The ligand-binding domain

Structural studies show that the LBDs of all NRs share a common overall 3D structure, consisting of 12 α -helices (H1–H12), two or three short β -sheets and connecting loops, arranged as a three-layered sandwich (**Figure 3a**).¹⁹ The top half of the LBD forms the structural core of the protein and is relatively invariant between receptors. In the lower half, the central helical layer is moved away to form a large cavity of the ligand-binding pocket (LBP). The size of the predominantly nonpolar ligand-binding site varies significantly between NRs, allowing for the recognition of unique ligands and hormones of varying sizes. The LBP is lined by residues from helices H3, H5, H6, and H11. Near the entrance of the LBP is the C-terminal helix, H12, that contains the residues of the ligand-dependent AF-2, which is crucial for coactivator binding. The position of helix 12 is highly flexible, and its structural transition and repositioning is essential for recruitment of transcriptional cofactors. On agonist binding, H12 moves over the entrance to the LBP, into a hydrophobic cleft formed by H3 and H4, and forms a charge clamp between a Lys at the C-terminal end of H3 and Glu on H12.²⁰ The hydrophobic cleft and charge clamp create a docking surface for coactivator interaction. The precise positioning of H12 depends on the size and shape of the binding ligand, thus allowing the ligand to regulate the

Figure 3 (a) Schematic representation of the different conformational states of ligand-binding domains (LBD) of retinoid NRs. The α -helices (H1–H12) are depicted as tubes and β -turns as broad arrows. The apo-LBD shows the three-layered sandwich structure of the 12 α -helices. In the agonist-bound holoLBD, H12 (red) moves over the LBP to form a binding site for coactivators. In the antagonist-bound LBD, H12 is moved away from the LBP and does not form the coactivator-binding site. The different colors of the tubes represent the different functions of the α -helices in the LBD: dimerization surface (green), coactivator-binding regions H3, H4, and H5 (orange), and the AF-2 function (H12) shown in red. (Adapted with permission from Bourguet, W.; Germain, P.; Gronemeyer, H. *Trends Pharmacol. Sci.* **2000**, 21, 381–388.) (b) X-ray crystal structure of ER α complexed with agonist estradiol (PDB code 1ERE), with agonist + coactivator peptide (PDB code 1GWR) and with antagonist raloxifene (PDB code 1ERR). Note that in the antagonist structure, H12 (yellow) occupies the same position as the coactivator peptide (red) in the agonist + coactivator structure. (Adapted with permission from Nagy and Schwabe, *Trends Biochem Sci.* **2004**, 29, 317–324.)

transcriptional activity of the NR. In one model, binding of an antagonist in the LBP may prevent H12 from docking in the hydrophobic groove. A corepressor binds in part of the groove, and H12 is forced out of its normal activating position, as is the case with antagonist binding to PPAR α .²¹ However, an antagonist may force H12 to dock in the coactivator-binding groove and block coactivator binding, as is the case when antagonist ligands tamoxifen and raloxifene bind the estrogen receptor ER α .^{22,23}

2.25.3.1.1.1 Ligand-binding pocket in absence of ligand

The first x-ray crystal structure of an unliganded LBD was that of the apo-retinoid X receptor alpha (RXR α).²⁴ While it conformed to the common canonical 3D structure of NRs, it appeared to lack an obviously discernible LBP. Comparison with the structure of the liganded RAR receptor²⁵ suggested that NRs may undergo a conformational rearrangement of helices that allows for ligand binding. In contrast, however, NRs such as PPARs, PXR, and LXR have large LBPs that appear as cavities in the unliganded receptor.^{26,27}

The size and 3D structure of the LBPs of various NRs offer several insights about the respective NR function.¹⁵ In classical nuclear hormone receptors, such as the steroid, thyroid, and retinoid receptors that are activated by endocrine and paracrine signaling molecules, the LBP is relatively small (400–500 Å) and the ligands typically occupy most of it. This close binding interaction explains both the high affinity of such hormonal ligands and their high specificity for the NR.

In contrast to these classical nuclear hormone receptors, the more recently characterized classes of NRs, such as the PPARs, LXR, and FXR, have large LBPs suggesting that these NRs may have different modes of cellular function via low affinity and structurally diverse ligands. The Y-shaped PPAR ligand-binding site is the largest LBP among the NRs, at 1400 Å.²⁸ Ligand binding in such a large pocket is less discriminate and enables the PPARs to bind structurally diverse ligands such as fatty acids of various chain lengths²⁹ and synthetic ligands such as the thiazolidinediones that

Figure 4 Structures of xenobiotics that bind PXR.

target the PPAR γ NRs and are used as insulin-sensing pharmaceuticals.³⁰ The LBP of LXR is also large, at 700–800 Å, and it binds a variety of hydroxylated cholesterol metabolites.³¹ Since the ligands for these receptors are naturally occurring metabolites of nutrients such as cholesterol and bile acids, it has been suggested that the PPARs, FXRs, and LXRs function primarily as nutritional sensors rather than as hormonal receptors for endocrine signaling ligands.^{15,32}

Another receptor whose structure suggests that it may be a nutritional sensor is the PXR receptor. PXR is a xenobiotic sensor and it regulates genes, such as CYP3A and MDR1, that are involved in the metabolism and transport of xenobiotics and diet-derived natural compounds (discussed in detail in the following section). The crystal structure of its large (1150 Å) LBP reveals several features that indicate its ability to interact with diverse, structurally unrelated xenobiotics. Its large (1150 Å) LBP contains several distinguishing characteristics, such as more β -strands and a helical insert, that result in a spherical LBP. The spherical shape of the LBP allows ligands as small as the cholesterol-lowering agent SR 12813 (**Figure 4**) to bind in multiple orientations,²⁷ and ligands as large as rifampicin and hyperforin (**Figure 4**) to bind PXR. All these xenobiotics are notorious for inducing CYP3A4 and causing drug–drug interactions during pharmaceutical use.^{15,33} Determining the crystal structures of the LBDs of oNRs, therefore, may offer important clues about the physiological function of oNRs and can be valuable in the search for the endogenous ligands for such NRs.

2.25.3.1.1.2 Ligands as structural cofactors

The 3D structures of NRs have also expanded our understanding of the role of ligands that bind NRs. The hepatocyte nuclear factors 4 (HNF4 α and HNF4 γ) have been shown to be constitutively active in cellular experiments.³⁴ The determination of the crystal structure of the native HNF4 revealed a relatively small LBP (625 Å) that was completely occupied by a fatty acid that cocrystallized with the NR, but did not interact with the AF-2 helix that capped the LBP, suggesting that the cocrystallized fatty acid may serve as a structural cofactor, rather than as a conventional ligand. Being constitutively active, HNF4 is not amenable to modulation by ligands through its LBP, but rather requires new approaches to regulate its activity via coactivator-binding sites or posttranslational modifications. Such approaches are being actively pursued in the pharmaceutical industry to target HNF4 as a potential treatment for Type 2 diabetes.³⁵ Another such example is the retinoid receptor-related orphan receptor ROR β , the crystal structure of which shows that it has a large LBP that cocrystallizes with a tightly bound stearic acid molecule, suggesting that ROR β may require fatty acid-related molecules as structural cofactors, rather than as regulatory ligands.³⁶

A third aspect of the NR structure and function revealed by 3D analysis is the discovery of NRs that lack LBPs entirely. Nurr1, an oNR that has been studied extensively for its essential functions in dopamine neurons,³⁷ does not possess an LBP. Instead, bulky, hydrophobic amino acids occupy the space in the lower half of the LBD that normally contains the LBP cavity in other NRs.³⁸ Such NRs will therefore require new approaches, other than the traditional ligand-based approach, for regulating their function as targets for drug discovery.

2.25.3.1.1.3 Coregulator binding site in the ligand-binding domain and the structural determinants of transactivation (agonism) and repression (antagonism)

The C-terminal end of the LBD contains the AF-2 domain, a conserved region involved in ligand-induced coregulator interaction and transcriptional regulation by the LBD. Helix 12 of the LBD contains residues that play a pivotal role in the function of AF-2, and hence H12 is sometimes referred to as the AF-2 helix.^{39,40} Regulation of NR-dependent transcriptional action requires recruitment of a complex series of proteins called coregulators (coactivators and corepressors) that are recruited by the AF-2 domain of the LBD. Most coactivators and corepressors contain multiple short NR interaction motifs, called NR boxes, of the general sequence LxxLL in coactivators (CoNR box)^{41,42} and LxxxIxxx[L/I] in corepressors (CoNRN box).^{43,44} These NR boxes directly interact with the LBD AF-2 domain.

Several crystal structures of LBD–coactivator peptide complexes (Table 2) reveal a general mode of coactivator binding to the LBD. The coactivators can possess multiple LxxLL motifs that adopt a two-turn helix, both ends of which are stabilized by a charge clamp formed with a conserved acidic residue from the AF-2 helix.^{23,26,42} Given that there are a large number of coactivators (see Section 2.25.4), each containing multiple LxxLL motifs, questions arise about how specific coactivators are recruited to given NR LBDs.

A crystal structure of GR-LBD bound to the TIF-2 coactivator peptide sheds light on the selectivity of specific coactivators for some NRs.⁴⁵ This structure reveals that GR uses two charge clamps to define its sequence-specific binding to the LxxLL motifs of TIF-2. The first charge clamp is with the highly conserved residues of the AF-2 helix and H3. The second charge clamp is composed of Arg585 and Glu590 in the GR-LBD, which form hydrogen bonds with the third LxxLL motif of TIF-2, but not the first and second motifs. The residues of the GR-LBD involved in the second charge clamp are conserved across the steroid receptors of Class I that bind oxysteroids (GR, PR, AR, and MR) but are not present in the ER or in RXR obligate heterodimers such as PPARs. This second charge clamp accounts for the differential binding of coactivator motifs by many NRs.

Since the coactivators and corepressors bind to nearly overlapping surfaces of the LBD and AF-2 domain, the choice of which coregulator is bound to the NR is controlled by the NR ligand.⁴⁶ In Class II NRs such as VDR and TR, which are typically found in the nucleus bound to their NREs, the LBD is bound to corepressors in the absence of ligand. The CoRNR box of corepressors NcoR1 (nuclear receptor corepressor 1) and SMRT (silencing mediator of retinoid and thyroid hormone) dock in a hydrophobic groove formed by H3 and H4 of the LBD and recruit specific histone deacetylases (HDACs). These HDACs generate a condensed chromatin structure over the promoter at the NRE, resulting in transcriptional repression in the absence of ligand. Agonist binding to the LBP induces conformational allosteric effects, leading to the movement of H12 and disruption of the interaction of H3 and H4 with the corepressor. The corepressor complex dissociates from the ligand-bound NR, and a coactivator is now able to bind to the coactivator-binding surface generated by H12, H3, and H4.⁴⁷ The bound coactivator then recruits other proteins to form a complex that leads to initiation of transcription and gene activation.

Steroid NRs from Class I NRs are usually present in the cytoplasm, associated with chaperone proteins such as Hsp90 and the immunophilin p23⁴⁸ that bind to the LBD. Ligand binding releases the chaperone proteins by a conformational adjustment, allowing the ligand to access the LBP. The ligand-bound receptor then dimerizes and is translocated to the nucleus, binds to its cognate response elements, and initiates transcription.

Antagonist NR ligands can interfere with LBD-mediated transcriptional regulation via different modes, as revealed by crystal structures of LBDs complexed with antagonists (Table 2). In LBD/antagonist complexes such as ER α with raloxifene,²² GR with RU486,⁴⁹ and RAR α with BMS614,⁵⁰ the steric hindrance afforded by the bulky side chains of the antagonist ligands (dimethylaniline in RU486, phenoxyethylpiperidine in raloxifene and quinoline in BMD614, Figure 3) prevents H12 from adopting the active conformation. Instead, H12 is forced to occupy the coactivator groove, effectively blocking the coactivator-binding surface (Figure 3b). Indeed, the H12 of NRs also does contain an LxxLL-like motif that allows H12 to sit in the coactivator groove, to relieve steric contacts imposed by bulky antagonist ligands.²² This mode of antagonism has been termed ‘active antagonism.’ It differs from the ‘passive’ mode of antagonism observed with antagonists such as MR antagonist spironolactone⁵¹ or ER β antagonist tetrahydrochrysenediol (THC).⁵² In these NRs, the agonist ligands provide critical hydrogen bond interactions with residues of the LBP that stabilize the agonist H12 position.⁵¹ When antagonists bind, they do not make these essential contacts, and therefore they destabilize the active H12 conformation, resulting in a transcriptionally inactive LBD. Partial agonists also fall into the passive mode of antagonism. In the ER β –genistein complex⁵³ and the PPAR γ –GW0072 complex,⁵⁴ the ligands are small, and they do not interact with or stabilize the AF-2 helix and result in a diminished transcriptional response. It is evident that the chemical structure of the NR ligand plays a significant role in the outcome of the NR interaction with natural and synthetic ligands.

2.25.3.1.1.4 Dimerization sites in the ligand-binding domain

Most NRs function either as homodimers (steroid receptors of Class I and RXR) or as heterodimers with RXR (Class II receptors). The residues that take part in the dimerization interaction are found in the LBD and are well characterized for the ER- and PR-LBD.^{22,55} Crystal structures of two different RXR heterodimers, RXR–RAR and RXR–PPAR, also reveal a common mode of dimerization in which residues of H10 from one monomer pack against H10 residues of the heterodimeric partner.^{56,57}

2.25.3.1.2 Ligand-independent activation function (AF-1) domain

The N-terminal AF-1 domain does not directly interact with the NR ligand, but it has been shown to be important in the recruitment of coactivators and formation of a transcriptionally active NR complex (see ⁵⁸ for a detailed review).

In the AR, an interaction between the AF-1 domain and the ligand-bound AF-2 domain is important for gene activation.⁵⁹ Ligand-independent, AF-1 domain-mediated transcriptional activation is also implicated in the tissue-selective effects of the selective estrogen receptor modulators (SERMs), such as tamoxifen. The relative contribution of AF-1-mediated transcriptional activation is dependent on the cellular context and tissue type.

2.25.3.1.3 DNA-binding domain

The DBD in NRs is a highly conserved region comprising about 60 amino acids and containing eight conserved Cys residues that coordinate two Zn ions and form the two zinc-finger motifs characteristic of all NR DBDs. Although the first structures of NR DBDs were solved by NMR (GR¹⁶ and ER DBD⁶⁰), crystal structures of several DBDs complexed with their consensus DNA response element sequences have also been solved and are reviewed by Renault and Moras.¹⁸

2.25.4 Coregulators and Nuclear Receptor-Dependent Transcriptional Control

As discussed above, the functional activity of an NR is not only regulated by hormones and other endogenous lipophilic ligands, but also by a complex array of regulatory proteins, including corepressors, coactivators, and chromatin modifiers. Recent studies indicate that transcription of NR-dependent genes is a dynamic process with continual exchange and turnover of NRs, coregulators, and other components of the transcriptional machinery.⁶¹ Once recruited, coregulators and NRs cycle on and off the target promoter many times, interacting only briefly with the regulatory elements (see ⁶¹). The NRs and their coregulators are also subjected to rapid modifications, such as ubiquitination, phosphorylation, acetylation, and methylation. The orderly and sequential recruitment of coactivators with different enzymatic activities has recently led to the concept of a 'transcriptional clock that directs and achieves the sequential and combinatorial assembly of a transcriptionally productive complex on a promoter.'⁶²

Class I NRs (including the steroid hormone receptors) reside in the cellular cytoplasm, where they are held in an inactive complex with chaperone (heat shock) proteins. The binding of their ligands induces release of the chaperone molecules, dimerization (homodimers), transport into the nucleus, and binding to specific NREs within the promoter regions of target genes, resulting in the recruitment of coactivators and chromatin rearrangement (e.g., see ⁶¹). However, the Class II NRs (e.g., VDR, TRs, RARs, PPARs, LXRs, and FXRs) are found primarily in the nucleus, bound to their respective NR response elements as heterodimers with RXR. These DNA–receptor complexes are normally associated with histone deacetylase (HDAC)-containing complexes tethered through the corepressors NCoR and SMRT. On ligand binding, the local chromatin structure is altered and the corepressors are dissociated from the DNA while coregulators are recruited.⁶³ Other recent studies suggest that both coactivators and corepressors can be found within the same complex, allowing for more efficient and more complex transcriptional control mechanisms.⁶⁴

2.25.4.1 Coactivators

Ligand-activated NRs bind to NREs embedded within chromatin, and this event initiates an ordered recruitment of a series of coactivators. Four major classes of NR coactivators have been described:

1. The p160/steroid receptor coactivator (SRC) family (SRC-1, SRC-2, and SRC-3), CBP (cAMP response element binding protein (CREB)-binding protein), p300, and PCAF (CBP/p300-associated factor). These coactivators possess acetyltransferase activity, which involves posttranslational modification of lysine residues within the N-terminal tail of histone proteins (e.g., see ⁶⁵).
2. Protein arginine methyltransferase 1 (PRMT1) and coactivator-associated arginine methyltransferase (CARM). Coactivators in this class methylate several arginine residues within histone H3 and, along with acetylases, are believed to neutralize the electrostatic interaction between the negatively charged phosphate backbone of DNA, which relaxes the association between the DNA and histone 3 protein.
3. The multiprotein thyroid receptor-associated protein (TRAP), VDR-interacting protein (DRIP), and SRB-MED-containing complex (SMCC) complexes bridge NRs to the general transcription factors associated with NR activation of target genes.
4. The ATP-dependent chromatin remodelers, including the SWI/SNF family. These coactivators introduce superhelical torsion into chromatin, creating a change in the topology of nucleosomal DNA. Furthermore, they slide nucleosomes into the *is* form, opening the compact structure of chromatin and making it more accessible to the general transcription factors (see ^{65,66} for reviews).

For a more detailed list of known coactivators, see ³⁷⁸.

2.25.4.2 Corepressors

The NR corepressors NCoR and SMRT associate with HDACs and DNA methyltransferases, and with histone methyltransferases on Class II NR target gene promoters. These enzymatic activities promote association of proteins important for maintaining heterochromatin and silenced regions of DNA.⁶⁷ Recent results have also made it clear that SMRT and NCoR are actually common repressors of all NRs, including the steroid hormone receptors ER, PR, and AR (see ⁶⁸ for a review). With Class I receptors, corepressor binding occurs only when the steroid hormone receptors bind their corresponding antagonists. For example, binding of tamoxifen to ER enhances the affinity between ER and NCoR. Over the past few years both the SMRT and NCoR complexes have been shown to associate with many other proteins, including transducing beta-like protein 1 (TBL1), TBL1-related protein (TBLR1), and HDAC3. These three components appear to be critical for the transcriptional repression caused by NRs.⁶⁸

Agonist binding to NRs can also recruit specific corepressors, as well as coactivators. These corepressors attenuate agonist-activated NR signaling by multiple mechanisms (see ⁶⁹ for more details). Two of these agonist-binding-dependent corepressors have been identified as the ligand-dependent corepressor (LCoR) and RIP40.⁶⁹ LCoR is widely expressed in fetal and adult tissues and interacts with ER, GR, PR, and VDR. LCoR also interacts with HDAC3 and HDAC6, but not with HDAC1 or HDAC4. RIP40 interacts with ERs and some Class II NRs, including TRs, RARs, and PPARs.⁶⁸

2.25.4.3 Modifications of Nuclear Receptors and Their Coregulators

2.25.4.3.1 Ubiquitination

Ubiquitin is a 76-amino acid polypeptide that is covalently linked to target proteins via a sequential enzymatic cascade involving an ubiquitin-activating enzyme, a ubiquitin-conjugation enzyme, and a ubiquitin ligase. Modification of proteins is central to the regulation of many biological pathways, including intracellular protein degradation, cell cycle regulation, signal transduction, and regulation of gene expression.⁶⁶ Current studies strongly suggest roles for ubiquitination in condensation of chromatin, regulation of histones, DNA repair, replication, and transcriptional control.⁶⁶ In keeping with the notion of an NR-dependent transcriptional clock, it is now believed that the cyclic interactions of NRs and their cofactors are most likely driven by the ubiquitin-proteasome pathway.⁶¹ The most plausible mechanism for this process seems to involve the removal of corepressors and/or coactivators to enable other regulators to subsequently bind the promoter complex.⁷⁰ However, the ubiquitination system can also function in transcriptional activation independently of proteolysis (see ⁶¹ for a detailed review). For example, it has been suggested that histones may be ubiquitinated to create new platforms for binding additional chromatin modifiers and thereby influence other modifications such as acetylation and methylation.⁷¹ Other studies have highlighted the involvement of the ubiquitination pathway in the elongation phase of transcription.⁷²

2.25.4.3.2 Acetylation

Acetylation of both histone proteins and coregulators constitutes an important regulatory event for the NR transcriptional apparatus. For example, the hyperacetylation of histones 3 and 4 correlates with increased transcriptional activity. Many NR coregulators, including CBP, possess intrinsic histone acetylation activity.⁶⁶ CBP/p300 is also known to acetylate other coregulators, resulting in a disruption of the association between histone acetyltransferase (HAT) coactivator complexes and promoter-bound NR. This CBP acetylase process can therefore provide negative regulation of ligand-dependent transcription.⁷³ In addition, some nuclear hormone receptors can also be acetylated (e.g., ER α and AR). Acetylation of ER α and AR results in completely different outcomes: ER α transactivation is attenuated, but AR transcription activity is induced.⁶⁶ Acetylation is documented to exert other biological effects such as regulation of the translocation of nuclear transcription factors.

2.25.4.3.3 Methylation

Histone arginine methylation is commonly associated with activated gene expression⁷⁴ that strengthens coregulator functions through a mechanism that releases histone proteins from DNA.^{65,66} This action complements the acetyltransferase activity of other coregulators. For example, the methyltransferase PRMT1 methylates histone H4, and this step facilitates subsequent acetylation of H4 by acetyltransferase p300. Crosstalk between another methyltransferase, CARM1, and CBP/p300 can also positively regulate the expression of estrogen-responsive genes.⁷⁵ Apparently acetylation enables tethering of CARM1 to the histone H3 tail, effectively producing a more efficient arginine methyltransferase. PRMT1 and CARM1 have also been shown to bind the p160 family of coactivators, resulting in increased receptor activation and NR-mediated gene transcription.⁷⁶

2.25.4.3.4 Phosphorylation

Phosphorylation plays an integral role in regulating both NR coregulator activity and subsequent NR function,⁶¹ adding yet another layer of complexity to the control of NR target gene regulation. Ongoing research has uncovered crosstalk between both Class I and II receptors and several kinase cascades.⁶¹ For example, estrogen (E₂) and retinoic acid (RA) signaling causes rapid activation of mitogen-activated protein kinases (MAPKs), which can then phosphorylate the N-terminal AF-1 domains of both ER α and RAR γ . This type of phosphorylation event controls chromatin rearrangement, in part by recruiting p160 coactivators. MAPK-induced phosphorylation also induces the ubiquitination (and degradation) of some NRs, including RARs and PR. The situation is even more complex because both corepressors and coactivators are also phosphorylated by MAPKs in response to steroidal and nonsteroidal hormones (e.g., see ⁷⁷). Phosphorylation of histones by MAPK highlights another important concept – the ‘histone code hypothesis’ – which states that a combinatorial and coordinated dynamic model exists whereby phosphorylation participates with acetylation, methylation, and ubiquitination to provide motifs for recruiting other chromatin-modifying or -remodeling complexes.⁶¹

Other new concepts relevant to the role of phosphorylation in regulating NR-mediated transcription have emerged over the past few years. For example, it now appears that the general transcription factor TFIID is also capable of phosphorylating NRs.⁷⁸ In addition, phosphorylation in response to several extracellular signals, including growth factors, insulin, stress, and cytokines that end in kinases such as MAPK, can provide a mechanism to terminate the response to the NR ligand and ensure the escape of the NRs (e.g., PPAR γ and RARs) from the transcription initiation complex.^{79,80}

2.25.5 Physiological Functions of Nuclear Receptors

The NR superfamily regulates many aspects of development, metabolism, and inflammation. As described above, these transcription factors share a common molecular structure and therefore can be considered as a functional entity. Dr Ronald Evans (The Salk Institute, San Diego) recently speculated that the evolution of this superfamily is related to survival of the organism.¹ To survive, all organisms need to acquire and manage energy stores. Generally, the PPARs regulate dietary endogenous fat (and cholesterol), the LXRs and FXRs respond to cholesterol and its derivatives, GR to sugar mobilization, MR to salt, VDR to calcium, TR to basic metabolic rate, while new studies show that ER α increases mitochondrial efficiency.⁸¹ The xenobiotic receptors (PXR and CAR) are specialized to respond to environmental toxins, many of which are present in the human diet. Reproduction is also a means of survival, and the gonadal steroid receptors (ER, AR, and PR) control this important biological function. The retinoid acid-dependent RARs are essential for embryonic development. Fertility depends on nutritional status, and thus these two regulatory branches of the family must communicate. Finally, the organism must protect itself from viral, bacterial, and fungal infections mainly through the inflammatory response, but also by depressing appetite, conserving fuel, and inducing sleep. On the other hand, GR signaling can also be anti-inflammatory, as can PPARs, RARs, and LXRs. This section outlines the physiological functions of each of the NRs for which endogenous ligands have been identified (Classes I and II). A discussion of the physiological functions of the less well-defined oNRs (Type III) is beyond the scope of this chapter (see ^{82,83} for reviews).

2.25.5.1 Class I Receptors

Class I receptors comprise the classical high affinity, steroid hormone receptors (ERs, PRs, AR, GR, and MR), that bind their DNA targets as homodimers and sometimes as monomers.

2.25.5.1.1 Estrogen receptors

Estrogen (E₂) is one of the most well-defined nuclear hormones from the point of view of biological effects and clinical implications. Estrogens mainly control three female biological processes: pubertal development, regulation of estrous cycles, and establishment and maintenance of mammary tissue (see ⁸⁴). The effects of E₂ are mediated predominantly by two distinct estrogen NRs, ER α and ER β . The physiological consequences of ER signaling pathways extend beyond female reproductive tissues to include control over the skeletal system, cardiovascular system, and the central and peripheral nervous systems (see ^{84–86}). General cellular responses include cell cycle progression, cell growth and survival, energy, and cellular maintenance.

E₂ mediates its physiological and cellular effects through direct binding of liganded ER α to target genes, a process known as genomic signaling. ER β is a weak transcription factor and its translocation to the nucleus is rarely reported. For a review of the known genomic targets of estrogen, see ⁸⁷. Briefly, ER α -regulated genes encode protein products that include nuclear hormone receptors (including ER α , RAR α , and PR), non-NR transcription factors (c-fos), growth

factors (e.g., vascular endothelial growth factor and transforming growth factor- α), hormones (e.g., insulin-like growth factor-1), enzymes (e.g., TERT), and various other important proteins, including the cell cycle-related cyclin D1 and the prosurvival Bcl-2. ERs can also indirectly associate with gene promoters through protein–protein interactions with other transcription factors such as activating protein-1 (AP-1) and Sp1.⁸⁷

Recent studies have uncovered yet another level of genetic control that involves plasma membrane-associated ERs that, upon ligand binding, initiate signaling cascades of phosphorylation events, resulting in unique sets of ER-dependent genes (e.g., see ^{87,88}). In addition, a G protein-coupled receptor (GPR300), localized to the endoplasmic reticulum, specifically binds E_2 resulting in intracellular calcium mobilization and synthesis of phosphatidylinositol 3,4,5-triphosphate in the nucleus.⁸⁹ This nonclassical type of NR-dependent gene activation is termed nongenomic signaling. The relative levels of ER α and ER β (ER β often suppresses the effects to ER α) and available coactivators and corepressors further increase the complexity of E_2 response in a tissue- and gene-specific manner.^{14,88} Relatively little information is available for the nongenomic targets of ERs. However, recent reports show that membrane-bound ER α activates the expression of the endothelial nitric oxide synthase (eNOS) enzyme.^{90–92} Furthermore, nongenomic signaling of ER α (but not ER β) is involved in the control of dopamine function and protection of astrocytes.⁹³ ER β , however, has been localized to the mitochondria of a variety of cell types, suggesting estrogens can directly affect mitochondrial function through the modification of calcium influx, ATP production, apoptosis, and ROS generation.⁹⁴

Transgenic mice harboring whole body-, tissue-, or cell-specific knockout of one or more specific genes have revolutionized the study of the physiological and pathological functions of NRs. For example, one study found that *Er α* knockout female mice are infertile because they are anovulatory, have disruption of luteinizing hormone (LH) regulation, and have estrogen-insensitive uteri.⁹⁵ The same study found that *Er β* knockout female mice are subfertile and display defective ovulation similar to that found in human polycystic ovarian syndrome presented as lack ovarian function. Knockout mice lacking both genes are similar to *Er α* knockout mice, but exhibit unique ovarian pathology.⁹⁵ Mice with inactivated ER α and/or ER β also display a number of other interesting phenotypes, including incomplete differentiated epithelium in tissues under steroid control (breast, ovary, prostate, and salivary glands), obesity, and insulin resistance.

ER α signaling is implicated in cardiovascular homeostasis, in part through stimulation of athero-protective prostaglandin 12 (PG12) formation via activation of cyclooxygenase-2 (COX-2).⁹⁶ The nongenomic induction of eNOS by ER signaling probably also contributes to vascular and myocardial homeostasis through the controlled production of nitric oxide (NO) (e.g., see ^{97–99}). The involvement of ER α in cardiovascular health is highlighted by the ability of estrogen to protect against coronary heart disease, including ischemia-reperfusion injury¹⁰⁰ and other atherosclerotic diseases (e.g., see ¹⁰¹) and its well-characterized ability to decrease low-density lipoprotein cholesterol (LDL-C) and increase high-density lipoprotein cholesterol (HDL-C). Estrogens are also well known to have beneficial effects on bone, but the roles of ERs in mediating these effects are not fully understood. A recent study of *Er α* knockout mice confirmed earlier data indicating that these mice have shorter bones, as well as a total absence of growth plates in the tibia of aged (*Er α* knockout) females. However, trabecular bone volume and thickness were enhanced in both female and male knockout animals.¹⁰²

Estrogens are also widely recognized for their neuroprotective effects in several models of neurotoxicity, both in vitro and in vivo.^{103,104} Interestingly, however, in most of these studies, the naturally occurring estrogenic hormone 17 β -estradiol (17 β E2) is as neuroprotective as its inactive diastereomer 17 α -estradiol, even though 17 α E2 does not bind to ER α or ER β to any significant extent. These observations led to the proposal that the neuroprotective effect of estrogens is achieved through a nongenomic mechanism, and not through the classical nuclear receptor-mediated gene transcription. Whether this effect is mediated through a plasma membrane-associated ER or other specific mechanisms such as mitochondrial stabilization^{105,106} is still under active investigation. Nevertheless, this interesting dichotomy opens up the possibility of using 17 α E2 and other estrogen derivatives that do not bind the classical ER, as selective neuroprotectants that are devoid of feminizing side effects of classical estrogens in the breast and uterus.¹⁰⁷ Such nonfeminizing estrogens have demonstrated efficacy in animal models of stroke and Alzheimer's disease¹⁰⁷ and are under development.¹⁰⁸

ER β is also believed to play a role in bone homeostasis in addition to contributing to prostate and colon homeostasis,^{85,109} and controlling hematopoiesis.^{110,111} Finally, ERs also influence the development, plasticity, survival, and regulation of neurons, including serotonergic, dopaminergic, and cholinergic neurons.¹¹¹

2.25.5.1.2 Progesterone receptor

The expression of the progesterone receptor is activated by ERs, and progesterone cooperates with E_2 in the control of female pubertal development, regulation of estrous cycles, and establishment and maintenance of mammary tissue.⁸⁴ Whereas estrogens usually induce cellular proliferation, progesterone causes differentiation and inhibits cell growth.¹¹² Progesterone exerts its cellular effects through binding and activation of two receptors, PR-A and PR-B. Unlike ERs,

the PRs are expressed from one gene, but alternative transcription from two promoters yields two distinct proteins.¹¹³ The molecular activation of PR involves direct binding of the ligand-activated receptor to the promoter regions of each gene (genomic signaling). However, growing evidence indicates that plasma membrane-bound PRs exert some of progesterone's effects via nongenomic signaling pathways.¹¹⁴

Recent studies using knockouts of the *Pr* gene have provided further evidence not only for the essential role of PRs in a variety of female reproductive systems, but also for their importance in nonreproductive activities (e.g., see ^{115,116}). Female mice lacking both PRs exhibit impaired sexual behavior and neuroendocrine gonadotrophin regulation, anovulation, uterine dysfunction, and impaired ductal branching morphogenesis and lobuloalveolar differentiation of the mammary gland (for a review see ¹¹⁶). The PRs also regulate thymic involution during pregnancy and the cardiovascular system through regulation of endothelial and vascular smooth muscle cell proliferation and response to injury.¹¹⁶ PRs have also been detected in mouse ovary and are believed to participate in the regulation of ovulation, along with suppression of granulosa cell apoptosis and promotion of cell survival.¹¹⁷ PRs have been identified in bone tissue and the central nervous system, where they may be involved in bone maintenance and cognitive function, respectively.¹¹⁶ More recent studies have described isoform-specific knockouts for *Pr-a* and *Pr-b*¹¹⁵ supporting previous in vitro observations. The knockout of PR-A function results in an infertile phenotype, whereas knockout of the PR-B protein did not affect fertility in mice. On the other hand, loss of PR-A has no effect on mammary morphogenesis, but pregnancy-associated mammary morphogenesis is severely impaired in *Pr-b* knockout mice. By virtue of its ability to suppress E₂-induced and PR-B-mediated uterine and mammary proliferation, the PR-A isoform is likely to be an attractive drug target for the next generation of selective PR modulators (SPRMs) in the treatment of uterine and mammary gland hyperplasia.

2.25.5.1.3 Androgen receptor

Androgens (e.g., testosterone) are steroid hormones necessary for normal male phenotype expression, including the outward development of secondary sex characteristics as well as the initiation and maintenance of spermatogenesis. AR directly regulates expression of an array of target genes that are important in male pubertal development and fertility. The androgen/AR system is also known to have a variety of other effects in many target organs, including brain, skeletal tissue, and heart (e.g., see ^{118–121}). Transgenic *Ar* knockout mouse studies have highlighted other physiological actions of AR, including promoting late-onset obesity of white adipose tissue, while mutant ARs (in a *Drosophila* model) show marked neurodegeneration.¹²² In addition, AR may also modulate specific immune functions. Androgens can exert a cardiovascular protective effect, in part by protecting against angiotensin (Ang) II-stimulated cardiac fibrosis (impairment of both the concentric hypertrophic response and left ventricular function). The molecular underpinnings of this action involve activation of expression and signaling through transforming growth factor- β 1, a well-known profibrotic cytokine, and subsequent upregulation of collagen I and III expression.¹²⁰ Interestingly, this same study suggests that transduction through an important signaling pathway, extracellular signaling-regulated kinases (ERK) 1/2 and ERK5, by Ang II was attenuated in the *Ar* knockout hearts compared with wild-type animals. These data imply that AR signaling, similar to other Class I NRs (ER and PR), may involve nongenomic pathways.

2.25.5.1.4 Glucocorticoid receptor

Glucocorticoids, such as cortisol, exert their effects by binding and activating the GR. New studies have identified a second GR, GR β , which is a splice variant of the classical receptor GR α and functions as a dominant-negative transcriptional inhibitor of GR α .¹²³ The glucocorticoid/GR system is central to protecting the body against stress by regulating glucose metabolism and blood pressure (e.g., see ¹²⁴ for a review). Glucocorticoids stimulate hepatic gluconeogenesis and reduce the ability of insulin to inhibit glucose production.¹²⁵ This NR is also involved in lipid metabolism and glycogen deposition in the liver. In addition, the glucocorticoid/GR system affects behavior and brain function, organ development, and calcium reabsorption.

GR is a potent anti-inflammatory and immunosuppressive modulator (e.g., see ¹²⁴). This control is achieved through an indirect negative regulation of gene expression (transrepression) whereby ligand-activated GR binds as a monomer to other transcription factors, such as the pro-inflammatory nuclear factor kappa B (NF κ B) and AP-1 transcription factors.^{124,126} The precise mechanism of action of GR transrepression remains unresolved, but it appears to involve the DBD of the GR protein that directly associates with the target transcription factor. The transcriptional induction of specific NF κ B and AP-1 target genes (including a number of pro-inflammatory genes) is subsequently repressed.^{124,126} GR also contributes to thymocyte and lymphocyte selection and survival.¹²⁴ Furthermore, activated GR is required for stress-induced red blood cell production,¹²⁷ and more recent data implicate the receptor in activation of human platelets.¹²⁸

2.25.5.1.5 Mineralocorticoid receptor

Aldosterone, the most potent endogenous activator of the MR, has long been recognized as an important component of the secretions of the adrenal cortex and the prime regulator of sodium and potassium homeostasis. The main site of action of this nuclear hormone system is the sodium-transporting epithelia, such as the distal part of the nephron and the distal colon, as well as sweat and salivary glands, the cardiovascular system, the central nervous system (hippocampus), and the brown adipose tissue.¹²⁹ Even though the receptor was cloned more than 17 years ago, many basic features of MR function and regulation have yet to be fully characterized. Although glucocorticoids can bind MRs and are in much greater circulating abundance than aldosterone, a ligand-selective regulation exists.¹³⁰ In this model, aldosterone binding, but not cortisol binding, recruits the cellular transcriptional complex to the receptor and to native MR target gene promoters. MR is also capable of forming heterodimers with the GR, which can modulate gene expression in a manner that is distinct from the MR and GR monomers. Furthermore, aldosterone/GR effects can be antagonized by the PR system and by the TR, but it remains uncertain whether MR can form heterodimers with these receptors.¹²⁹ Taken together, the available literature indicates that crosstalk among these four nuclear hormone receptors influences the complex physiological effects of MR. This regulatory control is made more complex by the fact that these NR actions depend on a number of factors including the tissue site, target gene, the relative distribution of each NR, ligands, and coregulators.

2.25.5.2 Class II Receptors

Class II NRs typically form heterodimers with RXR, a lipid sensor receptor that can also form homodimers. Type II NRs can be divided into functionally distinct nonpermissive (VDR and TRs) and permissive (PPARs, LXRs, and FXR) groups.⁶¹ The permissive partners generally function as low-affinity lipid sensors, while the nonpermissive partners are high-affinity hormone receptors.

2.25.5.2.1 Vitamin D receptor

The vitamin D–VDR system plays an essential role in calcium homeostasis, bone mineralization, and skeletal architecture. It also has antiproliferative, prodifferentiation, and immunomodulatory properties, and controls other hormonal systems both in cell culture and in animal models (e.g., see ¹³¹). VDR is expressed in many tissues, including the intestine, bone, kidney, and parathyroid glands. VDR is also considered to be a bile acid sensor/receptor in both the liver and the intestine, that causes induction of cytochrome P450 (CYP)3A4 expression.^{132,133} The control of bile acid homeostasis is complex and is known to involve other nuclear hormone receptors, including LXR, FXR, CAR, and PXR (see below).

Vitamin D, a steroid, is metabolically converted to the active metabolite, 1,25-dihydroxyvitamin D [$1,25(\text{OH})_2\text{D}_3$] in the renal proximal tubules, after facilitated uptake and intracellular delivery of the precursor to the enzyme 1- α hydroxylase. The 1- α hydroxylase protein has also recently been detected in the parathyroid glands.¹³⁴ Transgenic *Vdr* (and/or *1- α hydroxylase*) knockout mice models have shown both $1,25(\text{OH})_2\text{D}_3$ -dependent and -independent actions of the VDR as well as VDR-dependent and -independent actions of $1,25(\text{OH})_2\text{D}_3$.

Downstream physiological targets are influenced through VDR forming a heterodimeric transcriptional complex with RXR to exert its effects over target genes. Thus, not surprisingly, the vitamin D system most likely involves the participation of more than a single receptor and ligand. The presence of 1- α hydroxylase in many target cells indicates autocrine/paracrine functions for $1,25(\text{OH})_2\text{D}_3$ in the control of cell proliferation and differentiation. Local production of $1,25(\text{OH})_2\text{D}_3$ is dependent on circulating precursor levels, and fluctuations in these levels provide a potential explanation for the association of vitamin D deficiency with various cancers and autoimmune diseases (see [Section 2.25.6](#) for a discussion of the pathological implications of VDR and other NRs).

2.25.5.2.2 Retinoic acid receptor

Retinoic acid (RA), the most biologically active metabolite of vitamin A (retinol), influences embryogenesis and cell proliferation, differentiation, and apoptosis in the adult.¹³⁵ All-*trans* and 9-*cis* RAs exert their biological effects through RARs and RXRs, respectively. The highly pleiotropic effects of signaling through RARs are caused, in part, by the combinatorial action of the three types of RAR receptors (RAR α , RAR β , and RAR γ) and their isoforms ($\alpha 1$, $\alpha 2$, $\beta 1$ –4, and $\gamma 1$ and $\gamma 2$) with the three RXRs (RXR α , - β , and - γ) and with coregulators. This subsection focuses on the physiological functions of RARs in general. For detailed reviews of RXRs, see ^{2,14,136,137}.

The importance of retinoids and their receptors in development has been recognized for years.^{138,139} Retinoid receptors are widely expressed in the vertebrate embryo, and there appears to be little redundancy among the RAR subtypes. Vitamin A or RAR deficiency has been reported to affect the developing embryo at the time of the first organ

system initiation.¹³⁸ From that developmental time point onward, RARs control multiple stages of development for numerous tissues and organs. For example, RAR signaling is known to be essential for normal heart development, and loss of RAR expression leads to heart abnormalities in ventricular chambers and defects in the outflow tract. On the other hand, other studies now suggest that RARs are critical in embryo formation well before organ formation, and in a number of adult homeostatic functions.¹³⁷ For example, RA/RAR signaling was recently suggested to be essential in controlling the bilateral symmetry of vertebrate embryos.¹⁴⁰ RARs are also involved in heart asymmetry determinations – vitamin A and RARs provide a proper environment for the expression of adequate levels of heart asymmetry genes.¹³⁸ RARs play important roles in the development of the central nervous system and are required at the time of specification of the posterior hindbrain and for the subsequent specification of segments in that region and for neurite outgrowth and neural crest survival.^{138,141} RA and RAR have long been linked to vertebrate limb morphogenesis. For example, an analysis of the expression of genes in embryo limb buds revealed a critical role for RA/RAR in anteroposterior and dorsoventral patterning.¹⁴² Finally, RARs also contribute to the development of a normal respiratory tract.¹⁴³

In the normal adult, RARs have long been implicated in the proliferation and differentiation of epithelial cells. A common model of RAR dysfunction that involves a deficiency in vitamin A (VAD) presented several symptoms associated with VAD: blindness, immune response (to infectious disease) dysfunction, and skin disorders. RA has also been shown to promote tissue regeneration in a RAR-dependent manner in adult, nonregenerating tissues such as lung, inner ear, hair, and spinal cord.¹⁴⁴ Retinoids are also believed to protect the human lung against injury from elastase.¹⁴⁵ Thus, RARs are vital for the development and maintenance of a number of physiological functions, including vision, hematopoiesis, reproduction, and contribute to the normal functioning of the nervous, pulmonary, and immune systems. Some of these physiological properties are directly related to the ability of this NR to control cellular proliferation and differentiation.¹³⁷

New studies suggest that RAs/RARs are important inducers of genes involved in the reverse cholesterol transport (RCT) associated with increased macrophage lipid efflux, such as the cholesterol transporter adenosine triphosphate (ATP)-binding cassette A1 (ABCA1), ABCG1, and LXR α .¹⁴⁶ RCT is discussed in more detail in the PPAR and LXR discussions below. Finally, like GR and PPARs, RARs also display anti-inflammatory properties through transrepression (e.g., see ¹³⁷). Ligand-activated, monomeric RAR binds directly to pro-inflammatory transcription factor proteins (e.g., AP-1 and NF κ B) causing downregulation of a number of important inflammatory genes.^{126,137}

2.25.5.2.3 Thyroid hormone receptor

TRs are expressed throughout the body and are involved in normal growth, development, differentiation, and metabolism in vertebrates. The biologically active thyroid hormone (TH), L-3,5,3'-triiodo-L-thyronine [T_3], is derived from L-3,5,3',5'-tetraiodo-L-thyronine (T_4) through the action of the D2 iodothyronine deiodinase, and this hormone exerts its effects mainly through two known TRs (TR α and TR β). Recent studies indicate that the low-affinity TR-binding 3,5-diiodo-L-thyronine (T_2) is also active, involved in at least cellular-mitochondrial respiration, through a possible TR-independent mechanism.^{147,148} Alterations in the activities of the three selenocysteine-containing iodothyronine deiodinase enzymes have been reported during development and in specific cells and tissues in the adult. These deiodinases are envisaged as 'guardians to the gate of thyroid hormone action mediated by T_3 receptors'.¹⁴⁹

The two subtypes of TRs are known to exist in a complex distribution pattern throughout the body. For example, TR α is highly abundant in the heart, and most effects of T_3 on the cardiovascular system, including mitochondrial maturation and substrate metabolism after birth, are mediated through this receptor.¹⁵⁰ TR β preferentially regulates energy and cholesterol metabolism,¹⁵¹ offering the possibility that isoform-specific TR synthetic ligands might safely increase energy expenditure. TR α is also essential for skeletal development, regulating bone turnover and mineralization in adults. These physiological effects are now believed to include TH/TR control over growth hormone receptor and insulin-like growth factor-1 receptor.¹⁵² Finally, the TH/TR system is believed to play important roles in trophoblast function, early pregnancy maintenance, fetal neurodevelopment, and the adult central nervous system.¹⁵³

2.25.5.2.4 Peroxisome proliferator-activated receptors

The three closely related PPAR isotypes, PPAR α , PPAR γ , and PPAR δ , have recently been the focus of extensive research since the exciting discovery that PPAR α and PPAR γ were targets of major classes of drugs (the fibrates and glitazones, respectively) used to correct abnormalities of lipid and glucose homeostasis (see [Section 2.25.6.9](#) for a discussion of the current status of the pharmacology of PPARs). The PPARs function as lipid sensors that coordinate the expression of large gene arrays and thereby modulate important metabolic events.¹⁵⁴ The endogenous, low-affinity

ligands of PPARs include a wide range of fatty acids and oxidized fatty acid metabolites from the lipoxygenase and cyclooxygenase pathways. Each PPAR protein is encoded in a separate gene, and upon activation these ligand-dependent transcription factors form heterodimers with RXR. PPARs and RXRs can apparently function independently (in the absence of a hetero-partner) to modulate gene expression,¹⁵⁵ adding to the complexity of PPAR transcriptional control. PPARs are known to control multiple metabolic functions including fatty acid β -oxidation, cholesterol transport, and glucose and amino acid metabolism.¹⁵⁶ All three PPARs also participate in certain aspects of inflammation.¹⁵⁷ PPARs are able to regulate inflammatory responses as a result of their transactivation and transrepression capacities. Like GR and RARs,^{126,137} PPARs achieve transrepression by antagonizing NF κ B and AP-1.¹⁵⁸ In addition, PPAR γ can transrepress the pro-inflammatory transcription factor, signal transducer and activator of transcription (STAT3). Conversely, PPAR δ has been implicated in the activation of inflammatory macrophages through antagonism of BCL6, an inflammatory cytokine repressor.¹⁵⁹ The PPARs also control vascular wall biology, placental physiology, and immunity.^{160,161} The impressive multifunctional effects of the PPAR family, as those of the RARs, result partly from the combinatorial action of each PPAR protein with the three RXR proteins.

PPAR α is highly enriched in the liver, heart, muscle, brown adipose tissue, kidney, adrenal gland, and pancreas, where it primarily regulates fatty acid catabolism and glucose oxidation.^{162,163} Mice with targeted disruption of PPAR α exhibit low expression of a number of genes required for metabolism of fatty acids, including acyl-CoA oxidase,¹⁶⁴ and suffer from a variety of metabolic defects, including hypoketonemia, hypothermia, elevated plasma free fatty acid levels, and hypoglycemia.¹⁵⁵ Other studies have shown that activation of PPAR α increases lipoprotein lipase activity in skeletal muscle, with a reciprocal decrease in adipose tissue lipase (reviewed in ¹⁶⁰). Therefore, PPAR α agonists can reduce the uptake of triglycerides in adipose tissue while increasing uptake in muscle for fatty acid oxidation. PPAR α also contributes to glucose-stimulated insulin secretion from pancreatic β -cells while increasing fatty acid uptake and β -oxidation.¹⁶⁵ Activation of PPAR α (and PPAR γ) also induces cholesterol removal from human macrophage foam (lipid-laden) cells through stimulation of ABCA1¹⁶⁶ through a mechanism involving PPAR γ - and PPAR α -dependent upregulation of LXR α -dependent transcription.^{167,168} This process is a first step in RCT that involves net flux of cholesterol to the liver and disposal of it in the form of bile acids. PPAR α ligands are also linked to improved myocardial homeostasis (e.g., reduction in incidence of myocardial infarction); the ligands probably act at the artery wall (in part through control of smooth muscle proliferation) and systemically to control lipid homeostasis.¹⁶⁰ Furthermore, PPAR α is believed to be involved in wound healing through its effects on related inflammatory and keratinocyte responses.¹⁶⁹

The expression of PPAR γ is enriched in brown and white adipose tissues, and the receptor is also found in numerous other tissues, including macrophages, adipocytes, mammary epithelium, ovary, and lymphoid tissue.¹⁷⁰ This NR is a late marker of adipocyte differentiation, and its forced ectopic expression can push fibroblasts into the adipogenic program.¹⁷¹ Although *Ppar γ* mice are not viable (because of defects in placenta formation), genetic knockout models of tissue-specific deletion of *Ppar γ* imply that this protein is essential for the survival of mature adipocytes in the adult.¹⁷¹ PPAR γ is also involved in fat storage not only in adipocytes, but also in liver,¹⁵⁵ smooth muscle cells, activated macrophages,^{159,172} and pancreatic β cells.¹⁶⁵ For example, *Ppar γ* heterozygous mice challenged by a high-fat diet are less prone to liver cell accumulation of fat (steatosis) than their wild-type counterparts.¹⁷³

As discussed above, PPAR γ and PPAR α induce RCT.¹⁶⁷ In addition to its effect on ABCA1 via LXR synthesis, PPAR γ also increases the production of LXR ligands.¹⁶⁰ Other recent studies demonstrate the involvement of PPAR γ in the regulation of adipocyte cholesterol metabolism via oxidized low-density lipoprotein (LDL) receptor 1 (OLR1).¹⁷⁴ Although the physiological role of PPAR γ in cholesterol and LDL remains to be established, the induction of OLR1 is a potential means by which PPAR γ regulates lipid metabolism and insulin sensitivity in adipocytes.¹⁷⁴ Another seminal study found that muscle-specific *Ppar γ* deletion causes insulin resistance.¹⁷⁵ Furthermore, PPAR γ , in contrast with PPAR α , attenuates glucose-stimulated insulin secretion in pancreatic β -cells.¹⁶⁵ The concept that PPAR γ is an important regulator of glucose metabolism and improves insulin sensitivity in muscle offers an exciting link between adipocyte biology and peripheral insulin resistance.

PPAR γ , although expressed in very low levels in the heart, appears to contribute to overall cardiac homeostasis by limiting fibrotic effects of angiotensin II.¹⁶⁰ PPAR γ also controls cellular proliferation and possesses an antiproliferative effect in pre-adipocytes and mammary epithelial cells.¹⁷⁰ Interestingly, mice with knockout oocyte- and granulosa-specific *Ppar γ* have low fertility rates.¹⁷⁰ Finally, PPAR γ has been implicated in a number of processes associated with the central nervous system, including protection against oxidative stress and control of the amyloid cascade.¹⁷⁶

PPAR δ is ubiquitously expressed with high levels in colon, brain, skeletal muscle, heart, and skin.^{177,178} Data on the physiological roles for PPAR δ have just begun to emerge, but they underscore the multifunctional nature of this transcription factor. It plays a role in controlling not only lipid oxidation, but also many other physiological processes, including embryonic development, energy homeostasis, macrophage lipid and cholesterol levels, inflammation, cardiovascular homeostasis, wound healing, cell survival, differentiation, and proliferation.^{162,177,179–181}

Activation of this transcription factor increases lipid catabolism in skeletal muscle, heart, and adipose tissue, and thus this NR is a target for weight reduction.¹⁸² The major effects of PPAR δ on liver appear to involve the promotion of glycolysis, leading to reduced hepatic glucose output and lowered glucose levels.¹⁶⁰ PPAR δ also functions as a very low-density lipoprotein (VLDL) sensor in macrophages, regulating triglyceride accumulation. This important observation reveals a pathway through which dietary triglycerides and VLDL can directly regulate gene expression in atherosclerotic plaques.¹⁸³ In addition, PPAR δ has been found to contribute to inflammation by controlling the inflammatory switch of foam cells (lipid-laden macrophages) through its association and dissociation with transcriptional repressors such as BCL6.¹⁵⁹

Other studies suggest a role for PPAR δ in macrophage accumulation of cholesterol. For example, activation of macrophage PPAR δ with a high-affinity synthetic agonist (GW501516) resulted in increased expression of the cholesterol transporter ABCA1 and the induced apolipoprotein A1, and thereby led to cholesterol efflux (RCT).¹⁸⁴ This observation has been supported by in vivo studies showing PPAR δ activation improved cholesterol homeostasis in obesity-prone mouse models.¹⁸¹ Together, these data imply that PPAR δ plays a role, not yet clearly specified, in vascular homeostasis and disease.

PPAR δ has also been reported to play important roles in the control of cell proliferation, differentiation, and survival, especially in keratinocytes.¹⁶² Other work has suggested that PPAR δ , like PPAR α , is involved in wound healing, a process involving inflammatory myeloid cells (e.g., macrophages) and keratinocytes.¹⁵⁵ The Evans' group found that forced overexpression of PPAR δ in muscle led to a significant increase in the slow twitch fiber type and increased endurance in treadmill tests.¹⁶⁰ The same laboratory has also offered evidence that PPAR δ actually controls the expression of the other two PPARs, and thus acts as "a gateway receptor whose relative levels of expression can modulate PPAR α and PPAR γ activity."¹⁷⁸ The many diverse physiological roles of this ubiquitous NR remain controversial, but the available data certainly highlight the potential importance of all three PPARs in a number of critical physiological (and pathological) processes.

2.25.5.2.5 Liver X receptors

The LXRs (α and β) bind oxidized cholesterol derivatives (oxysterols) such as 24(S),25-epoxycholesterol. LXR α is expressed primarily in liver, adipose tissue, intestine, macrophages, and kidney, whereas LXR β is ubiquitous.¹⁵¹ Activated LXRs are deeply involved in RCT. Specifically LXRs induce the expression of proteins that stimulate export of cholesterol from macrophages (ABCA1 and ABCG1); promote cholesterol transport in serum and uptake in liver (apolipoprotein E, phospholipids transfer protein, lipoprotein lipase, and cholesterol ester transfer protein); increase cholesterol catabolism into bile acids (CYP7A1); increase biliary secretion of cholesterol (ABCG5 and ABCG8); and inhibit absorption of cholesterol in the intestine (ABCG5, ABCG8, and ABCA1).^{151,185,186} There are other routes for cholesterol efflux from macrophages, including loading onto mature high-density lipoprotein (HDL), involving the bidirectional scavenger receptor CLA-1/SR-B1, and oxidation of cholesterol to derivatives. LXR α and LXR β have also been shown to control major genes involved in each of these pathways.¹⁸⁶ LXRs increase fatty acid and triglyceride synthesis by increasing the protein synthesis of sterol regulatory element-binding protein 1c (SREBP-1c), the rate-limiting enzyme in fatty acid synthesis.¹⁸⁷

Like many of the other NRs, LXR also exhibits anti-inflammatory properties. For example, Joseph *et al.*, in a DNA microarray analysis, found that activation of LXR (with the synthetic ligand GW3965) suppressed many of the inflammatory-related genes induced by treatment of mouse (or human) macrophages with lipopolysaccharide (LPS).¹⁸⁸ These studies demonstrated reciprocal interference between the LXR and the pro-inflammatory NF κ B pathways,¹⁸⁶ a theme common among the NRs. Furthermore, LXR α is upregulated in macrophages in response to *Listeria* infection.¹⁶⁰ LXR induces genes that protect against programmed cell death (apoptosis) during bacterial infections in warm-bodied animals, contracted by consuming contaminated food. Not surprisingly, a new study (using high-throughput quantitative PCR analysis) documented the expression of 27 of the 48 known NRs in macrophages, and many of these proteins exhibited distinct temporal changes in expression following pro-inflammatory LPS stimulation (see ¹⁶⁰).

2.25.5.2.6 Farnesoid X receptor

FXR is a sensor of bile acids such as chenodeoxycholic acid and cholic acid.¹⁵¹ Target genes of this NR regulate the secretion of bile acids and phospholipids into bile (bile salt efflux pump and multidrug resistance proteins 2 and 3), the intestinal re-absorption of bile acids (ileal bile acid-binding protein (IBABP)), and hepatic cholesterol uptake from serum HDL (high-density lipoprotein; phospholipids transfer protein). Activated FXR increases transcription of short heterodimeric partner (SHP) and of CYP7A1, a repressor of the rate-limiting enzyme in bile acid biosynthesis, and this

mechanism effectively avoids negative feedback repression of bile acid synthesis. These properties were confirmed through the use of transgenic *Fxr* knockout mice. FXR-deficient mice display increased serum bile, total bile acid pool size, and fecal bile-acid excretion,¹⁵¹ findings that are consistent with altered bile acid homeostasis in response to impaired feedback inhibition of hepatic synthesis.

2.25.5.2.7 Constitutive androstane receptor and pregnane X receptor

CAR and PXR are xenosensors that mediate xenobiotic drug-induced changes by increasing transcription of genes that are involved in drug clearance and disposition (e.g., drug-metabolizing cytochromes P450, CYPs). Both receptors are highly expressed in the liver and small intestine. More recently, CAR and PXR have been implicated in the homeostasis of cholesterol, bile acids, bilirubin, and other endogenous hydrophobic molecules in the liver. CAR and PXR thus form an intricate regulatory network with other members of the NR superfamily, foremost LXR, FXR, and PPARs.¹⁸⁹ Through coordinated regulation of transcriptional programs, these NRs regulate key aspects of cellular and whole-body sterol homeostasis, including cholesterol absorption, lipoprotein synthesis and remodeling, lipoprotein uptake by peripheral tissues, RCT, and bile acid synthesis and absorption.¹⁹⁰

Table 3 summarizes some of the more pharmacologically relevant functions of Class I and II NRs and includes the specific receptors currently known to be involved in each of these mechanisms.

2.25.6 Pharmacology of Nuclear Receptor Ligands

The discussion in [Section 2.25.5](#) clearly demonstrates that NRs are involved in several important physiological functions. The NR superfamily therefore offers a plethora of targets for pharmacological intervention and development of therapeutics. Several widely used clinical drugs were discovered to act on NR targets (e.g., fibrates and glitazones). On the other hand, the identification of natural ligands for oNRs and development of synthetic agonists and antagonists has enabled significant advances in our understanding of the roles of the NR superfamily in health and disease. Several synthetic NR ligands are used clinically in the treatment of cancer, metabolic syndromes, inflammation, and immunosuppression. **Table 4** shows a list of approved drugs that target NRs.

An emerging concept in the area of NR pharmacology is the principle of selective NR modulators (SNRMs). SNRMs are NR ligands whose spectrum of activity can range from agonist to partial agonist to antagonist, in a tissue-selective manner. This phenomenon of tissue-selective action was first observed with the ER antagonist tamoxifen, widely used in the treatment and prevention of breast cancer. Tamoxifen has antagonist activity at the ER in breast tissue, but has protective effects in bone and cardiovascular tissue as an ER agonist. When the concept of SERMs was introduced, it sparked intense research to understand the molecular basis of the tissue- and cell-specific actions of

Table 3 Nuclear receptor involvement in human physiology

<i>Physiological function</i>	<i>Implicated NRs</i>
Reproduction	ER, PR, and AR
Fetal development	TR, RAR, and PPAR δ
Cardiovascular homeostasis	ER α , PR, RAR, TR, PPAR γ , and PPAR δ
Skeletal homeostasis	ER α , VDR, TR
Central nervous system homeostasis	ER, PR, GR, RAR, TR, and PPAR δ
Immunomodulation	GR, VDR, RAR, and PPAR
Hematopoiesis	ER β and RAR
Inflammation	GR, RAR, PPAR, and LXR
Wound healing	PPAR α and PPAR δ
Glucose homeostasis	ER, GR, and PPAR
Lipid and cholesterol homeostasis	VDR, TR, PPAR, LXR, FXR, CAR, and PXR
Toxin detoxification	CAR and PXR

Table 4 Selected approved drugs targeting nuclear receptors

<i>Target receptor</i>	<i>Drug</i>	<i>Compound class</i>	<i>Brand name</i>	<i>Indication</i>
ER α	Tamoxifen	SERM	Nolvadex	Breast cancer treatment, prevention
	Raloxifene	SERM	Evista	Osteoporosis
	Conjugated equine estrogens	Natural hormone	Premarin	Menopausal symptoms
PR	Norgestimate	Progesterone-based PR agonist	OrthoCyclen	Oral contraceptive
	Norethisterone	Testosterone-based PR agonist	Micro-Novum	Oral contraceptive
AR	Bicalutamide	Nonsteroidal androgen antagonist	Casodex	Prostate cancer treatment
	Flutamide	Nonsteroidal androgen antagonist	Drogenil	Prostate cancer treatment
GR	Dexamethasone	Steroidal GR agonist	Decadron, Dexameth,	Anti-inflammatory
MR	Eplerenone	Nonsteroidal MR antagonist	Inspra	Hypertension
RXR α , RXR β , and RXR γ	Bexarotene	Rexinoid	Targretin	Refractory cutaneous T-cell lymphoma
RAR α , RAR β , and RAR γ ; RXR α , RXR β , and RXR γ	Alitretinoin	Retinoid	Panretin	Kaposi's sarcoma (topical only)
RAR α , RAR β , and RAR γ	Tretinoin	Retinoid (e.g., all- <i>trans</i> -Retinoic acid)	Retin-A, Renova, Vesanoid	Acute promyelocytic leukemia, acne
	Isotretinoin	Retinoid (e.g., 13- <i>cis</i> -Retinoic acid)	Accutane	Severe nodular acne
Vitamin D receptor	Calcitriol	1,25-Dihydroxyvitamin D ₃	Rocaltrol, Calcijex	Hypocalcemia due to chronic renal failure and hypoparathyroidism
	Ergocalciferol	Vitamin D ₂	Calciferol	Vitamin D-resistant rickets, hypoparathyroidism, familial hypophosphatemia
TR α and TR β	Levothyroxine	Thyroid hormone	Levo-T, Unithroid, Levothyroid, Levoxyl, Synthroid	Hypothyroidism, euthyroid goiters, Hashimoto's thyroiditis
PPAR γ	Pioglitazone	Thiazolidinedione	Actos	Type 2 diabetes mellitus (monotherapy or combination therapy)
	Rosiglitazone	Thiazolidinedione	Avandia	Type 2 diabetes mellitus (monotherapy or combination therapy)
PPAR α	Fenofibrate	Fibrate	Tricor	Types IIa, IIb, IV, and V hyperlipidemia
	Gemfibrozil	Fibrate	Gemcor, Lopid	Types IIb, IV, and V hyperlipidemia

SERMs in particular and NRs in general.^{191,192} What we now know about the selective control of NR action by NR coactivators, corepressors, and other modifiers of NR action makes it possible to design NR ligands that dissociate desired NR effects from the undesired effects in a tissue-selective manner. Thus, the concept of SNRMs has been extended to other NRs such as the GR, PPAR, and AR. The development of SNRMs is an active area in pharmaceutical drug discovery and has yielded several potential clinical candidates.

2.25.6.1 Estrogen Receptor Ligands

The natural ligand for ER α and ER β is the steroidal hormone 17 β -estradiol (E2), which plays a critical role in the growth and function of reproductive tissues such as breast, uterus, and ovaries, as well as in maintaining bone mineral density, cardiovascular health, and cognitive function. E2 and synthetic estrogens such as ethinylestradiol (EE) and norethindrone acetate (Figure 5) have been widely used clinically for oral contraception and management of osteoporosis and postmenopausal symptoms in hormone replacement therapy (HRT). Although evidence from studies using animal models suggests that estradiol plays a critical neuroprotective role against multiple types of neurodegenerative diseases, recent clinical studies have reported either inconclusive or untoward effects of HRT on the brain.¹⁹³ HRT is a regimen generally including a variety of sex steroids such as estrogens and progestins, given to

Figure 5 Steroidal and nonsteroidal ER ligands.

postmenopausal women for the relief of menopausal symptoms and prevention of osteoporosis, cardiovascular disease and dementia. However, the Women's Health Initiative (WHI), the largest randomized clinical trial of HRT to date, showed that the combination of conjugated equine estrogen and progesterone medroxyprogesterone acetate (PremPro) as well as estrogen given alone, resulted in an 'increased' risk of strokes, breast cancer and blood clots and provided no significant benefit.¹⁹⁴ Although skeletal benefits and fracture reduction were observed, the overall lack of benefit prompted the discontinuation of the long-term use of HRT for chronic disease prevention in postmenopausal women.¹⁹⁵ An ancillary arm (WHI Memory Study) of this randomized study also evaluated the effect of HRT on cognitive function and found no benefit but an increased risk of stroke and Alzheimer's disease.^{196,197}

Synthetic estrogens function as ER agonists in all tissues that express ER α and ER β . Since ER also has a proliferative effect on breast and uterine tissue, long-term estrogen use, particularly in HRT, has been implicated as a risk factor for breast and uterine cancer.¹⁹⁸ However, ER antagonists, also sometimes referred to as antiestrogens, have been used to treat and prevent breast cancer for decades. Tamoxifen, a nonsteroidal antiestrogen (Figure 5), has been the mainstay for therapy of ER-positive breast cancer and is now also used as adjuvant therapy in early breast cancer and as a chemopreventive to reduce breast cancer incidence in healthy women at high risk for the disease. Tamoxifen's activity profile of estrogen antagonist effects in breast tumor tissue but estrogen-like agonist effects on the endometrium and bone led to the concept of tissue-selective effects of antiestrogens and SERMs.¹⁹⁹ Since then, several nonsteroidal and steroidal SERMs have been developed and used clinically not only for breast cancer, but also for other indications such as osteoporosis and HRT.²⁰⁰ Among the triphenylethylene class of SERMs similar to tamoxifen, toremifene (Fareston) is currently used in advanced breast cancer and has the same mixed agonist/antagonist profile as tamoxifen. Second- and third-generation SERMs have now been developed that have a much improved tissue profile than tamoxifen. Fixed-ring SERMs such as raloxifene are devoid of any estrogenic effects in the uterus, but are potent antiestrogens in the breast while retaining favorable estrogen-like agonist activity in the bone and cardiovascular system. Raloxifene is currently used for osteoporosis in postmenopausal women and is in clinical trials for breast cancer prevention. Newer SERMs such as lasofoxifene (Oporia), arzoxifene, and bazedoxifene (Figure 5) are also under development for prevention of breast cancer and osteoporosis.^{200–203} Among steroidal SERMs, SR16234 (TAS-108) (Figure 5), currently in clinical trials against advanced breast cancer, shows efficacy in tamoxifen-resistant breast cancer²⁰⁴ and has a favorable SERM profile without estrogenic effects on uterine tissue.

Another class of ER antagonists distinguishable from the SERMs in terms of pharmacology and molecular mechanism of action comprises the selective estrogen receptor downregulators (SERDs). Of the three steroidal SERDs developed thus far, only fulvestrant (ICI 162384, Faslodex) is currently used clinically as second-line therapy in advanced breast cancer. Although SERDs also bind the ER, they inhibit receptor dimerization and disrupt nuclear localization, with a concomitant increase in ER turnover and subsequent reduction in the number of ER molecules in the cell.^{205,206} Thus, SERDs inhibit the expression of estrogen-dependent genes by ER downregulation. This effect is independent of coregulator involvement and occurs in all ER-expressing tissues; thus these compounds are also referred to as 'pure antiestrogens,' in contrast to the tissue-selective SERMs.

SERMs also have the potential to be used for their cardiovascular benefits and favorable effects on cholesterol ratios. Indeed, lasofoxifene is in clinical trials for dyslipidemia. The beneficial effects of SERMs on cognitive function, however, have been underexplored, and an opportunity for future drug discovery in this area may exist.

The pharmacology of estrogen action mediated via the ER β subtype is only now being unraveled. While both ER α and ER β have significant homology in their DNA- and ligand-binding domains, the different expression patterns in tissues suggests that each receptor plays a distinct role in estrogen signaling.²⁰⁷ Although phytoestrogens such as genistein have ER β agonist activity and several other synthetic selective ligands have been identified, only a few have sufficiently high selectivity to be used to probe ER β pharmacology.²⁰⁸ The recent discovery of a highly selective ER β agonist, ERB-041, with a 200-fold selectivity for ER β led to the discovery of a new function for ER β in modulation of the inflammatory response^{209,210} in a model of chronic inflammation and in a model of inflammatory bowel syndrome. Thus, the discovery of ER β -selective ligands will aid in understanding the role of ER β in mammalian biology and discovering new therapeutic targets. Exploiting the role of ER β in the prostate for the treatment of prostate cancer is another area that will benefit from the discovery of ER β -selective ligands.¹¹¹

2.25.6.2 Progesterone Receptor Ligands

Progesterone, the natural ligand for the PR, exerts its physiological effects through the PR, which is expressed as two isoforms, PR-A and PR-B. Progesterone plays an important role in female reproduction, controlling ovulation and maintaining pregnancy, and in the growth and differentiation of endometrial and myometrial cells in the uterus.

Figure 6 Progesterone receptor ligands.

Several PR agonist ligands (progestins) and antagonist ligands (antiprogestins) have been developed for use as oral contraceptives and HRT. The synthetic progestins are testosterone derivatives (norethisterone and levonorgestrel) or progesterone derivatives (desogestrel, etonogestrel, gestodene, and norgestimate), shown in [Figure 6](#). Several new fourth-generation progestins, such as dienogest and drospirenone, have been synthesized in the past decade. These two new progestins have no androgenic effect but a partial antiandrogenic effect. Drospirenone also exerts antimineralocorticoid effects, leading to decreased salt and water retention and lowering of blood pressure in users of pills containing this progestin. The 19-norprogesterone derivatives such as trimegestone are specifically progestational and do not possess any androgenic, estrogenic, or glucocorticoid activity. They are referred to as 'pure' progestational molecules because they bind almost exclusively to the PR and do not interfere with the other steroid receptors.

The discovery of mifepristone (RU486), the first GR and PR antagonist, marked the beginning of drug discovery related to PR antagonists (antiprogestins). Several newer progesterone antagonists with reduced glucocorticoid activity (e.g., onapristone) ([Figure 6](#)) have also been synthesized. Most antiprogestins are used primarily for termination of pregnancy and postcoital contraception, and do possess undesirable side effects on the endometrium. A new class of SPRMs has now been developed that have antiproliferative effects on the endometrium and breast, but retain the protective effects of ovarian estrogen on bone and cardiovascular system. SPRMs are being developed for the treatment of uterine leiomyoma and endometriosis.²¹¹ Asoprisnil (J867) is the first SPRM to reach an advanced clinical stage and demonstrates a high degree of endometrial selectivity and partial agonist/antagonist PR activity.^{212,213} It is effective in reducing endometriosis-associated pain, shrinks uterine fibroids, and induces a reversible amenorrhea without estrogen deprivation, indicating that the endometrium is its preferred target tissue.

2.25.6.3 Androgen Receptor Ligands

The AR is expressed in several tissues, and androgens play a role in maintaining muscle mass and bone strength, decreasing fat tissue, and enhancing libido.¹¹⁸ In addition, androgens, acting through ARs, play a critical role not only in the physiological development and function of the prostate, but also in the genesis of prostate cancer.

Figure 7 Androgen receptor ligands.

Natural AR agonists, principally testosterone and 5- α -dihydrotestosterone (DHT) and their synthetic derivatives nandrolone, oxandrolone, and stanozolol (Figure 7), have been used to treat a number of clinical conditions, such as hypogonadism, delayed puberty, and muscle wasting, and as anabolic steroids. However, use of androgen therapy has been limited by lack of efficacious compounds with easy delivery options and concerns about side effects such as stimulatory effects on the prostate, hirsutism, hepatic toxicity, and steroid abuse.

These problems sparked drug discovery efforts for selective androgen receptor modulators (SARMs).²¹⁴ Although SARMs are not yet in clinical use, several nonsteroidal SARMs are under development.²¹⁵ Ideally, a tissue-selective SARM would have the beneficial anabolic effect of androgens with reduced risk of prostate cancer in men or hirsutism and virilization in women. An SARM for the treatment of hypogonadism or osteoporosis would be an AR agonist in the muscle and bone, with minimal hypertrophic agonist effects in the prostate. The first generation of SARMs was designed by making structural modifications of the antiandrogen bicalutamide.²¹⁶ SARMs S-1 and S-4 (Figure 7) demonstrate tissue selectivity in animal models and function as AR antagonists in the prostate without affecting gonadotrophin release or the effects of androgens on bone and muscle mass.²¹⁷ These SARMs have shown efficacy in benign prostatic hyperplasia (BPH)²¹⁷ and as male contraceptives.²¹⁵ SARMs with greater AR antagonist activity but with agonist activity in the bone are also being explored as potential prostate cancer therapies.²¹⁸

Approximately 80–90% of prostate cancers are androgen dependent at initial diagnosis, and prostate cancer therapy is directed toward reducing serum androgen (androgen ablation therapy) and inhibiting AR by antagonists (antiandrogens).²¹⁹ The four antiandrogens in clinical use are the nonsteroidal antiandrogens hydroxyflutamide, bicalutamide, and nilutamide and the steroidal antagonist cyproterone acetate. Antiandrogens bind to AR and downregulate the effects of endogenous circulating androgens and remain the first-line treatment for palliation of advanced prostate cancer.

2.25.6.4 Glucocorticoid Receptor Ligands

Glucocorticoids are the most effective and frequently used drugs to treat acute and chronic inflammatory and immunological diseases such as rheumatoid arthritis, lupus erythematosus, asthma, transplant rejection, and inflammatory bowel disease (IBD). Synthetic glucocorticoids such as hydrocortisone, prednisone, methylprednisone, and dexamethasone mediate their anti-inflammatory activity through the GR, whose endogenous ligand is the adrenal hormone cortisol. The use of glucocorticoids is associated with potentially severe side effects, including diabetes, osteoporosis, water retention, and psychosis.²²⁰ The potent anti-inflammatory activity of glucocorticoids has been shown to be due to transrepression of pro-inflammatory cytokines and inflammation mediators such as TNF- α , IL-6,

Figure 8 Glucocorticoid receptor ligands.

IL-12, and PGE₂. The side effects of glucocorticoids are thought to arise from transactivation of enzymes involved in gluconeogenesis and muscle metabolism.¹²⁴ In addition to transrepression mediated via the GR response elements in pro-inflammatory gene promoters, a direct interaction of ligand-bound GR, as a monomer, with other transcription factors, such as NFκB and AP-1, has been shown to inhibit pro-inflammatory gene expression via these transcription factors.²²¹ These studies on the molecular mechanisms of the anti-inflammatory activities and side effects of glucocorticoids led to the concept of ‘dissociated GR agonists’ that preferentially induce transrepression, but not the transactivation functions of GR, and have an improved therapeutic profile with reduced side effects.²²² Active interest in developing such selective GR agonists has led to the identification of two nonsteroidal GR agonists, AL-438²²³ (Figure 8) and ZK-216348,¹²⁶ that demonstrate anti-inflammatory activity comparable with that of prednisone, but with superior side-effect profiles in animal models. These are currently being used as tools to understand the complex pharmacology of the anti-inflammatory effects of glucocorticoids.

However, GR antagonists have been investigated for their potential to control peripheral glucose metabolism in Type 2 diabetes. As their name suggests, glucocorticoids raise blood glucose levels by antagonizing the action of insulin and increasing hepatic glucose output. Liver-selective GR antagonists could decrease blood glucose levels without adverse peripheral side effects. A-348441 (Figure 8) is a liver-targeting GR antagonist based on the prototype GR antagonist RU486 that shows improved glucose control in animal models of Type 2 diabetes.^{224,225} Thus, GR ligands with selective profiles of agonist and antagonist activity against several therapeutic targets are the focus of many drug discovery programs.

2.25.6.5 Mineralocorticoid Receptor Ligands

Aldosterone is the endogenous ligand for the MR, which is sometimes also referred to as the aldosterone receptor. Aldosterone binding to MR results in widespread physiologic effects in the kidney, heart, and vasculature, such as sodium retention and potassium excretion, ventricular hypertrophy, fibrosis, vasoconstriction, inflammation, and endothelial dysfunction.²²⁶ All these are risk factors for congestive heart failure (CHF). In addition, aldosterone production in the heart and plasma levels in blood are increased after myocardial infarction and CHF to an extent that correlates with the severity of the disease.²²⁷ Aldosterone receptor (MR) antagonists have now emerged as a new

paradigm in the treatment of CHF. Spironolactone was the first MR antagonist to be evaluated for hypertension, but its use is precluded by its poor specificity for the MR and the side effects from its antiandrogenic and progestational activities. Eplerenone (Inspra) (Figure 9), a spironolactone derivative, is the first selective aldosterone receptor antagonist to be developed, and it has recently been approved for the treatment of systemic hypertension. It has also been approved for the treatment of left-ventricular systolic dysfunction in acute myocardial infarction.²²⁸ A combination of eplerenone with angiotensin-converting enzyme (ACE) inhibitors offers further advantages in this setting.²²⁹

2.25.6.6 Vitamin D Receptor Ligands

1 α ,25-Dihydroxyvitamin D₃ or calcitriol (Figure 10), the active metabolite of vitamin D, is the physiological VDR ligand, known for maintaining calcium and phosphate homeostasis. In addition to the gut and bone, VDR has now been shown to be present in virtually all tissues, and its natural and synthetic ligands are increasingly recognized for their noncalcemic actions, such as potent antiproliferative, prodifferentiative, and immunomodulatory activities. The cellular VDR protein level is upregulated in several disease states, providing a rationale for using VDR ligands to treat these

conditions. The utility of VDR ligands has been explored for various therapeutic indications, such as rheumatoid arthritis, psoriasis, actinic keratosis, osteoporosis, autoimmune diseases (type I diabetes, lupus erythematosus, and multiple sclerosis), and several cancers (prostate, colon, breast, leukemia, head, and neck). See ^{230,231} for excellent in-depth reviews of the clinical use of VDR ligands. However, the use of VDR agonists is hampered by their dose-related toxicity, manifested as hypercalcemia/hypercalciuria.

A large number of synthetic vitamin D₃ agonists have been synthesized, and several are used clinically. Calcitriol is used orally for osteoporosis and in topical form for psoriasis. Several other analogs with reduced calcemic effects are also used clinically. Alfacalcidol (**Figure 10**), a precursor prodrug of calcitriol, is used in osteoporosis and arthritis. Calcipotriol, a metabolically labile analog of vitamin D₃, was developed for topical use in the treatment of psoriasis and has significantly less calcemic activity. Other modified agonist analogs include EB 1089, ED-71, maxacalcidol (OCT), and tacalcitol (**Figure 10**), in clinical trials for hyperparathyroidism, osteoporosis, prostate cancer, and psoriasis.²³¹ In contrast, significantly fewer VDR antagonists have been developed, and these have mainly been used as tools to study the physiological function of VDR and its interactions with other NR pathways.²³² VDR antagonists ZK 159222 and TEI-9647 (**Figure 10**) have been useful in studying the molecular aspects of VDR activation and coregulator interactions.²³³ TEI 9647 has also been tested in animal models of Paget's disease as a potential treatment for the excessive bone resorption and osteoclast formation seen in this disease.²³⁴ Elucidation of the mechanism of action of the different vitamin D analogs will enhance our understanding of vitamin D pathways and improve uses of VDR-based therapies.

2.25.6.7 Thyroid Hormone Receptor Ligands

3,5,3'-Triiodo-L-thyronine (T₃) is the physiologically active thyroid hormone that exerts significant effects on growth and homeostasis through its actions on the TR. T₃ is synthesized in peripheral target tissues by metabolic deiodination of the prohormone T₄ (3,5,3',5'-tetraiodo-L-thyronine), which is secreted from the thyroid gland. T₄ itself does not possess appreciable biological activity. The diverse actions of T₃ in regulating metabolic rate, cholesterol and triglyceride levels, cardiac output, and skeletal development are mediated through the two thyroid receptor subtypes, TR α and TR β , products of two different genes, but widely expressed in most tissues.²³⁵ Although T₃ binds with nearly equal affinity to both receptor subtypes, studies from knockout animals have shown that most effects of T₃ on the heart and cardiac rhythm are mediated through the TR α isoform, whereas most effects on the liver, skeleton, and other tissues are mediated through TR β .^{236,237} T₃ agonism, or high levels of T₃, can exert desirable effects, such as reduction in plasma LDL cholesterol, lipoprotein(a), and triglycerides and promotion of weight loss, all actions mediated by TR β . However, these are accompanied by undesirable effects mediated by TR α , including tachycardia, atrial arrhythmias, and heart failure. Like with other NR ligands, selective thyroid receptor modulators (STRMs) that bind preferentially to one isoform or have tissue-selective uptake are being actively pursued,^{238–240} particularly TR β -selective agonists, as hepatic-selective, cardiac-sparing drugs for therapeutic use as cholesterol-lowering agents. The most studied T₃ agonist in this regard is GC-1 (**Figure 11**), an analog of T₃ that was shown to reduce plasma cholesterol in rats and monkeys with greater efficacy than atorvastatin, the HMG-CoA reductase inhibitor widely used clinically as a cholesterol-lowering agent.²⁴¹ Although GC-1 is selective for TR β ,²⁴² its decreased uptake into the heart compared with the liver actually accounts for its selective pharmacological activity on cholesterol metabolism.²⁴³ GC-1 also reverses skeletal development and maturation defects of hypothyroidism in rats; this effect indicates that TR β -mediated thyroid action plays a role in bone development.²⁴⁴ Another promising STRM recently reported is KB-141 (**Figure 11**), which has a 14-fold higher affinity for TR β over TR α .²⁴⁵ Studies of KB-141 in monkeys, rats, and mice show reductions in plasma cholesterol, lipoprotein (a), and body weight, without significant cardiac side effects, demonstrating effective separation of potential therapeutic benefits of TR β agonism while sparing TR α stimulation.²⁴⁶ TR α -selective agonists may be developed for increasing cardiac performance and output in patients with CHF. For example, 3,5-diiodo-thyropropionic acid (DITPA) is a T₃ analog that has demonstrated clinical efficacy in increasing cardiac index and reducing serum cholesterol and triglyceride levels in patients with CHF and elevated cholesterol, suggesting a new therapeutic use for TR α -selective TR agonists.²⁴⁷

TR antagonists have a potential role in the treatment of hyperthyroidism, an area in which therapeutic choices are quite limited. The antiarrhythmic drugs amiodarone and the newer Dronedarone (**Figure 11**) have been reported to act by antagonizing T₃ binding to TR.²⁴⁸ Dronedarone, which has a better clinical profile and lower side effects, is a TR α -selective competitive antagonist; its effectiveness suggests possible therapeutic applications for isoform-specific TR antagonists.²⁴⁹ Several TR antagonists based on the GC-1 class of compounds have been designed.²⁵⁰ Compound NH-3 (**Figure 11**) is the first potent TR antagonist with nanomolar affinity for TR that also inhibits TR action in an animal model.²⁵¹ The significant therapeutic potential of STRM ligands merits an active interest in their development.

Figure 11 Thyroid receptor ligands.

Figure 12 Retinoid acid receptor (RAR) and retinoid X receptor (RXR) ligands.

2.25.6.8 Retinoid Receptor (RAR and RXR) Ligands

Naturally occurring retinoids, all-*trans*-retinoic acid (ATRA) and 9-*cis* retinoic acid (9-*cis* RA), regulate a wide variety of physiological functions (see Section 2.25.5.2.2) through two NR subfamilies called the retinoic acid receptors (RARs) and the RXRs. Each of these subfamilies has three subtypes (α , β , and γ), which are encoded by a single gene each. Retinoids, acting through the RARs and RXRs, have also been used clinically for a broad range of therapeutic applications, that are poised to expand even further with increasing development of receptor-selective NR ligands and the concept of tissue-selective NR action.¹⁵¹ The endogenous ligand for the RARs is ATRA (Figure 12), whereas 9-*cis* RA binds both RARs and RXRs. The RARs form heterodimers with RXR and bind to retinoic acid response elements (RAREs) to modulate target gene expression. RXRs, however, can either form homodimers or heterodimers with other NRs. This unique role of RXR as the preferred heterodimeric partner for several other NRs accounts for its ubiquitous actions in several physiological pathways and is the basis of the emerging expansion of the therapeutic applications of RXR-selective retinoids in several disease processes, as discussed below.

The RARs have been implicated in the regulation of cancer development and epithelial differentiation. Translocation of the RAR α gene is responsible for the development of acute promyelocytic leukemia (APL).²⁵² RAR α is also associated with elevations in triglyceride levels. RAR γ is associated with skin, bone, and teratogenic toxicity. RAR β is considered to have a tumor suppressor role since its expression is lost during early carcinogenesis as a result of methylation-induced silencing of the promoter region of its gene.^{253,254} In addition, RAR β contains a RARE in its

promoter region that mediates retinoic acid (RA)-induced RAR β gene expression. This upregulation of the RAR β gene plays a critical role in RA-induced growth inhibition and apoptosis in breast and lung cancer cells.^{255,256} ATRA, a RAR pan-agonist, has shown complete responses in APL patients,²⁵⁷ but ATRA therapy is associated with significant side effects and development of resistance. RAR α -selective ligands such as AM80 (Figure 12) have a high therapeutic index and have successfully induced remissions in ATRA-resistant patients, with a significantly milder side-effect profile.^{258,259} 9-*cis* RA, another RAR pan-agonist, is currently used as a topical agent for cutaneous AIDS-related Kaposi's sarcoma.²⁶⁰ Tazarotene (AGN 190168), a RAR β , γ -selective agonist, is currently used clinically for the treatment of psoriasis.²⁶¹ Several classes of subtype-selective RAR ligands have been developed; their discovery and selective pharmacology are extensively covered in two excellent reviews.^{262,263}

RXR-selective synthetic retinoids have been termed 'rexinoids'.²⁶⁴ One of the well-known rexinoids is LGD1069 (Bexarotene, Targretin) (Figure 12), clinically used in cutaneous T-cell lymphoma and in clinical trials against non-small cell lung cancer.²⁶⁵ However, use of LGD1069 is associated with significant toxicity, such as hypothyroidism and hypertriglyceridemia, attributed to its weak RAR agonist activity.

A newer, more specific rexinoid, LG100268,²⁶⁶ has been extensively evaluated to understand the pleiotropic pharmacology of RXR receptors in various metabolic pathways. NRs that form heterodimers with RXRs are subdivided into two functionally distinct groups – permissive and nonpermissive.²⁶⁷ A permissive heterodimer can be activated by agonists for either RXR or the NR partner, or both, for synergistic activation. Examples of permissive heterodimers include RXR heterodimers with PPAR, LXR, and FXR. Heterodimers with nonpermissive partners can only be activated by the agonist of the binding partner, not by an RXR agonist. Examples of nonpermissive partners are TR and VDR, which function primarily as hormone receptors that keep gene expression under tight hormonal control. Thus, RXR agonists can regulate the gene expression of multiple permissive NR partners, and can have widespread pharmacological effects on several important metabolic pathways. Indeed, LG100268 has been shown to have insulin-sensitizing effects (related to the PPAR γ -permissive partner) and to reduce atherosclerosis in animal models; the latter effect related to its LXR- and FXR-permissive activation.^{268,269} Even more selective RXR modulators now under development are specific for certain permissive partners, but not all. For example, LGD100754 (Figure 12) is a selective antagonist of the RXR homodimers and an agonist of the RXR:PPAR heterodimer, but not of RXR:LXR or RXR:FXR heterodimers.²⁷⁰ LGD100754 triggered PPAR-activated pathways such as adipocyte differentiation and also demonstrated insulin sensitization in db/db obese mice more effectively than the relatively nonselective rexinoid LGD100268.²⁶⁹ Thus, it now appears possible to design specific RXR modulators that can provide specific regulation of metabolic pathways.^{271,272}

2.25.6.9 Peroxisome Proliferator-Activated Receptor Ligands

The PPARs function primarily as lipid sensors and control several biological processes including energy and lipid homeostasis, cell differentiation and inflammation. Endogenous ligands for PPAR α include polyunsaturated and saturated fatty acids, leukotriene B₄ and more recently, oleoylethanolamide, which was shown to regulate feeding and body weight through activation of PPAR α .²⁷³ PPAR α binds to a wide range of physiological fatty acids albeit with low affinity, pointing to its role as a general lipid sensor. Its activation increases fatty acid catabolism and oxidation, modulates inflammatory response, and reduces triglyceride levels. These actions form the basis of the pharmacological lipid lowering and cardioprotective effects of the well-known hypolipidemic fibrate class of drugs, which were shown to be synthetic PPAR α ligands. The fibrates clofibrate, fenofibrate, bezafibrate, and gemfibrozil were used clinically as hypolipidemics long before PPAR α was identified as their pharmacological target.^{274,275} However, the fibrates show only weak PPAR α agonist activity and are 10-fold selective for PPAR α over PPAR γ .²⁷⁵ They function by increasing the clearance and decreasing the synthesis of triglyceride-rich VLDL, and increasing HDL-cholesterol levels by modulating the genes that control these processes.²⁷⁶ Recent data indicate that PPAR α agonists have direct vasoprotective effects and reduce the progression of atherosclerosis, particularly in diabetic patients.²⁷⁷ Cardiovascular disease is the major cause of mortality in Type 2 diabetes patients, a group in which dyslipidemia is also 2–3 times more prevalent than in the general population.²⁷⁸ More selective PPAR α ligands are now being actively sought and several new classes of PPAR α ligands have now been reported. For example, ureidofibric acids GW9578 (EC₅₀ 50 nM)²⁷⁹ and phenoxypropanoic acid LY518674 (EC₅₀ 42 nM)²⁸⁰ have been reported as potent PPAR α agonists with 20–200-fold selectivities. A group from Merck recently reported a novel class of highly potent (<10 nM) PPAR α agonists, exemplified by compound I (Figure 13) that lowered cholesterol and triglyceride levels in animal models at doses significantly lower than fenofibrate.²⁸¹

PPAR γ , expressed in adipose cells, is activated by polyunsaturated fatty acids and by prostaglandin J₂, and plays a crucial role in adipogenesis. PPAR γ is perhaps best known as the target for the insulin-sensitizing drugs, the glitazones

Figure 13 PPAR α ligands.

(thiazolidinediones). Pioglitazone and rosiglitazone (Figure 14), used for Type 2 diabetes, are among the top 100 selling drugs in the United States. They exert their antidiabetic effects through the activation of PPAR γ and improve insulin sensitivity in muscle and adipose tissue. However, their long-term use is associated with the development of side effects such as weight gain, edema, and anemia. The glitazones also have a deleterious effect on bone, since PPAR γ activation causes bone osteoblasts to undergo terminal differentiation to adipocytes.^{282,283} Netoglitazone (Figure 14) is a new selective glitazone that lowers blood glucose as effectively as rosiglitazone in diabetic animal models, at doses that do not affect the bone.^{284,285} Epidemiological studies show that Type 2 diabetes is associated with an increased risk for coronary heart disease and ischemic stroke. A majority of Type 2 diabetic patients are obese and have elevated triglyceride levels and low HDL levels.^{286,287} Since PPAR α regulates lipid and triglyceride homeostasis, there has recently been considerable interest in combining the beneficial effects of PPAR α and PPAR γ activation. Several PPAR α / γ dual agonists of different chemical classes other than the glitazones have been discovered, the most popular among which are the 'glitazars' farglitazar, ragaglitazar, and muraglitazar (Figure 14). Farglitazar,²⁸⁸ a potent PPAR γ agonist with moderate PPAR α efficacy, was in clinical trials but was dropped due to emergence of edema. Ragaglitazar (originally DRF2725)^{289,290} was also dropped from clinical development due to carcinogenicity in rodent toxicity models. The most recent addition to the glitazar family, muraglitazar,²⁹¹ is the only PPAR α / γ dual agonist to successfully advance to a nondisclosure agreement (NDA) filing (December 2004). At the time of writing this chapter, this drug received a 'non-approvable' letter, pending further information on its cardiovascular safety profile. The muraglitazar-treated patient group showed an increased incidence of CHF, ischemic attack, and death compared with placebo.²⁹² Bristol-Myers Squibb and Merck, who are jointly developing Muraglitazar, are considering the option of dropping this compound from further development.²⁹³ Regardless, the discovery of dual PPAR α / γ agonists of diverse chemical classes distinct from the glitazars, still continues at an active pace.^{294–296}

PPAR δ is the least understood among the PPARs and is not yet a clinical target, unlike PPAR α and γ . PPAR δ is expressed ubiquitously in all tissues and also binds long-chain fatty acids with low affinity.²⁹ There are only a few selective PPAR δ ligands known thus far. GW2433 (Figure 15) is a ureidofibrate that was potent and selective for PPAR δ but also activated PPAR α .²⁹⁷ L-165041, a leukotriene antagonist, was also a PPAR δ ligand with 10-fold selectivity over PPAR α and γ .²⁹⁸ The most potent and selective ligand reported thus far is GW501516 (Figure 15),¹⁸⁴ with a 1000-fold selectivity and subnanomolar potency at PPAR δ . GW501516 promotes RCT and increase HDL-c levels in obese rhesus monkeys.¹⁸⁴ It also attenuates weight gain and insulin resistance, in mice on high fat diets, by promoting fatty acid oxidation in skeletal muscle²⁹⁹ and adipose tissue.¹⁸² Several studies with GW501516, now suggest that PPAR δ agonists may have utility in metabolic syndrome.^{300,301} However, the role of PPAR δ in cell proliferation and differentiation is far from clear, and will have to be determined before PPAR δ -selective ligands can be considered for therapeutic development.¹⁶²

The NRs LXR α and LXR β regulate the expression of key genes in cholesterol, fatty acid, and glucose metabolism and function as cholesterol sensors.^{302–304} Several oxidized forms of cholesterol (oxysterols), but not cholesterol itself, have been reported as endogenous ligands for LXRs.^{31,305,306} 22(*R*)-hydroxycholesterol and 24(*S*), 25-epoxycholesterol (**Figure 16**) activate LXRs at their physiological concentrations. LXRs, as heterodimers with RXR, regulate the expression of various genes involved in cholesterol homeostasis, including *CYP7A1*, *CETP* (cholesterol ester transfer protein)³⁰⁷ and most importantly, *ABCA1*.^{187,308} The ATP-binding cassette transporter protein (ABCA1) is required for the first step in RCT of cholesterol from macrophage foam cells to nascent HDL particles, and plays a critical role in decreasing atherosclerotic plaques. Synthetic nonsteroidal LXR agonists T0901317¹⁸⁷ and GW3965³⁰⁹ (**Figure 16**) show significant atheroprotective effects and increased plasma HDL-c levels in mouse models.^{310,311} Synthetic LXR agonists also regulate the expression of genes involved in glucose metabolism and show antidiabetic activity in animal models of Type 2 diabetes.^{312,313} However, LXR also activates several genes associated with lipogenesis, particularly SREBP-1c, which is the master regulator of de novo lipogenesis³¹⁴ and fatty acid synthase. In addition, hypertriglyceridemia is another significant liability. These effects compromise the use of LXR agonists as a treatment for atherosclerosis. There is considerable effort underway to discover LXR modulators that are devoid of lipogenic activity, and to generate subtype selective LXR ligands.³¹⁵

Figure 16 Liver X receptor (LXR) ligands.

2.25.6.11 Farnesoid X Receptor Ligands

FXR is also commonly known as the bile acid receptor (BAR) since bile acids were shown to be the physiologically relevant endogenous ligands for this receptor.^{316–318} The bile acid chenodeoxycholic acid (CDCA) (**Figure 17**) has the highest affinity among bile acids at 10–30 μ M, while lithocholic acid, deoxycholic acid, and glycine–taurine conjugates also bind at physiological concentrations. Ursodeoxycholic acid and cholic acid do not bind to FXR. Bile acids are end products of cholesterol catabolism and are important for the intestinal absorption of dietary fat and vitamins. FXR is important for maintaining bile acid homeostasis by modulation of genes involved in bile acid synthesis as well as transport (*see Section 2.25.5.2.6*). In response to bile acids, FXR represses the transcription of *CYP7A1*, the liver-specific cholesterol 7 α -hydroxylase, which catalyzes the first rate-limiting step in cholesterol metabolism,¹⁶⁸ while inducing the transcription of bile acid transporter proteins.³¹⁹ The first synthetic FXR agonist, GW 4064 (**Figure 17**) was reported by GlaxoSmithKline to be an activator (nanomolar range) of FXR.³²⁰ The same group later reported a series of potent FXR ligands based on CDCA, of which 6 α -ethyl-CDCA is the most potent FXR agonist reported thus far.³²¹ and has demonstrated reversal of cholestasis in an in vivo rat model.³²² The GlaxoSmithKline group have now reported a similar series of potent FXR ligands based on the CDCA platform, but with a range of functional activities, from full agonism to antagonism, which should be useful for evaluating the therapeutic benefit of FXR ligands in metabolic diseases.³²³ Dussault *et al.*³²⁴ also reported a series of FXR ligands based on an RXR ligand scaffold. They reported a series of agonists (AGN29 and AGN31) as well as an antagonist (AGN34) (**Figure 17**) that appeared to be a selective FXR gene modulator. AGN34 like an agonist repressed expression of *CYP7A1*, but potentially antagonized the expression of bile acid transport protein IBABP. This selective regulation of genes related to cholesterol and bile acid homeostasis suggests that selective FXR ligands may be developed to selectively enhance cholesterol metabolism, without deleterious effects such as cholestasis or hypertriglyceridemia.³²⁵

2.25.6.12 Pregnane X Receptor and Constitutive Androstane Receptor Ligands

The orphan NRs CAR and PXR (and its human homolog SXR, steroid and xenobiotic receptor) function as xenobiotic sensors and regulate the expression of various Phase I and II drug-metabolizing enzymes as well as drug-transporter proteins, in response to xenobiotics.^{326,327} As discussed in *Section 2.25.3.1.1*, the LBDs of these NRs are relatively large and can accommodate a diverse series of structurally unrelated xenobiotics. However, these NRs demonstrate species specificity in their induction of drug-metabolizing enzymes. Rifampicin (**Figure 18**) is an agonist for SXR and induces *CYP3A4* in humans but not in rodents. Pregnenolone carbonitrile (PCN) (**Figure 18**), however, is an agonist for the rodent ortholog PXR and induces *CYP3A* in rodent assays but not in human hepatocytes.³²⁸ *CYP3A4* metabolizes a large number of pharmaceutical drugs and xenobiotic activation of PXR by one drug can lead to inadvertent increase in metabolism of another administered drug, causing a deleterious drug–drug interaction. PXR also transcriptionally regulates transporter proteins such as OATP2, MDR1 (multidrug resistance 1) and MRP2 (MDR-associated protein). Taxol was shown to induce MDR1 via PXR activation.

Figure 17 Farnesoid X receptor ligands.

Binding to CAR induces the CYP2B class of cytochrome P450 enzymes. Although CAR is constitutively active and is able to transactivate genes without a ligand, its activity is potentiated by CAR agonists such as phenobarbital and 1,4-bis[2-(3,5-dichloropyridoxyl)]benzene (TCPOBOP)³²⁹ (Figure 18) and is inhibited by antagonists such as androstanols.³³⁰ Recently, guggulsterone, a PXR and FXR ligand, and an active ingredient in the herbal Ayurvedic cholesterol-lowering remedy, guggulipid, was found to be an inverse agonist at CAR, and repressed the activation of CYP2B enzymes.³³¹ The recent discovery that CAR is also involved in thyroid metabolism suggests a potential role for CAR inverse agonists as antiobesity drugs.^{332,333}

2.25.7 Therapeutic Disease Applications for Nuclear Receptor Ligands

The discussion in Section 2.25.6 clearly shows that drugs that target NRs offer therapies for a multitude of diseases and disorders, such as cancer, metabolic diseases (including diabetes, obesity, and cardiovascular pathologies), inflammation, and osteoporosis. Several NRs are established targets for clinical therapeutics, whereas other NRs and orphan receptors offer the possibility of new therapeutic targets. Among established targets, the steroid hormone receptors ER α and AR and the retinoid receptors RAR β and RXR are known targets for cancer therapeutics.^{151,334,335} PPARs are known targets for metabolic diseases such as hyperlipidemia and Type 2 diabetes,³⁰¹ GR and MR are targets for anti-inflammatory therapies,³³⁶ VDR is a target for osteoporosis and psoriasis, while ER and PR are targets for oral contraceptives and HRT.

One area that is of tremendous interest and has a high potential for generating the next blockbuster drug targeting an NR is the so-called metabolic syndrome. Metabolic syndrome is a collection of disorders typified by obesity, Type 2

Figure 18 Pregnane X receptor and constitutive androstane receptor ligands.

diabetes, hypertension, hyperlipidemia, and atherosclerosis, which tend to occur in the same predisposed population. It appears that dysregulation of lipid metabolism and homeostasis is the primary imbalance that leads to the metabolic syndrome.³³⁷ Accordingly, NRs that are involved in maintaining lipid homeostasis are potential targets for diseases associated with the metabolic syndrome. A number of in-depth reviews discuss the involvement of several NRs, including LXR, FXR, PPARs, and LRH-1 in metabolic diseases. Some of these NRs are being actively pursued as targets for selective therapeutic modulation for the metabolic syndrome.^{325,338–340}

2.25.8 Genetic Diseases Associated with Nuclear Receptors

NRs contribute to a broad spectrum of physiological processes, and it is therefore not surprising that genetic alteration of any individual NR could result in a disease state. This section outlines the pathological conditions ascribed to documented genetic alterations in a number of NRs.

The ERs are by far the most extensively studied NRs, and many research efforts have focused on identifying alterations within the coding sequences of both ER α and ER β from clinical samples.³⁴¹ A number of groups have identified naturally occurring splice variants and mutations with constitutive activity, even in the absence of estrogen. ER α splice variants have been detected in various tumor types, including breast cancer, endometrial carcinomas, prolactinoma, and meningiomas (for a more extensive review see ³⁴¹). The ER α splice variant with a deleted exon 7 (ER α exon 7 deletion ($\Delta 7$)) is identified as the most frequently observed variant in breast cancer.³⁴² This variant encodes a protein lacking the AF-2 domain and a portion of the hormone-binding domain. It is not transcriptionally active, but it may act as dominant-negative isoform of both ER α and ER β to inhibit expression.³⁴³ ER $\alpha\Delta 7$ has not only been found in breast tumors, but also meningiomas, endometrial hyperplasias, moderate- to well-differentiated endometrial adenocarcinomas, prostate cancer cell lines, and lupus erythematosus.³⁴¹ Although current studies suggest that the dominant effect of ER $\alpha\Delta 7$ is not a significant cause of breast cancer, it nevertheless contributes to disease progression.

Compared with ER splice variants, only a handful of ER mutations have been identified or studied from human samples. However, some of the known mutants have been implicated in a variety of disease states, including breast and endometrial cancers, systemic lupus erythematosus, and psychiatric diseases.³⁴¹ There appear to be multiple hot spots for spontaneous ER mutations in the relatively short hinge region of the ER LBD. One of these mutations, ER α K303R (lysine to arginine substitution), is believed to lead to a receptor that is able to induce proliferation even when exposed to extremely low levels of hormone; the mutation is found with relatively high frequency in primary breast cancers.³⁴⁴

It has also been suggested that ER mutation frequency may be higher in metastatic breast tumors, and some ER mutations have been correlated with tamoxifen resistance and estrogen independence.^{345,346} These mutations have become the focus of intense research that has yielded valuable insights into potential mechanisms of hormone-independent signaling. Other ER α and ER β polymorphisms are also believed to contribute to osteoporosis, but these data await further confirmation.³⁴⁷

Not surprisingly, much less is known about ER β splice variants and natural point mutations. ER β Δ 5, like ER α Δ 7, acts as a dominant-negative isoform of both ERs, and it is believed to contribute to tumor progression. Although very little is known about ER β point mutations, a G250S mutation has been identified in obese male children and other silent mutations have been observed in both underweight and obese children.³⁴⁸

A number of gain of function mutations in the AR are known to contribute to prostate cancer.³⁴⁹ For example, T877A (threonine to alanine switch) and H874Y (histidine to tyrosine) allow transcriptional activation of the AR by the adrenal androgen dehydroepiandrosterone (DHEA) which does not normally cause substantial activation of wild-type AR. Although both mutations occur within the helix 11 region of the LBP, amino acid residue 877 contacts the ligand directly while residue 874 is distal to the pocket and may affect binding of coactivator proteins. The T877A mutation alters the stereochemistry of the binding domain and broadens the specificity of ligand recognition.³⁵⁰ The H874Y mutation also probably affects ligand binding, but indirectly. In support of these findings, it has been demonstrated that the AR-T877A mutant is activated by a broad range of other ligands including estrogen, progestins, pregnenolone (precursor of many steroids), and some antiandrogens (e.g., cyproterone and hydroxyflutamide).³⁵¹ The T877A mutation has been detected in a number of human prostate tumors.³⁴⁹ Other mutations have been found in prostate cancer cell lines, and all point to a mechanism involving prostate tumor cells surviving in the absence (or at low levels) of androgens.

Amplification of the AR gene is another level of genetic control of AR that can result in prostate cancer. This possibility is highlighted by studies showing amplified AR in 30% of recurrent tumors.³⁴⁹ Finally, genetic control over AR dysfunction appears to involve an N-terminal domain harboring from 8 to 39 glutamine residues. A decrease in glutamine-repeat length is associated with an increase in AR transactivation and a higher risk and a higher grade of prostate tumors.^{349,352} In summary, these studies show that alterations in AR protein structure probably promote the development and progression of prostate tumors.

The glucocorticoid-resistant syndromes are another well-established class of NR-related genetic diseases.³⁵³ Glucocorticoid resistance is a rare, familial or sporadic condition that is characterized by partial end-organ insensitivity to glucocorticoids. Affected patients exhibit compensatory elevations in circulating cortisol and ACTH concentrations. The clinical spectrum of the condition is broad, ranging from completely asymptomatic to severe hyperandrogenism or mineralocorticoid excess.³⁵⁴ Fatigue, anxiety, and hypertension are also associated with this condition, with fatigue considered to be a potential manifestation of muscular or CNS glucocorticoid deficiency.³⁵⁵ The molecular underpinnings for glucocorticoid-resistant syndromes involve mutations in the *GR α* gene that impair one or more of the molecular mechanisms of GR function (including reduced transactivation of GR α and therefore reduced target gene transcription and expression) and result in altered tissue sensitivity to glucocorticoids. A number of mutations within the LBD and DBD of the GR protein as well as 4-base pair deletion at the 3'-boundary of exon 6, have been described.^{354–356} A polymorphism of GR α that is associated with obesity rather than generalized glucocorticoid resistance has also been reported.³⁵⁶ Some of these polymorphisms have been shown to affect the interaction of GR α with the GR-interacting protein 1 coactivator.³⁵⁴ Another recent study suggested that high levels of GR β , which acts as a dominant-negative regulator of GR α , were found in some cases of Crohn's disease and may be caused by interleukin (IL)-18-dependent inappropriate mRNA splicing of the GR gene.³⁵⁷ ILs are also believed to be involved in the development of glucocorticoid resistance in multiple sclerosis, and this disease appears to have a genetic component in some patients.³⁵⁸

Perhaps the best known example of a NR genetic event resulting in a significant disease is translocation of RAR α in APL.³⁵⁹ APL is a common form of acute myeloid leukemia (AML) characterized by attenuation of myeloid differentiation and accumulation of immature promyelocytes in patient bone marrow and peripheral blood. RAR α is found fused to different partners, which often encode transcription factors or other chromatin modifying enzymes. These chimeric fusion oncogenes, generated by reciprocal chromosomal translocations (involving the RAR α gene on chromosome 17), are responsible for chromatin alterations on target genes whose protein products are critical to stem cell development or lineage specification in hematopoiesis. Five different partners of RAR α have been identified, including the promyelocyte gene (*PML*), the promyelocyte leukemia zinc finger gene (*PLZF*), the nucleophosmin gene (*NPM*), the nuclear mitotic apparatus gene (*NuMA*), and the signal transducer and activator of transcription 5b gene (*Stat5*). All translocations are reciprocal and generate X-RAR α and RAR α -X fusion proteins (X = RAR α partner genes). APL presents as X-RAR α chimeras. Unlike other types of AML, APL responds to RA treatment, which causes remissions highlighted by cellular differentiation of leukemic blasts.³⁶⁰

The final example of an NR-associated disease involves polymorphism of a PPAR γ isoform that offers a protective advantage to the organism. PPAR γ 1 and PPAR γ 2 isoforms of PPAR γ result from alternative splicing and are known to have both ligand-dependent and -independent activation domains. Insulin stimulates the ligand-independent activation of both proteins while obesity and nutritional factors only influence PPAR γ 2.³⁶¹ A relatively common amino acid substitution (Pro12Ala) of PPAR γ 2 was found to reduce body mass index and improve insulin sensitivity among middle-aged and elderly people.³⁶¹ Not surprisingly, subsequent studies found that this P12A PPAR γ 2 polymorphism protects against Type 2 diabetes.³⁶² Since the study of PPARs, and even the entire NR family, is still in its infancy, many more polymorphisms (and splice variants) of NR genes are likely to be identified and linked to other genetic diseases.

2.25.9 Perspectives and New Directions in Nuclear Receptor Research

It is clear that NRs are a rich source of therapeutic targets for the development of drugs against many important human diseases. With several oNRs waiting to be 'adopted' and understood, this class of receptors will continue to provide new therapeutic opportunities. However, monumental challenges need to be overcome to complete our understanding of NR pharmacology. With the advent of novel technologies such as selective genetic knockouts, gene microarrays and RNA interference (RNAi), we have begun to unravel the complexities of NR physiology and regulation of function in a tissue- and cell-specific context. Ideally, this knowledge can be utilized to discover new tissue-selective ligands to modulate NR function in disease processes. In this modern era of molecularly targeted and tailored medicine, the immense complexity of NR activation and function also makes the task of drug discovery more arduous. The trend toward developing SNRMs makes it important not only to characterize binding and functional activity of new ligands for a particular NR of interest, but to also examine gene expression profiles in response to ligands as functions of tissue and cellular contexts. Such data will be essential in understanding the tissue-selective action of the NR ligand, and allow educated judgments to be made regarding the pharmacological profile and side effects of each ligand in detail.

Another aspect of NR pharmacology that was not considered in great detail in this chapter is the nongenomic actions of NRs. In addition to directly modulating gene transcription (by binding to DNA response elements), many Class I and II NRs are now known to interact with other molecules in the signal transduction network either in the cytoplasm or by direct interaction with plasma membrane NR isoforms. This type of membrane-bound NR signaling therefore indirectly affects transcription of a number of mostly unidentified genes, adding yet another dimension to NRs as targets for drug discovery.

Finally, the many combinatorial coregulator complexes of ligand-bound NRs offer other sites that can be targeted by small-molecule or peptide ligands. Ligands that interfere with protein-protein interactions, while not a new concept per se, are being explored for disrupting NR-coactivator interactions.^{363–365} While such ligands have mainly been small peptides, these new target sites provide the opportunity to develop nonpeptidic chemical scaffolds that can mimic the α -helical binding surfaces of NR coactivators to disrupt NR function. Given the impact of NRs on the pathophysiology of so many human diseases, the above approaches will likely lead to the development of selective pharmaceuticals that could revolutionize modern molecular medicine.

Biographies

Nurulain T Zaveri is the Program Director for the Drug Discovery Program at SRI International. Dr Zaveri received her PhD in Medicinal Chemistry from Duquesne University, Pittsburgh, PA (1994) and postdoctoral training at SRI International (1992–94), after which she continued her tenure at SRI International as a Staff Scientist and then Program Director. Her main research interests are in drug discovery and medicinal chemistry in the primary areas of oncology and CNS therapeutics. Some of her active research projects include the design of novel synthetic analogs of green tea catechins, small-molecule antimetastatic compounds, discovery of small-molecule ligands for the nicotinic and nociceptin receptors and in collaboration with Dr Murphy, the design of novel PPAR δ ligands.

Brian J Murphy is Senior Molecular Biologist in the Biosciences Division at SRI International (Menlo Park, CA). He received his PhD in Comparative Biology from the University of British Columbia (Vancouver, Canada) (1980) and postdoctoral training in cellular and molecular biology at the Stanford University Medical Center (Palo Alto, CA) (1980–84) after which he joined SRI International. His main, NIH-funded, research interest relates to the involvement of the redox-sensitive metal transcription factor-1 (MTF-1) in tumor development, inflammation, and fibrosis. He is also involved in another research project, with Dr Nurulain Zaveri, focused upon the putative role of the peroxisome proliferator activated receptor-delta (PPAR δ) nuclear receptor in breast and prostate cancer and in the development of novel PPAR δ antagonists.

2.26.1 Introduction

Nucleic acids present a broad palate of drug targets, based on their function and structure. Nucleic acids are composed of four nucleotide 'letters' arranged by sequence into strands. The nucleotides consist of three chemical components: the heterocyclic base that defines the 'letter'; the sugar; and the internucleotide phosphate diester linker ([Figure 1](#)). There are two fundamental types of nucleic acids: ribonucleic acids (RNAs) and deoxyribonucleic acids (DNAs), whose structures are determined by the removal of a hydroxyl group from the ribose sugar and methylation of uracil to give thymine. Cellular DNA exists in a double-stranded form in the chromosomes of the nucleus, serving as the storage media for a cell's information and programming instructions. The double-stranded DNA is opened transiently to allow

Figure 1 Common building-blocks of nucleic acids.

transcription into RNA molecules. RNAs have a large range of sizes (20 to >100 000 nucleotides) and shapes generated by combinations of single, double, and higher-order strands, allowing them to perform a variety of functions in the cell. For example, messenger RNA (mRNA) acts as the template for the linking of amino acids into peptide chains by the ribosome. The mRNAs are produced from longer pre-mRNA transcripts through a series of complex splicing reactions performed by the spliceosome. The ribosome in turn is composed of three ribosomal RNAs (rRNAs) that serve as the macromolecular machine and chemical catalyst for amino acid coupling. The amino acids are delivered to the ribosome by transfer RNAs (tRNAs), which contain a three-nucleotide anticodon sequence complementary to three nucleotides on the mRNA. Additional small RNAs and RNA domains that control and edit RNA and DNA through chemical modifications have been discovered over the last 10 years (e.g., small nucleolar RNAs and guide RNAs). Among the most exciting are the abundant microRNAs (miRNAs), which appear to function as an intermediate level of transcriptional and posttranscriptional control on gene expression. Mitochondrial RNA and DNA have both structural similarities and differences with bacterial and human nucleic acids.

The divergence of bacterial and eukaryotic life, the increase in gene complexity in higher organisms, and the central role that nucleic acids play in all aspects of cellular growth, proliferation, and differentiation make them attractive targets for drug discovery. A number of older drugs now are known to be directed against nucleic acids. However, only a limited number of strategies have been employed to target RNAs and DNA with any level of specificity. Gene therapy has been demonstrated as a method to add new DNA to a cell to produce a new protein product, replace a mutated form of a protein, or to alter the sequence of endogenous DNA. The DNA bases have modest reactivity, and can be altered chemically by alkylating agents and metal complexes such as cisplatin. The phosphodiester backbone can be cleaved chemically by compounds such as bleomycin or enzymatically by endogenous nucleases that recognize RNA:RNA or DNA:RNA duplexes produced by administered oligonucleotide agents. Binding of small molecules or oligonucleotides to a sequence of mRNA or DNA can produce steric blocking that prevents subsequent processing or translation. Finally, small molecules and oligonucleotides can induce rearrangements or stabilization of RNA or DNA structures that block specific biological functions. Examples of these mechanisms are described in subsequent sections.

2.26.2 Deoxyribonucleic Acid

2.26.2.1 Structure and Nomenclature

Double-stranded (duplex) DNA is organized into chromosomes in the cell nucleus of higher organisms. These chromosomes contain duplex DNA wrapped around the histone proteins. The DNA can be bound to histones and transcriptionally silent or bound to histones in conjunction with transcriptional factors and polymerases that mediate transcription of the DNA into RNA. The normal DNA double helix adopts a supercoiled form from binding to histones.

Figure 2 Models of helical B form DNA (left) and A form RNA (right). B DNA has a wide major groove and a narrow minor groove, while A RNA has a very narrow and deep major groove, and a wide and shallow minor groove.

Duplex DNA is a helical structure composed of two antiparallel strands linked through hydrogen bonds formed between the complementary donor/acceptor groups of deoxyadenosine (dA) and deoxythymidine (dT) residues and deoxyguanosine (dG) and deoxycytidine (dC) residues, respectively. These base pairs form a ladder that gives the DNA its natural right-handed twist ([Figure 2](#)). The DNA helix has two grooves, the deep and narrow minor groove and the shallow, wide major groove. As discussed below, these grooves present unique hydrophobic, electrostatic, and hydrogen bonding environments where small molecules are known to bind.

The nomenclature for nucleic acids has been specified in detail by the International Union of Pure and Applied Chemistry (IUPAC).¹ DNA bases, nucleosides, and nucleotides are referred to by their standard common names, and the numbering system for the bases and sugars are presented in [Figure 1](#). The purine heterocycles (adenine and guanine) are attached to the 2' deoxyribose sugars through N9, and the pyrimidine heterocycles (uracil and cytosine) are bonded through N1. In all natural DNA, the 3' hydroxyl and the 5' hydroxyl of the subsequent nucleotide are linked through a phosphate diester. Typically, DNA and RNA strand sequences are written from the 5' end toward the 3' terminus.

2.26.2.2 Prototypical Function and Pharmacology

As noted above, all RNAs and proteins in a cell are derived from information stored in the DNA sequence. In contrast to prokaryotes, the majority of DNA present in eukaryotic cells is not transcribed. Why this is the case is not well understood. Single base changes in DNA sequence are responsible for more than 100 human diseases.² Transcription of human DNA is regulated by both protein binding to DNA and methylation of specific sites in the DNA. Drugs that target DNA can alter cellular physiology by inhibiting transcription of RNA or by preventing DNA replication in dividing cells. In all cells, irreversible damage to the DNA (alkylation, strand cleavage, etc.) or inhibition of DNA replication leads to cell cycle arrest. In mammalian cells, cell cycle arrest may trigger apoptosis and cell death. A therapeutic index can be realized by exploiting the difference in rates of cell division between rapidly growing cells and normal human tissue. Hence, most agents targeting DNA are used in treatment of bacterial infection or cancer.

2.26.2.3 Prototypical Therapeutics

The DNA strands stored in a supercoiled form are cleaved to allow transcription or replication to initiate, and subsequently ligated back together by a topoisomerase protein. Many therapeutics target this process. As described above, the rate of RNA transcription is controlled by binding of activator and suppressor proteins with specificity for the DNA surfaces of certain sequences. Therapeutic agents such as intercalators can disrupt the shape of the DNA helix and alter transcription. DNA is copied by the enzyme DNA polymerase, and nucleoside analogs can prevent DNA chain extension. Maintaining the fidelity of the DNA sequence is critical, and the cell has multiple enzymes that inspect and repair the DNA duplex.

2.26.2.3.1 Transition metal complexes

The electron-rich environment at N7 of adjacent purine bases provides a good coordination site for transition metals such as platinum, whose affinity is sufficient to block proper DNA replication and transcription. Cisplatin and analogs are among the most effective anticancer drugs in treatment of solid tumors. New platinum complexes with different binding modes and ruthenium-imidazole complexes are in clinical and preclinical development.^{3,4} Mithramycin has been demonstrated to form a 2:1 complex with Fe(II) that induces a conformational change in DNA which may facilitate strand cleavage.⁵

2.26.2.3.2 Intercalation

The DNA duplex can be altered through intercalation of small molecules between the base pairs or in the minor groove. The base pairs have modest separation and are known to open partially at 37 °C. Small, planar, aromatic groups can be inserted between the base pairs, resulting in a local distortion of the helical geometry. Many classes of drugs are known to work through intercalation, which inhibits the ability of DNA topoisomerase and polymerase enzymes to replicate the DNA. Doxorubicin traps a cleavage intermediate between topoisomerase II and torsionally strained DNA. Analogs of anthracycline drugs with attached saccharides have been shown to intercalate and position carbohydrates at specific sites in the groove.⁶ DNA intercalating drugs also reduce the activity of DNA methyltransferases, and can induce apoptosis through this inhibition.⁷ Many intercalating drugs reduce levels of mitochondrial DNA in mammalian cells through altered metabolism or inhibition of replication.⁸

2.26.2.3.3 Minor groove binders

The interactions between proteins and DNA are mediated by hydrogen bonding networks of side chains along the minor groove of the DNA. Distamycin-related molecules bind in the narrow minor groove of duplex DNA, often as dimers that widen and distort the shape of the groove. The ability of aromatic polyamides to bind in the hydrophobic minor groove has been exploited to develop compounds that form sequence-specific H-bond donor and acceptor interactions with the bases.^{9,10} These compounds can have very high (<100 pM) affinity and selectivity for the target sequence, and have been shown to block the binding of transcription factors to the DNA. In addition, conjugation of regulatory peptides to these molecules produces molecules that upregulate gene expression or recruit additional transcription factors.¹¹

2.26.2.3.4 Nonnatural nucleosides

Nucleoside analogs can be incorporated into DNA and block natural maturation processes. For example, enzymatic methylation (and demethylation) of dC residues at C5 is a natural tagging process used to silence transcription of genes that are no longer required for cell function. In some cancers, specific methylation of tumor suppressor genes promotes uncontrolled cell growth. Treatment of B cell leukemias with 5-azadeoxycytidine generates DNA containing dC residues that cannot be methylated, and the tumor suppressor genes are left in the 'on' state. Other nucleoside drugs can act as inhibitors of DNA replication.

2.26.2.3.5 Other structures

DNA can form higher-order structures, such as the G quartets present as telomeres at the ends of genes. These G quartet DNAs are very stable, and are recognized specifically by cellular proteins. Hence, artificial G quartet structures have been prepared and demonstrated to have anticancer activity.

DNA:RNA duplexes formed during transcription are potential targets for drug discovery. These structures are present during transcription, and may be long-lived. For example, the transcription of human immunodeficiency virus (HIV) RNA has stall sites where DNA:RNA structures are formed as sites for recruitment of additional protein factors. DNA:RNA duplexes also are formed during trailing strand DNA synthesis (Okazaki fragment) and subsequently cleaved.

2.26.3 Ribosomal Ribonucleic Acids

2.26.3.1 Structure and Nomenclature

Ribosomes are large ribonucleoprotein particles, with a bacterial ribosome from *Escherichia coli* having a molecular mass around 2700 kDa, a diameter of approximately 200 angstroms, and a sedimentation coefficient of 70S. The rRNA constitutes nearly two-thirds of the mass of the ribosome, and makes up nearly all of the key sites for ribosomal function. Because of this, ribosomes can be viewed as RNA enzymes, or ribozymes, and drugs which exert their effects via binding to ribosomes interact predominantly with rRNA.

Bacterial ribosomes are composed of a small (30S) and a large (50S) subunit. The small subunit (30S) consists of a large, highly structured RNA molecule of over 1500 nucleotides (the 16S rRNA), along with 21 proteins (referred to as S1 through S21). The large subunit consists of two RNAs, the 23S (about 2900 nucleotides) and the 5S (120 nucleotides), along with 34 different proteins (designated L1 through L34). The large and small subunits join to provide for three tRNA binding sites at the interface, the A (aminoacyl) site, the P (peptidyl) site, and the E (exit) site. The 'active site' of the ribosome, the peptidyl transferase center, is near the P site on the large subunit. A common structural feature to all ribosomes is a tunnel, from the interface at P site through the large subunit to the cytoplasmic side.

Eukaryotic ribosomes are slightly larger (80S) than their bacterial counterparts, with a mass of roughly 4200 kDa. The eukaryotic small subunit (40S) contains a rRNA (18S) which is homologous to the slightly smaller bacterial 16S rRNA. The large subunit (60S) contains 28S and 5S homologs of the bacterial rRNAs, as well as an additional RNA, the 5.8S rRNA. Mitochondria also contain ribosomes that contain similar structural features,¹² despite consisting of more protein than rRNA. These mitochondrial rRNAs must be considered as potential sites of side effects of antibacterial rRNA acting drugs, as they have rRNA components similar in structure to bacterial ribosomes.

2.26.3.2 Physiological Function

The ribosomal RNA is the cellular machine that synthesizes proteins by reading the genetic code of a particular mRNA. Recent cryoelectron microscopic and crystallographic studies have provided astounding insights into both the structure and function of ribosomes,¹³ and illustrated how many antibiotics act to inhibit protein synthesis.¹⁴ A recent review provides a detailed analysis of how the ribosome functions in light of these studies.¹⁵

The rRNA of the small subunit (16S in bacteria) functions primarily to decode the genetic message. This is accomplished by recognition of correct Watson–Crick base pairing between a particular three nucleotide sequence on an mRNA (the codon) with a three-nucleotide sequence on a tRNA which carries the appropriate amino acid. This recognition occurs at a portion of the small subunit termed the A site, which is the binding site of the aminoglycoside antibiotics.

The large subunit functions to append the selected amino acid on the A site tRNA onto the growing peptide chain, which releases the chain from the P site tRNA. This task involves movement of the A site tRNA to the peptidyl transferase center, which is the catalytic site for peptide bond formation. The appropriate amino acid is then transferred onto the growing peptide chain, which exits the ribosome through the tunnel. Many antibiotics bind at or near the peptidyl transferase center, including chloramphenicol and the macrolides such as erythromycin. The macrolides function by blocking the exit of the growing peptide chain through the tunnel.

A translocation of the P site tRNA to the E site, and the A site tRNA to the P site allows for the cycle to be repeated. The peptidyl transferase and decoding centers consist predominantly of RNA, and the key processes and reactions of protein synthesis are carried out by the rRNA. Prokaryotic 5S rRNA interacts with ribosomal proteins L5, L18, and L25 and enhances protein synthesis by stabilization of the ribosome structure but its exact role in protein synthesis is still not known, and 5S rRNA remains a largely unexplored target.

2.26.3.3 Prototypical Pharmacology

Because of the central importance of ribosomes to the synthesis of all proteins, rRNA is not a target well suited to host diseases. However, because of subtle differences in ribosome structure between prokaryotes and higher eukaryotes, rRNA is an excellent target for antibacterial chemotherapy. Most antibiotics which target the rRNA and inhibit bacterial protein synthesis prevent bacterial growth (bacteriostatic). These include the tetracyclines, chloramphenicol, and the macrolides. While each class of drug has a slightly different mechanism of action, they all interfere with the function of the ribosomal machinery and inhibit protein synthesis. This leads to a reduction or cessation of bacterial growth. In contrast, the aminoglycosides which act at the A site to induce miscoding are rapidly lethal to bacteria (bactericidal). This is likely due to a progressive build-up of aberrant proteins, which ultimately cause a disruption of multiple cellular processes leading to cell death.

2.26.3.4 Prototypical Therapeutics

2.26.3.4.1 Aminoglycosides

There are several related structural classes of aminoglycoside antibiotics, representative structures of which are shown in [Figure 3](#).¹⁶ Uniquely differentiated from the majority of aminoglycosides is streptomycin, which contains a

Figure 3 Aminoglycosides which bind at the bacterial 16S rRNA site.

guanylated streptamine core, as opposed to the deoxystreptamine core of the other aminoglycosides. Streptomycin binds near the A site at different location from that of the other aminoglycosides, but still interferes with decoding. The 2-deoxystreptamine based aminoglycosides can be classified into the 4,5-substituted analogs such as paromomycin and neomycin, and the 4,6-substituted analogs such as kanamycin, tobramycin, and gentamicin. These compounds all bind to the 16S rRNA A site, and force two conserved adenosine residues to swing into the minor groove formed by the mRNA/tRNA codon/anticodon base triplet formed during decoding. This stabilizes both cognate and noncognate tRNA pairings, and leads to miscoding and inhibition of protein synthesis.

Tobramycin long has been administered intravenously for treatment of bacterial infections, and has been approved recently as an inhaled formulation for the treatment of cystic fibrosis patients with *Pseudomonas aeruginosa* infections. Also in the kanamycin family is amikacin, which is a semisynthetic derivative that contains a 2-hydroxy-4-aminobutyl chain at the 1-amino group of kanamycin. This substitution confers resistance to a large number of aminoglycoside deactivating enzymes, which modify various portions of the aminoglycoside skeleton and render it pharmacologically inactive. Because of this unique resistance to a broad array of resistance enzymes, amikacin is one of the broadest spectrum aminoglycosides known. It has broad-spectrum activity against a variety of Gram-positive and Gram-negative organisms. However, because of the availability of many other safer, orally acting classes of antibiotics, amikacin and other aminoglycosides such as gentamicin are primarily used against serious Gram-negative infections. In particular, amikacin is used either alone or in combination to treat multidrug resistant nosocomial infections such as *P. aeruginosa*.

All aminoglycosides suffer from potentially severe nephro- and ototoxicities, which limit the use of these excellent antibacterial agents. The nephrotoxicity presents as mild renal impairment in approximately 10–25% of patients receiving an aminoglycoside for more than several days. The nephrotoxicity is generally reversible, and can be monitored by common kidney function tests. In contrast, aminoglycoside-induced ototoxicity is not generally reversible. Both vestibular and auditory dysfunction are evident, and the degree and type of ototoxicity vary with the specific aminoglycoside. The ototoxicity has been correlated with mutations in the 12S mitochondrial A site rRNA, which supports aminoglycoside interaction with this rRNA as a source of aminoglycoside toxicity.¹⁷

2.26.3.4.2 Macrolides

The macrolide antibiotics are an important class of orally active antibiotics.¹⁸ Major members of the class include erythromycin and azithromycin, as well as telithromycin, which was approved in 2004 (Figure 4). The macrolides are most commonly used against Gram-positive organisms, as they are weakly active against most Gram-negative bacilli. The macrolides are generally bacteriostatic agents that bind to the 23S rRNA on the large subunit and block the ‘tunnel’ through which the growing peptide chain exits. Resistance to macrolides arises from a methylase which modifies the ribosomal target and reduces binding, along with enzymes that chemically modify the drug structures and more general uptake/efflux resistance mechanisms. Unlike the aminoglycosides, the macrolides are generally well tolerated and give rise to few serious toxicity issues, and as such are used broadly.

2.26.3.4.3 Other ribosomal ribonucleic acid binding antimicrobials

Several other classes of antibacterial agents bind rRNA, including the tetracyclines, chloramphenicol, clindamycin, spectinomycin, and the oxazolidinones (Figure 5).¹⁸ Tetracycline and its close relatives such as oxytetracycline,

Figure 4 Macrolides that bind to the 50S subunit.

Figure 5 Other antibacterials that bind to the bacterial ribosome.

minocycline, and doxycycline are bacteriostatic agents which function by binding to the small subunit near the A site, hindering movement of the A site tRNA so that it cannot interact with the peptidyl transferase center. Spectinomycin is also bacteriostatic, and binds to the 16S rRNA of the small subunit in a location distinct from the aminoglycosides or tetracycline. It functions to inhibit translocation of the A site tRNA to the P site, presumably by inhibiting a conformational change required to accomplish this translocation. In contrast, clindamycin and chloramphenicol function by binding near the macrolide-binding sites on the rRNA of the large subunit near the peptidyl transferase center. Clindamycin has been useful for the treatment of anaerobes, as has chloramphenicol. However, the toxicity of chloramphenicol to bone marrow restricts its use to serious infections that cannot be otherwise treated.

Linezolid (the prototypical oxazolidinone) represents one of the newer chemical classes of antibacterial agents discovered. It binds to the 23S rRNA of the large subunit, and functions to prevent assembly of the functioning 70S ribosome. Linezolid is broadly active against Gram-positive organisms, and is used for the treatment of vancomycin and/or methicillin-resistant infections. Because of the unique structural class and mechanism of action, there is no cross-resistance with other antibacterials; however, resistance due to a mutation of the 23S rRNA has emerged in clinical practice in a surprisingly short period.^{19,20}

2.26.4 Messenger Ribonucleic Acids

2.26.4.1 Structure and Nomenclature

All nucleic acid sequence information is collected and annotated by the National Center for Biotechnology Information (NCBI), and mRNAs are uniquely identified by their accession number from GenBank.²¹ However, mRNAs are more generally referred to by their common gene name and species.

RNA is synthesized on a DNA template by RNA polymerases. Bacteria utilize a single RNA polymerase to make all RNA. Messenger RNA molecules are made as either monocistronic or polycistronic molecules in bacteria. Translation can occur on bacterial RNA coincident with transcription.

Figure 6 Two-dimensional representation and a model of the three-dimensional structure of the HIV-1 TAR stem loop RNA (PDB ID 1ANR). The 5' strand of the stem is shown dark gray, and the 3' strand is shown light gray. The loop is medium gray.

In contrast, eukaryotes utilize three distinct RNA polymerases to transcribe rRNA, mRNA, and tRNA plus other small RNAs: RNA polymerase I, II, and III, respectively. Eukaryotes also compartmentalize transcription and translation, with transcription occurring in the cell nucleus and translation occurring in the cytoplasm. Eukaryotic mRNA is transcribed as a monocistronic precursor molecule in the nucleus which must undergo several processing steps before it is translocated into the cytoplasm where it is translated.

The 5' terminus of eukaryotic mRNAs is modified with a unique 5' cap structure consisting of an inverted 5'-5'-triphosphate linkage between the first transcribed nucleotide and 7-methylguanine. Many eukaryotic mRNAs are further modified on their 5' terminus by methylation of the 2' oxygen of the ribose nucleotides. The presence of the methyl group adds stability, and also changes the sugar conformation such that it is predominantly (60%) in the C3' endo conformation.²² The 5' cap on an mRNA contributes to export out of the nucleus to the cytoplasm, acts as a recognition element for translation initiation factors, and confers exonuclease stability to the 5' termini of mRNAs.

The primary transcript for most eukaryotic mRNAs is significantly larger than the mature mRNA due to the presence of extraneous nucleotides called intervening sequences or introns. These introns are removed by a complex cleavage and reannealing process called RNA splicing.^{23,24} The reason why eukaryotic RNA contain these intervening sequences is poorly understood. Most eukaryotic RNAs are also modified at their 3' termini by the addition of 50 to 250 adenosines referred as the poly(A) tail. Finally a select few mRNA transcripts are modified by specific deaminases that either deaminate adenosines or cytosines.^{25,26} Once each of these steps is complete the mRNA can then be exported out of the nucleus through nuclear pores to the cytoplasm. Thus in contrast to prokaryotes, eukaryotic mRNA must undergo a series of complex processing events before they can be translated.

Unlike DNA, mRNAs fold into complex three-dimensional structures. These structures tend to be dominated by Watson–Crick base pairing interactions, which drive the folding of mRNAs into self-complementary stemlike structures. Imperfections in the duplex structure lead to unique shapes which can interact with other portions of the mRNA to form more complex structures in a manner similar to protein folding. Expressed in two-dimensional space, RNA structures can be binned into several classes, including stem loops, internal loops, and bulges, junctions, and pseudoknots.²⁷ Stem loops consist of a self-complementary duplex portion, the stem, which is connected by a loop portion of unpaired nucleobases. Internal loops and bulges are formed as a result of imperfect pairing in a stem. This often allows the normally rigid duplex to bend, and the loop or bulge region can be an attractive binding pocket for a potential drug molecule. A representative structure of a stem loop with a bulge is the HIV transactivation response (TAR) element (Figure 6). Junctions typically join three or more stems together, and can form intricate structures.²⁸ Pseudoknots are complex elements in which two stems from nearby regions of sequence stack on top of each other. The stem regions are connected by necessary loops, and the resulting structure is usually tightly folded and stable. Pseudoknot structures are utilized by several viral genomes to promote frameshifting²⁹ and are also found in eukaryotic RNAs such as telomerase RNA.^{30,31}

2.26.4.2 Physiological Function

Messenger RNA, as its name implies, has been well established as the intermediary in the expression of genetic information contained within DNA as proteins. In that every protein produced in a cell derives from a specific mRNA,

targeting mRNA represents a viable alternative to targeting proteins as potential therapeutic agents. However, it is also clear that the role of mRNA extends beyond being simply an information carrier, and that many interactions with mRNAs are important determinants in the level of expression of the encoded protein. Many mRNAs contain complex structures outside of the coding sequence, e.g., the 5' and 3' untranslated regions (UTR). While the precise biochemical functions of these regions are only just being elucidated, it is becoming evident that many of these elements are involved in regulation of the ultimate expression of the encoded gene.

These mechanisms are illustrated by the example of iron regulation in eukaryotes. The mRNAs for ferritin, an iron storage protein, and transferrin receptor, a receptor for the iron carrier transferrin, both contain stem loop structures. A structure in the ferritin 5' UTR termed the iron-responsive element (IRE) binds an IRE-binding protein which serves to prevent translation. In the presence of iron, the IRE-binding protein binds iron, which prevents it from binding the IRE, and translation can take place. This produces ferritin to store the excess iron. In contrast, transferrin receptor mRNA contains IREs in the 3' UTR. In iron-free conditions, IRE-binding protein binds the IREs in the transferrin 3' UTR, and stabilizes the mRNA, preventing degradation, increasing the levels of transferrin receptor. This increases the uptake of iron-rich transferrin from outside the cell. Iron levels are therefore tightly controlled by cells using this posttranscriptional regulatory process.

2.26.4.3 Prototypical Pharmacology

Modulating mRNA levels can in theory lead to dramatic pharmacological effects, as the expression of particular proteins can be reduced by inhibiting translation of or destroying the mRNA which codes for that protein. Conversely, the expression of a particular protein can be increased by stabilizing a particular message such that more is produced from each message. These effects can be observed for a great many mRNA targets by direct measurement of RNA levels by quantitative methods, or by quantitation of the encoded protein. The downstream pharmacological consequences are many, and depend on the particular mRNA target. Targeting mRNA, therefore, represents an orthogonal means to attack any potential protein target, and is especially attractive for 'undruggable' protein targets strongly implicated in a disease state.

Unfortunately the strategies for selectively modulating an mRNA inside a cell are still only nascent and have only started to be developed over the last 15 years. Messenger RNAs present unique challenges as drug target. Current RNA structure prediction programs are unlikely to predict accurately the structure of an mRNA as it exists in a cell. This is due in part to the length limitations of most computational programs, but more importantly mRNAs have dynamic three-dimensional structures as they are being processed and translated. Additionally, mRNAs are bound by cellular proteins that tend to exhibit low sequence selectivity. Thus it is not currently possible to predict structure of an mRNA in a cell nor to identify routinely which regions can be targeted with drug molecules.

2.26.4.4 Prototypical Therapeutics

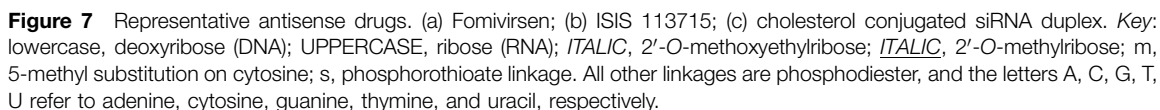

2.26.4.4.1 Antisense-based strategies

One of the most direct methods for selectively targeting RNA is through antisense-based strategies, wherein oligonucleotides are designed to interact with RNA by Watson–Crick base pairing. Representative antisense drugs are shown in [Figure 7](#). Antisense-based approaches are broadly used to modulate expression of genes in cell culture, in animal models, and in the clinic. There are two basic antisense mechanisms: oligonucleotide-induced cleavage of the targeted RNA and steric blocking of RNA. Examples of the former mechanism include ribonuclease (RNase) H mediated cleavage, small interfering RNAs, and ribozymes.^{32–36} Examples of steric effects of antisense oligonucleotides include inhibition of translation, alternative RNA processing, and disruption of RNA regulatory structures.^{37–39}

2.26.4.4.1.1 Oligodeoxynucleotides

The most widely utilized antisense mechanisms are RNase H based cleavage of RNA and the more recently described RNA interference (RNAi) mechanism. RNase H is a ubiquitously expressed enzyme, present in viruses, prokaryotes, and eukaryotes, which hydrolyzes the RNA strand of a DNA–RNA duplex. In general, oligonucleotides that support the RNase H based mechanism are 15–25 nucleotides in length and contain at least 7–10 consecutive deoxynucleotides. RNase H based oligonucleotides ([Figure 7](#)) are the most advanced with the approval of one drug that selectively targets a viral mRNA (fomivirsen⁴⁰) and multiple drugs in clinical trials.⁴¹

Fomivirsen, as well the other early antisense agents to enter clinical trials, are phosphorothioate oligodeoxynucleotides, which are short (typically 20 bases) DNA oligomers that contain a phosphorothioate linkage in place of the phosphodiester linkage. These molecules activate RNase H cleavage of the target mRNA after binding, and reduce

The properties of the first-generation phosphorothioate oligodeoxynucleotides have been dramatically improved by incorporating nucleosides modified at the 2' position on the sugar into the 5' and 3' ends of the molecule while keeping the 2' deoxy core region, or gap, and the phosphorothioate linkage. These modifications serve to further improve metabolic stability, and also improve potency by increasing the binding affinity for the target mRNA.^{43,44} They also activate RNase H cleavage of the target mRNA due to the presence of the 2' deoxy gap. Uniformly 2' modified oligonucleotides are not substrates for RNase H, and generally show reduced potency relative to the gapped versions. The most advanced of these chemistries, 2'-methoxyethyl (MOE), typically employs a design of 5 MOE residues at each end, flanking a 10-base deoxy gap. Several MOE oligonucleotides shown to produce the desired pharmacological endpoints in animal models have advanced to human clinical trials and have shown early evidence of efficacy. These include ISIS-113715, an inhibitor of protein-tyrosine phosphatase 1B (PTP1B) which has shown efficacy in models of diabetes,⁴⁵ and the human specific version (ISIS-301012) of a mouse-specific apolipoprotein B-100 (apoB-100) antisense drug, which has shown benefit in lowering low-density lipoprotein (LDL) cholesterol.⁴⁶

Although there has been tremendous progress in defining the biochemical mechanisms by which siRNA oligonucleotides promote specific degradation of RNA, progress in identifying strategies for systemic use of these molecules as drugs has been slower. Structure–activity relationship studies⁵³ and subsequent optimization have led to motifs with dramatically altered structures that have increased potency and metabolic stability relative to unmodified siRNA oligonucleotides⁵⁴; however, rigorous *in vivo* pharmacokinetic studies have not been reported for any siRNA to date. There is one preliminary report demonstrating activity of systemically administered siRNA *in vivo*, in which

conjugation of cholesterol to the sense strand enhanced delivery to mouse tissue.⁵⁵ Liposomal and particulate formulations are also being explored for systemic delivery of siRNA, and have shown in vivo effects.^{56–58} However, more work is needed to further optimize siRNA constructs and/or formulations for broad systemic delivery, and most current therapeutic strategies are focused on local delivery of siRNA molecules.

2.26.4.4.1.3 5' Cap of messenger ribonucleic acid

Several investigators have exploited the unique chemical reactivity of the 5' cap structure, identifying molecules that selectively hydrolyze the triphosphate bond.^{59,60} Indiscriminate interference with function of 5' caps present on all mRNA would globally inhibit translation and would be predicted to be rather toxic. Such a strategy is utilized by several viruses as a strategy to compete for host cell translation factors.⁶¹

In contrast, selective interference with the function of the 5' cap can be used to specifically modulate the production of a protein product. Antisense-based strategies represent the most direct way of doing so. Antisense oligonucleotides can be designed to the 5' terminus of a transcript and sterically interfere with the recognition of the 5' cap by translation factors.³⁸ Another strategy is to conjugate reactive groups to an oligonucleotide that induce cleavage of the 5' cap structure, the oligonucleotide providing the specificity. Thus antisense-based strategies represent the most direct and efficient approach for modulating the function of the 5' cap structure present on mammalian mRNAs.

2.26.4.4.1.4 Other antisense strategies

In addition to promoting the degradation of a target mRNA, oligonucleotides can be utilized to modulate RNA maturation selectively. The best-characterized example is use of oligonucleotides to selectively modulate RNA splicing.⁶² Oligonucleotides can be used to correct aberrant splicing events such as occurs in thalassemia.³⁹ Alternatively oligonucleotides can be used to redirect splicing such that different alternative spliced variants are produced.^{63,64} As the role of alternative spliced protein products in human disease becomes better characterized, the latter approach will be an increasingly important application for oligonucleotide-based drugs.

2.26.4.4.2 Internal ribosomal entry site

Translation of most eukaryotic mRNAs is initiated at the 5' cap structure. However, some viral⁶⁵ and eukaryotic^{66,67} mRNAs contain a sequence in the 5' UTR which functions as an internal ribosome entry site (IRES), although the exact function of the IRES remains controversial.⁶⁸ IRES elements were first discovered in picornavirus and later in other viral mRNAs. More recently IRES-like sequences have been found in some eukaryotic mRNAs such as the mRNAs encoding vascular endothelial growth factor, fibroblast growth factor-2, *c-myc*, *N-myc* and the antiapoptotic protein Apaf-1.^{69,70}

One of the best-characterized IRESs is that of extrahepatic hepatitis C virus (HCV). The HCV IRES occurs in the 5' UTR of the positive strand polycistronic mRNA. It is approximately 360 nucleotides in length, extending approximately 30 nucleotides 3' to the AUG translation initiation codon for the core protein. The IRES consists of three major structural domains which extend from a pseudoknot structure.⁷¹ The pseudoknot and domain IV are centrally located with the other domains radiating out from the central region. Domain III is required for IRES function and contains a large four-way junction and two stem loop structures (III_d and III_e). Domain III_d contains an E-loop motif presenting a unique narrowed major groove and a distorted phosphodiester backbone.^{72,73} This structure is similar to the sarcin/ricin loop in 28S rRNA. Domain IV includes the translation initiation codon.

As the HCV IRES is essential for translation of the HCV genome, it represents a unique structure for drug targeting. There are multiple approaches being pursued to interfere with the HCV IRES. Several investigators have designed synthetic oligonucleotides to bind to the IRES and disrupt its function.^{74–76} These oligonucleotides were shown to block translation of HCV proteins in a cell culture model. In a related approach, oligonucleotide aptamers were selected to bind to the HCV IRES.⁷⁷ Aptamers selected to bind to domains II–IV had the highest affinity, and were shown to contain a consensus sequence ACCCA which base pairs to the apical loop of domain III_d.

Several efforts to identify small molecules have also been reported. Screening of chemical libraries has resulted in the identification of phenazine⁷⁸ and guanidine⁷⁹ small molecules capable of inhibiting HCV IRES dependent translation. In related work, a class of benzimidazoles (Figure 8) was found to bind to an internal loop region of the HCV 5' UTR stem II, and subsequently to inhibit HCV replication in a cellular assay.⁸⁰

2.26.4.4.3 Human immunodeficiency virus transactivation response

One of the best-characterized and explored structured RNA drug targets is the TAR within the HIV RNA genome (Figure 6). TAR is recognized and bound by a virally encoded protein, Tat, which promotes transcription of viral RNA. As a correlation between Tat binding to TAR and HIV mRNA transcription has been shown, the Tat–TAR interaction is

Figure 8 Small molecules that target RNA.

an interesting drug target for HIV chemotherapy. The TAR structure is a stem loop, containing an asymmetric internal loop, or bulge, of three bases. It therefore contains two unique elements for the recognition of drugs and the Tat protein: the terminal stem loop and the internal bulge.

To identify small molecule inhibitors of the Tat–TAR interaction, a corporate library of 150 000 compounds was screened in a high-throughput format. A 1–2% hit rate was found for molecules that showed significant inhibition at 20 μ M in the screen. From these hits, approximately 20 compounds were identified that had dose-responsive activity in a cellular assay at nontoxic levels.⁸¹ In continued investigations of the mode of action using mass spectrometry, two compounds, a quinoxaline-2,3-dione and a 2,4-diaminoquinazoline (Figure 8), were found to bind the TAR RNA in different locations, and one demonstrated antiviral activity in a cellular assay.⁸² Although this work has not resulted in movement of an RNA-binding drug to clinical trials, it clearly demonstrates that high-throughput screening approaches can be successfully applied to structured RNA drug targets.

Computational screening has been used to identify compounds that should bind to the 5' bulge of TAR RNA. An acetylpromazine (Figure 8) lead was identified that inhibited Tat protein binding to TAR RNA at a 100 nM concentration. The nuclear magnetic resonance (NMR) structure of TAR RNA with the ligand showed that binding of the ligand to the bulge induces a modest conformational change but prevents stacking of the upper and lower stems of the RNA via intercalation at the bulge.⁸³

2.26.4.4.4 Berberine

Berberine (Figure 8) is an alkaloid present in a number of clinically important medicinal plants, extracts of which have been used in Chinese medicine for many years, predominantly as antimicrobial treatments. Recently, berberine has been shown to lower cholesterol in animal models of hyperlipidemia, as well as in humans.⁸⁴ This activity has been attributed to the stabilization of the mRNA for low-density lipoprotein receptor (LDLR), resulting in increased production of protein. The LDLR receptor regulates plasma LDL cholesterol levels, and increased expression of LDLR receptor results in increased clearance of LDL cholesterol. That berberine was having a direct effect on the mRNA was further shown by mutational studies in a reporter system where the stabilization effect was mapped to the 5' proximal region of the LDLR 3' UTR. The precise biochemical interactions that underlie berberine's effects are unknown. However, the observed clinical and mechanism of action data strongly support that increasing the expression of a protein via stabilization of an mRNA is a viable means to achieve a therapeutic result in patients.

2.26.5 New Directions

2.26.5.1 Riboswitches

Riboswitches are metabolite-binding domains present within certain mRNAs.^{85,86} To date riboswitches have been identified as occurring in bacterial, archaeal, fungal and plant mRNAs. Although not identified to date, it is possible that

they will also be found to occur in mammalian mRNAs as well. Riboswitches typically contain two domains, an aptameric domain responsible for binding the metabolite and another domain responsible for genetic regulation. Examples of riboswitch ligands include glycine, coenzyme B12, thiamine, flavin mononucleotides, *S*-adenosylmethionine, and guanine.^{87,88} As such, riboswitches represent unique target opportunities for drugs. It should, in principle, be possible to identify agonists and antagonists which modulate riboswitch function in an analogous manner to protein receptors. However, studies validating such an approach have yet to be published.

2.26.5.2 Signal Recognition Particle and tmRNA

Additional large RNA targets that may be good therapeutic targets are the bacterial tmRNA and signal recognition particle (SRP) RNA. Both adopt complex tertiary folds stabilized through interactions with the ribosome or cognate proteins. The SRP RNA binds to a stalled ribosome through an unknown structure present in the mRNA for membrane proteins, and translocates the ribosomal machinery to the cell wall to facilitate insertion of hydrophobic proteins directly into the membrane. Knockout of SRP results in bacterial cell death. The tmRNA is a large (~340 nucleotide) RNA that recognizes bacterial ribosomes that have stalled on a damaged mRNA. The tmRNA provides a pseudo-mRNA that swaps into the 30S subunit to replace the damaged mRNA, then presents a tRNA-like domain to the ribosome to add a short peptide sequence that targets the mRNA for degradation.

2.26.5.3 MicroRNA

MicroRNAs (miRNAs) are a newly discovered class of 20–24 nucleotide RNAs critical to a variety of cellular processes in organisms from yeast to humans.⁸⁹ They appear to work as inhibitors of translation by binding imperfectly to the 3' UTR of mRNAs as part of a complex with RISC. miRNAs have also been shown to result in reduction of certain target mRNAs, and it appears that they may also play roles in the transcriptional regulation of gene expression via DNA methylation^{90,91} and heterochromatin formation.^{92,93} miRNAs are generated from structured regions of transcribed RNAs called pri-miRNAs through the action of the double-stranded RNA nuclease Drosha. The resulting immature hairpin RNAs termed pre-miRNAs are then exported from the nucleus and cleaved in the cytoplasm by another double-stranded RNA nuclease (Dicer) to generate the mature miRNA.⁴⁹

miRNAs are an attractive new class of therapeutic targets, as they are differentially expressed in tissues, and are associated with tumorigenesis, regulation of adipocyte differentiation, insulin secretion, and activation of immune cells.^{94–96} Since miRNAs are similar in structure to siRNAs, it is possible to envision the use of siRNA analogs as miRNA mimetics, which would presumably inhibit the expression of the target genes. Perhaps more importantly, inhibition of miRNAs would be expected to increase the expression of its target genes. Inhibition of miRNAs can be achieved with antisense oligonucleotides,⁹⁷ which provides a straightforward way to examine the potential of miRNAs as targets, as well as a means to develop therapeutics. This is exemplified by studies in which inhibition of a liver specific microRNA (miR-122) was achieved in vivo via the use of uniformly modified oligonucleotides, either with⁹⁸ or without⁹⁹ cholesterol conjugation. These studies showed upregulation of several target genes, and gave a phenotypic effect of lowered cholesterol and decreased steatohepatitis, suggesting a potential therapeutic indication for microRNA modulation. An additional therapeutic indication for inhibitors of miR-122 is suggested by a connection between miR-122 function and HCV RNA replication, and the observation that inhibition of miR-122 with an antisense oligonucleotide resulted in reduction of HCV RNA levels in an HCV replicon assay.¹⁰⁰ Furthermore, the pre-miRNA and pri-miRNA structures contain bulges and mismatched bases at key regions. These structures are potential binding pockets for small molecules which could interfere with their processing and alter miRNA levels.

Biographies

Eric E Swayze received a BS in chemistry degree from the University of Michigan honors college in 1987, and a PhD in organic chemistry from the University of Michigan in 1994 under the guidance of Prof Leroy B Townsend. In 1994, Dr Swayze joined Isis Pharmaceuticals as a Sr Scientist, where he has focused on developing drugs which act on RNA targets, including both oligonucleotide and small molecule therapeutics. Dr Swayze is currently Vice President of Medicinal Chemistry at Isis Pharmaceuticals of Carlsbad, CA.

Rich H Griffey is currently a Senior Engineer at SAIC in San Diego. He received a BA in chemistry from Rice University in 1978. His PhD in organic chemistry was obtained in 1983 under the guidance of C Dale Pounter at the University of Utah. After a postdoctoral fellowship with Alfred Redfield, Dr Griffey has held jobs in both academia and industry. His interests include analytical and synthetic chemistry at the chemistry/biology interface, cycling, and astrophotography.

C Frank Bennett is Senior Vice President of Research at Isis Pharmaceuticals. He is responsible for preclinical antisense drug discovery research, manufacturing and pharmaceuticals. Dr Bennett is one of the founding members of the company. He has been involved in the development of antisense oligonucleotides as therapeutic agents, including research on the application of oligonucleotides for inflammatory and cancer targets, oligonucleotide delivery, and pharmacokinetics. He also runs the company's antisense mechanism program which is focused on the development of RNase H, RNAi, micro-RNA, and splicing. Dr Bennett has published more than 120 papers in the field of antisense research and development and has more than 100 issued US patents.

Prior to joining Isis, Dr Bennett was Associate Senior Investigator in the Department of Molecular Pharmacology at Smith Kline and French Laboratories (currently GlaxoSmithKline).

Dr Bennett received his BS degree in pharmacy from the University of New Mexico, Albuquerque, New Mexico and his PhD in pharmacology from Baylor College of Medicine, Houston, Texas. Dr Bennett performed his postdoctoral research in the Department of Molecular Pharmacology at SmithKline and French Laboratories.

2.27.1 Introduction

It has been said that reduction–oxidation (redox) reactions are the foundation of life – an accurate reflection in that much of cellular anabolic and catabolic metabolism is based on enzyme-catalyzed redox reactions. It is impossible to characterize coherently the biochemical complexity, regulatory networks, and mechanistic insights of all redox enzymes in one chapter. However, comprehensive reviews and texts cover this ground, such as the recent text by Copeland.¹

Readers interested in the redox biology of oxygen- and nitrogen-centered radicals, and their interactions, are encouraged to consult the comprehensive two-volume series edited by Sen and Packer in *Methods in Enzymology*,² the classic text by Halliwell and Gutteridge,³ and the works by Cadenas and Packer,⁴ Balaban *et al.*,⁵ and Duncan and Heales.⁶ Similarly, readers interested in mitochondrial biology and bioenergetics would do well to consult the books by Nicholls and Ferguson,⁷ Beal *et al.*,⁸ Scheffler,⁹ Lane,¹⁰ and Berdanier.¹¹

Although redox enzymes have received much attention from analytical and pharmaceutical perspectives, this is not the case for the medicinal chemistry of these systems in mitochondria. Indeed, mitochondrial dysfunction and failure are increasingly implicated in the etiology of both acute and chronic human diseases. For example, acute mitochondrial collapse and ensuing apoptosis cause cell death in the lesion penumbra resulting from transient ischemia in stroke, myocardial infarction, and other instances of ischemia–reperfusion.^{12,13} On the other hand, accelerated mitochondrial senescence and dysfunction are central events in a host of neurodegenerative diseases, including Parkinson's, Huntington's (HD), amyotrophic lateral sclerosis (ALS), Friedreich's ataxia, and likely Alzheimer's (AD), many retinodgenerative diseases, including retinitis pigmentosa, glaucoma and age-related macular degeneration (AMD), and in metabolic diseases such as type II (noninsulin-dependent) diabetes (NIDDM).^{14–24} This is in addition to the more than 75 syndromes and diseases caused by well-defined mutations in the mitochondrial DNA (mtDNA) and/or in nuclear genes of proteins destined for import into the mitochondria. The journal *Neuromuscular Disorders* publishes

periodic updates on mitochondrial diseases, and the most recent review at the time of this writing of mitochondrial encephalomyopathies is from DiMauro and Hirano.²⁵

It is clear that mitochondrial pathology is maturing into a major arena for therapeutic intervention, and hence a rapidly expanding field for medicinal chemists. As a result, this is a timely opportunity to summarize current understandings of mitochondrial function and dysfunction in disease, the chemistry of known mitochondrial inhibitors, and ongoing pharmaceutical development efforts targeting mitochondrial integrity as a therapeutic strategy. Given the complexity and diversity of mitochondrial redox systems, restricting perspective to mitochondrial biology does not correspondingly limit the breadth of topics anticipated in a review of redox or transporter biology; the redox systems in mitochondria provide a microcosm of the panoply of [Fe-S], heme, and other metalloprosthetic moieties found in nonmitochondrial biology.^{26–29}

When mitochondria fail, the cell dies. In large measure, this dictum reflects why the study of mitochondrial physiology and pathology has been reinvigorated in recent years. Increased understanding of the separate redox reactions that constitute the electron transport system (ETS) has helped illuminate the sites and character of potential dysfunction, typically reflected by free radical production, collapse of membrane potential, and cellular energetic impairment.^{15–17,30,31} Such electron flow does not occur without highly regulated spatial constraints, which entails an understanding not only of protein–protein interactions, but also of how the lipid domain of the inner membrane contributes to mitochondrial function and failure. Indeed, mitochondrial failure can be most basically defined as the loss of the inner membrane impermeability to protons, which imposes both oxidative and energetic crises that conspire to undermine cellular viability.

There has been a pervasive myth in the pharmaceutical realm that ‘mitochondria are undruggable,’ fostered in part because mitochondrial dysfunction characteristically yields multiorgan pathology that is often profoundly debilitating, and that seems to defy rational symptom-oriented drug development strategies. Many of the known mitochondrial diseases are rare by pharmaceutical industry standards, early-onset, and often lethal, which discourages many companies from even entering the arena. To some extent, the current paucity of mitochondrial medicines also reflects a lingering legacy of the fact that the first mitochondrial drug, dinitrophenol (DNP) was highly toxic, and in many cases, lethal. DNP was sold in the early part of the twentieth century for weight loss, and although it was effective at low doses, it was justifiably included in the US Food and Drug Administration’s (FDA’s) list of snake oils and injurious medicines that resulted in the 1938 Federal Food, Drug, and Cosmetic Act. This Act gave the FDA enforcement power to actively assess and pursue drug safety. Moreover, the ‘undruggable’ myth has been fueled by the inaccurate notion that ‘all mitochondria are the same,’ thereby precluding the opportunity to capitalize on tissue selectivity to limit potential drug side-effects and toxicity. It is our hope that this chapter will help dispel these myths that have previously impeded mitochondrial drug development.

Because no single chapter can do justice to the vast literature on mitochondrial physiology and pathology, citations have been skewed toward reviews that provide more comprehensive treatments of individual topics. In addition to directing the reader to the relevant literature, other goals here are to provide an overview of:

- mitochondrial biology and genetics, and how dysfunction contributes to human disease;
- the respiratory complexes, including electron flow, redox centers, and known inhibitors. It is hoped that consideration of inhibitors, many of which are natural products, will encourage exploration of structural variations;
- how oxidative phosphorylation (OxPhos) and oxidative pathology converge, and how these interactions may provide therapeutic opportunities;
- mitochondrial failure;
- strategies that have been used to develop mitochondrially directed therapeutics.

2.27.2 Mitochondria

2.27.2.1 Biology

Mitochondria are a double-membraned organelle of prokaryotic origin found in almost all eukaryotic organisms in direct proportion to the energy demand of the cell and tissue.^{32–34} Highly active cells can contain hundreds to thousands of individual mitochondria, and in those rare instances where mitochondria are absent, they have been lost via secondary deletion with a corresponding increased reliance on anaerobic glycolysis. A number of independent lines of evidence indicate that mitochondria originated from a free-living bacterial endosymbiont some 2 billion years ago.^{9,10} The transition from ancestral endosymbiont to modern mitochondrion has been accompanied by major changes in its proteome, extensive metabolic remodeling, and profound reduction of the endogenous genome via gene transfer to the

nuclear genome.^{35,36} Mitochondria reproduce independently of the cell cycle, contain their own genome with a genetic code that differs from that in the nuclear genome, and are dynamic structures within the cell, fusing into megamitochondrial networks in some instances, while budding into the classically shown bean shape, as shown in **Figure 1**, in others. The images in **Figure 1** use electron tomography to generate three-dimensional reconstructions from serial two-dimensional images, as described by Frey and Mannella.³⁷

A more reticular structure of the mitochondrial population is shown in **Figure 2**, where staining with an anticytochrome *c* antibody reveals the mitochondrial network encircling the nucleus in the cell body, and extending into the dendrites and axon of a rat hippocampal neuron in primary culture.

The equilibrium between solo mitochondria and a reticulum is largely regulated by the mitofusin family of proteins which has become an area of active investigation, and may offer a viable avenue for pharmaceutical development.^{38–41} The dynamic nature of this equilibrium is revealed via time-lapse imaging.

Figure 1 Electron tomography imaging of individual mitochondrion from chick cerebellum showing three-dimensional ultrastructure. (a) The outer membrane (dark blue) is reminiscent of the endoplasmic reticulum in composition. The inner membrane invaginates into the matrix space to form cristae (yellow); this increases surface area, and hence oxidative phosphorylation capacity. The cristae form 30 nm tubular junctions, with the inner boundary membrane (light blue), forming a continuous surface. (b) Four individual cristae are shown to highlight anatomical complexity ranging from simple tube (red), more elaborate examples with several cristal junctions variability (green and gray), to one with many junctions plus both lamellar and tubular components (yellow). Many of the proteins involved with transmembrane exchange of substrates and proteins, such as the adenine nucleotide translocator (ANT) and voltage-dependent anion transporter (VDAC), are localized at the cristal junctions. (Reproduced with permission from Frey, T. G.; Mannella, C. A. *Trends Biochem. Sci.* **2000**, 27, 319–324.)

Figure 2 Characteristic reticular anatomy and perinuclear density of mitochondria. Budding into typically shown 'Bean' shape and aggregation of reticulum is dynamic. Mitochondria stained with an anticytochrome *c* antibody. (Reproduced with permission of Sandra Wiley, University of California at San Diego.)

Although mitochondria generate >90% of the energy required for aerobically poised cells to survive, in so doing they also generate >90% of the highly reactive oxygen-centered radicals that undermine cell viability.^{2–6} Collapse of mitochondrial function is lethal for aerobically poised cells, leading to apoptosis or necrosis depending on the severity and duration of mitochondrial dysfunction. Mitochondria integrate a host of pro- and antiapoptotic and necrotic signaling pathways, and are the initial domino in several cell death cascades.^{13,42} Indeed, mitochondrial dysfunction is rapidly becoming appreciated as an important etiological component in a wide variety of both acute and chronic human diseases,^{43–45} as well as in toxicity of drugs, including antivirals and cisplatin.⁴⁶ This is increasingly reinforced by insights into free radical-mediated regulation of respiration, which in turn alters the oxidative poise of the organelle and the cell.^{15,47,48}

2.27.2.2 Membranes and Electron Transport Complexes

The outer, relatively permeable, mitochondrial membrane is reminiscent of endoplasmic reticulum in both lipid composition and transport physiology. Not so the inner membrane surrounding the central matrix space which contains the Krebs's cycle enzymes. The inner membrane contains approximately twice the amount of phosphatidylethanolamine, and half the amount of phosphatidylcholine, of the outer membrane, plus about 20% by weight cardiolipin (diphosphatidylglycerin), an atypical membrane lipid with four highly unsaturated acyl chains found in the cell almost exclusively in the mitochondrial inner membrane.⁴⁹

Over 80% (by weight) of the inner membrane is composed of proteins, the highest density within the cell. In large measure, these proteins are the four respiratory complexes: C-I, NADH-CoQ oxidoreductase; C-II, succinate dehydrogenase-CoQ oxidoreductase; C-III, CoQ-cytochrome *c* oxidoreductase; and C-IV, cytochrome *c* oxidase (COX), plus adenosine triphosphate (ATP) synthase, frequently referred to as Complex V, although unlike the other four complexes, it does not catalyze a redox reaction.

OxPhos includes two separate, but interdependent, processes: electron transfer system (ETS) and ATP synthase (Figures 3 and 4). The first entails the sequential redox transfer of electrons, removed from pyruvate in the Krebs cycle within the matrix, down a potential energy gradient via the four respiratory complexes, ultimately reducing molecular O₂ to H₂O. In so doing, protons are translocated out of the matrix to yield a transmembrane electrochemical potential. In the second phase of OxPhos, the chemiosmotic potential generated by ETS drives ADP phosphorylation via ATP synthase.⁹

2.27.2.3 Electron Transfer Models

The initial models of mitochondrial respiration described electron transfer as a 'chain' of respiratory centers, connoting a 1:1 linkage with a coordinated linear redox transfer. However, it was noted early on that the molar ratios of the various respiratory components were not uniform, and for every C-I, there were 3 mol C-III, 9 mol cytochrome *c*, 50 mol

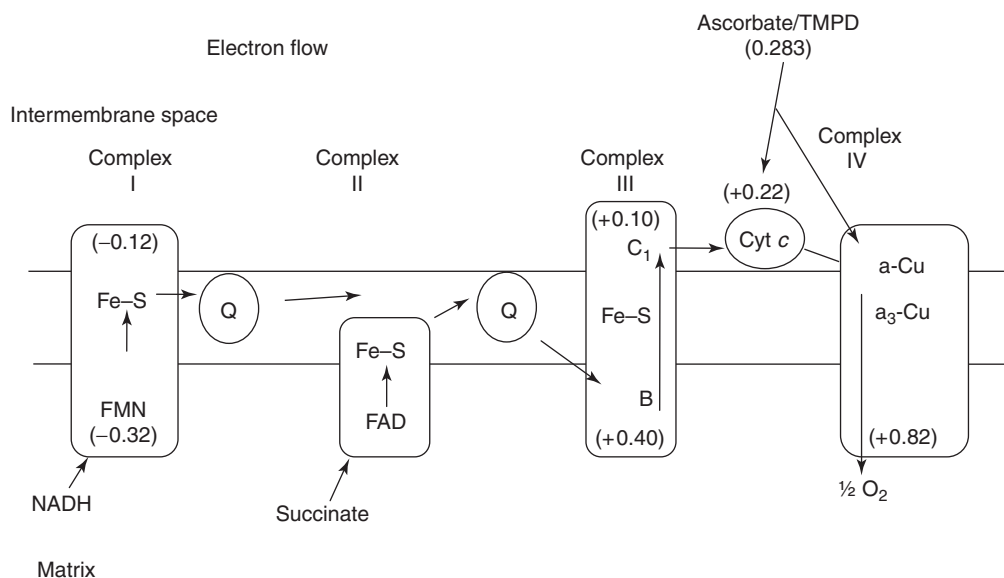

Figure 3 Schematic of the four respiratory complexes within the inner mitochondrial membrane, with electron flow and some of the mid-point redox potentials indicated.

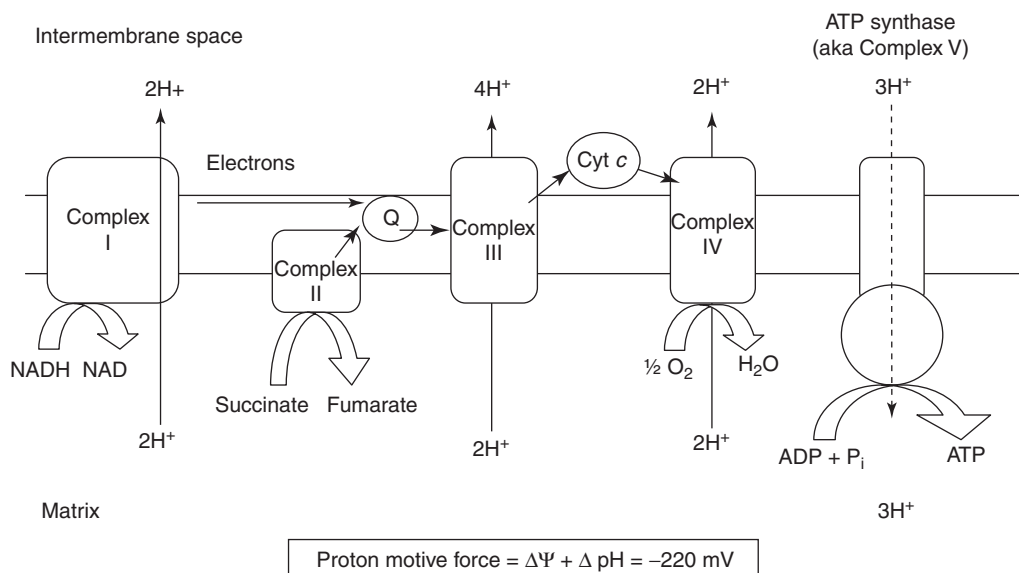

Figure 4 Three respiratory complexes couple redox catalysis with proton translocation, thereby generating a transmembrane potential of $\sim 220 \text{ mV}$ (matrix negative) due to both electrical and pH gradients. ATP synthase, also known as Complex V, couples the dissipation of the proton motive force to phosphorylation of ADP.

ubiquinone, and 7 mol C-IV.⁵⁰ Despite molar inequalities, factoring in the lateral diffusion coefficients of the respiratory complexes yielded a model of electron transfer much closer to unity, suggesting that catalysis of respiration was mediated by collisions between individual ETS components within the inner membrane.⁵⁰ More recent studies of *Escherichia coli*, *Saccharomyces cerevisiae* and mammals have revealed that individual respiratory complexes congregate into larger heteromeric assemblies, and that these in turn aggregate into higher-order supercomplexes called ‘respiratosomes’.⁵¹ These supercomplexes can be dissociated via detergent treatment, and the presence of cardiolipin is required to maintain quaternary structure, at least for the association between C-III/C-IV in yeast.⁵² In mammals the respiratosomes appear to be constructed of two aggregates consisting of C-I and 2 C-II and 4 C-IV, and 2 C-III and 4 C-IV.⁵¹ Note that the subunit composition of such supercomplexes reflects the molar concentrations noted above, and that it may be that the lateral diffusion coefficients of ubiquinone and cytochrome *c* serve as the proximate determinants of catalytic rates within these supercomplexes (although pool behavior may not always hold).⁵¹

2.27.2.4 Nernst Equation

Within the dictates of reactant concentration, and importantly pH, the equilibria of redox reactions follow the half-cell potential of the redox pair, as predicted by the Nernst equation:

$$E = E^0 \frac{RT}{nF} \ln \frac{a_{[\text{red}]}}{a_{[\text{ox}]}}$$

where E^0 , the standard electrode potential, is the electrode potential at the standard conditions of temperature 298 K, 1 atm pressure, and at 1 mol of the activity of redox participants of the half-reaction. And where:

- R is the gas constant, equal to $8.31 \text{ J K}^{-1} \text{ mol}^{-1}$
- T is the temperature in Kelvin
- a is the chemical activities on the reduced and oxidized side, respectively
- F is the Faraday constant, equal to $9.648 \times 10^4 \text{ C mol}^{-1}$
- n is the number of electrons transferred in the half-reaction
- $[\text{red}]$ is the concentration of the reduced species
- $[\text{ox}]$ is the concentration of the oxidized species

Moreover, since:

$$\Delta G^0 = -nF\Delta E^0$$

it follows that an electron transfer is spontaneous (negative ΔG) if $E^{0'}$ (mid-point potential) of the e^- donor is more negative than $E^{0'}$ of the e^- acceptor, i.e., when there is a positive $\Delta E^{0'}$.

Thus, the mid-point potentials of the individual redox reactions within the ETS can, in large measure, predict the sequence of reactions, as shown in the schematic of ETS (Figure 3). However, from a more constrained biological perspective, redox chemistry need not dictate physiological outcome. For example, given the highly positive E^0 for the reduction of oxygen, it is apparent that any of the ETS components is capable of reducing O_2 , but this is not the case biologically. Indeed, because of spatial and other considerations, only three sites on ETS are apparently capable of directly catalyzing O_2 reduction, namely C-I, ubiquinone, and C-IV. Similarly, a simplistic linear arrangement of redox potentials does not faithfully predict the Q-cycles entailed in proton translocation in C-III, and likely in C-I.⁵³

2.27.2.5 Inner Membrane

The oxidation of glucose, amino acids, and fats to CO_2 and water coupled with generation of ATP via OxPhos yields 36 mol ATP per mole of glucose, 18-fold more than anaerobic glycolysis. This process is entirely dependent on both the impermeability of the inner mitochondrial membrane, and the catalytic function of the respiratory complexes, which is also dependent upon their orientation, quaternary assemblages, and lateral mobility within that membrane. As such, the inner mitochondrial membrane becomes a dominating determinant of mitochondrial function and failure, and thus an attractive target for therapeutic intervention.^{54,55} Indeed, during pathogenic Ca^{2+} loading, Ca^{2+} binding directly to cardiolipin in the inner membrane leads to immobilized lipid clusters, particularly around the adenine nucleotide translocator (ANT), increases in free radical production, and accelerated lipid peroxidation.^{56–58} As such, cardiolipin oxidation and Ca^{2+} binding are likely early, and crucial, events in mitochondrial failure under pathogenic conditions. This notion is reinforced by the association between repressed cardiolipin production and the mitochondrial disorder, Barth syndrome.⁵⁹

2.27.2.6 Membrane Potential

The sequential redox reactions of the respiratory system are coupled stoichiometrically to translocation of protons from the matrix to the intermembrane space, resulting in a ~ 220 mV electrochemical potential (matrix-negative) (see Figure 5). The majority of this (~ 180 mV) is due to ion potential and is termed $\Delta\psi_m$, with the remainder due to a pH gradient (ΔpH). Peter Mitchell was awarded a 1978 Nobel Prize for his work showing that the potential energy of this gradient is coupled to ADP phosphorylation via activity of $F_0 - F_1$ ATP synthase, the molecular mechanisms of which have now been elucidated.⁵¹ In any event, establishment and maintenance of $\Delta\psi_m$ is directly dependent not only on the ETS, but also on the impermeability of the inner membrane. Loss of inner membrane impermeability, with complete mitochondrial failure, can occur via several mechanisms discussed below, but the well-known ability of agents such as cyclosporine A and bongkreic acid to moderate $\Delta\psi_m$ collapse, and conversely the ability of carboxyatractylsides to induce it, suggests that it is amenable to therapeutic intervention.⁶⁰

2.27.2.7 Mitochondrial Genome

Mitochondrial assembly and function is the only cellular system regulated by two separate genomes, mtDNA and the nuclear DNA (nDNA). Human mtDNA is an intronless, circular, double-stranded molecule of DNA, containing 16 569 bp, and each organelle contains 5–15 copies.⁶¹ Unlike the nDNA, which is characterized by vast sequences of unencoding ‘junk’ DNA, mtDNA is exceedingly concise; it encodes on both strands, depending on direction, 13 polypeptides that are key subunits of the OxPhos system, plus 22 tRNAs and 2 rRNAs required for translation. Of the respiratory complexes, only C-II is entirely encoded by nuclear genes, as are the remaining ~ 112 subunits of the OxPhos system, plus the several thousand other proteins and RNAs required to assemble and maintain the mitochondria, including Krebs cycle and beta oxidation pathways, as well as heme biosynthesis.^{51,62}

Within a given cell or tissue, under normal conditions, all the mtDNA in the entire mitochondrial population is identical, a condition termed homoplasmy. When mutations occur, they are typically evident in only a subset of mtDNA molecules, resulting in two or more subpopulations of mtDNA within the cell, a condition termed heteroplasmy. Mitochondrial division and mtDNA replication are continuous, with a half-life of several weeks in human hepatocytes, and are independent of cell cycle. As such, in long-lived, terminally differentiated cells like neurons, the relative ratio

of normal to mutated mtDNA can drift over time.⁶¹ When the proportion of damaged copies of mtDNA exceeds a threshold, set as a function of cellular energetic demand, oxidative status and nature of the mutation, pathology emerges. Most cancers are homoplasmic with localized mutations,⁶³ and there are now over 100 diseases attributed to over 190 specific mutations in mtDNA, or in mutations in nuclear-encoded proteins that are secondarily transported into the mitochondria.⁶⁴ An example of the latter is frataxin, where a recessively inherited CAG repeat expansion disrupts mitochondrial iron homeostasis, exacerbating endogenous oxidative stress and assembly of [Fe-S] centers, resulting in the disease Friedreich's ataxia.^{21,65}

2.27.2.8 Mitochondrial Diseases

Mitochondria are not only the key determinants of cellular energetic and oxidative status, thermogenesis, and Ca^{2+} -buffering capacity, but they also integrate the various pro- and antiapoptotic signals into actions that will ultimately either induce or repress apoptosis.^{12,13,66} Given such crucial roles, it should not be surprising that mitochondrial dysfunction figures centrally in aging,^{5,19,45,67–71} chronic neurodegenerative diseases,^{72–74} and acute pathologies such as those associated with transient ischemia and reperfusion in a host of aerobically poised tissues, such as central nervous system (CNS) stroke and myocardial infarction.^{16,17} Since the initial identification of a mitochondrial disease by Rolf Luft in 1959, dozens of diseases with a mitochondrial etiology have been described, including mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes syndrome (MELAS), and myoclonus epilepsy with ragged-red fibers (MERRF). Many of these diseases are associated with known deletions or other defects in mtDNA.^{25,75–77} For example, impairment of C-I in the electron transport system in systemic and neuronal tissues is found in Parkinson's disease patients,⁷⁸ whereas in HD, the extent of expanded CAG repeats in the mitochondrial protein huntingtin predicts the degree of mitochondrial impairment via membrane intercalation, and hence age of onset.⁷⁹

Indeed, our insight into the molecular etiology of a host of neurodegenerative diseases, and acute conditions such as stroke or myocardial infarction, has been fundamentally altered by studies implicating mitochondrial dysfunction in Ca^{2+} dyshomeostasis, free radical production, and cell death.^{15,80} Similarly, our understanding of the normal aging process has been substantially illuminated by genetic and bioenergetic studies implicating mitochondrial senescence and associated radical generation and energetic decline in gradual cellular deterioration.

Despite the strides made in characterizing the symptoms and etiology of these ailments, the continuing paucity of therapeutic agents remains a major hurdle, and thus an opportunity for drug development.

2.27.2.9 Mitochondrial Failure and Radical Production

The convergence of mitochondrial failure, free radical pathophysiology, and disease has also been fostered by evidence linking mitochondrial radical production and bioenergetic physiology as synergistic contributors to cell senescence and death.^{15–18,81} For example, free radical exposure greatly potentiates the catastrophic loss of inner membrane impermeability and consequent mitochondrial permeability transition (MPT), that yields irreversible collapse of $\Delta\psi_m$.⁸² MPT is readily induced by excessive Ca^{2+} exposure,^{15–18,83} such as occurs when ionotropic dicarboxylate ion channels, including *N*-methyl-D-aspartate (NMDA), kainate and ibotenate receptors, are excessively stimulated. The major pathogenic receptor in ischemia–reperfusion and excitotoxicity is the NMDA channel. This excitotoxicity receptor has redox-susceptible disulfides that potentiate activation when exposed to reducing radicals and to various NO species which can, depending on redox status, exacerbate Ca^{2+} influx. The latter provides a facile explanation for the synergistic effects of oxidative stress and MPT in excitotoxicity.⁸⁴ Calcium ionophores such as A-23189, ionomycin, and others are used to mimic pathogenic NMDA receptor activation.⁸⁵ Despite its disastrous nature, MPT is moderated by cyclosporine A and bongkreic acid, not only implicating the ANT in MPT formation, but also providing encouragement that small-molecule development strategies targeting MPT hold promise.⁶⁰

A likely cause for MPT is an irreversible conformational shift in the ANT, a transmembrane carrier that uses $\Delta\psi_m$ to exchange ATP for ADP across the inner membrane.⁸⁶ ANT is usually associated with a number of other proteins, including cyclophilin D (the binding site of cyclosporine A), creatine kinase, and voltage-dependent anion channel (VDAC), which have all been implicated in the formation of the MPT 'megapore',⁸⁷ although VDAC is also found in the plasma membrane.⁸⁸ Interestingly, for full catalytic capacity, ANT requires small amounts of cardiolipin, suggesting the possibility of allosteric modulation as a strategy for compound development with fewer potentially deleterious pitfalls than agents binding at the adenylate site.

Collapse of $\Delta\psi_m$ obviously abrogates ATP production, and also causes mitochondrial swelling as water enters down its osmotic gradient. In response to swelling, mitochondria release a number of proapoptotic proteins, such as cytochrome *c*, apoptosis-inducing factor (AIF), Smac/DIABLO, Omi/HtrA2, and endonuclease G, that activate various

caspase and other apoptotic pathways.^{13,89–91} Release of mitochondrial proapoptotic factors occurs upon osmotic swelling, but swelling is not necessarily required in all cases; for example, cytochrome *c* can be released prior to $\Delta\psi_m$ collapse.⁹²

Under some circumstances, MPT also accelerates free radical production from mitochondria.¹⁵ When provided with adequate oxidizable substrates and O_2 , free radical production from coupled mitochondria isolated from rat cerebral cortex and cerebellum is below the levels of detection of electron paramagnetic resonance spin-trapping techniques. However, immediately upon exposure to $\mu\text{mol L}^{-1}$ Ca^{2+} concentrations akin to those occurring during pathogenesis, spin adducts with hyperfine splitting characteristics consistent with both carbon- and oxygen-centered radicals are readily detected.^{15–18} Moreover, radical exposure (H_2O_2 plus Fe-EDTA) increases subsequent radical production almost 10-fold, suggesting that radicals arising from one mitochondrion can imperil neighboring organelles.^{15–18,93} It bears reiteration that accelerated radical production after hydroxyl radical exposure was detected in the presence of excess catalase, implicating an alternative source for these radicals, such as mitochondrial peroxynitrite, and not H_2O_2 .⁹³

In contrast to the potentiation of MPT induced by radical exposure, high ATP-to-ADP ratios, and even the mere presence of adenylates, serve to protect against Ca^{2+} -mediated induction of MPT.^{94,95} Indeed, mitochondria exposed to physiologically relevant concentrations (mmol L^{-1}) of ATP tolerate eightfold higher Ca^{2+} concentrations before undergoing MPT. As such, susceptibility to MPT results from an equilibrium between oxidative and energetic factors, suggesting that slightly shifting this equilibrium might be a more readily attainable therapeutic goal than complete MPT blockade, which may have undesirable consequences from the standpoint of adenylate exchange or $\Delta\psi_m$ regulation. Not unexpectedly, given the declines in mitochondrial function and corresponding increases in oxidative markers associated with normal aging, mitochondria in tissues from aged animals show increased susceptibility to MPT.^{96,97}

2.27.3 Mitoprotective Drug Development

2.27.3.1 Mitochondrial Permeability Transition as Target

In acknowledgement of importance of mitochondrial integrity to cell viability, a number of drug development campaigns have been mounted to moderate MPT under pathogenic conditions such as acute Ca^{2+} loading. Using assays that monitor mitochondrial membrane potential, several groups have found molecules that inhibit MPT with varying potencies. For example, Fuks *et al.*⁹⁸ screened compounds against isolated liver mitochondria exposed to $200 \mu\text{mol L}^{-1}$ Ca^{2+} and reported that 5-(benzylsulfonyl)-4-bromo-2-methyl(2H)-pyridazine (BBMP) moderates MPT with comparable sub- $\mu\text{mol L}^{-1}$ potency as minocycline,⁹⁹ and only somewhat less efficiently as cyclosporine A (Figure 5).

Figure 5 Several molecules that moderate mitochondrial permeability transition in isolated liver mitochondria upon exposure to $200 \mu\text{mol L}^{-1}$ Ca^{2+} .

Figure 6 Screening of >1000 marketed drugs reveals that many *N*-substituted phenothiazine or dibenzazepine analogs moderate permeability transition in isolated mitochondria exposed to $100\ \mu\text{mol L}^{-1}\ \text{Ca}^{2+}$.

Figure 7 Heterocyclic and tricyclic motifs were also reported as potent mitochondrial permeability transition inhibitors by Hoffmann-La Roche. Ro-68-3400 is almost as potent an inhibitor of MPT as cyclosporine A ($\text{IC}_{50} \sim 0.5\ \mu\text{mol L}^{-1}$).

Similar screening strategies have yielded classes of molecules that are likely amenable to further chemical refinement. For example, Stavrovskaya *et al.*¹⁰⁰ screened >1000 FDA-approved pharmaceuticals against MPT in liver mitochondria exposed to elevated $100\ \mu\text{mol L}^{-1}\ \text{Ca}^{2+}$. A series of >25 heterocycles, marketed for a host of clinical indications, were shown to be effective MPT blockers (Figure 6). Interestingly, many are *N*-substituted phenothiazine or dibenz(b,f)azepine analogs. Most of these molecules were optimized and marketed for behavioral indications, not mitochondrial stabilization, which suggests that there is ample opportunity to refine these basic structures toward more potent MPT inhibition. Moreover, the structural similarities of these MPT inhibitors to inhibitors of the multidrug resistance transporter may be of some interest.¹⁰¹ Among the most potent MPT inhibitors from this screen are those shown in Figure 6.¹⁰⁰

This heterocyclic and tricyclic motif also emerged from Hoffmann-La Roche who screened against MPT (swelling) in liver mitochondria during a $40\text{--}80\ \mu\text{mol L}^{-1}\ \text{Ca}^{2+}$ challenge.¹⁰² Several MPT inhibitors were found (Figure 7), and one, Ro-68-3400, has activity comparable to cyclosporine A ($\text{IC}_{50} \sim 0.5\ \mu\text{mol L}^{-1}$). This group used Ro-68-3400 and protein cross-linking techniques to identify the binding partner as the 32 kDa isoform 1 of the VDAC, which had previously been associated ‘megapore’ formation.⁸⁷

2.27.3.2 Caveats

The notion that MPT is a viable drug development target for a host of diseases is not new, but its acceptance as a viable strategy has been championed primarily by specialists.^{15,16,103,104} There are important caveats. For example, bongkreikic acid, or exposure to uncouplers such as *p*-trifluoromethoxy carbonyl cyanide phenyl hydrazone (FCCP) to moderate Ca^{2+} uptake during excitotoxicity, correspondingly moderate mitochondrial dysfunction and cell death in the short term.^{105,106} However, by preventing mitochondrial adenylate exchange, and by uncoupling OxPhos, respectively, both strategies are cytotoxic in the long run. As a result, screening programs based on improving binding affinities for potential ligands to ANT, VDAC, or any of the other components of MPT may yield potent MPT inhibitors, but in so doing may also undermine normal mitochondrial function such as ATP–ADP exchange with the cytosol.

2.27.3.3 Novel Steroids with a Novel Mechanism

In acknowledgement of the above, several successful drug development strategies have focused less on specific protein interactions to moderate MPT, and more on assays that report mitochondrial function. For example, by following mitochondrial membrane potential during acute Ca^{2+} load, a variety of steroid analogs known to be cytoprotectants were shown to be mitoprotectants (Figure 8).^{54,55,107–109} Structure–activity relationship (SAR) studies with these molecules indicate that the A-ring phenol is the sine qua non for mito- and cytoprotection, and that planarity of the steroid ring structure, lipophilicity, and extended resonance all increase potency.¹¹⁰ Conversely, substitutions at the 17' position are relatively innocuous, separating drug development from hormonal activities.^{109,111} The current mechanistic model, supported by cell-based studies of glutathione (GSH) turnover and cytoprotection, as well as by in vitro rotational-echo double-resonance nuclear magnetic resonance (REDOR NMR) and lipid peroxidation studies,^{55,111} indicates that these molecules preserve mitochondrial integrity by preserving the impermeability of the inner membrane during pathogenic conditions, such as oxidative stress and excess Ca^{2+} loading.⁵⁵ They do not moderate Ca^{2+} uptake, but rather serve as catalysts to allow the reducing potential of mitochondrial GSH to terminate and repair lipid peroxidation that leads to membrane failure and MPT.^{54,55} Because the mitochondrial GSH pool is metabolically maintained at extraordinarily high concentrations ($8\text{--}10\text{ mmol L}^{-1}$), the steroids can catalytically forestall lipid peroxidation at low nanomolar concentrations.

Figure 8 A-ring phenolic steroid analogs moderate mitochondrial collapse in response to Ca^{2+} and oxidative stress. Hormonal response of 17β-estradiol is reduced several hundred-fold by reversing chirality at the 17' position to yield 17α-estradiol, while increasing lipophilicity via adamantyl addition increases potency. Planarity of the steroid is essential for cytoprotection.

Figure 9 The antioxidant flavanoid caffeic acid phenethyl ester (CAPE) slows Ca^{2+} -induced cytochrome *c* release from isolated liver mitochondria, and provides neuroprotection in the 6-OH-dopamine model of Parkinson's disease.

Figure 10 Celastrol, a planar quinone methide triterpene, inhibits mitochondrial membrane peroxidation with $\text{IC}_{50} \sim 7 \mu\text{mol L}^{-1}$. In vivo, this molecule significantly protects dopaminergic neurons from the C-I inhibitor MPTP, but also striatal neurons from the mitochondrial C-II inhibitor 3-nitropropionic acid, suggesting utility for both Parkinson's and Huntington's diseases.

2.27.3.4 Other molecules

Another recent report finds that the antioxidant flavanoid caffeic acid phenethyl ester (CAPE), derived from honey bee propolis, has antiviral, antiinflammatory, antioxidant, and immunomodulatory properties (Figure 9).¹¹² It has provided neuroprotection against ischemia and low potassium-induced apoptosis, and it has shown neuroprotection in the 6-OH-dopamine model of Parkinson's disease.¹¹² In isolated liver mitochondria, CAPE slowed Ca^{2+} -induced cytochrome *c* release, suggesting clinical utility for Parkinson's disease and perhaps other neurodegenerative diseases.¹¹² Although a mitochondrial mechanism has not been elucidated, the extended resonance and several redox-reactive moieties might encourage examination of its interactions with GSH similar to those that are responsible for mitochondrial stabilization by the phenolic steroids.^{54,55}

Other polycycles similar to the A-ring phenolic steroids have shown similar cytoprotective effects in comparable mitochondrial assays. For example, celastrol (Figure 10), a quinone methide triterpene extracted from a member of the Celastraceae (e.g., staff tree and bittersweet), forestalls proinflammatory cytokine production, reduces inducible NO synthase (iNOS) expression, represses lipid peroxidation, and is a highly specific activator of heat shock transcription factor 1.^{113,114} Importantly, celastrol has an $\text{IC}_{50} \sim 7 \mu\text{mol L}^{-1}$ as an inhibitor of mitochondrial membrane peroxidation, which is some 15-fold more potent than α -tocopherol in this assay.¹¹⁵ The mechanistic model proposes that the dienonephenol moiety moderates peroxidation by direct radical scavenging, while the anionic carboxyl repulses negatively charged oxygen radicals at the surface of the membrane.¹¹⁶ In vivo, this molecule significantly protects not only dopaminergic neurons in the substantia nigra pars compacta from the C-I inhibitor 1-methyl-4-phenyl-1,2,3,6-tetra-hydropyridine (MPTP), indicating utility for Parkinson's disease, but also striatal neurons from the mitochondrial C-II inhibitor 3-nitropropionic acid, suggesting utility for HD.¹¹³ Its induction of heat shock protein 70, coupled with decreased tumor necrosis factor- α and nuclear factor kappa B (NF κ B) immunostaining, further recommend this class of molecules as potential mitotherapeutics.¹¹⁴

2.27.4 Mitochondrial Radical Production

2.27.4.1 Biology and Sites of Production

Free radicals are produced by the mitochondrial ETS in direct proportion to concentration of the reactants, i.e., reduced ETS components, and availability of O_2 .¹¹⁷ This mass action relationship was succinctly expressed by Turrens *et al.*¹¹⁸ as:

$$\frac{d[\text{O}_2]}{dt} = k[\text{O}_2][R\cdot]$$

Mitochondrial radical production is induced not only by Ca^{2+} loading, and/or by transient ischemia in aerobically poised cells such as myocardial myocytes and neurons, but also by tumor necrosis factor- α .^{15–18,83,119}

Although redox reactions within the normally functioning ETS occur via paired electron transfers, orbital spin restrictions dictate that O_2 reduction proceed univalently, the first product of which is superoxide anion ($\text{O}_2\cdot^-$) (reaction 1).³ Superoxide either spontaneously or enzymatically (via superoxide dismutases) dismutates into peroxide, which is not a radical but is capable of diffusing long distances and through membranes.³ In the presence of reduced transition metals, which abound in biological systems, peroxide can undergo Fenton chemistry to yield hydroxyl radical, the most reactive, and hence injurious, radical in biology.³

1. $\text{O}_2 + e \rightarrow \text{O}_2\cdot^-$ superoxide radical
2. $\text{O}_2\cdot^- + 2\text{H}^+ \rightarrow \text{H}_2\text{O}_2$ hydrogen peroxide
3. $\text{H}_2\text{O}_2 + \text{Fe}^{2+} \rightarrow \text{Fe}^{3+} + \text{OH}^- + \cdot\text{OH}$ hydroxyl radical

Most studies of mitochondrial $\text{O}_2\cdot^-$ and H_2O_2 production assess the effect of various inhibitors of electron transfer based on the reasoning that ‘downstream’ blockade will increase the number of ‘upstream’ carriers in the reduced state, and correspondingly increase the probability of their undergoing autoxidation and redox cycling. For example, by using rotenone and antimycin A, inhibitors of electron transfer that block electron transfer between ubiquinone (coenzyme Q) and cytochrome *b*, and between cytochrome *b* and *c*1, respectively, it was shown that NADH-CoQ reductase (C-I) and ubiquinone were the two most likely sources for radical production.^{69,81}

C-II has also been implicated as a radical generator, especially in the presence of mutation in one of the four constituent proteins.¹²⁰ However, it seems likely that such radical efflux is mediated by ubisemiquinone autoxidation rather than redox cycling of prosthetic groups within the protein. Moreover, production of oxyradicals from this region of the respiratory system is exacerbated by numerous pathologically relevant perturbations, such as transient hypoxia, exposure to $\text{O}_2\cdot^-$ or $\cdot\text{OH}$, and increases in mitochondrial Ca^{2+} . Of course, the toxicity of superoxide production is exacerbated by adventitious transition metals within the mitochondria, which certainly contributes to the etiology of Friedreich’s ataxia.^{21,121,122} As an aside, mitochondrial dysfunction is often assessed by monitoring H_2O_2 efflux from isolated organelles. Although this provides a reflection of superoxide production from ETS, it does not report oxidative damage occurring to ETS components or the membranes. For example, membrane lipid peroxidation is initiated by $\cdot\text{OH}$ generated via Fenton chemistry from H_2O_2 .³ As such, assessments of H_2O_2 efflux from mitochondria report only that fraction of H_2O_2 that did not initiate peroxidation, with no accounting for H_2O_2 that did. This may be an important caveat in the evaluation of compounds that moderate lipid peroxidation, such as the phenolic steroids.

2.27.5 Mitochondrial Diversity

2.27.5.1 Biology

Dogma holds that ‘all mitochondria are the same’ and hence do not provide the tissue- or disease-specificity that encourages modern drug development programs. However, mitochondria in neuronal subtypes collapse when confronted with Ca^{2+} transients normally occurring during cyclical myocardial depolarizations, which provides a priori evidence that ‘not all mitochondria are the same.’

2.27.5.2 Electron Paramagnetic Resonance Studies

A growing literature is now documenting such functional differences between mitochondria from different tissues, and even between neuronal subtypes. For example, electron paramagnetic resonance spin-trap data show that conditions that elicit copious free radical production from isolated, respiring cerebral cortical mitochondria^{15–18} fail to do so in mitochondria identically isolated from rat liver (Figure 11). This finding was recapitulated using mitochondria isolated simultaneously from brain and liver from the same animal (Figure 12). Upon addition of Ca^{2+} and Na^+ as before, a robust electron paramagnetic resonance signal is obtained from the cortical mitochondria (Figure 11a), but not liver mitochondria (Figure 11b).

By increasing the biomass of liver mitochondria within the electron paramagnetic resonance magnet (Figure 11b), the 10 G electron paramagnetic resonance signal from the membrane-bound semiquinone in ETS becomes apparent as a centerfield asymmetry. This signal is so readily visible not only because the mitochondrial density in the liver isolates

Figure 11 Electron paramagnetic resonance (EPR) spin-trap radical signals are barely visible from normoxic mitochondria isolated from rat liver exposed to $2.5 \mu\text{mol L}^{-1} \text{Ca}^{2+}$ and $14 \text{ mmol L}^{-1} \text{Na}^{+}$ (a). Increasing the biomass of mitochondria in the sample reveals the membrane bound semiquinone radical as a center field asymmetry, but no substantial increase in spin-trap adducts (b). Mitochondria are suspended in $100 \text{ mmol L}^{-1} \text{KCl}$ containing $50 \text{ mmol L}^{-1} \text{KH}_2\text{PO}_4$, 10 mmol L^{-1} succinate, and $10 \text{ mmol L}^{-1} \text{ADP}$, and held in an oxygen-permeable Teflon tube with O_2 passing through the chamber thereby maintaining normoxia.^{15–18}

Figure 12 Differences between mitochondrial responses from different tissues are readily shown using mitochondria simultaneously isolated from the brain and liver of the same animal. Exposure to $2.5 \mu\text{mol L}^{-1} \text{Ca}^{2+}$ and $14 \text{ mmol L}^{-1} \text{Na}^{+}$ elicits robust POBN spin-trap signals from cerebral (a), but not liver (b), mitochondria. The POBN hyperfine splitting values of the signal from cerebral mitochondria range from $a_N = 15.2$ to 15.9 G and $a_H = 2.4$ to 3.0 G , indicative of a mixture of several radical species. Identical EPR experiments using DMPO instead of POBN reveal production of both OH and carbon-centered radicals, so that the most likely explanation is that the observed POBN signals arise from a mixture of hydroxyl radical adducts ($a_N = 14.96 \text{ G}$, $a_H = 1.68 \text{ G}$) plus a variety of short chain carbon-centered radicals with larger splitting constants, and not solely lipid peroxy radicals ($a_N = 15.8 \text{ G}$, $a_H = 2.6 \text{ G}$ for lipid peroxy in aqueous media).^{15–18}

it severalfold higher than in the brain samples, but also because the semiquinone is apparently not autooxidizing to yield spin-trappable radicals, as is the case from brain mitochondria. To some extent, the ability of liver mitochondria to tolerate Ca^{2+} as shown here artifactually results from a lower absolute Ca^{2+} concentration relative to the mitochondrial biomass; a full dose response of Ca^{2+} using identical mitochondrial density from brain versus liver would resolve this issue.

A parsimonious explanation of this difference is that mitochondrial antioxidant activities are higher in the liver compared to the brain, and this is indeed the case: Mn superoxide dismutase (MnSOD) activity in isolated liver mitochondria is threefold higher ($149.9 \text{ U mg}^{-1} \text{ protein} + 20.1 \text{ SE}$, $n = 4$) than those in brain ($40.8 + 7.1 \text{ SE}$, $n = 5$, $P < 0.001$) (Dykens, unpublished data). Clearly the antioxidant side of the oxidative equilibrium is only part of the equation. Nevertheless, these tissue differences in mitochondrial antioxidants and radical production, combined with the cytosolic paucity of both catalase and total SOD activity in brain ($107.4 \text{ U mg}^{-1} \text{ protein} + 8.6 \text{ SE}$, $n = 4$) versus liver ($967.5 + 75.5 \text{ U mg}^{-1} \text{ SE}$, $n = 4$, $P < 0.001$) (Dykens, unpublished) may help explain why the CNS is the primary site of pathology in a host of neurodegenerative disorders, such as Parkinson's disease, where comparable mitochondrial defects are seen in both CNS and systemic tissues.⁷⁸

Figure 13 Parasite-specific respiratory systems offer potential targets for chemotherapy for trypanosome diseases such as African sleeping sickness, and Ascarial infection. Screening for inhibitors of parasite mitochondrial reductases has yielded nafuridin, a specific inhibitor of nematode complex I.

These electron paramagnetic resonance data also highlight diversity in the amount of Ca^{2+} tolerated by mitochondria from different tissues. Data directly addressing this point have been published by Kushnareva *et al.*,⁸³ who report that Ca^{2+} uptake capacity by mitochondria isolated from cerebral cortex is substantially lower compared to those isolated from cerebellar cortical neurons.⁸³ The justified inference is that the varying susceptibility among different neuronal subpopulations to a host of pathogenic stimuli is largely determined by mitochondrial constraints. The evidence indicates that, analogous to cellular differentiation, mitochondria contain a constitutive complement of proteins and other molecules required for the basic functions of replication, signaling, and OxPhos, but that there are subtle differences between tissues, and even between cellular subpopulations within a tissue, that could provide avenues for insightful drug development programs. Indeed, just this approach has been used to target selectively parasite mitochondrial pathways, while avoiding host mitochondria, in several diseases, and has led to compounds like nafuridin, a selective inhibitor of helminth C-I (Figure 13).¹²³

2.27.6 Mitochondrial Drug Targeting

2.27.6.1 Membrane Potential

In a variation on the theme that mitochondria differ in different cell types, it was noted years ago that mitochondria within many tumor cells maintain $\Delta\psi_m$ 10–15 mV greater than surrounding, normal tissues,¹²⁴ and that this difference could be used to target tumor mitochondria selectively.¹²⁵ Trapp and Horobin report that the characteristics of molecules most likely to be taken up selectively by tumor mitochondria are polar acids with pK_a between 5 and 9, because of ion-trapping, lipophilic bases with $\text{pK}_a > 11$ or permanent cations, because of electrical attraction, and monovalent cations or strong bases with $\log K$ (octanol–water) between –2 and 2, with an optimum near 0.¹²⁶

Several groups have followed this line of reasoning to design cationic drug delivery systems to target selectively cytoprotective or toxic molecules to mitochondria, a strategy that is likely also adaptable for gene therapy in mtDNA diseases.^{127,128} Indeed, because of the Nernst equation, a monovalent cationic carrier is predicted to accumulate in the mitochondrial matrix a thousandfold over the cytoplasm, a factor that is raised another three orders of magnitude simply by using a divalent cation.¹²⁸ This strategy was tested by linking simple alkyltriphenylphosphonium cation with coenzyme Q and vitamin E derivatives.¹²⁹ It was found that mitochondrial accumulation of the antioxidants conferred significantly more cytoprotection against oxidative insult compared to the untargeted compounds. However, this same group also evaluated mitochondrially targeted free radical scavengers 4-hydroxy-2,2,6,6-tetramethylpiperidin-*N*-oxide (TEMPOL) and Salen-Mn(III) complex of *o*-vanillin and found that, although treatment delayed apoptosis after an exogenous oxidative insult, neither of the mito-targeted agents was any more effective than the untargeted compounds.¹³⁰

A similar mito-targeting strategy was used to develop a selective antitumor compound, the rhodacyanine dye MKT-077 (Figure 14), which was evaluated in a phase I clinical trial.¹³¹ They reported that, at toxicity, profile at the recommended dose was consistent with preferential accumulation of the agent within tumor cell mitochondria. Although MKT-077 was developed as a mitochondrial metabolic inhibitor, its exact mechanism was not well characterized at that time. Later, MKT-077 was found to have several nonmitochondrial effects, such as binding to mortalin (mot-2), an hsp70 family member, thereby preventing its interactions with p53.¹³² This group reports MKT-077 released wild-type p53 from cytoplasmically sequestered p53-mot-2 complexes which rescued its transcriptional activity in cancer cells, but not normal cells. This activity suggests utility against cancers with wild-type p53.¹³² Similar hsp binding was also reported by Tikoo *et al.*, who also found that MKT-077 directly binds actin and by cross-linking, prevents membrane ruffling.¹³³ Nevertheless, despite technical hurdles and ancillary nonmitochondrial activities of MKT-077, the notion of selectively accumulating a therapeutic agent 10^3 – 10^6 -fold higher within the mitochondria of tumor cells continues to be an attractive strategy for antitumor therapies, as well as possible mtDNA gene therapies.

Figure 14 The rhodacyanine dye MKT-077 was developed with an eye toward preferential accumulation of the agent within tumor cell mitochondria because of elevated membrane potential there.

Figure 15 The flavanoids 2',4'-dihydroxy-6'-methoxy-3',5'-dimethylchalcone (DMC), isolated from the buds of *Cleistocalyx operculatus*, induces mitochondrial instability and ensuing apoptosis in human leukemia K562 cells via a downregulation of Bcl-2.

2.27.7 Other Mitoactive Compounds

Flavanoids such as the chalcones have also shown a variety of cytotoxic, and depending on substitutions, cytoprotective responses that involve mitochondrial pathways. For example, 2',4'-dihydroxy-6'-methoxy-3',5'-dimethylchalcone (DMC; **Figure 15**), isolated from the buds of *Cleistocalyx operculatus*, induces mitochondrial instability and ensuing apoptosis in human leukemia K562 cells via a downregulation of Bcl-2.¹³⁴ These structures raise questions about redox reactivity and other mitochondrial mechanisms similar to those for the A-ring phenolic steroids, a suggestion reinforced by SAR data showing that rigidity, lipophilicity, and conformation of rings A and B are crucial for the cytotoxicity shown by novel chalcone-derived pyrazoles such as 3,5-diphenyl,1*H*-pyrazole.^{135,136}

In a similar vein, the bisphenol triclosan (2,4,4'-trichloro-2'-hydroxydiphenylether (TRN) **Figure 16**) is a synthetic, nonionic, broad-spectrum antibacterial, antifungal, and antiviral agent. It is widely used in hand soaps, skin care preparations, and mouthwashes:

TRN is a picomolar inhibitor of bacterial NADH-dependent enoyl-[acyl carrier protein] reductases and its homologs in several bacteria, and in *Plasmodium falciparum*, where it is a potent inhibitor of parasite development.¹³⁷ However, Newton *et al.* found that, at doses much lower than those generally used in commercial preparations, TRN uncouples OxPhos and induces mitochondrial depolarization.¹³⁷ They conclude that mitochondrial impairment is an unintended consequence of interfering with bacterial fatty acid metabolism that warrants further examination.

2.27.8 Electron Transport Components

2.27.8.1 Complex I (EC 1.6.5.3)

2.27.8.1.1 Biology

This is the entry point into ETS for most of the electrons from Krebs's cycle. It is first of three sites in ETS where redox transfer is coupled with translocation of protons, in this instance with a $4\text{H}^+ / 2\text{e}^-$ stoichiometry, to generate the membrane potential that drives ADP phosphorylation.⁵¹ C-I is a huge, 1000 kDa holoenzyme composed of >40 proteins, fully justifying the name 'complex.' It is a major site of free radical production from ETS, especially under hypoxic conditions when the ETS components are more completely reduced and thus more susceptible to redox cycling to yield superoxide or carbon-centered radicals.

2.27.8.1.2 Inhibitors

From a medicinal chemist's perspective, over 60 inhibitors of C-I have been described, including the rotenoids, such as rotenone and deguelin, which can induce apoptosis via oxidative pathways (**Figure 17**).^{138,139} There are a number of synthetic insecticides/acaricides with C-I as their target and they can be grouped into two main classes: (1) pyrazoles and substituted pyrimidines, and (2) pyridines and quinazolines.^{123,138} Prominent examples of these two classes are

Figure 16 The bisphenol triclosan 2,4,4'-trichloro-2'-hydroxydiphenylether is a synthetic, nonionic, broad-spectrum antibacterial, antifungal, and antiviral agent that induces mitochondrial depolarization. Such mitochondrial impairment may be an unintended consequence of interfering with bacterial fatty acid metabolism that warrants further examination.

Figure 17 Over 60 inhibitors of respiratory Complex I have been described including the rotenoids, such as rotenone and deguelin. A number of synthetic insecticides/acaricides have C-I as their target and can be grouped into two main classes: (i) pyrazoles and substituted pyrimidines, and (ii) pyridines and quinazolines. Prominent examples of these two classes are fenpyroximate and 2-decyl-4-quinazolinyl amine, respectively. Other C-1 inhibitors include annonaceous acetogenins rolliniastatin-1, rolliniastatin-2 [bullatacin], vanilloids (capsaicin), amylal, and MPP⁺.

fenpyroximate and 2-decyl-4-quinazolinyl amine (DQA: formerly known as SAN 548A), respectively. Further study has suggested that all hydrophobic or amphipathic C-I inhibitors occupy the ubiquinone-binding domain, which is formed by apposition of several subunits, notably ND2.¹⁴⁰ Other inhibitors include annonaceous acetogenins (rolliniastatin-1, rolliniastatin-2 (bullatacin), vanilloids (capsaicin), amylal, and 1-methyl-4-phenyl pyridinium salt (MPP⁺), that is used to generate an animal model of Parkinson's disease.¹³⁸

Although C-I has been considered resistant to inhibition via its NADH-binding domain, an NADH analog has shown potent ($K_i \sim 10 \text{ nmol L}^{-1}$) inhibition of C-I and other NADH reductases.¹⁴¹ This analog was generated via prolonged alkaline exposure under aerobic conditions. The mass and absorption spectroscopic studies suggest that the inhibitor is derived from attachment of two oxygen atoms to the nicotinamide moiety of NADH, with a tentative structure shown in Figure 18.¹⁴¹

Figure 18 Inhibition of C-1 via its NADH-binding domain is shown by this NADH analog.

2.27.8.1.3 Composition

Bovine myocardial C-I consists of 45–46 subunits, 6 tetranuclear and 2 binuclear [Fe-S] clusters, only some of which are electron paramagnetic resonance-visible, probably more than one ubiquinone-binding site, and noncovalently bound flavin adenine nucleotide.⁵¹ Of these 46 polypeptides, seven are encoded by the mtDNA. Fourteen subunits are essential for catalysis, with the remainder likely involved in regulation, assembly, and maintenance of its quaternary structure.^{142–144} This is not ubiquitously the case in that *S. cerevisiae* lacks C-I, substituting a single polypeptide NADH-ubiquinone oxidoreductase lacking [Fe-S] centers but having an FAD cofactor.¹⁴⁴ Plants and fungi show much heterogeneity in that both the simpler oxidoreductase and the rotenone-sensitive form coexist in some species. Similarly, bacteria contain one of three different forms that catalyze electron transfer between NADH and a membrane-bound quinol, and these are variously inhibited by Ag^+ , 2-*n*-heptyl-4-hydroxyquinoline-*N*-oxide (HQNO), and by the antibiotic korormicin.^{51,145} This diversity of proteins and posttranslational modifications, and corresponding diversity of inhibitors, may offer an opportunity to develop selective fungal, plant, insect, or mammalian inhibitors of electron entry into ETS.¹⁴⁶

Single-particle electron microscopy studies in several species, including the filamentous fungus *Neurospora crassa* and aerobic yeast *Yarrowia*, have revealed two major structural components that form an L-shape quaternary structure, with a hydrophobic membrane-bound leg containing all seven mitochondrially encoded proteins, and a more hydrophilic peripheral leg that faces the matrix containing all the nuclear-encoded proteins, all the redox active centers, and the ubiquinone-binding domain.^{51,140}

2.27.8.1.4 Catalysis

C-I function has been difficult to parse, primarily because of a lack of crystal structure data and inaccessibility of some of the catalytic domains to electron paramagnetic resonance. Nevertheless, the electron transfer route has been generally established as starting from flavin adenine nucleotide and traversing all eight [Fe-S] clusters, ending at N2. Several models of the mechanism responsible for proton pumping have been proposed, but are essentially of two constructs: direct transfer of RedOx energy into a coupled vectorial proton translocation, and an indirect mechanism where such energy imposes a conformational change, resulting in proton translocation.¹⁴⁰ The latter seems more reasonable, and is supported by several lines of evidence.¹⁴⁰

Given that the ‘catalytic core’ of 14 proteins in bacteria can competently catalyze the redox and proton translocation reactions, the function of the remaining 31+ ‘accessory proteins’ in mammalian and other species remains an area of active investigation.⁵¹ Several of these proteins have enzymic activities quite separate from C-I function. For example, sequence homology places the 39 kDa subunit into the reductase isomerase family, while others are related to acyl carrier proteins involved with fatty acid anabolism.⁵¹ Mutations in the latter quadrupled the phospholipid content of mitochondrial membranes, but also impaired C-I assembly in *N. crassa*.¹⁴⁷ Likewise, subunit B16.6 is highly homologous to GRIM19, a nuclear gene product involved in interferon/retinoic acid-induced apoptosis. Homologous deletion of GRIM19 is embryonic lethal, and it is required for proper assembly of C-I, thus providing yet another direct connection

between ETS, mitochondrial function, and apoptotic pathways.¹⁴⁸ Of course, many of these proteins could also be serving a secondary service of simply insulating the reactive redox centers from interactions with bulk fluids in the matrix, thereby ensuring regulated and uninterrupted electron flow.

2.27.8.1.5 Pathogenesis

The association with C-I defects in human disease is striking, clearly defined, and presents numerous opportunities for pharmaceutical intervention. Indeed, as Nitjman points out,⁵¹ defects in C-I are the most frequently encountered of the human mitochondrialopathies. Mutations in mtDNA-encoded ND4 are responsible for Leber's hereditary optic neuropathy (LHON), while mutations in the remaining mtDNA-encoded C-I subunits are associated with Leigh syndrome, MELAS, and a host of other syndromes. Although many of the defects that yield a phenotype are in subunits that contain a redox prosthetic group, some are also found in the assembly proteins, as is the case for C-IV.⁵¹

C-I activity is elevated in familial ALS patients,¹⁴⁹ yet it is diminished in Parkinson's disease patients, to some extent as a consequence of oxidative inactivation.^{15,144,150} Rotenone exposure induces a Parkinson's syndrome, and the C-I inhibitor MPTP was found to be the cause of a drug-induced Parkinson's syndrome.¹⁵¹ Indeed, depending on dose and route of administration, MPTP and rotenone selectively lesion the dopaminergic neurons of the substantia nigra pars compacta, the same cells that are at risk in Parkinson's disease. Animal models showing dyskinesia and dementia characteristic of Parkinson's disease are generated by various dosing regimes of MPTP and rotenone.^{113,152} The gene *DJ-1* is linked epidemiologically to sporadic Parkinson's disease in humans, and in *Drosophila* deletion of the two orthologs of *DJ-1* renders them exceptionally susceptible to C-I inhibition by rotenone, and to oxidative stress induced by paraquat or H₂O₂.¹⁵³ As noted above, mitochondrial stabilizers will likely provide therapeutic benefit in Parkinson's disease.^{113,154}

2.27.8.1.6 Drug development

Rasagiline (*N*-propargyl-1*R*-aminoindane) is a potent, irreversible inhibitor of monoamine oxidase (MAO) B used as treatment of Parkinson's disease. Unlike selegiline, it is not metabolized to a neurotoxic methamphetamine analog (Figure 19).^{155,156} Importantly, the *S*-isomer of rasagiline is substantially inactive as an MAO inhibitor, yet shows comparable neuroprotection in both cell culture and in *in vivo* models of neurotoxicity such as anoxia and excitotoxicity.¹⁵⁶ SAR studies have shown that neuroprotection is afforded by mitochondrial protection, and is due to the propargyl group. For example, *N*-propargylamine prevented apoptosis of SH-SY5Y cells induced by the dopaminergic neurotoxin *N*-methyl(*R*)salsolinol, whereas *N*-methylpropargylamine and propionaldehyde did not.¹⁵⁷ Such cytoprotection was via stabilization of mitochondrial membrane potential, as well as induction of antiapoptotic Bcl-2, and it occurred at concentrations substantially lower than those required for MAO inhibition.^{155,158}

Figure 19 Rasagiline (*N*-propargyl-1*R*-aminoindane) is a potent, irreversible inhibitor of monoamine oxidase (MAO) B used as treatment of PD. Unlike selegiline, it is not metabolized to a neurotoxic methamphetamine analog. SAR studies have shown that neuroprotection is afforded by mitochondrial protection, and is due to the propargyl group.

Figure 20 Addition of carbamate or morpholino moieties (VK-28) to repress Fenton chemistry to the methylpropargylamine core, increases cytoprotective potency. M-30 has both antioxidant and MAO inhibition activities.

Further modifications to the methylpropargylamine core, such as addition of carbamate or morpholino moieties to chelate iron and thus repress Fenton chemistry, increase potency in cytoprotection assays and in in vivo models of Parkinson's disease, such as 6-OH-dopamine (Figure 20).¹⁵⁹ Evaluation of additional compounds that ligand VK-28, a morpholino chelator that is able to cross the blood–brain barrier, to several MAO inhibitors show that some, like M-30, have both antioxidant activity and MAO inhibition, whereas others, like M-32, show potent antioxidant activity with no MAO effects (Figure 20).^{156,158} It is interesting to note again the phenolic heterocycle, which has been identified with cytoprotective activities of nonhormonal estradiol-derived steroids.

2.27.8.2 Complex II (EC 1.3.5.1)

2.27.8.2.1 Biology

C-II (succinate-ubiquinone oxidoreductase) is the only membrane-bound component of the Krebs's cycle, and it consists of only four nuclear-encoded polypeptides containing, in mammals, a heme b_{558} , three linearly aligned [Fe-S] clusters, and a covalently bound FAD.⁵¹ It is not a site of proton pumping, but mutations and dysfunction in C-II have become an active area of investigation.¹⁶⁰

2.27.8.2.2 Composition

Subunits A and B are within the matrix and are anchored to the inner mitochondrial membrane by subunits C and D that each have three membrane-spanning domains.⁵¹ Subunit A contains the FAD flavoprotein, while subunit B contains the three [Fe-S] clusters. When released from the membrane, A and B show succinate dehydrogenase (DH) activity when provided with an exogenous electron acceptor. The two membrane-binding proteins contain ubiquinone-binding sites, thereby effectively coupling matrix oxidations to membrane-bound ubiquinone reduction. C-II from various phyla can be parsed on the basis of the number of hydrophobic units and heme contents, with the mammalian subunits C and D both containing heme and ubiquinone-binding domains.⁵¹

The crystal structure of C-II at 0.24 nm resolution has been published,¹²⁰ which has fostered important insights. For example, the classical catalytic pathway proposed electrons sequentially traversing FAD, [2Fe-2S], [4Fe-4S], [3Fe-4S], heme b_{558} to ubiquinone. However, analysis of the edge-to-edge distances suggest that direct ubiquinone reduction by [3Fe-4S] is more likely than via heme b_{558} reduction, despite the predictions of midpoint-reducing potentials.¹²⁰ Further, binding of the inhibitor 3-nitropionate at the succinate site, and binding of 2-thenoyltrifluoroacetone (TTFA), has more clearly revealed the contralateral membrane positions of the two ubiquinone-binding sites.¹²⁰

2.27.8.2.3 Inhibitors

While screening soil fungi extracts for ascaris NADH-fumarate reductase inhibitors, Miyadera *et al.* identified harzianopyridone (Figure 21), a highly selective C-II inhibitor with some 1600 fold greater potency than TTFA, with antifungal, antibacterial, and herbicidal activities.¹⁶¹ Interestingly, this molecule, and even more potent aptenin analogs A4 and A5 (Figure 21), more effectively inhibit bovine than ascarid C-II. Given the structures, it is not surprising that inhibition appears to be by binding to a site that partially overlaps with the physiological ubiquinone-binding site(s). These molecules show nmol L^{-1} IC_{50} values, yet are unable to inhibit completely C-II activity, even at $10 \mu\text{mol L}^{-1}$, supporting the notion of incomplete occlusion of the ubiquinone-binding site(s). Also of interest is that, despite their potent inhibition of C-II, neither A4 nor A5 inhibits C-III, suggesting that these molecules are not simply competitively occupying ubiquinone-binding domains, but rather are interacting with ancillary components peripheral to the ubiquinone-binding site.¹⁶¹

Figure 21 Harzianopyridone is a highly selective C-II inhibitor with antifungal, antibacterial, and herbicidal activities. Atpenin analogs A4 and A5 more effectively inhibit bovine than ascarid C-II. Given the structures, it is not surprising that inhibition appears to be via binding to a site that partially overlaps with the physiological ubiquinone-binding site(s).

2.27.8.2.4 Pathology

Over 20 nuclear mutations in C-II subunits have been linked to human disease.¹²⁰ Mutations in subunit A that impede succinate interactions with its binding site result in reduced C-II activity, and cause the neurological disease Leigh syndrome, an early-onset neurodegenerative disease characterized by ataxia, dystonia, blindness, and deafness, among other classical mitochondrial symptoms. Mutations in the B, C, and D subunits are all associated with familial paragangliomas and pheochromocytomas, typically in neural crest-derived tissues of the neck and head.^{51,162} Some of these substitution mutations keep the redox centers intact, but greatly exacerbate free radical production, presumably by impeding ubiquinone binding and/or by exposing the flavin or [Fe-S] centers to ambient O₂. Physiologically, mutations leading to C-II impairment are the functional equivalent of chronic hypoxia (increased reliance on pyruvate/lactate), where ETS would preferentially rely on pyruvate as substrate rather than succinate, suggesting a role of heme *b*₅₅₈ in O₂ sensing.¹⁶² Regardless, this direct connection between cancer and mutations in mitochondrial proteins has reinvigorated the examination of likely links between mitochondrial dysfunction and tumorigenesis.

2.27.8.2.5 Huntington's Disease Model

In rodents and primates, the C-II inhibitor 3-nitropropionic acid (3-NP) produces the principal features of HD, including degeneration of striatal medium-sized spiny GABAergic neurons, abnormal movements, and cognitive deficits.^{163,164} 3-NP induces mitochondrial dysfunction, accelerates both free radical production and release of proinflammatory cytokines, and induces gliosis.¹¹³

2.27.8.3 Ubiquinone (Coenzyme Q, Q₁₀)

2.27.8.3.1 Biology

Ubiquinone is a parabenzoquinone with methoxy groups on carbons 2 and 3 and a methyl group on carbon 5, plus a polyisoprene chain the length of which varies among species (Figure 22). Almost 80% of the CoQ₁₀ in the cell is within the inner mitochondrial membrane, with the remainder widely distributed in other cellular membranes.⁵¹ Ubiquinone serves as the electron shuttle between C-I and C-II to C-III. It typically undergoes two reductions to form the ubiquinol via a single electron reduction to the radical semiquinone, autooxidation of which is believed to be a major source of superoxide production from ETS.^{3,15–18} It is found in various forms in all living organisms, although the length of the acyl chain varies among groups, with rodents and other mammals having 6–10 isoprenoids that confine the molecule to the most lipophilic interior membrane domains.

In the reduced form, ubiquinol serves as an antioxidant by reducing lipid peroxyls to form the more stable semiquinone, which in turn is reduced by ETS.^{3,51} The quinol can also reduce the vitamin E radical, tocopheroxyl, to allow continued redox cycling of the vitamin. Vitamin E is likely the more important of the two in terms of maintaining the impermeability of the inner mitochondrial membrane,¹⁶⁵ but, unlike the vitamin, ubiquinone is synthesized within cells and is obviously also serving as a key component in ETS.

Figure 22 Idebenone, a synthetic ubiquinone (CoQ₁₀) analog provides cardioprotective effects in Friedreich's ataxia patients, although its inability to cross the blood–brain barrier prevented beneficial effects in the CNS. It has shown therapeutic promise in Parkinson's disease.

2.27.8.3.2 Pathology

A number of pathologies are associated with CoQ₁₀ deficiency, as outlined in the most recent review of mitochondrial encephalomyopathies in the ongoing series from the *Journal of Neuromuscular Disorders*.²⁵ For example, many of the clinical phenotypes entail myopathies with an associated CNS involvement, including seizures, ataxia, or mental retardation. Muscle biopsies often show ragged red fibers and lipid storage, and such patients often respond well to oral CoQ₁₀ supplementation. On the other hand, a more common presentation is childhood-onset cerebellar ataxia, inconsistently accompanied by seizures, weakness, mental retardation, pyramidal signs, and peripheral neuropathy. Muscle biopsy in this group of patients can appear normal, and although ataxic patients also respond to CoQ₁₀ supplementation, they improve less dramatically and less consistently than 'myopathic' patients.^{25,75} CoQ₁₀ deficiency is also associated with a severe, potentially fatal, encephalomyopathy of infancy, associated with renal disease, where CoQ₁₀ supplementation can be lifesaving.²⁵

2.27.8.3.3 Drug development

Tissue distribution of oral CoQ₁₀ is skewed toward liver and away from brain or skeletal muscle,¹⁶⁶ but clinical trials of high-dose CoQ₁₀ for Parkinson's disease have already shown some benefit,¹⁶⁷ and such treatment may well provide benefit in other neurodegenerative diseases with a mitochondrial etiology.^{18,73,74} Indeed, CoQ₂₀ was approved in Japan in 1974 as an adjunct therapy for congestive heart failure, and clinical trials have demonstrated improvement in cardiovascular performance.¹⁶⁸ Similarly, idebenone, a synthetic CoQ₁₀ analog (Figure 22), affords cardioprotective effects in Friedreich's ataxia patients,¹⁶⁹ although its inability to cross the blood–brain barrier precluded effects on the CNS deterioration in this disease.¹⁷⁰

Mevalonic acid is an obligatory intermediate in the synthesis of CoQ₁₀, and the cholesterol-lowering 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) target the synthesis of mevalonate, which raises the question of whether the iatrogenic condition of statin myopathy may be due to coincident CoQ₁₀ depletion.^{122,171,172} In one clinical trial to address this issue, 48 patients with hypercholesterolemia were randomly assigned to receive simvastatin, atorvastatin, or placebo for 8 weeks.¹⁷³ Although markers of endogenous cholesterol synthesis decreased in both statin groups, muscle ubiquinone concentration was significantly reduced by simvastatin, but not by atorvastatin or placebo. Respiratory enzyme and citrate synthase activities were assessed in a subset of patients with depressed ETS function associated with simvastatin treatment, leading to the conclusion that some high-dose statins may secondarily affect mitochondrial function.¹⁷³ Finally, although the possibility exists, the clinical data do not yet show that statin therapy, with an unintended consequence of lowering CoQ₁₀ levels, worsens Parkinson's disease.¹⁷⁴

2.27.8.4 Complex III (EC 1.10.2.2)

2.27.8.4.1 Biology and composition

C-III (ubiquinol:cytochrome *c* oxidoreductase; cytochrome *b*_c₁ complex) is the second site of ETS where the free energy of ETS redox reactions is converted into the proton gradient that drives phosphorylation of ADP. The holoenzyme is composed of 11 proteins, described by their electrophoretic mobility, of which only subunit III is encoded by mtDNA.⁵¹ Subunit III (aka cytochrome *b*) contains two of the three hemes in C-III, a low potential cytochrome *b*₅₆₆, and a high potential cytochrome *b*₅₆₂. Subunit IV contains the third heme, cytochrome *c*₁, and this assemblage of hemes has fostered the less formal name of cytochrome *b*_c₁. In addition to the hemes, subunit V contains

a [2Fe-2S] center, called the Rieske complex after its discoverer. Subunits I and II, the so-called ‘core proteins,’ are essential for proper assembly of the holocomplex, as are the remaining proteins, at least in yeast.⁵¹ The primary sequences from several species have been collated. Crystal structure indicates a homodimer with a twofold axis perpendicular to the membrane plane.^{175–178}

2.27.8.4.2 Catalysis

The coupling between the ubiquinone–cytochrome c_1 redox reaction and proton translocation, the so-called ‘protonmotive Q cycle,’ has been a focus of intense interest ever since Mitchell’s initial proposal of the protonmotive OxPhos coupling models, in large measure because it personifies how ETS redox potential is transduced into the proton gradient.^{179,180} The initial linear models of ETS based solely on redox potentials could not account for the observations, as outlined in the classic review by Trumpower.⁵³ The currently accepted model entails two separate ubiquinone reaction centers in subunit III that catalyze the oxidation of ubiquinol to reduce two molecules of cytochrome c , and hence to O_2 via C-IV, plus the translocation of four protons from the mitochondrial matrix (N, or negative side) into the intermembrane space (P, or positive side).

Although the details are beyond the scope of this chapter, an overview of the Q cycle is warranted, if only to put the diversity of C-III inhibitors into context. The first quinol is oxidized at the SQ_0 site in subunit III, releasing two protons to the P side of the membrane, with the two electrons following divergent pathways. One follows a high potential path by reducing cytochrome c via the Rieske [Fe-S] and cytochrome c_1 centers. The other electron follows a low potential route, via transfer from cytochrome b_{556} to b_{562} to SQ_1 , a second quinone reaction site in subunit II closer to the matrix, where it generates a semiquinone. A second oxidation of QH₂ at SQ_0 then reduces yet another cytochrome c_1 via the high potential pathway, and in so doing releases another two protons at the P side of the membrane, with the other electron following the low potential route to eventually reduce the semiquinone at the SQ_i site to the ubiquinone by recruitment of two protons from the nearby matrix. Thus one turn of the Q cycle entails oxidation of two molecules of ubiquinol to ubiquinone, with the subsequent regeneration of one of the ubiquinols. In so doing, the high potential reaction leading to O_2 reduction via cytochrome c occurs twice, while the reaction via the low potential route occurs only once. It is the redox flow from SQ_0 to SQ_1 that provides the electrogenic work to translocate two protons from the N to the P side of the membrane.

Much of the above has been summarized by Anthony Crofts in a review of Q-cycle research.¹⁸¹

2.27.8.4.3 Inhibitors

The known inhibitors function at either of the quinol reaction centers. The SQ_i inhibitors, such as antimycin, target electron transfer between heme b and ubiquinone/ubisemiquinol bound to the SQ_i site.¹⁸² Illicolins H (Figure 23), an antibiotic isolated from the fungus *Cylindrocladium ilicicola*, is another SQ_i site inhibitor with an IC_{50} of 200–250 nmol L^{-1} for bovine bc_1 complex, but its IC_{50} for *Saccharomyces cerevisiae* complex is 3–5 nmol L^{-1} .¹⁸³ The inhibitors of SQ_0 can be divided into three classes that reflect both structural and binding diversity. The methoxyacrylate derivatives myxothiazol and MAO-stilbene bind close to heme₅₆₆ whereas the hydroxyquinone mimics 5-undecyl-6-hydroxy-4,7-dioxobenzothiazol (UHDBT) bind closer to the [Fe-S]. Binding of the third group of chromones like stigmatellin overlaps the other two.¹⁸³ This diversity might encourage investigation into selective C-III inhibitors for anticypertroliferative indications.

2.27.8.4.4 Pathology

Mutations in C-III were among the first to be identified with human disease, when Johns and Neufeld showed that, in addition to well-known mutations in various C-I genes, mtDNA mutations in subunit III also led to dysfunction and LHON.¹⁸⁴ Other mtDNA mutations in subunit III are associated with various phenotypes, including hypertrophic cardiomyopathy and exercise intolerance.⁴⁰ In light of the discussion above identifying autooxidation of ubisemiquinone as a primary source of mitochondrial radical production, any functional restriction of C-III activity would yield a more highly reduced ubiquinone pool, correspondingly accelerating radical production via autooxidation. In this light, observation of impaired C-I activity associated with C-III mutation may well result from semiquinone radical production and the corresponding oxidative susceptibilities of the [Fe-S] centers in C-I.¹⁸⁵ A deletion in the *QP-C* gene, one of the C-III nuclear-encoded proteins, yields C-III deficiency with hypoglycemia and lactic acidosis, while mutations in the assembly protein BCS1L are associated with tubulopathy, encephalopathy, and liver failure.¹⁸⁶

Figure 23 Complex III inhibitors function at either of the quinol reaction centers. Illicicolin H has an IC_{50} of 200–250 nmol L⁻¹ for bovine bc_1 complex, but some 75-fold lower for *Saccharomyces cerevisiae*. Binding of chromones like stigmatellin should encourage investigation into selective C-III inhibitors for anticytotoproliferative indications.

2.27.8.5 Cytochrome *c*

2.27.8.5.1 Biology

Cytochrome *c* is one of the two electron shuttles in ETS. It is a small, highly conserved protein of 104 amino acids, with a molecular weight of ~12 kDa. The heme in *c*-type cytochromes differs from *b*-type in that the two vinyl side chains are covalently bound to the protein in the former.^{51,187} Cytochrome *c* does not bind O₂, it carries only a single electron, and its deletion is embryonic-lethal.¹⁸⁷ It is the only water-soluble component of ETS, and although it is loosely associated with the outer surface of the mitochondrial inner membrane facing the intermembrane space, it is readily extracted under high salt conditions. Indeed, this ionic interaction with the membrane has consequences for its release as a proapoptotic activator.⁸⁹

It had been mainly studied from physiochemical and evolutionary perspectives. Because of its near-ubiquitous distribution in both obligate and facultative aerobic organisms, sequence analysis provides evidence for evolutionary divergence, and thus phylogenetic trees. Most mutations are quite conservative, such that despite numerous substitutions and many other mutations, human cytochrome *c* functions well in yeast ETS, even though there is only a 40% sequence homology.⁵¹ The folding patterns and resulting tertiary structures have been well defined, and are also highly conserved.¹⁸⁸ In large measure this is because only about a third of the amino acids in the sequence are required for function.¹⁸⁹ Reassuringly, phylogenies based on cytochrome *c* sequences nicely recapitulate those derived from morphology and other criteria.¹⁹⁰

2.27.8.5.2 Apoptosis

Study of cytochrome *c* has been reinvigorated by its identification as one of the main proapoptotic signals released from mitochondria that, along with others, activates the caspase and nuclease cascades that are the proximate mediators of apoptosis.^{89,191,192} In cells overexpressing Bcl-2 (or Bcl-XL), the release of cytochrome *c* is blocked, thereby aborting the apoptotic response.¹⁹³ In most models, loss of $\Delta\psi_m$ and mitochondrial swelling precede cytochrome *c* release. However, this is not universally the case,⁹² suggesting alternate pathways whereby mitochondrial failure can precipitate

cell death. Indeed, alternate activities of cytosolic cytochrome *c* have been identified, such as increased release of Ca^{2+} from the endoplasmic reticulum after binding of cytochrome *c* to the inositol 1,4,5-triphosphate receptor.¹⁹⁴

There are two separate populations of cytochrome *c* within the mitochondria, with ~15% within a compartment more readily available to participate in induction of apoptosis.⁶⁶ The evidence indicates that the initial release of cytochrome *c* during proapoptotic stimulation does not directly undermine $\Delta\psi_m$ and OxPhos, but rather these mitochondrial factors are undermined via caspase activation and disruption of cytosolic Ca^{2+} homeostasis.⁶⁶ Nevertheless, sustained depletion of cytochrome *c* inevitably leads to $\Delta\psi_m$ loss, C-I and C-III inactivation, increased mitochondrial free radical production, and cell death. It is of interest that the cytochrome *c* heme must be in the oxidized form in order to participate in the formation of the apoptosome, a heteromeric aggregation of apoptotic protease-activating factor 1 (Apaf-1), caspase 9, and other cofactors.¹⁹⁵

2.27.8.5.3 Cardiolipin interactions

Cytochrome *c* has also been implicated in other pathways that highlight the interdependence of both the proteins and the lipid domains in establishing mitochondrial functional integrity, and in causing cell death. The presence of anionic phospholipids, especially cardiolipin and phosphatidylserine, weakens the heme–protein bonding in cytochrome *c*, thereby inducing a previously repressed peroxidase activity by the heme.¹⁹⁶ As a result, in the presence of H_2O_2 or ONOO^- , especially when accompanied by chloride anion,¹⁹⁷ tightly bound cytochrome *c* exacerbates cardiolipin oxidation and correspondingly undermines the integrity of the inner mitochondrial membrane, leading to cell death. In this way, cytochrome *c* redox cycling may well be initiating or facilitating apoptosis via destabilizing mitochondrial membrane integrity, independent of that portion that is released to the cytoplasm.¹³

2.27.8.6 Complex IV (EC1.9.3.1)

2.27.8.6.1 Composition and catalysis

Complex IV (COX) catalyses the oxidation of four electrons from cytochrome *c* to the tetravalent reduction of dioxygen to yield two molecules of water, coupled with the translocation of four protons.⁵¹ Similar to the case for C-III, C-IV is composed of 13 proteins, with the three central proteins containing the catalytically essential prosthetic groups encoded by mtDNA, and the remaining 10 proteins encoded by the nuclear genome. C-IV exists as a homodimer, with each monomer containing two heme *a* groups, three Cu^{2+} atoms, one Zn^{+} , and one Mg^{2+} , the latter two likely serving structural rather than catalytic functions.⁵¹ Subunit I contains both heme *a* groups, with heme *a*₃ forming a binuclear center with Cu_B to form the active site for O_2 reduction.⁵¹

Studies of the crystal structure of C-IV from several species have substantially clarified the biophysics of electron flow through C-IV and have raised the possibility of allosteric cooperativity akin to O_2 binding to polymeric hemoglobins.^{198,199} Given the intense study and analytical techniques brought to bear, several models of redox energy coupled to proton translocation have evolved.^{200,201} Briefly, cytochrome *c* shuttles single electrons to the bimetallic Cu_a that extends well above the membrane into the intermembrane space. Cu_a reduces heme *a*, 1.9 nm away and embedded within the membrane, with no change in iron coordination, although conformational shifts have been detected that may be important for proton translocation.²⁰¹ Electrons are transferred laterally within the protein to heme *a*₃, some 1.4 nm distant, where they fully reduce the heme *a*₃– Cu_B center. Once the latter is fully reduced, O_2 is able to bind, and with an additional electron from heme *a*, is reduced to water.^{198–201} Although complete reduction of the heme *a*₃– Cu_B center site is required for O_2 and CO binding, it is not the case for NO binding, which plays a regulatory role.

2.27.8.6.2 Inhibitors

The classical inhibitors of cyanide and H_2S act via irreversible interaction with Fe^{3+} in the heme moieties.²⁰² CO is a competitive inhibitor of O_2 by binding to the fully reduced heme *a*₃– Cu_B center, but, with a K_m some 100-fold higher, it is a low-affinity interaction. It has long been recognized that C-IV was a key regulatory center of respiration by responding to adenylate status, and that several mutations yield pathology.^{203–205}

2.27.8.6.3 Oxidative regulation

More recently, interest in COX regulation has been rekindled by the observation that NO rapidly, selectively, and potently inhibits mitochondrial respiration by impeding electron flow through C-IV,^{15,206} an observation first reported in the mid-1960s by Gibson and Greenwood.²⁰⁷ This inhibition is readily reversible, a hallmark of physiological flux control. It appears that NO is a competitive ligand for the active O_2 site, with nanomolar IC_{50} values that increase in

proportion to the square of oxygen concentration.²⁰⁸ The K_m of O_2 for respiration is $\sim 20\text{--}30\ \mu\text{mol L}^{-1}$, such that respiration in the presence of physiological amounts of NO is exquisitely susceptible to decreasing O_2 availability.²⁰⁶

The initial observations of inhibition of respiration by NO were ascribed to reactions with O_2^- to yield peroxynitrite $ONOO^-$, and other reactive nitrogen species (RNS), with deleterious consequences for the [Fe-S] centers and other radical-susceptible centers in ETS.^{15,209} These reactions do indeed occur, but the kinetics are in large measure dependent upon the coincident availability of O_2 , which is the net result of production via redox cycling, competing reactions, and the efficiency of the antioxidant defenses.^{144,210}

Rather, NO is enzymatically generated from L-arginine via three isozymes of NO synthase, the distributions of which are not limited to the tissues for which they are named: eNOS (endothelial), nNOS (neuronal), and an inducible (iNOS) form associated with the inflammatory response. Although several studies identified eNOS with mitochondrial outer membrane, more recent work has indicated a Ca^{2+} -dependent nNOS on the matrix side of the inner membrane.^{4,211}

The interplay between NO as a normal physiological regulator of respiration that responds to P_{O_2} , and NO as a deleterious prooxidant involved in reactive oxygen species (ROS)/RNS-induced injury, is difficult to parse without considering the oxidative status within the mitochondrial compartment.^{47,144,201,212,213} When GSH and other antioxidants are depleted, reactions favoring $ONOO^-$ formation are likely to dominate, whereas when O_2^- is low, regulatory activities likely dominate. This 'Janus-faced' complexity also raises questions about what were previously thought to be well-understood pharmaceuticals, such as nitroglycerin which, although clearly imparting beneficial vasodilator effects, may at the same time also be imposing unintended deleterious consequences at the level of mitochondrial respiration.^{15,214,215}

2.27.8.6.4 Regulation versus pathology

Schon and DiMauro have proposed an intriguing model of the mitochondrial disease MELAS based on the duality of NO as a radical versus its regulatory roles at both C-IV and within the vasculature.⁶¹ They note that MELAS, which is caused by a mutation in mtDNA gene for leucine tRNA, is atypical of most mitochondrial diseases because of its angiopathy and strokes. In many other mitoproliferative disorders like MERRF, mitochondrial accumulation results in histopathologically characteristic 'ragged red' muscle fibers where C-IV activity is diminished. However, in MELAS the hypertrophied mitochondrial populations contain elevated amounts of C-IV. This is the case for the vascular smooth muscle in MELAS, yielding a model wherein stroke-like episodes and cortical blindness arise from paradoxical vasoconstriction when NO, which should have induced vasodilatation, is preferentially taken up by the excess C-IV in the vascular muscle bed. As such, exogenous NO might provide therapeutic benefit to MELAS patients, a contention for which there are supportive data.⁶¹

Several groups are also pursuing strategies that combine NO donors with other pharmacological agents or medical devices.²¹⁶ For example, a postangioplasty stent coated with an NO donor is in development to improve restenosis outcome,²¹⁷ and COX-2 inhibitors have also been coupled with NO donors,²¹⁸ a strategy that may help address the vascular comorbidity that undermines some COX-2 inhibitors.

2.27.8.7 Complex V (EC 3.6.1.34)

2.27.8.7.1 Composition and catalysis

C-V (ATP synthase, F_1F_0 -ATPase) is the transmembrane protein aggregation that couples the protonmotive force generated by ETS respiration to ADP phosphorylation. It is composed of two functional hydrophilic domains, F_0 and F_1 , that regulate proton flow at the intermembrane space, and ADP phosphorylation within the matrix, respectively.⁵¹ F_1 is composed of five proteins that catalytically function as a nanomotor akin to the bacterial flagellum.^{51,86,199,219–221} The 'stalk' connecting the two catalytic subunits and the F_0 component are comprised of at least 10 proteins, of which two are encoded by mtDNA. It exists as a dimer, and the details of the catalytic mechanism are fascinating,²²² but attention here focuses on its physiological regulation and xenobiotic responses.

2.27.8.7.1 Regulation

The energy demand of tissues can vary widely depending on a host of variables. For example, ATP demand of mammalian heart can easily vary 5–10-fold depending on workload.²²³ The classical models of respiratory regulation contended that C-V activity is directly and predominantly modulated by ADP availability within the mitochondrial matrix. Although this is indeed part of the regulatory mechanism(s), it has also been found that Ca^{2+} upregulates C-V activity, thereby increasing ATP production, via release of an endogenous inhibitor 'Ca²⁺-binding inhibitor.'²²³

Similarly, under pathogenic conditions, such as neuronal excitotoxicity and/or prolonged hypoxia, $\Delta\psi_m$ is dissipated, thereby reversing the equilibrium across C-V. In response, C-V runs in reverse, with ATP hydrolysis being used to preserve $\Delta\psi_m$.²²⁴ Clearly, such unregulated adenylate depletion will eventually become injurious to the cell, but aerotolerant organisms have a constitutive F_1 -inhibitor protein, IF-1, that slows such reverse ATP hydrolysis upon binding to F_1 .²²⁴ The 84-amino-acid IF-1 protein has a well-defined binding domain, and crystallographic studies have also revealed how other inhibitors interact with the ATPase, including binding sites for aurovertin B, efrapeptin, polyphenolic phytochemicals such as resveratrol and piceatannol, nonpeptidyl lipophilic cations, and amphiphilic peptides like melittin inhibitors competing for the aurovertin B-binding site (or sites). The nonpeptidyl lipophilic cation rhodamine 6G acts at a separate unidentified site, indicating that there are at least five inhibitory sites in the F_1 -ATPase.²²⁵

As noted previously, ATP is among the most potent inhibitors of MPT. From a medicinal chemistry perspective, development of small molecule mimetics of IF-1 might be useful for treatment of transient ischemia, such as stroke or myocardial infarction, to preserve mitochondrial function by slowing ATP depletion. Conversely, polycationic inhibitors of IF-1 might be a reasonable approach to exacerbate induction of apoptosis in antitumor therapies.

2.27.8.7.2 Other inhibitors

In addition to the inhibitors noted above that interact directly with subunits of F_1F_0 -ATPase, indirect xenobiotic C-V inhibitors are also known, such as oligomycin, a macrolide antibiotic isolated from *Streptomyces*. Oligomycin, and analogs, interact with a separate protein, the 'oligomycin sensitivity-conferring protein' (OSCP), that binds to well-characterized subunits of F_1 and impedes proton flow.²²⁶ Interestingly, OSCP also binds 17β -estradiol, 17α -estradiol, an isomer with substantially lower hormonal-transactivating potency, and diethylstilbestrol.²²⁷ These data suggest that estradiol, and other related compounds, in addition to classical genomic mechanisms, may also interact with ATP synthase to modulate cellular energy metabolism.²²⁷ Indeed, transient estrogen binding to OSCP could well inhibit reverse ATP hydrolysis during hypoxia or Ca^{2+} overload, thereby preserving ATP and correspondingly preventing MPT. This would be an additional mechanism whereby phenolic steroids like estrogen and its analogs provide cytoprotection during pathogenic ischemia, oxidative stress, excitotoxicity, and other stressors.^{54,55,108}

Other groups have focused on OSCP as potential drug target, and Bz-423, a 1,4-benzodiazepine, has been shown to bind to OSCP, resulting in accelerated O_2^- production, which initiates apoptosis.²²⁸ These data suggest the potential utility of Bz-423 as a cytotoxic agent against autoimmune lymphocytes, rendering OSCP a viable target for novel lupus therapeutics.²²⁸

2.27.8.7.3 Pathology

A point mutation in the mt-DNA-encoded subunit 6 of the F_0 is associated with the mitochondrial diseases neurogenic muscle weakness, ataxia, and retinitis pigmentosa (NARP) and Leigh syndrome, and other mutations have been identified.^{229,230} Das has highlighted how inadequacies in physiological and genetic regulation of C-V may be contributing to a host of human pathologies, such as neuronal ceroidlipofuscinoses, as well as methylmalonic and glutaric acidurias.²²³

2.27.9 Other Mitochondrial Drug Development Strategies

2.27.9.1 Uncoupling OxPhos

2.27.9.1.1 Pharmacological approach

The notion of purposefully rendering the inner mitochondrial membrane permeable to protons, i.e., uncoupling ETS from OxPhos, is intriguing, but also disquieting. Such uncoupling increases heat production at the expense of caloric efficiency, a mechanism unknown when DNP was touted as a weight-loss drug in the early twentieth century. DNP did reduce patient weight, but the narrow therapeutic window was determined empirically by patients altering intake, not without a host of deleterious consequences, ranging from cataracts to death.

However, judicious and transient use of uncoupling agents has been shown to confer neuroprotection during acute Ca^{2+} overload associated with dicarboxylate excitotoxicity.^{105,106} For example, Stout *et al.* used three different inhibitor treatments to dissipate the mitochondrial membrane potential, and correspondingly eliminate Ca^{2+} uptake, including the protonophore uncouplers carbonyl cyanide *p*-(trifluoromethoxy) phenyl-hydrazine (FCCP), and DNP, or the C-I inhibitor rotenone in combination with the ATP-synthase inhibitor oligomycin.¹⁰⁵ Glutamate exposure significantly increased intracellular free calcium concentrations, and this was exacerbated by mitochondrial inhibition. However,

regardless of elevated cytoplasmic Ca^{2+} , transiently preventing mitochondrial Ca^{2+} uptake correspondingly prevented cell death. These beneficial effects of uncoupling OxPhos have also been demonstrated in vivo where DNP reduces the cerebral infarct volume approximately 40% in a rat model of focal ischemia–reperfusion.¹⁰⁶ Additional studies indicate that moderation of Ca^{2+} uptake preserves mitochondrial function, represses oxyradical generation, and moderates cytochrome *c* release.¹⁰⁶ These studies, among others, suggest that transiently uncoupling ETS may be a viable therapeutic strategy to reduce infarct volume during excitotoxicity associated with acute ischemia or trauma. Of course, although transient uncoupling serves to preserve mitochondrial function in the short term, the uncoupling agent must subsequently be removed in order to allow for resumption of ATP production.

2.27.9.1.2 Uncoupling proteins

Physiologically relevant uncoupling proteins have been identified and may serve as viable drug targets. For example, uncoupling protein UCP-1 (thermogenin) was isolated from rodent brown adipose tissue specialized for nonshivering thermogenesis, where it regulates proton leak.^{231,232} Such UCPs have been found in bacteria, fungi, and plants, particularly in the arum family, where thermogenic activities are important for reproduction.^{231,232} UCPs are members of the mitochondrial anion carrier superfamily, and five isoforms are now known from mammals. All have molecular weights 31–34 kDa, with UCPs 1–3 sharing much sequence homology, whereas UCPs 4 and 5 do not.²³² UCPs 1–3 function within the inner mitochondrial membrane as homodimers, and may be responsible for the well-known thermogenic responses to elevated thyroid hormones.²³³ Interestingly, mitochondria UCP activity requires activation by superoxide exposure from the matrix side of the inner membrane, and such activation is impeded by mitochondrially targeted lipophilic antioxidants.^{130,232} This could well reflect a tightly regulated feedback system, where oxyradicals generated by redox cycling of highly reduced ETS components serve to dissipate $\Delta\psi_m$, thereby accelerating electron flow and shifting ETS to a more oxidized state.²³⁴ It would be instructive to monitor radical production and UCP activation under conditions unfavorable for acceleration of electron flow, such as anoxia or C-IV inhibition.

UCPs are expressed in brain, and UCP-2 mRNA is upregulated in response to excitotoxicity (kainate administration) and ischemia.²³⁵ In accord with studies showing transient uncoupling and prevention of mitochondrial Ca^{2+} uptake is neuroprotective, overexpression of UCP-2 is also neuroprotective against oxidative stress in vivo and in vitro.²³⁵ For example, UCP-2 is elevated twofold in the substantia nigra in a transgenic rodent model overexpressing UCP-2 in catecholaminergic neurons.²³⁶ This was accompanied by partial mitochondrial uncoupling, reduced oxidative stress, and substantial neuroprotection against the C-I inhibitor MPTP, recommending UCP intervention as potential treatment for Parkinson's disease.²³⁶ Although these data are convincing, pharmacological mitochondrial uncoupling may be too precipitous a strategy, at least until safety issues can be resolved. In the interim, it may be that small-molecule inducers or activators of UCPs can provide a more circuitous avenue to achieve the same result.

2.27.9.1.3 Caveat

Physiological caveats to any systemic uncoupling strategy are that prolonged myocardial uncoupling will carry catastrophic consequences, and that, even at lower doses, glucose-stimulated insulin secretion (GSIS) from pancreatic islet β cells is tightly coupled to adenylate charge. The ATP/ADP ratio is a key component in how β cells 'sense' glucose, and hence regulate insulin secretion.²³² Untoward systemic UCP activity might impede glucose-induced ATP increase, and correspondingly moderate insulin secretion. Again, tissue-specific differences between mitochondrial phenotypes may offer solutions to these conundrums.

2.27.9.2 Manipulating Mitochondrial Biomass

Endurance training increases the mitochondrial biomass, and recent studies have revealed a number of the signaling pathways involved.^{237,238} Several such pathways are outlined here, if only to stimulate thought of pharmacological interventions designed to increase mitochondrial biogenesis in the contexts of human physical performance and the increasing prevalence of obesity and diabetes in the developed countries.

2.27.9.2.1 Transcriptional regulation

Two transcriptional regulators involved in the coordinated expression of nuclear-encoded respiratory genes and mitochondrial biogenesis in mammals are nuclear respiratory factors NRF-1 and NRF-2.²³⁹ It is now clear that one or both regulate the majority of the nuclear genes encoding subunits of the respiratory chain complexes. They are also involved in the expression of mitochondrial transcription and replication factors, heme biosynthetic enzymes, and other proteins required for respiratory function.²³⁹ For example, mtDNA transcription requires expression of mitochondrial

RNA polymerase and a mitochondrial transcription factor A (Tfam), and is greatly enhanced by the mitochondrial transcription specificity factors TFB1 M and TFB2 M.²³⁹ NRF-1 and NRF-2 not only regulate human TFB1 M and TFB2 M promoters, but are also required for maximal *trans* activation by the PGC-1 family coactivators, PGC-1 (peroxisome proliferator-activated receptor gamma (PPAR- γ) coactivator-1) and PRC (PGC-1 related coactivator). The latter two can induce mitochondrial biogenesis when expressed ectopically in cultured cells or in transgenic mice.²⁴⁰

Taken in toto, the coordinated regulation and expression of nuclear- and mitochondrially encoded proteins, and mitochondrial biosynthesis, are primarily under the control of PGC-1 and NRF family coactivators, via an ever-expanding series of interactions involving other transcription factors, such as Sp1, CREB, and YY1, among others. Nuclear genes for other mitochondrial functions such as beta-oxidation of fatty acids are controlled by transcription factors such as PPAR- α that are not involved with expression of the respiratory subunits.

2.27.9.2.2 Pharmacological approach

The notion that manipulation of mitochondrial biogenesis can be a therapeutic strategy amenable to pharmaceutical intervention is under evaluation. For example, coadministration of 17 β -estradiol and flutamide improves cardiac outcome following trauma hemorrhage in rats by increasing PGC-1.²⁴¹ Estrogen and flutamide normalize cardiac PGC-1, NRF-2, Tfam, COX-4, beta-ATP synthase expression, mitochondrial ATP, cytochrome *c* oxidase activity, and mitochondrial DNA-encoded gene COX 1.²⁴¹ However, the estrogen receptor antagonist ICI 182,780 abolishes the flutamide-mediated PGC-1 upregulation, indicating that both estrogen and flutamide upregulate PGC-1 via classical estrogen receptors.^{24,242} This is intriguing, given data localizing at least some of the classical estrogen receptor β to mitochondria.²⁴³

It has long been thought that the biguanide metformin and related thiazolidenediones (TZDs) such as troglitazone, pioglitazone, and rosiglitazone (Figure 24), improve insulin sensitivity in diabetic patients by several mechanisms, including increased uptake and metabolism of free fatty acids in adipose tissue, increased insulin-stimulated glucose uptake by skeletal muscle, and adipocyte differentiation via activation of PPAR- γ .²⁴⁴ However, independent of PPAR-, TZDs also have direct deleterious effects on mitochondria such as reduced glutamate/malate oxidation and elevated lactate release.^{244–246}

Direct inhibition of complex I by TZDs, and mitochondrial uncoupling, have been demonstrated in isolated mitochondria and skeletal muscle strip-preps.²⁴⁷ Selective C-I inhibition by metformin was noted early on,²⁴⁸ and the resulting elevated plasma lactic levels are a hallmark of mitochondrial inhibition and diseases. Metformin appears to interact directly with C-I, whereas C-I inhibition by TZDs appears to be indirect. For example, both PPAR- γ antagonists and agonists lacking a TZD structure inhibit C-I, whereas compounds with weak PPAR- γ affinity, such as the oxadiazolidinedione YM440, do not.²⁴⁹ Burnmaier *et al.* interpret this to mean that complex I inhibition is not mediated by PPAR- γ activation per se, but rather that the properties responsible for PPAR- γ binding are also conducive to C-I inhibition.²⁴⁷ Moreover, in addition to C-I inhibition, both rosiglitazone and pioglitazone decrease respiratory control and ADP-to-oxygen ratios due to increased oxygen consumption in state 4, a clear indication of uncoupled

Figure 24 The biguanide metformin and related thiazolidenediones, such as troglitazone, pioglitazone, and rosiglitazone, improve insulin sensitivity in diabetic patients by several mechanisms. However, TZDs inhibit C-I and uncouple mitochondria via direct (metformin) and indirect interactions (TZDs). A testable inference is that the resulting impairment of aerobic ATP production results in compensatory increased glucose uptake and glycolytic flux.

OxPhos.²⁴⁷ The reasonable supposition is that reduced aerobic ATP production due to C-I inhibition, and uncoupling in some cases, results in compensatory increased glucose uptake, glycolytic flux, and ensuing lactate production.²⁴⁷

Interestingly, at least one of these TZDs, pioglitazone, has been shown to increase mitochondrial biogenesis in adipose tissues of diabetic patients.²⁴² A number of studies have reported reduced expression of PPAR coactivator-1 α (PGC-1 α), a key regulator of mitochondrial biogenesis, and mitochondrial dysfunction in patients with insulin resistance, type 2 diabetes, and in morbidly obese prediabetic patients. Conversely, troglitazone treatment of Zucker diabetic rats restored PGC-1 α and NRF-1 expression in muscle, while rosiglitazone treatment of 3T3-L1 adipocytes increased the number of mitochondria.²⁴² It would be illuminating to examine the possibility that increased mitochondrial biogenesis in these instances is actually a compensatory response to xenobiotically induced respiratory inhibition.

2.27.9.3 Antiviral Effects on Mitochondria

Secondarily discovered mitochondrial pathology also pertains to some antiviral therapeutics, where mitochondrial function is systemically undermined and causes several iatrogenic complications. For example, currently approved antiretroviral therapies focus on human immunodeficiency virus-1 (HIV-1) reverse transcriptase and HIV-1 protease as potential targets. Nucleoside reverse transcriptase inhibitors (NRTIs; nucleoside analogs) directly terminate DNA elongation, while nonnucleoside reverse transcriptase inhibitors (NNRTIs) inhibit enzyme activity.²⁵⁰ The current standard of care, termed highly active antiretroviral therapy (HAART), is a combination of reverse transcriptase inhibitors and protease inhibitors. However, long-term toxicity and the lipodystrophy syndrome (LDS), consisting of dyslipidemia, metabolic abnormalities of insulin resistance, and redistribution of body fat, has emerged as a limiting factor for HAART and hence an important hurdle in HIV care.²⁵⁰ This may also be the case for steatohepatitis and nonalcoholic steatohepatitis (NASH), which can also be induced by drugs such as amiodarone, tamoxifen, and some antiretroviral drugs. Increasingly, evidence is accumulating that respiratory chain deficiencies play a role in the pathophysiology of NASH.²⁵¹

Many of the toxicities of various HAART regimes are due to tissue-selective mitochondrial effects.²⁵¹ For example, AZT (zidovudine) selectively reduces mitochondrial mass and function in subcutaneous adipose tissue, which surely contributes to lipodystrophy syndrome,²⁵² while high-dose AZT induces skeletal and cardiac myopathies where mitochondria are enlarged with disrupted cristae and paracrystalline inclusions, hallmarks of mitochondrial failure.²⁵⁰ In retrospect, such pathologies could have been anticipated: NRTIs inhibit DNA polymerase γ , which is required for mtDNA replication. By undermining mitochondrial biogenesis, OxPhos is compromised, leading to clinical lactic acidosis, and apoptotic cell death is exacerbated.^{250–252}

In contrast with the above, a combination of protease inhibitors nelfinavir and ritonavir reduced mitochondrially mediated apoptosis *in vivo* in models such as Fas-induced fatal hepatitis, enterotoxin B-induced shock, and middle cerebral artery occlusion model of stroke.²⁵³ Computer modeling based on the crystal structure of ANT indicates that nelfinavir interacts directly with ANT to prevent permeability transition.²⁵³ Although this seems reasonable, it remains to be seen whether such ANT inhibition also prevents adenylate exchange, which of course would have deleterious consequences for long-term cell viability, and may also contribute to the toxicity of current HAART regimes.

2.27.10 Summary

Mitochondrial dysfunction contributes to a host of well-characterized human diseases; mitochondrial failure will be increasingly implicated in widespread degenerative illnesses and aging, as well as in acute indications such as stroke and heart attack. Therapeutics that restore or maintain mitochondrial integrity will have profound and fundamental consequences in human health and well-being. In acute indications, transient and well-regulated mitochondrial uncoupling could provide novel treatments for acute ischemia–reperfusion pathology in brain, myocardium, and other aerobically poised tissues, not to mention organ transplantation. As a result, mitochondrial function and failure will increasingly fall within the purview of medicinal chemists. Contrary to received knowledge, mitochondrial physiology lends itself to targeted drug delivery strategies, and mitochondrial phenotypic diversity offers potential refinements to such strategies, including the possibility of tissue-selective targeting. Numerous inhibitors of the individual electron transfer components have been described, and crystal structures are providing mechanistic insights into both catalysis and inhibition. We know that mitochondria are proximate determinants of cell death and viability, and therefore offer therapeutic possibilities for both cytoprotection and cytotoxicity. The more concisely we characterize the underlying factors that determine and maintain mitochondrial integrity, and thus the equilibrium between cell death and life, the more effective, safe, and elegant will be the drugs of the future.

Biography

James A Dykens earned his PhD from the University of Maine studying photosensitized oxidative physiology of corals on Australia's Great Barrier Reef. He pursued postdoctoral research in the Department of Pharmacology at New York University Medical Center, where he studied tryptophan metabolism and hemoglobin biochemistry. His work at NYU was among the first to propose the oxidative pathology of excitotoxicity and its role in the etiology of neurodegenerative diseases. He was on faculty at Grinnell College prior to joining the Immunopathology Department at Warner-Lambert, Parke-Davis Pharmaceutical Research, in Ann Arbor (now Pfizer). At Parke-Davis, he continued his work on oxidative neuropathology, using electron paramagnetic resonance spectroscopy to characterize free radical production during mitochondrial failure. In 1996, he joined MitoKor in San Diego (now Migenix) in order to focus on the mitochondrial etiology of both chronic degenerative diseases and the cytotoxicity resulting from acute ischemia-reperfusion. Dr Dykens founded EyeCyte Therapeutics to develop novel, nonhormonal, cytoprotective steroids to preserve retinal function and vision in blinding diseases.
