Foreword: The Past Recalls the Future

In the three short years since the first edition of this seminal volume was published, myriad events in gene therapy have occurred. It is far beyond the scope of this short introduction to review events in detail, but several serve as pivotal reminders that within the goal of promoting and enhancing the public health to serve the disenfranchised, progress depends on the highest ethical framework for clinical investigation and the most rigor that medicine and science can offer.

Jesse Gelsinger's death in 1999 led to a reexamination by the Food and Drug Administration (FDA) of the state of gene therapy clinical trials conducted in the United States. In an unprecedented approach, a random sampling of all gene therapy investigative new drugs led to FDA bioresearch monitoring (BIMO) inspections of 70 clinical sites. Results of that intensive effort were reported at an FDA Biological Response Modifiers Advisory Committee Meeting in April 2001 (http://www.fda.gov/ohrms/dockets/ac/01/briefing/3739b1.htm). An important conclusion was that ''The random surveillance inspections of Phase 1 and 2 gene therapy clinical trials indicate that the trials were being properly conducted with fewer deviations than found in Phase 3 studies.'' Although reassuring, there were common deficiencies, such as failure to follow the protocol and inadequate consent form, that need to be corrected on a continual basis in order to ensure that meaningful information can be gathered from clinical trials.

Another issue raised by Jesse's death was that for adenoviral vector gene therapy studies, no adequate means existed in 1999 to compare dosing across clinical studies. At a December 1999 Recombinant DNA Advisory Committee meeting, a challenge was made to create a reference material, and the response by the community bears remarking. An international task group along with the FDA and the Williamsburg Bioprocessing Foundation undertook a unique proposal (see details under Reference Materials Projects at http://www.wilbio.com). Pro bono bids were solicited for various aspects of creating a reference material, such as production of a seed lot, characterization and testing, vialing, and shipping. As of August 23, 2002, the Adenoviral Reference Material is available for purchase from the American Type Culture Collection (ATCC), with full characterization data. The availability of this material allows production of more consistent, safer, quality adenoviral vectors and comparability between preclinical and clinical studies, and greatly aids the development of regulatory policy.

A final remarkable event concerns the poignant clinical study of the use of murine retroviral vector–based gene therapy of X-linked severe combined immunodeficiency disease (XSCID), conducted by Dr. Alain Fischer and colleagues in France. Nine of ten children treated in that trial have had successful immune reconstitution that appears to be superior to that seen with conventional bone marrow transplantation. In August and December 2002, Dr. Fischer communicated to gene therapy investigators and regulatory agencies that two of the nine successfully treated children have developed T cell leukemia-like syndromes. Both adverse events appear to be caused, in whole or in part, by insertion of the therapeutic gene in or near a proto-oncogene locus called LMO-2. A number of select committees worldwide have and are continuing to investigate these findings, with the emerging consensus being that the gene therapy works in XSCID, but, because of the adverse events, gene therapy should be used only when no available alternatives exist.

Several items bear further discussion. First, Dr. Fischer and colleagues must be credited and thanked for having the courage to communicate these adverse-event findings, even before the molecular cause was known. Without this open communication, progress in therapies will be slowed and in jeopardy. Second, it must be taken in context that most clinical trials fail in achieving even preliminary data suggesting therapeutic benefit. Here we have a study in which the therapy clearly benefits but where there are now known adverse events associated with the therapy. Third, it is rare that scientific methodology allows us to determine

rapidly that the therapy is the direct cause of the adverse events. The challenge to all of us is, given this knowledge of benefits and risks, how can we preserve that which is desired—the cure of X-SCID—and mitigate and/or eliminate the adverse events?

I am once again honored by the request of the publisher and editors to provide this brief introduction. The authors are representative of the large arena of gene therapy participants, and as such they and others forward the field in a professional, collegial, and rigorous manner. It is my hope that the authors continue to consider the FDA to be a partner in these efforts.

In conclusion, from the previous edition: ''And to end this brief foreword, let us be sober and focus on the word 'reality'. At this writing, no gene therapy product has been approved by the FDA as safe and effective for any disease. It is the hope that that will happen in the future. How near that future is depends on all of us, the public, the FDA, the NIH, the industry, to work, debate, negotiate, and create the new millennium.''

Preface

Since the first publication of this book in 2000, gene therapy clinical trials have yielded some remarkable successes and some disappointing failures. In many research laboratories, valuable insights have been gained that will enable us to overcome many of the difficulties encountered to date and to move gene therapeutics toward routine use in the clinic. As with any new therapy, such as heart transplantation, many failures must be expected before treatment becomes routine. Long-term success requires that we rationally assess each failure and determine what additional knowledge is required to solve each problem we encounter. Once again, the authors of this second edition have provided thoughtful insights into the challenges that must be met for specific applications of gene and cell therapies.

The ongoing development of gene therapy draws from many disciplines, including virology, molecular biology, medicine, genetics, immunology, biochemistry, physiology, chemistry, biophysics, molecular imaging, cellular biology, microbiology, pharmacology, and toxicology. This book includes topics in each of these areas and has been planned to facilitate its ongoing use as a textbook for classes in gene therapy and gene transfer. The chapters are written so that readers from all backgrounds, including students, physicians, scientists, and other interested persons, can understand the current status of gene therapy and how these diverse disciplines contribute to this field. Several contributors have broadened their introductions to facilitate use of this edition as an educational textbook and have contributed information to provide context for their focused research efforts. Hopefully, this volume will provide all readers with a broad knowledge of all aspects and tools available in the evolving field of gene therapy.

Retroviral Vectors for Gene Therapy

Paula M. Cannon and W. French Anderson
University of Southern California Keck School of Medicine
Los Angeles, California, U.S.A.

I. INTRODUCTION

Gene therapy aims to treat both genetic and infectious diseases by the introduction of new genetic material into the appropriate cells in the body (1). In the simplest case of a defective gene causing disease, addition of the new gene will restore function. Alternatively the new genetic material can be designed to selectively kill a tumor cell, to induce an immune response, or to protectively ''immunize'' a cell against an incoming pathogen. Nontherapeutic uses of gene therapy include gene marking, which has proved especially useful in identifying the sources of recurring malignancies in autologous bone marrow transplant patients. These potential applications of gene therapy are described in Table 1.

The first approved gene therapy clinical protocol began in September 1990, using retroviral vectors to introduce copies of the adenosine deaminase (ADA) gene into T cells from a patient with ADA deficiency (2,3). In 2002, over 600 clinical protocols have been approved worldwide, incorporating over 3500 patients. Most of these trials have used viral vectors, with the largest number (34% of trials, 50% of total patients) involving retroviral vectors. This chapter explores the features of retroviral vectors that make them so versatile for gene therapy and highlights both their current limitations and potential improvements.

II. RETROVIRAL VECTORS

Retroviruses can efficiently carry out gene transfer to many cell types, where they stably integrate their genomes into the host cell chromosome. Gene transfer vectors derived from retroviruses therefore provide the possibility of long-term gene expression. To date, the most common vectors used in clinical gene therapy protocols have been based on the murine leukemia virus (MuLV), and various packaging systems to enclose the vector genome within viral particles have been developed [reviewed in (4)]. The vectors themselves have all the viral genes removed, are fully replication defective, and can accept up to approximately 6–8 kilobase (kb) of exogenous DNA.

A. Retroviral Life Cycle

Fundamental to the utility of retroviral vectors are the particular characteristics of the retroviral life cycle, illustrated in Fig. 1. The initial steps of the life cycle, from binding of the virus to a target cell through integration of its genetic material into that cell's genome, do not require the *de novo* synthesis of any viral proteins. Accordingly, a retroviral particle can be used as a vector to deliver genetic material without the requirement for any viral protein synthesis or infectious particle production.

The retroviral genome codes for 3 basic polyproteins (Fig. 2A), produced by alternate splicing of the RNA transcript, which are further processed into their component proteins. The *gag* gene products produce the protein core of the viral particle, which encapsidates 2 copies of the linear RNA genome. Also associated with the viral core are the products of the *pol* gene, the enzymes involved in particle maturation (protease) and DNA metabolism (reverse transcriptase and integrase). The *env* gene product is a glycoprotein that is anchored in the plasma membrane of the host cell. It is therefore incorporated into the lipid envelope that surrounds the retroviral particle as a result of its budding from a host cell. The budding process does not kill the host cell, which allows for the establishment of stable producer cell lines that continuously release retroviral vector particles.

Table 1 Gene Therapy Applications

1. Gene replacement/augmentation
   Especially suited to single gene defects and discrete populations of target cells (e.g., ADA deficiency, cystic fibrosis)
2. Suicide/toxic genes
   To eliminate certain cells (e.g., HSV thymidine kinase for cancer cells)
3. Protective genes
   Expression of the gene product renders the cell resistant to viral attack (e.g., intracellular antibodies, antisense constructs for HIV gene therapy)
4. Immune stimulation
   To stimulate the host's immune system, in particular, to cancer cells (e.g., HLA genes, immune stipulatory cytokines)
5. Cell marking
   For autologous bone marrow transplantation in cancer therapy (e.g., neomycin)

A retrovirus binds to a new host cell by virtue of the interaction of the Env glycoprotein with an appropriate cellular receptor. This interaction triggers a series of events that ultimately lead to the fusion of the lipid envelope surrounding the virus with the target cell membrane. Entry of the retroviral core into the cell allows the reverse transcriptase enzyme to copy the viral RNA genome into a double-stranded DNA provirus, which is then randomly inserted into a host chromosome through the action of the integrase protein. Certain sequences in the RNA genome are essential for packaging, reverse transcription, and integration to occur, and are highlighted in Fig. 2B.

B. Basic Components of Retroviral Vectors

The simplest type of vector system comprises 2 components: a packaging construct that provides all the viral proteins in *trans* but is not itself packaged because of a deletion in the packaging signal (ψ) at the 5′ end of the genome, and a vector genome that codes for no viral proteins but retains all the necessary RNA regions for packaging, reverse transcription, and integration (5). This basic principle of vector design is illustrated in Fig. 3. The gene to be delivered is cloned into the vector genome construct, and in the simplest arrangement uses the 5′ long terminal repeat (LTR) promoter to drive its subsequent expression. When both the vector and packaging constructs are present in a producer cell, retroviral vector particles are released that are capable of delivering the vector genome with its inserted gene. This process of gene delivery is referred to as transduction. Such strategies have been applied to derive vector systems from several different types of retroviruses, including the murine and avian oncoviruses (5,6), human and nonhuman lentiviruses (see Section V.B), and foamy retroviruses (7).

C. Improvements in Vector Design

The basic arrangement described above is functional but unsatisfactory in several ways. In particular, the considerable sequence overlap that exists between the vector and packaging components means that there is a very high risk of recombination occurring that could create an infectious replication-competent retrovirus (RCR) (8). Overlap occurs because extensive sequences of the *gag* gene are retained in the vector to enhance the efficiency of packaging (9), although Gag protein expression itself is prevented by mutation. In addition, early vector systems retained both the 5′ and 3′ LTRs in the packaging construct to provide promoter and polyadenylation sequences. Finally, because most of the early MuLV-based packaging cell lines were established in murine NIH 3T3 cells, the possibility also exists for RCR generation through recombination between vector components and endogenous MuLV-like sequences present in the mouse genome.

To minimize the risk of RCR production, an early improvement in vector design was to split the packaging component, placing the Gag-Pol and Env genes on 2 separate plasmids that could be introduced separately into the packaging cell (10,11) (Fig. 4A). The risk of recombination has been further reduced by the use of heterologous Env proteins that have no homology with the parental virus but are able to be incorporated into the viral particle (a process referred to as pseudotyping), and the use of nonmurine producer cell lines. Finally, it has now been shown for MuLV vectors that the *gag* sequences can be removed from the vector genome without significant loss of packaging efficiency (12).

The problem of the LTR overlap that exists between the vector components has been solved through the use of heterologous promoters and polyadenylation signals in the packaging constructs. This can also have the advantage of enhancing titer (13) because the MuLV LTR promoter will not always drive high-level gene expression in nonmurine producer cell lines. In the vector itself, the LTR sequences can also be significantly deleted. Heterologous promoters, frequently the cytomegalovirus (CMV) immediate-early promoter, have been used to replace the 5′ U3 promoter (13), which is possible because the U3 sequences in the retroviral vector are derived from the 3′ LTR. Even the 3′ U3 sequences can be significantly deleted, as is the case with self-inactivating (SIN) vectors, as long as the sequences necessary for recognition by the integrase protein are retained (14). These features are summarized in Fig. 4B.

Improvements have also been made in the titer [number of colony-forming units (cfu) per milliliter] achieved by retroviral vectors. For example, in stable producer cell lines, vector production can be maximized by linking expression of the Gag-Pol and Env components to selectable markers to facilitate screening for high titer producer cells (15). Titers have also been boosted through the development of transient expression systems, which are capable of producing very high titers during a brief and very active burst of activity in a transiently transfected cell. Typically, these systems rely on the use of a highly transfectable cell line such as 293T cells, com-

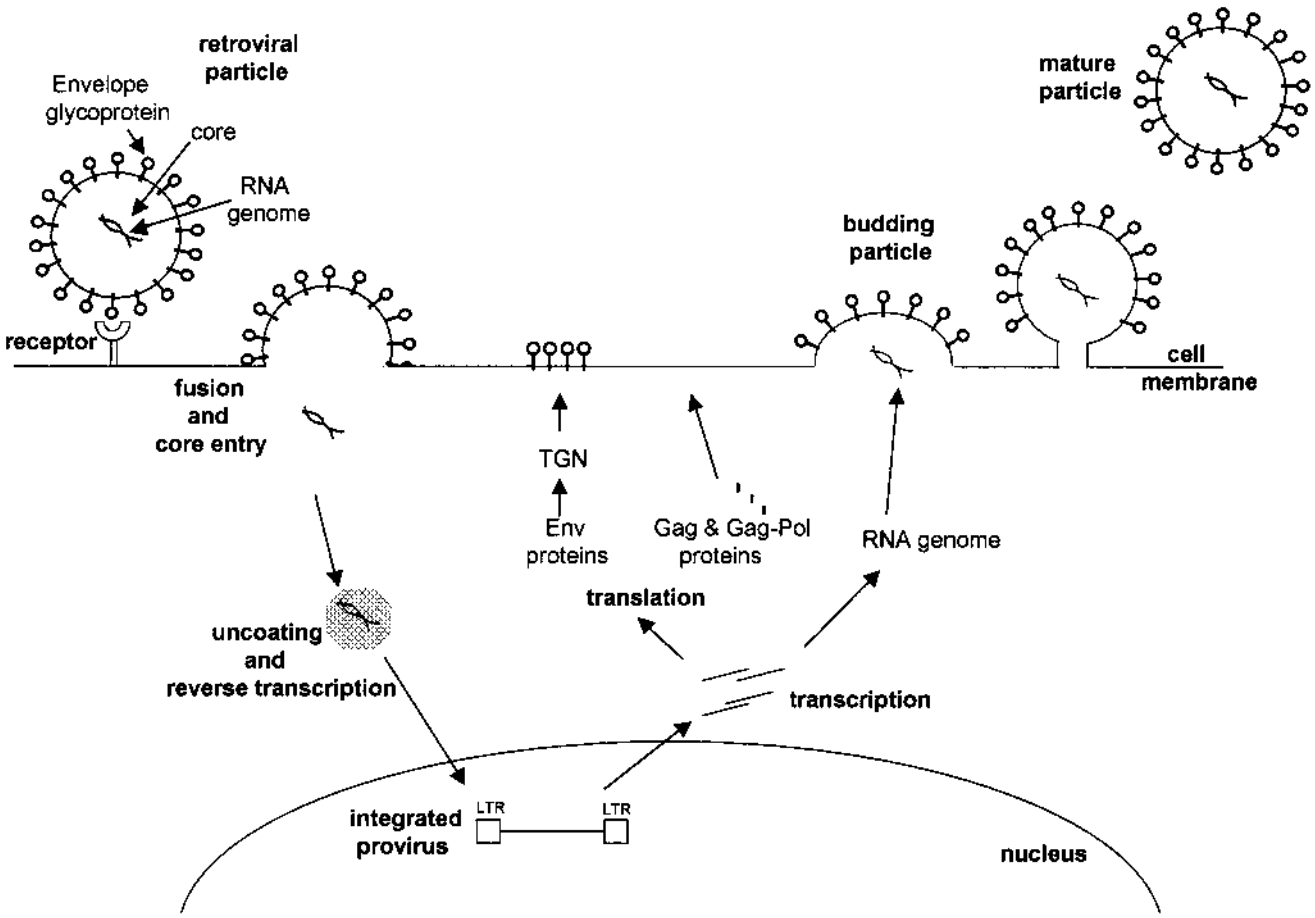

Figure 1 Retroviral life cycle. Retroviral infection is initiated by binding of the envelope glycoprotein embedded in the outer lipid membrane of the retrovirus to a specific cell surface receptor. This interaction triggers fusion between the viral and host cell membranes and releases the viral core into the cytoplasm of the cell. The viral RNA genome is transcribed into a DNA copy by the viral reverse transcriptase protein and is integrated into the host cell chromosome by the action of the integrase protein. The inserted provirus is flanked by complete copies of the LTR sequence, resulting from the reverse transcription process. The 5′ LTR drives transcription of the retroviral genome, which gives rise to RNAs that code for the viral proteins (Gag, Pol, and Env) as well as the viral genome. Gag and Gag-Pol proteins assemble as viral core particles at the plasma membrane and package the viral RNA genome. The particles bud from the surface of the cell, taking with them a lipid envelope derived from the host plasma membrane containing the Env glycoprotein. TGN, trans-Golgi network.

bined with strategies to maximize the production of the individual components through the use of the strong CMV promoter and treatment with the transcription enhancer sodium butyrate (13). We have also shown that titers can be further improved by the inclusion of the adenovirus VAI gene to enhance translation (Lin and Cannon, unpublished data). The combination of these various approaches enables the routine production of vector supernatants in the laboratory with titers in excess of 10^7 cfu/mL. Whether such transient production systems will ever be useful for large-scale production is uncertain because of potential difficulties in the scale-up and vector characterization procedures.

Although currently preferred for large-scale vector production, the use of stable producer cell lines precludes the use of cytotoxic components. These can include both the therapeutic gene product itself as well as components of the vector system. A notable example is the vesicular stomatitis virus G protein (VSV-G), which is an extremely useful fusion protein for producing pseudotyped retroviral vectors with a very broad host range (16), but is unfortunately very toxic to its host cell. One way around this problem is to use transient systems as described above (17), but an alternate strategy is to regulate its expression through use of an inducible promoter. In particular, the tetracycline-regulated Tet system (18) has been exploited to regulate VSV-G (19), where expression is suppressed in the producer cell line by the addition of tetracycline to the culture and activated by removal of the antibiotic at an appropriate time before harvesting the vectors. In this way,

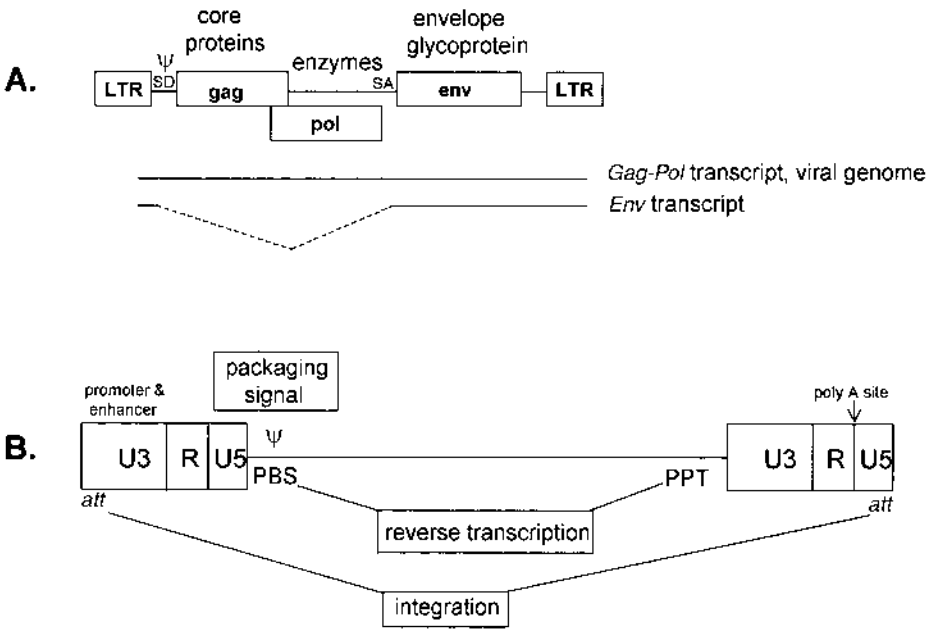

Figure 2 (A) Retroviral proteins. The LTR sequences contain promoter (5′) and polyadenylation (3′) sequences and produce full-length and spliced transcripts. These code for 3 major polyproteins; Gag and Gag-Pol are translated from the full-length transcript and Env is translated from the spliced transcript. The full-length transcript also serves as the RNA genome. SD, splice donor; SA, splice acceptor. (B) RNA sequences. The LTRs consist of three regions, designated U3, R, and U5. The promoter and enhancer sequences are active in the 5′ LTR only and are located in the U3 region, whereas the polyadenylation (poly A) site in the 3′ LTR defines the R/U5 boundary. The primer binding site (PBS) and polypurine tract (PPT) are important for the process of reverse transcription, whereas the *att* sequences at the ends of the LTRs are necessary for integration. At the 5′ region of the genome is a packaging signal (ψ) that is necessary for the incorporation of the genome into viral particles.

the cells can be grown to an optimum density before this toxic fusion protein is expressed. However, although such cell lines are appropriate for laboratory-scale preparation, it is not clear if such a system will be sufficiently stable for industrial production.

As stated in the introduction, retroviral vectors are the most common gene delivery system to have been used in human gene therapy protocols. This is partly for historical reasons; vectors derived from MuLV were the first real vector system to be established and a relatively large amount of information about the performance of such vectors in patients is available. However, their most characteristic feature, the ability to integrate into target cells, can have a downside as well as being advantageous. In the following 2 sections, we review the key properties of retroviral vectors that have made them such attractive gene delivery vehicles and also point out their current limitations and the steps being taken to improve this vector system.

III. ADVANTAGES OF RETROVIRAL VECTORS

A. Fully Defective Vectors

Retroviral vectors represent a truly defective vector system; none of the viral proteins need to be expressed in the target cell for efficient gene transfer to occur and can simply be provided in *trans* in the producer cell. In addition, no *de novo* viral protein synthesis is needed to maintain or repair the integrated provirus. This has implications for long-term gene expression in the transduced cells as even a low-level production of viral proteins will increase the likelihood of an unwanted immune response being triggered against the transduced cells (in addition to any immune response that may be mounted against the transgene itself). Such vector antigenicity is largely responsible for the transient nature of the gene expression seen with current adenoviral vectors, although the problem is being aggressively pursued through the development of helper-dependent or ''gutless'' adenoviral vectors.

B. Vector Integration

A major advantage of retroviral vectors has been that they integrate into the host cell genome. The only other vector system that allows efficient integration is based on adeno-associated virus, reviewed elsewhere in this book. A great deal is known about the process of retroviral integration, which is carried out by the viral integrase protein. Integrase recognizes sequences at the ends of the LTRs of the DNA provirus (the *att* sites, Fig. 2), and inserts the provirus more or less randomly

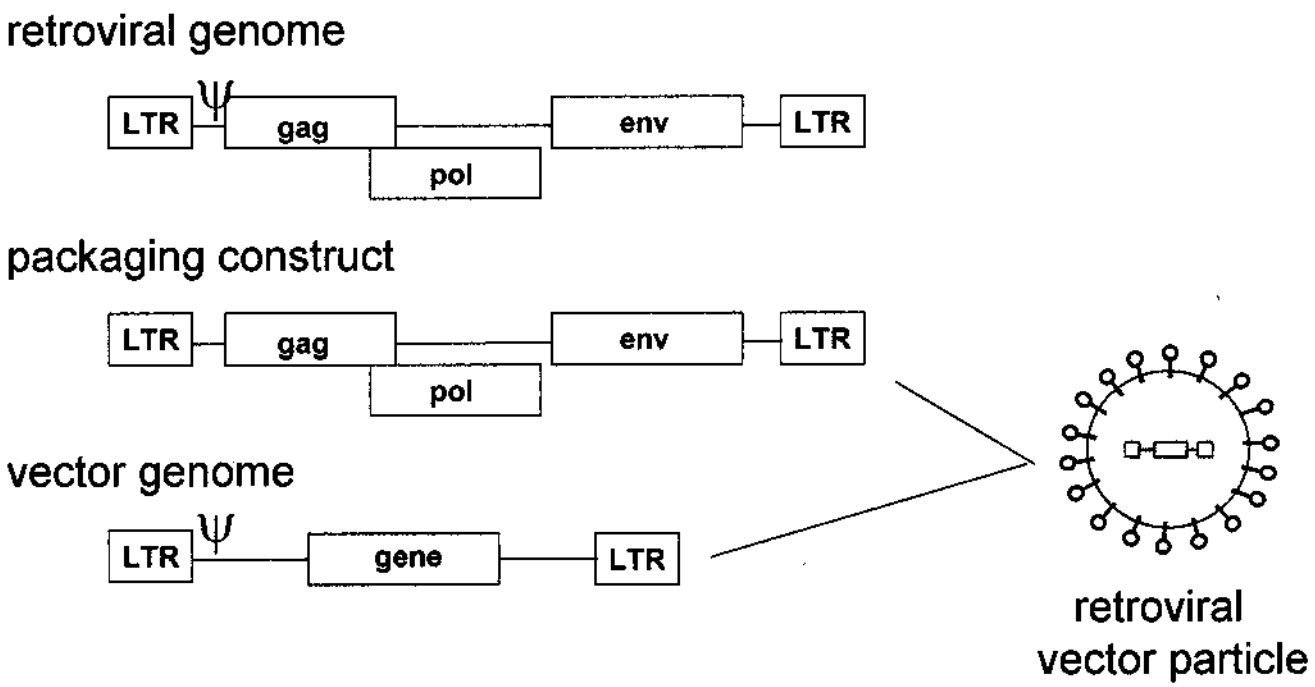

Figure 3 Basic retroviral vector design. The packaging construct provides all the viral proteins in *trans* to the vector genome, which codes for no viral proteins but retains all the necessary *cis* elements. The deletion of the packaging signal from the packaging construct prevents its incorporation into viral particles.

into the host genome, although some sequence preferences have been reported for human immunodeficiency virus-1 (HIV-1) and its vector derivatives (20,21).

The ability of vectors to integrate is a two-edged sword. On the one hand it allows for the possibility of stable long-term gene expression, with the integrated provirus being passed on to all daughter cells. On the other hand, the possibility of insertion into a nonfavorable site also exists, which could influence both the ability of the vector to drive gene expression, and also interfere with the normal functioning of nearby host genes. Most worryingly, the vector insertion event could lead to the activation of an oncogene or inactivation of a tumor suppressor gene, with the risk of subsequent tumor formation. Indeed retroviruses were first identified on the basis of their ability to cause oncogenic transformation, and the possibility of insertional mutagenesis is of great concern. This is discussed in greater detail in Section VII.B.

One possible way around the negative aspects of retroviral integration would be to engineer the integrase protein to direct integration only into certain preselected regions of the host cell genome. The rationale for such an approach is based on the integration site preference exhibited by the related integrase protein of certain yeast transposable elements, such as Ty3, which preferentially integrates upstream of Pol III promoters (22). To date, chimeras between the integrase proteins of Ty3 and MuLV have been shown to be functional, although no redirection of MuLV integration has yet been demonstrated (23).

In a different approach, site-specific integration is being attempted through engineering of the retroviral integrase protein to contain additional DNA targeting domains that will direct the integration complex to specific sites. Some specificity of site selection has been demonstrated in vitro for chimeras containing DNA-binding zinc finger proteins (24), but the ability to redirect integration in vivo has not yet been demonstrated (reviewed in 25).

C. Modularity of Components

The 3 basic components of a retroviral vector—the structural core particle and its enzymes, the envelope-embedded fusion protein, and the vector genome itself—can be viewed as discrete components that in many cases can be ''mixed and matched'' for custom applications. This flexibility enables the exploitation of the natural variations in host range of different viruses and, in some cases, may allow transduction of a cell that is resistant to standard vector combinations. The clearest example is in the use of different envelope proteins to pseudotype the vector particles. For example, when compared with MuLV vectors containing the amphotropic MuLV Env protein, pseudotyping with VSV-G, RD114, 10A1, or gibbon ape leukemia virus (GALV) Env proteins enhances the transduction of primary human hematopoietic cells (26–31).

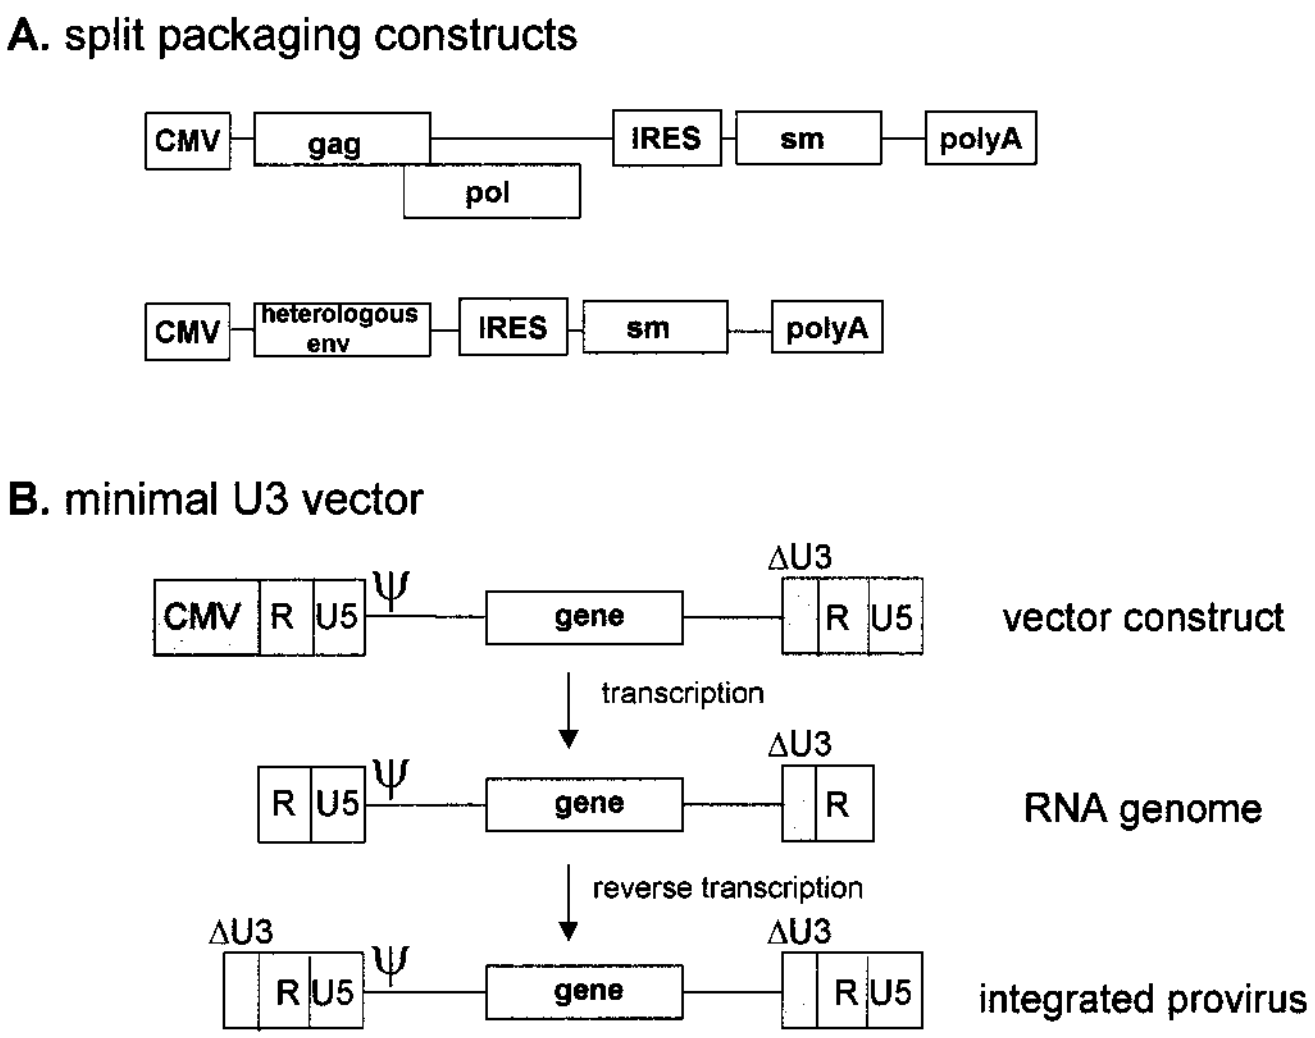

Figure 4 Improvements in vector design. (A) Packaging construct. The Gag-Pol and Env proteins are separated onto 2 different plasmids, and safety is further increased by the use of heterologous envelope proteins. Expression is maximized from the packaging construct through the use of a non-LTR promoter (CMV) and linkage to a selectable marker (sm). (B) Vector construct. The U3 sequences are replaced at the 5′ LTR and minimized in the 3′ LTR. Following reverse transcription, the deleted U3 sequences (ΔU3) are copied into both the 5′ and 3′ LTRs of the provirus. The 5′ LTR therefore has greatly reduced promoter activity. This is the basis of self-inactivating (SIN) vectors.

In addition, different core and vector components can also be used. The combination of GALV cores with MuLV or GALV vector genomes has been reported to enhance the transduction of certain human cell lines (32), and both hybrid retroviral/lentiviral genomes (33) and cores (34) have been constructed that may offer new properties. Finally, the vector LTRs can also be manipulated to improve gene expression in certain cell types. The related myeloproliferative sarcoma virus (MPSV) LTR has been used in place of the MuLV LTR to enhance gene expression in embryonic stem cells (35), and the enhancer elements of the native LTR can be replaced with more specific sequences in order to optimize gene expression in a given host cell (see Section IV.B).

D. Flexibility of Gene Expression Strategies

Because the 5′ retroviral LTR is itself a promoter, the simplest vector design uses the LTR to drive transgene expression (36) (Fig. 5). In addition, the use of heterologous promoters placed internally within the retroviral transcription unit increase the flexibility of gene expression, as constitutive, inducible, or tissue-specific promoters can be included. Expression of more

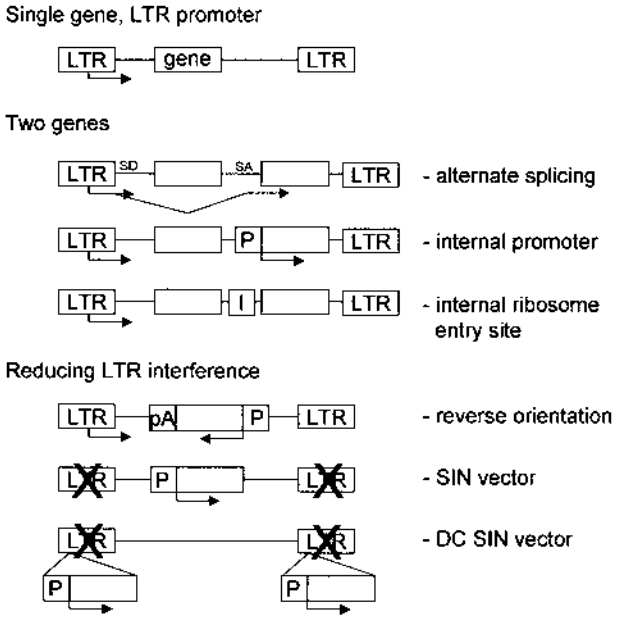

Figure 5 Gene expression from retroviral vectors. Strategies to drive expression of 1 or 2 genes, and to minimize interference by the 5′ LTR promoter. SD, splice donor; SA, splice acceptor; P, promoter; I, internal ribosome entry site; pA, polyA sequences; SIN, self-inactivating; DC, double copy.

than 1 transgene can be achieved through the use of both the LTR and an internal promoter, or by exploiting the differential splicing of the vector that occurs when the major splice acceptor site upstream of the *env* gene is retained (37). In addition, the expression of 2 genes can be linked by the use of an internal ribosome entry site (38).

The transcriptional activity of the LTR can in some cases be a problem, interfering with the activity of internal promoters (promoter interference) (39). These problems can be reduced by the use of SIN vectors, where extensive sequences of the LTR are deleted to effectively silence its promoter. The level of gene expression from integrated vectors can also be increased through the use of double copy vectors (40). Here, the therapeutic gene and its promoter are inserted into the 3′ LTR itself, with the result that after reverse transcription, 2 copies of this expression cassette are created in the provirus.

IV. CURRENT LIMITATIONS OF RETROVIRAL VECTORS

There are several problems investigators face in developing retroviral vectors that will be clinically effective. First, the vector genomes themselves have limited capacity for insertion of foreign sequences, based on the packaging constraints imposed by the viral core proteins; MuLV-based vectors cannot greatly exceed the 8.3-kb size of the MuLV genome. The stability of the engineered vectors can also be a concern. The presence of 2 copies of the vector genome in a viral particle and the process of reverse transcription both contribute to a relatively high level of rearrangement and instability, which is also influenced by the nature of the inserted sequences. The retroviral life cycle and the process of reverse transcription preclude the use of intron-containing sequences in a vector unless the gene is inserted in reverse orientation in the vector, and even with a cDNA copy of a gene, cryptic splice sites can become apparent when the gene is placed inside the retroviral vector.

Major improvements are also required in the overall efficiency of delivery of retroviral vectors. This will involve both the Env-directed entry process and overcoming any postentry blocks to transduction that might occur in specific cells, notably the inability to transduce nondividing cells. Once delivered to a target cell, improvements will be needed in the ability of the vectors to sustain gene expression long term, and for the therapeutic gene and its controlling sequences to respond to appropriate stimuli—be they natural developmental or physiological signals, or regulatory drugs administered to the patient. Finally, cost-effective ways to manufacture the vector at high enough titers will be required, with appropriate assurances of safety.

Specific issues related to the transduction of nondividing cells are dealt with in Section V.B, and manufacturing and safety concerns are discussed in Section VII. Below, we review current attempts to improve the specificity of gene delivery with retroviral vectors and the strategies designed to improve gene expression from those vectors.

A. Obtaining Efficient and Specific Gene Delivery

An ideal retroviral vector is one that could specifically home in on its target cell in the body and limit its transduction to only that type of cell. This would allow the in vivo delivery of the vector and greatly facilitate the clinical procedure for gene therapy. The entry of a retrovirus into a cell is determined in large part by the properties of its envelope glycoprotein and the specificity of the interaction of that protein with its receptor. To some extent, these restrictions can be circumvented by the use of heterologous fusion proteins to pseudotype the vector particles. However, other host range restrictions also exist, including several postentry blocks to transduction. An obvious example of this is the requirement for nuclear membrane breakdown for MuLV entry to the nucleus, but other less well-characterized resistance mechanisms are also present in some cells. For example, certain human cell lines that were poorly transduced by MuLV-based vectors were shown to be more susceptible to transduction by vectors based on GALV (32). In addition, the LTR promoter can also be considered a determinant of tropism and if gene expression is to be driven from that promoter, then its function in a particular cell type will also be an important consideration.

Current clinical protocols for retroviral vectors use an ex vivo approach. Because many of the cells to be transduced

by the vectors express a high level of the natural amphotropic MuLV receptor and are actively dividing at the time of exposure to the vector (either naturally or as a result of culturing conditions), they are relatively easily transduced by MuLV vectors coated with the amphotropic MuLV Env. An important exception at present are primitive hematopoietic stem cells, which are reported to have a low level of the amphotropic receptor and be poorly transducible (41). However, the use of both the GALV and VSV-G fusion proteins has gone some way toward enhancing transduction, as has the use of lentiviral vectors (42,43).

Pseudotyping with natural viral fusion proteins that interact with different cell surface receptors, such as the amphotropic, xenotropic, polytropic, and 10A1 MuLV Env proteins and the GALV and VSV-G proteins, may provide enhanced transduction of a particular cell type ex vivo, but these are all still broad host range proteins that do not provide much specificity. This therefore limits the ability of such vectors to be useful in vivo because introducing the vectors systemically would result in the particles binding to the majority of cells that they encountered and being diluted out before reaching their target cells. The problem can be quantitated. The human body contains approximately 5×10^{13} cells. Using concentrated stocks of retroviral vectors pseuodtyped with VSV-G (which have been reported to give titers of up to 10^9/mL), and infusing 100 mL of such a vector into a patient, would result in the delivery of about 10^{11} active vector particles. Even if every vector particle were 100% efficient, only 1 cell in 500 could possibly be transduced, and this scenario does not take into account the sequestering of the vectors into the first tissue that they come into contact with (typically the lungs), or the inactivation of particles in vivo by both innate immunity and more specific humoral responses. In addition, there will very likely be detrimental side effects resulting from the delivery of the vector to nontarget tissues as a result of the broad host range of the vector. An important step towards the in vivo use of retroviral vectors will clearly be the development of retroviral particles that can preferentially bind to and transduce their target cells and can be manufactured at a high titer.

B. Targeting Retroviral Vectors

Efforts to target retroviral vectors to specific cell types have concentrated largely on engineering natural retroviral envelope proteins, and in particular the rodent cell-specific ecotropic Moloney MuLV protein [reviewed in (44,45)]. Retroviral Env proteins exist as an oligomeric complex (in the case of MuLV Env, probably a trimer), comprising 2 subunits, the surface (SU) protein that contains the receptor recognition domain and the transmembrane (TM) protein that anchors the complex in the retroviral envelope (Fig. 6A). The binding of SU to a specific cell surface receptor is believed to trigger conformational changes in SU and the associated TM protein that result in the exposure of a hydrophobic stretch of amino acids at the N-terminus of TM, the fusion peptide, and the subsequent fusion between viral and host cell membranes (Fig. 6B). The challenge of engineering Env has been to redirect

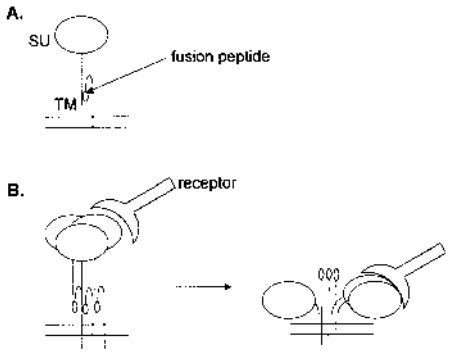

Figure 6 Retroviral Env protein. (A) The Env protein consists of 2 noncovalently linked subunits, the SU protein, which contains the residues that interact with the receptor, and the membrane-anchored TM protein, which promotes the fusion of viral and host cell membranes. At the N-terminus of TM is a stretch of hydrophobic amino acids called the fusion peptide. (B) The retroviral Env protein is oligomeric and MuLV Env probably exists as a trimer. Following binding to its receptor, the Env complex is believed to undergo conformational changes that result in the exposure of the fusion peptide, enabling it to interact with the host cell membrane and initiate the fusion process.

binding of the SU moiety to a heterologous cell surface molecule, while retaining the ability of such an interaction to recapitulate the natural postbinding events that lead to fusion. This has proved a daunting task and, despite early optimism in the field, there have now been numerous reports of failure of targeting strategies with MuLV Env proteins (45–48). Even the few reported success stories appear to be ligand speicifc (49), and a robust and general strategy for targeting MuLV Env proteins has not been forthcoming. The Env protein of spleen necrosis virus may be more amenable to engineering (50,51), although success here also appears to be ligand specific (52)

Two broad approaches have been taken to produce targeted envelope proteins (Fig. 7). First, the natural receptor-binding domain of the SU protein can be replaced with a ligand or single-chain antibody designed to bind to a specific cell surface molecule on the target cell. A whole range of receptors have been targeted in this way, but the difficulty remains that even when specific binding can be obtained between the engineered vector and the target cell receptor, the subsequent fusion event is not triggered and gene transfer is correspondingly low (46,48). It is apparent that engineering the receptor-binding domain of SU to redirect binding while maintaining the ability of the envelope protein to carry out fusion will require a better understanding of the structure–function relationships within the envelope protein complex. The 3-dimensional structure of the receptor-binding domain of the murine ecotropic (Friend strain) SU protein is available (53), and several structure–function studies have delineated various functional domains within MuLV Env that shed light on the pathway of

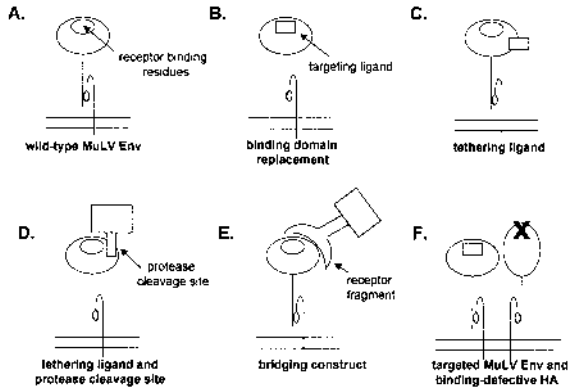

Figure 7 Targeted Env proteins. (A) Wild-type Env protein. (B) Targeting to heterologous receptors: the region of SU that interacts with the natural receptor is replaced by a heterologous binding ligand, such as a small peptide or scFv insert. (C, D) Tethering strategies: the natural receptor-binding interaction is retained, but the vectors are first concentrated on target cells by the action of the additional targeting ligand. In some cases (D), the targeting ligand obscures the natural receptor binding site, which is only revealed after the binding ligand has been removed, for example, by proteolytic cleavage. (E) Bridging strategy: a chimeric protein comprising a soluble receptor and a targeting ligand binds the vector to target cells. The soluble receptor activates the Env protein, allowing fusion to occur with a cell that does not express the natural receptor. (F) Coexpression strategy: receptor binding and fusion functions are separated between 2 different molecules. For example, target cell binding is directed by a chimeric MuLV Env and the fusion component is provided by a binding-defective but fusion-competent influenza HA protein.

signal transmission within the Env protein complex (54–57). Hopefully, such information will allow a more rational approach to engineering retroviral Env proteins in the future.

In a second broad approach to Env targeting that could be called ''tethering,'' the interaction with the native receptor is maintained so that entry occurs through the natural route, but the vectors are concentrated on certain cell types or at certain sites by the presence of an additional binding moiety. The insertion of a collagen-binding ligand into the ecotropic MuLV Env protein, for example, did not perturb the ability of the protein to transduce rodent cells but did allow an effective concentration of the vector at sites of collagen deposition (58). More recently, incorporating this targeting motif into amphotropic (human cell tropic) MuLv Env proteins has resulted in enhanced gene delivery to sites of wound healing following balloon angioplasty, and allowed in vivo gene delivery to human cancer xenografts in nude mice following systemic administration (59).

A different strategy to concentrate vectors on cells expressing the epidermal growth factor (EGF) receptor has been reported that uses a chimeric MuLV Env protein where the natural receptor-binding site is initially blocked by an EGF moiety (60). Following binding to the EGF receptor-expressing cells, the EGF ligand is removed by the action of a protease (envisioned to be present on the cell surface and which can therefore be made cell specific). This cleavage event frees the Env protein to interact with its natural receptor and to subsequently enter the cells. Such a strategy seems particularly suited to cancer cell targeting.

Recently, ''bridging constructs'' have been described for the Env protein from avian leukosis virus (ALV) that combine an EGF targeting domain with the extracellular domain of the ALV receptor (61). These hybrid proteins can be preloaded onto ALV Env pseudotyped vectors and can subsequently ''bridge'' them to target cells expressing the EGF receptor (62). The interaction of the receptor fragment with Env protein triggers the normal fusion process, thereby allowing entry of the vector to the EGF receptor-expressing target cells in the absence of the natural receptor. The success of this system appears to be the result of 2 fortuitous properties of the ALV entry process: (1) the receptor is a single membrane-spanning protein that is amenable to engineering as a soluble domain, and (2) the ALV Env is triggered to induce virus–cell fusion in a 2-stage process, requiring both receptor binding to prime the Env and low pH exposure during endocytosis to complete the process (63).

Finally, in a strategy mimicking the 2-protein approach used by several enveloped viruses, notably the paramyxoviruses, it is possible to combine 2 different moieties on a retroviral vector particle—a targeting protein to bind the vectors to specific cells and a fusion protein that will then promote entry (64). Using a modified influenza hemagglutinin (HA) protein that is no longer capable of binding to its native receptor, the ubiquitously expressed sialic acid (65), we have demonstrated enhanced entry into Flt-3-expressing cells when this HA is coexpressed with a binding-competent but fusion-defective MuLV Env containing the Flt-3 ligand (66).

C. Sustaining and Regulating Gene Expression

Assuming that efficient gene transfer strategies can be developed, the next issue to be addressed is how to maintain an appropriate level of gene expression. With their ability to integrate into host cell chromosomes and therefore be passed on to daughter cells, retroviral vectors have clear advantages as a delivery system when lifelong gene expression is required. However, maintaining gene expression from an integrated provirus has proved problematic in the past. This is perhaps the largest shortcoming of all present vector systems. Because sustaining gene expression in the target cell is not just a problem facing retroviruses, much of the following discussion applies to gene transfer vectors of all types.

Several factors are involved in maintaining the stable expression of genes after their transfer, which can be broadly divided into two categories. The first set concern the activity of the promoter and regulatory sequences themselves. De-

pending on the site of integration of the vector, host mechanisms may suppress (or inappropriately activate) expression from a promoter, and even if gene expression is initially high, it is frequently not sustained long term. There is a tendency for the cell to recognize foreign promoters (particularly viral promoters such as SV40 and CMV) and inactivate them—for example, by methylation—and the retroviral LTR promoter is subject to suppression, particularly in embryonic cells, although strategies have been developed to reduce this problem (35).

The second mechanism that causes loss of gene activity is due to the fact that, even if gene expression remains active, the transduced cell often loses viability. The body can recognize as foreign a therapeutic gene product and can mount an immune response that will eventually eliminate the gene-engineered cells. Even a normal human protein appears abnormal to an immune system that has never been exposed to it.

The problems identified with the use of constitutive viral promoters in vectors have led to recent attempts to use more authentic regulatory sequences to direct gene expression. The use of a gene's own promoter and regulatory sequences may provide more stable long-term gene expression than can be obtained with current viral promoters, but identifying all the necessary components can be difficult. As an extreme case, the regulatory sequences involved in β-globin expression are spread over nearly 100 kb, and because a retroviral vector can only accommodate 6–8 kb, the minimal functional regulatory sequences need to be identified.

Alternatively, certain key elements can be included in the LTR region to provide a measure of cell-specific expression, as has been demonstrated by the insertion of a minimal tyrosinase promoter into the MuLV U3 region that results in melanoma-specific gene expression (67,68). The use of cell-specific gene expression is likely to be an alternative or supplemental approach to targeting at the cell entry stage, because even if the entry of a vector cannot be restricted to the desired target cell population, its subsequent gene expression could.

Finally, the use of authentic genomic elements in retroviral vectors also holds promise for improving gene expression strategies. Chromosome remodeling sequences such as scaffold attachment regions (69), locus control regions (LCR) (70), and insulator sequences (71) may promote stable gene expression whatever the integration site of the vector. In addition, such elements may reduce possible deleterious effects of the vector transcriptional unit on neighboring host genes. We have recently shown that the ADA LCR and promoter can specifically enhance gene expression from retroviral vectors in T lymphocytes (Ball and Anderson, unpublished data).

An additional factor that can influence gene expression is the environment of the host cell being used to express the therapeutic gene. Even when natural regulatory elements are used, they may not function out of context in a different cellular environment. For example, the insulin enhancer/promoter still cannot direct regulated expression of that protein when expressed in fibroblasts. This highlights further the need to develop vectors that are capable of gene transfer to specific cell types.

Although in some gene therapy scenarios, low levels of essentially unregulated expression may be appropriate (e.g., hemophilia, ADA deficiency), for other situations, regulatable gene expression will be desirable. Many of our important genes are not expressed at the same level all the time, but respond to physiological signals within the body. One approach will be to use regulatory sequences that respond to the body's own physiological signals in the vector, so that the therapeutic gene will function in the same way as normal endogenous genes. However, if knowledge of such signals and the corresponding DNA sequences is insufficient to attempt such a strategy, alternate synthetic gene regulation systems could be used where drugs could be administered to control gene expression, such as with the Tet system (72).

D. Integration and the Risk of Insertional Mutagenesis

The potential for a deleterious outcome following retroviral vector insertion has always been acknowledged. Before 2002, the only example of unintentional tumor production in a retroviral gene transfer experiment in large animals occurred when 3 cases of lymphoma were reported among 10 Rhesus monkeys that had received myeloablative irradiation and then been transplanted with hematopoietic stem cells that had been exposed to a large number of RCR, together with the experimental vector. Subsequent analyses revealed that the cancers resulted from integration of an RCR (not the original retroviral vector), were clonal events, and developed only after long periods (6–7 months) of retroviremia (73,74). In addition, analysis of vector integration sites in 1 of the original 2 ADA patients (A.D.), 10 years after she received 11 separate infusions of retroviral vector-transduced peripheral blood lymphocytes, revealed polyclonal integrations sites, even in a subset of T cells that appeared to have expanded in vivo since that time (3).

However, the news that two children treated in a French gene therapy trial for severe combined immunodeficiency (SCID)-XI (75) has developed leukemia is a worrying development. Furthermore, the integration site of the vector in the leukemic cells are near a known oncogene, LMO2. This is a very clear demonstration of the risk inherent in using integrating vectors.

V. DIVIDING AND NONDIVIDING CELLULAR TARGETS

MuLV, and the vectors derived from it, are only able to infect dividing cells. This is because the preintegration nucleoprotein complex is unable to cross an intact nuclear membrane. In contrast, the prototypical lentivirus HIV-1 has been shown capable of nuclear import even when an intact membrane exists, and HIV-1-derived lentiviral vectors are therefore able to transduce nondividing cells (76). This property of HIV vectors

makes them particularly attractive candidates for gene therapy when the target cell is nondividing and stable integration of the transgene is required. However, as outlined below, the restricted tropism of MuLV for dividing cells can also be used to advantage, limiting transduction to dividing cells such as tumor cells.

A. Tropism for Dividing Cells in Cancer Gene Therapy

The selectivity of MuLV for dividing cells has been exploited in a phase III clinical trial that tested the efficacy of a suicide gene therapy approach to treating glioblastoma multiforma, a malignant brain tumor (77). The rationale of such gene therapies is to insert a gene capable of killing cells into the tumor while protecting the normal brain cells. The vector contains the herpes simplex thymidine kinase (TK) gene, which is able to phosphorylate the drug ganciclovir, resulting in a toxic derivative that is incorporated into DNA. The vector is produced in situ in the residual tumor and peritumor areas, following surgical resection of the tumor, by the injection of a mouse producer cell line that generates the retroviral particles. Although both tumor cells and healthy cells in the area of a growing brain tumor could potentially be transduced, only the tumor cells themselves and the vasculature supplying blood to the tumor are considered likely targets as they will be actively dividing. Tumor killing is achieved by giving the drug ganciclovir to the patient; the TK enzyme converts this to a toxic nucleotide that is incorporated into the DNA of the tumor cells, so killing them. However, despite the encouraging preclinical data (78), this trial has now been suspended due to lack of benefit in the gene therapy-treated patients (79).

B. Lentiviral Vectors Transduce Nondividing Cells

There are many situations where one would want to insert a therapeutic gene into normal nondividing cells. In vivo, only certain blood cells and the cells lining the gastrointestinal system are continually in division, so the majority of potential target cells in the human body are nondividing. Lentiviruses such as HIV-1 are able to infect nondividing cells and the demonstration that HIV vectors could also transduce such cells has been an exciting development in retroviral vector technology (76). The mechanism whereby HIV can infect nondividing cells remains somewhat controversial, but there appears to be more than one mechanism involved in making the HIV preintegration complex karyophilic (80–82). Attempts to transfer into murine retroviral vectors the specific signals from the HIV virus that allow transduction of nondividing cells have not been successful (34), underlying the complexity of the process, although the creation of a nuclear localization signal in the matrix protein of SNV has been reported to increase transduction of growth-arrested canine cells (88).

Vectors constructed from lentiviruses, and HIV in particular, raise safety concerns because of the possibility of a pathogenic RCR arising by recombination. Recently constructed HIV-based vectors contain less than 5% of the HIV genome and do not express any viral proteins. Furthermore, non-HIV envelope proteins such as VSV-G are used to pseudotype the vectors. The safety of such systems is constantly being improved, for example, by the development of CMV-driven SIN vectors (89), or minimal packaging constructs with all the nonessential genes removed (90). Much is known about the pathogenicity of HIV and removal of these genes from a vector would, in theory, produce a crippled RCR, even if one did arise. Finally, vector systems based on nonprimate lentiviruses such as feline immunodeficiency virus and equine infectious anemia virus are also being developed (reviewed in Ref. 91).

VI. NEW APPROACHES

Several new gene transfer systems based on retroviral vectors are currently being developed. As reviewed elsewhere in this book, lentiviral vectors, which have the ability to infect nondividing cells, are an exciting new development. In addition, novel approaches to overcome certain deficiencies in retroviral gene delivery are being taken. For example, hybrid vector systems have been created using adenoviral vectors or herpes simplex virus amplicons as carrier systems to deliver the components of a retroviral packaging system. The principle is that the ''first-stage'' vector system will achieve efficient delivery of the retroviral packaging system to target cells (or in close proximity), with these initial cells then acting as a reservoir to produce retroviral vector particles in situ. Subsequent ''second-stage'' transduction by the retroviral vectors will result in both amplification of the first-stage vector titer and stable integration of the transgene. Recently, complete 2-stage vector systems have been incorporated into single molecule vectors, such as herpes-Epstein Barr amplicons and helper-dependent adenoviral vectors (83–85).

Another new development in the use of retroviral vectors is the use of conditionally replicating retroviruses. Such vectors are being developed to carry suicide genes and are envisioned to have utility for cancer gene therapy, where efficient replication and spread of the virus throughout the tumor will be allowed to occur before treatment with the appropriate prodrug. Improved stability of MuLV viruses carrying exogenous genes through judicious choice of insertion site and transgene has recently been demonstrated (86), and virus replication may be further restricted to the tumor cells through replacement of the permissive U3 promoter/enhancer with tumor-specific elements. For example, restricted replication in prostate cancer cell lines has been demonstrated for a green fluorescent protein (GFP)-expressing MuLV with a chimeric LTR containing the androgen-responsive region from the highly prostate-specific probasin promoter (87).

VII. RETROVIRAL VECTORS AS PHARMACEUTICALS

A. Manufacturing Considerations

Although any consideration of how pharmaceutical companies would be able to manufacture gene therapy vectors was an

irrelevant concern in the 1990s, this has now become a real issue. Retroviral vectors are biological agents that can only be made by living cells, and such systems are not easy for carrying out good manufacturing practice and quality assurance/quality control (QA/QC) assays. Furthermore, the large-scale production of retroviral vectors requires the establishment of producer cell lines that maintain a stable arrangement of vector sequences and sufficiently high vector production levels during the procedure. In addition, the subsequent purification of vectors from the supernatant of producer cells is a relatively cumbersome procedure and some loss of titer is inevitable. For vectors pseudotyped with the amphotropic MuLV Env, much of the loss of activity is due to the relative lability of the Env protein (the 2 subunits are noncovalently attached and can dissociate under conditions of sheer stress). In part, this problem could be countered by the use of a single polypeptide fusion protein such as VSV-G, although the inherent cytotoxicity of this protein makes the use of stable producer cell lines difficult (see Section II.C).

B. Safety Considerations

Currently, the 2 most significant concerns for the use of retroviral vectors in humans stem from the possibility of an RCR arising, or insertional mutagenesis leading to tumor formation. RCR formation can occur during the manufacturing process (which can be screened for) (92), or in the patient following vector administration. Such a virus could result from recombination between the vector and packaging components in the producer cells, even with split packaging cell lines (93), or be due to the acquisition of sequences from endogenous retroviruses. Essentially all mammalian cells have their own endogenous retroviruses that could potentially recombine with the vector to produce a new and possibly pathogenic RCR, and many of these endogenous viruses are still unknown. Although any cell line is suspect, the use of primate or human cells as packaging cells raises the greatest safety concerns in this regard. There is no way to predict the pathogenicity of such potential recombinants, and it would be naive to assume that nonnatural combinations of viral components will not be infectious. For example, it has been demonstrated that if the use of an simian immunodeficiency virus (SIV)-based vector pseudotyped with the amphotropic MuLV Env protein gave rise to an RCR, such a chimeric virus could indeed replicate in vivo in monkeys (94).

The subjects of RCR production, safety, and potential tumor induction were extensively analyzed in a report to the National Institutes of Health recombinant DNA advisory committee (NIH RAC) and the Food and Drug Administration (FDA) (95). The report concluded that the QA/QC procedures required by the FDA make it unlikely that any patient could receive sufficient RCR to be pathogenic. However, the manufacturing and testing processes required to ensure this degree of safety are complex and expensive.

As already discussed, a major concern for the use of retroviral vectors is the possibility of insertional mutagenesis. In response to the serious adverse events in the SCID-XI trial in France, clinical trials with retroviral vectors in the US have been put on clinical hold. Until more is known, it is unclear how significant this risk will be, and whether the use of these vectors for life-threatening diseases with no therapeutic alternatives will still be warranted.

C. In Vivo Use

A major goal of present research in retroviral vector development is the production of a gene therapy vector that could be injected directly into the body. Such in vivo use poses additional problems that must be considered. For example, mouse packaging cells produce retroviral vectors that are rapidly destroyed by human complement, markedly reducing their half-life in vivo and the overall efficiency of gene transfer. The major component of this sensitivity arises from the presence of unique sugar groups on the glycoproteins produced in the murine packaging cells (96). However, such an acute problem can be overcome by the use of other, including human, producer cell lines (97). A humoral immune response against the retroviral vector particles themselves and components of the vector supernatant may also occur. Muul et al. (3) reported persistent antibodies in 1 of the original ADA patients against both fetal calf serum and the MuLV core and Env proteins. Antivector antibodies are a concern when repeat administrations are required, although the problem of preexisting immunity that is seen with adenoviral vectors should not occur with current retroviral vector systems.

VIII. CLINICAL TRIALS

A. Strategies for Gene Delivery in Clinical Applications

There are three categories of somatic cell gene therapy (Table 2). The first and most common is ex vivo, where cells are removed from the body, incubated with a vector, and then returned to the body. This procedure is usually done with blood cells because they are the easiest to remove and return. The second category is in situ, where the vector or a producer cell line is placed directly into the tissues to be transduced. Examples of this include direct injection into tumors, or delivery of vectors into the bronchi for cystic fibrosis therapy. The third category is in vivo, where a vector would be injected directly into the bloodstream but subsequent transduction (or expression) would be restricted to a limited cell population. Although no patients have yet been treated, a clinical protocol has been approved for such a therapy for metastatic colon cancer in the liver, using collagen-targeted retroviral vectors expressing a transdominant cyclin G1 protein (98).

B. Summary of Current Clinical Trials

Currently, there are over 600 approved clinical protocols worldwide. Detailed information is available from the RAC on the 545 protocols that were approved in the US as of the end of 2002, and helpful statistical summaries are available on the website of the Journal of Gene Medicine (http://www.wiley.co.uk/genetherapy/clinical/). The original ADA

Table 2 Gene Delivery Strategies

1. Ex vivo
Cells are removed from body and incubated with vector; engineered cells are then returned (e.g., T lymphocytes for anti-HIV therapy)
2. In situ
Vector or producer cells are placed directly into the tissues to be transduced (e.g., TK vectors in brain tumors)
3. In vivo
Vector would be directly injected into the bloodstream and would home in on its target cells (no examples yet)

deficiency gene therapy trial (2) was begun in 1990, giving gene-corrected autologous T lymphocytes to 2 girls suffering from this disease. ADA deficiency is a rare genetic disorder that produces severe immunodeficiency in children. Patient 1 (A.D.) received a total of 11 infusions, the last being in the summer of 1992. Her total T cell level and her level of transduced T cells have remained essentially constant since then, at approximately 20% and at considerably higher levels than patient 2 (C.C.) (<0.01%). Due to differences in cell harvest and transduction efficiencies, patient 1 received greater than 2 logs more vector-transduced cells than patient 2, who also developed persisting antibodies against components of the gene transfer system. These 2 factors likely resulted in the large discrepancy in the frequency of modified T cells seen in the 2 patients. Although patient 1 in particular may have benefited from gene therapy, because both patients continue to receive PEG-ADA treatment in addition to their gene therapy treatments, no final conclusion can be drawn as to the relative roles of PEG-ADA and gene therapy in their excellent clinical course. More recently, Aiuti et al. (99) reported successful results for ADA gene therapy following transduction of hematopoietic stem cells (HSC) without PEG-ADA treatment.

Only 1 large phase III clinical trial using retroviral vectors has been conducted for the treatment of glioblastoma multiforma. This approach was based on the in situ production of amphotropic retroviral vectors expressing TK from a mouse producer cell line, inoculated into the residual tumor and surrounding areas following tumor resection. The phase III trial included a total of more than 40 centers in North America and Europe and was scheduled to enroll a total of 250 patients, but has been abandoned due to lack of therapeutic effect (79).

In 2000, great excitement was generated by the announcement from Alain Fischer's group in France that gene therapy had been used to effectively cure patients undergoing gene therapy for SCID-XI (75). This is an X-linked disorder where the γc cytokine receptor subunit is missing, and is characterized by early blocks in T and NK cell development. The vector used was based on MFG, expressing the γc subunit under the control of the vector LTR. However, great concern has now been raised by the announcement that two patients have developed leukemia. At the present time, gene therapy trials in the U.S. using retroviral vectors are on clinical hold.

IX. CONCLUSIONS AND FUTURE PROSPECTS

To date, retroviral vectors have been the most commonly used gene delivery vehicle in human gene therapy protocols. The simplicity of their design, their broad host range and their ability to integrate into a cell's genome are responsible for their popularity. As with any viral vector system, the potential for RCR formation remains a concern, even with the latest vector designs, but assays are in place to detect such recombinants and guidelines for the production of clinical grade vectors are well established. The risk of insertional mutagenesis is recognized as a downside of their ability to integrate, and highlights the fact that this therapy should be used only in cases where the benefits outweigh the risks.

Adenovirus Vectors for Gene Therapy

Neil R. Hackett and Ronald G. Crystal
Weill Medical College of Cornell University
New York, New York, U.S.A.

I. INTRODUCTION

The emergence of recombinant DNA as a tool to study medicine quickly promulgated the concept of cloned genes as therapeutics. As originally conceived, the concept of gene therapy was simply to introduce a wild-type copy of a deficient gene into cells to restore function *in trans* (1–4). Viewed in this way, the technical challenge was to efficiently deliver the gene to the appropriate cell and have it expressed for sufficient time, or readminister as often as needed, for the therapeutic application. Adenovirus (Ad) gene transfer vectors offer one strategy to achieve this. The focus on Ad for gene transfer was based on basic research establishing the biology of Ad, and the knowledge that Ad efficiently delivers the viral genome to the target cells. Importantly, Ad are not oncogenic in humans, the genomes of common Ad are completely defined, the Ad genome can be easily modified, and recombinant Ad can be readily produced in large quantities and highly concentrated without modifying the ability of the virus to infect cells.

In retrospect, the original goal of using Ad as simple delivery systems to permanently complement genetic defects seems naive. Whereas Ad gene transfer vectors can achieve robust expression of the transgene in many target organs, expression of the transgene is limited in time, resulting from a complex combination of innate and adaptive immune host defenses against the virus (5,6). In this context, Ad vectors in their present form are most useful in applications where transient (days to weeks) expression is sufficient to have the desired therapeutic effect. For applications where persistent expression is required to achieve a therapeutic goal, there are still many challenges before and if Ad vectors will be successful. In this chapter, we summarize the biology of Ad, the construction and use of first-generation Ad vectors, the current status of advanced forms of Ad vectors, clinical applications of Ad vectors, and the future prospects of using Ad in gene transfer applications.

II. BIOLOGY OF ADENOVIRUSES

Adenoviruses are a group of double-stranded DNA viruses that infect a variety of vertebrate hosts, including rodents, chickens and primates. Human Ad have been isolated from several sources including the upper respiratory tracts of military recruits with respiratory infections, adenoids, conjunctiva, and the stool of infants with diarrhea (7). As with other viruses, there is an immune response to Ad infection that includes the production of neutralizing antibodies, defined as antibodies which prevent Ad infection in vitro. Neutralizing sera have been used to distinguish 49 different adenovirus serotypes, which are divided into subgroups A through E (8). The presence of antibodies against one serotype generally protects against reinfection by the same serotype. In the context of gene therapy, serotypes 5 and 2 of the subgroup C have been used most because their structure and biology is well described and there are convenient biological reagents available to produce recombinant subgroup C Ad gene transfer vectors in large quantities. Adenoviruses of subgroups C cause various respiratory infections either as outbreaks in confined groups (e.g., military recruits) or children, which are sometimes associated with conjunctival infections (9). The known predilection of subgroup C in the respiratory tract led to the initial uses of Ad gene therapy for the treatment of cystic fibrosis, and thus the focus on serotypes 2 and 5.

A. Structure

Adenovirus consists of an icosahedral protein capsid of approximately 70–100 nm diameter and, within that capsid,

a single copy of a double-stranded DNA molecule of length approximately 36,000 bp [Fig. 1; reviewed in (10)]. In the context of gene therapy, the fiber, penton base, and hexon are the most important capsid proteins. The 20 triangular faces of the viral capsid are built from hexon, the major capsid protein. The 240 hexon capsomeres in the capsid are each trimers comprising 3 copies of the 105-kDa hexon subunit, with each trimer interacting with 6 others in a pseudoequivalent fashion. The 3-dimensional structure of hexon shows that the homotrimer has loops that project from the capsid surface (11). Capsid proteins VI, VIII, and IX are associated with hexon, and their role is to stabilize the capsid structure. The 12 capsid vertices are made up of the penton capsomere, a complex of 5 copies of the penton base, and 3 copies of fiber. Each penton capsomere interacts with 5 hexon capsomeres, 1 from each of the 5 faces that converge at the vertex. The fiber protein projects outward from the penton base. The DNA is wrapped in the histone-like core protein VII, and there is a terminal protein attached to the 5′ end of each DNA strand.

Neutralizing antibodies are directed primarily against epitopes located on the loops of the hexon. This is expected, as the loops project from the surface of the virus where they are accessible to antibodies. When the primary structures of the capsids of different serotypes are compared, related Ad differ most in these loops, suggesting the selective pressures applied by the immune system result in the emergence of mutations in the external hexon loops (12).

The fiber protein is a trimer consisting of 3 domains: the base, shaft, and knob. The N-terminal base domain interacts with the penton base. The shaft includes an extended domain consisting of variable numbers of a 15 amino acid pseudorepeat. The number of repeats, and therefore the length of the shaft, varies between 23 copies for the group A viruses and 6 copies for the subgroup B viruses. The distal C-terminal domain of the fiber protein, referred to as the ''knob,'' interacts with the high-affinity receptor on the surface of the target cell. The high-affinity receptor for adenoviruses except those of subgroup B is referred to as CAR (coxsackie-adenovirus receptor), reflecting the fact that the coxsackie B viruses and most serotypes of Ad share the same receptor (13,14). CAR is a single membrane-spanning protein with two extracellular immunoglobulin-like domains. Apart from acting as a virus receptor, the function of CAR is unknown.

A sequence motif on the penton base is involved in internalization of the virus after high-affinity CAR–fiber interaction. In serotypes 2 and 5 the amino acid motif arginine-glycine-aspartate (RGD) interacts with $\alpha_V\beta_3$ and $\alpha_V\beta_5$ integrins of the cell surface, and this interaction is essential for efficient internalization (15).

For adenovirus type 5, the most commonly used Ad for gene transfer vectors, the complete 35,935 bp DNA sequence is known. For convenient reference, the genome is divided into 100 equally sized map units. A detailed transcription map at various time points postinfection is used to divide the genome into interspersed early (E) and late (L) regions [Fig. 2; reviewed in (10)]. There is considerable transcriptional overlap among the genes, making manipulation of some areas of the genome difficult. Each of the 5 early genes is comprised of a complex transcription unit with alternative sites for transcription initiation, termination, and

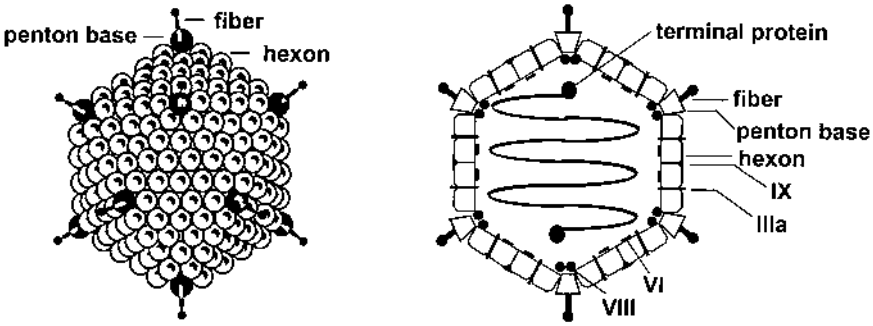

Figure 1 Structure of the adenovirus capsid. Shown (left) is a 3-dimensional representation and (right) a simplified cross-section of the capsid showing the deployment of the capsid proteins and Ad genome. The capsid is an icosahedron with 20 faces and 12 vertices. The faces are composed of hexons, each comprised of trimers of the hexon protein. The hexons are trapezoid shaped, with three loops on top, extending from the face of the capsid. The loops represent the variable regions that differ among serotypes and are the major epitopes for neutralizing antibodies. Proteins IX and VIII are associated with the hexon and are believed to stabilize the capsid. The vertices are composed of a fiber and penton base. The fiber has 3 domains: the base that interacts with penton, the shaft, and the knob. The knob interacts with a high-affinity receptor on the target cell and the shaft holds the virus away from the surface of the cell, depending on the length of the shaft. The penton base interacts with the hexon and the fiber, and contains epitopes that interacts with integrins on the cell surface. The 36-kb double-stranded DNA genome is wrapped around capsid core protein VII and the terminal protein is attached to the two 5′ ends of the Ad genome. (Adapted from Ref. 10.)

splicing. The E1A and E1B genes are transcribed rightward at the left-hand end of the genome close to the DNA replication origin and DNA packaging signal. The E4 region is transcribed leftward at the right-hand end of the genome. Distal to the E1 and E4 regions are the termini of the DNA, which are inverted copies of the same sequence. Replication of the ends of the DNA is achieved by the attachment of terminal protein to the 5′ end of the DNA, which acts as a primer to initiate unidirectional replication. This terminal protein is one of the components of the E2 transcriptional unit, which is transcribed leftward commencing at map unit 75. The remaining early transcription unit is the E3 gene, which is transcribed rightward commencing at map unit 77.

The 5 late genes are expressed after the beginning of DNA replication and encode the viral structural proteins. These late transcripts are all transcribed rightward originating from map unit 17 and contain the same 3-part leader sequence before alternate splicing generates different mature mRNAs.

B. Viral Replication

The Ad viral life cycle is understood best for subgroup C, which is another factor in the choice of Ad5 and 2 as gene therapy vectors (Fig. 3). The knob of the fiber protein binds to the CAR receptor (13), followed by an interaction of the RGD sequence in the penton base with cell surface $\alpha_V\beta_3$ or $\alpha_V\beta_5$ integrins (15). Excess soluble integrins inhibit Ad internalization but not binding, suggesting that penton base–integrin interaction is instrumental in internalization (16). Ad modified with deletion of the RGD motif replicate effectively in vitro so the penton base–integrin interaction is likely related to efficiency of Ad infection, but is not essential (17). The Ad enters the cell by endocytosis into clathrin-coated pits, a process that can be blocked by dynamin inhibitors (18). After endocytosis, Ad is very rapidly released into the cytoplasm prior to extensive endosome fusion. The virus proceeds rapidly to the nucleus, probably actively transported on microtubules using the dynein motor (19), and then binds to the surface of the nucleus near the nuclear pore (20). Using fluorescent viruses, this process has been shown to be efficient and rapid, with >90% of Ad5 delivered to the nucleus within 1 hr (21). At the nuclear membrane, the DNA and terminal protein are internalized by an unknown mechanism, and are assembled into the nuclear scaffold for active transcription.

With wild-type Ad, the viral E1A gene is transcribed immediately after infection (10). After alternate splicing, the E1 mRNAs are translated into the two E1A proteins

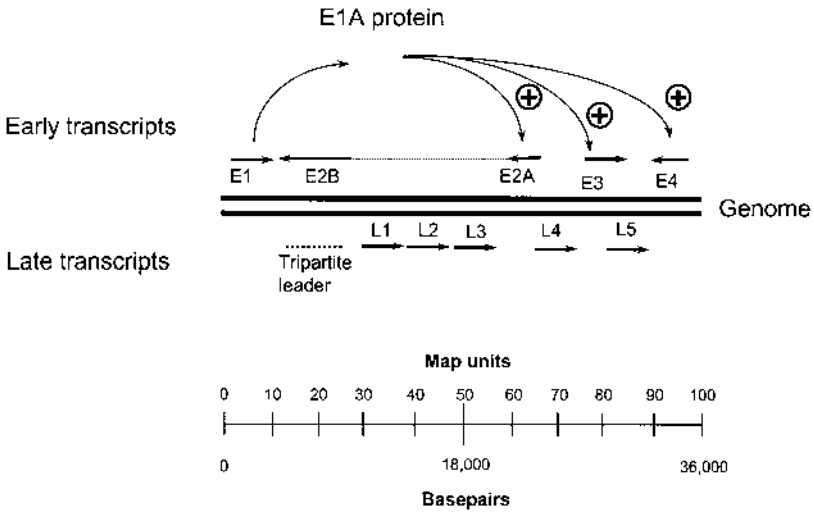

Figure 2 Structure and transcription of the major genes of the adenovirus type 5 genome. Schematic summary of the transcription of adenovirus during lytic infection. The genome is represented as 2 parallel lines and is divided by the scale shown on top into 100 map units (1 map unit = 360 bp). There are 9 major complex transcription units divided into early (above the genome) and late transcripts (below). The 4 early transcripts are produced before the commencement of DNA replication and specify regulatory proteins and proteins required for DNA replication. Upon initial infection of a cell, the E1A protein is produced from transcripts in the E1 region. E1A is a major regulatory factor required for transcription of E1B, E2, E3, and E4. In replication-deficient adenovirus vectors, the E1 region is deleted. Proteins coded by the E2 and E4 regions are required for late gene transcription. The E3 region codes for proteins that help the virus to evade host defenses. All late transcripts rightward originate at the same point and are produced by alternate splicing. The tripartite leader sequence is present at the 5′ end of all late transcripts. The L3 region specifies hexon, the L5 region specifies fiber, and the L2 region specifies penton.

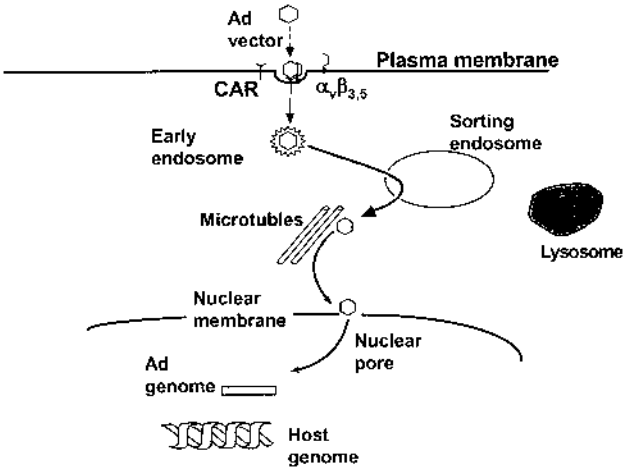

Figure 3 Trafficking of adenovirus from membrane to nucleus. The initial contact between the virus and cell is mediated by the knob of fiber and the coxsackie adenovirus receptor (CAR). This allows the secondary interaction between the penton and $\alpha_V\beta_3$ or $\alpha_V\beta_5$ integrins, which is required for internalization. The initial internalization is via coated pits, which give rise to coated vesicles. After a very short interval, prior to fusion of early endosomes into sorting endosomes, a conformational change in the viral capsid allows escape of the virus into the cytoplasm. Microtubules carry the virus toward the nucleus. The whole capsid attaches to the outside of the nucleus but only the DNA and terminal protein are inserted into the nucleus itself, where they are assembled onto the nuclear matrix to allow transcription. (Courtesy of P. Leopold, Weill Medical College of Cornell University, New York, NY.)

essential for transcription of other early viral mRNAs. E1A proteins promote the expression of cellular genes needed for DNA replication by interacting with the retinoblastoma susceptibility protein (Rb), which normally suppresses entry into S phase of the cell cycle by complexing with the host transcription factor E2F. E1A also interacts with numerous cellular transcriptional factors to promote the assembly of complexes that promote transcription of other early adenoviral genes. Among the important downstream products induced by E1A is the product of the E1B gene, which blocks the apoptotic pathway through interaction with p53 long enough for a productive viral infection. The E1B 55-kDa protein also complexes with the ORF6 protein from the E4 region to modulate expression of the viral late genes, which begin to be expressed around 6 hr postinfection. At that time, DNA replication begins and the transcription of late genes commences, providing the capsid components that assemble into mature virions (10). The new virions are assembled in the nucleus, necessitating transport of capsid proteins into the nucleus. As the viral infection proceeds, the integrity and viability of the cells decreases, but the mechanism of viral release from the cell is not understood.

In the context of gene therapy, the E3 region is important as it encodes immunosuppressive functions that work through two mechanisms (22). The E3 gp19-kDa protein prevents major histocompatibility complex (MHC) class I-mediated antigen presentation on the cell surface, thereby inhibiting the differentiation of cytotoxic T lymphocytes directed against viral antigens (22). The E3 14.7-kDa and E3 10.4-kDa proteins inhibit apoptosis of infected cells initiated by fas/fas ligand and/or tumor necrosis factor (23). The promoter for the E3 region requires E1 products, and thus in $E1^-$ deleted Ad vectors, the presence or absence of the E3 region is not relevant (see below).

Transcripts from the E2 region specify the three nonhost proteins directly involved in DNA replication: the DNA polymerase, the single-stranded DNA-binding protein (ssDBP) and the preterminal protein (10). Like other viruses, adenovirus has developed a specific strategy for the faithful replication of the ends of its DNA. The last 103 nt at both ends of the genome consist of inverted copies of the identical sequence. The terminal protein binds covalently to the 5′ end and acts as a primer for DNA synthesis by the adenoviral DNA polymerase of the leading strand starting at either end. DNA polymerase proceeds by a strand displacement mechanism, creating a duplex and a displaced strand that is sequestered by the ssDBP and has terminal protein attached to one end. Base pairing of the ends of the single strand creates a panhandle structure with ends identical to those of the duplex. Reformation of duplex from the single-stranded form occurs by the same mechanism with the Ad polymerase initiating at the terminal protein and displacing the ssDBP. Interestingly, the viral genomes undergoing replication are at a different location from those being transcribed (24). DNA is packaged into capsids as directed by a DNA sequence close to the left-hand end of the virus. The efficiency of packaging depends on the length of DNA; genomes greater than 105% or less than 95% of the normal length propagate much less efficiently (25,26).

The E4 region plays important roles in the viral life cycle by promoting the selective expression of viral genes at the expense of cellular genes. For example, the E4-ORF3 and ORF6 proteins inhibit the transport of transcripts of cellular genes from nucleus to cytoplasm while promoting the transport of late viral transcripts (10). The E4 region is therefore essential for viral gene expression and subsequent viral replication.

III. CONSTRUCTION AND USE OF FIRST-GENERATION ADENOVIRUS VECTORS

A. Construction

Although the pathology associated with wild-type adenovirus infections is generally mild, there is a potential risk of using $E1^+$ Ad for gene transfer in that the inflammatory host responses to Ad infection may alter organ function (9). There is also the possibility of overwhelming infection if Ad replication is allowed to progress when there are deficiencies in the

host defense system. Because the E1A products are essential for expression of other early and late genes and for DNA replication, the most direct approach to eliminating replication is to delete the E1A genes. To produce $E1^-$ Ad vectors, the classic approach is to transfect the recombinant $E1^-$ Ad vector genome into the human embryonic kidney cell line 293, a cell line originally established by transforming primary cells with Ad5 (27,28). The 293 cells contain approximately 11 map units of the Ad5 genome, originating at the left-hand end (29).

One example of a so-called ''first-generation'' adenovirus vector expresses the human cystic fibrosis transmembrane conductance regulator (CFTR) cDNA under control of the constitutively highly active cytomegalovirus (CMV) immediate/early promoter (Fig. 4) (30). A polyadenylation site is located following the cDNA, and the whole expression cassette in a left to right orientation replaces the E1A and part of the E1B genes. Because the expression cassette is 5601 bp in length and the E1 deletion is 3062 bp, it is necessary to delete part of the E3 region to construct the vector. Because the E3 region is nonessential in vitro, this deletion does not affect propagation of the replication-deficient virus in 293 cells. However, for some therapeutic genes, if the extra space is not necessary, the E3 region can be retained.

The genomes of first-generation ($E1^-$, $E3^-$) Ad are now typically constructed and amplified as *Escherichia coli* plasmids (Fig. 4), followed by transfection into 293 cells for the production of vector. In one widely used system (31), the Ad genome is created by homologous recombination between a shuttle plasmid and a backbone plasmid. The shuttle plasmid consists of the extreme right- and left-hand ends (map units 1–16 and 97–100) of the Ad genome with the expression cassette for the transgene in the deleted E1 region (map units 2–10 deleted). The backbone plasmid contains most the Ad genome (map units 10–100), except for the extreme left-hand end and a deletion of E3. Recombinants between the shuttle and backbone plasmids containing the whole vector genome are selected by appropriate antibiotic resistance markers.

Once made, a new vector is plaque purified repeatedly in 293 cells (to remove any contaminating wild-type virus) and is then propagated to produce the required amounts of the vector. Under standard laboratory conditions, it is possible to produce up to 2×10^{13} viral particles from fifty 150-mm cell culture plates (about 10^9 293 cells). The recombinant Ad is easily purified from cell lysates on equilibrium cesium chloride density gradients. After purification, the vector is assayed for infectivity by plaquing efficiency on 293 cells, the presence of contaminating replication-competent Ad (RCA) by the plaquing efficiency on A549 cells (an $E1^-$ cell line) (32), and the activity of the transgene (using whatever assay is relevant). Titer on 293 cells gives the titer in plaque-forming units (pfu) per milliliter. This has historically been the activity unit used to standardize doses for experimental animals and patients. However, it has become evident that the pfu is an arbitrary, poorly reproducible measurement, and thus most laboratories now use particle units (pu) as the dosing unit, based on the premise that highly purified viruses made by a standard protocol represent a uniform population of potentially infectious units. The particle count is calculated from the absorbance at 260 nm using the formula $1A_{260} = 1.25 \times 10^{12}$ particles/mL, and is typically 10 to 100 times the titer in pfu (33).

B. In Vitro Studies

The methods outlined above have been used to make a large number of first-generation $E1^-$, $E3^-$ adenoviral vectors. Among the most widely used are those that express readily monitored reporter genes such as β-galactosidase, luciferase, chloramphenicol acetyl transferase, and green fluorescent protein (34,35). As a control, viruses with the same promoter-driving expression of no transgene (AdNull) are used.

Using the reporter gene Ad vectors, there are many studies examining the ease of gene transfer to different primary cells and cell lines. Some primary epithelial cells are easily infected by wild-type adenovirus type 5 and, as expected, are easily transfected by adenoviral vectors. By contrast, macrophages (36) and lymphocytes (37,38) are more difficult to infect and only very high multiplicities of infection in concentrated cell suspensions are effective. The discovery that CAR is the adenoviral receptor partially accounts for the relative ease of infection. There are several studies in which the overexpression of CAR was shown to be sufficient to make an otherwise refractory cell line susceptible to gene transfer by Ad (36,39). But integrins and postinternalization factors must also affect the efficiency of gene transfer.

A large number of cancer cell lines have been shown to be susceptible to gene transfer, including cells derived from hepatoma (40,41), glioblastoma (42), myeloma (43,44), melanoma (45), prostate cancer (46), and ovarian cancer (47,48). In contrast, lymphoma cell lines are resistant to infection (44). Studies in which cells are infected in vitro are instructive in indicating what cell types and therefore diseases might be candidates for adenoviral gene therapy. It is difficult to evaluate if studies with reporter genes show that therapeutic levels of proteins are achievable in any cell type due to the use of Ad vectors with different promoters, reporter genes, multiplicities of infection, and times of exposure.

In cells infected in vitro with E1 deleted, replication-deficient adenovirus vectors, a low level of transcription of early and late genes (49,50), and a small amount of DNA synthesis (51) can be detected. The reason for this is not entirely understood but is hypothesized to result from E1-like activities in the target cell, which support expression of Ad genes. In dividing cells there would also be a high level of E2F, which would support adenoviral transcription. However, measurements of viral load in cultures suggest that this does not translate into the production of infectious viral particles in the absence of contaminating wild-type adenovirus. Although cells may continue to divide after infection, the absolute level of vector does not increase or decrease even if the amount of vector per cell decreases to the point when a small minority of cells are infected. Based on this evidence, the Ad genome is likely to remain episomal and is not integrated into the cellular genome,

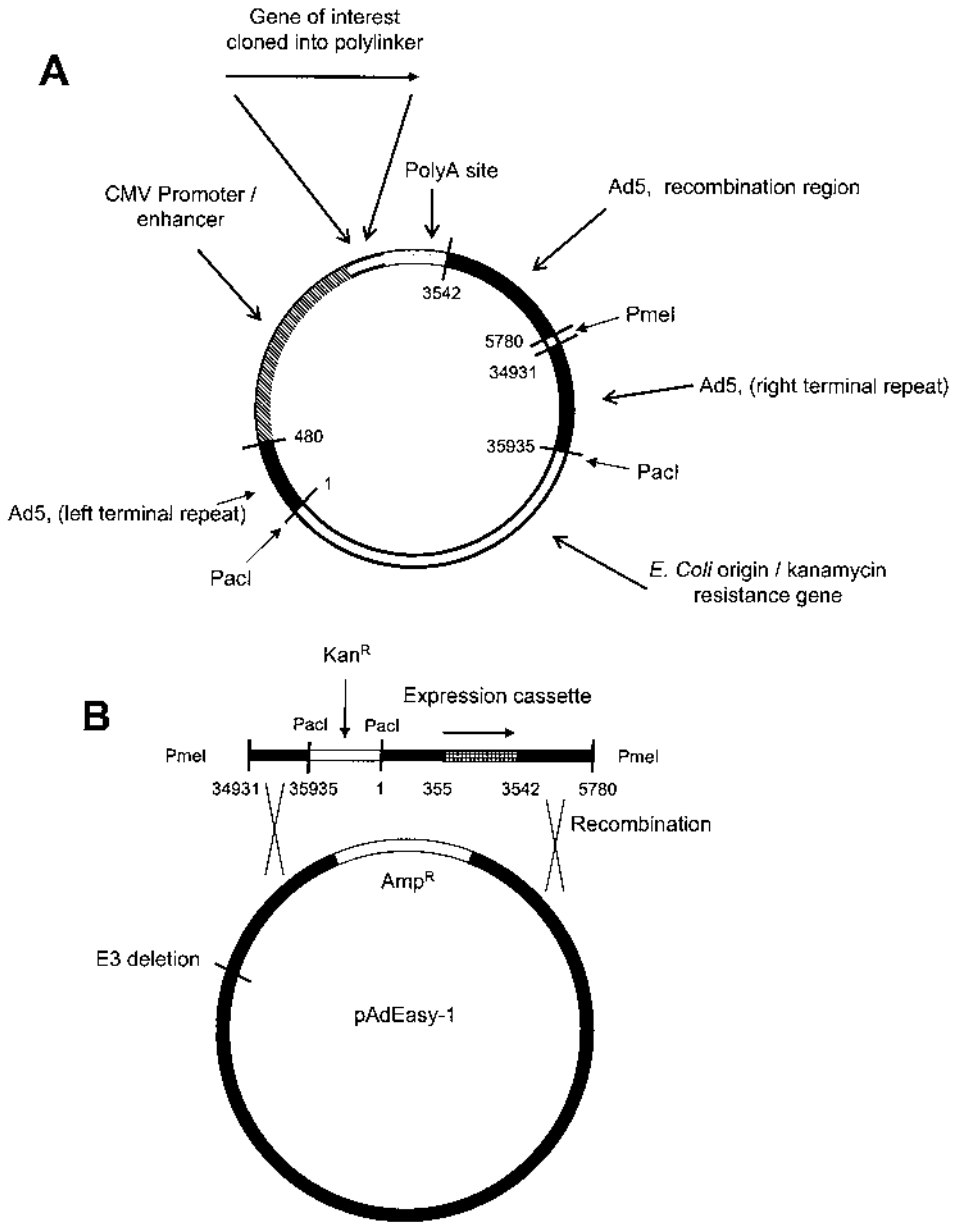

Figure 4 Production of the genome of a replication-deficient adenovirus vector by homologous recombination in *E. coli*. (A) A new cDNA is cloned into the kanamycin-resistant plasmid pShuttleCMV between the CMV promoter and the polyadenylation (poly A) site of SV40. Analogous plasmids are available that allow other promoters to be used (31). The expression cassette lies between 2 portions of the Ad genome, nt 1–480 and 3542–5780. (B) Homologous recombination between PmeI-linearized pShuttleCMV containing the gene of interest and supercoiled pEasy1 results in a kanamycin-resistant plasmid with a full-length adenovirus genome bordered by PacI sites. Plasmid pEasy-1 is used to make E1-E3-E4+ vectors or pEasy-2 to make E1-E3-E4-vectors. The recombinant prepared in large amounts for transfection into E1 complementing cell lines, where it will give rise to the desired vector.

although this is difficult to prove, as it is hard to detect integrated DNA at a very low frequency.

C. In Vivo Studies and Tissue Specificity of Gene Transfer

The feasibility of Ad vector-mediated gene transfer in vitro posed the question of the efficiency of this vector system in vivo. Because Ad gene transfer vectors are made from human adenoviruses, there was no a priori reason to believe they would infect rodents or other model animals. Some early studies used cotton rats because this species had been shown previously to be permissive for replication of human adenoviruses (52–54). For example, intratracheal administration of a replication-deficient virus expressing the reporter gene β-galactosidase to cotton rats resulted in expression of β-galactosidase in the airway epithelium (55). Numerous other animals have been used to demonstrate efficient adenovirus vector-mediated gene transfer, including rats, mice, pigs, rabbits, and nonhuman primates. From these studies, a number of general conclusions can be drawn. Importantly, many tissues can be infected based on the route of administration. As expected from the tropism of Ad5, the transgene delivered to the respiratory epithelium is readily expressed after intranasal or intratracheal administration. But intravenous injection into rodents results primarily in transgene expression in the liver and spleen (56–58). It is not known if the hepatocytes or hepatic endothelium account for this tropism as, surprisingly, the preference for liver does not correspond to the distribution of the CAR receptor among organs (13). Direct injection into the peritoneum (34), kidney (59), pancreas (60), cerebral spinal fluid (61), skeletal muscle (62), brain (63), cardiac muscle (64), coronary artery (65), and many other tissues results in local expression of the transgene. However, the absolute efficiency of gene transfer and expression and leakage to other organs has seldom been calculated, and it is often unclear if therapeutic levels of transgene expression can be achieved.

D. Host Responses

Another important concept that emerged from in vivo studies in experimental animals was the short duration of transgene expression mediated by Ad vectors. Typically, transgene expression levels peak in 1 to 7 days and decline rapidly to undetectable levels by 2 to 4 weeks (Fig. 5). This is true for most routes of administration with the exception of direct injection into a few immunoprivileged tissues such as brain (66–68). Immediately upon administration, the innate immune system serves to eliminate a large amount of vector. Using viral DNA levels as a means to monitor viral clearance from the liver, approximately 90% of an intravenous bolus is cleared after 24 hr (69). Inhibitors of the reticuloendothelium system reduce this early loss of vector, suggesting that macrophages are responsible for early vector clearance (70).

It is known that infection by wild-type human adenoviruses results in a strong immune response in experimental animals and humans. It was not clear whether replication-deficient

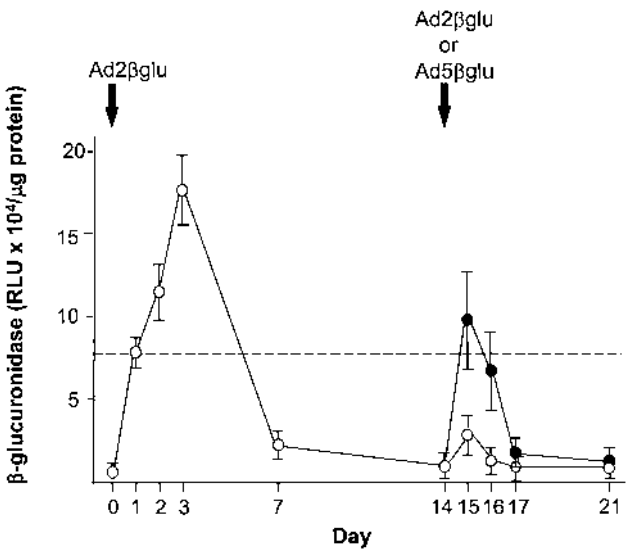

Figure 5 Quantification of β-glucuronidase expression in the lung over time following repeat administration of the same serotype vector or a vector from an alternate serotype. β-Glucuronidase expression in the lung after initial intratracheal administration of Ad2βglu (10^{11} particles), followed 14 days later by intratracheal administration of either the same vector (Ad2βglu, 10^9 pfu, ○) or a vector of the alternate serotype [Ad5βglu, 10^9 pfu, ● (71)].

gene therapy vectors would have the same effect because the net expression of viral genes would be so much lower and the tissues involved would be different from those involved in natural infections. In practice, both cellular and humoral antivector immune responses are observed in rodents after intratracheal (71–73), intravenous (74,75), and intraperitoneal (34) administration. Antibodies against various adenoviral proteins including hexon are induced that can be detected by Western blotting and neutralizing assays. Antivector cytotoxic T lymphocyte (CTL) responses are also observed. The CTL are assumed to eliminate cells infected by the vector in vivo.

When a transgene is used that is foreign to the host, CTL and antibodies are usually, but not always, detected against the expression product of transgene (50,76,77). The basis for this is not fully understood. In classical antigen presentation pathways, a cellular immune response would result from antigens expressed in the antigen-presenting cell and presented in the context of MHC class I. This would imply that Ad infect antigen-presenting cells directly, and there is good evidence both in vivo and in vitro that this occurs (78). But in vivo there is also a strong humoral antitransgene response to many proteins that would not be expected to be taken up by antigen-presenting cells and presented by the class II-dependent pathway. It is possible that apoptosis of Ad-infected cells, followed by uptake of apoptotic cells by antigen-presenting cells, is critical (cross-presentation). The strong antitransgene

product response has proven useful in using Ad as a carrier for genetic vaccination in situations where both cellular and humoral immunity is desired as described below.

These observations lead to the hypothesis that the immune response is essential for the elimination of adenoviral vectors. Although the initial rapid phase of Ad clearance attributed to the innate immune system was equally rapid in immunodeficient mice and immunocompetent mice (79), overall duration of gene expression has been shown to be much longer in immunodeficient mice (79–81). Practically, this suggests ways in which a partial, transient deficiency in the immune system might be exploited to prolong the expression of a therapeutic gene. Conventional immunosuppressants such as corticosteroids (82) and cyclosporin (83–85) have been used to reduce anti-Ad immune responses and increase the duration of transgene expression in experimental animals. The danger of applying this to human is that opportunistic infections or infection from contaminating wild-type adenovirus may result. But greater persistence of Ad vectors can also be achieved via simultaneous systemic administration of molecules such as antibodies against CD40 ligand (86,87) and CTLA4Ig (88,89), which block interaction between T cells and antigen-presenting cells. These immunomodulators could be used locally, possibly coexpressed on the same adenovirus as the therapeutic gene, to provide more specific immunosuppression.

The humoral and cellular responses also evoke immunological memory, which prevents effective gene expression following subsequent administration of the same vector (Fig. 5). Neutralizing antibodies sequester the readministered vector before it infects cells and cause its immune clearance. Thus, the barriers to readministration of a second vector should be serotype-specific, a concept that has been proven in experimental studies (Fig. 5) (71). Cellular immune system memory can also eliminate any readministered vectors that escape neutralization and infect host cells. The determinants of the cellular immune response are more conserved between serotypes and a second vector of different serotype is eliminated faster from immune animals than from naive animals (Fig. 5).

IV. IMPROVED ADENOVIRUS VECTORS

Two salient points emerge from the data discussed above. The first is that only some cells and tissues can be efficiently infected by adenovirus vectors. The second is that there is a strong immune response against adenoviral vectors, which results in elimination of cells infected by the vector and the inability to achieve effective gene transfer and expression following readministration of the same vector. Numerous approaches are being developed that might mitigate these problems.

A. Elimination of Replication Competent Adenovirus

Adenoviral vectors are produced in the 293 cell line, which provides *in trans* the E1 functions that render them conditionally replication competent, permitting vector growth. The difficulty with this approach to propagate vectors is that there is the possibility of homologous recombination between the replication-deficient vector and the chromosomal copy of the Ad5 genome (Fig. 6) (32). This inevitably occurs at a low frequency, resulting in the production of $E1^+$, $E3^-$ replication-competent adenovirus (RCA). Once formed, RCA will outgrow the replication-deficient gene therapy vector in vitro. To minimize the production of RCA, Ad are plaque purified several times on 293 cells and exhaustively tested for the presence of RCA, which is readily detected on the basis of its ability to form plaques on E1 negative cell lines such as the human lung epithelial cell line A549 (32). For clinical studies, adenoviral vectors should be uncontaminated by RCA (level <1 RCA per dose). However, the preparation of Ad vector of this quality is difficult and most in vivo animal and in vitro

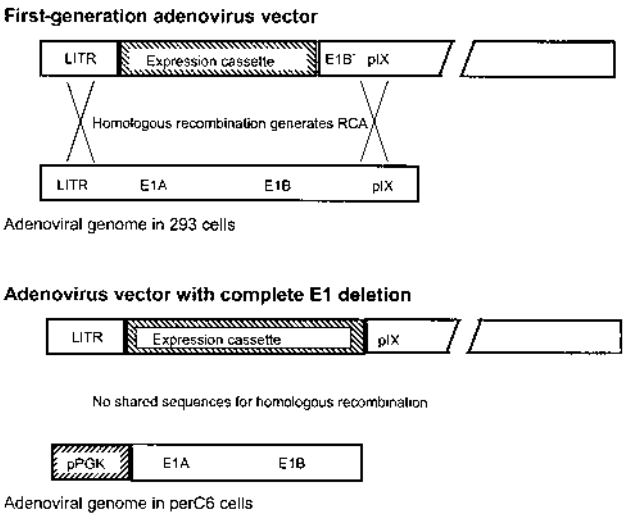

Figure 6 Production of replication-competent adenovirus by homologous recombination between Ad vector and genome of 293 cells. The 293 cell line (open rectangle) contains nucleotides 1 through 4344 from adenovirus type 5, including the left inverted terminal repeat (LITR), the E1A and E1B genes, and the adjacent protein IX gene (pIX). The E1 deletion in most first-generation vectors (top rectangle) stretches from nucleotide 355 through 3328, which is replaced by the expression cassette for the therapeutic gene. Therefore, 2 homologous recombination events (crossed line) can occur that restore the E1 region and give a replication competent (albeit $E3^-$) virus. In the second example, the extent of the E1 deletion in the vector has been extended to encompass all the E1A and E1B genes. At the same time, the E1A and E1B genes in the complementing cell line [i.e., perC6 cells (159)] have no flanking sequence and expression is driven by the phosphoglycerol kinase promoter (p PGK). As a result, there is no homology at either end and only 2 illegitimate recombination events can result in the production of RCA. Therefore, the frequency is very low.

studies are done with preparations with uncharacterized levels of RCA that are probably >1 RCA per 10^8 particles.

To reduce RCA production, two approaches can be used: reduce the size of the trans-complementing E1 region in the cell line or increase the size of the E1 deletion in the vector. Several cell lines have been developed that have less of the Ad genome (compared with 293 cells), while retaining the ability to supply the E1A and E1B functions *in trans* and the high productivity of the 293 cell line (Table 1). The E1 deletion in the first-generation clinical vectors was smaller than optimal, retaining 31% of the 3′ end of the E1B gene. Deleting this sequence in conjunction with cell lines that express E1A/B from nonadenoviral promoter allows production of adenoviruses in circumstances where there is no overlap between the cellular sequence and the vector (Fig. 6B). In these cell lines, RCA is virtually eliminated because it can only arise through two illegitimate recombination events, an occurrence that is very rare.

B. Vectors with Additional Early Gene Deletions

First-generation Ad vectors permit limited Ad gene expression and DNA replication, which probably contributes to the immune response against the vector. In addition, the possibility of making RCA during propagation is a potentially dangerous feature. By making additional mutations or deletions in the Ad genome, both of these problems can be avoided. One implementation is to make an $E1^-$ vector with an E2A mutation that renders the vector replication incompetent at 37°C (90). Such temperature-sensitive vectors can be propagated at 32°C but cannot replicate in the mammalian host at 37°C, even if E1-like activities are present. Further, if homologous recombination in 293 cells during production results in a E1+ viral genome, the ability to replicate in a mammalian host is not restored. In vivo studies show that this defect reduces the inflammatory response following vector administration and

Table 1 Adenovirus Deletions and Complementing Cell Lines

Cell line (genotype)	Deletions complemented	Comments	Ref.
293 ($E1A/B^+$)	$E1^-$	Human embryonic kidney cells transformed by nucleotides 1–4344 of Ad5.	28,29
911 ($E1A/B^+$)	$E1^-$	Human embryonic retinoblast cells containing nucleotides 79–5789 of Ad5. Enhanced plaquing efficiency over 293.	161
perC6 ($E1A/B^+$)	$E1^-$	Nucleotides 459–3510 of Ad5 driven by phosphoglycerate kinase promoter. Reduced production of RCA compared with 911 and 293.	159
293-E4 ($E1A/B^+$, $E4^+$)	$E1^-$, $E4^-$	293 Derivative with E4 gene expression driven by mouse alpha-inhibin promoter.	162
293-ORF6 ($E1A/B^+$, $E4(ORF6)^+$)	$E1^-$, $E4^-$	293 Derivative expressing E4-ORF6 from metallothionein promoter.	93
IGRP2 ($E1A/B^+$, $E4(ORF6/7)^+$)	$E1^-$, $E4^-$	293 Derivative with ORF 6 and 7 of E4 driven by MMTV-LTR promoter.	163
VK2–20 & VK10–9 ($E1A/B^+$, pIX^+ $E4^+$)	$E1^-$, $E4^-$, pIX^-	293 Derivative expressing E4 and pIX from MMTV-LTR or metallothionein promoters allows larger genes to be inserted in E1 region.	164
293 ($E1A/B^+$, pTP^+)	$E1^-$, TP^-	293 Derivative expressing terminal protein inducible by tetracycline.	165
293 ($E1A/B^+$, pTP^+, pol^+)	$E1^-$, TP^-, pol^-	293 Derivative expressing both terminal protein and DNA polymerase.	166
293-C2 ($E1^+$, $E2A^+$)	$E1^-$, $E2A^-$	293 Derivative with 5.9-kb fragment of Ad5 containing E2a region.	167
AE1–2a ($E1A/B^+$, $E2A^+$)	$E1^-$, $E2A^-$	Lung epidermal carcinoma line A549 derivative transformed by E1 and E2A gene under glucocorticoid-responsive promoters.	51
AE1–2a ($E1A/B^+$, $E2A^+$)	$E1^-$, $E2A^-$	293 Derivative with tetracycline repressible E2a gene.	168
293-Cre ($E1A/B^+$, Cre^+)	All viral genes (with lox containing helper)	293 Derivative expressing cre recombinase that excises packaging signal from helper virus.	169

permits longer transgene expression (51,91,92). However, the temperature-sensitive mutation is unstable and partially replication competent at 37°C.

Other mutations in early genes have been used in Ad vectors, including partial and complete E2 and E4 deletions. Both of these genes are essential for viral replication and therefore necessitate the production of cell lines that complement both the E2 or E4 deletion, as well as the E1 deletion. In general, this has been achieved using 293 cells transfected with the appropriate E2 or E4 gene driven by an inducible promoter (Table 1). In a typical example, E4 deleted vectors were constructed in a cell line that expressed the E4 OFR6 behind an inducible metallothionein promoter (93). Cell lines of this type are more difficult to work with than 293 cells, and the efficiency of vector production is often lower. There is inconsistent data on whether additional genomic deletions result in a blunted immune response and whether this translates into longer persistence of transgene expression. Some studies are complicated by the immune response to the foreign transgene and to the vector, and by the tendency of the commonly used CMV promoter to be inactivated over time without vector elimination. For example, one report (94) indicated that a complete E4 deletion has no effect on the time course of gene expression in immunocompetent animals after administration to lung or liver. This is at variance with other reports (50,95,96) showing that E4 deletion results in a reduced immune response and longer transgene expression. The details of vector construction, route of administration, promoter used (97), dose, and genotype of the recipient are critical to the efficacy of E4 (and other) deletion(s). It is likely that studies in humans will be necessary to determine if additional genomic deletions have an impact of the duration of expression of the therapeutic gene and whether this translates into a significant clinical impact.

C. E3 Restored Vectors

The E3 region encodes genes that repress host response to infection through both reducing antigen presentation on the cell surface and protecting infected cells against tumor necrosis factor-α (TNF-α) and/or fas/fasL-mediated apoptosis. E3 is deleted in most adenovirus vectors to make room for the transgene within the length constraints of packaging. Arguing that E3 expression might increase persistence of vectors, several groups have sought to restore one or more E3 function. In mice, expression of the E3gp19K protein has been shown to reduce MHC class I expression in vitro (98) and cytotoxic T lymphocyte levels in vivo (99), but there are contradictory results on whether this translates into prolonged persistence (98,100). However, two studies have shown that the whole E3 region does in fact prolong vector persistence in vivo. This is true whether the E3 region is expressed from an exogenous promoter in the E1 region (101) or expressed from its own promoter in the normal position (102). Because E1 function is required for E3 expression, the latter result is surprising and may indicate that a low level of E3 expression is sufficient to prolong persistence. As with other modifications of the viral backbone, the critical question is if the expression of $E3^+$ vectors would be longer in humans when administered in the route intended for therapy. This has not yet been answered.

D. Helper-dependent Vectors

On the premise that any adenoviral gene expression would cause an immune response, some investigators have developed methods to eliminate all the adenovirus genes from the vector. In fact, the size constraints imposed by some large genes such as dystrophin require that most of the Ad genome be deleted simply to make space for the therapeutic gene (103). An additional benefit of the higher capacity is the possibility of using the endogenous promoter and control elements such as matrix attachment regions to exactly regulate the expression level of the therapeutic gene (104). But deletion of all adenovirus genes requires that those functions be provided *in trans* for vector production. This is achieved by using helper viruses that are deficient in packaging. In an early implementation, a helper virus with defective packaging signals was used that is packaged into virion with much lower efficiency than the therapeutic virus, which has two intact packaging signals. By this method, a mixed lysate is formed with two viruses that differ in size and therefore can be separated on cesium chloride equilibrium density gradients (105).

A refinement of this technology uses the lox/Cre system to negatively select for helper virus in a coinfection of helper and helper-dependent virus vectors (106). In the lox/Cre system, the DNA recombinase Cre from bacteriophage lambda efficiently mediates recombination between lox sites; thus, sequences between two lox sites in the same orientation are deleted. A helper virus called psi5 has been engineered that has lox sites flanking the packaging signal so that Cre recombinase excises the packaging signal and prevents packaging of the genome. The psi5 vector propagates normally in 293 cells but packages inefficiently in 293 derivatives expressing the Cre recombinase. Coinfection of psi5 and helper-dependent vector results primarily in packaging of the helper-dependent vector using proteins specified by the psi5 genome.

Helper-dependent vectors are beginning to attain widespread use and give long-term transgene expression in models where the recipients are immunologically tolerant to the expressed transgene. A helper-dependent vector expressing the human α1-antitrypsin (α1-AT) genomic configuration from the α1-AT promoter can be administered to mice (107) and baboons (108), resulting in prolonged high-level gene expression with little decline over 10 months. Similar data has been reported for factor IX (109), erythropoeitin, and dystrophin. In the case of apoE-deficient mice, the genetic defect that results in high serum cholesterol has been corrected for over 2 years by administration of a helper-dependent vector expressing the wild-type apoE (110). It is clear that the toxicology for helper-dependent vectors is less than for first-generation vectors in some situations, but the acute response to vector, particularly in recipients that are immune to adenovirus type 5, is not affected by use of helper-dependent vectors.

E. Seroswitch Vectors

The induction of neutralizing antibodies is presumably one of the barriers against successful readministration of the same Ad gene transfer vector. In experimental animals, this has been observed for intravenous (111), intratracheal (71,112), and intraperitoneal (34) administration where the vector is exposed to antibodies prior to contact with the tissue. Effective readministration of the same vector has also been demonstrated to be impossible using direct tissue injection (113).

Because prior infection by one Ad does not protect against infection by a different serotype (71), using different serotypes of gene therapy vector should allow readministration of the same transgene. Extensive testing of this concept is difficult because existing vectors are only of serotypes 2 and 5, as the E1 functions of these two viruses can be efficiently complemented by the 293 cell line. For example (Fig. 5), when rats were administered intratracheally with Ad of serotype 2-expressing β-glucuronidase, there was expression that peaked at 3 days and declined to undetectable levels by 14 days. Readministration of the same vector resulted in a very low level of gene expression due to the immune response to the first vector administration. However, a second administration of a vector expressing the same transgene but of serotype 5 resulted in a level of gene expression at day 1 comparable to that seen in a naive rat. The decline to baseline was faster than in naive animals, probably due to the elimination of infected cells by the cellular immune system using epitopes conserved between serotypes 2 and 5 (71).

These data posed the question as to which epitopes are responsible for preventing readministration of the same serotype. Vectors have been constructed with the capsid of serotype 5 but with the fiber gene of serotype 7a. Fortunately, the fiber protein from serotype 7a interacts with the penton base of serotype 5, allowing the assembly of serotype 7a/5 chimeric capsids. In vivo experiments show that the fiber switch from 5 to 7a does not facilitate readministration, suggesting that the immune response to fiber is not the barrier that prevents readministration of the same serotype (114). This is consistent with the concept that the primary humoral immune response is directed to the external loops of the hexon protein. Vectors have been constructed in which the hexon gene of Ad5 has been replaced by that of Ad serotype 2 (115). Even though the level of serological cross-reaction between the pure Ad5 capsid and the variant with hexon from Ad2 was low, the hexon switch did not allow successful readministration in vivo. This illustrates the importance of other arms of the immune system and the diversity of epitopes that are involved in immune response to gene therapy vectors.

It is not clear whether seroswitching is a viable strategy for long-term gene therapy. First, the difficulty of making efficient complementing cell lines for viruses of different subgroups is unknown. Second, the delivery of a therapeutic gene to the target tissue and its subsequent expression would not necessarily be the same among serotypes. Finally, even if this could be achieved, the therapeutic advantage of expressing the transgene once for a few days rather than several times for a few days might not be all that great in terms of genetic disease where persistent gene therapy is needed.

F. Vectors with Modified Tropism

The specificity of adenoviral infections in vitro is dictated by the presence of the CAR receptor and integrins. The role of these receptors in vivo is less certain as the cell types to which a vector is exposed becomes a critical issue. Because a majority of vector administered intravenously in rodents is found in the liver, gene therapy for other tissues requires both detargeting from the normal trafficking route to the liver and a delivery system to the target (116,117). For lung epithelium, intratracheal administration is feasible. Direct injection is possible in some other applications, for example, into the myocardium or directly into a tumor. But vector that is inadvertently injected into capillaries or drains into the circulation through the lymphatic system will find its way to the liver. Alternatively, there are cells types such as lymphocytes (38) that are very difficult to infect with type 5 Ad vectors. These considerations raise questions about whether vectors can be retargeted to cells or tissues of interest, or at least whether the expression of the transgene could be limited to that tissue.

Many vectors use the CMV immediate/early promoter/enhancer, which was chosen on the basis that it directs a high level of transgene expression and is expressed in most tissues studied. However, often expression in a specific tissue or cell type is more desirable and expression in other tissues might be toxic. Therefore, the promoters of genes specific to a cell type have sometimes been used for specific applications (118–120). For example, carcinoembryonic antigen and alpha-fetoprotein (AFP) are tumor-specific antigens that are not expressed by normal cells. When a therapeutic gene is expressed from an Ad vector with an AFP promoter, expression should be confined to specific tumor cells expressing AFP and not normal cells. Kaneko et al. (118) showed this theory to be correct and further demonstrated that the expected selectivity is maintained in vivo. In this context, the vector Av1AFPTK1 [expressing thymidine kinase from herpes simplex virus (HSV-TK) from the AFP promoter] can prevent tumor growth in gancyclovir-treated nude mice implanted with a AFP-expressing tumor cell line but not in identical mice implanted with a control (non-AFP expressing) tumor cell line. In contrast, the vector Av1TK1, which expresses HSV-TK from the Rous sarcoma virus promoter, protects gancyclovir-treated nude mice regardless of which cell line is used to transduce the tumor.

Alternatively, modifications of the fiber/high-affinity receptor interaction or the penton–integrin interaction might be used to modify tissue tropism. In this context, the seroswitch vectors described above (114), as well as capsid chimeras with part of the Ad3 fiber (121,122) or the fiber gene from Ad17 (123), might be more effective in certain tissues because, a priori, different serotypes of wild-type adenoviruses with different known pathologies should target different tissues. In an extensive survey of the tropism of Ad5-derived vectors, but with fibers derived from different serotypes, the fiber gene

of Ad16 was found to be better at targeting fibroblasts and chondrocytes, that of Ad35 better at targeting dendritic cells and melanocytes, and that of Ad50 better at targeting myoblasts and hematopoietic stem cells (124).

Some groups have taken the approach of directly screening for serotypes that replicate preferentially in brain or lung epithelium. In both cases, wild-type strains were screened for efficient replication and certain subgroup D viruses, including serotype 17, were identified to replicate more efficiently. On this basis, a serotype 2 virus with the fiber from Ad17 was constructed and used to study infection of various cell types in vitro. This hybrid is much more efficient at gene transfer to human umbilical vein endothelial cells, neurons, glioma cell lines, and lung epithelial cells than the pure Ad2 gene transfer vector (123). However, it is sufficiently proficient in infecting 293 cells that it can still be propagated and titered for production purposes. It is not known if this translates into better gene transfer efficiency in vivo.

Numerous other approaches to modifying tropism have been identified. For example, the fiber protein can tolerate some manipulation without impairing virus production. The determination of the 3-dimensional structure of fiber in conjunction with mutagenesis studies (125) assists in the identification of amino acids essential for the interaction with CAR and of domains where insertions might be tolerated without grossly affecting structure. An early modification to fiber was the addition of an oligolysine motif to the C-terminal of the fiber protein, giving the virus an affinity for polyanions such as heparin sulfate (126). This profoundly affects the cell types that can be infected in vitro, allowing cells lacking CAR, such as vascular smooth muscle cells and B cells, to be infected. It has also been shown that this oligolysine addition allows for more efficient gene transfer to smooth muscle cells in vivo. Additional manipulations to either the C-terminus or in the HI loop of fiber (summarized in Table 2) have been described to modify the tropism of Ad vectors. The most widely used is the addition of an additional RGD integrin-binding motif to the fiber knob domain, thereby increasing the efficiency of infection of some important cell types, including ovarian cancer cells, fibroblasts, and dendritic cells (127–129). In a study that may point to future developments, phage display technology was used to identify peptide motifs that preferentially target human umbilical vein endothelial cells. When this peptide sequence was incorporated into the HI loop of fiber, adenoviruses were generated with a high preference for endothelium (127,128).

Bispecific antibodies have been used as a reagent to direct Ad toward particular cell types (38,130,131). For example, using a bispecific antibody conjugate with one arm binding the Ad fiber and the other binding the epidermal growth factor (EGF) receptor (130), is was possible to increase the specificity of Ad vectors toward glioma cell lines with low levels of CAR but high levels of the EGF receptor.

The route by which Ad reach the tissue and cell type is complex, especially after intravenous injection. The half-life of Ad in blood is about 2 min, and the interactions with cellular and protein components of blood are unknown (132). In addition the degree to which Ad penetrate endothelium in various tissues is unknown, meaning that in vivo tissue tropism is not a simple outcome of the abundance of CAR primary receptor and integrin secondary receptor. Moreover, in humans there will generally be antibodies against Ad so the formation of complexes with antibody will further complicate tropism. If retargeting is to be successful after an intravenous injection, both detargeting from the normal pathways (117), as well as retargeting to the novel pathways, must be achieved.

Therefore, a number of groups have eliminated the amino acids in the knob of fiber that are essential for interaction with CAR. This makes the resultant vectors difficult to propagate in 293 cells and therefore substitute pseudoreceptor–ligand systems have to be devised. For example, the addition of an HA epitope from the influenza hemagglutinin gene permits a 293 derivative with an anti-HA single-chain antibody to be used for propagation of vectors unable to interact with CAR or integrins (117). The interaction of integrin and penton base has been modified both by elimination of the RGD motif in penton base and by its replacement by the LDV motif, which should promote interaction with $\alpha_4\beta_1$ integrins, characteristic of lymphocytes and monocytes (17).

V. APPLICATIONS

Before commencing clinical studies, batches of vector must be made under the Food and Drug Administration (FDA) current good manufacturing practice and satisfy rigorous lot release criteria. As with all drugs, the identity (now including full DNA sequencing), purity, and potency of the vector must be verified in validated assays. For safety reasons, the absence of RCA is a major concern and vector destined for human usage must contain <1 RCA per dose. As dose increases, the challenge of making vector free of RCA in the 293 cell line becomes more problematic. Vectors must also be verified for the absence of not only human viruses, but also animal viruses, including porcine and bovine viruses that may be carried through from reagents used in cell culture. Taken together, these studies impose a high hurdle of cost and time before a vector suitable for human administration is on hand. Most production is now done in dedicated facilities with high overhead having the trained personnel, facilities, and quality control units.

Human clinical studies also require prior toxicology studies in experimental animals assessing the effects of both vector and transgene expression. There is now considerable human data on the effects of administration of first-generation Ad5-based vectors so the effects of the transgene are usually the focus. Depending on the novelty of the application and the phase to which clinical studies have progressed, toxicology studies may need to conform to FDA good laboratory practice and may require nonhuman primates in addition to rodents. The information derived from toxicology studies is necessarily limited due to biological differences between experimental animals and humans, especially as it relates to the innate and acquired immune response. Experimental animals are naive

Table 2 Examples of Retargeting of Adenovirus Gene Transfer Vectors

Modification	Target	Rationale	Ref.
Ad5 (fiber7a)	Cells expressing Ad7 high-affinity receptors	Replace whole of Ad5 fiber by that of Ad7a (subgroup B).	114
Penton LDV	Lymphocytes, monocytes	Replace RGD $\alpha_v\beta_5$ binding motif in penton base by LDV, which interacts with $\alpha_4\beta1$ integrin.	17
Conjugations to anti-Ad Fabs	Tumor cells	Conjugate ligands (e.g., FGF, folate) to Fab fragments specific to fiber; bind to vector before delivery to cells bearing cognate receptor.	170,171
Bifunctional antibody	Tumor cells	Retarget to EGFR[a] expressing cells; bind virus with bispecific antibody against EGFR and Ad fiber.	130
Bifunctional antibody	Smooth muscle cells, endothelium	Create vector with penton modified to express defined epitope (AdFLAG); use bispecific antibody vs. FLAG and α_v integrin (or E selection) to target cells expressing α_v integrin (or E selectin).	172
Bispecific antibody (anti-CD3)	T cells	Use AdFLAG vector and bispecific antibody (Anti-FLAG, anti-CD3) to target CD3+ T cells.	38
Oligolysine	Cells with surface heparin sulfate	Add lysine residues to C-terminus of fiber.	126,173
Fiber RGD	Cells expressing $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins	Add RGD integrin-binding motif to knob of fiber.	39,127
Ad5 (fiber 17)	Endothelium, lung epithelium, brain	Replace fiber gene of Ad2 vector with that of Ad17 (subgroup D).	123
Ad5/9 (short shaft)	Melanoma, glioma, smooth muscle cells	Place knob of Ad9 on shaft of Ad5 after 8 repeats.	174

[a]EGFR, epidermal growth factor receptor.

to human adenoviruses so the immune response to vector is primary, while most humans have preexisting immunity to Ad5 and therefore the immune response is secondary. There are differences in antigen processing and presentation between inbred animals and humans, and the effects of some E3 genes are limited to human MHC proteins. In addition, the potential effects of RCA are different because human adenoviruses do not replicate in rodent cells, but some human Ad are actually oncogenic in rodents but not in humans.

The final step of commencing a clinical study is obtaining regulatory approval, which is also complex. Gene therapy in general and adenovirus in particular are generally perceived as being particularly hazardous and therefore multiple levels of review are required. The local Institutional Review Board (IRB) and Institutional Biosafety Committee (IBC) must approve, as well as the Recombinant DNA Advisory Committee of the National Institutes of Health. The Investigational New Drug application to the FDA represents the last phase of approval. Each group has slightly different concerns, and the final result is a protocol that is conservative yet likely to be safe, ethical and informative. All revisions to the protocol must be approved by all regulatory groups, therefore keeping the protocol current needs well-organized administration. The actual clinical study must be performed under good clinical practice with timely reporting of all adverse events to the FDA, RAC, IRB, and IBC. In addition, many institutions have added a data safety monitoring board to further ensure the safety of gene therapy studies.

Data on models of disease in experimental animals provided sufficient basis to proceed to adenovirus vector-mediated gene transfer in humans. The first human studies were commenced in 1993, and a total of 143 studies are listed in the current update of the database of the RAC. These have generally been small phase I or phase II studies (Table 3). Although the first studies were directed at cystic fibrosis, the currently active studies are focused on cancer and cardiovascular disease. In total, 72% of the listed studies involve cancer with the same vector being studied in a number of different tumors or different patient subsets or concurrently with different concurrent therapies. In general, capsid modified vectors and second-generation vectors have not been used in humans, and it is unknown if the advantages these new vectors sometimes offer in experimental animals apply in humans.

In general, gene transfer of Ad vectors has been safe and well tolerated (133,134). The notable exception is that intravenous administration results in dose-dependent toxicity that has resulted in 1 death (135–138). This reaction is rapid and is believed to be related to the innate immune system. In addition to showing safety, several studies have shown that there is also effective delivery of the vector to the patient and subsequent

[a]Compiled from the 143 protocols in the RAC database as of February 2003. Duplicate, closely related protocols from the same investigator are listed only once. Protocols are organized first by general area, therapeutic approach, transgene and then route of administration.
Abbreviations: CFTR, cystic fibrosis transmembrane regulator; OTC, ornithine transcarbamylase; AFP, alpha fetoprotein; CD40D, CD40 ligand; IL, interleukin; GM-CSF, granulocyte macrophage colony-stimulating factor; IFN, interferon; PSA, prostate-specific antigen; TNF, tumor necrosis factor; HSV-TK, herpes simplex virus thymidine kinase; CD, cytosine deaminase; VEGF, vascular endothelial growth factor; FGF, fibroblast growth factor; HIF, hypoxia-inducible factor; PDGF, platelet-derived growth factor; PEDF, pigment epithelium-derived factor; NSCLC, non-small-cell lung cancer.

expression of the therapeutic gene. Demonstrations of actual therapeutic benefit will require critical placebo-controlled testing. If an Ad vector does prove to be effective in a large study, there remain substantial production and support issues that will require a significant investment of time and money to provide the reliable supply of a marketed drug.

A. Genetic Diseases

When gene therapy is conceived as the addition of a good copy of a defective gene, it is natural that the initial focus was on genetic diseases such as cystic fibrosis (CF). As described above, the feasibility of intratracheal administration to the lung was demonstrated in animals and the first clinical trial of an adenovirus vector was to the lung of CF patients (139). The initial study was a dose-escalating safety study in which vector was administered to the bronchi in 20 mL of fluid. It became clear that this volume was not well tolerated, so subsequent studies used smaller volumes or a spray of aerosolized vector into the bronchi. The relative accessibility of the site of administration allows that samples of respiratory epithelium can be recovered by bronchial brushing and the presence of vector and therapeutic gene expression can be assessed repetitively. By sensitive quantitative polymerase chain reaction methods, the expression of the CFTR gene delivered by the vector is seen at the site of administration at vector doses of 5×10^8 pfu and greater. The level of vector-derived CFTR mRNA is approximately 5% of the level of expression of the endogenous CFTR gene, and this is believed to be sufficient for therapeutic effect. However, this level of expression is only achieved for a period of a few days and expression rapidly declines to baseline by 30 days (140). Interestingly, the administration of the vector to the airway does not lead to a significant immune response against adenovirus reflected in either neutralizing antibodies (141) or adenovirus-specific T-cell proliferation.

Since the initial safety of vectors expressing CFTR was demonstrated, a study with repetitive administration has been completed. The important result of this study is that expression is reduced or eliminated in subsequent administrations as expected from the data from experimental animals, presumably from the immune response to the first dose (140).

To date, only one study of adenoviral vectors for any metabolic disease has been initiated. This is not surprising because all animal data suggest only a short time of expression of genes

delivered by Ad vectors to most tissues, and the rationale for a human study was not firmly established. Ornithine transcarbamylase (OTC) deficiency is a recessive metabolic disorder of nitrogen metabolism. A $E1^-$, $E4^-$ deleted adenovirus vector expressing the cDNA for OTC was constructed and administered by the intrahepatic route to adults with partial OTC deficiency and safety parameters and the efficiency of gene transfer are currently being assessed (135). During this study it became apparent that a large dose of intravenous vector could be fatal. The use of a helper-dependent vector for the treatment of hemophilia by intravenous administration was stopped when toxicity was observed.

B. Oncology

Due to the unknown safety profile of adenovirus vectors, it is was generally easier to design the early human trials for life-threatening disease. Of the protocols listed by the RAC, 72% involve cancer. Four basic approaches can be identified: local prodrug activation, tumor suppressor genes, immunotherapy, and oncolytic viruses.

One of the first strategies of human gene therapy for cancer was to locally deliver novel enzymes that metabolize prodrugs into the active chemotherapy agent. The general concept of these studies is that local activation of the prodrug in the tumor will concentrate the active agent in the tumor, thus limiting the systemic toxicity from the active drug. Two genes have been used in human clinical trials: HSV-TK and the *E. coli* cytosine deaminase (CD) gene. The HSV-TK protein activates the prodrug ganciclovir to ganciclovir monophosphate, an inhibitor of DNA polymerase. For CD, the prodrug is 5-fluorocytosine, which is activated by CD into the active chemotherapeutic agent 5-fluorouracil. For both agents and activating enzymes, a theoretical benefit is the bystander effect in which active drug would be excreted from the vector-infected cells to kill the neighboring cells of the tumor. Thus, it is not essential to infect every cell of the tumor with the adenovirus vector.

Currently, active protocols apply the prodrug strategy to many types of cancer, including prostate cancer, central nervous system malignancies, ovarian cancer, mesothelioma, hepatic metastases of colon cancer, and squamous cell carcinoma of the head and neck (Table 3). Most studies involve phase I/II studies with intratumoral injection of escalating doses of vector prior to chemotherapy with the prodrug and subsequent scheduled surgery. Tumor removal provides samples for analysis of vector levels, expression of the therapeutic gene, and for analysis of the activation of prodrug and histological studies for cell death and inflammation. The primary end point of these studies is safety, which has been established in some cases.

Tumor suppressor genes have also been used in human clinical studies: p53 (for ovarian cancer, prostate cancer, squamous cancer of the head and neck, breast cancer, non-small-cell lung cancer, hepatic carcinoma, and hepatic metastases); retinoblastoma susceptibility gene (for bladder cancer); mda7 gene for melanoma; and p16 gene for prostate cancer. The concept is that tumor cells have defective tumor suppressor genes that cannot limit cell division, but restoration of the wild-type gene will limit cell division. The theoretical limitation of using antiproliferative genes for tumor therapy is that they will only inhibit proliferation of the cell they infect and have no *cis* effect on neighboring cells. The trial designs are generally similar to those for the prodrug strategy.

A third general approach to adenovirus gene therapy for cancers has been immunostimulatory genes (Table 3). Several different genes have been used in human studies, including CD40 ligand for chronic lymphocytic leukemia, granulocyte macrophage colony-stimulating factor for melanoma and non-small-cell lung cancer, interleukin-2 for neuroblastoma, MART-1 (a melanoma-specific antigen), and B7 (CD80) for melanoma. The concept of immunostimulatory gene therapy is to promote the natural immune surveillance and elimination of tumors that express abnormal antigens by giving a general boost to the cellular immune system (e.g., with IL-2) or a with a tumor-specific antigen (e.g., MART-1) and anti-erbB-2 single-chain antibodies (for ovarian cancer) (Table 3).

A novel antiproliferative approach has been used in human studies using conditionally replication-competent viruses. As described above, the E1B gene is essential to protect adenovirus-infected cells from apoptosis, and its mode of action is through interaction with p53. It follows that E1B function would only be effective in p53 positive cells, but not in p53 deficient tumor cells (i.e., E1B positive viruses would induce apoptosis only in p53 negative tumor cells), whereas normal cells should be protected by the p53 gene. In this context, E1A negative and E1B positive viruses have been demonstrated in animal models to show selective cytolytic effects against tumors. The same viruses have been used in phase I and phase II studies of human ovarian cancers, pancreatic cancer, and head and neck cancer with direct intratumoral injection in conjunction with chemotherapy. These studies are now being extended to phase III testing.

The simplest approach to therapy is to directly administer the vector to the tumor. But for some special applications an ex vivo approach is possible. This is complex due to the need to protect the cells cultured and infected ex vivo from adventitious agents while they are outside the patient. Three approaches have been used. The most common is to infect the tumor cells with an immunostimulatory vector (e.g., Ad expressing a cytokine), expecting to evoke an antitumor immune response upon returning the cells to the patient. Alternatively, dendritic cells, a potent antigen-presenting cell, have been infected ex vivo with Ad expressing a known tumor antigen to evoke an immune response upon returning to the donor. Finally, bone marrow-derived stem cells have been purged of possible contaminants by infection by an anti-proliferative vector prior to returning to a donor.

C. Cardiovascular

With the observation that there is only short-term gene expression from Ad vectors, the question arose as to which medical applications might benefit from transient expression of a therapeutic gene. The general area of tissue repair and engineering

emerged as a good candidate where secreted growth factors would initiate the desired cascade of tissue remodeling, which once initiated would not require the continuous presence of the therapeutic gene. For example, expression of vascular endothelial growth factor (VEGF) after injection of an Ad vector expressing VEGF into rat retroperitoneal fat pad is brief, reverting to baseline after 10 days (Fig. 7). By contrast, the VEGF protein induces an angiogenic response that persists long after the stimulus has disappeared.

On the basis of extensive preclinical testing in animal models of angiogenesis, a number of groups performed clinical studies of adenoviral gene transfer to ischemic heart or ischemic limb in an effort to induce the growth of new vessels and increase blood flow. Although there is no rigorous efficacy data, there is preliminary evidence of improved cardiac function in a number of patients receiving either Ad expressing FGF-4 in the coronary arteries or Ad expressing VEGF121 in the myocardium (142,143). Moreover, when injected into muscles of patients with peripheral vascular disease, Ad expressing VEGF resulted in marginal improvements in some parameters of blood flow to that limb.

D. Normals

The early Ad gene therapy trials demonstrated that, although effective gene transfer could be achieved, persistence of expression is clearly a problem for Ad vectors. There was clearly an immune response to the vector and possibly the transgene itself; however, the biology of that response is not well understood. Animal models, particularly those involving inbred mice, have limited utility in predicting the immune response in humans. To assess the human host response to Ad vectors, 2 trials with normal subjects have been performed using intradermal (144) or intratracheal administration of an Ad vector expressing the *E. coli* CD gene. The intent of these trials is to describe the immune response in humans to an $E1^-$, $E3^-$ Ad vector to provide a background to assess more advanced vectors on a rational basis.

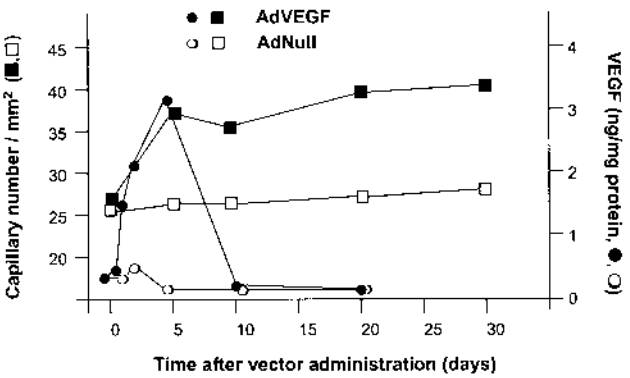

Figure 7 Time course of gene expression and anatomical response after administration of Ad expressing vascular endothelial growth factor (VEGF). The retroperitoneal fat pad of rats was injected with 5×10^8 pfu of either AdVEGF (a first-generation $E1^-E3^-$ vector expressing the 165 amino acid form of human VEGF, solid symbols) or the control vector expressing no transgene (AdNull, open symbols). At intervals, animals were anesthetized, a laporatomy performed, and the fat pad photographed. The number of vessels crossing a circle of 1 cm diameter centered on the injection site were measured (left axis – □, ■). The fat pad was also homogenized and the level of VEGF determined by enzyme-linked immunosorbent assay [right axis – ○, ●; (160)].

VI. FUTURE PROSPECTS

A. Decreasing Vector Elimination

A number of approaches have been developed that should reduce the immune response to Ad vectors, prolong transgene expression, and enhance the efficiency of readministration. The basic hypothesis is that by reducing adenoviral gene expression, there should be a decrease in the host response to the vector and an increase in persistence. This is observed in some experimental animal models but not others. The basic problem posed by these data is whether prolonged persistence and reduced host response will be observed in humans with an administration route compatible with treatment. The only way to answer this question will be to perform the appropriate clinical studies in humans.

The limitations of Ad have prompted some investigators to make hybrids that exploit the wide range of cell types infected by Ad, but allow persistence using features of other viruses such as retroviruses. For example, retroviruses can be produced in situ by coinfection of cells by two Ad vectors (145,146). The first Ad contains the expression cassette for the therapeutic gene flanked by the retrovirus terminal repeats with the necessary *cis* sequences for packaging, all being transcribed from a CMV promoter. The second Ad expresses the the *trans* factors (pol/gag /env) required for assembly of infectious retroviral particles that will then infect the neighboring cells and result in long-term gene therapy. The use of such hybrids has been demonstrated both in vitro and in vivo but does not overcome the need of retroviral vectors for dividing cells, a limitation that might be overcome by making Ad/lentivirus hybrids or Ad/adeno-associated virus hybrids (147,148).

Phage display technology has provided an approach to selecting a peptide sequence with desirable binding properties. This has been exploited in selecting phages that target to different tissues after intravenous injection, presumably through interacting with the endothelium of that tissue. It is likely that these peptide motifs can be incorporated into the knob of the adenovirus fiber to facilitate targeting of adenovirus vectors to a desired tissue. This requires that the knob-modified vector be able to propagate in 293 cells, but strategies have been developed to overcome this production hurdle (117).

B. Applications for Transient Gene Therapy

The technical innovations described above are at best laboratory proofs that will require extensive animal studies before clinical testing. However, the clinical data to date suggests that success with currently available Ad vectors is possible in applications where transient expression might be sufficient. For example, studies of therapeutic angiogenesis for coronary artery disease described above are a prototype of this type of application. Medical indications such as cancer, infectious disease, tissue remodeling (angiogenesis, recovery from surgery, stroke, or injury) are areas where development might be most appropriate. In contrast, metabolic and genetic disease, autoimmune disease, and other chronic conditions would seem to need substantial advances in adenoviral vector design or more likely some kind of hybrid vector before they become treatable on a persistent basis. Importantly, the knowledge of the cellular and host response to Ad infection in humans is still quite rudimentary and will need to be described in much greater detail before more rational approaches to prolonging expression can be devised.

C. Ad Vaccine Carriers

The strong humoral and cellular immune response to the expressed transgene suggests that adenovirus vectors may be effective as vaccines for infectious diseases and cancer. It is possible that there is an inflammatory response to Ad capsids or to residual Ad gene expression that enhances the immune response over that obtained by expression from a plasmid vector. Alternatively, the ability of Ad to directly infect dendritic cells in vivo (78,149) and express the antigen gene may result in antigen presentation by the class I pathway. Examples of exploiting the cellular antitransgene response include eliciting a cellular immune response to tumor antigens as discussed earlier. This property may also be useful in elimination of virus-infected cells (150–152) or malaria (153). It is clear that antigens expressed by Ad also elicit a strong humoral immunity that can be used to block initial infection by viruses (154,155). In the context that most humans have been infected by wild-type adenoviruses and have preexisting antibodies (156), it is possible that use of Ad derived from other mammals may provide more effective vaccines (157,158).

Modified Adenoviruses for Gene Therapy

I. INTRODUCTION

An intense recent research effort into adenovirus (Ad) biology has revealed crucial steps involved in gene transfer. The tropism of Ads is determined by two distinct virus–cell interactions. Initially, there is high-affinity binding of the fiber knob to the primary receptor, which is the coxsackie-adenovirus receptor (CAR) for most serotypes, including 2 and 5, which are most commonly used for gene therapy approaches (1,2). Binding is followed by interaction between cellular integrins and an arginine-glycine-aspartic acid (RGD) motif located at the penton base (3). The latter event leads to formation of endosomes and viral internalization. Subsequently, the adenoviral DNA is transported to the nucleus and adenoviral protein synthesis, or in the case of replication-deficient Ads, transgene expression, begins. Ad DNA is not frequently integrated into the host genome, thereby resulting in a low risk of mutagenesis. Nevertheless, the limited duration of gene expression may render Ads less desirable for the therapy of metabolic diseases, where long-term expression is needed, but is adequate for cancer gene therapy approaches, where the purpose typically is to kill the target cells. Infection is not dependent on cell-cycle phase. Therefore, both cycling and nondividing cells are infected. Importantly, appealing features of Ad for cancer therapy include stability and unparalleled capacity for gene transfer and expression in vivo. Further, production of high titers of current good manufacturing practices quality Ad, necessary for clinical trials, is well established. Nearly 80% of patients enrolling into gene therapy clinical trials are cancer patients (4). Therefore, Ad is currently the most commonly used clinical agent. Many examples given here will be from the field of cancer gene therapy.

Considering the biology of viral entry, it is logical the degree of gene transfer is determined chiefly by the degree of CAR expression (5–17), reviewed in (18,19). Nevertheless, integrin levels may also play a role. This aspect is not as well understood as various $\alpha_v\beta$-class integrins can mediate the second step of virus entry. $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins were the earliest receptors implicated (3,20), but others, such as $\alpha_v\beta_1$ may also be involved, and further molecules may be currently unidentified (21). Also, alternative receptors, such as major histocompatibility complex and heparan sulfate proteoglycan have been implicated although their role is not yet clear (22,23). Finally, some recent data suggests that a heparin sulphate proteoglycan-binding moiety present in the midsection of the fiber may have a role in mediating transduction of hepatocytes (24).

The biodistribution of Ad is not determined only by receptor tropism. In fact, in mice, intravascular Ad results in accumulation mainly in the liver, spleen, heart, lung, and kidneys (25–28), although these tissues may not necessarily be the highest in CAR expression. Instead, the degree of blood flow and the structure of the vasculature in each organ probably contribute to the biodistribution. Importantly, tissue macrophages such as Kupffer cells of the liver have a major role in clearing Ad from blood (29,30). This is an active and non-CAR-mediated process, and uptake via this mechanism leads to rapid degradation of Ad DNA and ineffective transgene expression. Uptake by Kupffer cells saturates when the dose of Ad is increased, resulting in more effective circulation of Ad. This threshold is approximately $1–2 \times 10^{10}$ viral particles in mice, but is not known for humans (28). The threshold effect is probably a major factor contributing to discrepancy between different studies reporting discordant biodistribution and gene transfer rates, as variable dosing has been used. These phenomena also complicate preclinical specificity stud-

ies, and it is unclear how well murine results correlate with human data.

Although CAR is expressed ubiquitously on most normal epithelial tissues, lack or down-regulation of CAR has been reported for various tumor types, such as ovarian, prostate, lung, breast, and colorectal cancer, as well as melanoma, glioma, and rhabdomyosarcoma (10–13,14,15,17,31–36), reviewed in (18,19). Further, this could be a general phenomenon associated with the carcinogenesis of various tumor types, as inverse correlation with tumor grade has been suggested (14,15). The function of CAR is not well understood but it may be associated with cell adhesion and perhaps cell-cycle regulation. Localization to tight junctions has been suggested (16) as has a role in suppression of tumor growth (15). Interestingly, a preliminary report has suggested inverse correlation between activity of the *RAS-MAPK* pathway and CAR expression (37). For treatment of cancer, these associations are concerning, if confirmed. In particular, the population most desperately needing novel treatments is patients with advanced disease, and if CAR is variably expressed in these tumors, CAR-dependant approaches may not be useful. Thus, targeting of Ad to tumor cells may useful for increasing the clinical efficacy and safety of approaches. Further, considering the widespread expression of CAR, targeting approaches may be advantageous for increasing the specificity of any clinical Ad gene therapy application.

Two main approaches have been used for modification of Ad for the purposes of increased safety and efficacy. Transcriptional targeting restricts expression of transgenes to target tissues, whereas transductional targeting approaches limit the entry of agents to target cells. The former can be achieved by using tissue-specific promoters (TSPs). These promoters are typically associated with genes highly expressed in tumor tissue with lower expression in normal tissues, of which the liver is the most important. Transductional targeting can be achieved by using adapter molecules, genetic modification of the fiber, serotype chimerism, or completely replacing the fiber with heterologous targeting moieties. Also, attempts have been made to use other regions of the capsid for targeting, but little data exists on the feasibility of the approach in vivo. These approaches are discussed in the following section. In addition to introducing new tropism, many applications would benefit from ablation of binding to CAR (38). For systemic treatment, blocking of Kupffer cell uptake may be even more important (30).

II. ADAPTER-BASED TARGETING

The formation of a molecular bridge between Ad and a cell surface receptor constitutes the adapter-based concept of Ad targeting (Fig. 1). Adapter function is performed by bispecific molecules or molecular conjugates that link the Ad to alternative cell surface receptors, often concurrently ablating native CAR tropism. This approach is predicated by the aforementioned two-step entry mechanism of Ad, wherein attachment is distinct from internalization. In this way, alternative means

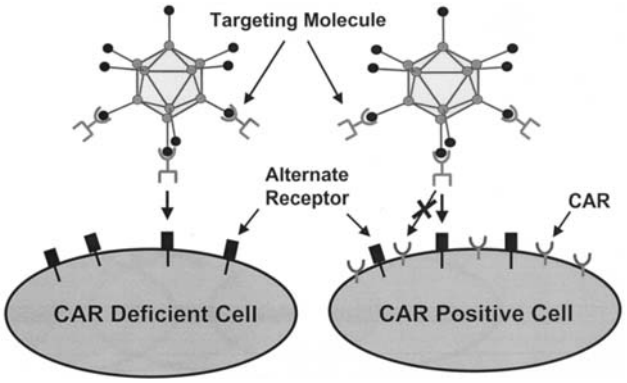

Figure 1 Adapter molecules for epitope-specific adenovirus targeting. The adapter ablates native CAR-based tropism and targets adenovirus to a disease-associated cellular receptor or other surface molecule.

of cellular attachment do not impede Ad cell entry. Bispecific adapter molecules include bispecific antibodies, chemical conjugates between knob-binding single-chain antibodies (Fab) and cell-selective ligands such as folate, Fab-antibody conjugates using antibodies against target cell receptors [e.g., epidermal growth factor receptor (EGFR)], Fab-peptide ligand conjugates [e.g., basic fibroblast growth factor 2 (FGF2)], and recombinant fusion proteins that incorporate Fabs and peptide ligands.

The first in vitro demonstration of Ad targeting via the adapter modality resulted in CAR-independent, folate receptor-mediated cellular uptake of the virion by cancer cells overexpressing this receptor (39). This was accomplished using a bispecific conjugate consisting of a neutralizing Fab chemically linked to folate. A similar targeting adapter consisting of the same Fab fused to FGF2 was used to target Ad vectors to FGF receptor-positive Kaposi's sarcoma and ovarian cancer substrates (40–42). Upon intraperitoneal injection of Ad-Fab-FGF2 coding for herpes simplex virus type I thymidine kinase (HSV-TK) into tumor-bearing mice, survival was prolonged (43). Importantly, decreased hepatic toxicity was demonstrated (44,45). Other Fab–ligand conjugates have been targeted against epithelial cell adhesion molecule, tumor-associated glycoprotein 72, EGFR, CD-40, and others (32,46–52).

An alternative to the chemical conjugate approach was developed by creating a single recombinant fusion molecule formed by the soluble extracellular form of CAR (sCAR) fused to epidermal growth factor (EGF) (53). Increased reporter gene expression was achieved in several EGFR-overexpressing cancer cell lines compared with untargeted Ad or EGFR-negative cells in vitro. EGF-directed targeting to EGFR-positive cells was shown to be dependent on cell surface EGFR density. Initial proof-of-concept studies were followed up with construction of adenoviruses coding for the adapter and capable of achieving production and secretion of sCAR-EGF in human cells. Further, the effect of such retarget-

ing on the oncolytic potency of replication competent agents was tested in vitro and in vivo (54). To improve Ad–sCAR–ligand complex stability, a trimeric sCAR-fibitin-anti-erbB2 single-chain antibody (sFv) adapter molecule was developed (55). The adapter displayed increased affinity to the Ad fiber knob while augmenting gene transfer up to 17-fold in breast and ovarian cancer cell lines.

The above proof-of-principle studies and others have rationalized testing targeting adapters in vivo. A novel bispecific adapter composed of an antiknob Fab chemically conjugated to a monoclonal antibody (9B9) was constructed. 9B9 binds angiotensin-converting enzyme, a surface molecule expressed preferentially on pulmonary capillary endothelium and upregulated in various disease states of the lung (48,56). Following peripheral intravenous injection of the Ad/Fab–9B9 complex, reporter transgene expression and viral DNA in the lung was increased 20-fold over untargeted Ad. Importantly, reporter gene expression in the liver was reduced by 83%.

Adapter-based Ad targeting studies provide compelling evidence that Ad tropism modification can be achieved by targeting alternate cellular receptors, and that this modality augments gene delivery to CAR-negative target cells. Although two-component targeting has shown promising results for retargeting adenovirus to new receptors, such delivery systems have more complex pharmacodynamics and -kinetics, and their stability in humans has not yet been studied. Therefore, one-component systems may be more easily applicable to human trials.

III. GENETIC MODIFICATION OF THE FIBER KNOB

Genetic manipulation may be advantageous over adapters in that all virions harbor an identical modification and lack of stability is less likely. Although conceptually elegant, genetic targeting efforts must work within narrow structural constraints. Key to this approach is the successful modulation of complex protein structure instead of function relationships that result in Ad tropism modification without disrupting native molecular interactions indispensable for proper function. Specifically, genetic modification can affect capsid protein production, fiber trimerization, and packaging of virions. Based on an increasing understanding of native Ad entry biology, development of genetically targeted vectors has rationally focused on the fiber knob domain, the primary determinant of Ad tropism (Fig. 2).

To circumvent variable expression of CAR, targeting ligands have been incorporated into the Ad knob domain without ablating native CAR binding. This results in Ad vectors with expanded, rather than restricted, cell recognition. These efforts are based on rigorous structural analysis of the knob domain and have exploited two separate locations within the knob that tolerate genetic manipulation without loss of fiber function, the C-terminus and the HI loop. Because the C-terminus of the Ad knob is exposed, extension of the knob peptide to include a targeting peptide moiety is conceptually simple.

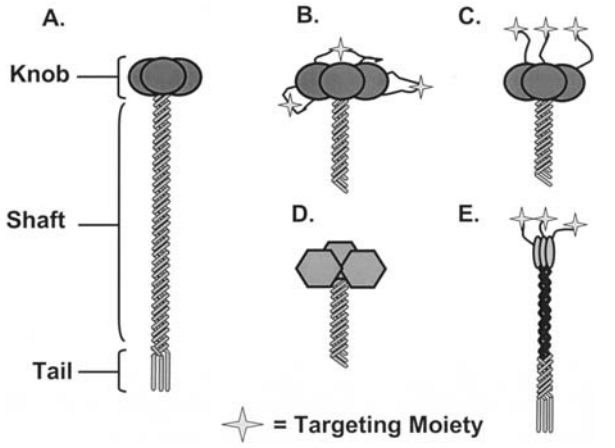

Figure 2 Genetic targeting of adenovirus. (A) Trimeric wild-type adenovirus fiber; tail, shaft, and knob regions are shown. (B) Knob containing targeting ligand in the flexible HI loop. (C) Knob containing a C-terminal targeting ligand. (D) Pseudotyped chimeric fiber bearing an alternate human serotype knob domain. (E) Knobless fiber bearing a heterologous trimerization sequence and a C-terminal targeting moiety.

Ads with C-terminal RGD and polylysine ligands have yielded some promising results in vitro and in vivo, but other peptide ligands were rendered ineffective in the C-terminus context (57). To circumvent this problem, Dmitriev and coworkers introduced an RGD peptide sequence (RGD-4C) into an exposed loop structure that connects beta-sheets H and I (HI-loop) within the knob (31). The expanded tropism of this vector has been useful for several purposes, including carcinomas of the ovary, pancreas, colon, and head and neck, all of which exhibit frequent CAR deficiency (33,35,58–60). Incorporation of various other ligands into the HI-loop has been attempted, but based on the limited number of publications available, the loop may not be a suitable locale for all targeting moieties. The combination of C-terminus and HI-loop targeting has also been performed and was reported to increase gene transfer over either approach alone (61).

A. Serotype Chimerism

Ad fiber pseudotyping refers to genetic replacement of either the entire fiber or just the knob domain with its structural counterpart from another Ad serotype. An Ad5 agent that expressed a chimeric fiber displaying the Ad serotype 3 knob domain (Ad5/3) demonstrated the same CAR-independent cell recognition as Ad3 (62). The use of another Ad5/3 chimeric vector selectively targeted low-CAR lymphoid cell lines in vitro, whereas these cells were refractory to Ad5 infection (63). Ad5/3 has been useful for retargeting Ad5 to low-CAR primary ovarian carcinoma cells and cell lines in vitro and in vivo (27,64).

Importantly, the serotype 3 receptor does not seem to be subject to down-regulation during carcinogenesis, in contrast to CAR. Further, Ad5/3 biodistribution, liver toxicity, and rate of blood clearance in mice appear to not be significantly different from Ad5 when administered intravenously or intraperitoneally, suggesting a good safety profile for Ad5/3. In the context of ovarian cancer, comparison of 5/3 chimerism to infectivity enhancement with RGD-4C was performed and chimerism was found superior. Therefore, it is currently the best available targeting approach for that disease. As with the RGD-4C modification, 5/3 modified viruses are also able to partially escape anti-Ad5 neutralizing antibodies (27). Other chimerism strategies have also been tested (17,65).

B. Knobless Viruses and Other Capsid Proteins for Targeting

Structural conflicts emerging from knob modifications and the observation that fiber-deleted Ad vectors could be produced (66,67) provided the conceptual basis for replacing the native fiber with a chimeric knobless fiber, which would result in ablation of CAR binding. Simultaneous addition of a targeting ligand to the knobless fiber would result in a more specifically targeted Ad. The technical barrier to this approach is the innate trimerization function of the knob, required for proper fiber function and capsid assembly. A solution was devised by using the T4 bacteriophage fibritin protein for trimerization, while proof-of-concept targeting was achieved with a six-histidine (6-His) moiety and cells expressing an artificial 6-His receptor (68). A similar strategy was employed whereby the staphylococcal protein A allowed trimerization and subsequent utilization of an integrin-binding RGD motif or proof-of-concept sFv-mediated targeting (69,70). These approaches could be extremely valuable if they become fully applicable to versatile targeting moeties, such as sFvs, in vivo.

An exciting new approach to Ad targeting is incorporation of targeting proteins into other capsid proteins such as pIII and pIX, which have an accessory function in capsid assembly but have access to the surface of the virion and may thus be usable for incorporation of targeting moieties (71). Also, given that adapter molecules can change the biodistribution of Ad, perhaps alteration of length of the fiber could achieve the same. This hypothesis was tested with promising results, although packaging was compromised with longer shaft extensions (72,73).

IV. TRANSCRIPTIONAL TARGETING WITH TSPs

Transductional targeting approaches attempt to restrict vector entry into target cells. In contrast, transcriptional targeting does not change the tropism of viruses but instead restricts gene expression to target cells. One of the earliest TSPs explored for cancer was the carcinoembryonic antigen promoter, expressed in most gastric, pancreatic, and lung cancers (74). For hepatomas, the promoter of the alpha-fetoprotein has been investigated (75,76), while the L-plastin promoter (LP-P) was used in ovarian and breast cancer cell lines (77,78). Other promoters tested for ovarian cancer include DF3, Cox-2, and midkine (79,80). The Cox-2 promoter has also been explored in the context of gastric carcinomas (81).

Osteocalcin (OC) is a bone protein expressed in osteotropic tumors and differentiated osteoblasts, as well as numerous solid tumors, including osteosarcoma and prostate cancer (82,83). An Ad using the OC promoter to drive *HSV-TK* expression in prostate cancer cells resulted in destruction of tumor cells in vitro and in subcutaneous or bone tumor xenografts. Interestingly, tissue-specific toxicity was seen to bone metastases. OC is expressed in osteoblastic lesions, thus offering the possibility for cotargeting of regenerating bone and tumor. Further, many types of cancers metastatic to the bone could be amenable to treatment.

The secretory leukoprotease inhibitor (SLPI) gene is expressed in several different carcinomas, including ovarian cancer. Its expression in normal organs, such as the liver, is low. Therefore, the SLPI promoter was used to drive transgene expression in ovarian cancer cell lines and primary tumor cells isolated from patient samples (84). The promoter was activated in both cell lines and primary tumor cells in an Ad context in vitro. A murine orthotopic model of peritoneally disseminated ovarian cancer was used to demonstrate high tumor gene expression vs. low liver expression with the SLPI promoter, and that Ad-delivered *HSV-TK* under the control of the SLPI promoter was able to increase survival.

A. Vasculature-specific Promoters

Targeting the endothelium of tumors may be amenable to gene therapy. This tissue may be independent of tumor type and is easily accessible to intravascular vector administration. Also, endothelial cells (ECs) are not malignant, and thus are less sensitive to selection pressure and rarely gain resistance to treatment. E-selectin expression is minimal in normal blood vessels but high in the capillaries of tumors, and the promoter was used for driving gene expression in an Ad. Upon infection, EC cell lines expressed high levels of reporter gene expression, whereas non-EC cell lines showed low expression. The addition of TNF-α, an inducer of the promoter, further increased the E-selectin's activity (85). The murine preproendothelin-1 (PPE-1) promoter was also used as a TSP for adenoviral-mediated delivery to EC cells. Systemic administration to lung tumor-bearing mice resulted in gene expression in the new vasculature of primary tumors (86).

B. Treatment-responsive Promoters

Another strategy for cancer gene therapy involves regulating gene expression with another form of treatment, such as radiation. For example, the early growth response gene 1 (EGR-1) promoter, which is radiation inducible, has been used as a TSP for the specific expression of *lacZ* and *HSV-TK* in glioma and hepatocellular carcinoma cells. Radiation-induced transcription of EGR-1 in these cells was accomplished with rela-

tively low doses (87). Another approach for dynamically controlling promoter expression involves chemically inducible promoters. For example, a tetracycline-activated promoter can be used to regulate gene expression and subsequent protein production by giving oral tetracycline (88). Withdrawal of the drug rapidly abrogates gene expression.

V. DOUBLE-TARGETED ADENOVIRUSES

Transductional and transcriptional targeting can be combined to create double-targeted viruses. Conceivably, this approach could be synergistic with regard to safety and efficacy. Initial proof of concept was achieved by using a pulmonary vasculature specific promoter and a lung endothelium-targeted adaptor strategy (56). Impressively, the tumor-to-liver ratio of gene expression was increased 300,000-fold when both targeting modalities were used. Also, double targeting for ovarian cancer has been achieved in vitro and in vivo (89). Transductional targeting with a sCAR-fibritin-antiErbB2-sFv adapter was able to increase gene transfer to target cells while reducing transduction of nontarget cells. When combining transcriptional targeting with the SLPI promoter, an increase in selectivity was seen. Also, the transductional targeting increased the level of SLPI-mediated transgene expression in target cells, thereby compensating for the lower gene expression typically seen with TSPs.

VI. TRANSCRIPTIONAL AND TRANSDUCTIONAL TARGETING FOR CONDITIONALLY REPLICATING ADENOVIRUSES

Although nonreplicating first-generation Ad vectors have provided high in vitro and in vivo transduction rates and good safety data, clinical cancer trials have suggested that the single-agent antitumor effect may not be sufficient for all treatment approaches (18). Viruses that replicate and spread specifically inside the tumor have been suggested as a way to improve tumor penetration with an additional benefit of local amplification of effect. To this end, conditionally replicating adenoviruses (CRAds) have been explored. These viruses are genetically modified to take advantage of tumor-specific changes that allow preferential replication of the virus in target cells (19,90–94). The viral replication cycle causes oncolysis of the cell, resulting in the release of newly generated virions and subsequent infection of neighboring cells. Thus, the antitumor effect is not delivered with a transgene but by replication of the virus per se. In theory, the oncolytic process continues as long as target cells for the virus persist. There are two main ways to control viral replication. One method is the control of replication regulators, such as the viral early genes, with TSPs. The other method involves introduction of deletions in the viral genome that require specific cellular factors to compensate the effects of these deletions. Further, both approaches can be combined with the potential for increased specificity. Therefore, CRAds are by definition transcriptionally targeted agents.

Various promoters have been used to control viral replication (95–101), reviewed in (19). Typically, the TSP is placed to control expression of *E1A*, the crucial regulator of Ad replication, sometimes combined with other genes such as *E1B* or *E4*. An interesting concept is targeting CRAds to tumor vasculature (102). However, this strategy is more challenging to study preclinically, as animal models are unavailable – endothelial cells derive from the host in xenograft systems and murine cells do not support replication of human Ads. To further increase the oncolytic effect, transgenes for cytokines or prodrug-activating enzymes have been included in CRAds (103,104). This approach may also allow noninvasive imaging and abrogation of virus replication in case of toxicity.

Heretofore, two approaches have been used for creation of deletion-type CRAds. The first was ONYX-015 (initially reported as dl1520), which has two mutations in the gene coding for the E1B 55-kd protein (105,106). The purpose of this protein is binding and inactivation of p53 in infected cells, for induction of S-phase, which is required for virus replication. Thus, this virus should only replicate in cells with an aberrant p53-p14ARF pathway, a common feature in human tumors (107). Although this is still subject of debate, initial studies suggested that this agent replicates more effectively in tumor than in normal cells (108–111). Unfortunately, the function of E1B55kD is not limited to p53 binding, which causes inefficient replication compared with wild-type adenovirus (105,106,112).

The second group of deletion-mutant CRAds have a 24-bp deletion in the constant region (CR) 2 of *E1A* (113,114). This domain of the E1A protein is responsible for binding the retinoblastoma tumor suppressor/cell cycle regulator protein (Rb), thereby allowing Ad to induce S-phase entry. Therefore, viruses with this type of deletion have reduced ability to overcome the G1-S checkpoint and replicate efficiently only in cells where this interaction is not necessary (e.g., tumor cells defective in the *Rb-p16* pathway). Appropriately, this pathway seems to be inactive in most all human tumors (115). It has been shown that replication of CR2-deleted viruses is attenuated in nonproliferating normal cells (113,114). Importantly, abrogation of replication was also demonstrated when Rb was reintroduced into otherwise permissive cells (113). Ads with mutations in both CR 1 and 2 of *E1A* have also been found to replicate selectively in tumor cells, although increase in selectivity in comparison to just CR2-deleted CRAds has not yet been demonstrated (116–119).

Like Ad vectors, most published CRAds rely on CAR for entry into cells. Unfortunately, CAR levels are variable in many types of clinical cancers (10–13,31–36) (14,15,17). Nevertheless, even CRAds with wild-type tropism have shown evidence of clinical utility (120). These initial successes suggest that if efficiency of infection and specificity of replication of these agents could be enhanced, further improvements in clinical efficacy could be gained. This is corroborated by demonstration of the close association between infectivity and oncolytic potency (54,121,122). Consequently,

infectivity-enhanced CRAds have been constructed, with impressive preclinical efficacy. Ad5-Δ24RGD features an RGD-4C modification of the fiber (123), and displays similar oncolytic potency to wild-type virus in ovarian cancer cells (124). Further, this virus is able to replicate in ovarian cancer primary cell spheroids and results in significantly prolonged survival in an aggressive orthotopic ovarian cancer model (124).

A Δ24-based agent featuring the serotype 3 knob (Ad5/3-Δ24) was created (125). This agent demonstrated dramatic antitumor efficacy in ovarian cancer cell lines, primary tumor specimens, and orthotopic animal models of ovarian cancer. The first TSP-controlled infectivity-enhanced CRAd has recently been constructed and tested on ovarian and pancreatic cancer substrates [Masato Yamamoto, submitted; (126)]. Replicative specificity was achieved with a Cox-2 promoter controlling expression of *E1A*, whereas the fiber was modified with RGD-4C.

A major problem in assessing CRAd efficacy and safety preclinically, is the lack of an appropriate animal model. Human serotype Ads or CRAds do not replicate productively in commonly used animal models. Therefore, meaningful safety data are difficult to obtain, and efficacy data may be skewed due to deficient immune responses in xenograft models. Further, evaluation of host–virus interactions and their modulation has not been possible. This problem could be partially alleviated if a syngeneic CRAds could be developed for existing animal models of cancer (129).

VII. CLINICAL TRIALS WITH MODIFIED ADENOVIRUSES

No trials have yet been completed with targeted adenoviruses. Nevertheless, numerous trials are in progress. Specifically, an ovarian cancer trial using the Fab-FGF2 adapter for targeting an Ad coding for HSV-TK (and subsequent ganciclovir administration) to FGF receptors is in progress (Hemminki, personal communication). Modification of the fiber with RGD-4C has been used to create advanced generation vectors for human trials. RGDTKSSTR incorporates an HSV-TK cassette for cell killing and ganciclovir analog imaging, whereas the somatostatin receptor cassette can be used for somatostatin analog imaging. The agent achieved effective killing of ovarian cancer substrates including cell lines, primary tumor samples, and efficacy in murine models of human ovarian cancer (58,59). Also, noninvasive imaging was performed and found feasible even during ganciclovir treatment for a period of more than 2 weeks (58).

RGDTKSSTR was used to demonstrate an important aspect of fiber modified Ads. Neutralizing antibodies (NAbs) are the main component of the humoral immune system responsible for inhibition of Ad infection, and are present in a large proportion of the population. Further, NAb titers are quickly induced following treatment with Ad (127). Many NAbs are conformation sensitive, and when the fiber shape is changed slightly, such as when incorporating a targeting moiety, partial escape from NAbs can be seen (58,59,127,128). An ovarian cancer trial with RGDTKSSTR is in process (Hemminki, personal communication). A similar virus employing a cytosine deaminase prodrug-converting enzyme has been tested for treatment of head and neck cancer and a trial is pending (Hemminki, personal communication). The first transductionally targeted CRAd trial with Ad5-Δ24RGD has received National Cancer Institute funding and will soon start enrolling glioma and ovarian cancer patients (Hemminki, personal communication).

VIII. CONCLUSIONS

Ads are currently the most widely used platform for gene delivery, due to their unparalleled efficacy in gene expression in dividing and nondividing cells. They are particularly useful for treatment of cancer, where temporary gene expression and immunogenicity are acceptable or even beneficial. Nevertheless, unimpressive clinical results with first-generation Ads has led to construction of infectivity-enhanced, retargeted agents capable of more effective gene delivery to target organs while reducing side effects to nontarget tissues. Also, an important field is transductional improvement of conditionally replicating viruses, which may be required for realization of the full clinical potential of the approach. Combinations of transductional and transcriptional targeting approaches are likely to increase the feasibility of using Ads and CRAds for treatment of human disease.

I. INTRODUCTION

Gene therapy is the amelioration of disease through the use of nucleic acid. This broad definition reflects the large spectrum of diseases that can be potentially considered for treatment, as well as the many methods of introducing the nucleic acid into target cells, which may or may not be directly affected by the disease. This chapter focuses on a very specific area of gene therapy research—the development and application of helper-dependent adenoviral vectors (HDAds) (also referred to as gutless, gutted, mini, fully deleted, high-capacity, Δ, pseudo) for gene therapy. Successful gene therapy requires a gene transfer vector that is able to efficiently transduce the target cells in vivo and provide high-level and long-term transgene expression in the absence of toxicity. How HDAds have measured up to these expectations is reviewed in this chapter.

II. THE ADENOVIRUS

The adenovirus (Ad) has a nonenveloped icosohedral capsid containing a linear double-stranded DNA genome of ~30–40 kilobase (kb). Of the ~50 serotypes of human Ad, the most extensively characterized are serotypes 2 (Ad2) and 5 (Ad5) of subgroup C [reviewed in (1)]. The 36-kb genomes of Ad2 and Ad5 are flanked by inverted terminal repeats (ITRs), which are the only sequences required in *cis* for viral DNA replication. A *cis*-acting packaging signal, required for encapsidation of the genome, is located near the left ITR (relative to the conventional map of Ad). The Ad genome can be roughly divided into 2 sets of genes (Fig. 1): the early region genes, E1A, E1B, E2, E3, and E4, are expressed before DNA replication; and the late region genes, L1 to L5, are expressed to high levels after initiation of DNA replication. The E1A transcription unit encodes 2 major E1A proteins that are involved in transcriptional regulation of the virus and stimulation of the host cell to enter an S-phase-like state and is the first early region to be expressed during viral infection. The two major E1B proteins are necessary for blocking host mRNA transport, stimulating viral mRNA transport, and blocking E1A-induced apoptosis. The E2 region encodes proteins required for viral DNA replication and can be divided into two subregions; E2a encodes the 72-kD DNA-binding protein and E2b encodes the viral DNA polymerase and terminal protein precursor (pTP). The E3 region, which is dispensable for virus growth in cell culture, encodes at least 7 proteins, most of which are involved in host immune evasion. The E4 region encodes at least 6 proteins, some functioning to facilitate DNA replication, enhance late gene expression, and decrease host protein synthesis. The late region genes are expressed from a common major late promoter (MLP) and are generated by alternative splicing of a single transcript. Most of the late mRNAs encode virion structural proteins. In addition to the early and late region genes, 4 other small transcripts are also produced. The gene-encoding protein IX (pIX) is colinear with E1B but uses a different promoter and is expressed at an intermediate time, as is the pIVa2 gene. Other late transcripts include the RNA polymerase III-transcribed VA RNA I and II.

Virus infection is initiated through the Ad fiber protein binding to the primary coxsackie-adenovirus receptors (CAR)

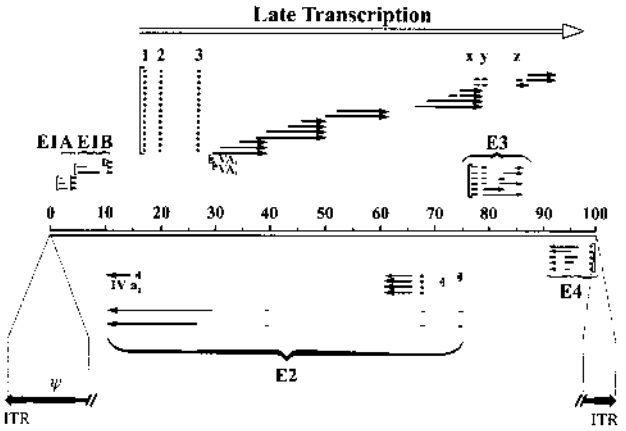

Figure 1 Transcription map of human adenovirus serotype 5. The 100 map unit (~36 kb) genome is divided into 4 early region transcription units, E1–E4, and 5 families of late mRNA, L1–L5, which are alternative splice products of a common late transcript expressed from the major late promoter located at 16 map units. Four smaller transcripts, pIX, IVa, and VA RNAs I and II, are also produced. The 103 bp inverted terminal repeats (ITRs) are located at the termini of the genome and are involved in viral DNA replication, and the packaging signal (ψ) located from nucleotides 190 to 380 at the left end is involved in packaging of the genome into virion capsids.

on the cell surface (2–4), followed by a secondary interaction between the virion penton base and $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins (5). The efficiency with which Ad binds and enters the cell is directly related to the level of primary and secondary receptors present on the cell surface (6,7). Penton–integrin interaction triggers Ad internalization by endocytosis, following which the virion escapes from the early endosome into the cytosol prior to lysosome formation (8,9). The virion is sequentially disassembled during translocation along the microtubule network toward the nucleus where the viral DNA is released into the nucleus (10). Once in the nucleus, viral DNA replication, beginning 6–8 h postinfection, and assembly of progeny virions occur. The entire life cycle takes about 24–36 h, generating about 10^4 virions per infected cell. Ads have never been implicated as a cause of malignant disease in their natural host and, in immunocompetent humans, most infections caused by the most common serotypes are relatively mild and self-limiting. For a more comprehensive discussion of adenoviruses, the reader is referred to the excellent review by Shenk (1).

III. FIRST-GENERATION ADENOVIRAL VECTORS

Ads are excellent mammalian gene transfer vectors due to their ability to efficiently infect a variety of quiescent and proliferating cell types from various species to direct high-level gene expression. Consequently, Ad vectors are extensively used as potential recombinant viral vaccines, for high-level protein production in cultured cells and for gene therapy (for reviews, see 11–15). First-generation Ad vectors (FGAds) typically have foreign DNA inserted in place of early region 1 (E1). E1-deleted vectors are replication deficient and are propagated in E1-complementing cells such as 293 (16). Typically, FGAds also have a deletion in the nonessential E3 region to maximize cloning capacity. The fundamental principle underlying all current methods of constructing FGAds is based on the discovery that up to 10% of Ad viral DNA molecules become circularized following infection of mammalian cells (17). This permitted cloning of the entire Ad genome as an infectious bacterial plasmid that could be manipulated with relative ease by standard molecular biology techniques. This Ad genomic plasmid could be stably propagated in *Escherichia coli* and was capable of generating infectious virus following transfection into permissive mammalian cells at efficiencies comparable to purified virion DNA. An excellent review by Danthinne and Imperiale (18) covers the plethora of methods for constructing FGAd. Although FGAd remain very useful for many applications, it has become clear that transgene expression in vivo is only transient. Several factors contribute to this, including strong innate and inflammatory responses to the vector (19,20), acute and chronic toxicity due to low level viral gene expression from the vector backbone (21), and generation of anti-Ad cytotoxic T-lymphocytes due to *de novo* viral gene expression (22–25) or processing of virion proteins (26). Although high-level transient transgene expression afforded by FGAd may be adequate, or even desirable, for many gene transfer and gene therapy applications, the toxicity and transient nature of expression kinetics renders these vectors unsuitable in cases where prolonged, stable expression is required

IV. MULTIPLY DELETED ADENOVIRAL VECTORS

Although the deletion of E1 in FGAds theoretically results in a replication-defective vector following transduction of cells devoid of trans-complementing E1 functions, it has become clear that this is not the case and that the E2, E3, and E4 promoters are active resulting in viral DNA replication and expression of the late viral genes, especially following high multiplicities of infection (27–30). Therefore, in an attempt to further attenuate Ad, additional deletions of essential viral genes have been pursued. Examples of these include deletion or mutation of the E2 or E4 regions in addition to E1. These multiply deleted Ad vectors (also referred to as second- or third-generation Ad vectors) are helper virus independent for propagation but require the generation of new producer cell lines that trans-complement the additional deletion. Despite the potential offered by these multiply deleted Ad vectors, viral coding sequences still remain and therefore so does the potential for their expression. The advantages of multiply de-

leted Ad over FGAd remain controversial because some studies show them to be superior in terms of toxicity and longevity of transgene expression (31–37), whereas others do not (21,38–41). Detailed discussion of multiply deleted Ad vectors is beyond the scope of this chapter; therefore, the reader is referred to an excellent and comprehensive review covering this subject by Parks and Amalfitano (42).

V. HELPER-DEPENDENT ADENOVIRAL VECTORS

A. Historical Perspective

In theory, the easiest way to completely eliminate the toxicity associated with viral gene expression is to delete all the viral coding sequences from the vector. Adenoviruses with large deletions of viral sequences were among the very first vectors reported. For example, in 1970, Lewis and Rowe (43) described a recombinant Ad in which essential viral genes were replaced with SV40 DNA. This replacement rendered the hybrids replication defective and they could only be propagated in the presence of a coinfecting wild-type helper Ad, which provided trans-complementation. A recombinant Ad was also described in 1981 by Deuring et al. (44), following repeated passages at high multiplicity infection of wild-type Ad serotype 12 through human KB cells. These hybrids were found to contain symmetrically duplicated human chromosomal DNA flanked by approximately 1 kb of DNA from the left end of the Ad genome. As in the case of the Ad-SV40 hybrids, these symmetrical recombinants (SYRECs) were replication defective and could only be propagated in the presence of a coinfecting helper Ad12 by trans-complementation. The SYRECs were maintained for years in this manner and could be partially purified from the helper virus by cesium chloride (CsCl) density equilibrium centrifugation, owing to differences in their genome sizes that bestowed different buoyant densities.

The defective helper virus-dependent Ad-SV40 and SYREC hybrids demonstrated the possibility of generating vectors completely devoid of Ad coding sequences. In principle, only ~500 bp of *cis*-acting Ad sequences necessary for DNA replication (ITR) and encapsidation (ψ) are required for propagation of these HDAds in the presence of a coinfecting helper virus. The advantages of HDAds are considerable: like first-generation (FG) and multiply deleted Ads, HDAds would retain the ability to efficiently transduce a wide variety of cell types from numerous species in a cell-cycle-independent manner. However, unlike FG and multiply deleted Ads, deletion of all viral coding sequences would drastically reduce vector-mediated toxicity and significantly prolong the duration of transgene expression as described in detail below.

B. Early Systems for Generating HDAds

Although, as mentioned above, the first Ad vectors were defective, helper-dependent viruses, with the development of E1-complementing 293 cells vector development focused on FGAd (E1 deleted) vectors. These were much easier to isolate and propagate than HDAds. The possibility of using HDAds for gene transfer was reexamined in studies reported by Mitani et al. (45). These investigators used a β-galactosidase-neomycin fusion gene to replace 7.3 kb of essential Ad sequences in an Ad genomic plasmid. Although this modification did not remove all the viral coding sequences, it did render the recombinant defective and helper dependent. This vector was rescued by cotransfection of 293 cells with purified Ad2 DNA, which provided helper functions. One percent to 5% of the resulting plaques turned blue following X-gal staining, indicating rescue of the recombinant virus. Blue plaque isolates were expanded by serial propagation on 293 cells and finally purified by CsCl ultracentrifugation. Fractionation through the gradient resulted in partial purification of the vector from the helper virus due to the difference in their buoyant densities. Significantly, the ability of the vector to transduce cells in vitro and express the reporter gene was demonstrated. However, the yield of vector was quite low. Furthermore, helper virus contamination remained rather high, at about 200- to 500-fold greater than the vector. In addition, the genome of the vector had undergone rearrangement.

Using a different strategy, Fisher et al. (46) constructed a plasmid bearing a 5.5-kb HDAd genome containing the Ad 5′ ITR and packaging signal, LacZ reporter gene, and 3′ ITR. 293 Cells were infected with a FGAd to serve as a helper virus and subsequently transfected with the HDAd plasmid DNA. The HDAd was amplified by serial coinfections and finally purified by CsCl ultracentrifugation. Using this method, partial purification of the vector could be achieved, but with the helper virus still in 10- to 100-fold excess. In addition, considerable genomic rearrangements in the form of concatemerization of the vector were observed, which were likely due to the small size of the vector's genome (47). Nevertheless, the vector was demonstrated to be capable of transducing cells in vitro. Using this strategy, a vector bearing cystic fibrosis transmembrane conductance regulator (CFTR) (46) and dystophin (48) expression cassettes was generated and shown to transduce cells in vitro.

Another strategy for generating HDAds was reported by Kumar-Singh and Chamberlain (49). In this system, 293 cells were cotransfected with a plasmid bearing the HDAd genome and purified Ad DNA to provide helper functions. The HDAd contained a LacZ reporter gene and dystrophin cDNA, whereas the helper virus contained the alkaline phosphatase (AP) reporter gene. The vector was amplified by serial propagation and purified by CsCl ultracentrifugation. This resulted in a final vector preparation with 4% helper virus contamination, as determined by AP:LacZ ratio. Importantly, this vector was capable of transducing myogenic cell cultures and express dystrophin in myotubes.

These early systems showed that HDAds could indeed be generated and could transduce a variety of target cells in vitro to direct transgene expression. However, they also emphasized the need to further improve production strategies because the high levels of helper virus contamination, low vector yield and, in many cases, vector genome rearrangement were clearly obstacles that needed to be addressed before the full

potential of HDAd could be realized. In particular, relying solely on physical separation between the vector and the helper by CsCl ultracentrifugation was clearly inadequate to achieve the desired vector purities. Therefore, strategies to preferentially inhibit helper virus propagation, while not affecting its ability to trans-complement the HDAd, were required.

One system designed to specifically address preferential inhibition of helper virus propagation was reported in 1996 by Kochanek et al. (50). This strategy was based on early studies in Ad packaging by Gräble and Hearing (51), which showed that deletion of 91 bp from the packaging signal severely reduced, but did not abolish, encapsidation of the Ad genome into virions while not affecting viral DNA replication. More important, Gräble and Hearing observed a competition for packaging in cells coinfected with 2 Ads: one containing a wild-type packaging signal and the other having a mutant packaging signal. The former was packaged preferentially, almost to the exclusion of the latter. Taking advantage of these observations, Kochanek et al. deleted this 91-bp deletion from the Ad packaging signal of the helper viral genome, thus impairing its ability to be packaged but not affecting its ability to replicate and thus trans-complement the HDAd genome (50). In addition, because the HDAd genome contained the wild-type Ad packaging signal, it would be preferentially packaged over the helper viral genome. The combination of this strategy in conjunction with CsCl ultracentrifugation resulted in a final vector preparation with 1% helper virus contamination. A similar strategy, but using a different packaging signal mutation, was employed by Alemany et al. (52) to generate HDAds. These strategies represented a significant improvement over the previous methods in terms of lower levels of helper virus contamination. However, 1% helper virus contamination would still likely be too high for human use, especially if high doses of HDAds were required. Furthermore, the 91-bp packaging signal deletion resulted in 90-fold reduction in yield of helper virus. From a practical standpoint, this would render production of helper virus stocks problematic because large amounts would be needed to produce the considerable quantities of HDAd needed for clinical applications.

Another system designed to specifically address propagation of the helper virus was reported by Liber et al. (53). This system took advantage of the bacteriophage P1 Cre recombinase, which catalyzes site-specific recombination between 34 bp loxP. In this method, an FGAd was engineered to contain 2 parallel loxP sites, one immediately downstream of transgene expression cassette used to replace E1 and the other in E3. Following infection of 293 cells expressing Cre, 25 kb of Ad sequences was excised from the FGAd, leaving behind a 9-kb HDAd. Thus, the unrecombined FGAd acted as the helper virus for the propagation of a 9-kb HDAd. Unfortunately, the small HDAd was unstable in vivo, providing limited duration transgene expression for reasons that are still not fully understood. Furthermore, the vector still retained Ad coding sequences and, because the HDAd originated from an FGAd, had limited cloning capacity. Clearly, further improvements were needed if HDAd were to progress into clinical applications.

C. The Cre/loxP System for Generating HDAds

The first efficient and currently most widely used method for generating HDAd was the Cre/loxP system developed by Graham and coworkers in 1996 (54) (Fig. 2). In most versions of this system, the HDAd genome is first constructed in a bacterial plasmid. Minimally, the HDAd genome contains the expression cassette of interest and ~500 bp of *cis*-acting Ad sequences necessary for vector DNA replication (ITRs) and packaging (ψ). As described in detail in Section V.E, inclusion of stuffer DNA in the HDAd genome is often required for efficient packaging. To rescue the HDAd (i.e., to convert the ''plasmid form'' of the HDAd genome into the ''viral form''), the plasmid is first digested with the appropriate restriction enzyme to liberate the HDAd genome from the bacterial plasmid sequences. 293 Cells expressing Cre are then transfected with the linearized HDAd genome and subsequently infected with the helper virus. The helper virus bears a packaging signal flanked by loxP sites and thus, following infection of 293Cre cells, the packaging signal is excised from the helper viral genome by Cre-mediated site-specific recombination between the loxP sites. This renders the helper viral genome unpackagable, but still able to undergo DNA replication and thus trans-complement the replication and encapsidation of the HDAd genome. The titer of the HDAd is increased by serial coinfection of 293Cre cells with the HDAd and the helper virus (Fig. 3). Maximum HDAd titer of $\sim 10^8$ infectious particles/mL (~1000–2000 infectious particles/producer cell) is usually obtained by the third serial passage (Fig. 3)(55). Typically, the level of helper virus contamination is ($\leq$1%, as determined by Southern blot hybridization analysis, before vector purification by CsCl ultracentrifugation (55) and, provided that the genome sizes of the vector and helper are sufficiently different, purities of $\leq$0.1% helper virus contamination can be achieved following CsCl ultracentrifugation as determined by Southern blot hybridization or quantitative real-time polymerase chain reaction (PCR) (56). Detailed methodologies for producing HDAd using the Cre/loxP system are described elsewhere (57). A similar system was subsequently reported by Hardy et al. (58).

D. The FLP/frt System for Generating HDAds

Based on the Cre/loxP strategy, systems were later developed using the yeast site-specific recombinase FLP, which catalyzes recombination between 34-bp frt sites (55). In this case, the packaging signal in the helper viral genome is flanked by frt sites so that, following infection of 293 cells stably expressing FLP, the packaging signal is excised, rendering the helper viral genome unpackagable but still able to replicate and trans-complement propagation of the coinfecting HDAd. This system was shown, by direct comparison, to be compara-

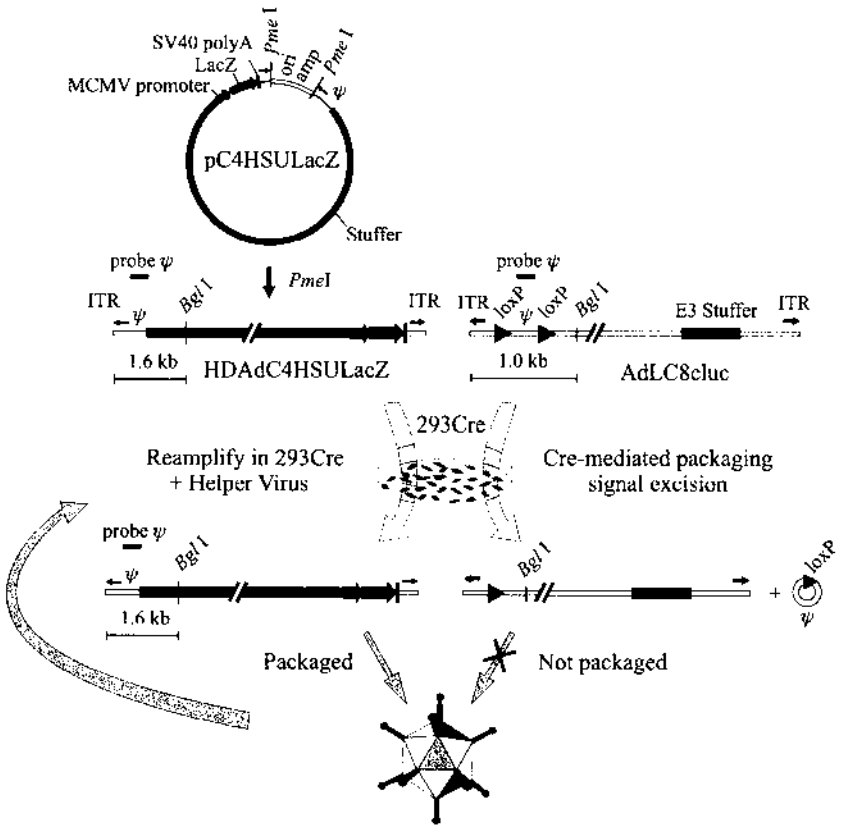

Figure 2 The Cre/loxP system for generating HDAds. The HDAd contains only ~500 bp of *cis*-acting Ad sequences required for DNA replication (ITRs) and packaging (ψ), the remainder of the genome consists of the desired transgene, in this case, a LacZ expression cassette, and non-Ad ''stuffer'' sequences. The HDAd genome is constructed as a bacterial plasmid (pC4HSULacZ in this example) and is liberated by restriction enzyme digestion (e.g., *Pme*I). To rescue the HDAd (HDAdC4HSULacZ), the liberated genome is transfected into 293Cre cells and infected with a helper virus bearing a packaging signal (ψ) flanked by loxP sites (e.g., AdLC8cluc,54). The helper viral genome also contains a stuffer sequence in E3 to prevent the formation of RCA in 293-derived cells. Cre-mediated excision of ψ renders the helper virus genome unpackagable, but still able to replicate and provide all the necessary *trans*-acting factors for propagation of the HDAd. The titer of the HDAd is increased by serial coinfections of 293Cre cells with the HDAd and the helper virus. Shown for the HDAd and the helper virus are the relevant BglI sites and the corresponding DNA fragment sizes, as well as the location of the packaging signal probe (probe ψ) used for Southern blot hybridization analysis illustrated in Fig. 3.

ble to the Cre/loxP system in terms of efficiency of HDAd amplification and low helper virus contamination levels (55). A similar FLP-based system for generating HDAds was also reported by Umana et al. (59). The availability of 2 alternative systems for generating HDAd should expand the utility of HDAds by permitting use of recombinase-activated ''molecular switches'' (60) in which one recombinase can inhibit helper virus propagation while the other regulates transgene expression. Furthermore, it has been suggested that the 2 site-specific recombinase systems may be combined to further reduce the level of helper virus contamination, perhaps by flanking the packaging signal with both loxP and frt sites and using producer cells that express both Cre and FLP (55).

E. Characteristics of the Helper-dependent Vector

In addition to the minimal *cis*-acting Ad sequences required for DNA replication and encapsidation, Sandig et al. (56) showed that inclusion of a small segment of noncoding Ad sequence from the E4 region adjacent to the right ITR increases vector yields, possibly by enhancing packaging of the HDAd DNA. Early studies of Ad have established a maximum packaging capacity of 105% of the wild-type genome (~37.8 kb) (61). Subsequently, using the Cre/loxP system for generating HDAds, Parks et al. (47) established that the minimum genome size for efficient packaging into Ad virions was 27 kb.

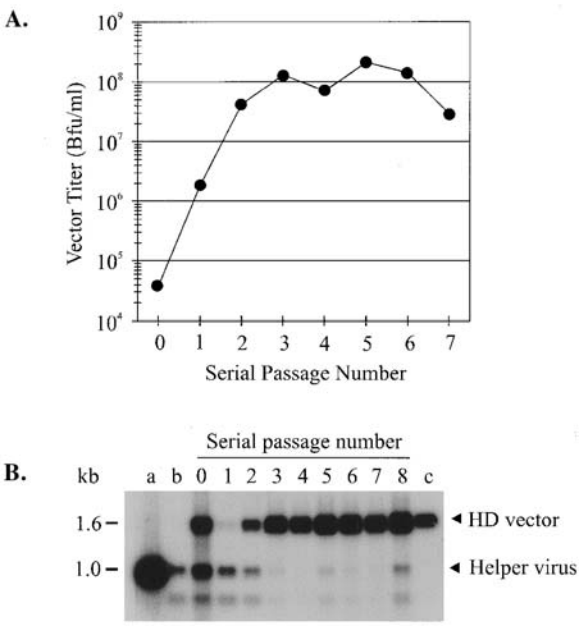

Figure 3 Amplification of HDAd. (A) Amplification of HDAdC4HSULacZ by serial coinfections of 293Cre cells with the HDAd and the helper virus. HDAdC4HSULacZ contains a LacZ reporter gene (Fig. 2). Therefore, the amount of HDAd produced at each serial passage can be determined by X-gal staining and is expressed as blue-forming units (bfu)/mL. (B) Southern blot hybridization analysis of HDAd amplification from (A). Total DNA was extracted from the coinfected cells at each serial passage, digested with BglI, and analyzed with a packaging signal probe (see Fig. 2 for details). The amount of HDAd DNA (1.6-kb band) increases from passage 0 to a peak by passage 3, consistent with amount of infectious vector produced as shown in (A), whereas the amount of packagable helper viral DNA (1.0-kb band) remains low. Lane a, total DNA extracted from helper virus-infected 293 cells. Lane b, total DNA extracted from helper virus-infected 293Cre cells. Lane c, pC4HSULacZ digested with BglI and *Pme*I. (Adapted from Ref. 55.)

Vector genome sizes above the maximum packaging capacity were not efficiently packaged, if at all. Vector genome sizes below 27 kb were inefficiently packaged and frequently underwent DNA rearrangements to produce genomes closer to that of wt viruses (approximately 36 kb) (46,47,62). Therefore, the size of the vector is an important consideration: for efficient packaging and stability, the vector genome should be between ~75% (>27 kb) (47) and 105% (<37.8 kb) (61) of wild-type. Because the minimal Ad *cis*-acting sequences and the transgene of interest are usually well below the minimal size required for efficient packaging, the vector must often include ''stuffer'' DNA. The choice of stuffer DNA is important with regard to vector stability, replication efficiency and in vivo performance (56,63,64). Although it remains unclear what constitutes a good stuffer, in general, noncoding eukaryotic DNA has been preferred, whereas repetitive elements and unnecessary homology with the helper virus should be avoided to ensure vector stability and prolonged transgene expression.

In addition to the absolute size of the HDAd, its relative size compared with the helper virus has an impact on the production of (nearly) helper-free vectors. This is because Cre-mediated selection against the helper virus, although efficient, is not absolute (65) (see Section V.G). If the genome size of the HDAd is sufficiently different from that of the helper virus then the 2 species can be physically separated by CsCl ultracentrifugation due to their different buoyant densities. HDAds between 28 and 31 kb have proven ideal because they are efficiently packaged and replicated, as well as easily separated from residual helper viruses (35–37 kb) following CsCl ultracentifugation.

It is also becoming clear that the nature of the transgene has a significant influence on the degree and duration of transgene expression. Specifically, transgenes in their native genomic context have consistently been demonstrated to be superior to their cDNA counterparts with respect to level and duration of expression (64,66,67). This is likely due to a more natural regulation of gene expression. In this regard, because of the large cloning capacity of 37 kb, HDAds offer the advantage of potentially transferring many genes in their genomic context, whereas other vectors (e.g., FG and multiply deleted Ads, retroviral, lentiviral, or adeno-associated viral vectors) cannot due to their limited cloning capacity. In the case of cDNA, expression from a tissue-specific promoter was found to be superior to nonspecific promoters in terms of toxicity and duration of expression (64,68). This has been attributed to a reduction of transgene expression in transduced antigen-presenting cells, following systemic delivery of vectors that carry expression cassettes under the control of tissue-specific promoters (68). Expression from tissue-specific promoters has been demonstrated to be more ''tissue specific'' within the context of an HDAd than a FGAd (69). This may be due to the influence of Ad sequences from the FGAd backbone on transgene expression specificity, which does not occur with HDAds (69). In addition, use of tissue-specific promoters may result in more robust amplification of the HDAd because high-level transgene expression in the producer cells may negatively impact viral replication during serial coinfections, especially if the transgene product is toxic to the producer cells.

Titration of FG and multiply deleted Ads is straightforward. These vectors can form plaques on monolayers of the appropriate complementing cell lines in a standard plaque assay. The infectious titer can then be determined by enumerating the plaques and expressed as the number of plaque-forming units (pfu)/mL. In addition to infectious titer, the virion particle concentration, based on DNA content, can be readily obtained by measuring the optical density at 260 nm (OD_{260}) of the vector preparation. Comparison of the particle: infectious unit ratio provides a measure of the infectivity of the vector preparation and current Food and Drug Administration standards require a ratio of <30:1 for FG vectors used in

clinical trials (70). Like FG and multiply deleted Ads, the physical titer of HDAds can be readily obtained by measuring OD_{260}. Measurements of infectious titers are, however, not as straightforward because, unlike FG and multiply deleted Ads, HDAds cannot form plaques on cell monolayers, thus precluding infectious titer determination by standard plaque assays. If the HDAd contains a transgene that can serve as a reporter, such as LacZ, an infectious titer can be obtained (see, for example, Fig. 3A). However, this is not the case with the majority of therapeutic HDAds, thus rendering the infectivity of HDAd preparations difficult to ascertain. Kreppel et al. (71) developed a DNA-based method of measuring the infectivity of HDAds that assays ability of the vector to deliver its genome into target cells. However, it is important to note that this method measures only cellular entry of the vector DNA, whereas infectious titer assays for FG and multiply deleted Ads also depend on viral gene expression (resulting in plaque formation or reporter gene product) following entry of the genome into the nucleus and are thus more stringent.

F. Characteristics of the Helper Virus

The most commonly used helper virus is a serotype 5, FGAd (E1 deleted) with its packaging signal flanked by loxP sites (Fig. 2). As with all FGAds propagated in 293 or 293-derived cells, the potential exists for the generation of replication-competent Ad (RCA; $E1^+$) as a consequence of homologous recombination between the helper virus and the Ad sequences present in 293 cells. To prevent the formation of RCA, a ''stuffer'' sequence was inserted into the E3 region to render any $E1^+$ recombinants too large to be packaged (54). The length of the E3 stuffer is such that the total size of the helper virus genome is $<105\%$ of wild-type, but $>105\%$ following homologous recombination with Ad sequences in the 293 cells. As of this writing, the emergence of RCA has yet to be reported using helper viruses with an E3 stuffer. In contrast, RCA is readily detected using helper viruses without an E3 stuffer when propagated in 293 and 293-derived cells (41,54). The choice of sequence used as stuffer in the E3 region may be important as it has been observed that some E3 inserts result in poor virus propagation, perhaps due to interference with fiber expression (Authors' unpublished data). Although it remains unclear what sequences constitute a good E3 stuffer, in general, noncoding sequences with no homology to the HDAd would be preferred. A number of sequences have been found to be stable and not to adversely affect virus propagation, including bacterial plasmid sequences, bacteriophage λ sequences, and human DNA (54–56,59,72). The use of other E1-complementing cell lines engineered to preclude the formation of RCA is another option (73,74). Such cell lines have been used for the production of RCA-free FGAd, but there are not yet any reported of the development of Cre-expressing derivatives and their use for the production of HDAd.

One strategy to further enhance safety is to attenuate the helper virus to reduce its toxicity. To this end, a helper virus with a deletion of E2a was developed by Zhou et al. (75). E2a encodes the Ad 72-kD DNA-binding protein, which is essential for viral DNA replication. In theory, the E2a-deleted contaminating helper viruses would be unable to undergo viral DNA replication and thus would be unable to express the late Ad structural proteins, which are responsible for cytotoxicity and induction of cellular immunity. However, whether this modification truly improves safety is questionable, considering some studies have shown that the immune response and toxicity elicited against Ad is the same regardless of whether the vector has a defective E2a (21,41) (also see Section IV).

Because the HDAd genome does not integrate into the host chromosomes, but rather presumably remains episomal, it is likely that transgene expression will not be permanent. If transgene expression fades over time, it would be desirable to simply readminister the vector. Unfortunately, this simplistic approach is not possible because the initial administration elicits immunity in the form of neutralizing anti-Ad antibody, which renders subsequent readministrations ineffective. One strategy, known as ''serotype switching'' may help to overcome this problem. In addition to the Ad serotype 5-based helper virus, Parks et al. have generated a serotype 2 helper virus (72). Helper viruses based on serotypes 1 and 6 have also been generated (Authors' unpublished data). Therefore, genetically identical HDAds of different serotypes can by generated simply by changing the serotype of the helper virus used for vector amplification. Parks et al. demonstrated that mice injected with a serotype 2 HDAd produced serotype 2 neutralizing antibodies, which prevented successful transduction with the same serotype HDAd (72) but did not prevent successful transduction following administration of a serotype 5 HDAd. Successful readministration of HDAd of alternative serotypes has also been demonstrated by Kim et al. (66) (see Section VI.A). As discussed in Section II, there are ~50 human serotypes of Ad. Therefore, it may be possible to create a panel of different serotype helper viruses and use these to generate different serotype but genetically identical HDAds. These HDAds could then be given sequentially every 2 to 3 years when transgene expression wanes from the previous vector administration. Because of the large number of Ad serotypes, this could theoretically continue for the lifetime of the patient, although development of the many helper viruses needed for this approach might prove challenging.

G. Helper Virus Contamination

Currently, the final purity of HDAd preparations is dependent on two enrichment steps. The first is Cre-mediated packaging signal excision during vector amplification. This alone results in about $\leq 1\%$ helper virus contamination (65). If the genome sizes of the HDAd and the helper virus are sufficiently different, further enrichment can be obtained by CsCl ultracentrifugation, which can reduce contamination levels to as low as 0.1% or less. Although the final level of helper virus contamination is quite low, further reduction is desirable to minimize any potential toxicity associated with the helper virus, especially in therapies where very high doses of the HDAd may be required. Furthermore, in those cases where the genome sizes of the HDAd and helper virus are unavoidably similar,

physical separation of the 2 species by CsCl ultracentrifugation will not be possible and contamination levels of ≤0.1% will likely be unachievable. Finally, CsCl ultracentrifugation is impractical for large-scale clinical grade vector production. The source of the residual contaminating helper virus that persists during HDAd propagation using the Cre/loxP has been investigated in detail (65). That study revealed that the contaminating helper virus has escaped Cre-mediated packaging signal excision and propagated. Detailed investigations revealed that this was not due to acquisition of Cre-resistant mutations or to the reverse Cre reaction, which would reinsert the excised packaging signal. Nor was it due to inaccessibility of a fraction of the helper viral DNA to Cre. Rather, the results revealed that incomplete packaging signal excision was the result of Cre levels being limiting in the producer cells due to low endogenous levels. Further exacerbating this problem may be Ad-mediated host cell shut off, a well-documented phenomenon in which synthesis of cellular protein is inhibited as a consequence of Ad infection [reviewed in (76)]. The results of this study suggested that further reduction in helper virus contamination may be achieved by increasing the amount of Cre in the producer cells. However, given that very high, constitutive levels of Cre expression have been reported to be cytotoxic in various cell lines, including 293 (77), this strategy may be difficult to achieve.

It is important to ascertain the level of helper virus contamination accurately because high levels of helper virus contamination may affect experimental results and compromise safety. Knowing the level of helper virus contamination also allows for meaningful comparisons between different studies. A variety of methods for determining helper virus contamination have been reported, all of which can be divided into 2 basic categories. The first is based on determining the infectious titer of the contaminating helper virus in an HDAd preparation. These methods included plaque assay on 293 cells (or 293-derived cells) or infectious unit assay, based on the presence of a reporter transgene in the helper virus. Using these infectious titer assays, the level of helper virus contamination is often reported as a percent or a ratio of infectious helper virus in the vector preparation. However, these methods suffer from numerous shortcomings. First, the units of measurement for the HDAd and helper virus are not the same and thus not directly comparable, making it difficult to accurately determine the level of helper virus contamination. Second, it has been shown that infectious assays are 10- to 50-fold less sensitive than DNA-based assays described below, thus grossly underestimating the true level of contamination, and may be incapable of detecting very low levels of helper virus contamination (41,71). Alternative methods of determining helper virus contamination use direct measurement of the amount of HDAd and helper viral DNA in a vector preparation. This has been accomplished by standard Southern blot hybridization analysis (55,71) or quantitative real-time PCR assays (41,56,59). Not only are these methods more sensitive and reliable, but also the unit of measurement is the same for both the HDAd and the helper virus therefore allowing the level of helper virus contamination to be expressed simply as a percentage of the total DNA [% helper contamination = helper DNA/(vector DNA + helper DNA)]. The reader should keep the distinction between the 2 methods of determining helper virus contamination levels in mind when critically reading primary publications. In general, most studies published prior to the year 2000 used infectious titer assays, whereas most (but not all) studies published after the year 2000 used DNA-based methods to determine helper virus contamination levels.

VI. IN VIVO STUDIES

As of this writing, numerous examples of in vivo gene transfer using HDAds have been reported. This chapter does not provide a comprehensive review of these studies; instead, examples of particular significance or interest are described. In general, all these studies demonstrate that compared with FG and multiply deleted Ads, HDAds are significantly less toxic and can permit prolonged transgene expression in vivo.

A. Transduction of the Liver

The liver is very attractive target for gene therapy. The fenestrated structure of its endothelium permits exposure of the parenchymal cells to intravenously delivered vector and secretion of vector-encoded therapeutic proteins into the circulation for systemic delivery. Ads are particularly attractive vectors for liver-directed gene therapy because of their efficiency at transducing hepatocytes following intravenous injection.

α_1-Antitrypsin antagonizes neutrophilic elastase and is abundantly expressed in hepatocytes and at a lower level in macrophages. α_1-Antitrypsin-deficient patients have shortened life expectancies due to emphysema. The utility of HDAds for liver-directed gene transfer was demonstrated in a series of studies using a HDAd containing the 19-kb genomic human α_1-antitrypsin (hAAT) locus (AdSTK109). In the first of these studies, immunocompetent C57BL/6J mice, which do not generate anti-hAAT antibodies, were intravenously injected with 2×10^{10} particles of AdSTK109 (67). Serum hAAT levels reached a plateau of ~50 μg/mL 3 weeks postinjection and were sustained for the duration of the 10-month experiment. In contrast, in C57BL/6J mice injected with 2×10^{10} particles AdhAATΔE1, a FGAd vector bearing the hAAT cDNA, hAAT concentrations reached a peak of 2 μg/mL 3 days postinjection, followed by a slow decline over 10 months to less than 10% of the peak levels. The superior expression levels induced by AdSTK109 compared with AdhAATΔE1 were attributed to the more favorable genomic context of the hAAT in the HDAd compared with the cDNA inserted in the FGAd. The duration of hAAT expression correlated with persistence of vector genome in the liver. Specifically, a total of 65% of the FGAd genome was lost between 3 days and 12 weeks compared with a loss of only 30% in the case of AdSTK109, with only a 6% loss at 6 and 12 weeks. Histopathological examination of livers from C57BL/6J mice injected with AdSTK109 revealed normal morphology between 3 days

and 12 weeks postinjection, whereas significant hepatotoxicity was observed from 6 to 12 weeks in the livers of mice injected with AdhAATΔE1. To further examine the issue of hepatotoxicity, *Rag1*-immunodeficient mice were injected with AdSTK109 or AdhAATΔE1. As with C57BL/6J mice, no evidence of liver toxicity was associated with AdSTK109. In contrast, hepatotoxicity was observed in AdhAATΔE1-injected *Rag1* mice, similar to that observed in C57BL/6J mice. These results suggested that the observed hepatotoxicity resulted from direct cytotoxic affect of the viral proteins expressed from the AdhAATΔE1 backbone, instead of toxicity due to induction of a cytotoxic T lymphocyte (CTL) response because *Rag1* mice do not produce CTLs (67).

Increasing the dose of AdSTK109 to 1.1×10^{11} particles resulted in 1 mg/mL hAAT in the serum, which is close to the normal human range (1.3 mg/mL) (78). Further increases in vector dose to 3.2×10^{11} particles resulted in supraphysiological levels of 5–6 mg/mL, which were sustained for the duration of the experiment (8 weeks). In contrast, injection of identical doses of AdhAATΔE1 resulted in only transient hAAT expression. Clinically relevant markers of liver toxicity (ALT, alanine aminotransferase; AST, aspartate aminotransferase; and AP, alkaline) remained within the normal range in mice injected with AdSTK109 throughout the observation period, beginning 3 days to 8 weeks postinjection. In contrast, these markers were significantly elevated in mice injected with AdhAATΔE1 for at least 6 weeks. Histopathological studies performed 5 days postinjection with the highest dose of AdSTK109 (3.2×10^{11} particles) revealed only mild signs of liver injury, including minor evidence of inflammation as quantitated by neutrophil infiltration. In contrast, extensive liver injury was observed at the highest dose of AdhAATΔE1 (3.2×10^{11} particles), including cell degeneration, cell necrosis, and abundant inflammation. Morphological changes were also observed in the spleen at the highest dose, including large, expanded lymphoid follicles with active germinal centers and increased extramedullary hematopoiesis. These splenic changes were more pronounced in mice injected with AdhAATΔE1. Southern blot analyses on liver DNA revealed that AdSTK109 DNA did not decline significantly for the duration of the experiment. In contrast, the amount of AdhAATΔE1 DNA in the liver at 8 weeks was significantly reduced compared with 5 days in mice injected with high dose, consistent with the observed decline in hAAT expression.

To evaluate the utility of HDAds in a large animal model, three baboons were intravenously injected with $3.3–3.9 \times 10^{11}$ particles/kg of AdSTK109 (79). hAAT expression persisted for more than 1 year in 2 of the 3 animals (Fig. 4). Maximum levels of serum hAAT of 3–4 mg/mL were reached 3 to 4 weeks postinjection in these 2 baboons and slowly declined to 8% and 19% of the highest levels after 24 and 16 months, respectively. The slow decline in hAAT expression was attributed to the fact that the baboons were young (7.5 and 9 months old) when injected and that the decrease in hAAT concentrations was correlative to the growth of the animals. The third baboon injected with AdSTK109 had significantly lower levels of serum hAAT, which rapidly declined

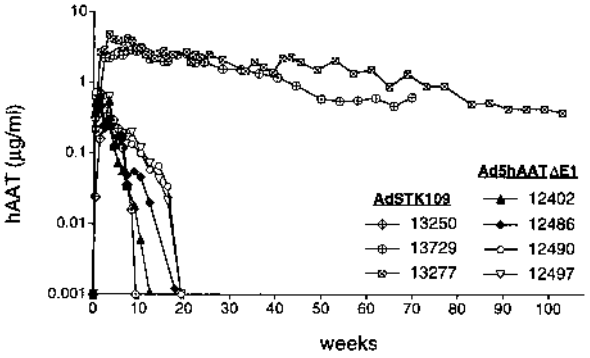

Figure 4 Serum levels of hAAT in baboons following intravenous administration of the HDAd AdSTK109 or the FGAd Ad5-hAATΔE1. Baboons 12402 and 12486 were injected with 6.2×10^{11} particles/kg of Ad5hAATΔE1. Baboons 12490 and 12497 were injected with 1.4×10^{12} particles/kg of Ad5hAATΔE1. Baboons 13250, 13729, and 13277 were injected with 3.3×10^{11} particles/kg, 3.9×10^{11} particles/kg, and 3.6×10^{11}particles/kg, respectively, of AdSTK109. (From Ref. 79, copyright 1999 National Academy of Sciences, USA.)

to undetectable levels after 2 months (Fig. 4). This baboon had generated anti-hAAT antibodies, thus accounting for the low level and rapid loss of serum hAAT. No abnormalities in blood cell counts and chemistries were observed in these 3 baboons at any time, starting 3 days postinjection. In contrast to baboons injected with AdSTK109, hAAT expression lasted only 3 to 5 months in all 4 baboons injected with AdhAATΔE1 (Fig. 4). This was shown not to be due to the generation of anti-hAAT antibodies but was attributed to the generation of a cellular immune response against viral proteins expressed from the vector backbone, resulting in the elimination of vector-transduced hepatocytes. These early experiments convincingly demonstrated that HDAd were superior to FGAd with respect to duration of transgene expression and hepatotoxicity in mice and, significantly, in a nonhuman primate.

Leptin is a potent modulator of weight and food intake. Leptin deficient *ob*/*ob* mice gain considerable weight (~70 g) compared with lean littermates (~28 g) at 8 to 12 weeks of age. Morsy et al. (62) compared HDAd with FGAd, with respect to safety and efficacy, for leptin gene therapy in *ob*/*ob* mice. Intravenous injection of $1–2 \times 10^{11}$ particles of a FG vector encoding murine leptin (Ad-leptin) into *ob*/*ob* mice resulted in an increase in serum leptin levels for only the first 4 days, returning to baseline levels 10 days postinjection (Fig. 5A). Increased leptin levels were associated with transient weight loss of ~25% followed by weight gain 2 weeks after treatment (Fig. 5B). In contrast, *ob*/*ob* mice injected with an HDAd-encoding leptin (HD-leptin) resulted in about 2-fold higher serum levels of leptin up to ~15 days postinjection (Fig. 5A). However, expression was transient and gradually returned to baseline levels 40 days postinjection. Rapid weight loss to levels approaching that of normal lean mice (>60%

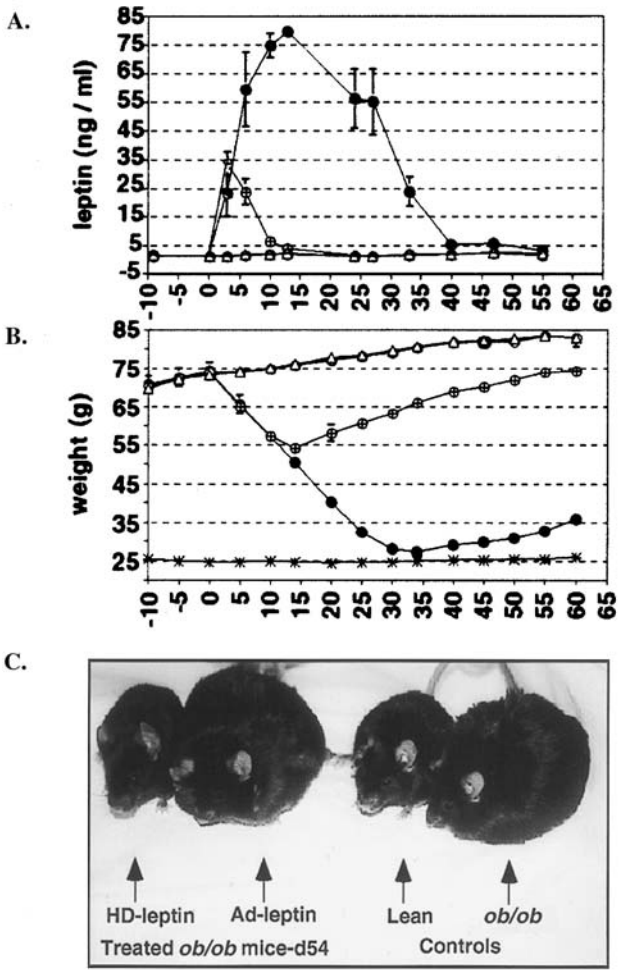

Figure 5 Phenotypic correction of leptin-deficient *ob*/*ob* mice with HDAd-mediated gene therapy. (A) Serum leptin levels and (B) weights of *ob*/*ob* mice intravenously injected with HD-leptin (black circle), Ad-leptin (crossed circle), or uninjected controls (white triangles). Weights of normal lean mice are shown in (B) as ∗. (C) Phenotypic correction of *ob*/*ob* mice. On the left is an *ob*/*ob* mouse treated with HD-leptin, next to an *ob*/*ob* littermate treated with Ad-leptin at 54 days postinjection. Control normal lean mouse and untreated *ob*/*ob* mouse are shown to the right for comparison. See the color insert for a color version of this figure. (Modified from Ref. 62, copyright 1998 National Academy of Sciences, USA.)

weight reduction) was observed in the HD-leptin-treated animals by 1 month, but the loss was only maintained for 6 to 7 weeks postinjection (Figs. 5B and 5C). Analogous to the case of hAAT in 1 baboon, loss of leptin in both Ad-leptin and HD-leptin mice correlated with the development of antileptin antibodies. This is undoubtedly due to the fact that *ob*/*ob* mice are naive to leptin. Hepatotoxicity was compared in mice treated with HD-leptin and Ad-leptin 1, 2, and 4 weeks postinjection. Pronounced liver toxicity, as measured by ~10-fold increase in AST and ~5-fold increase in ALT, was observed in Ad-leptin, but not HD-leptin treated mice. Liver histopathology at these time points revealed evidence of inflammation and cellular infiltration in livers of Ad-leptin-treated mice, whereas livers from HD-leptin-treated mice were histologically indistinguishable from untreated control livers. These results indicated that HDAd were significantly less toxic than their FG counterparts. Importantly, in contrast to *ob*/*ob* mice, sustained high levels of serum leptin were observed in lean mice, for which leptin would not be a foreign antigen, following injection of HD-leptin but not Ad-leptin (62). Therefore, this study, together with the hAAT baboon study (79), suggested that in the absence of an immune response to the transgene product HDAds can provide prolonged transgene expression to achieve phenotypic correction of a genetic disease with negligible toxicity.

Kim et al. (66) investigated correction of hypercholesterolemia in apolipoprotein E (apoE)-deficient mice by using either an FGAd-encoding mouse apoE cDNA (FG-Ad5-cE), an HDAd-encoding mouse apoE cDNA (HD-Ad5-cE), or an HDAd-bearing mouse genomic apoE locus (HD-Ad5-gE). Intravenous injection of ApoE-deficient mice with 5×10^{12} particles/kg of FG-Ad5-cE resulted in an immediate fall in plasma cholesterol levels to within normal range (Fig. 6A). However, this effect was transient and plasma cholesterol levels increased after 28 days, returning to pretreatment levels by 112 days. Correlative with the plasma cholesterol levels, the levels of plasma apoE immediately increased shortly after injection but rapidly declined to pretreatment levels by day 28 (Fig. 6B). Similarly, intravenous injection of 7.5×10^{12} particles/kg of HD-Ad5-cE produced a complete and immediate lowering of plasma cholesterol to normal levels, but in contrast to FG-Ad5-cE, the reduced levels lasted about 1 year before gradually increasing (Fig. 6A). ApoE appeared in plasma within 1 week and remained at a level ~25% of wild-type (<10% of normal plasma levels of apoE is sufficient to maintain normal plasma cholesterol) but slowly declined to <10% of wild-type after about 1.5 years (Fig. 6B), at which time plasma cholesterol levels rose to ~50% of untreated mice (Fig. 6A). Intravenous injection of 7.5×10^{12} particles/kg of HD-Ad5-gE also resulted in a complete and immediate lowering of plasma cholesterol to subnormal levels for about 9 months, with levels subsequently staying within the normal range for the rest of the natural lifespan of the animal (2.5 years) (Fig. 6A). In this case, plasma apoE reached ~200% wild-type levels within 4 weeks and remained at supraphysiological levels for >4 months, at which time it slowly declined to about wild-type levels at 1 year and remained at 60% to 90% physiological concentrations for the lifetime of the animals (2.5 years) (Fig. 6B).

Because the duration of ApoE expression from HD-Ad5-gE was superior to HD-Ad5-cE, it would appear that genomic-based transgenes may be more effective than cDNA-based transgenes. Although the duration of expression from HD-Ad5-gE was impressive, lasting the lifetime of the mice, it would likely not be sustained in animals with significantly

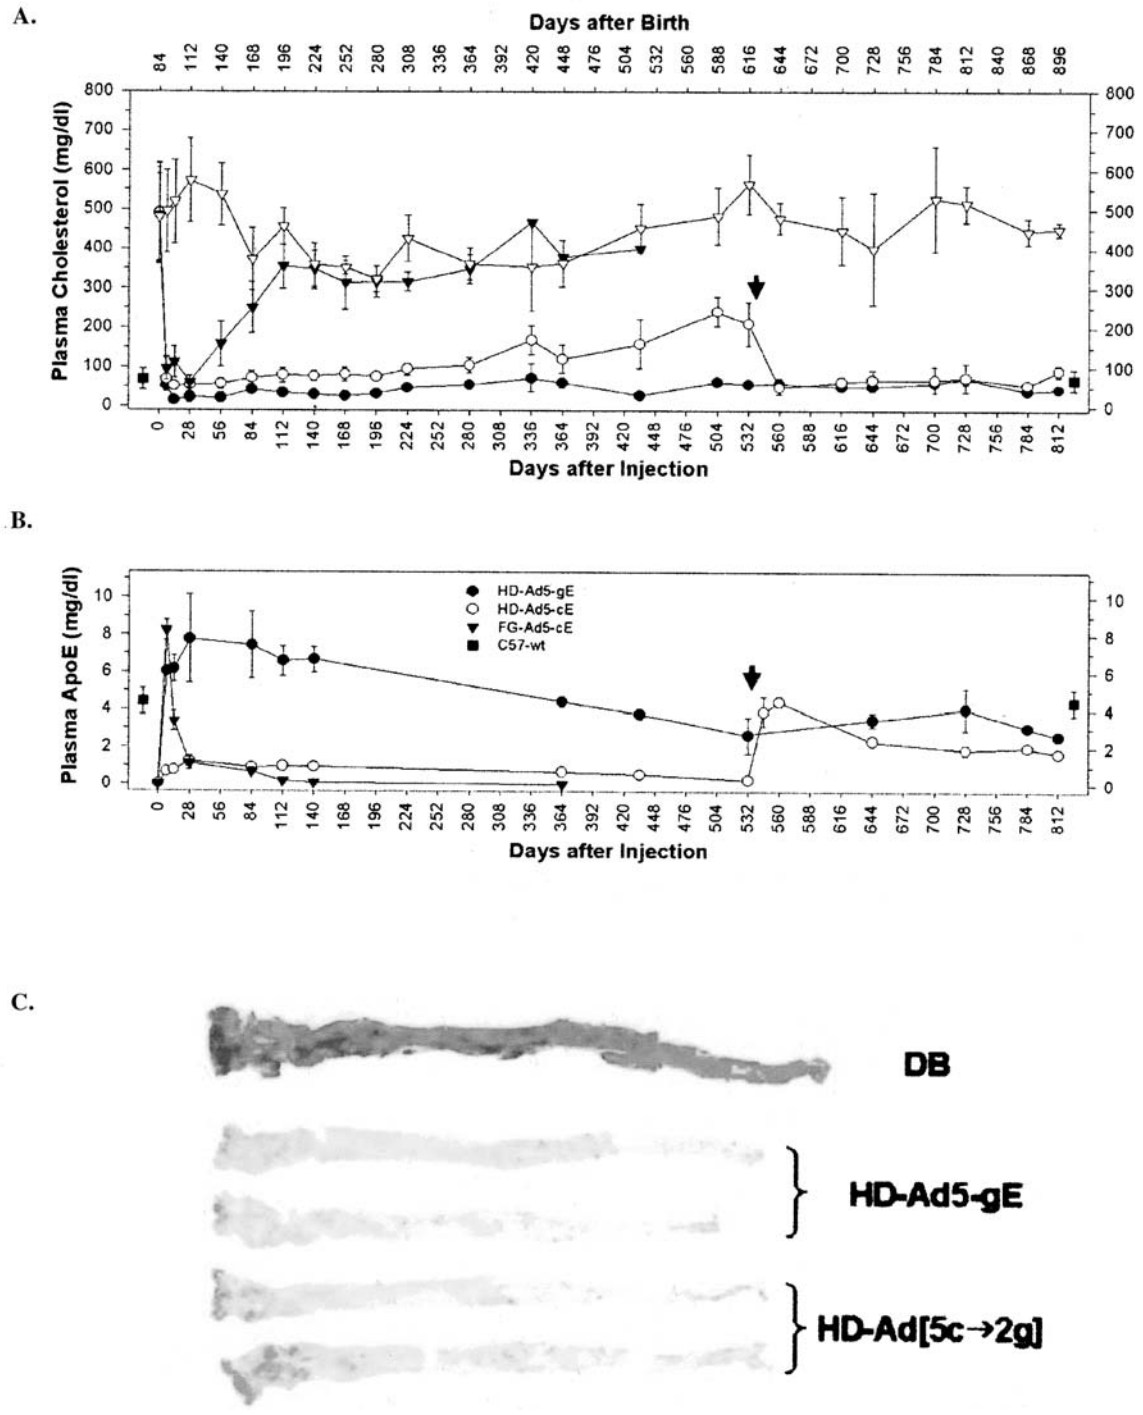

Figure 6 HDAd-mediated phenotypic correction of atherosclerosis in ApoE-deficient mice. (A) Plasma cholesterol and (B) plasma ApoE levels in ApoE-deficent mice injected with dialysis buffer (white triangle), FG-Ad5-cE (black triangle), HD-Ad5-gE (black circle), or HD-Ad5-cE followed (indicated by the bold arrow) by HD-Ad2-gE (white circle). (C) Aortas from HDAd-treated and control dialysis buffer (DB)-treated mice stained with Oil Red at 2.3 years postinjection. Atherosclerotic lesion areas, stained red, determined by quantitative morphometry were 91.45 mm^2 for DB-treated animals; 0.81 mm^2 and 0.31 mm^2 for HD-Ad5-gE-treated animals; and 5.89 mm^2 and 1.74 mm^2 for HD-Ad5-cE followed by HD-Ad2-gE-treated animals. See the color insert for a color version of this figure. (Modified from Ref. 66, copyright 2001 National Academy of Sciences, USA.)

longer lifespans, such as humans. Simply readministering the vector when transgene expression wanes is not possible due to the potent neutralizing anti-Ad antibody response that is elicited by the first administration. Indeed, mice previously treated with HD-Ad5-cE could not be successfully retreated again with the same vector. One solution to overcoming this problem is to administer a vector of a different serotype (72) (see Section V.F). To evaluate this strategy, Kim et al. generated a serotype 2 version of the genomic ApoE vector (HD-Ad2-gE) (66), using the serotype 2 helper virus described by Parks et al., (72) and showed that it could be successfully administered to mice previously treated with the serotype 5 HD-Ad5-cE to lower plasma cholesterol levels and raise plasma ApoE levels for the remainder of the animals' lives (Figs. 6A and 6B).

Aortas in all mice, examined at 2.3 years after treatment with HDAds, were essentially free of atherosclerotic lesions as determined by quantitative morphometry (Fig. 6C), demonstrating that a single injection of HDAd-encoding ApoE could confer lifetime protection against aortic atherosclerosis. Kim et al. also investigated the associated toxicities and found that, whereas injection of FG-Ad5-cE resulted in significant hepatotoxicity as indicated by significant elevation of AST and ALT (>10- to 20-fold), no such evidence of damage was observed following injection of any of the various HDAd constructs, even after a second administration with the serotype 2 HDAd (66).

In summary, this study elegantly demonstrated many of the advantages of HDAds for gene therapy. First, the large cloning capacity of the vector permits delivery of transgenes in their native chromosomal context, resulting in superior kinetics and duration of expression. Indeed, a single intravenous injection of HDAd, in this case, resulted in lifelong expression of the therapeutic transgene and permanent phenotypic correction of a genetic disease. Second, if transgene expression diminishes over time, administration of an alternative serotype HDAd is effective at circumventing the humoral immune response generated by the initial treatment. Third, negligible hepatotoxicity was associated with HDAd administrations.

Hemophilia A is the most common inherited severe bleeding disorder; it is caused by a deficiency in coagulation factor VIII (FVIII) and affects about 1 in 10,000 males. Patients with <1% normal plasma FVIII activity suffer from spontaneous and prolonged bleeding into joints, muscle, and internal organs. Hemophilia A is an attractive target for gene therapy because it is caused by a single gene defect, and even moderate increases of FVIII levels can convert a severe phenotype to a milder form. Reddy et al. (41) compared the efficacy and safety of hemophilia A gene therapy using a multiply deleted (E1, E2a, E3 deleted) Ad vector (Av3H8101) and an HDAd (AGV15huFVIII), both containing the identical B-domain-deleted human FVIII expression cassette. In this study, hemophiliac A mice were intravenously injected with 6×10^{10} particles of AGV15huFVIII or Av3H8101. Plasma hFVIII levels in mice treated with AGV15huFVIII peaked at 2 weeks postinjection and were 10-fold higher than levels achieved using Av3H8101 (Fig. 7A). Expression of hFVIII in AGV15-huFVIII-treated mice was sustained for at least 40 weeks although a ~10-fold decrease in plasma levels was observed between weeks 2 and 40 (Fig. 7A). In contrast, plasma hFVIII levels in Av3H8101-treated mice rapidly decreased to below the limit of detection (<25 mU/mL) by 12 weeks (Fig. 7A). It is interesting to note that the decrease in plasma hFVIII levels in both AGV15huFVIII and Av3H8101 mice was not due to the development of anti-hFVIII antibodies. At a dose of 3×10^{11} particles (1.5×10^{13} particles/kg), both AGV15-huFVIII and Av3H8101 induced hepatotoxicity as evident by ~10-fold increase in AST and ALT levels measured 1 day after vector administration (Fig. 7B). These levels returned to baseline by day 3. However, by day 7, animals treated with Av3H8101 showed a 10-fold elevation in AST and ALT levels, whereas those treated with AGV15huFVIII remained at baseline levels (Fig. 7B). AST and ALT levels did not return to baseline levels until day 28 in the Av3H8101-treated animals. These results suggested that the initial increase in liver transaminases observed at day 1 was caused by direct toxicity of the virion capsid protein from both AGV15huFVIII and Av3H8101. The toxicity observed at day 7 and beyond for Av3H8101, but not AGV15huFVIII, may have been due to viral gene expression from the Av3H8101 backbone. This study, unlike most others (see above), investigated vector-mediated toxicity shortly after administration and showed that HDAd can cause acute hepatoxicity by day 1. This toxicity was resolved by day 3, explaining why most others (who measured hepatotoxicity ≥3 days postinjection) have not observed hepatoxicity with HDAds.

Reddy et al. (41) also investigated the affect of helper virus contamination on the level and duration of hFVIII expression, vector-mediated toxicity, and development of anti-hFVIII antibodies, and found that these parameters were unaffected following intravenous injection of AGV15huFVIII preparations with 0.5%, 1%, 2.5%, 5%, and 10% helper virus contamination.

B. Transduction of Muscle

Duchenne muscular dystrophy (DMD) is a lethal, X-linked, degenerative muscle disease with a frequency of 1 in 3500 male births caused by mutations in the dystrophin gene. Dystrophin is an essential structural component of the skeletal muscle cell membrane, linking intracellular actin filaments with the dystrophin-associated proteins (DAPs) in the sarcolemma. Dystrophin deficiency results in instability of the muscle cell membrane causing muscle fiber degeneration. The length of the dystrophin cDNA (14 kb) precluded its inclusion into most gene therapy viral vectors. Following the development of HDAds with large cloning capacity, gene transfer of the full-length dystrophin cDNA became feasible. Indeed, the first in vivo application of HDAds was transduction of skeletal muscle for DMD gene therapy (50). In that study, an HDAd, AdDYSβgal, was constructed bearing the dystrophin cDNA under the control of a muscle-specific murine creatin kinase promoter and the LacZ reporter gene under the control of the CMV promoter (50). Direct intramuscular injection of 2×10^7 particles of AdDYSβgal into the gastrocnemius muscle

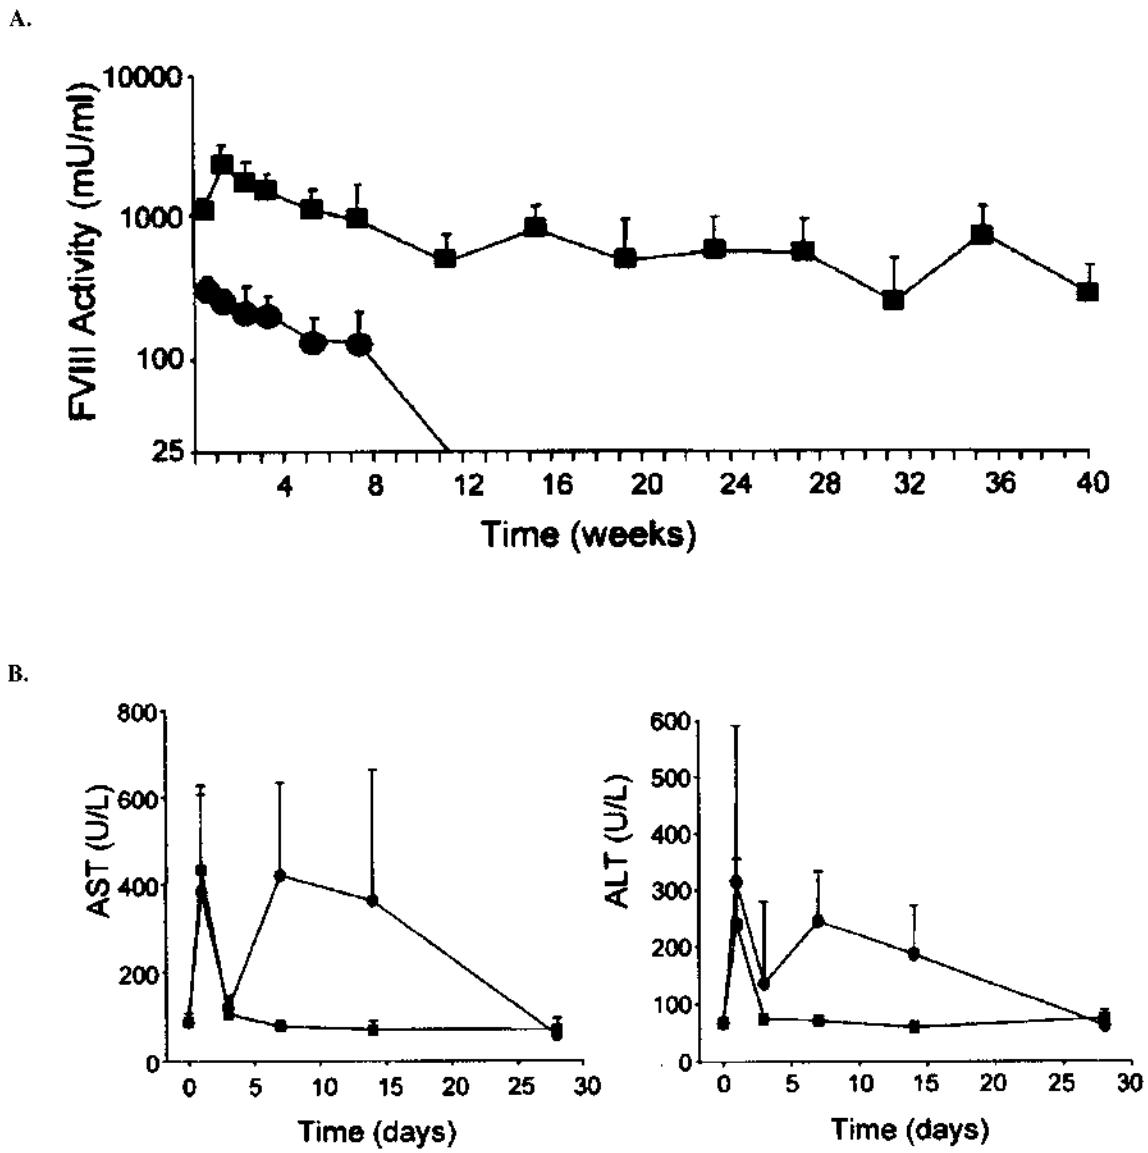

Figure 7 (A) Comparison of serum hFVIII levels in hemophiliac mice injected with 6×10^{10} particles of the HDAd AGV15huFVIII (squares) or the multiply deleted Ad Av3H8101 (circles). (B) Comparison of hepatotoxicity, as determined by measuring the serum levels of AST and ALT, in hemophiliac mice injected with 3×10^{11} particles of AGV15huFVIII (squares) or Av3H8101 (circles). (Modified from Ref. 41.)

of *mdx* mice, a genetic and biochemical model for DMD, resulted in expression of the 400-kDa full-length dystrophin protein, which was correctly localized to the sarcolemma membrane, restoring the DAPs to the muscle membrane and resulting in significant improvement of the histological phenotype (80). Most muscle fibers that expressed dystrophin also expressed β-galactosidase. However, by 6 weeks postinjection, the proportion of muscle fibers expressing dystrophin and β-galactosidase decreased. Expression of β-galactosidase from AdDYSβgal was identified as the principle cause of the loss of dystrophin expression (81). When immune response to β-galactosidase was eliminated, transgene expression persisted for at least 84 days with no significant loss of the AdDYSβgal vector DNA (81). Of course, for clinical use, therapeutic vectors would not contain an immunogenic reporter transgene such as LacZ.

More recently, Gilbert et al. (82) demonstrated that a single injection of an HDAd carrying two copies of the full-length human dystrophin cDNA under the control of a powerful hybrid CMV-enhancer/β-actin promoter, resulted in transduction of 34% of the fibers of the total tibialis anterior (TA) muscle in neonatal *mdx* mice. The amount of dystrophin produced in these muscles was 5 times that in normal human muscle, as determined by Western blot analyses. However, only 7% transduction was achieved following injection into the TA muscle of adult *mdx* mice. In these transduced adult fibers, the amount of dystrophin produced was only 10% of the amount in normal humans. However, the high levels of transduction were transient and a humoral immune response was mounted against the foreign human dystrophin protein in the *mdx* mice. Importantly, such a response was not observed in immunodeficient SCID mice suggesting that sustained expression could be achieved in the absence of an immune response to the transgene product. Interestingly, a 6-fold increase in transduction was observed in TA muscles by the HDAd in the presence of an FGAd vector. The authors proposed that gene products synthesized by the cotransducing FGAd acted in *trans* to increase transgene expression from the HDAd. The exact mechanism responsible for this intriguing result remains to be fully elucidated, although the Ad E4 region has been implicated to play a role (83).

Despite these encouraging results, effective gene therapy for DMD would likely require transduction of a critical number of muscle fibers in numerous major muscle groups throughout the body, including the limb, trunk, and respiratory muscles, a feat that is not currently feasible. However, muscle remains an attractive tissue for transduction because, like the liver, it may serve a more general purpose in gene therapy: (1) muscle constitutes as much as 40% of the total body mass and much of it is readily accessible, (2) skeletal myocytes can be transduced in vivo, (3) skeletal myofibers have a relatively long half-life and therefore represent a stable platform for transgene expression, (4) muscle is highly vascularized and skeletal muscle can efficiently secrete recombinant proteins into the circulation for systemic delivery, and (5) the high seroprevalence in the adult human population of preexisting anti-Ad neutralizing antibodies, an obstacle for intravenous vector delivery, may be minimized through localized delivery into the muscle. This strategy was investigated in a study by Maione et al. (84) in which mice were intramuscularly injected with C4AFO-mEPO, an HDAd-expressing mouse erythropoietin, as a marker gene. All mice intramuscularly injected with a dose of 1×10^6 infecious units (i.u.) or 3×10^5 i.u. retained transgene expression for at least 4 months. At a dose of 3×10^6 i.u., 30% of the mice slowly lost transgene expression. In contrast, all mice injected intramuscularly with FGAd lost transgene expression by day 21. The effect of preexisting anti-Ad antibody on the effectiveness of intramuscular administration was also investigated. Mice were first immunized with 1×10^{10} particles of a FGAd and, following generation of anti-Ad antibodies, the mice were challenged with intramuscular injections of HDAd at various doses. The authors found that successful intramuscular gene transfer could be accomplished in preimmunized mice, although a 30- to 100-fold higher dose was required to achieve 87% and 100%, respectively, the levels of transgene expression in naive mice. This is in sharp contrast to intravenous gene transfer in which 60% of preimmunized mice were completely refractory to transduction, whereas the remaining 40% were transduced but exhibited transgene expression levels comparable to naive mice intravenously injected with 1000-fold lower dose.

C. Transduction of the Brain

Stable, long-term transgene expression, in the absence of toxicity, is critical for the use of gene therapy to treat central nervous system (CNS) structural and functional deficits, such as aging-related memory loss, Parkinson's disease, Alzheimer's disease, or amyotrophic lateral sclerosis. Zou et al. (85) compared the efficiency, toxicity, and persistence of HDAd and FGAd vector-mediated gene transfer into the CNS of 20-month-old rats. An FG Ad vector or an HDAd-expressing β-galactosidase (5×10^8 particles) was stereotactically injected into the hippocampus or lateral ventricle. Transgene expression peaked 6 days postinjection for both vectors. In the hippocampus, transgene expression from the FGAd decreased rapidly after day 6, being significantly lower than HDAd-injected hippocampus by day 16, and undetectable by day 183. In the ventricle, transgene expression from FGAd was significantly lower than HDAd by day 33 and undetectable by day 66. In contrast, transgene expression from the HDAd remained relatively stable with expression remaining >60% of peak levels on day 183. Overall, expression from HDAd was significantly higher than from FGAd at all time points after 6 days. FGAd induced a substantial inflammatory and immune response as indicated by the presence, proliferation, and activation of microglia and asytocytes, as well as lymphocyte infiltration, which were significantly higher than those induced by HDAd at all time points after 3 h. Although both vectors induced a rapid increase in the proinflammatory cytokine IL-1β that peaked at 3 h postinjection, by 3 days, the level of IL-1β was significantly lower in the HDAd-treated brains than in the FGAd-treated brains. Similarly, both vectors induced the proinflammatory cytokine tumor necrosis factor (TNF)-α reaching peak levels by 3 to 6 h. However, the level of TNF-α remained significantly lower following injection of HDAd compared with FGAd. These results, along with those of Reddy et al. (41) (see Section VI.A) suggest that, although HDAd are significantly less toxic than FG and multiply deleted Ads, they are not completely benign.

VII. OUTSTANDING ISSUES

A. Large-scale Production

For those skilled in the art, the Cre/loxP system has been adequate for producing modest amounts of vector suitable for small animal experiments and limited low-dose large animal studies. However, the system's complexity, requiring a helper virus and multiple serial coinfections, renders large-scale vec-

tor production time consuming, laborious, and costly, especially for those with little practical experience with Ads. Although technical in nature, this difficulty is arguably the most significant obstacle currently hindering the progress of this promising gene therapy technology. Large quantities of vector will certainly be required for meaningful safety and efficacy studies of high-dose administration in large animal models and for clinical applications. Clearly, development of improved methods for large-scale vector production will be needed if this technology is to progress beyond the laboratory and into the clinic.

B. Helper Virus Contamination

HDAd produced using the current systems (54,55,59) are invariably contaminated with helper virus. Currently, the final level of helper virus contamination using these systems is $\leq$0.1% as determined by DNA-based methods of quantification (Southern blot hybridization or real-time PCR). Although these levels of contamination are low, they may not be acceptable for human use under conditions where high doses are needed. However, it should be noted that, even if high doses of HDAd were administered, a contamination of $\sim$0.1% would still represent a very small amount of helper virus (which is essentially an FGAd) relative to the much larger amounts of FGAd that have been given to numerous patients in clinical trials without adverse effect. It should also be noted that in mouse models, intravenous (41) or intramuscular (84) injection of HDAd with up to 10% helper virus contamination did not reduce the duration of transgene expression or result in significantly higher toxicity compared with preparations with only 0.1% to 0.5% contamination. However, because mice are much more tolerant to high doses of Ad, it remains to be determined whether this also holds true for larger animals.

C. Acute Toxicity

FG and multiply deleted Ads result in long-term, chronic toxicity owing, in large part, to expression of viral genes from the vector backbone in transduced cells rendering them targets for CTLs. A plethora of studies have now convincingly demonstrated that HDAds are considerably safer than FG and multiply deleted Ads in terms of long-term, chronic toxicity due to the absence of viral coding sequences. However, in addition to chronic toxicity, systemic high-dose administration of FG and multiply deleted Ads also results in acute toxicity in mice (86), nonhuman primates (87–89), and humans (90). Schnell et al. (88) proposed that Ad-mediated acute toxicity results from activation of the innate immune response as a consequence of Ad vector uptake by antigen-presenting cells (APCs). As a consequence, these APCs are immediately activated to secrete large amounts of inflammatory cytokines. This can lead to devastating consequences, which in its most severe form is lethal systemic inflammatory response syndrome (SIRS). For nonhuman primates, systemic injection of a FGAd at $\geq 1 \times 10^{13}$ vp/kg is lethal (87,89), whereas a dose of 6×10^{11} vp/kg of a multiply deleted (E1 and E4 deleted) Ad vector was lethal in a partially OTC-deficient patient who developed SIRS and succumbed to adult respiratory distress syndrome and multiorgan failure (88,90). Ad-mediated innate immune response occurs within hours of virus administration, and is believed to be unrelated to expression of viral genes from the vector backbone, but rather triggered by the Ad capsid proteins. This model would imply that HDAd, like FGAd, would also elicit a potent innate immune activation following high-dose systemic delivery into humans and nonhuman primates, with possible devastating consequences. Indeed, this notion is further supported by the observation that high-dose systemic injection into nonhuman primates of an FGAd rendered transcriptionally inactive by exposure to psorlen and ultraviolet irradiation, but still able to bind and enter cells, yielded similar laboratory and clinical manifestations of innate immune activation as did biologically active FGAd (88). It is important to note that while activation of innate immunity is also observed in mice given comparable systemic doses of biologically active or inactivated FGAd, lethal SIRS does not occur and may reflect species-to-species differences in the quality of the innate immune response or sensitivities of the end organs to pathological sequelae (91). Thus, it is important to ascertain whether HDAd would also elicit an acute, innate immune response as early generation Ad vectors do in nonhuman primates, and if so, to determine whether there are any qualitative and quantitative differences in the responses. Unfortunately, the challenge of producing the large quantities of HDAd required for such experiments remains a significant obstacle that first must be addressed (see above).

D. Immune Response to the Transgene Product

The most encouraging results demonstrating prolonged transgene expression from HDAd were all obtained in cases where an immune response was not mounted against the transgene product (62,66). However, in cases where an antibody response was mounted against the transgene product, expression was shortened, although to a lesser extent than when FGAds were used (62). Clearly immune response to the therapeutic proteins is an important issue because they may be antigenic in individuals suffering from some genetic deficiencies. This situation is, of course, not unique to HDAds but universal to gene therapy, regardless of vector type employed. Clearly, strategies such as immunosuppression or induction of tolerance to circumvent this obstacle may be essential for successful gene therapy of many genetic diseases.

VIII. CONCLUDING REMARKS

HDAds offer a number of advantages as gene transfer vehicles for gene therapy. The absence of viral coding sequences results in significant reduction in chronic toxicity and prolongation of transgene expression. Their large cloning capacity permits insertion of large genes, inclusion of *cis*-acting regulatory elements for regulated transgene expression and, in some

cases, insertion of genes in their genomic context for endogenous regulation, none of which may be possible with other viral vectors. The HDAd genome does not integrate into the host cell chromosomes but probably remains episomal within the nucleus. Although this precludes permanency and may be a serious limitation for transduction of rapidly dividing cell populations, it also minimizes the possibility of germline transmission or insertional mutagenesis, which may lead to oncogenic transformation, as may be possible with integrating vectors such as those based on retroviruses (92) or lentiviruses. Several important issues remain to be addressed before the full potential of this technology can be realized. Chief among these are improved methods for large-scale production, evaluation of acute toxicity following high-dose systemic delivery in a large animals, and the problem of host immune response to the therapeutic protein.

Adeno-associated Virus and AAV Vectors for Gene Delivery

Barrie J. Carter, Haim Burstein, and Richard W. Peluso
Targeted Genetics Corporation
Seattle, Washington, U.S.A.

I. INTRODUCTION

In this chapter we summarize the state of development of adeno-associated virus (AAV) vectors and provide an overview of AAV as well as some historical comment on early seminal studies that are generally overlooked in current reviews. We do not attempt to provide an exhaustive collection of references on development of AAV vectors but do discuss the key advances in the last several years, including improvements in vector production and studies on the applications for persistent gene expression. Other references provide general reviews of AAV (1,2) and extensive summaries on earlier development of AAV vectors (3–7).

AAV vectors have a number of advantageous properties as gene delivery vehicles. The parental virus does not cause disease. AAV vectors are the smallest and most chemically defined particulate gene delivery system and potentially could be classified as well-characterized biologics for therapeutic applications. AAV vectors contain no viral genes that could elicit undesirable cellular immune responses and appear not to induce inflammatory responses. The primary host response that might impact use of AAV vectors is a neutralizing antibody response. The vectors readily transduce dividing or nondividing cells and can persist essentially for the lifetime of the cell. Thus, AAV vectors can mediate impressive long-term gene expression when administered in vivo. Consequently, these vectors may be well suited for applications where the vector is delivered infrequently and where any potential host antibody response to the AAV capsid protein may be less inhibitory. One limitation for AAV vectors is the limited DNA payload capacity of about 4.5 kilobases (kb) per particle.

The lack of good production systems that could generate high titer vectors was an early obstacle to development of AAV vectors, but this has been overcome through significant advances in both upstream production and downstream purification of AAV vectors. Clinical development of AAV vectors has progressed significantly and studies of an AAV vector in cystic fibrosis patients (8–11) have been extended to phase II trials. Other AAV vectors have now entered clinical trials for hemophilia B (12) and limb girdle muscular dystrophy (13).

Since the first edition of this book (14), there have been extensive advances in application of AAV vectors in many animal models and further analysis of AAV vector safety profiles and host cell responses. There have also been remarkable advances in understanding the structure and biology of AAV vectors, including uptake into cells, trafficking to the cell nucleus, and the mechanism of genome persistence. These studies suggest possible ways to modify the biological targeting of AAV vectors, enhance transduction efficiency, and overcome the packaging limitation.

Most of the early studies on AAV used AAV serotype 2, but genomes of several other AAV serotypes have been cloned and sequenced (15). The biological properties of individual serotypes include differences in the interactions with cellular receptors (16). Other studies are now providing information on the structure of the AAV capsid and how its interaction with the cell may be modified. Notably, the crystal structure of AAV2 was recently described (17). Thus, together with additional studies on cellular trafficking pathways, it may be possible to modify the targeting of AAV vectors as well as to enhance their transduction efficiency (18).

Studies on the mechanism of persistence of vector genomes in transduced cells indicate that this involves formation of

polymeric DNA structures or concatemers. Concatemers can also be formed between 2 different vector genomes introduced into the same cell. This provides a way to partly circumvent the packaging limit of AAV by dividing a gene expression cassette between 2 AAV vectors (''dual vectors'') and allowing recombination in the cell to generate the intact expression cassette.

II. ADENO-ASSOCIATED VIRUS

A. AAV Discovery

AAV is a small, DNA-containing virus that belongs to the family Parvoviridae within the genus *Dependovirus*. AAV was originally observed as a contaminant of laboratory preparations of adenovirus, then was recognized as a virus that was different from adenovirus but that was dependent on adenovirus for its replication (19,20). Soon after the discovery of AAV in laboratory stocks of adenoviruses, it was isolated from humans (21). AAV has not been associated with any disease but has been isolated from humans, generally in association with an infection by adenovirus (21).

Several serotypes of AAV have been distinguished. AAV1, AAV2, AAV3, and AAV4 have extensive DNA homology and significant serological overlap (22–25), but AAV5 is somewhat less related (26,27). AAV2 and AAV3 are the most frequently isolated serotypes from humans (21), whereas AAV5 has been isolated from humans only once (28). AAV4 is a simian isolate that does not infect humans, and AAV1 originally may have been isolated from a simian source (29). Additional recent isolates, AAV6 (30), AAV 7, and AAV8 (31), are discussed below. Other AAV have been identified in a variety of animal species, but little characterization of these AAV isolates has been reported (1).

B. Epidemiology

In the United States, a significant proportion of the population over age 10 years may be seropositive for AAV2 and AAV3 (21). AAV2 and AAV3 appear to be transmitted primarily in nursery populations in conjunction with the helper adenovirus and thus also appear to be replication defective in the natural human host. A signal epidemiological study of AAV was carried out in a population of children in an orphanage in Washington, DC, in whom seroconversion to AAV was observed during the course of an adenovirus infection (21). In infected individuals, the virus is shed in body fluids including sputum and stool. It is noteworthy that the early epidemiological studies also analyzed neutralizing antibody responses to AAV in humans. The presence of serum-neutralizing antibody against AAV2 or AAV3 did not prevent reinfection of humans but did prevent shedding of the virus (21). This observation is significant for use of AAV as a gene delivery vector because it suggests that repeat delivery may be feasible (32).

C. Biology of AAV Life Cycle

AAV is a defective parvovirus that replicates only in cells in which certain functions are provided by a coinfecting helper virus, generally an adenovirus or a herpes-virus (1). AAV has both a broad host range and wide cell and tissue specificity, and replicates in many cell lines of human, simian, or rodent origin provided an appropriate helper virus is present. There may be some limitations to AAV tissue specificity in vivo or at least some significant differences in efficiency of transduction of different tissues and organs. These limitations may reflect the receptor and coreceptors apparently used by different AAV serotypes for entry into cells as well as cellular trafficking of AAV. This aspect of AAV biology is becoming of increasing importance for development of AAV vectors. A second set of parameters that may impact AAV tissue and organ specificity and its replication reflect the nature of the helper function provided by helper viruses.

An additional event required by AAV to function efficiently as a gene delivery vehicle is the need to convert the incoming single-stranded DNA genome to a double-stranded molecule to permit transcription and gene expression. This process is termed single-strand (ss) conversion or metabolic activation (33), and the rate at which it occurs may depend in part on the physiological state of the host cell. However, the process may be accelerated by treatment of the cell with genotoxic agents or by certain helper virus functions.

Infection of certain cell lines by AAV in the absence of helper functions results in its persistence as a latent provirus integrated into the host cell genome (34,35). In such cell lines, the integrated AAV genome may be rescued and replicated to yield a burst of infectious progeny AAV particles if the cells are superinfected with a helper virus such as adenovirus. Importantly, in cultured cells, AAV exhibits a high preference for integration at a specific region, the AAVS1 site, on human chromosome 19 (36,37). The efficiency and specificity of this process is mediated by the AAV *rep* gene (38–40). *Rep*-deleted AAV vectors do not retain specificity for integration into this chromosome 19 region (41) and indeed may not integrate efficiently but remain as episomes.

D. Mode of Cell Entry and Host Tropism

AAV appears to have a broad host range and different AAV serotypes replicate in vitro in many human cells and in a variety of simian and rodent cell lines if a helper virus with the appropriate host range is also present. AAV also infects various animal species, and human isolates of AAV will grow in mice or monkeys if the appropriate mouse or monkey adenovirus is also present. This indicated that cellular receptors for AAV were likely to be relatively common on many cell types.

Recent experiments demonstrated (42) that AAV2 particles can use heparin sulfate proteoglycans (HSPGs) as a receptor, and some cell lines that do not produce HSPGs are impaired for AAV binding and infection. Additional studies suggest that AAV2 also uses a coreceptor for efficient internalization and 2 possible coreceptors, $\alpha_v\beta_5$ integrin (43) and human fibroblast growth factor receptor 1 (FGFR1) (44), were identified.

It is of interest that the $\alpha_v\beta_5$ integrin coreceptor, which is used for a similar purpose by adenovirus type 2 and 5, is preferentially located on airway epithelial cells in the more distal areas of the conducting airway (45). This maybe important for use of an AAV2 gene therapy vector for cystic fibrosis because the distal airway is the region of the lung most impacted by the disease. It is also noteworthy that FGFR is expressed in most tissues but is of highest abundance in skeletal muscle and neuroblasts and glioblasts in the brain, and these 2 organs appear to be good targets for AAV2 transduction.

The existence of more than one coreceptor suggests that AAV may have multiple mechanisms for cell entry, and there is already some evidence to support this concept (46). Also, real-time imaging of entry into HeLa cells by individual AAV2 particles labeled with the dye Cy5 (47) showed that endocytosis was rapid and that some particles could reach the nucleus within 15 min of first contacting the cell. However, there was evidence of free diffusion of both endosomes and AAV particles, and also evidence for movement of each of these entities being driven by cellular motor proteins. Furthermore, cellular trafficking events following endocytosis of AAV that may involve the ubiquitin-proteosome pathway appear to play a significant role (48–50), as discussed in Section VIII.A.

Cell entry may also be impacted by the route of delivery, and AAV vectors can transduce airway cells when delivered directly to the lung (51,52), or brain cells (53) and myocytes (54,55) when delivered directly to these organs. However, when delivered intravenously by tail vein injection in mice (56,57), the vector preferentially accumulated in the liver, and this may reflect both the presence of a much more porous vasculature in the liver and also the small size of the AAV particles. The small size of the AAV particle may also be of advantage in passing through the basal lamina pores in muscle, thus accessing a large number of myoblasts and myotubes.

III. AAV MOLECULAR BIOLOGY

A. Particle Structure

AAV is a nonenveloped particle about 20 nm in diameter with icosahedral symmetry, which is stable to heat, mild proteolytic digestion, and nonionic detergents. The AAV particle is comprised of a protein coat, containing the 3 capsid proteins, VP1, VP2, and VP3, which encloses a linear single-stranded DNA genome having a molecular weight (mw) of 1.5×10^6. The VP1, VP2, and VP3 proteins are present in the viral capsid in the ratio of 1:1:8. The DNA represents 25% by mass of the particle that therefore exhibits a high buoyant density (1.41 g/cm^3) in cesium chloride. The relative stability of the AAV particle is an important property because it can withstand robust purification procedures, which facilitates scaled-up production of AAV vectors.

The crystal structure of AAV 2, determined at 3.0 Å resolution by X-ray crystallography, reveals several interesting features that will be helpful for efforts aimed at modifying the AAV capsid to alter targeting specificity (17). The structure shows that each capsid comprises 60 protein subunits arranged in T = 1 icosahedral symmetry. All the amino acids, except the 14 amino-terminal residues of VP1, could be localized in the structure. The surface of the capsid shows a distinctive topology with 3 peaks clustering around each 3-fold icosahedral axis (Fig. 1). Each 3-fold proximal peak is formed from 2 interacting protein subunits, and the sides of these peaks appear to be the regions that mediate the receptor-binding interactions with heparin sulfate. An additional feature of the AAV capsid is that, like all other parvoviruses, it appears to contain a phospholipase A2 activity that in AAV is located in the unique amino-terminal region of the VP1 protein (58), and this activity appears to be essential for infectivity to mediate exit from endosomes.

A novel feature of AAV is that, although each particle contains only one single-stranded genome, strands of either complementary sense, ''plus'' or ''minus'' strands, are packaged into individual particles. Equal numbers of AAV particles contain either a plus or minus strand. Either strand is equally infectious and AAV displays single-hit kinetics for infectivity (59).

When DNA is extracted from AAV particles, the plus and minus strands anneal to generate duplex molecules of 3.0 ×

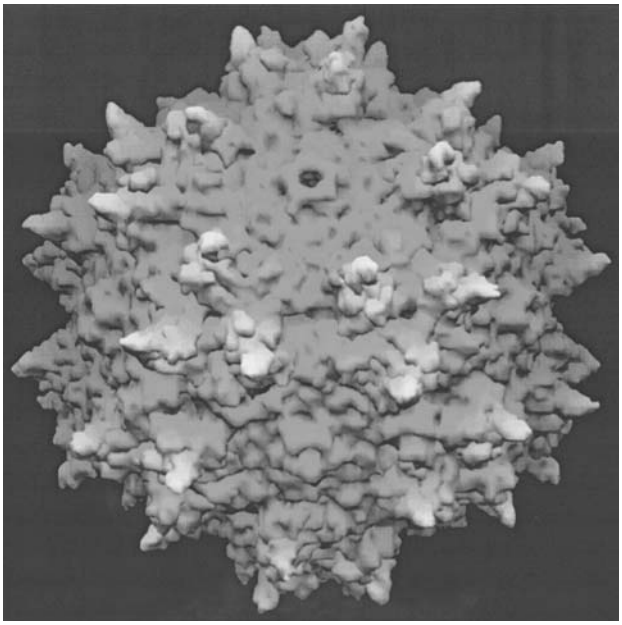

Figure 1 Structure of AAV serotype 2. The structure was determined by X-ray crystallography at a resolution of 3.0 Å. The surface topology is shown drawn to scale. The view is down a 2-fold axis (center of the virus) with 3 folds left and right of center, and 5 folds above and below. Overall, the outside surface is positively charged with a prominent ring of symmetry-related positive patches in a depression surrounding the 5-fold axis. See the color insert for a color version of this figure. (Reprinted with permission from Ref. 17.)

10^6 mw. However, Crawford and his colleagues (60) showed that, on the basis of a careful physical characterization of AAV particles, each particle appeared to contain only DNA of 1.5 $\times$ 10^6 mw. They suggested that the only way to reconcile this conundrum was to propose that individual plus and minus strands must be packaged into individual particles. An elegant proof of this conundrum was provided by Rose and his colleagues (61) who made 2 preparations of AAV particles, in which one preparation had thymidine substituted by bromodeoxyuridine (BudR) and the other was unsubstituted. The preparations of particles were mixed prior to extraction of DNA. Analysis of the duplex DNA obtained upon extraction showed components with intermediate density formed by individual strands from substituted or unsubstituted particles that had annealed during extraction. This constituted formal proof of the novel DNA strand segregation exhibited by AAV during packaging of its DNA. BudR substitution of AAV DNA also permits separation of the plus and minus strands, and this was used along with 5′ end-labeling and restriction endonuclease cleavage to determine the strand polarity of the AAV genome (62).

B. AAV Genome Structure

The AAV2 DNA genome (22,63) is 4681 nucleotides long, and includes 1 copy of the 145-nucleotide long inverted terminal repeat (ITR) at each end and a unique sequence region of 4391 nucleotides long that contains 2 main open reading frames for the *rep* and *cap* genes (Fig. 2). The unique region contains 3 transcription promoters, p_5, p_{19}, and p_{40}, which are used to express the *rep* and *cap* genes. The ITR sequences are required in *cis* to provide functional origins of replication (*ori*), as well as signals for encapsidation, integration into the cell genome, and rescue from either host cell chromosomes or recombinant plasmids. The genomes of other AAV serotypes have been sequenced and appear to have a structure similar to AAV2 (24–26,30).

The *rep* gene is transcribed from 2 promoters, p_5 and p_{19}, to generate 2 families of transcripts and 2 families of rep proteins (Fig. 1). In addition, splicing of these mRNAs yields 2 different carboxyl terminal regions in the rep proteins. The capsid gene is expressed from transcripts from the p_{40} promoter that accumulate as two 2.3-kb mRNAs that are alternately spliced. The majority 2.3-kb transcript codes for the VP3 protein initiated from a consensus AUG initiation codon. However, at about a 10-fold lower frequency, translation of this transcript also occurs slightly upstream at a nonconsensus ACG initiation codon to yield VP2. The minority 2.3-kb mRNA is spliced to an alternate 3′ donor site 30 nucleotides upstream, and this retains an AUG codon that is used to initiate translation of VP1. Thus, VP1 and VP2 have the same polypeptide sequence as VP3 but have additional amino-terminal sequences. This elegant arrangement results in generation of VP1, VP2, and VP3 in ratios of about 1:1:8, which is the same as the ratio of these proteins in the viral particle.

C. Replication

In a productive infection in the presence of a helper such as adenovirus (4,64), the infecting parental AAV ss genome is converted to a parental duplex replicating form (RF) by a self-priming mechanism that takes advantage of the ability of the ITR to form a hairpin structure (Fig. 3). The parental RF molecule is then amplified to form a large pool of progeny RF molecules in a process that requires both the helper functions and the AAV *rep* gene products, Rep78 and Rep68. AAV RF genomes are a mixture of head-to-head or tail-to-tail multimers or concatemers and are precursors to progeny ss DNA genomes, which are packaged into preformed empty AAV capsids (65). Rep52 and Rep40 interact with the preformed capsid, apparently to provide a DNA helicase function for DNA packaging (66)

The kinetics of AAV replication and assembly has been investigated (64,67). In human HeLa or 293 cells simultaneously infected with AAV and adenovirus, there are 3 phases of the growth cycle. In the first 8 to 10 h, the cell becomes permissive for AAV replication as a result of expression of a subset of adenovirus genes, including E1, E2A, E4, and the VA RNA (68). During this period, the infecting AAV genome is converted to the initial parental duplex RF DNA by self-priming from the terminal base-paired 3′ hydroxyl group provided by the ability of the ITR to form a self-paired hairpin. This initial generation of a duplex genome also provides a template for transcription and expression of AAV proteins. In a second phase, from about 10 to 20 h after infection, the bulk of the AAV rep and cap proteins are synthesized, and there is a large amplification of monomeric and concatemeric duplex AAV RF genomes to a constant level (67). During the third phase of AAV growth, between 16 and 30 h, ss progeny molecules are synthesized by a strand-displacement replication mechanism and packaged into preformed capsids followed by accumulation of mature, infectious AAV particles (65,67).

The rep proteins perform important biochemical functions (4). Rep68 and Rep78 bind to the ITR and are site- and strand-specific endonucleases that cleave the hairpin in an RF molecule at the site that is the 5′ terminus of the mature strand. In addition, these proteins contain an ATP-binding site that is important for the enzymatic activity but not for binding to the ITR. Further, Rep78 and Rep68 have both DNA and RNA helicase activity. These rep proteins also regulate transcription (4,6,7). Rep78 is a negative autoregulator of the p5 promoter (i.e., of its own synthesis), but is an activator of the p40 promoter to enhance capsid protein production. Rep52 and Rep40 do not bind to the ITR but provide a helicase in assembly of mature particles. Also, the smaller rep proteins are antirepressors and block the negative autoregulation of p5 by Rep78 (69).

The AAV replication cycle is highly coordinated with respect to expression of rep and cap proteins and the relationship between replication and assembly (67,69). Any vector production process that provides the rep and cap functions by complementation may decrease the efficiency of this highly regulated

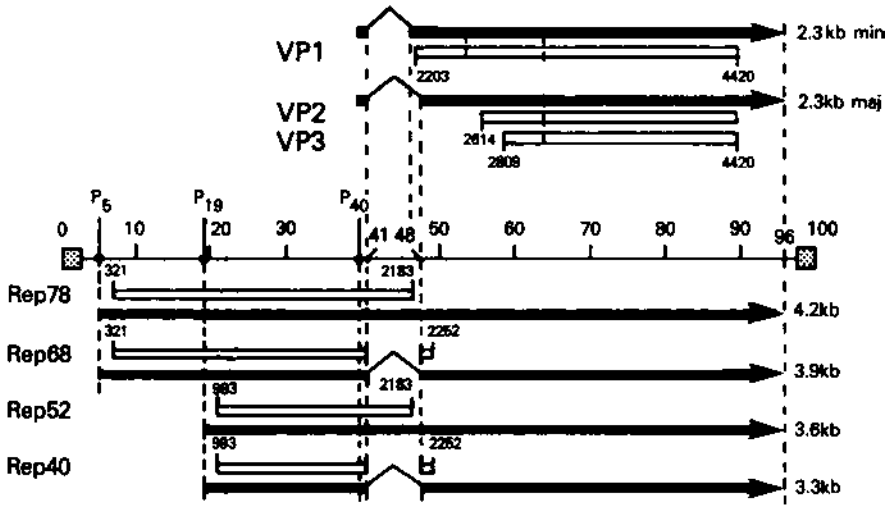

Figure 2 Structure of the AAV 2 genome. The AAV2 genome is shown as a single bar with a 100 map unit scale (1 map unit ≅ 47 nucleotides). Stippled boxes indicate inverted terminal repeats (ITRs; replication origins) and solid circles indicate transcription promoters (p5, p19, p40). The poly A site is at map position 96. RNAs from AAV promoters are shown as heavy arrows with introns indicated by the caret. The coding regions for the 4 rep proteins (Rep78, Rep68, Rep52, Rep40) and for the viral capsid proteins (VP1, VP2, VP3) are shown with open boxes, and the numbers indicate the locations of initiation and termination codons. (Reprinted with permission from Ref. 63.)

process. Nonetheless, AAV has one of the largest burst sizes of any virus and following infection of cells with AAV and adenovirus as helper, this may be well in excess of 100,000 particles per cell (11). These considerations imply that a high yield of AAV vector particles per cell theoretically is attainable. Attaining high specific productivity is of crucial importance in developing scaled-up vector production because the ability to obtain maximum yields ideally requires high specific productivity (yield of particles per cell) or large biomass (total number of cells). Maximizing the specific productivity may avoid unnecessary increases in biomass.

D. Genetics

The cloning of infectious AAV genomes in bacterial plasmids facilitated a molecular genetic analysis of AAV (70,71). These studies showed that the *rep* and *cap* genes are required in *trans* to provide functions for replication and encapsidation of viral genomes, respectively, and that the ITR is required in *cis* (4,6,63). Mutations in the ITR have an Ori phenotype and cannot be complemented in *trans*.

Mutations that affect the Rep78 and Rep68 proteins have a Rep phenotype, and are deficient for both the bulk replication and amplification of duplex RF molecules and for accumulation of ss, progeny genomes. A mutation that affected only the Rep52 and Rep40 proteins showed an Ssd phenotype in which duplex RF replication occurred normally but no ss progeny DNA accumulated.

The *cap* gene encodes the proteins VP1, VP2, and VP3 that share a common overlapping sequence, but VP1 and VP2 contain additional amino terminal sequence. All 3 proteins are required for capsid production. Mutations that affect VP2 or VP3 have a Cap phenotype, and block capsid assembly and prevent any accumulation of ss DNA. This indicates that VP3 and VP2 are primarily responsible for forming the capsid and that ss DNA does not accumulate unless it can be packaged into capsids. Mutations that affect only the amino terminus of the VP1 protein do not prevent accumulation of capsids or ss DNA, but no infectious AAV particles accumulate. This phenotype has been described as either Inf or Lip (low infectivity particles).

These genetic studies, together with additional biochemical studies, show that Rep68 and Rep78 are required for replication, that VP2 and VP3 are required to form the capsid, and that Rep52 and Rep40 appear to act in concert with VP1 to encapsidate the DNA and stabilize the particles (4,5,66). An additional role of VP1 appears to be to provide the phospholipase activity that is required for infectivity (58).

The rep proteins exhibit several pleiotropic regulatory activities, including positive and negative regulation of AAV genes and expression from some other viral or cellular promoters, as well as inhibitory effects on the host cell. Because of the inhibitory effects of expression of *rep* gene products on cell growth, expression of rep proteins in stable cell lines was difficult to achieve, and this delayed development of AAV packaging cell lines (72). For this reason, various approaches to AAV vector production have employed transient transfection of cells with AAV vector plasmids and complementing *rep-cap* plasmids. However, even in these transfection systems, the closely coordinated regulation of *rep* and *cap* gene

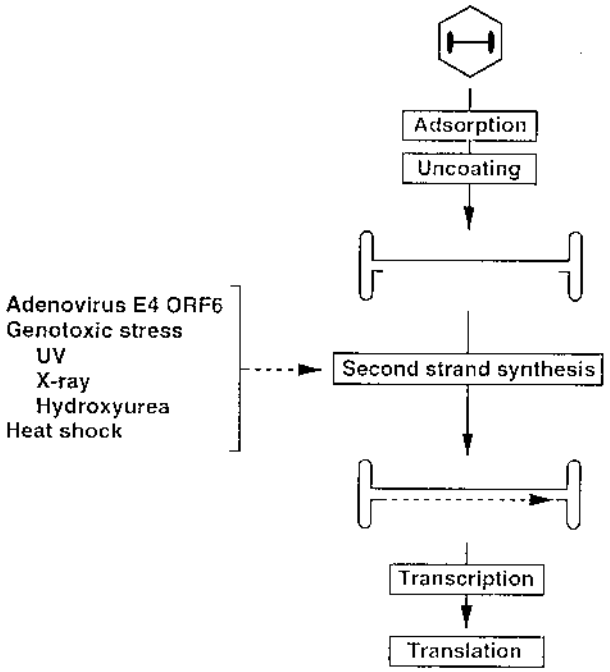

Figure 3 Metabolic pathway of AAV genomes in cells. Binding of AAV to cells is independent of helper virus functions. Trafficking of AAV to the nucleus may be enhanced by agents that interact with the ubiquitin pathway and proteosome processing. Conversion of the infecting single-strand genome to a duplex structure (or parental RF) through the process of metabolic activation (second-strand synthesis) can occur independently of helper virus. This process may be enhanced by infection with helper adenovirus genes such as E4orf6 or by other metabolic insults, including genotoxic stress or heat shock. Treatments that enhance metabolic activation may enhance gene expression from the vector template. The single strand and duplex strands are drawn to show the ITR in the base-paired hairpin conformation that allows self-priming of replication to form a duplex template using cellular DNA polymerases. For further details see text. (Reprinted with permission from Ref. 165.)

expression and the interactions of the 3 AAV promoters (69) are important considerations in optimizing vector production.

IV. AAV LATENCY AND PERSISTENCE

A. Latency

A U.S. government screening program to assess human cell lines for vaccine production led to the observation that infection of primary cultures of human embryonic kidney cells with adenovirus resulted in rescue of infectious AAV. The hypothesis that some cultures may have carried a latent form of AAV was tested directly (34) by infecting a human cell line, Detroit 6, with AAV at a high multiplicity of infection and passaging the cell cultures until no infectious AAV genomes were present, which required at least 10 cell passages. Following this, superinfection of the cultures with adenovirus resulted in rescue of infectious AAV. This provided an important demonstration of a way in which AAV may survive in a cell if conditions are not permissive for replication.

B. Integration

Analysis of a human cell line, Detroit 6, carrying latent AAV showed that the cells contained a relatively low number of AAV genomes that were integrated into the host cell chromosome, mostly as tandem repeats. Early studies of cell lines stably transduced with AAV vectors expressing selectable markers also showed that most stable copies in the cell existed as tandem repeats with a head-to-tail conformation (35). Analysis of chromosomal flanking sequences showed that, for wild-type AAV, 50% to 70% of these integration events occurred in a defined region (36,37). When wild-type AAV infects human cell lines in culture, up to 50% to 70% of these integration events occur at a region known as the AAVS1 site on chromosome 19 at 19q13ter. Both the specificity and efficiency of AAV integration are mediated by the AAV rep protein that binds to the ITR and to a site in the AAVS1 site on human chromosome 19 (38). These studies were performed on cells in culture, and it is noteworthy that naturally occurring, latent, integrated AAV genomes have not been well characterized in humans or any other animal species. In a single study, wt AAV infection of rhesus macaques was examined in the presence and absence of adenovirus infection (73). In this study, a wtAAV-AAVS1 host cell DNA junction could be detected by polymerase chain reaction (PCR) amplification in only 1 of 9 animals, suggesting that integration of AAV even under favorable conditions is very rare.

C. Vector Persistence

Some early studies with AAV vectors expressing selectable markers suggested that these vectors also integrated at AAVS1 (36,74). However, the vectors used in these studies were also were contaminated by wild-type AAV particles and may represent rare integration events mediated by rep and enriched by the selectable marker. In contrast, AAV vectors that contain no AAV *rep* coding sequences and no selectable marker have reduced efficiency and specificity for integration at the chromosome 19 AAVS1 site (40,41), and more usually persist in an episomal state. Initial evidence for this episomal persistence came from fluorescent in situ hybridization (FISH) analysis of cell lines transduced with AAV vectors, which carried a low number of copies of an AAV vector as determined by Southern blot hybridization. FISH analysis of interphase nuclei compared with FISH analysis of metaphase chromosomes showed a reduced proportion of the cells carrying all copies at a metaphase chromosomal site (41).

Studies performed in vivo in a variety of animal models now indicate that, in the absence of selective pressure, AAV

vectors generally persist as episomal genomes. A number of studies have now shown that AAV can persist for extended periods of time when administered in vivo (51–56) and that the predominant form of the persisting vector genomes appears to be multimeric structures, which are head-to-tail concatemers (52,75–78) that are circular (79–81). How these head-to-tail multimers are formed is unknown, but it cannot involve the normal AAV replication process because that requires rep protein and gives only head-to-head or tail-to-tail concatemers. Whether the circular concatemers are integration intermediates, as has been suggested for AAV integration (39,82), is also unknown. However, available evidence indicates that the majority of these head-to-tail concatemers are episomal and that integrated copies of vector in organs such as liver or muscle are very rare (83,84).

D. Targeted Integration

Although AAV vectors that do not contain the *rep* gene do not integrate at the AAVS1 site at any significant frequency, they can be directed to integrate at the chromosome 19 site by supplying the *rep* gene in *trans*. For instance, a plasmid containing an AAV vector comprised of a reporter gene between the AAV ITRs and having a rep gene also in the plasmid, but outside the ITRs, resulted in integration of the AAV ITR vector cassette into the chromosomal site at 19q in human 293 cells in vitro (85). Also, a baculovirus vector that contained an AAV reporter gene vector and separately contained an AAV rep gene was able to direct integration of the AAV vector into the AAVS1 site in human 293 cells (86). Similarly, cotransduction of an epithelial tumor cell line (HeLa) or a hepatoma cell line (HepG2) with 2 hybrid Ad/AAV viruses, one carrying an AAV vector and the other expressing the *rep* gene, resulted in integration of the AAV vector into the AAVS1 site (87).

In another study, the ability of AAV vectors to carry sequences that could mediate homologous recombination with chromosomal sequences was examined in cultured human cell lines. Homologous recombination at specific chromosomal sites could be attained (74), and additional studies showed that careful design of the interacting homologous sequences could raise the efficiency of the process to about 1% (88). However, this still requires a selective marker so its application to gene therapy may be limited.

V. AAV PERMISSIVITY

A. Helper Functions Provided by Other Viruses

The precise mechanism of the helper function provided by adenovirus or other helper viruses has not been clearly defined. These helper functions may be complex but relatively indirect and probably affect cellular physiology rather than providing viral proteins with specific functions in the AAV replication system. Studies with adenovirus (68) have clearly defined that only a limited set of adenovirus genes are required, and these comprise the early genes E1A, E1B, E2A, E4orf6, and the VA RNA. The primary role of E1A is to transcriptionally activate the other adenovirus genes, but it may also transcriptionally activate the AAV p5 promoter. E1B and the E4orf 6 protein of adenovirus interact to form a complex, and these 2 genes provide the minimal function required to permit AAV DNA replication. The E2A gene of adenovirus has a complex function because it is a ss DNA-binding protein that is directly involved in adenovirus replication; however, it also has an important role in regulating adenovirus gene expression. The role of E2A for AAV appears not to be a DNA replication function but to involve enhancement of AAV gene expression, particularly expression of AAV capsid protein. The VA RNA is also important in maximizing the level of AAV gene expression.

B. Alternate Pathways to Permissivity

The concept that the helper virus renders the cell permissive by enhancing AAV replication in an indirect way is consistent with the evidence that helper virus genes do not appear to provide enzymatic functions required for AAV DNA replication, and that these functions are provided by AAV rep protein and the cellular DNA replication apparatus (68). This is also consistent with the observations that in certain cell lines, particularly if they are transformed with an oncogene, helper-independent replication of AAV DNA can occur if the cells are also treated with genotoxic agents such as ultraviolet (UV) or x-irradiation, or with hydroxyurea (89,90). In these circumstances, a small proportion of the cells could be rendered permissive for AAV replication, but the level of replication and production of infectious AAV was very low.

C. Replication or Persistence

Two distinguishable phases of the AAV life cycle occur in permissive or nonpermissive cells. In either case, the infecting single-stranded genome is converted to a duplex structure. There is evidence that the single-stranded genome may be converted to either linear duplexes or circular duplex molecules (79,80). However, in permissive cells in the presence of helper virus, this duplex genome then appears to follow the pathway of bulk replication using the self-priming property of the ITR to yield a large pool of head-to-head and tail-to-tail RF molecules, and ultimately a large burst of progeny particles. In nonpermissive cells in the absence of helper, these genomes follow a pathway that leads to generation of head-to-tail concatemers that persist as episomes or become integrated into the host cell chromosome. In this nonpermissive state, there are 2 important parameters that may have different consequences for AAV or AAV vectors. In either case, there are no helper functions provided by another virus. However, for wild-type AAV, the *rep* gene is present and therefore may be expressed. This may explain why AAV integrates efficiently into the chromosome 19. For an AAV vector, the *rep* gene is not present; thus, vectors may progress through the integration

pathway more slowly, or not at all, and rather follow the pathway of persistence as a circular episome (83,84).

VI. AAV VECTORS

A. Design of AAV Vectors

The ability to generate AAV vectors was facilitated by the observation that molecular cloning of double-strand (ds) AAV DNA into bacterial plasmids followed by transfection into helper virus-infected mammalian cells resulted in rescue and replication of the AAV genome free of any plasmid sequence to yield a burst of infectious AAV particles (5). This rescue may occur by a mechanism analogous to that used in reactivation of a latent provirus after superinfection of cells with adenovirus. The general principles of AAV vector construction (4,5,12) are based on modifying the molecular clones by substituting the AAV coding sequence with foreign DNA to generate a vector plasmid. In the vector, only the *cis*-acting ITR sequences must be retained. The vector plasmid is introduced into producer cells that are also rendered permissive by an appropriate helper virus such as adenovirus. To achieve replication and encapsidation of the vector genome into AAV particles, the vector plasmid must be complemented for the *trans*-acting AAV *rep* and *cap* functions that were deleted in construction of the vector plasmid. AAV vector particles can be purified and concentrated from lysates of such producer cells.

The AAV capsid has 3 important effects for AAV vectors. There is a limit of about 5 kb of DNA that can be packaged in an AAV vector particle. This places constraints on inclusion of very large cDNAs and may also limit the ability to include extensive regulatory control sequences in the vector. The capsid also interacts with the AAV receptor and coreceptors on host cells, and thus mediates cell entry. The capsid may also induce humoral immune responses that could limit delivery of AAV vectors for some applications.

Except for the limitation on packaging size and the requirements for ITRs, there are no obvious limitations on the design of gene cassettes in AAV vectors. The ITR can function as a transcription promoter (91) but does not interfere with other promoters. Tissue-specific promoters appear to retain specificity (92,93) and a number of other regulated expression systems have now been used successfully in AAV vectors (94–96). Introns function in AAV vectors and may enhance expression, and more than 1 promoter and gene cassette can be inserted in the same vector. Importantly, transcription from AAV does not seem to be susceptible to in vivo silencing, as shown by expression for over 1 year after intramuscular delivery in rodents (54,55,97).

B. Production of AAV Vectors

AAV has one of the largest burst sizes of any virus, as noted above, and this implies that a high yield of AAV vector particles per cell theoretically is attainable (7). Maximizing the specific productivity may avoid unnecessary increases in biomass during vector production. However, the cytostatic properties of the AAV rep protein presented an obstacle to generation of stable packaging cell lines for producing AAV vectors (72). Consequently, AAV vector production initially was based on transient transfection of a vector plasmid and a second plasmid, to provide complementing rep and cap functions, into adenovirus-infected cells, usually the transformed human 293 cell line. The original vector production systems yielded a mixture of AAV vector and adenovirus particles, and exhibited relatively low specific productivity (6,7). Furthermore, recombination between the vector plasmid and complementing plasmids generated wild-type AAV (AAV), pseudo wild-type or replication-competent AAV (rcAAV), or other recombinant AAV species (98,99).

Upstream production of AAV vectors can now be accomplished by DNA transfection-based methods in which adenovirus infection is replaced by DNA transfection with the relevant adenovirus genes or by cell-based AAV production systems that do not require DNA transfection. Both the transfection and cell-based approaches can give a specific productivity in excess of 10^4 vector particles per cell. However, the cell-based systems are probably more amenable to scale-up for commercial production than are DNA transfection systems. Downstream processing and purification are now usually accomplished by chromatographic procedures that give a higher degree of purity than the earlier purification procedures using ultracentrifugation.

C. Complementation Systems

Three approaches have been taken with respect to upstream production of AAV vectors. First, in DNA transfection-based procedures, various modifications have been made to the complementing *rep-cap* gene cassette in an attempt to enhance specific productivity and to decrease production of rcAAV. One group demonstrated that expression of rep and cap proteins may be limiting (100), but 2 other studies (101,102) suggested that cap proteins were limiting due to down-regulation of cap by increased production of rep. A packaging plasmid that has the Rep78/68 expression down-regulated by changing the initiation codon AUG to ACG was reported to give higher cap expression and higher yields of vector particles (102).

The only adenovirus genes required for full helper function are E1, E2A, E4, and VA, and transfection of the latter 3 genes into cells that contain the E1 genes, such as human 293 cells, can provide full permissivity for AAV (68). The infectious adenovirus can be replaced as the helper with a plasmid containing only the adenovirus E2A, E4, and VA genes (103,104) that, together with the E1A genes supplied by 293 cells, provide a complete helper function in the absence of adenovirus production. Another group (105) used a plasmid containing nearly all the adenovirus genome except the E1 region, but this yielded infectious adenovirus, probably by recombination with the E1 region in the cell. All these systems require transfection with 3 plasmids, for vector, rep-cap, and adenovirus helper function, respectively. In contrast, Grimm et al. (106) combined all 3 adenovirus genes and the *rep-cap*

genes into a single plasmid. In general, all these approaches increased vector productivity compared with earlier systems such as pAAV/Ad (107), and productivities of at least 10^4 particles per cell have been reported. Nevertheless, these approaches still require DNA transfection and may be unwieldy for production scale-up.

An alternate approach to AAV vector production is to generate stable cell lines that contain the *rep* and *cap* complementing genes, the vector genome, or both. To avoid DNA transfection, the cells must still be infected by a helper virus, adenovirus, but this can be removed readily as a result of advances in downstream purification processes (see Section VI.E). Rescue of vector from a producer cell line having the vector stably integrated was demonstrated by transfecting the cells with a rep-cap helper plasmid and infecting with adenovirus (108). Stable cell lines containing a *rep* gene capable of generating functional rep protein were constructed by Yang et al. (72) who replaced the p_5 promoter with a heterologous promoter. Clark et al. (109) generated cell lines containing the *rep* and *cap* gene cassettes but deleted for AAV ITRs. Furthermore, the vector plasmid could be stably incorporated into the packaging cells to yield AAV vector producer cell lines (109,110). Producer cell lines provide a scalable AAV vector production system that does not require manufacturing of DNA and may reduce generation of rcAAV. However, a new producer cell line must be generated for each individual AAV vector and this may be laborious.

A modification of the packaging cell line method is to use a cell line containing a *rep-cap* gene cassette that is then infected with an Ad/AAV hybrid virus. The Ad/AAV hybrid is an E1 gene-deleted adenovirus containing the AAV ITR vector cassette (111,112). After infection of cells containing the *rep-cap* genes, the AAV-ITR cassette is excised from the Ad/AAV, amplified, and then packaged into AAV particles. This allows the same packaging cell line to be used for production of different AAV vectors simply by changing the Ad/AAV hybrid virus, but it requires coinfection with adenovirus to provide the E1 gene function. It is worth noting that the Ad/AAV hybrid viruses can also be used as delivery vehicles for AAV vectors (113–115), but this might suffer some disadvantages such as induction of innate immune responses characteristic of the adenovirus capsid interaction with cells. Another packaging cell system was described (116) in which the packaging cell contains both a *rep-cap* gene cassette and the AAV ITR vector cassette, and both cassettes are attached to an SV40 replication origin. Also in the cells is a SV40 T antigen gene that is under control of the *tet*-regulated system such that addition of doxycycline induces T antigen, which in turn results in amplification of the *rep-cap* and the vector cassettes. Subsequent infection of the cells with adenovirus renders the cells permissive for vector production.

Herpes simplex virus also can be used in production of AAV vectors by generating 2 types of HSV/AAV hybrid viruses. One approach (117,118) uses an HSV/AAV hybrid virus in which the AAV *rep-cap* genes, under control of their native promoters, were inserted into the HSV genome. This HSV/AAV *rep-cap* virus could generate AAV vector when infected into cell lines along with a transfected AAV vector plasmid or into cell lines carrying an AAV vector provirus. Alternatively, an HSV/AAV hybrid virus was constructed by inserting an AAV ITR vector cassette between HSV genome replication origins and then packaging this construct into an HSV particle using an HSV amplicon system (119,120). These HSV/AAV vector hybrids were infectious for neural cells, but the biological properties and fate of these HSV/AAV hybrid genomes after infection of cells is complex and not yet well understood. Finally, insect cells can also be used to produce AAV vectors. In this system, baculovirus vectors containing *rep-cap* gene cassettes or the AAV-ITR vector cassette are used to infect insect cells and AAV vectors can be generated (121).

D. Replication-competent or Wild-type AAV

Wild-type AAV is not a human pathogen but generation of wild-type or rcAAV during vector production needs to be avoided for several reasons. The presence of wild-type AAV in vector preparations may increase the likelihood of vector mobilization following a helper virus infection in the patient, which could increase the likelihood of cellular immune responses to AAV proteins and can cause significant alterations in the biology of the vector because of the pleiotropic effects of the rep proteins. The earliest AAV vectors (4,5) were produced by cotransfection with helper plasmids that had overlapping homology with the vector, and this generated vector particles contaminated with wild-type AAV due to homologous recombination. Reduction of the overlapping AAV sequence homology between the vector and helper plasmids reduced, but did not eliminate, generation of wild-type AAV (98,107,108).

A combination of vector plasmid and packaging plasmid in which the AAV region containing the P_5 promoter was not present in either plasmid prevented generation of wt AAV but some pseudo wild-type AAV (rcAAV) was generated at very low frequency by nonhomologous recombination (98,108). This nonhomologous recombination was decreased to undetectable levels in a packaging system (split-gene packaging) carrying *rep* and *cap* genes in separate cassettes (98) so that 3 or 4 recombination events would be required to generate rcAAV. An alternate approach to decreasing pseudo wild-type or recombinant AAV is to insert a large intron within the rep gene in the helper plasmid so that any recombinants would tend to be too large to package in AAV particles (122).

It is likely that all vector production systems may have a propensity to generate pseudo wild-type AAV or other recombinants of AAV at some low frequency because it is not possible to eliminate nonhomologous recombination in DNA. This may be more likely in DNA transfection systems, especially in view of the very large genome numbers that are normally introduced into transfected cells. Thus, packaging systems in which transfection is avoided may help to reduce the frequency of such recombination. Standardized assays to analyze and evaluate such rcAAV or recombinant species in AAV vector preparations have not yet been developed. However,

to detect replication competent species, an assay that employs 2 cycles of amplification in non-*rep*/*cap* expressing cells, and then a sensitive readout such as hybridization or PCR (rather than rep or cap immunoassays), is likely to be required.

E. Purification

Historically, AAV was purified by proteolytic digestion of cell lysates in the presence of detergents followed by banding in CsCl gradients to concentrate and purify the particles and separate adenovirus particles. Significant progress has been made in the downstream processing of AAV vectors, and this has led to much higher quality and purity. This is critically important for preclinical studies and clinical trials. The reliance upon the original CsCl centrifugation techniques is being abandoned because it is a cumbersome procedure that does not provide high purity, it may inactivate some AAV vector, and it is difficult to envision its use for commercial production. Several groups have employed nonionic iodixonal gradients as an initial bulk-recovery method (123,124). A variety of chromatographic methods, including ion exchange resins and antibody, heparin, or sialic acid affinity resins, in both conventional and high-performance liquid chromatography formats, have been employed (106,125–134). Chromatographic procedures will be generally more acceptable for the biopharmaceutical manufacturing as therapeutic applications are developed for AAV vectors.

F. Assay of AAV Vectors

Characterization and testing of AAV vectors are critical elements for clinical development. Although there is variability in assay methods and properties measured, the minimal testing should include measure of vector strength by determining the concentration of capsids containing vector genomes, a measure of total capsids, a measure of ''infectivity'', and an assessment of vector purity. The efficiency of transgene expression or potency of the vector should also be measured. In some cases, it is difficult to measure potency using in vitro assays because transgene expression may be mediated by weak or tissue-specific promoters.

Early in the development of AAV vectors, the concentration was measured using dot-blot hybridization of vector genomes and comparing the signal intensity with a standard curve derived from a plasmid containing the vector genome (135). Recently, more precise and quantitative assays have largely supplanted the dot blot assay. Measurement of vector concentration by real-time PCR amplification (TaqMan) of the vector genome has resulted in increased precision and accuracy (126). These assays measure the number of vector genomes that are encapsidated and thus protected from digestion by DNAse. Consequently, vector concentration is expressed in units of DNAse-resistant particles (DRPs). This type of assay can be used to facilitate reliable quantitation of vectors during process development for production of multiple AAV serotypes (118).

Infectivity measurements of vector preparations are important mainly to establish a consistency of vector manufacturing rather than being an indication of vector potency in vivo. By their nature, AAV vectors are replication defective, so in vitro measurements of infectivity are artificial and generally require complementation with *rep* and *cap* as well as helper virus functions. Initially, vectors were measured by an infectious center assay in which wtAAV as a source of rep and cap and adenovirus were added, along with dilutions of vectors to infect cells (136). Cells that were replicating the vector genome were then scored by probe hybridization to individual cells collected on a filter, hence the term ''infectious center''. The development of cell lines containing rep and cap (137) has allowed infectivity measurements of vectors to be performed in a 96-well format in an assay that yields data with higher precision than the infectious center assay, and is amenable to a high-throughput format that can be used for purification development (138). In conjunction with the real-time PCR assay, this type of infectivity assay yields data on particle to infectivity (P:I) ratios of vectors with high precision, thus aiding process development. It is important to recognize that the apparent particle to infectivity ratio of vectors based on different serotypes of AAV may be quite different due to the natural variation that exists in receptor usage and potentially in intracellular trafficking among the serotypes. A cell line containing rep and cap may be more efficiently transduced by one serotype as compared with a second serotype, yielding differences in P:I ratios that may not be reflective of differences in vector potency in vivo but rather a difference in the ability of a given serotype to efficiently infect the *rep*/*cap*-expressing cell line used in the assay.

Other aspects of vector preparations are also worth measuring. These include a measure of the ratio of empty to full capsids such as a capsid enzyme-linked immunosorbent assay (139), negative-stain electron microscopy analysis (131,132), or a measure of total protein compared with concentration of genome-containing vectors and an assessment of vector purity, usually by acrylamide gel electrophoresis analysis. For clinical development it is important to measure the residual contaminants, including host cell protein, DNA, and serum components. In cases where the vector is manufactured from a cell line of tumor origin (e.g., HeLa cells), determination of the residual level of host cell DNA is an important part of the release testing. If the vector is of high purity, its aggregation state can be assessed by using dynamic laser light scattering. This method enables a measurement of the hydrodynamic radius and provides a size distribution of particles in solution and the relative amount of particles in each size class. This measure is useful for vectors at high concentration and can aid in development of formulations that maintain vectors in a monomeric, nonaggregated state.

VII. GENERAL PROPERTIES OF AAV VECTORS

A. Serotypes of AAV

Growing appreciation of natural variation among AAV serotypes, as well as its application to vector production and usage,

has added to the attractiveness of rAAV as a gene therapy modality. There are currently 8 serotypes of AAV described with the complete genome sequence information available for AAV1–AAV6 (22–27,30) and capsid gene sequence for AAV7 and AAV8 (31). AAV6 has been shown to be a recombinant between AAV1 and AAV2 and is not a distinct serotype because it is neutralized by anti-AAV1 antiserum (140). In addition, there are two isolates and sequences of AAV3 that differ from each other in a number of amino acids in both rep and cap (30). Table I summarizes current knowledge of receptor usage by these viruses (42–44,141,142). This variation in receptor usage is at least in part responsible for the increasingly appreciated efficiency of vectors of different serotypes to transduce specific cell types and tissues in vivo. The serotypes of AAV are highly related to each other with the notable exception of AAV5 (26,27). AAV5 is the most distantly related of the serotypes, and also displays a serotype-specific terminal resolution site (trs) in its ITR (143). Even though rep proteins from other serotypes will bind the AAV5 ITR, they do not efficiently cleave at the trs.

Most early studies with AAV vectors used serotype 2. A number of studies demonstrated transgene expression in muscle, liver, central nervous system (CNS) tissues, lung, and retina (51–55,75–78,92,93,97), with persistence for months to years. As other serotypes of AAV have been used in vector production, it has become apparent that there are distinct and often advantageous differences among vector serotypes in their efficiency of transgene expression in various tissues and cell types. It is difficult to list a hierarchy of transduction efficiencies of target organs relative to individual serotypes because there are conflicting data in the literature both with regard to organ tropism and the threshold of expression differences reported from different laboratories. These differences may reflect differences among strains of mice used in the studies or differences in vectors produced by different investigators. However, some general conclusions can be made. For example, AAV1 and AAV7 appear to be superior, by several orders of magnitude in transgene expression, to other serotypes for transduction of murine muscle tissue, but AAV5 vectors also demonstrate enhancement compared with AAV2 vectors (31,144–146). AAV8 is the most efficient serotype for murine liver transduction (31) being up to 100-fold higher than AAV2 vectors, and AAV5 appears superior in transduction of cells in the murine respiratory tract (147,148). AAV5 generally appears to be superior to AAV2-based vectors in all tissue types so far tested, including CNS, muscle, liver, and retina (144–146,148–150). Similarly, AAV6 vectors are more efficient than AAV2 in transducing murine airway epithelia and alveoli, whereas AAV3 vectors are superior in transducing smooth muscle cells (151,152).

The increased transduction efficiency noted for AAV5-based vectors in mouse airway may be due in part to the demonstrated increase in binding to the apical surface of polarized airway epithelial cells, suggesting that receptors are an important part of vector tropism (46,147). However, trafficking of vectors also plays a role in transduction efficiency (50). Approximately 5% of hepatocytes are transduced following delivery of AAV2-based vectors to mice (153), in spite of the fact that every cell contains vector DNA 1 day following administration. This points out that events postbinding and internalization are important for successful transduction (see below). Interestingly, when vectors based on AAV5 or AAV8 were administered to mice, increased numbers of hepatocytes were transduced (>15%) and increased levels of transgene expression were observed (31,150).

AAV4 vectors transduce ependymal cells in the murine CNS almost exclusively, whereas AAV5 vectors transduce both neurons and astrocytes (149). In retina, a number of studies have demonstrated large differences among serotypes in the ability to transduce photoreceptor cells and the retinal pigmented epithelium (141,154,155).

Overall, there is a great variability among different AAV serotypes in their ability to transduce various cells, tissues, or organs efficiently, depending on the route of administration and the capsid type. Further work will be needed to understand the relative importance of the factors contributing to differences in transduction efficiencies with different serotypes of AAV vectors.

It may be possible to exploit this natural tropism variation to target transgene expression to specific organs and/or cell types by selecting the appropriate capsid for vector production. The increase in transduction efficiency among serotypes should also allow transgene expression to be achieved with a decreased vector dose. This may have importance for decreased cost of goods in manufacturing therapeutics and decreased antigenicity of the vector dose.

Table 1 Cellular Receptors for AAV Serotypes

Serotype	Primary receptor	Secondary receptor
AAV1	Unknown	Unknown
AAV2	Heparin sulfate	$\alpha_\gamma\beta_5$ Integrin/FGFr
AAV3	Heparin sulfate	Unknown
AAV4	O-linked sialic acid	Unknown
AAV5	N-linked sialic acid	PDGF receptor
AAV7	Unknown	Unknown
AAV8	Unknown	Unknown

VIII. VECTOR METABOLISM

Early studies of AAV vectors led to the suggestion that the major factor limiting the efficiency of transduction was the process of converting the ss genome to a duplex molecule. More recent studies are beginning to reveal a complex pathway of events that impact the function of AAV vectors. Thus, delivery of the AAV vector genome to the cell nucleus may be influenced by the availability of specific receptors and coreceptors for AAV binding and entry, and by cellular trafficking, including a potential diversion of AAV particles into a ubiquitin-mediated proteosome degradation pathway. After the ge-

nome is successfully delivered into the nucleus, a succession of events results in the vector genome becoming transformed into larger concatemeric molecules. Most of these concatemeric molecules appear to be maintained for prolonged periods, perhaps for the lifetime of the cell, in the nucleus as episomal molecules; very few, if any, integrate into the host genome.

A. Cellular Binding and Trafficking of AAV Vectors

The ability of a vector particle to interact with a specific receptor molecule on a target cell is critical for successful transduction. Table I lists currently identified primary and secondary receptor molecules for AAV serotypes. The primary receptors identified (heparin sulfate and sialic acid) are commonly found on many cells and are also the receptor molecules used by a large number of viruses besides AAV. This suggests that additional receptors that lend more specificity to attachment and penetration of cells might exist, and several such coreceptors have been identified (Table I).

Although attachment is a critical first event, it does not necessarily imply that the vector will be able to efficiently transduce the cell. This has been increasingly apparent in recent years as a more detailed understanding of the trafficking and uncoating of AAV vectors has been accumulated (46–50). For example, polarized human airway epithelial cells are transduced with varying efficiencies by AAV2-based vectors, depending on the route of delivery and entry from the basolateral surface, results in about a 200-fold increase in gene expression in the cells compared with vector administered from the apical surface (46,156). Surprisingly, the difference in vector attachment to the 2 cell surfaces is only about 5-fold. This finding led to the discovery that the vectors traffic differently in these cells, depending on the side of the polarized airway to which they bind (46,156). Vectors administered from the apical surface are modified by ubiquitination. The addition of proteosome or ubiquitin-ligase inhibitors led to an increase in transduction following apical administration of vectors. These comparisons of differences in binding and differences in transduction efficiency have led to an appreciation that cellular trafficking of vectors is important to successful transduction, and that it may differ between cell types and even within individual polarized cells between the apical and basal surfaces.

After binding to the cellular receptor, AAV2 is internalized by an endocytosis mechanism that for heparin binding appears to be mainly via clathrin-coated pits (157,158), although some clathrin-independent uptake may also occur (157,158). Additional studies using fluorescent Cy3-conjugated AAV2 vector particles showed that endocytosis can be mediated by an $\alpha_v\beta_5$ integrin/Rac1-dependent mechanism and that subsequent trafficking to the nucleus requires activation of PI3K pathways, as well as functional microtubules and microfilaments (160). Evidence for the involvement of early endosomes in AAV trafficking, as well as the involvement of microtubules and microfilaments, exists mainly from the use of inhibitors (48,49). There is a growing consensus that, in the absence of helper virus, there is a block at the step of import of viral vector genomes into the nucleus of the cell (161–163). However, there is no clear understanding as to how or where uncoating of the viral genome occurs, or how the vector enters the nucleus, although it does not appear to use the nuclear pore complex for this step (163,164).

B. Vector DNA Metabolism

For rAAV vectors to transduce a cell, the ss DNA genome must be converted into a double-stranded form (33), as shown in Fig. 3. Several reports, based on transduction of cells in vitro, indicated that this single- strand to double-strand (DS) conversion step might be rate limiting in the absence of helper virus coinfection (165–167). The adenovirus E4 ORF6 protein has been shown to increase the level of transgene expression and to increase second-strand DNA synthesis (168). More recently, a cellular protein that bound to the single-stranded D-sequence of the AAV ITR was identified as the well-known FK506-binding protein (FKBP-52). This protein has been implicated in controlling the conversion of ss to ds DNA in vector-infected cells and phosphorylation of FKBP-52 influences its ability to bind the D sequence (169,170). When phosphorylated at tyrosine residues (by the epidermal growth factor receptor protein tyrosine kinase), FKBP-52 binds to the ss D sequence region of the ITR that is present in infecting vector genomes, and second-strand DNA synthesis is impaired. The efficiency of transduction in a number of cell types in vitro and in vivo correlates with the phosphorylation state of FKBP-52. In HeLa cells, overexpression of a cellular phosphatase (TC-PTP) that can use the FKBP-52 protein as a substrate, led to dephosphorylation of the FKBP-52, an increase in AAV second-strand DNA synthesis, and an increase in transgene expression. Transgenic mice expressing either the wt or a catalytically mutant form of the phosphatase were created. Hematopoietic stem cells from transgenic mice expressing the wt TC-PTP phosphatase were transduced by an AAV2 vector, but those from mice expressing the phosphatase-negative mutant were not. These results suggest that the block to second-strand DNA synthesis is due to binding of FKBP-52 to the D-sequence of infecting vector genomic DNA and that this binding is regulated by phosphorylation.

A second mechanism for conversion of ss DNA to ds DNA has been proposed. In this model, annealing of negative and positive sense ss DNA genomes (both of which are efficiently packaged in AAV particles) occurs in cells to form ds DNA in the absence of second-strand DNA synthesis. There is some experimental evidence for this self-annealing model both in vitro and in vivo (171), although it is not consistent with observations that AAV infection displays single-hit kinetics (59). However, it is possible that double-stranded DNA may be formed via either pathway in cells transduced with rAAV vectors.

Further support for the idea that conversion of single-stranded vector genomes into transcriptionally active, double-stranded forms is crucial for transduction and is a rate-limiting step comes from a study demonstrating that vector genomes

smaller than half the size of the AAV genome are packaged in multiple ways (172). Particles contain either a single vector genome, two copies of the small vector genome, or a covalently linked double-stranded hairpin molecule equivalent to a replicative-intermediate formed during vector genome replication. In a separate study, vectors containing these small self-complementary genomes were shown to be relatively insensitive to the enhancing effects of adenovirus on transduction, to be resistant to the effects of DNA synthesis inhibitors, and displayed altered kinetics of transgene expression in vivo (173). When these vectors were administered to mice, an increase in transduction from the usual 5% to more than 50% of hepatocytes was observed (174,175). These results strengthen the model that second-strand DNA synthesis is a rate-limiting step for transduction, at least in hepatocytes.

Once the vector genome is converted into a double-stranded DNA molecule, a number of fates have been reported. One group of studies convincingly demonstrates that the viral genome circularizes, and that these circular monomers recombine at the AAV ITRs to form larger circular concatemers of head-to-head, head-to-tail, and tail-to-tail arrangements both in vitro and in vivo (79,80,176,177). These genomic concatemeric molecules, containing a ''double-D'' ITR structure (an ITR bracketed on each side by the D sequence and presumably formed by an ITR-ITR recombination event) persist extra chromosomally as episomes and are responsible for the long-term persistent transgene expression seen with rAAV vectors. Recently, it was reported that severe combined immunodeficiency (SCID) mice that are deficient in DNA-dependent protein kinase activity (DNA-PK) lack the ability to convert rAAV genomes into circular concatemers (178). Rather the concatemers formed in these mice appear to be linear molecules, suggesting that DNA-PK activity is involved in the formation of circular episomes. In both cases (normal and SCID mice) transgene expression persisted for 1 year at similar levels. A second group of reports (171,179,180) suggest that vector genome concatamerization occurs by recombination of linear monomeric genomes. It is possible that both mechanisms of concatamerization are operative and one pathway is more likely to occur than another in a tissue-specific manner (e.g., muscle vs. liver). Despite the differences reported on the substrate for concatemer formation, it is clear that long-term transgene expression is mainly mediated by episomal concatemers of viral genomes rather than integrated molecules (83,84).

Evidence that DNA repair and recombination are directly involved in circularization or concatamerization of AAV vector genomes is supported by recent insights into possible biochemical mechanisms of their formation (178,180). In fibroblasts from a patient with ataxia telangiectasia (ATM), there is greatly enhanced formation of AAV vector circular forms and enhanced integration of the head-to-tail concatemers as proviral genomes (181). The ATM gene is a PI-3 kinase that regulates the p53-dependent cell-cycle checkpoint and apoptotic pathways, and in these ATM cells the DNA double-strand break (DSB) repair systems that normally can be activated by UV irradiation appear to be already activated maximally. Consequently, AAV vectors in these cells yield a high level of transduction and this is not activated further by UV irradiation (181), in contrast to the observations in normal cells (165–167). Additional evidence that DSB repair pathways are involved in regulating AAV transduction comes from observations that the proteins Ku86 and Rad52, which are known to recognize DNA hairpin structures and DNA termini and to promote repair of DSB, could associate with the AAV DNA ITR (182).

C. Dual Vectors

The ability of AAV vectors to form concatemers and the evidence that intermolecular recombination is directly involved in their generation has been used to extend the capacity of AAV vectors beyond the 4.5-kb payload limit in the dual-vector system. It is now possible to divide a gene expression cassette that is up to 9 kb in size between 2 AAV vectors and, following coinfection with both vectors, take advantage of the intermolecular recombination to generate the intact expression cassette. This process has been demonstrated both in vitro and in vivo, and shows remarkable efficiency (179,183–185).

Both *cis*-activation (183) and *trans*-splicing (184) modes of dual vectors have been described. In *cis*-activation, one vector carries a high-efficiency enhancer of transcription, and the other vector carries the transcription promoter and the gene sequence to be expressed. Recombination after infection places the enhancer in *cis* with the expression cassette and increases transcription. In the *trans*-splicing mode, one vector carries the transcription promoter and the 5′ part of a gene, and the other vector carries the 3′ part of the gene. By judicious arrangement of splice donor and acceptor sites, the appropriate mRNA can be derived from the read-through transcript using the heteroconcatemeric template. Interestingly, the intervening ITR sequence does not appear to inhibit read-through transcription or RNA splicing (183,184). It does appear, however, that in these dual-vector constructs, some transcription may be seen directly from the ITR, either because of its own promoter activity or because of enhancement from the *cis*-acting elements provided by the second vector (183,184).

Cis-activation was demonstrated using a vector containing super-enhancer elements comprising parts of the SV40 and CMV enhancers, together with a second vector containing the luciferase gene. This dual enhancer combination gave robust expression of luciferase in mouse skeletal muscle at levels that compared well with that from administration of a single vector expressing the same elements (183). In another study, 2 vectors containing a LacZ reporter cDNA or an enhancer promoter cassette from human elongation factor EIFα, respectively, were shown to yield reporter gene expression in livers of mice after dual administration by portal vein injection (179).

Trans-splicing was demonstrated using one vector that contained a transcription promoter and the 5′ part of the erythropoietin (epo) genome locus, and a second vector that contained the 3′ region of the epo locus (184). Dual injection of the 2 vectors into mouse skeletal muscle provided therapeutic

levels of epo sufficient to protect the mice from adenine-induced anemia. Similarly, another group used 2 vectors, one containing the CMV promoter with the 5′ half of the LacZ gene and the second containing the 3′ half of the LacZ gene (185). These vectors also gave robust expression of intact LacZ after dual injection into mouse skeletal muscle.

Recently, the dual-vector approach to packaging and expressing large genes in rAAV vectors was extended to an investigation of the use of homologous recombination between 2 vectors, each containing an overlapping DNA sequence to drive recombination (186,187). The data demonstrated that non-ITR-mediated recombination between 2 genomes can occur and result in expression of a large transgene. However, the efficiency of this homologous recombination process may vary, depending on the tissue type. In mice, the efficiency in muscle was low and yielded less than 1% of the level of expression seen from an intact vector, whereas in lung the efficiency approached that seen with an intact vector construct.

The dual-vector approaches to packaging and expressing larger transgenes in AAV particles offer a way to almost double the payload capacity of AAV vectors that should extend the utility of this vector system to larger genes. Careful analysis will be required to determine additional safety issues or risks this approach might present for clinical use. For instance, for some applications such as hemophilia A, it may be deleterious to express a partial FVIII protein. Nonetheless, as these systems are better characterized they may well prove to have clinical utility.

D. Capsid Modifications and Targeting of Vectors

There is an interest in modifying the capsids structure of AAV vectors to target transgene expression to a specific cell type (18). In general two approaches have been taken. In one approach, retargeting was obtained by the use of a bispecific antibody having one arm specific for AAV capsids and the second arm specific for a receptor on a cell (188). Although not involving capsid modifications, this method did achieve vector targeting to the specificity of the antibody used. The other approach to targeting involves alterations or additions to the amino acid sequence of the capsid proteins directly. With capsid protein modifications, the goal is to eliminate the natural receptor interactions of the capsid and replace it with a receptor interaction that would be engineered into the capsids as an amino acid sequence or receptor ligand. There are a number of studies that describe such attempts at vector retargeting, and some recent reports describe a systematic analysis of insertions into the capsid and the effect on vector yield and tropism (189–192). It is possible to generate vector particles with modified tropism as a result of amino acid substitution or addition to the capsid, and further work will reveal the usefulness of this approach for clinical gene therapy applications. Peptide ligands specific for various receptors have been successfully engineered into AAV2 capsids (189,191, 193–195), with the resultant vector target specificity being achieved. The recent determination of the crystal structure of AAV2 should aid these attempts in the future because positions of loops on the surface of the particle have been mapped along with residues responsible for interaction with heparin sulfate (17).

IX. HOST RESPONSES AND TOXICITY

Host immune responses, including innate immune responses, cellular immunity, or humoral antibody responses, may hinder the use of some gene therapy vectors. However, administration of AAV vectors has not been reported to induce innate immune responses or proinflammatory cytokines. Also, AAV vectors are replication defective and contain no viral genes, so cellular immune responses against the viral components should not be evoked readily. In all the in vivo studies of AAV vectors in rodents, rabbits, or rhesus macaques, there is little evidence of cellular immune responses to viral components.

AAV vectors may be used mainly for clinical applications requiring only infrequent delivery, but potential humoral immune responses against the viral capsid, either preexisting in the human population or induced by vector administration, must be considered (3,18). Reinfection of humans by AAV is not prevented by serum neutralizing antibodies (3,18). However, more extensive studies will be required to assess whether induction of neutralizing antibody responses will pose any limitations to AAV vectors.

Induction of anti-AAV capsid antibody responses after vector administration may reduce the efficiency of transduction upon readministration (54,196,197). This depends on the route of administration (73,198,199) and also may depend on the quality of the vector preparations. In one study in which 2 AAV vectors expressing the reporter genes bacterial β-galactosidase or human alkaline phosphatase were successively administered to lungs of rabbits, expression from the second administered vector was impaired and this was ascribed to a neutralizing antibody response (200). Similar studies in mice also implied that neutralizing antibodies impaired readministration of AAV vectors, but that this could be partially or completely overcome by transient immunosuppression with anti-CD40 ligand antibodies or soluble CTLA4-immunoglobulin at the time of the initial vector administration (197,201). However, interpretation of such studies may be complicated by the expression of the foreign reporter proteins that could represent confounding variables. Furthermore, other studies showed that immune responses were greatly reduced following airway administration of AAV (73) and that vector transduction could be seen after at least 3 repeated administrations to the lung of rabbits (32). Thus, up to 3 successive administrations of AAV vectors to rabbit lungs over a 20-week period did not prevent gene expression from the third delivery of vector (32).

It remains to be determined how neutralizing antibody responses to AAV vector capsids might impact applications of AAV vectors. This will most likely require studies in humans

to determine if the various animal models such as rodents or rabbits are predictive for the immune response to AAV vectors in humans and whether such immune responses will pose any limitations to their therapeutic application. For relatively infrequent administration of AAV vectors, transient immune blockade (196,197) may not be an attractive option for therapeutic use of AAV or any other gene delivery vectors. An alternate possibility might be to use vectors that have capsids of different serotypes for subsequent administrations (152).

Immune responses to the transgene expressed by an AAV vector vary and may depend on the route of delivery. Both MHC class II-restricted antibody responses and MHC class I cytotoxic T lymphocytes have been reported, but this may vary with the route of administration (199). In some studies, such as intramuscular delivery in mice, there was no immune response to an expressed foreign reporter gene such as bacterial β-galactosidase, and it was suggested that AAV may be a poor adjuvant or may not readily infect professional antigen-presenting cells in muscle (202,203). However, an AAV vector expressing the herpes simplex virus type 2 gB protein was delivered intramuscularly into mice and elicited both MHC class I-restricted CTL responses against the gB protein and anti-gB antibodies (204). Following intramuscular delivery of an AAV human factor IX vector (205,206), there was an antibody response but not a CTL response against the FIX protein. The rules governing immune responses to foreign transgenes following AAV vector delivery remain to be elucidated more fully, but AAV may have utility as a viral vaccination vector (see Section X.H).

There have been few, if any, documented reports or indications of toxicity mediated by AAV vectors. The toxicity of AAV vectors has been extensively tested for a vector expressing the cystic fibrosis transmembrane regulator (CFTR) protein following delivery of these AAV-CFTR vector particles directly to the lung in rabbits and nonhuman primates. In rabbits, the vector persisted and expressed for at least 6 months, but no short- or long-term toxicity was observed and there was no indication of T cell infiltration or inflammatory responses (51). Similarly, in rhesus macaques, AAV-CFTR vector particles were delivered directly to one lobe of a lung and also persisted and expressed for at least 6 months (207). Furthermore, no toxicities were observed by pulmonary function testing, radiological examination, analysis of blood gases and cell counts, and differential in bronchoalveolar lavage or by gross morphological examination or histopathological examination or organ tissues (207). Studies in rhesus macaques were also performed to determine if the AAV-CFTR vector could be shed or mobilized from a treated individual (52). AAV-CFTR particles were delivered to the lower right lobe of the lung, and a high dose of adenovirus and wild-type AAV particles were administered to the nose of the animals. These studies indicated that the vector was not readily mobilized and suggested that the probability of vector shedding and transmission to others is likely to be low. The favorable safety profile of AAV in these preclinical studies has been predictive of a similar safety profile observed in clinical trials of the AAV-CFTR vector in CF patients (9–11). Importantly, preclinical studies of biodistribution of the AAV–CFTR vector following pulmonary delivery in rabbits and macaques showed that there was minimal spread of vector to organs outside the lung, no vector in gonads, and no toxicity was noted in any organ. However, use of different delivery routes may lead to more extensive biodistribution.

An AAV-FIX vector has been studied in preclinical rodent and canine models in support of clinical trials in hemophilia B patients via intramuscular injection or intravenous delivery via the hepatic portal vein. The vector showed a good safety profile when administered by intramuscular injection to hemophilia dogs that was reflected in the intramuscular injection clinical trial (12). However, in a second clinical trial, following intravenous hepatic administration of the AAV-FIX vector, patient semen was positive for the vector genome for a few weeks. This indicated that vector had apparently been distributed to gonads, although further investigation indicated that the vector was not present in sperm and the clinical trial has continued (208). A more extensive study of AAV-FIX vector delivery by both intramuscular and intravenous routes showed that, using a sensitive DNA-PCR assay, there was a dose-dependent detection of vector genomes sequences in the gonads of males of several animal species including mice, rats, rabbits and dogs (208). However, although testis tissue of these species was positive for vector for a short period after delivery, in both rabbits and dogs, semen and sperm were negative for vector sequences, suggesting that the risk of inadvertent germline transmission of vector sequences after intramuscular or intravenous delivery is extremely low (209). Two additional studies of AAV vectors expressing FIX (210) or α-1-antitrypsin (211) genes, after intramuscular delivery into rhesus macaques, again showed excellent safety profiles and did not detect transmission of vector sequences to gonads.

AAV has never been associated with any disease or shown to promote tumorigenesis. Indeed, several studies show that AAV or AAV ITRs can inhibit tumorigenesis (212,213). Also, recent studies in rhesus macaques infected with wild-type AAV2 by intramuscular, intravenous, and intranasal routes showed that, although there were some antibody responses against the AAV capsid, there was no cellular immune response to AAV components and no indication of any tumorigenesis (73). However, there was a recent anecdotal observation of tumors occurring in mice having a homozygous mutation in the β-glucuronidase gene, that were treated as neonates via head vein injection with an AAV vector expressing β-glucuronidase (BGUS). These mice exhibit the lysosomal storage disease mucopolysaccharidosis VII (Sly syndrome) that is characteristic of the human disease and, if left untreated, the animals die in several months. The mice treated with the AAV-BGUS vector survived up to 18 months and showed a remarkable biochemical and physiological correction of the disease (214). However, at 12 to 18 months some of these mice developed hepatic tumors, but vector genomes could not be found in all the tumors and not at any higher frequency than in nontumor tissue from the same animals (214). Thus, these tumors were probably not caused by insertional mutagenesis and clonal expansion. Furthermore, no

other studies of AAV vectors, including intravenous delivery in the same animal model and a variety of other animal disease models, have ever shown any tumor formation (214,216). The tumors in these MPSVII mice remains as an anecdotal observation because there were no sham-treated control mice that survived as long. It is possible that the tumor formation is specific for this disease, or the particular animal model, for overproduction of BGUS or to some other unknown cause and does not have any direct relation to the use of an AAV vector. However, some caution needs to be exercised and MPSVII disease possibly may not be an attractive candidate for gene therapy with an AAV vector.

X. AAV VECTOR APPLICATIONS

AAV vectors are now being developed for therapeutic applications. On the basis of extensive preclinical studies performed in rabbits and nonhuman primates, an AAV vector expressing the CFTR cDNA has been introduced into clinical trials in cystic fibrosis patients. This was the first AAV vector to undergo clinical trials that have now advanced to phase II (8–11). An AAV vector expressing factor IX is now undergoing phase I clinical trials in patients with hemophilia B (12).

In this section, we describe a series of therapeutic applications that are being developed with AAV vectors that either are now in clinical trials or are expected to enter clinical testing in the next several years. All the examples that we discuss are chronic diseases that affect various organ systems and require different routes of delivery. These examples serve to illustrate the potential wide applicability of AAV vectors, particularly for persistent gene expression in nondividing or slowly dividing cells.

A. Cystic Fibrosis

Cystic fibrosis (CF) is a lethal autosomal recessive disease that is caused by a mutation in the CFTR gene. The defect in the CFTR protein, which is a chloride ion channel expressed in epithelial cells, leads to complex biochemical changes in several organs, including lung and often the exocrine pancreas. In the lung, there is a decreased mucociliary clearance, increased bacterial colonization, and a chronic neutrophil-dominated inflammatory response that leads to progressive destruction of tissue in the conducting airways. The usual cause of morbidity and eventual mortality in CF patients is progressive loss of lung function. Thus, the goal of a gene therapy for CF is to deliver the CFTR cDNA into the epithelial cells in the conducting airways of the lung. An AAV vector expressing the CFTR cDNA has been introduced into clinical trials in CF patients by delivery of the vector to the lung and the nasal epithelium (8,10) in addition the maxillary sinus (9,11). One challenge in constructing an AAV vector expressing the CFTR protein was that the coding region requires a minimum cDNA size of 4.4 kb, thus leaving little space for a transcription promoter. To package this cDNA into a single AAV vector, advantage was taken of the discovery of the transcription promoter properties of the AAV ITR (91).

Although the lung is the target for a therapeutic gene therapy for CF, delivery to the maxillary sinus was undertaken as a novel attempt to obtain an early indication of the potential of the AAV CFTR vector. The maxillary sinuses of CF patients exhibit chronic inflammation and bacterial colonization that is reflective of some aspects of the CF disease in the lung. In addition, in CF patients who have undergone surgical bilateral anstrostomy, the maxillary sinus is accessible to instillation of vectors and for sampling and biopsy. In an initial trial, 15 sinuses of CF patients were treated with increasing doses of the AAV-CFTR vector (9). DNA PCR analysis of sinus biopsies showed dose-dependent delivery of the vector genome that persisted in the sinus for at least 70 days after instillation. In epithelial cell surfaces of CF patients, the transmembrane potential is hyperpolarized compared with normal patients because of the absence of a functional CFTR chloride channel. In the treated sinuses at the higher doses of vector, there was some reversal of the electrophysiological defect, thus providing suggestive evidence for expression of the CFTR protein from the delivered vector.

A follow-up, double-blinded, randomized, and placebo-controlled phase II study was performed in 23 CF patients in whom vector was administered to one maxillary sinus, while the contralateral sinus received a placebo treatment (10). This study confirmed the safety of the AAV-CFTR vector delivered to the sinus. In addition, the anti-inflammatory cytokine interleukin-10 showed a significant difference between vector- and placebo-treated sinuses over a 90-day period. This suggested that gene transfer could modulate levels of cytokines that may provide a useful surrogate marker for additional trials. Because several patients had participated in the previous phase I trial, the phase II study further suggested that the vector remains safe after multiple administrations to the sinus without induction of serum-neutralizing antibodies (10).

A phase I, single administration, dose escalation trial designed to assess safety and delivery of AAV-CFTR by inhaled aerosol to the lung was carried out in 12 adult CF patients exhibiting mild lung disease. The vector was well tolerated and no apparent safety concerns were demonstrated in the study. Vector administration at the highest dose of 10^{13} genome-containing particles resulted in significant gene transfer to the airway. A clear dose–response relationship was observed in vector gene transfer over 30 days, although the vector DNA declined over 90 days (11).

Following this study, a multidose, double-blinded, placebo-controlled, and randomized phase II trial was conducted in 37 CF patients with mild CF disease. Patients received 3 doses (10^{13} DRP per dose) at monthly intervals, administered by inhaled aerosol. This trial also was notable for enrolling patients as young as age 12 years, which is important because the eventual target population to treat CF is likely to be younger patients. The preliminary results of this study were presented recently (R. Moss, North American CF Meeting, Oct. 3, 2002, New Orleans). The multidose vector administration was safe and well tolerated. Interestingly, there was a significant treatment-related effect upon pulmonary function measured at 30 days and on the proinflammatory cytokines

IL-8 at 14 days. This is the first trial in CF patients to show an indication that gene delivery can positively affect a pulmonary function. Previous clinical trials in CF gene therapy had generally focused on measurement of molecular endpoints. However, clinical endpoints, such as pulmonary function that can be used for eventual approval of a successful therapeutic, are much more important.

Measurement of molecular endpoints, such as DNA PCR for vector genome delivery or gene transfer and RNA PCR or protein assay for gene expression, may be useful but in many cases it is difficult. Whereas these measurements can be performed readily in animal models on tissues obtained after necropsy, this generally is not an option in clinical trials except perhaps from autopsy samples, and even that is now uncommon.

For CF clinical trials, molecular endpoint measures have proven particularly challenging. First there is no good assay for CFTR protein. DNA and RNA PCR can be conducted on airways cells that are obtained via a brush inserted through a bronchoscope. This has several disadvantages including poor quality of the samples, which often contain very few cells. Consequently, it has been possible to obtain data from DNA PCR, but it has proven extremely difficult to obtain reliable RNA samples. In the clinical trials of the AAV CFTR vector in lungs of CF patients, gene transfer has been demonstrated but data on RNA expression has not been obtained. Other problematic issues are that the invasive bronchoscopy procedure disrupts other measures of pulmonary function and inflammation. Furthermore, the bronchoscopic procedure can only provide samples from the upper airways, whereas the vector needs to function in the lower airways, which is the primary site of the disease. In view of these considerations, measurement of inflammatory cytokines in sputum may be a less invasive way to obtain surrogate marker information and has the added advantage of reflecting events in the lower airways.

B. Hemophilia

Hemophilia is a severe X-linked recessive disease that results from mutations in the gene for either blood coagulation factor VIII (FVIII) in hemophilia A or IX (FIX) in hemophilia B. The absence of functional FVIII or FIX leads to severe bleeding diathesis. Expression of these clotting factors at less than 1% of normal levels results in severe disease, whereas levels over 5% of the normal range appear to be sufficient for normal function. Levels between 1% and 5% lead to much milder disease, and prophylactic delivery of these clotting factors at these levels of 1% of the normal levels (2–10 ng/mL and 50–250 ng/mL for FVIII and FIX, respectively) can decrease the risk of spontaneous bleeding into joints and soft tissues, and lower the risk of fatal intracranial bleeding. However, the FVIII and FIX proteins have a very short half-life, and this has stimulated interest in developing gene therapy approaches in which the clotting factors may be produced more persistently. Several groups have provided evidence that FIX protein can be expressed for prolonged periods in both murine and canine models after delivery of AAV-FIX vectors, either by portal vein injection to target the liver or by intramuscular injection (76,77,217–219). Generally, the levels of expression, as measured by the whole blood clotting time (WBCT) assay, have indicated that at least a partial correction of the defect in both the murine and the canine disease models can be achieved and suggest that accumulation of therapeutic amounts of FIX may be achievable in humans.

AAV vector delivery of the human factor IX gene into either immunodeficient or immunocompetent mice by portal vein injection into liver resulted in prolonged expression of factor IX for up to 36 weeks at serum levels of 250 to 2000 ng/mL, which is equivalent to about one-fifth of the normal human level (76). Similar portal vein delivery of human factor IX in hemophiliac dogs resulted in expression of factor IX at about 1% of normal canine levels, an absence of inhibitors, and sustained partial correction of whole blood clotting time (WBCT) for at least 8 months (217). In another study by Herzog et al. (76), intramuscular injection of an AAV human FIX vector into immunodeficient mice led to prolonged expression at about 350 ng/mL in serum for at least 6 months, but in immunocompetent mice there was generation of inhibitory antibody. These same investigators (218) subsequently showed that in hemophiliac dogs, intramuscular injection of high doses of the AAV-canine FIX vector achieved expression for over 17 months and demonstrated a stable, dose-dependent partial correction of the WBCT. Moreover, at the highest dose there was a partial correction of the activated partial thromboplastin time (APT). The APT assay may be a more reliable measure than WBCT. However, in another study (219), intramuscular injection of an AAV human FIX vector also led to a transient reduction of WBCT in the first week, but this was rapidly lost as the animals developed antifactor IX antibody.

Development of AAV vectors to deliver FVIII faces an extra challenge in that the FVIII protein cDNA is over 7 kb, which is too large to package into a single AAV vector. However, the FVIII protein is processed by excision of an internal B-domain such that the secreted protein consists of heavy and light chains. Removal of the B-domain DNA sequence reduces the size of the cDNA to about 4.2 kb, which can be packaged into a single AAV vector with space to include only small regulatory elements. This permits the generation of an AAV-FVIII vector expressing the human B-domain deleted FVIII that can correct the WBCT when injected via the tail vein into FVIII-deficient mice (220). An alternate strategy is to express the heavy and light chains from separate AAV vectors (221), but this would be less desirable for clinical application if it leads to unbalanced production of the two chains. Alternatively, use of dual *trans*-splicing AAV vector may also be feasible for expression of FVIII (222).

A clinical study of intramuscular injection of an AAV vector expressing human FIX in adults with severe hemophilia B was recently completed. Preliminary data from this study suggested that there was low-level expression of FIX in transduced muscle with no apparent formation of inhibitory antibodies. In addition, some possible modest changes in clinical endpoints were noted, including circulating levels of FIX and reduced frequency of FIX protein self-administration by 2

patients (12). A second phase I clinical trial with the same vector has been initiated in hemophilia B patients, but in this trial the vector is administered via portal vein injection to target the liver, which may be the natural source of FIX production. Clinical trials of AAV vectors in hemophilia A patients have not been initiated.

For hemophilia clinical trials, in contrast with the CF trials, a molecular endpoint is readily available because the level of the FIX or FVIII in serum can be directly measured and the level of protein will likely be related to degree of clinical benefit. In contrast, DNA or RNA measures again would require invasive biopsy, especially following portal vein delivery to the liver.

C. Muscular Dystrophy

The muscular dystrophies are a clinically and genetically heterogeneous group of disorders that show myofiber degeneration and regeneration, and are characterized by progressive muscle wasting and weakness of variable distribution and severity. They are associated with mutations in genes encoding several classes of proteins ranging from extracellular matrix and integral membrane proteins to cytoskeletal proteins, but also include a heterogeneous group of proteins including proteases, nuclear proteins, and signaling molecules [for a recent review, see (223)].

The most common myopathy in children, Duchenne muscular dystrophy (DMD), is a severe X-linked neuromuscular disease that affects approximately 1 of every 3500 males born and is caused by recessive mutations in the gene for the muscle protein dystrophin. Affected boys begin manifesting signs of disease early in life, cease walking at the beginning of the second decade, and often die due to cardiac arrest or respiratory insufficiency by age 20 years. The most common mutation in the dystrophin gene that causes the severe DMD phenotype is a deletion that results in a premature stop codon. The mutant protein is unable to bind to dystrophin-associated proteins at the muscle membrane. This lack of a functional dystrophin protein in DMD results in loss of muscle fiber integrity by disrupting the physical linkage between the actin cytoskeleton within the muscle fiber and the extracellular matrix (224).

Attempts to develop gene therapy for DMD have been complicated by the enormous size of the dystrophin gene, which is the largest known gene with a full-length cDNA that is 14 kb in size. However, dystrophin can retain significant function even when missing large portions of its sequence. For example, large, in-frame deletions in the central-rod domain often lead to the milder Becker muscular dystrophy (225). The *mdx* mouse is a naturally occurring murine model that has a premature stop codon generated by a point mutation in exon 23 of the dystrophin gene (226). Functional analysis of dystrophin structural domains in transgenic dystrophin-deficient *mdx* mice revealed multiple regions of the protein that can be deleted in various combinations to generate potentially highly functional minidystrophin genes (227). Three groups have generated functional miniature versions of the human dystrophin gene that can be readily packaged into AAV vectors (228–230). When injected into the muscle of *mdx* mice, efficient and stable expression was noted in a majority of myofibers, and the missing dystrophin and dystrophin-associated protein complexes were restored onto the plasma membrane. This treatment ameliorated dystrophic pathology in the *mdx* muscle and led to normal myofiber morphology, histology, and cell membrane integrity.

The limb girdle muscular dystrophies (LGMDs) are a heterogeneous group of inherited autosomal recessive neuromuscular diseases characterized by proximal muscular weakness and variable progression of symptoms. LGMD disease is caused by mutations in a number of genes, including 1 of the 4 small (cDNA $<$ 2 kb)-muscle sarcoglycan genes (α,β,γ,δ) expressed predominantly in striated muscle. These transmembrane glycoproteins associate with each other in equal stoichiometry to form the sarcoglycan complex, and a deficiency of one component typically leads to partial or complete absence of all the other sarcoglycan proteins on the sarcolemma. The Bio 14.6 cardiomyopathic hamster is a naturally occurring LGMD model due to a deletion in the δ-sarcoglycan gene. Administration of AAV δ-sarcoglycan vectors to these animals either by intramuscular or intravascular administration led to genetic, biochemical, histological, and functional rescue of relatively large regions of muscle (231–234). Mice that are null mutants for ψ-sarcoglycan exhibit severe muscle pathology that can be partly corrected if treated at less than 3 weeks of age by intramuscular injections of an AAV vector expressing the ψ-sarcoglycan gene from a muscle-specific promoter (235). Also, AAV α- or β-sarcoglycan vectors can rescue an α- or β-sarcoglycan defect in the corresponding knockout mouse model. Interestingly, while the β-sarcoglycan vector showed long-term sustained expression for more than 21 months and led to widespread biochemical and histological rescue of the dystrophic muscle, transduction of myofibers by the α-sarcoglycan vector was transient and correlated with induction of significant immune response (236). The transience of the latter vector was attributed to cytotoxicity resulting from overexpression, by more than 100-fold over normal levels of the protein rather than due to an immune response to the transgene. A phase I clinical trial of AAV to deliver sarcoglycan genes was initiated, but it enrolled and treated only 1 patient (12).

D. CNS Disease

Parkinson's disease (PD) is a common progressive neurodegenerative movement disorder that affects 5% of the population over 65 years of age. In this disease there is loss of dopaminergic neurons, mainly in the substantia nigra, which leads to deficiency of the neurotransmitter dopamine (DA) in the striatum. The clinical symptoms typically appear after extensive loss of 60% to 80% of the dopaminergic neurons has occurred, which is correlated with the DA deficiency. DA is synthesized from tyrosine, first through conversion to L-dihydroxyphenylalanine (L-DOPA) by tyrosine hydroxylase (TH), and then to DA by aromatic amino acid decarboxylase (AADC). L-DOPA therapy is very efficacious, but response

declines as the disease progresses and is complicated by adverse side effects. Thus, the different enzymes involved in DA synthesis have been targeted for gene transfer replacement therapy in order to restore dopaminergic stimulation of the striatum.

Dopamine-deficient mice ($DA^{-/-}$), lacking TH in dopaminergic neurons, become hypoactive and aphagic and die by 4 weeks of age but can be rescued by daily treatment with L-DOPA. Bilateral coinjection of AAV vectors expressing human TH or GTP cyclohydrolase 1 (GTPCH1) into the striatum of these mice restored feeding behavior for several months. However, locomotor activity and coordination were only partially improved. A virus expressing only TH was less effective, and one expressing GTPCH1 alone was ineffective. TH immunoreactivity and DA were detected in the ventral striatum and adjacent posterior regions of rescued mice, suggesting that these regions mediate a critical DA-dependent aspect of feeding behavior (236).

Sustained and long-term transduction of striatal neurons and glial cells accompanied by significant behavioral recovery following administration of an AAV vector encoding the human TH cDNA has been demonstrated in the 6-hydroxydopamine (6-OHDA) rat model of PD (53). Also, using the 6-OHDA-lesioned rat model of PD, a single intrastriatal infusion of an AAV2-AADC vector led to an enhanced conversion of L-DOPA to restore DA to 50% of normal levels 12 weeks after vector administration (237). The vector-mediated increase in striatal decarboxylase activity remained undiminished over a 6-month period and persistence of transgene expression was demonstrated for at least 1 year (238). Coexpression of TH and AADC, using 2 separate AAV vectors in this Parkinsonian rat model, resulted in more effective DA production and more remarkable behavioral recovery compared with the expression of TH alone (239).

Convection-enhanced delivery of AAV2-AADC into 6 sites in the striatum of neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated monkeys restored AADC activity to levels that exceeded the normal range (240). Injection of a bicistronic AAV vector expressing genes for human TH and AADC to asymptomatic but dopamine-depleted monkeys that had been treated with MPTP demonstrated successful transduction of the primate neurons in the striatum over a period up to 2.5 months with suggestive evidence of biochemical phenotypic effects and without significant toxicity (241). Finally, triple transduction with AAV-TH, AAV-AADC, and AAV-GTPCH1 to the striatum of either 6-OHDA-lesioned rats or MPTP-treated monkeys has resulted in restoration of DA synthesis and motor function (242,243).

Another strategy for gene therapy of PD involves the use of neuronal-specific growth factors to regenerate or halt ongoing degeneration of dopaminergic neurons of the substantia nigra. Glial cell line-derived neurotrophic factor (GDNF) is a potent neurotrophic molecule for nigral dopaminergic neurons both in vitro (244) and in vivo (245). Using the 6-OHDA-lesioned rat model of PD, perinigral injection of an AAV vector encoding the rat GDNF 3 weeks prior to a striatal 6-OHDA treatment resulted in stable transgene expression for 10 weeks and significant protection of neurons from degeneration in the substantia nigra. However, there was no recovery of striatal TH-containing fibers and no recovery of motor function, suggesting that striatal dopaminergic recovery is necessary for functional improvement (246). In another study, both nigral and striatal long-term transduction of up to 6 months provided significant protection of nigral DA neurons against 6-OHDA-induced degeneration. However, only the rats receiving AAV-GDNF in the striatum displayed behavioral recovery, accompanied by significant reinnervation of the lesioned striatum. (247). In both studies (246,247), AAV-GDNF was administered before or shortly after the injection of the neurotoxin 6-OHDA. To better model the progressive DA depletion and significant neuron degeneration, which typically occur before symptoms appear, additional studies were carried out to examine the effect of AAV-mediated GDNF gene delivery into the striatum 4 weeks after injection of 6-OHDA. These studies showed that there was retrograde transport of GDNF to the substantia nigra that halted the ongoing degeneration of nigrostriatal DA neurons, with functional recovery, even after substantial numbers of DA cells had been lost (243,248,249).

Several clinical trials of AAV vectors in the CNS may begin soon. First, a novel approach to treatment of PD was proposed (250). In this clinical study, patients suffering from PD will be administered 2 different AAV vectors, each expressing, respectively, the gene for the 2 isoforms of the enzyme glutamic acid decarboxylase (GAD-65 and GAD-67) by coinjection into the subthalamic nucleus (STN) region of the brain. The STN, which has a central role in the region of the brain that is responsible for regulation of movement, becomes disinhibited in PD. Preclinical evidence suggests that the gene delivery can inhibit the STN.

A clinical trial to treat Canavan's disease, a childhood leukodystrophy, has been proposed (251). This disease results from an autosomal recessive mutation in the gene for aspartoacyclase, which causes a toxic accumulation of the metabolite N-acetyl-aspartate. In this trial, up to 21 patients ages 3 months to 6 years will be administered in up to 6 sites in the frontal, varietal, and occipital regions of the brain.

E. Ophthalmic Diseases

AAV vectors may be well suited for efficient long-term treatment of ocular diseases because they efficiently and stably transduce retinal pigment epithelium and photoreceptor cells following subretinal injection (93,252–257). Retinitis pigmentosa (RP) is a group of inherited retinal degenerative diseases that lead to progressive reduction in visual field extent and impairment of visual acuity. The disease is triggered by mutations in various genes that cause degeneration and death of photoreceptors by apoptotic pathways (258).

Modulation of photoreceptor apoptosis may offer an effective therapeutic approach to RP. AAV vectors carrying various genes including those encoding for cilliary neurotrophic factor; fibroblast growth factors FGF-2, FGF-5, and FGF-18; and glial cell line-derived neurotrophic factor were evaluated in rodent models of RP subretinal injections. In general, these

studies demonstrated long-term expression of the transgene, delayed photoreceptor degeneration, increased rod photoreceptor survival, and functional improvement (260–263).

Other therapeutic approaches to RP are aimed at specific mutant genes. Twelve percent of Americans with the blinding disease, autosomal retinitis pigmentosa, carry an autosomal dominant P23H mutation in their rhodopsin gene, and a similar transgenic rat model of this disease is available. Delivery with an AAV vector of a ribozyme targeted at this mutation in the rodent model, protected photoreceptors from death and resulted in significantly slowing the degenerative disease for 3 months (264). Mutations in the gene *Prph2*, which encodes the photoreceptor-specific membrane glycoprotein peripherin-2, cause several photoreceptor dystrophies, including autosomal dominant retinitis pigmentosa and macular dystrophy. A common feature of these diseases is the loss of photoreceptor function, also seen in the retinal degeneration slow ($Prph2^{Rd2/Rd2}$) mouse. Subretinal injection of AAV- Prph2 in these mice gave stable restoration of photoreceptor ultrastructure and electrophysiological function correction (265).

Control of angiogenesis in the retina is essential to the preservation of vision. Ocular neovascularization (NV) is a major threat to vision and a complicating feature of many eye diseases, including proliferative diabetic retinopathy, age-related macular degeneration, and retinopathy of prematurity. Regulation of vascularization in the mature retina involves a balance between endogenous positive growth factors (e.g., vascular endothelial growth factor), and inhibition of angiogenesis [e.g., pigment epithelium-derived factor (PEDF)]. Several studies examined ocular administration of AAV vectors to mice exhibiting ischemia-induced retinal NV. Expression of antiangiogenic proteins, either PEDF or the Kringle domains 1–3 of angiostatin (K1K3), gave sustained therapeutic levels of PEDF and K1K3 in the mouse eye and significantly reduced the level of retinal NV (266,267). Expression of a soluble VEGF receptor also led to significant reduction in the number of neovascular endothelial cells and inhibited retinal NV (268,269).

Recently, efficacy of AAV-based gene therapy directed at photoreceptors and retinal pigment epithelium has been demonstrated in a canine model of Leber congenital amaurosis, a childhood blindness disease. Intraocular administration of AAV-RPE65, encoding the gene for a 65-kD membrane-associated protein involved in retinoid metabolism to $RPE65^{-/-}$ dogs, resulted in partial restoration of visual function (270).

F. Rheumatoid Arthritis

Rheumatoid arthritis (RA), the most common inflammatory joint disease, is a chronic autoimmune disorder that affects approximately 1% of the population and causes significant disability. The etiology of RA is largely unknown, although current evidence suggests contributions from both environmental and genetic components (271). The chronic inflammation in the arthritic joint is characterized by recruitment of immune cells, including lymphocytes, macrophages, and plasma cells, leading to massive thickening of the synovium accompanied by release of inflammatory mediators, ultimately leading to invasion and destruction of articular cartilage and bone. At the molecular level, chronic inflammatory arthritis is characterized by diminution of T cell factors and an abundance of cytokines and growth factors, such as interleukin-6, tumor necrosis factor α (TNF-α), and interleukin-1β (IL-1β), which are produced by macrophages and synovial fibroblasts and play a major role in the progression of joint destruction (272). IL-1β, in particular, is a key cytokine that induces cartilage degradation, whereas TNF-α is a major cytokine involved in joint inflammation (273).

Conventional treatment to manage the symptoms of arthritis uses general anti-inflammatory agents, including both steroidal and nonsteroidal drugs, and disease-modifying drugs such as methotrexate. However, none of these pharmacologic agents have yet proven effective in halting the progression of disease. Recently introduced biological agents are more effective in ameliorating arthritis symptoms and halting the progression of disease. In particular, inhibitors of TNF-α and IL-1β have proven effective in preclinical studies as well as in human clinical trials, and the Food and Drug Administration (FDA) has approved the use of IL-1 receptor antagonist (IL-1Ra), soluble TNF-α receptor immunoglobulin Fc, and an anti-TNF-α monoclonal antibody for the treatment of RA.

The use of biologics for arthritis therapy presents several challenges. Because of the relatively short half-life of these proteins and the need for frequent, daily, or weekly dosing, effective levels of the therapeutic protein may not be maintained for extended periods. In addition, therapeutic proteins are administered systemically and may have reduced bioavailability in some affected joints. Also, production of biologics such as these proteins often is inefficient, leading to low yields and consequently high costs. Gene transfer may be a more efficient means of delivery of these biological agents. If persistent transgene expression could be achieved following gene transfer, it should circumvent the need for frequent repeat dosing and should allow attainment of steady levels of the product, as opposed to the peaks and troughs associated with intermittent protein administration. Furthermore, with the current advances in manufacturing, the production cost of vectors such as AAV may compare favorably with production costs of biologics.

AAV vectors encoding genes that selectively target key mediators, or that interfere with key biological processes, involved in the pathogenesis of RA have been evaluated in rodent models of inflammatory arthritis. In mice with collagen-induced arthritis (CIA), an AAV vector encoding interleukin-4 demonstrated protection, for up to 7 months, from articular cartilage destruction and amelioration of disease severity (274,275). The therapeutic efficiency of an AAV vector carrying the viral interleukin-10 (vIL-10) under the transcriptional control of the regulated TetON system was evaluated following intramuscular administration to mice with CIA. Expression of vIL-10, specifically induced by doxycycline, persisted for at least 4 months and reduced significantly the incidence and severity of arthritis (275a). In TNF-α transgenic mice, intra-articular injection of AAV encoding soluble TNF recep-

tor type I significantly decreased synovial hyperplasia, and cartilage and bone destruction (276).

In the streptococcal cell wall-induced rat arthritis model, administration of an AAV vector encoding the rat TNFR:Fc fusion gene, either systemically (intramuscular) or locally (intra-articular), resulted in profound suppression of arthritis. This was reflected in decreased inflammatory cell infiltration, pannus formation, cartilage and bone destruction, and mRNA expression of joint proinflammatory cytokines (277). Moreover, administration of the vector to one joint suppressed arthritis in the contralateral joint. An AAV vector encoding IL-1Ra cDNA was evaluated in a lipopolysaccharide (LPS)-induced arthritis model in rats using therapeutic, recurrence, and preventative protocols (278). IL-1Ra expression was upregulated by LPS-induced joint inflammation and proved efficacious in all protocols. Importantly, the IL-1Ra transgene persisted for more than 3 months and could be induced to express therapeutic levels of soluble IL-1Ra upon LPS administration. This resulted in suppression of inflammation and IL-1β production in the treated knee joints.

G. Lysosomal Storage Diseases

Lysosomal storage diseases (LSDs) are a large class of at least 40 rare genetic diseases that cause a deficiency in one of numerous acidic hydrolases that normally function in lysosomes to catabolize glycoproteins, glycolipids, or glycosaminoglycans [for a review, see (279)]. Most of these diseases are autosomal recessive, except for Hunter and Fabry, which are X linked. The enzyme deficiencies lead to accumulation of toxic substrates and can affect many organ systems. These proteins can be secreted and taken up by other organs via mannose-6-phosphate receptors, and this has allowed development of protein therapies for Gaucher and Fabry disease. However, most of these diseases also have a CNS pathology, which adds an additional challenge because systemically secreted proteins are not taken up across the blood–brain barrier. Consequently, gene therapy will likely require delivery both systemically, as well as directly to the brain, to correct the neurological defects. An additional challenge is that these diseases develop early in life; thus, the target patient population will likely be infants, even though therapy will be required for life. However, there are a large number of animal models and some impressive corrections of the disease in these models have been demonstrated with AAV vectors.

One well-characterized animal model is the rodent model of MPSVII, which is also know as Sly syndrome. The animal model shows many of the clinical and behavioral abnormalities of the human disease resulting from the deficiency of β-glucuronidase (GUSB) and the consequent accumulation of glycosaminoglycans. Intravenous administration (280) but not intramuscular injection (281) of an AAV-GUSB vector into MPS VII animals resulted in biochemical correction of the disease, although correction of the neurological and behavioral defects and cognitive function required direct injection into the brain (282–284). Injection of the vector into neonates in order to circumvent the blood–brain barrier resulted in prolonged correction of the disease in the GUSB-deficient mice for over 1 year (214). In this later study, as noted above, there was an anecdotal finding of some development of primarily hepatic tumors in some of the long-term corrected animals, but there was no evidence that these tumors were caused by the AAV vector (215,216)

Fabry disease results from a deficiency of the enzyme α-galactosidase A (α-galA) and is characterized by accumulation the lipids globotriaosylceramide (GL3) in the vascular endothelium, leading to CNS defects, vascular occlusion, and particularly renal dysfunction. An AAV2-α-galA vector delivered via the portal vein into Fabry mice showed enhanced levels of the enzyme and corresponding reductions in the levels of GL3 in liver, spleen, and heart for up to 6 months (285).

Pompe disease is caused by a lack of the enzyme acid α-1,4-glucosidase (GAA) and leads to excessive accumulation of glycogen and generalized myopathy of both skeletal and cardiac muscle. Treatment of $Gaa^{-/-}$ mice with an AAV2 vector containing the GAA cDNA by intramuscular or intramyocardial delivery resulted in near normal enzyme activities, and skeletal muscle contractility was restored as measured in the soleus muscle. Interestingly, intramuscular delivery of an AAV1 GAA vector lead to expression of the enzyme at more than 8 times the normal level with concomitant glycogen clearance (286).

H. Vaccines

Early reports on administration to animals of AAV vectors expressing some neoantigenic transgenes demonstrated the long-term durability of transgene expression in the muscle and showed that the use of AAV vectors did not result necessarily in an immune response against the vector-encoded transgene (54,55,287,288). However, other studies in mice showed that under certain conditions both humoral and antigen-specific T cell responses to the transgene protein could be observed. Production of these immune responses probably depends on several parameters that include the nature of the neoantigen and its level of expression and localization within transduced cells, the mouse strain used, and the vector dose. Transgene-specific immune responses have been observed in mice following administration of AAV vectors expressing genes encoding *Escherichia coli* β-galactosidase (203,289,290), ovalbumin (199), HSV-2 glycoproteins B (gB) and D (gD) (204), influenza virus hemagglutinin, and HIV-1 Env (290–292), human alpha-1-antitrypsin (97), and clotting factor IX (206).

The ability to elicit immune responses implies that there is no general mechanism by which AAV blunts the immune system. Although the mechanism of antigen presentation following administration of recombinant AAV vectors to the muscle is not clear, one report suggests that activation of T cells in the draining lymph nodes occurs exclusively through cross-presentation by antigen-presenting cells rather than by direct transduction of dendritic cells (DCs) (289). Whether cross-presentation is a phenomena occurring for all transgenes in the context of recombinant AAV vectors is unknown, but

it suggests a possible role for these vectors as vehicles for prophylactic or therapeutic vaccines. For example, one study demonstrated that a recombinant AAV vector expressing a secreted HSV-2 gB led to the activation of gB-specific CTL, which were most likely activated via cross-presentation of the secreted protein by DC (195). In contrast, mice injected intramuscularly with an AAV vector expressing ovalbumin developed a robust humoral response to the transgene product but only a minimal ovalbumin-specific CTL response (199).

The use of AAV to stimulate an antihuman immunodeficiency virus (HIV-1) response has been tested in mice. A single, intramuscular injection of an AAV vector encoding the HIV-1 *env*, *tat*, and *rev* genes (AAV-HIV) induced robust, long-term production of HIV-1-specific serum IgG and MHC class I-restricted CTL activity (292). HIV-specific cell-mediated immunity was enhanced strongly by coadministration with an AAV vector encoding interleukin-12, whereas boosting with AAV-HIV resulted in rapid and strong HIV-1-specific humoral responses. When AAV-HIV was administered orally, a strong systemic and regional HIV-specific humoral immunity and MHC class I-restricted CTL response was induced, which significantly reduced viral load after intrarectal challenge with a recombinant vaccinia virus expressing the HIV-1 *env* gene (293).

In rhesus macaques, a single-dose, intramuscular administration of an AAV vector expressing the simian immunodeficiency virus (SIV) major structural genes resulted in long-term $CD8^+$, antigen-specific CTL responses against multiple SIV protein epitopes that were similar to responses observed in monkeys directly infected with pathogenic SIV. Neutralizing antibody responses were also robust and persisted for more than 1 year. More recent studies have begun to test the efficacy of AAV-SIV vaccines in an SIV-macaque challenge model. The data so far strongly suggest that immunized macaques have significantly lower virus burden at peak (2 weeks) and set point (10 weeks) after intravenous challenge with SIV than do mock-vaccinated control animals (294).

AAV vectors are also being examined as potential vehicles for tumor vaccines. In one study, an AAV-based tumor vaccine was developed by constructing a chimeric gene containing a human papillomavirus (HPV) type 16 E7 CTL epitope fused to a heat shock protein. When administered intramuscularly, this vaccine was able to eliminate tumor cells in syngeneic animals in a manner that was dependent on $CD4^+$ and $CD8^+$ cells. This suggests that vaccination with this gene could be a therapeutic treatment for cervical cancer containing HPV-16 E7 (295)

XI. SUMMARY

The work summarized in this chapter illustrates the increasingly rapid progress that is now being made in developing therapeutic applications of AAV vectors. The early clinical testing of AAV vectors for the treatment of CF has been extremely important in initiating the regulatory environment for AAV vectors and demonstrating the inherent good safety profile of AAV vectors. As more groups have extended investigations to additional in vivo models, the potential utility of AAV vectors as therapeutic gene delivery vehicles has gained more widespread interest. The development of more sophisticated production systems for AAV vectors has enhanced both the quantity and quality of vectors that can be produced. Additional work to modify the transduction efficiency by judicious choice of serotype for the capsid or by modification of the capsid structure will expand the use and potency of AAV vectors. In addition, further understanding of the intracellular metabolism of AAV vectors also will increase the sophistication with which these vectors can be deployed. It is likely that in the next few years there will be a significant increase in clinical testing of AAV vectors for additional therapeutic applications.

I. INTRODUCTION

A. General Overview

Research into the genetic foundations of disease, both acquired and inherited, has fostered progress of molecular medicines. Exemplified by the recent decoding of the complete human and mouse genomes; medical scientists have ever-expanding tools useful to engineer and employ therapeutic gene transfer in medical research programs. In contrast to traditional drugs, which act by modifying existing gene product activity, therapeutic gene transfer, or gene therapy, alters the genetic makeup of the cell with the intention of ameliorating the target disease phenotype. Successful gene therapy requires the identification of therapeutic genes that will correct a genetic defect or rectify a disease process, as well as the design and construction of suitable vehicles for delivery and expression of these genes in vivo. Identification of genes with therapeutic potential and engineering of effective gene transfer vectors are rapidly proceeding, making gene therapy an imminent practical reality. Considerable progress has been made in vector design, and clinical trials for the treatment of a number of diseases are underway. Success in these initial gene therapy endeavors is providing incentive for research into additional gene therapy applications, holding promise for creating a new age of molecular medicine in which genomics and proteomics dovetail with genetic diagnostics and therapeutic gene transfer.

Although remarkable progress has been made in the development of gene vector technologies, substantial hurdles remain. These include the development of strategies for vector targeting, modifications to increase transgene stability, regulation of gene expression, and circumvention of undesirable immune responses. Delivery of transgenes into target cells can be accomplished using either viral or nonviral vectors, with viral strategies remaining the most prevalent in human clinical trials. Virus-mediated gene delivery requires efficient methods for vector construction, vector production, and target cell infection. In this chapter, the relative merits and potential applications of herpes simplex virus type 1 (HSV-1) vectors are discussed. In the context of vector development, the natural history of HSV infection in the host is reviewed, highlighting unique features of the virus biology. Remaining potential pitfalls and approaches to their solution are also discussed.

B. Advantages of HSV Vectors

Although each viral gene transfer vector possesses distinct attributes, successful gene therapy will require construction of gene transfer vectors that are tailored to specific applications. The human herpes viruses represent promising candidate vectors for several types of gene therapy applications that include neuropathological disorders, cancer, pain control, autoimmune syndromes, and metabolic diseases.

Herpes viruses are large DNA viruses, with the potential to accommodate multiple transgene cassettes, that have evolved mechanisms that allow lifelong persistence in a nonintegrated latent state without causing disease in an immune-competent host. Among the herpes viruses, HSV-1 is an attractive vehicle for gene transfer to the nervous system because natural infection of humans results in a usually benign, lifelong persistence of viral genomes in neurons. This latent state is characterized by the absence of lytic viral protein expression, and the pres-

ence of these latent genomes does not alter nerve cell function or survival. The HSV-1 genome contains a unique, neuron-specific promoter complex that remains active during latency, the latency active promoter (LAP). This promoter can be adapted to express therapeutic proteins without compromising the latent state or stimulating immune rejection of transduced cells. The establishment of latency does not appear to require the expression of viral lytic functions. Essential genes required for expression of the viral lytic functions can therefore be deleted to create completely replication-defective vectors that nonetheless effectively establish a latent state, but cannot cause disease or reactivate from latency. Experimental HSV infection is not limited to neurons; the virus is capable of infecting most mammalian cell types, and does not require cell division for infection and gene expression. Accordingly, HSV may be generally useful for gene transfer to a variety of nonneuronal tissues, particularly where short-term transgene expression is required to achieve a therapeutic effect.

Considerable technical progress has been made in developing HSV-1 into a practical gene transfer vector, including the development of efficient methods for vector construction and high-titer vector production. The obstacles requiring satisfactory resolution in order to realize the full potential of these vectors include (1) the elimination of vector toxicity, (2) the design of promoter cassettes that provide for sufficient level and duration of transgene expression, and (3) targeting of transgene expression to specific cell populations through the use of tissue-specific promoters, or by altering the virus host range through modifying receptor utilization for attachment and entry. This chapter concentrates on the design, production, and utilization of replication-deficient genomic HSV vectors.

II. VECTOR DESIGN STRATEGIES

A. Biology of the Viral Lytic Cycle

HSV-1 is a double-stranded DNA virus whose capsid is surrounded by a dense layer of proteins, the tegument, which is contained within a lipid bilayer envelope (Fig. 1A). Glycoproteins embedded in the viral envelope mediate infection of the host cell, which takes place in 2 identifiable stages: (1) attachment to the cell surface, and (2) fusion with the cell membrane, resulting in virus penetration. The envelope of HSV-1 contains at least 10 glycoproteins (gB, gC, gD, gE, gG, gH, gI, gJ, gL, and gM) and 4 nonglycosylated integral membrane proteins (products of the UL20, UL34, UL45, and UL49.5 genes). Of the 10 glycoproteins, gB, gD, gH, and gL are essential for viral infection (1–4), whereas gC, gE, gG, gI, gJ, and gM are dispensable for infection in vitro (5–7).

Attachment of the viral particle is mediated by several glycoproteins (5,6,8). The sequential attachment steps in infection result in fusion of the viral envelope with the cell surface membrane and entry of the viral capsid into the cell cytoplasm. Even though the molecular events of penetration are not well understood, it is clear that multiple viral glycoproteins are required (e.g., gB, gD, gH/gL) (2,4,9–11). In addition, following new virion assembly, viral glycoproteins are also involved in a less well-defined process of egress and release of mature particles from the infected cell membrane. Viral particles are also capable of spreading from cell to cell across cell junctions, a process requiring the functional activities of several glycoproteins that are not required for initial infection (e.g., gI/gE) (12,13).

The genome structure of HSV can be divided into viral genes that are essential or accessory for replication in cell culture (Fig. 1B). The accessory functions may be deleted without significantly hampering virus growth in culture. However, removal of essential genes necessitates the use of complementing cell lines that express the essential products in order to propagate these viral recombinants. In human infections, HSV binds to and enters epidermal cells following direct contact with an infected individual that is shedding virus or has an active lesion. Following virus attachment, the viral capsid penetrates the surface membranes of epithelial cells of the skin or mucosa and is transported to the nuclear membrane where viral DNA is injected through a nuclear pore (Fig. 2A). Once inside the nucleus, the viral DNA is circularized and transported to nuclear domain 10 (ND10) structures (14,15), where the immediate early (IE) genes are expressed as part of the sequential cascade of lytic gene synthesis (16) (Fig. 2B). Transcription of the 5 IE genes (ICP0, ICP4, ICP22, ICP27, and ICP47) does not require *de novo* viral protein synthesis. Expression of the IE genes is controlled by promoters that contain 1 or more copies of an enhancer element responsive to the viral tegument protein VP16 (a.k.a. Vmw 65 or TIF, a transactivator that is transported into the nucleus along with viral DNA) (17–19). The IE genes ICP4 and ICP27 encode products required for expression of the early (E) and late (L) genes (20–23); the former (E) gene class specifying primarily enzyme functions required for viral DNA synthesis and the latter (L) comprising primarily virion structural components. ICP4 regulates viral promoter function (21), whereas ICP27 affects the processing and transport of viral RNA (24,25). The IE gene products ICP0 and ICP22 contribute to viral gene transcription but are not essential to virus replication in cultured cells (26–29). ICP0 is a promiscuous transactivator that exerts its effect prior to the transcription initiation event; it is not a DNA-binding protein (30). ICP22 has been found to regulate the level of ICP0 expression (31). ICP47 does not affect transcription but rather has been reported to interfere with a transporter function transporter of antigen presentation (TAP) that is responsible for loading major histocompatibility (MHC) class I molecules with antigenic peptides (32–35). Expression of late genes is dependent on both viral DNA synthesis and IE gene functions (21,23,36,37). Following translation of the late gene products, which become viral structural components of the capsid, tegument, and envelope, genome-length copies of viral DNA are packaged into the newly assembled capsids. Tegument proteins accumulate around the capsid and the immature particle buds through the inner nuclear membrane where the viral glycoproteins are localized. Double-membrane-enveloped virus containing virus-encoded glycoproteins modified by the Golgi apparatus

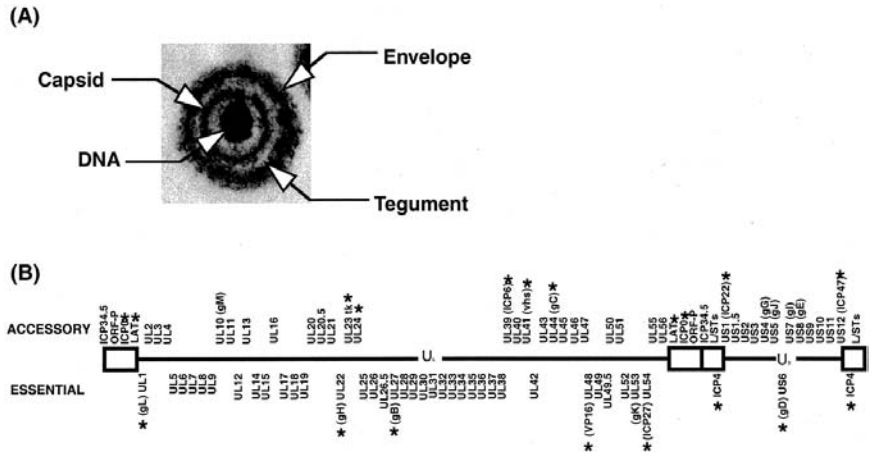

Figure 1 HSV-1 virion structure and genome organization. (A) Electron micrograph of the HSV particle, showing the capsid, tegument, and glycoprotein-containing lipid envelope. (B) Schematic representation of the HSV genome, showing the unique long (U_L) and unique short (U_S) segments, each bounded by inverted repeat (IR) elements. The location of the essential genes, which are required for viral replication in vitro, and the nonessential or accessory genes, which may be deleted without affecting replication in vitro, are indicated. The 5 IE genes, various glycoprotein genes, LAT, and other important loci are highlighted by asterisks.

enzymes fuse with the cell membrane forming a mature, extracellular virus particle with a single membrane bilayer (38). The infectious particles can infect neighboring cells by cell-to-cell transmission or can be released for infection of distal cells. With the exception of sensory neurons, cell lysis accompanies productive viral infection.

B. Complementation of Essential Genes and Elimination of Cytotoxicity

Because HSV genes are expressed in a sequential cascade during lytic infection (16), removal of the single essential IE gene ICP4 severely inhibits the expression of later E and L genes (21), resulting in a defective vector incapable of producing virus particles. In addition, the IE gene products, with the exception of ICP47, are individually toxic to most cell types when expressed at high levels by transfection (39). The elimination of multiple IE genes reduces the cytotoxicity of HSV-based vectors for cell lines and primary neuronal cell cultures (40–44) (Figs. 3A and B). Cytotoxicity of a genomic HSV vector deleted for ICP4, ICP22, and ICP27 in cultured Vero cells is reduced compared with a virus-only deficient for ICP4 (44). Such mutants are also less toxic to primary neurons (41) or undifferentiated cells such as umbilical cord blood-derived stem cells (Wechuck and Glorioso, unpublished observation, 2003). Mutants deleted for ICP0, ICP4 and ICP27 and defective for ICP22 expression in noncomplimenting cells are essentially nontoxic, even when infected at very high multiplicities (45); in this regard they are similar to UV-irradiated particles that do not express viral functions (46). We created a mutant background for gene therapy applications that require short-term, high-level expression by constructing an HSV-1 vector deleted for multiple viral functions, including the IE genes ICP4, ICP22, ICP27, and ICP47. We chose to remove the ICP47 gene in this vector to avoid interference with antigen presentation in applications intended for induction of specific immunity, but we did not delete the ICP0 gene because this gene product improves transgene expression and permits efficient construction of recombinant vectors (47,48). In this mutant background, we eliminated the virion host shut-off function (vhs) encoded by UL41 because this virus tegument component indiscriminately interferes with translation of mRNA in infected cells (49–51). A similar vector background has been used to express transgenes for up to 21 days in cultured primary neurons without causing neuronal cell death (41). For applications involving infection of cancer cells in vivo, the transient arrest of cell division offered by ICP0 and subsequent recovery of cell growth at high multiplicity of infection should prove advantageous because transducted cells produce high levels of transgene product prior to induction of cell death.

C. Vector Transgene Capacity

The treatment of monogenic diseases requires only limited vector capacity, but complex applications may require the delivery of large or multiple independent genetic sequences. A comparison of the genome structure and capacity of several current vector systems is shown in Fig. 4. The overall size of the HSV-1 genome (152 kb) represents an attractive feature for employing the vector for the transfer of large amounts of exogenous genetic sequences. Approximately one-half of the HSV-1 coding sequences are nonessential for virus replication in cell culture and therefore may be deleted to increase transgene capacity without blocking viral replication (Fig.

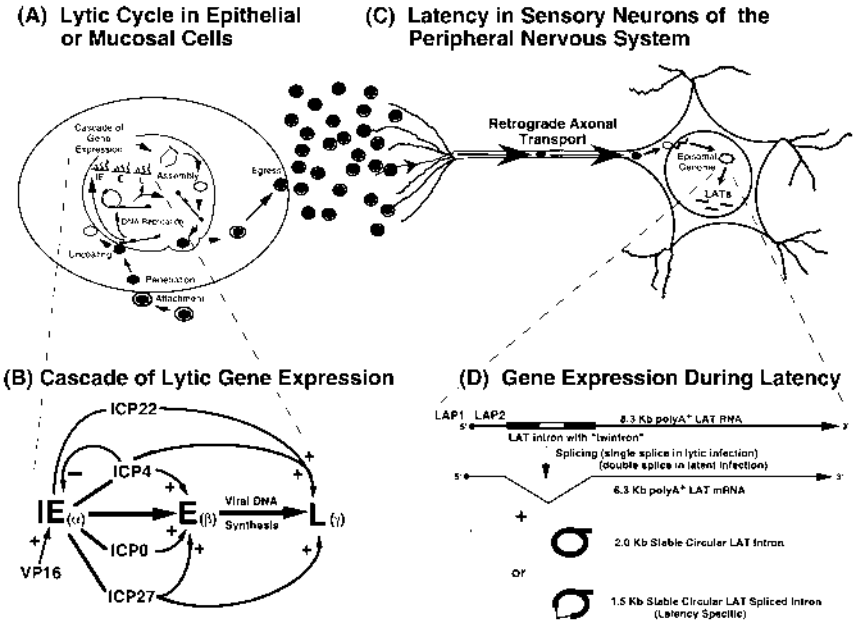

Figure 2 HSV-1 life cycle in the host. (A) Lytic infection. Primary lytic infection of epithelial or mucosal cells results from the attachment and penetration of HSV particles to host cells, a complex process involving many HSV surface glycoproteins. Following transport of the capsid to the nuclear membrane and injection of linear dsDNA into the nucleus, the genome circularizes and begins to express the lytic HSV gene functions in a highly regulated sequential cascade, yielding the expression of proteins involved in viral DNA synthesis and virion structural components. Following assembly of newly synthesized particles within the nucleus, virion maturation results in the egress of these virions from the infected cell. (B) Schematic diagram of the sequential cascade of lytic gene expression. The 5 IE or α genes are expressed immediately upon infection through transactivation by the VP16 tegument protein. The ICP4, ICP27, and ICP0 IE gene functions are responsible for the activation of the early or β genes that are primarily involved in viral DNA synthesis. In addition, ICP4 acts to shut off expression of the IE genes. Following viral DNA replication, ICP4, ICP22, and ICP27 participate in the activation of true viral late or γ genes, which mainly encode virion structural components. (C) Latent infection. When virion particles encounter and bind to axonal termini that innervate the site of primary infection, viral capsids are transported in a retrograde manner to the nerve cell body. At this point the circular viral genome can persist as an episomal molecule in a latent state within the neuron, wherein viral lytic gene expression is silenced and a series of latency-associated transcripts (LATs) are produced. (D) Gene expression during latency. The major 2.0-Kb latency-associated transcript (LAT) arises from the large 8.3-Kb polyA$^+$ through a splicing event that yields an unstable 6.3-Kb LAT and a circular LAT lariat of 2.0 Kb. The location of the latency active promoter (LAP) regions LAP1 and LAP2 relative to the LATs is depicted.

1B). The latency region of the virus genome represents approximately 8 kb of sequence that can be removed and the joint region of the virus is composed of 15 kb of redundant sequence that can be eliminated without compromising virus replication (52). In one set of experiments we removed an 11-kb section of the U_S region of the genome (Laquerre and Glorioso, unpublished data, 1998) containing gD, the only essential gene in this region, which can be propagated on a cell line that expresses gD in trans (4). Approximately 44 kb of HSV sequence can potentially be removed and vectors propagated in cells engineered to complement just 3 viral functions (ICP4, ICP27, and gD). Transgene expression cassettes can also be inserted into deleted essential gene loci to avoid transfer of foreign sequences to wild-type virus by recombination that could potentially occur between the vector and wild-type genomes in vivo. We have observed that some nonessential genes (e.g., IE genes ICP0 and ICP22) are toxic to some cell types, yet the products of these genes are required for high-titer vector production. The toxicity of these products makes it difficult to produce a complementing cell line carrying these genes. However, it is possible to engineer the promoters for these genes in a manner to make their function dependent on viral IE genes present only in complementing cells (44). By the judicious selection of viral gene deletions and promoter alterations, high-titer vectors can be produced with minimal complementation.

We have developed a panel of novel HSV-1 vectors with a background suitable for expression of multiple transgenes

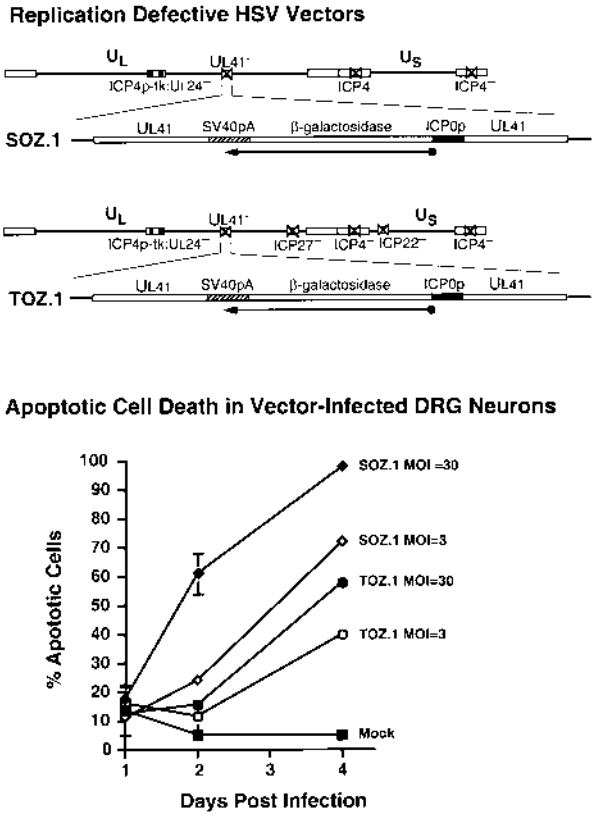

Figure 3 Reduced toxicity following infection of primary dorsal root ganglia neurons. (A) Schematic representation of the first-generation SOZ.1 (ICP4$^-$, UL41$^-$:ICP0p-lacZ: UL24$^-$:ICP4p-tk) and the third-generation TOZ.1 (ICP4$^-$, ICP22$^-$, ICP27$^-$, UL41$^-$:ICP0p-lacZ, UL24-:ICP4p-tk) replication-defective vectors displaying the lacZ transgene inserted into the UL41 locus under the control of the ICP0 promoter using the SV40 polyadenylation signal. (B) The number of primary dorsal root ganglion (DRG) neurons undergoing apoptosis was determined at various times following infection with either SOZ.1 or TOZ.1. Even at an MOI of 30, TOZ.1 was less toxic than the first-generation vector (SOZ.1) at the lower MOI (3.0).

using a rapid gene insertion procedure (53). To take advantage of the reduced cytotoxicity resulting from the deletion of ICP4, ICP22, and ICP27 genes (41,43), we designed a single vector in which 9 viral genes were deleted, removing a total of 11.6 kb of viral DNA that was replaced with multiple transgenes under control of different promoters. These HSV multigene vectors were constructed with either 4 or 5 independent transgenes at distinct loci (47) with all the transgenes simultaneously expressed for up to 7 days. These multigene vectors demonstrate the potential for using HSV-1 vectors for the expression of complex sets of transgenes that have coordinated or complementary functions.

Recent work inserting bacterial artificial chromosome (BAC) elements into large viruses including HSV promises to increase the speed of recombinant construction as well as allow the creation of extensively modified vectors without the necessity of creating complementing cell lines. We have introduced the BAC elements into multiply defective HSV vectors and propagated them in *Escherichia coli* (Wolfe and Glorioso, unpublished data, 2003). Transfection of HSV:BAC DNA purified from bacteria into complementing cells is much more efficient than using viral DNA purified from mammalian cells. Infectious virus produced can be recovered back into *E. coli* for further modification. Several methods have been used to modify the viral genome in bacteria with high frequencies of recombinant production in a greatly shortened time frame. We are further modifying vector genomes and engineering additional methods for recombinant engineering in bacteria.

D. Amplicons as an Alternative Vector System

Often referred to as ''defective'' HSV-1 vectors, amplicons are plasmids engineered to contain both an HSV origin of replication and packaging signals and a bacterial origin of replication (54). Amplicons are propagated in bacteria and then cotransfected with a defective HSV ''helper'' virus to create a mixed population of HSV particles containing either the defective HSV helper genome or concatemers of the plasmid packaged within an HSV capsid. In concept, the production of virion-packaged amplicons uses transient complementation of the entire HSV genome to provide replication machinery and viral structural components. A comparison of replication-defective genomic HSV vectors and helper virus-free amplicons are shown in Figs. 5A and B). Amplicons have been used to express reporter genes (55–61) or biologically active peptides (55,62–70) transiently in tissue culture systems.

In vivo, prolonged expression of both a *lacZ* reporter gene (59,71–75) and of the TH gene (71) following amplicon injection into brain have been reported. However, the production of amplicons requires repeated passaging of the amplicon/helper virus preparation, which results in the emergence of recombinant wild-type virus that, although estimated to occur at the low frequency of 10^{-5} (71,72), results in the death of 10% of infected animals in experiments in vivo (71). The production of true helper virus-free amplicon preparations using multiple restriction fragments of the helper virus genome that lack packaging signals has recently been reported (76). However, the maximal yield obtained with that method has remained low ($<10^7$ pfu/mL), and expression in vivo has not been fully tested (76). The presence of cytotoxic helper virus and the generation of replication-competent contaminants represent technical hurdles to the effective production and use of amplicons in human patients. Helper-free amplicons will likely require the development of new helper systems to make their use practical enough for human applications.

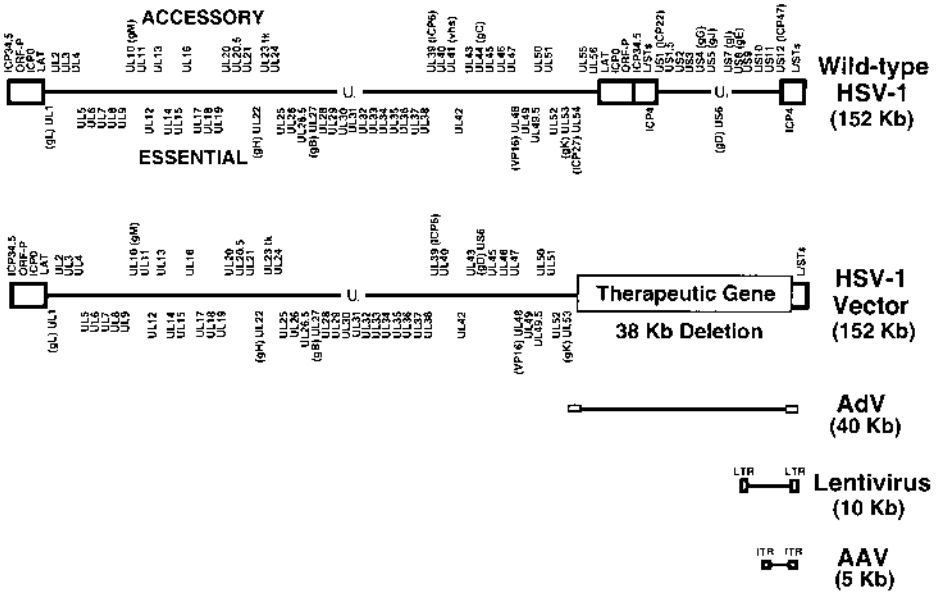

Figure 4 Comparison of viral vector payload capacities. Schematic diagram of various viral vector genomes currently in use for gene transfer and therapy studies, including the overall size of the entire vector genome. The HSV-1 vector, which contains a 38-kb deletion of sequences comprising the joint region and the entire unique short (U_S) segment of the viral genome (ICP4$^-$, ICP22$^-$, ICP27$^-$), can accommodate foreign trangene sequenes that are larger than lentivirus or AAV vectors and equivalent in size to the complete adenoviral (AdV) genome.

III. VECTOR TARGETING

One method to achieve cell-specific expression of the therapeutic gene is targeting vector recognition and infection of cells to unique receptors present principally on target cells. Exploration of this approach has been limited thus far, but several recent reports have shown convincing targeting of adenovirus (77–79) or retrovirus (80–83). Targeted viral infection requires (1) the identification of cell-specific surface receptor(s) to which viral binding/entry can be directed, and (2) the modification of viral glycoproteins to recognize novel receptors while eliminating the binding of these viral ligands to native receptors, a process that ideally should be accomplished without compromising infectivity. These steps can be combined if it is possible to replace the natural receptor-binding domain of viral glycoproteins responsible for infection with binding domains specific for alternate receptors.

The complexity of the glycoproteins in the viral membrane and the fact that multiple glycoproteins are required for the sequential steps of virus attachment and entry has made redirecting HSV infection difficult. Early electron microscopic studies showed that the trans-plasmalemmal entry of HSV into cells occurs in two morphologically definable stages: cell surface attachment and virion–cell fusion. It is convenient to consider these stages separately, although in reality the transition from one to the other is rapid and seamless.

Initial virus attachment is cooperatively mediated by numerous glycoproteins (5,6,8). Binding of viral particles to cell surface heparan sulfate (HS) and other glycosaminoglycans (GAGs) (10,84–90) is mediated by exposed domains of glycoproteins C (91–94) and B (86,92), as evidenced by the diminished cell attachment of gC and gB mutants, and the interference with cell attachment by (1) pretreatment with anti-gB or anti-gC antibodies, (2) enzymatic removal of cell surface GAGs, and (3) competition studies using heparin. The role of gB is complex as this glycoprotein functions both in the initial binding of virus to the cell surface (nonessential for cell entry) and in later stages in the virion–cell fusion program (essential for cell entry). Molecular dissection of the domains of gB responsible for each distinct process has allowed the generation of a gB mutant that shows isolated loss of GAG-binding functions, dissociated from preserved cell entry functions. This mutant, generated by deletion of a positively charged lysine-rich region within gB (designated gB:pK$^-$), is an important resource in the generation of viral vectors with targeted cell binding and preserved entry (see below). The initial gB/gC-HS/GAG-mediated cell attachment greatly enhances but is not essential for subsequent events in the cell entry cascade; thus, cell attachment represents a reasonable target for strategies aimed at effecting restricted cell entry.

In initial studies to manipulate the cell attachment properties of HSV, we focused on the elimination of HS binding by removal of appropriate binding domains from the virus envelope, leaving intact the viral determinants mediating the downstream events in cell entry. We hypothesized that subsequent replacement of the HS-binding ligands with avid spe-

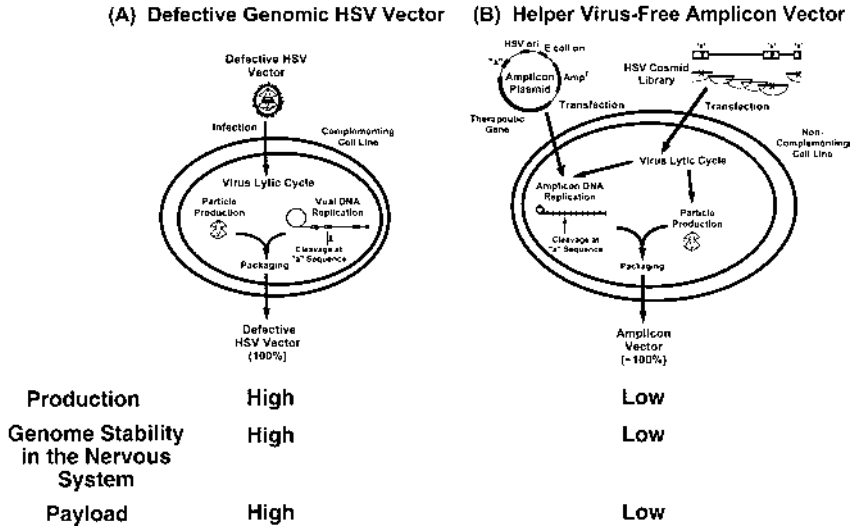

Figure 5 Strategies for HSV-1 vector design. (A) The production of defective full-length genomic HSV vectors is carried out in cell lines engineered to provide the deleted essential genes *in trans*. These vectors can be produced in high titers, are capable of long-term persistence in neurons in vivo, can accommodate large or multiple transgenes, and are incapable of replicating in neurons or other cells because of the missing essential genes. (B) Helper-free amplicons can be readily propagated in bacteria using the bacterial origin of replication (*E. coli* ori), and then transfected into a noncomplementing cell line along with 5 cosmids that encompass the entire HSV genome. Unlike the standard amplicon system in which the final preparation consists either of a mixture of amplicon concatemers and defective HSV particles, only amplicon concatemers get packaged into new virus particles because the overlapping cosmids lack the HSV packaging sequence (''a'' sequence). The helper-free amplicon preparations suffer from low titer yields, decreased stability of the amplicon DNA, and decreased transgene payload.

cific receptor-binding sequences might achieve at least partial targeting. A double-mutant virus, KgBpK-gC-, was derived from wild-type KOS strain (Figs. 6A and B). In this mutant, the coding sequence for the nonessential gC gene was removed from the viral genome and the wild-type gB sequence replaced by the gB:pK$^-$ mutation (92) (Fig. 6B). The resulting virus demonstrated an 80% reduction in binding to Vero cells compared with wild-type virus (Fig. 6D). By replacing the HS-binding domain of gC with the coding sequence of erythropoietin (EPO) in the background of the KgBpK$^-$gC$^-$ mutant virus (Fig. 6C), we demonstrated that the gC:EPO fusion protein was incorporated into the budding virion and that recombinant virus was specifically retained on a soluble EPO-receptor column (95). The gC:EPO virus demonstrated a 2-fold increase in infection of K562 cells (Fig. 6D) (Laquerre and Glorioso, unpublished data, 1998), which express the EPO receptor. The EPO-expressing particle also stimulated the proliferation of FD-EPO cells (95), an EPO-dependent cell line, indicating that virus binding to specific cellular receptor had occurred. However, virus attachment was followed by delivery of the viral particle to the endosome compartment resulting in virus degradation, thus preventing the normal pathway of entry resulting in productive infection. These studies stress the importance of appropriate receptor interactions to ensure virus entry by the normal route of virus penetration.

An alternative strategy for effecting targeted cell entry through engineering cell attachment was subsequently considered. In the gC-EPO experiments described above, entry of HSV into the endosome prevented cytoplasmic penetration, probably because of the low pH of the endosome compartment; trans-plasmalemmal cellular entry of HSV occurs at physiological pH, and it is unlikely that the native viral entry determinants would be functional in the acidic environment of the endosome. Several viruses, however, enter cells through a trans-endosomal route, exploiting the low pH of the endosome to effect fusion-triggering alterations in viral receptors. An example is provided by vesicular stomatitis virus (VSV). The VSV-G spike glycoprotein had previously been successfully used to redirect the tropism of lentiviruses, expanding their host cell range and reconfiguring the usual trans-plasmalemmal route of entry of lentiviruses into cells, to enable a trans-endosomal route to be taken. We thus explored pseudotyping HSV using VSV/HSV fusion proteins. A mutant virus was used in which the short unique segment of the HSV genome U_S3–8 (encoding gD in addition to nonessential glycoproteins gE, gG, gJ, and gI) was deleted. The gD-null phenotype of this vector was transiently rescued by using a series of plasmid expression cassettes encoding chimeric VSV-G/HSV glycoprotein fusion proteins (96). Chimeras containing the ectodomain of VSV-G linked to either the C-terminal or

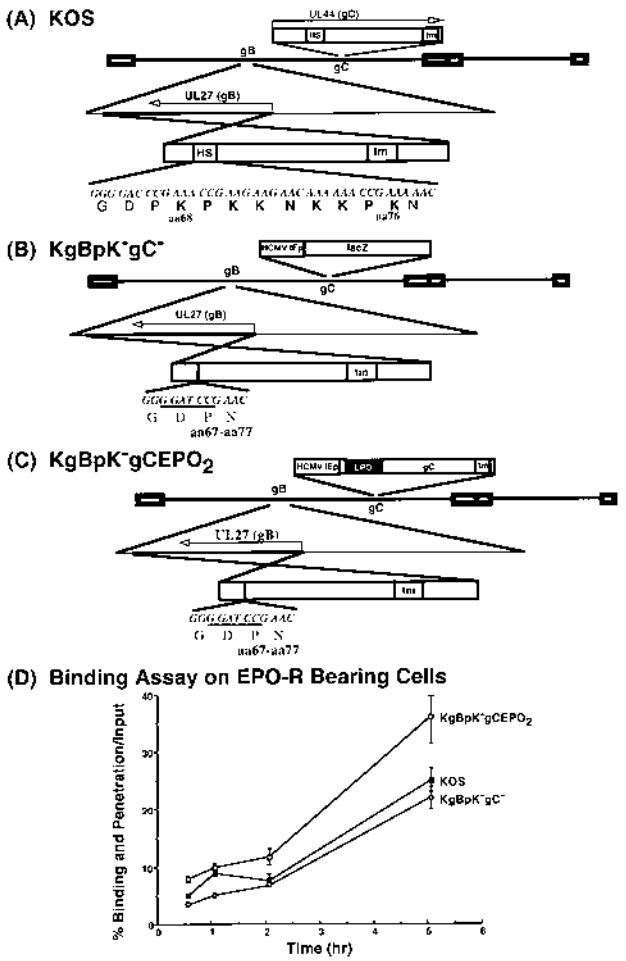

Figure 6 Targeted binding of HSV-1 particles expressing gC:EPO fusion molecules to EPO receptor (EPO-R)-bearing cells. (A) Diagram of the KOS wild-type HSV-1 genome depicting the location of the two HSV glycoproteins (gB and gC) involved in heperan sulfate-binding. The heperan sulfate binding domain of gB consisting of a series of polylysine (pK) residues is shown in greater detail. (B) The $KgBpK^{-}gC^{-}$ recombinant virus deleted for binding to heperan sulfate was constructed by deleting the pK region from the essential gB gene and deletion of the nonessential gC gene by insertion of an HCMV IEp-lacZ expression cassette into the gC locus. (C) The $gC{:}EPO_2$ recombinant ($KgBpK^{-}gCEPO_2$) was constructed by introducing EPO into the gC gene, replacing aa#1–162 in the $KgBpK^{-}gC^{-}$ recombinant virus, which could readily be purified by X-gal staining. (D) The percentage of radiolabeled wild-type HSV-1 (KOS), the recombinant deleted for heperan sulfate binding ($KgBpK^{-}gC^{-}$), and the EPO-expressing ($KgBpK^{-}gCEPO_2$) viruses that bound to K566 cells bearing the EPO-R was determined and is expressed compared with input virus. These data demonstrate that the $KgBpK^{-}gCEPO_2$ recombinant virus binds to the EPO-R and this binding conferred increased infectivity of the $KgBpK^{-}$gCEPO2 virus for cells bearing the EPO-R (K566).

transmembrane domain of either gD or gB were generated. A number of different constructs were tested to facilitate the identification of chimaeras that were effectively packaged into the virion, because it was previously suggested that the structural requirements for incorporation of glycoproteins into the envelope of the mature virus particle were stringent with respect to transmembrane or endodomains (97–100). It was demonstrated that VSV-G chimeras containing the transmembrane domain of gD, or a truncated gB transmembrane domain, were incorporated into the viral envelope efficiently, and that the wild-type VSV-G protein was incorporated rather less efficiently (96). The latter, however, was able to partially rescue the gD-deficient phenotype, whereas the chimeric proteins were nonfunctional. Neutralizing anti-VSV-G antibodies blocked the partial VSV-G mediated rescue (96). The poor efficiency of phenotypic rescue of the U_S3–8 null virus by VSV-G may be attributable to either (1) inefficient incorporation of the foreign viral glycoprotein, or (2) acid degradation of HSV in the endosome compartment. We have studied this issue further in order to elucidate and exploit the mechanisms contributing to partial rescue. A recombinant virus was generated in which the VSV-G expression cassette was incorporated into the genome of the U_S3–8 deleted virus (the resulting vector is null for gD, gE, gG, gJ, and gI, but expresses VSV-G). The recombinant particle enters cells possessing the VSV receptor. However, an abortive infection ensues, culminating in endosomal degradation of the virion at low pH, similar to that observed when the gC-EPO-expressing recombinant enters cells (Goins and Glorioso, unpublished data, 2003). The use of lysomotropic agents that raise endosomal pH, such as chloroquine (101), enables release of viral contents from the endosome into the cytoplasm, resulting in plaque formation. An acidic environment is required for the activation of VSV-G fusion functions (102,103). It follows that, in the presence of lysomotropic drugs, fusion of the VSV-G expressing, U_S3–8 null, recombinant with the endosomal membrane must be mediated by HSV fusion glycoproteins (gB or gH/gL). It thus appears likely that, in this situation, VSV-G functions as a ligand for an internalized receptor, rather than a pH-dependent mediator of viral envelope fusion with the endosome membrane. We are currently examining the mechanism in more detail because this strategy might be exploited to allow specific targeting of HSV to internalized cellular receptors.

Viral gC/gB-mediated binding to cell surface HS is followed by a second binding event between viral gD and specific cellular receptors. An essential role for gD in virus penetration is supported by the finding that recombinant virus deleted for gD is capable of binding to cells but is unable to penetrate (9,11). In addition, infection can be neutralized by anti-gD antibodies that do not block attachment of virus to the cell (9,11). Several distinct cellular gD receptors have been identified. The first HSV gD receptor herpesvirus entry mediator (HVEM or HveA), isolated by screening a cDNA expression library in HSV refractory Chinese hamster ovary (CHO) cells, was determined to be a member of the tumor necrosis factor (TNF)/nerve growth factor (NGF) receptor family (104). Subsequently, a number of other entry mediators have been identi-

fied, including HveB [poliovirus receptor-related protein 2 (Prr2)] (105), and HveC [nectin-1, poliovirus receptor-related protein 1 (Prr-1)] (106). The latter, an alternatively spliced member of the immunoglobulin superfamily that bears no structural relation to HVEM/HveA is the major gD receptor and is widely expressed. Finding multiple, unrelated receptors capable of mediating HSV infection via gD suggests that several distinct receptor-binding domains exist within gD. The recent publication of the crystal structure of the HveA-gD receptor–ligand complex is an essential first step in the recognition of gD domains that are essential for interaction with specific cellular ligands. This knowledge may assume great importance in the rational design of gD mutants that are restricted for binding/entry functions through prespecified cellular HSV receptors, and ultimately for engineering gD to target new ligands. Targeted infection might be accomplished by manipulation of the specificity of gD while leaving the HS-binding activity of gC and gB intact. The ability of gD to bind to a range of cellular receptors suggests that the partial or complete substitution of gD with other sequences capable of mediating viral entry may provide a means of HSV vector targeting. Mutation of, or antibody binding to, N-terminal amino acids of gD eliminates HveA binding while leaving HveC binding and the penetration function intact, but the reverse has yet to be accomplished (107). Initial mutagenesis studies suggest that the binding and entry functions of gD may be dissociable and dependent on overlapping but distinct subsets of amino acid residues within the HveA/HVEM- and HveC/nectin-1/Prr-1-binding domains of gD (Bai and Glorioso, unpublished data, 2002), suggesting that targeted entry may be at least theoretically possible. A subsequent study has shown limited evidence that cell entry might occur through engineered gD (108). A recombinant virus was generated, in which the binding sites for HS in gB and gC were deleted. The amino-terminal of gC was replaced by IL-13 and a second copy of IL-13 was inserted into gD, disrupting the binding site for HveA/HVEM but not the binding site for HveC/nectin/Prr-1. The recombinant and wild-type viruses replicated in a variety of cell lines that expressed HveC/nectin/Prr-1. The recombinant failed to replicate in a cell line that does not express HveC/nectin/Prr-1, but did replicate in a derived clone that expressed the IL-13 receptor. Although mutants that are unable to enter cells through HveA/HVEM, but which have preserved HveC/nectin/Prr-1-mediated entry functions, have been previously described, this study provides preliminary evidence that gD engineering might allow viral entry through generation of a novel binding specificity. However, the crucial test of this strategy for viral targeting will be whether viral entry functions of gD remain preserved after disruption of the HveC/nectin/Prr-1-binding site, an observation that was notably absent from this report. Ongoing studies will determine whether engineering a novel binding ligand into the gD N-terminus will substitute for gD binding to HveA and HveC and preserve the role of gD in penetration.

An alternative strategy might use a bispecific soluble adapter molecule to bind to the HveC/nectin/Prr-1 site of gD, inducing the viral entry cascade. The molecule would also contain a binding site for a specific cellular ligand, thus providing the following 3 properties essential for targeted entry: (1) targeted cellular binding, (2) promotion of viral fusion, and (3) blocking the gD HveC/nectin/Prr-1-binding domain that would enable entry to nontargeted cells expressing this receptor. We have shown proof of principle that viral entry might be triggered by a soluble HveC/nectin/Prr-1 fragment containing the gD-binding domain (Bai and Glorioso, unpublished data, 2002) in the absence of a specific interaction between the soluble adapter and the cell surface.

Binding of gD to its cognate cellular receptor is followed by gB/gH/gL-mediated virion envelope–plasmalemmal fusion. As might be predicted, mutants deleted for gH/gL or gB are defective for virus penetration but are not defective in attachment (1,2,109). Furthermore, antibodies directed against gB, gH, or gL are able to prevent entry without interfering with attachment. The mechanisms of viral envelope–plasmalemmal fusion remain uncertain. In the absence of a specific role ascribed to a cellular receptor, it seems unlikely at present whether this part of the cell entry cascade will be amenable to manipulation resulting in targeted cell entry.

IV. VECTOR TRANSGENE EXPRESSION

A. Lytic Gene Promoters

We have explored the activity of many viral and cellular promoters in the background of replication-defective viral vectors (47,110–118). These lytic gene promoters display transient activity in both neuronal and nonneuronal cells. Thus, viral IE promoters are effective for applications that require only transient transgene expression. The human cytomegalovirus (HCMV) IE gene promoter produced vigorous transgene expression for up to 21 days post infection in vivo (Ramakrishnan and Fink, unpublished data, 1991) and in neuronal cell cultures in the background of a vector deleted for ICP4, ICP27, and ICP22 (41). Studies in rabbits and primates have demonstrated transgene expression under control of the HCMV promoter for at least 1 year following infection of rabbit joints (119). Other promoters, such as SV40 and various retroviral LTRs, are also transiently active (113,120) following infection of brain. Cellular promoters such as the muscle-specific muscle creatinine kinase (MCK) enhancer support muscle-specific expression in myotubes in culture (Akkaraju and Glorioso, 1991). Several reports have described long-term transgene expression from similar promoters in neurons (121–124), but expression declined significantly after the first week and may represent activity of aborted reactivation events. However, many therapeutic applications will require prolonged transgene expression from latent genomes. For this purpose, we and others have studied the native latency gene promoters in considerable detail.

B. Biology of Latency and the LAP

Following infection of epithelial cells of skin or mucous membrane, viral particles come into contact with sensory neuron axon terminals in which the particle is transported along mi-

crotubules to the nerve cell body where the viral DNA enters the nucleus (125,126) (Fig. 2C). Although the virus can express lytic functions in sensory neurons (127–129), lytic gene expression is curtailed through a set of largely undefined molecular events and the virus enters a latent state. Latency is typified by expression of a series of latency-associated transcripts (LATs) from the repeat regions flanking the long unique segment (U_L) of the viral genome partially antisense to and overlapping the 3′ end of ICP0 mRNA (130–132) (Fig. 2D). Two colinear, nonpolyadenylated (poly A^-) LAT RNA species of 2.0 and 1.5 kb (133,134), which accumulate in the nuclei of latently infected neurons (135), are stable nonlinear intron lariats derived from a large, unstable 8.3-kb polyadenylated primary transcript (136–140). The virus can remain latent for the life of the individual, although sporadically viral genomes may reactivate in response to a variety of stimuli including immune suppression, ultraviolet light, fever, and stress (126,141).

The promoter/regulatory region that controls LAT expression is of interest to gene therapy applications because that promoter remains active during latency when all other viral promoters are silenced. LAT expression is differentially directed by 2 LAPs, LAP1 (142–145) and LAP2 (145–147). LAP1, predominantly responsible for LAT expression during latency (142,145), is located 5′ proximal to the unstable 8.3-kb LAT. LAP2 is primarily responsible for LAT expression during lytic infection, but is also capable of driving low-level expression of LAT in the absence of LAP1 during latency (145) and is located immediately upstream to the 2.0-kb LAT intron (145–147). Deletion of both LAP1 and LAP2 completely eliminates expression of detectable levels of LAT during latency in animals (145), demonstrating that both promoters contribute to LAT expression during latency in neurons in vivo. The continuous expression of the LAT region of the HSV genome during neuronal latency suggests that it should be possible to exploit the LAT promoter to express therapeutic genes from latent viral genomes in neurons. Both LAP1 and LAP2 have been employed to achieve long-term transgene expression from the HSV vector genome during latency. For example, a LAP1-β-globin recombinant produced transgene expression in murine peripheral neurons during latency (142), but the level of product decreased over time (148). Other examples include recombinants with LAP1 driving expression of β-glucuronidase (149), NGF (148), β-galactosidase (123,146,148,150), or murine α-interferon (113) that either displayed a similar expression pattern or were not active in latently infected animals (113,123,148). These data suggest that LAP1 may lack the *cis*-elements required for long-term transgene expression in the context of the HSV viral genome. However, long-term transgene expression was achieved when LAP1 was juxtaposed to the Moloney murine leukemia virus (MoMLV) promoter (123), unlike recombinants employing either LAP1 or the LTR alone, suggesting that the elements responsible for extended expression lie elsewhere within the LAT promoter/regulatory region. These *cis*-acting elements may be complemented by elements within the MoMLV promoter, thus allowing transgene expression to continue during latency. When LAP2 was added to the LAP1-reporter cassette in the ectopic site within the genome, long-term expression was restored although the transcription start site was not determined (150). The LAP1–LAP2 complex was capable of driving long-term transgene expression when a lacZ reporter gene cassette was introduced into the LAT intron in the native LAT locus [(151), Chen and Glorioso, unpublished data, 1995] or when a LAP2-lacZ expression cassette was present in an ectopic locus within the viral genome (147). We have also shown that a LAP2-NGF cassette present either in the tk or Us3 loci of the vector expressed this gene product in latently infected rodent neurons both in culture and in vivo (111). Although, expression of β-galactosidase from the LAP-lacZ vectors could be detected in neurons of the mouse peripheral nervous system (PNS) for up to 300 days [(147), Chen and Glorioso, unpublished data, 1995], prolonged expression in the central nervous system (CNS) was at very low levels detectable only by reverse transcriptase-polymerase chain reaction (RT-PCR) techniques (Chen and Glorioso, 1995). Recently, we have determined that both the HCMV IE gene promoter and LAP2 are capable of long-term NGF expression in rabbits following intra-articular injection with a replication-defective HSV vector (119). These unanticipated findings will be important for designing treatment regimens where continuous therapeutic protein production will be required to achieve a therapeutic outcome.

C. Drug-regulated Promoters

For many applications, it may be desirable to regulate expression of a therapeutic transgene in vivo, either to limit toxic effects from high-level expression or more closely resemble physiological expression profiles. We created a viral vector with regulatable transgene expression by using an autoregulatory loop that consisted of a promoter with 5 tandem copies of the 17-bp Gal4 DNA recognition element that could be transactivated by vector-encoded chimeric Gal4/VP16 protein (Fig. 7A), based on the ability of the chimeric protein to transactivate promoters containing this site (152–154) despite the repressive presence of nucleosomes (155,156). The constitutive Gal4/VP16 transactivator was able to induce transgene expression from a Gal4-sensitive minimal promoter in the background of the virus (115). Regulation was achieved by replacing the constitutive transactivator with a chimeric molecule consisting of the hormone-binding domain of the mutated progesterone receptor fused to the transactivation domain of VP16 and DNA-binding domain of Gal4 (157,158). In the presence of the progesterone analog RU486, the inactive chimeric transactivator assumes a conformation allowing it to bind to and transactivate the Gal4 recognition site-containing promoter driving transgene expression. Compared with control (Fig. 7B), the completion of the autoregulatory loop following administration of RU486 (Fig. 7C) resulted in substantial enhancement of expression of the transgene in the CNS (115) (Fig. 7D). Following infection of the rat hippocampus with the regulatable virus, levels of viral vector-derived transgene expression are stimulated by administration of the inducing agent RU486 (159).

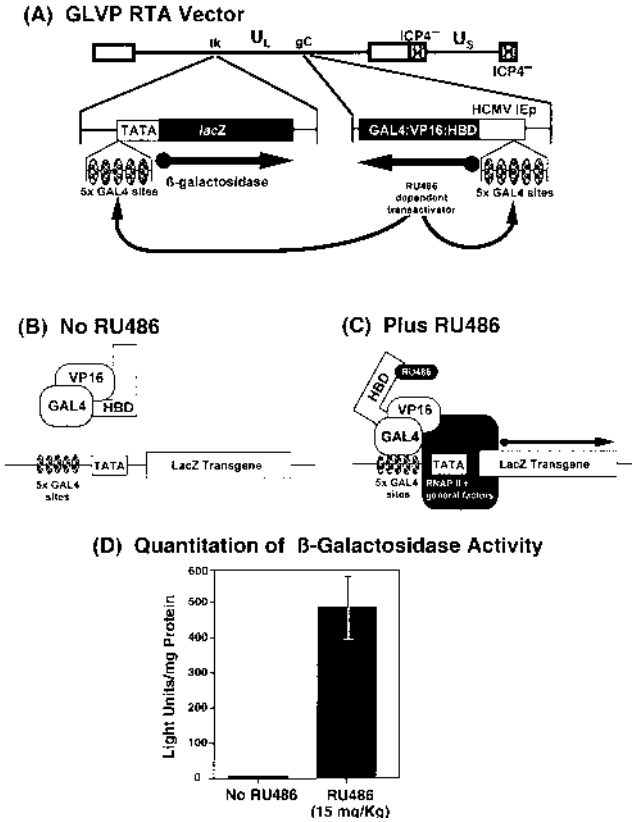

Figure 7 In vivo regulated transgene activation from HSV vectors by drug-inducible recombinant transactivator (RTA). (A) The GLVP RTA vector contains the inducible chimeric transactivator GAL4:VP16:HBD, composed of the yeast GAL4 DNA-binding domain fused to the HSV VP16 transactivation domain fused in frame to a mutant form of the progesterone receptor hormone-binding domain, which can be activated by RU486. In addition, the vector contains a promoter-reporter cassette ($GAL4_5TATA$-lacZ) that is responsive to activation by the transactivator (RTA). (B) In the absence of the drug, the GAL4:VP16:HBD recombinant transactivator cannot bind to the GAL4 sites in the minimal TATA box promoter, resulting in no expression of the β-galactosidase transgene. (C) Following administration of RU486, the tripartite transactivator undergoes a conformational change that allows the RTA to bind to the GAL4 binding sites to yield β-galactosidase expression. (D) Quantitation of β-galactosidase transgene expression in the presence of RU486 displays activation of the transgene promoter by the inducible transactivator following injection of the vector into rat CNS.

V. APPLICATIONS

A. HSV Gene Transfer for Neuropathy and Pain

In some sense, the most natural target for the therapeutic use of HSV-mediated gene transfer is the PNS. Recombinant replication-defective vectors, such as wild-type HSV, target with high efficiency to dorsal root ganglion (DRG) neurons following subcutaneous inoculation, a process that benefits from high-level expression of the HveC HSV receptor on sensory nerve terminals in the skin (160) and specific interactions between capsid and tegument proteins and dynein to mediate retrograde axonal transport along microtubules (161), followed by injection of the DNA through a nuclear pore into the nucleus. We have used HSV-mediated gene transfer to the PNS in rodent models of peripheral neuropathy and in the treatment of pain. The underlying rationale for using HSV-mediated gene transfer in these 2 conditions is similar. In both cases, peptides of proven efficacy have been identified. Peripheral neuropathy can be prevented in animal models by treatment with neurotrophic factors, and pain can be substantially ameliorated by the delivery of opioid peptides. However, it is difficult to deliver these short-lived peptide factors in adequate doses to achieve therapeutic effects without causing intolerable side effects that result from the widespread expression of the cognate receptors throughout the nervous system and in nonnervous structures in the body. Targeted gene delivery using HSV vectors can be used to overcome these limitations.

1. Neuropathy

We used subcutaneous inoculation of HSV-based vectors in the foot to deliver and express neurotrophic factors in DRG neurons in order to protect against peripheral nerve degeneration in models of neuropathy. We constructed vectors to express neurotrophin 3 (NT3) under the control of a fusion LAP2 HCMV promoter (vector QL2HNT3) and NGF under the control of the HCMV or LAP2 promoters (vectors SHN and SLN) (111). In the pyridoxine (PDX)-intoxication model of large-fiber sensory neuropathy, rats transduced by subcutaneous inoculation into the foot with QL2HNT3 and then intoxicated with pyridoxine PDX demonstrated a dramatic preservation of sensory nerve function, measured by sensory nerve recording (foot sensory amplitude and velocity), h-wave reflex, and behavioral assessment of proprioceptive function [Figs. 8A, B, and C from (162)]. Morphometric examination of the sciatic nerve demonstrated a substantial and statistically significant loss of predominantly large myelinated fibers in control vector-treated PDX-intoxicated animals, which was prevented by the NT-3 expressing vector QL2HNT3 (162). The NGF-expressing vector SHN provided a similar protective effect in the same model.

Mice rendered diabetic by the injection of streptozotocin develop a pure sensory neuropathy, manifest by reduction in the evoked sensory amplitude. Injection of either vector SHN or vector SLN 2 weeks after the onset of diabetes protected the animals from the development of neuropathy, measured by the foot sensory amplitude at 6 weeks of diabetes (163). This protective effect persists through 6 months of diabetes (Goss and Fink, unpublished data, 2002). In addition, expression of neuropeptide (calcitonin gene-related peptide and substance P) genes in the in the DRG was preserved in the vector-inoculated animals, demonstrating protection of the neuro-

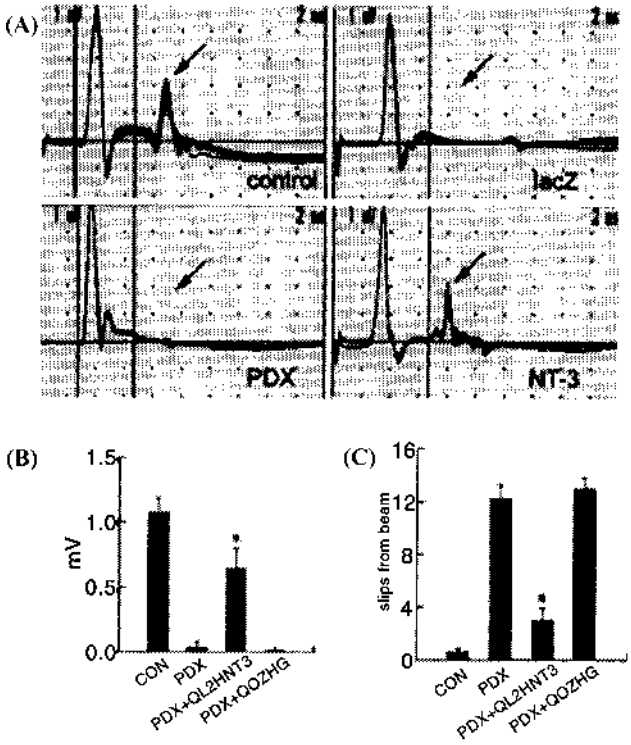

Figure 8 Neuroprotective effects of HSV vector-mediated NT-3 expression. (A) Examples of individual M wave and H reflex (arrows) recorded from the gastrocnemius muscle after stimulation at the sciatic notch. Control is naive animal, PDX is an animal treated with pyroxidine, lacZ is treated with PDX and the control lacZ vector QOZHG, and NT-3 is treated with PDX and the NT-3 expression vector. (B) The mean H-wave reflex amplitude from the measurements in A. (C) Behaviorial analysis of propriceptive function. Rats were trained and tested on a 3-cm beam with the number of slips from the beam measured during a 3-minute session. The PDX-treated animals have great difficulty traversing the beam; however, treatment with the NT-3 expression vector prevents this deficit. (From Ref. 162.)

chemical phenotype (163). We have observed similar protective effects against the development of neuropathy using the same vectors (QL2HNT3, SHN, and SLN) in the rodent model of neuropathy resulting from administration of the chemotherapeutic drug cisplatin (164).

In each model tested, the HSV vector coding for a neurotrophic factor has been inoculated prior to the onset of neuropathy. We have not examined whether the vectors might be used to enhance recovery from neuropathy, but achieving prevention alone would be a major advance in the treatment of neuropathy. Most sensory neuropathies develop gradually over a period of months to years; patients with diabetes, for example, characteristically present with loss of sensation in their toes, but there is no available therapy that will prevent progression of neuropathy. Gene transfer at that stage, if it prevented the development of a severe sensory neuropathy, would represent a substantial advance (165). Neuropathy caused by chemotherapeutic drugs represents one model in which the onset of neuropathy is temporally defined and pretreatment is possible. This type of neuropathy may serve as a convenient model for the first human trials of such therapy.

2. Pain

The treatment of pain uses the same approach, subcutaneous inoculation to transduce DRG neurons, to achieve local expression of peptides in sensory neurons. Wilson first constructed a replication-competent HSV-based vector to express proenkephalin (117). Subcutaneous injection of that vector into the dorsum of the foot in mice produced an antihyperalgesic effect that could be demonstrated by an increased latency to withdraw the foot from noxious heat after sensitization of C fibers by application of capsaicin, or sensitization of Aδ fibers by application of dimethyl sulfoxide (117). Although no antinociceptive effect was demonstrated in the absence of prior sensitization using the experimental paradigms reported, substantial expression of methionine-enkephalin could be demonstrated by immunocytochemistry (117). A replication-competent HSV-based vector expressing proenkephalin reduced pain in a rodent model of arthritis (166).

We extended these results by constructing a replication-incompetent HSV vector with the human PE gene (coding for 6 copies of met-enkephalin and 1 copy of leu-enkephalin) in the tk locus of the ICP4$^-$ recombinant d120 (designated vector SHPE). Inoculation of the vector into the foot transduced DRG neurons, and expression of the human proenkephalin gene and RNA was confirmed in DRG by PCR and RT-PCR. Expression of the peptide could be demonstrated in DRG neurons transduced in vitro by immunocytochemistry (167). We examined the biological activity of enkephalin (ENK) expression of SHPE transduction in the formalin model of inflammatory pain. Rats injected with SHPE 1 week prior to formalin testing showed a significant reduction in nocisponsive behaviors during the delayed phase (30–60 min after formalin injection). The antinociceptive effect was reversed by intraperitoneal naloxone (50 mg/kg i.p.) and by intrathecal administration of naltrexone. The effect of SHPE transduction waned over time. Animals tested 2 weeks after SHPE transduction showed a smaller reduction in nocisponsive behavior than those tested 1 week after transduction, and by 4 weeks after transduction there was no longer any significant antinocisponsive effect. Reinoculation of SHPE at 4 weeks reestablished the antinociceptive effect, measured 1 week later (5 weeks after the initial inoculation) by formalin test. These results suggest that the loss of effect was not a result of tolerance and demonstrate that prior inoculation with the nonreplicating vector does not prevent the reapplication of therapeutic gene transfer with the HSV vector.

To determine whether the effect of vector-mediated ENK release in DH is restricted to the distribution of transduced neurons projecting to DH, we repeated the experiment, but compared the pain response in animals injected with formalin

ipsilateral to vector footpad inoculation or contralateral to vector inoculation. There was a significant reduction in nocifensive behavior in the delayed phase of the formalin test when formalin was injected ipsilateral to SHPE inoculation 1 week after vector inoculation. There was no reduction in nocifensive behavior observed in animals injected with formalin into foot contralateral to the SHPE inoculation. SHZ injection had no effect on nocifensive behavior observed in either foot. In conjunction with the evidence that intrathecal naltrexone blocks the vector-mediated effect, these results suggest that vector-mediated ENK released from the central terminal of transduced primary afferent neurons to act locally in DH in the distribution of the central projection of those neurons.

We next examined the antinociceptive effect of the PE-expressing vector in the spinal nerve ligation (SNL) model of neuropathic pain, established according to the method described by Kim and Chung (168). Under chloral hydrate anesthesia, the left transverse process of L6 was removed, and the L5 spinal nerve was gently isolated and ligated tightly with 6.0 black silk suture distal to DRG but proximal to the formation of the sciatic nerve. Tactile threshold was determined using calibrated von Frey filaments (169,170). Subcutaneous inoculation of SHPE 1 week after SNL caused a significant reduction in tactile allodynia in the injected foot (171). The antiallodynic effect was maximal 2.5 weeks after vector inoculation and declined over the subsequent 4 weeks. Reinoculation of the vector reestablished the analgesic effect (171), which then persisted for approximately 6 weeks. The antinociceptive effect of SHPE was reversed by intraperitoneal naloxone. These results are consistent with published evidence, suggesting that mechanical allodynia in SNL models of neuropathic pain results from aberrant electrical activity in undamaged fibers from DRG, that project along with degenerating fibers from the ligated sensory root into the same peripheral nerve (172). The time course of the biological effect of transgene expression from this vector, in which the HCMV IEp is used to drive transgene expression suggests that at least 6 weeks of expression may be achieved in transduced DRG neurons.

Vector transduction enhanced the effect of morphine. Uninoculated animals with neuropathic pain responded to intraperitoneal morphine with an ED_{50} of 1.8 mg/kg (CI_{95} 1.1–2.8 mg/kg). Animals inoculated with SHPE 1 week after SNL and tested with morphine 1–2 weeks later demonstrated a reduction in the ED_{50} of morphine to 0.15 mg/kg (CI_{95} 0.06–0.34 mg/kg, $P < 0.05$) (171). Inoculation with SHZ had no effect on the response to morphine. In addition, twice daily administration of morphine resulted in a graduate decrease in the antiallodynic effect in the neuropathic rats, with no detectable effect by day 7. Animals that had been inoculated with SHPE 1 week after SNL showed a significantly greater response to morphine at days 1 and 2, consistent with the interaction of SHPE with morphine, and continued to exhibit an antiallodynic effect at day 7, when morphine alone was no longer effective (171).

Pain resulting from cancer metastatic to bone has features of both inflammatory and neuropathic pain. To evaluate the potential therapeutic effect of HSV-mediated gene transfer and expression of PE in pain due to cancer, we tested the vector in the osteogenic sarcoma model in the mouse (173). Tumor-injected mice demonstrated spontaneous pain, increasing to 2 weeks after tumor inoculation and remaining at the same level up to 4 weeks postinoculation. Subcutaneous inoculation of SHPE 1 week after tumor implantation resulted in a substantial and significant reduction in spontaneous behavior recorded 2 and 3 weeks after tumor implantation (1 and 2 weeks after vector inoculation) (174). The analgesic effect of the vector was reversed by intrathecal naltrexone.

Taken together, the results of studies demonstrate that a nonreplicating genomic HSV vector expressing PE is antinociceptive in models of neuropathic pain, inflammatory pain, and pain resulting from cancer in rodent models. A proposal for the first human trial employing these vectors in the treatment of intractable pain resulting from cancer metastatic to a vertebral body was presented to the Recombinant DNA Advisory Committee at the National Institutes of Health in June 2002. In the near future, we should be able to determine if this approach will be as successful in treating the human disease as it has been in the animal models.

B. Cancer

Cancer gene therapy may offer a treatment modality to patients who have exhausted all other standard treatment regimens such as surgery, chemotherapy, and radiation therapy. There are a number of considerations in applying gene therapy to the treatment of cancer that include the selection of the appropriate therapeutic gene(s), the specific effect or mechanism, target tissue, and method of gene delivery. The overriding problem is that cancer is generally a systemic disease, and thus, even if gene transfer is effective in destroying a tumor locally, metastases will promote continued disease.

Strategies to treat cancer by gene therapy can be considered in 3 categories: (1) tumor cell destruction using conditionally replicating viruses that selectively replicate in and kill tumor cells (175,176) compared with the surrounding normal tissue, (2) tumor cell destruction by expression of transgenes whose products induce cell death, or sensitize the cells to chemo- (177) or radiation therapy (178), and (3) tumor vaccination through expression of transgenes whose products recruit, activate, or costimulate immunity or provide tumor antigens. The latter approach is more likely to be effective in treating metastatic disease. Because these strategies are complementary, it has also been suggested that they can be used in combination. Examples of these various approaches include the use of (1) prodrug-activating genes such as thymidine kinase (TK) or cytosine deaminase (179); (2) cytokines such as TNF-α, γIFN and various interleukins (180); (3) MHC products such as costimulatory molecules (B7.1) (181–183); (4) allotypic class I or class II molecules (181–184); and (5) tumor antigens (185,186), which together may assist in the recruitment and activation of nonspecific inflammatory responses (187) or the induction of tumor-specific immunity.

The first strategy involves the use of vectors that are replication competent, but depend on attributes unique to the tumor cell to support viral growth. For example, E1b-deficient adenoviral vectors can replicate in tumor cells mutant for p53 but generally not in normal cells (175,188–190). Thus, the intent of this strategy is to provide a mechanism for virus spread locally in the tumor to increase the number of infected tumor cells. However, this treatment is limited to p53-defective tumors. Similarly, HSV vectors have been engineered that replicate in dividing cells, such as tumor cells, but not in normal neurons. The use of conditional replication-competent viruses could in theory allow for spread in tumor tissue without damaging normal brain, thereby increasing the specificity and effectiveness compared with nonreplicating vectors that express transgenes that augment tumor cell killing. HSV vectors of this type include mutants lacking the 34.5 gene, which is required for growth specifically in neurons (191–193). Deletion of this gene alone (1716), or in combination with the UL39 ribonucleotide reductase (RR) large subunit (G207), creates viruses that are highly compromised for their ability to replicate in and kill neuronal cells, yet that retain the ability to replicate in and kill dividing tumor cells.

Although these vectors were originally used to treat animal models of malignant glioma (194–198), they have now been employed to treat breast (199,200), lung (201,202), head and neck (203), melanoma (204,205), colorectal (206–209), prostate (210–213), ovarian (214,215), peritoneal (216–218), bladder (211,219), renal (220), cervical (221), and gallbladder (222) tumors in various animal models, demonstrating their utility. Moreover, in addition to their application for direct tumor cell killing, they have also been employed in tumor vaccination models (201,206,209,223,224). They have also been employed to augment the host immune response to the tumor by expressing either cytokines such as IL-12 (225) or immunomodulatory molecules such as B7–1 (226). In addition, they have also been used in conjunction with suicide gene therapy (227), low-dose ionizing radiotherapy (208,221), and chemotherapeutic agents like cisplatinum (202,228).

The safety and biodistribution of these vectors following intracranial administration has been examined in both rodents and nonhuman primates. The G207 vector deleted for 34.5 and UL39 (RR) displayed a very good safety profile (229–232) in both mice and nonhuman primates (rhesus macaques and Aotus nancymae), and vector remained locally surrounding the injection site. In addition, injection of vector was unable to reactivate endogenous resident wild-type HSV (230,233), a major issue concerning the use of these vectors in a human population that may already possess latent virus, again demonstrating the safety of HSV as a therapeutic vector. Safety studies using the 1716 vector have shown that deletion of 34.5 alone does not necessarily render the vector nontoxic. Vector injection into the ventricles of immune-deficient nude mice resulted in animal fatalities (234), or persistent ependymal cell loss in immune-competent mice (235), with virus spread to distal sites being observed in immune- competent rats (236). Another major question that needs to be addressed with the use of HSV vectors in a human population that is 60% to 90% seropositive for the virus, concerns whether preexisting immunity to the virus will prevent effective therapeutic treatment following vector administration. Although prior immunized animals displayed both humoral and cell-mediated responses to the virus, these responses did not significantly alter the ability of the vector to kill tumor cells and increase animal survival in preimmune vs. naive animals (218,228,237).

Based on these preclinical studies, two phase I clinical trials have now been reported using conditionally replicating HSV vectors. These studies have demonstrated the feasibility of inoculating recombinant HSV viruses into glioblastomas. No evidence of viral encephalitis or reactivation of wild-type virus was seen in either study. Furthermore, no adverse events could be unequivocally attributed to the vectors. One study, which used the G207 virus deleted for the 34.5 neurovirulence gene and the UL39 ribonucleotide reductase gene, showed safety up to a dose of 3×10^9 pfu (176). A second study using a 34.5 mutant with a complementing mutation in the US11 gene, which restores the growth characteristics of wild-type virus without reversing the attenuated neurovirulence phenotype of the 34.5 mutant, showed safety to a final dose of 10^5 pfu (238). A total of 30 patients were treated in the 2 trials. These trials were not designed to test whether the vectors were efficacious in the treatment of glioblastoma (GBM); phase II efficacy studies are ongoing.

The second approach to treat cancer involves suicide gene therapy (SGT) for the treatment of cancer in experimental animals and in phase I human clinical protocols (177,239–243). This strategy uses the bystander destruction of tumor cells mediated by a variety of mechanisms other than virus spread, including the recruitment of natural killer (NK) cells by expressing the appropriate cytokines, the activation of anticancer drugs at the tumor site that kill multiple tumor cells in addition to those transduced by the vector, and the use of antigens and cytokine-expressing genes to elicit specific antitumor immunity. Transfer of the HSV gene TK into tumor cells results in tumor cell death when combined with the antiviral drug ganciclovir (GCV). TK has been shown to convert the prodrug into a toxic nucleoside analog that, upon incorporation into nascent DNA, results in the interruption of DNA replication by chain termination. A uniquely powerful characteristic of the TK-GCV approach is that only a small fraction of the tumor cells need to be transduced with the suicide gene to result in significant antitumor activity, an activity known as the ''bystander effect'' (239,240,243–245). It has been demonstrated that cell-to-cell transfer of activated GCV via gap junctions between transduced tumor cells and untransduced neighboring cells is a major mechanism of the bystander effect (246–249). A variation on this strategy is to introduce cell lines into the tumor site that produce TK-expressing retroviruses that then infect tumor cells locally. Although setting up virus production factories in this manner is logical, the practice of this strategy has been disappointing because the xenogeneic producer cell lines induce rapid inflammatory processes that lead to brain swelling and little detectable gene transfer (250). Although these TK-GCV SGT strategies suffer from limitations, approaches of this nature are under evalua-

tion for efficacy in phase I–II clinical trials for patients with brain tumors; however, they have met with limited success.

In our initial experiments using replication-defective HSV vectors expressing HSV-TK for SGT, we employed both vectors deleted for single (ICP4$^-$) and multiple (ICP4$^-$/ICP27$^-$/ICP22$^-$) essential IE genes that expressed the TK gene from an HSV IE promoter to ensure its expression from the replication-defective virus backbone (Fig. 9A). We tested the ability of these TK overexpressing replication-defective HSV vectors to act as a treatment for established tumors in rodent glioma models and demonstrated significant increases in survival following administration of the HSV-TK vector and GCV (114,251). However, the magnitude of the bystander effect was inversely proportional to the overall toxicity of the vector. Thus, more cytotoxic vectors like the ICP4 deletion mutant resulted in the cytotoxic death of the transduced tumor cells before they were able to produce and release significant levels of modified GCV, thereby dampening the overall bystander-mediated killing (251). We have now seen similar results using vectors that express CD alone or in combination with HSV-TK (252), suggesting that further modifications will be required to achieve more effective tumor cell killing.

To augment the cell killing seen in SGT we have taken two approaches. In the first approach, we attempted to augment the bystander effect by altering the makeup of tumor–cell gap junction complexes. Connexins are the components of gap junctions (253) that play a major role in intercellular communication to control homeostasis and cell proliferation. Reduced intercellular communication through gap junctions has been regularly observed in transformed cells (254–256) and may be due to reduced connexin expression. Retrovirus-mediated introduction of the connexin 43 (Cx43) gene limited the growth of transformed cells that shared the characteristic of reduced gap junctional activity (257), and other studies have reported similar findings supporting the suggestion that connexins alone have tumor-suppressor activity (258–261). Gap junctions also play a critical role in the HSV-TK/GCV bystander effect by enabling the transfer of activated GCV from TK-positive to neighboring TK-negative cells (246,262–265). Tumor cells having reduced gap junction formation are less susceptible to the bystander effect (265), suggesting that transfer of connexin genes into these cells to restore or augment intercellular communication would improve the effectiveness of HSV-TK/GCV therapy. Indeed, it has been demonstrated both in vitro and in vivo that the bystander effect can be potentiated by the expression of connexin (264,266,267). The bystander effect requires connexin expression not only by the TK-positive GCV-activating cell, but also by the TK-negative recipient cell (265). This suggests that gene therapy approaches aimed at codelivery of connexin with HSV-TK to mediate an enhanced bystander effect may not be extremely effective against tumors that express no connexin at all. However, it may from a study of 17 cell lines measuring bystander effects and gap junctional activity (263); this will be an extremely small group. Furthermore, overexpression of connexin in the transduced cells will increase transfer of activated

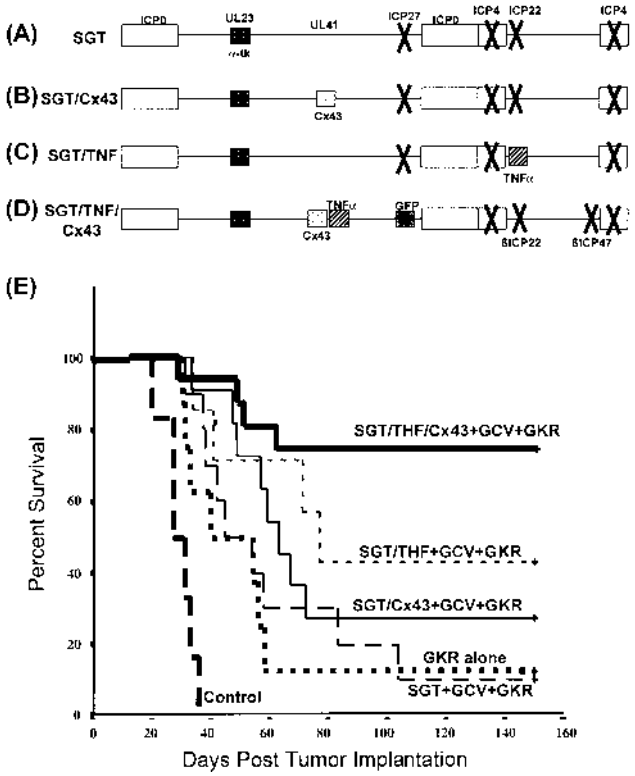

Figure 9 HSV-vector mediated tumor cell killing. Diagrams of replication-defective HSV-1 expression vectors for expressing (A) HSV-TK (SGT), (B) HSV-TK and connexin 43 (SGT/Cx43), (C) HSV-TK and TNF-α (SGT/TNF), and (D) HSV-TK, connexin 43, and TNF-α (SGT/TNF/Cx43). All vectors express ICP0 from both copies of the inverted repeat element flanking the unique long segment (UL) of the HSV genome, and TK as an IE gene from a copy of the ICP4 IE promoter replacing the native TK promoter in the UL23 gene locus. All vectors have the ICP4 and ICP27 genes deleted, and all but the SGT/TNF/Cx43 vector have inactivating deletions in ICP22. This vector has the IE genes ICP22 and ICP47 turned into early genes by mutation of the TAATGARAT sequences in these promoters converting these to early (β) genes. The SGT/Cx43 vector contains the Cx43 gene driven by the ICP0 IE promoter inserted into the UL41 locus. The SGT/TNF vector has TNF inserted into the ICP22 gene locus under control of the HCMV IE promoter. The SGT/TNF/Cx43 vector has both the ICP0p-Cx43 and HCMV IEp-TNF expression cassettes inserted into the UL41 locus. The ability of these vectors to destroy tumors and effect animal survival in the immunocompetent rat 9L tumor model was evaluated by intratumoral vector injection 3 days following implantation of the 9L tumor cells into the frontal lobe of Fisher rats. Animals received i.p. injections of GCV at the time of vector injections for 10 consecutive days and gamma-knife radiosurgery (GKR) at 2 days post vector injection.

GCV, providing even limited connexin expression in neighboring cells.

We tested the potential benefit of coexpressing connexin with HSV-TK for the treatment of glioblastoma (268). Human U-87MG tumor cells express detectable amounts of Cx43 and are sensitive to bystander killing in vitro, but this effect is not sufficient to control tumor formation with TK-transduced cells and GCV treatment alone (254). Replication-defective vectors ($ICP4^-/ICP27^-/ICP22^-$) that we engineered to express Cx43 (Fig. 9B) were able to enhance TK-GCV tumor cell killing in cultures of U-87MG tumor cells that express Cx43 (268). Thus, although U-87MG cells already showed a good bystander effect, the expression of additional Cx43 in a fraction of the population further enhanced the effectiveness of GCV treatment. We also were able to demonstrate a pronounced bystander effect with L929 cells (268) that did not show a bystander effect when infected with a TK-expressing vector, in agreement with recent findings by others (265). This indicated that vector-directed connexin expression enabled bystander killing among these otherwise bystander-resistant cells. Together, these results suggested that vector-directed Cx43 expression should be beneficial regardless of whether the target cells express significant levels of connexin.

These in vitro assays were extended to animals using an ex vivo flank tumor model and in vivo using animals bearing U-87MG tumors in the CNS (268). Dramatically, all animals implanted with Cx43 vector-infected cells and treated with GCV in were tumor free 1 week after cessation of GCV administration, whereas no other animal was tumor free at this time, including animals treated with Cx43 vector alone or the TK-expressing vector plus GCV. Moreover, all animals in this treatment group were alive at the end of the observation period (72d), whereas no animals in any of the other groups survived past day 41. Encouraged by these promising results, experiments were initiated to test the effectiveness of combined Cx43/tk gene delivery in vivo because the ex vivo approach enables one to infect every tumor cell that does not readily mimic the actual situation in human patients with glioblastoma. In the in vivo experiments, virus was injected directly into the tumor mass 3 days following tumor cell implantation and GCV was administered for 10 days after vector inoculation. In these studies, all animals in every treatment group died by day 50, whereas 50% of the Cx43-expression vector-treated animals survived past 50 days and one-third were still alive at the end of the study (70d), indicating a beneficial effect of connexin/tk gene codelivery in vivo.

In the second approach to augment SGT, we created vectors that express cytokines in the hope of stimulating a host response to the tumor. There has been a considerable amount of recent interest in using cytokine genes, costimulatory molecules, tumor antigens, and recruitment molecules to enhance the immune response to the tumor. Antitumor immunity should prove effective in treatment of metastatic cancer. The development of antitumor immunity could circumvent the need for replication-competent vectors because tumor-specific cytotoxic T lymphocytes constantly move through the brain parenchyma searching for target cells. A growing body of literature suggests that local expression of cytokines can enhance CTL activation at least in animal model systems and these bear testing in human brain cancer. HSV offers the potential for combinational gene therapy in this regard because multiple immunomodulatory genes can be recombined into the virus and comparatively tested (47).

Tumor necrosis factor-α (TNF-α) has been demonstrated to possess an array of antitumor activities, including potent cytotoxicity exerted directly on tumor cells (269), enhancement of the expression of HLA antigens (270) and ICAM-1 (271) on tumor cell surfaces, enhancement of interleukin-2 receptors on lymphocytes (272), and stimulation of such effector cells as NK cells, lymphokine-activated killer cells, and cytotoxic T lymphocytes (CTL) (272–276). However, despite this promising antitumor profile, the clinical use of TNF-α has been constrained by the toxicity of systemic TNF-α delivery (275,276). This problem could be minimized by local production of TNF-α at the site of tumor growth, which may allow for effective use of this cytokine as an antitumor agent. Furthermore, TNF-α has a radiosensitizing ability that could optimize its antitumor effects. In an effort to augment the effectiveness of HSV-TK-mediated suicide gene therapy, we created the replication-defective, triple IE gene-deleted HSV vector ($ICP4^-$, $ICP27^-$, $ICP22^-$) that expresses HSV-TK and TNF-α (Fig. 9C).

In vitro studies demonstrated that high levels of TNF-α could be detected in the media of vector-infected cells during the first 24-h period, but this was followed by a precipitous decline in production on day 2 and subsequent days with the protein being no longer detectable on day 7 (114). The bioactivity of TNF-α produced in this experiment was tested by exposure of cultured TNF-α-sensitive L929 fibrosarcoma cells to medium collected after the first day of infection. A dramatic reduction in cell viability was observed for cells treated with medium from TNF vector-infected cells, and this reduction was essentially identical over time to that seen with unconditioned medium supplemented with 10 ng recombinant TNF-α protein (114). These results demonstrated that TNF-α produced by the TNF vector was biologically active and comparable in specific activity to recombinant TNF-α. We then determined that intracellular production of TNF-α could enhance HSV-TK/GCV-mediated cell killing of both the TNF-α-sensitive L929 cell line, as well as the TNF-α-resistant U-87MG cell line. Although the mechanism is unclear, this enhancement indicated that the combination of vector-directed TNF-α expression and HSV-TK expression with GCV treatment could be beneficial not only against TNF-α-sensitive tumor cells such as L929, but also against TNF-α-resistant tumors.

To determine if the increased effectiveness of combination gene treatment evident in vitro could also be observed in vivo, we first tested the effect of intratumoral vector injection followed by GCV treatment on established L929 tumors (TNF-α sensitive) in the flanks of immune-competent mice (114). Tumor treatment with the TNF vector plus GCV resulted in significantly greater growth inhibition and extended animal survival compared with all other treatments. These results

demonstrated the promise of combination TNF/TK gene therapy for the treatment of TNF-sensitive tumors and added an incentive to test the same treatment against TNF-resistant tumors. However, the results in the U-87MG TNF-α-resistant intracerebral tumor model in immunodeficient mice were not as significant as those observed with the L929 model, although 2 of 14 animals in the TNF/GCV treatment group survived past 80 days (114). This reduced response in the U-87MG model may be due to the fact that the tumor cell killing mediated by TNF is only the result of the cytotoxic effects of TNF expression intracellularly and is not augmented by its ability immunomodulatory ability. Together, these results suggest that combined HSV-TK/TNF therapy is beneficial, but that a more effective strategy may be required.

Fractionated radiotherapy has been shown to confer a small but significant survival benefit to patients with glioblastoma. Unfortunately, the dose of radiotherapy that may be tolerated by the brain (about 60 Gy) is inadequate for tumor eradication. To circumvent inherent toxicity problems, techniques have been developed that allow focusing of radiation to the tumor bed, allowing a higher dose to be delivered (radiosurgery). This enables eradication of the central portion of the tumor, but does not allow delivery of an augmented radiation dose to the tumor periphery. Gamma-knife radiosurgery (GKR) allows for precise delivery of a single high dose of radiation to brain tumors without opening the skull. In this technique, tumors are targeted by the application of a tightly focused high-energy radiation field, which results in minimal collateral damage to the surrounding normal tissue. Radiosurgery has been used for boost irradiation of patients with malignant glial tumors, in addition to conventional wide-margin fractionated radiotherapy (277,278). Unfortunately, glioma cells are often seen invading the normal tissue surrounding the tumor, often migrating along normal white matter tracts (279,280). This feature of glioma is largely responsible for the inability to effect a surgical cure by resection and the correspondingly poor prognosis. We have therefore examined ways in which the response to radiotherapy may be enhanced by gene delivery. One such approach involves selectively sensitizing tumor cells to radiotherapy. This would confer a major advantage, in that the sensitized cells could be effectively killed by a low dose of radiotherapy that is not toxic to surrounding brain tissue. In this strategy, we combine GKR with the injection of replication-defective HSV vectors expressing HSV-TK, Cx43, and TNF.

In the first series of experiments, we used GKR in conjunction with vector-mediated TNF expression because TNF has previously been shown to have a synergistic effect with ionizing radiation when delivered as a recombinant protein (281–287), by plasmid-based delivery (288–292) or by using an adenoviral vector (293–297). Moreover, the TNF-α approach has proven safe and shown some efficacy in human phase I clinical trials (297,298). Experiments were carried out to determine whether HSV-TK/TNF gene transfer along with GCV treatment was more effective in the presence of low-dose gamma-knife radiation. Both the TNF/TK vector and gamma-knife radiation alone were effective in protecting a proportion of animals from tumor growth and animal death when used in the U-87MG model of glioblastoma in nude mice (299). The results using the TNF/TK vector with SGT and GKR demonstrated that the combination of TNF, GCV, and GKR was superior to other treatments, such that 89% of the animals in that treatment group surviving for the length of the study (75d) and 67% of the animals were found to be tumor free at 75 days (299).

We then extended these results to an immunocompetent tumor model that may more closely mimic the human disease by carrying out survival studies comparing the efficiency of HSV-TK, TNF, and Cx43 in combination with GCV, with and without radiosurgery using the 9L gliosarcoma model in immunocompetent Fisher 344 rats (Niranjan and Glorioso, unpublished data, 2002). In this study, GKR was found to enhance the survival of 9L intracranial tumor-bearing rats compared with the control (Fig. 9E); however, treatment resulted in an overall survival of 15%, similar to what has been reported in human patients (277,300,301). Combining the TNF and connexin-43 genes in a HSV-TK/ICP0 vector (Fig. 9D) further improved animal survival (Fig. 9E). Eleven of 15 animals treated with the HSV-TK/TNF/Cx43 vector, GCV, GKR survived for more than 150 days compared with 7 of 15 treated with TNF, GCV, and GKR. These results demonstrate that our most effective current strategy for the treatment of animal brain tumors involves the multigene vector, which simultaneously expresses TNF-α Cx43, HSV-TK, and HSV-ICP0, combined with radiosurgery and GCV treatment. This combination approach employs genes whose products that are tumorcidal (HSV-TK, TNF), augment this process by increasing the bystander effect (Cx43), sensitize tumor cells to radiation (TNF), and stimulate the host immune response to the tumor (TNF). This combination approach may also prove to be effective against metastatic disease, but remains to be tested in these animal models.

VI. SUMMARY AND FUTURE DIRECTIONS

This overview of HSV biology and gene transfer has focused on the use of highly defective HSV genomic vectors that are blocked very early in the virus lytic cycle. These vectors express few viral functions and are highly reduced in vector toxicity, even for primary neurons in culture that are readily killed by less-defective HSV vectors. Moreover, these vector backgrounds are suitable for expression of multiple transgenes or single large genes (e.g., dystrophin) in applications where expression of single- or multiple-gene products are required to achieve a therapeutic outcome (e.g., tumor cell killing, vaccination). Expression of these transgenes can be coordinated, even sequentially, using strategies similar to those employed by the virus to regulate its own genes. Expression can also be controlled by drug-sensitive transactivators, which may prove to be important for regulating the timing and duration of transgene expression. HSV vectors may be most suited for expression of genes in the nervous system where the virus has evolved to remain lifelong in a latent state. The highly

defective viruses deleted for multiple IE genes are able to efficiently establish resistance in neurons and serve as a platform for long-term gene expression using the latency-active LAP2 promoter system. These mutants can not reactivate from latency and cannot spread to other nerves or tissues following infection of cells. Delivery of these vectors requires direct inoculation of tissue to achieve direct contact with neurons. Ideally, HSV vectors would be most effective if infection could be targeted to specific cell types using enveloped particles defective for their normal receptor recognition ligands, but modified to contain novel attachment and entry functions. This area of research is still very early in development, and it remains to be determined to what extent this will be feasible. Finally, it should be emphasized that current viral delivery systems may each become reduced to highly defective transfer vectors, retaining only those elements required for vector DNA maintenance and transgene expression. Fortunately, the natural biology of many persistent viruses, including HSV-1, indicates that long-term vector maintenance will be possible and we continue to learn from the highly evolved biology of persistent and latent viruses in order to mimic their strategies for gene transfer and therapy.

Lentiviral Vectors

Douglas Jolly
BioMedica, Inc.
San Diego, California, U.S.A.

I. INTRODUCTION

Lentiviruses are a genus of the family *Retroviridae* (retroviruses) (1) that have been modified to be used as gene transfer agents. The major attraction of this class of vector is its perceived potency in transducing and permanently modifying nonreplicating cells, not only in tissue culture but also in animals and, it is hoped, eventually in humans. This chapter summarizes the opportunities and issues surrounding the use of lentiviruses as clinical vectors, and so tries to cover a lot of ground. The references provide examples and leads for further information, and are not meant to be comprehensive.

II. BRIEF HISTORY

Retroviruses are RNA viruses that reverse transcribe their genome into DNA and then integrate it in the host cell genome. The name was coined after the characterization of murine leukemia viruses (MLVs) and their life cycle in the late 1970s and early 1980s. The molecular understanding of the viral life cycle led to, among other things, the development of retroviral vectors based on these types of viruses (mainly C-type retroviruses such as MLV) (2) and their extensive use in the clinic (refer to http://www.wiley.co.uk/genetherapy/clinical/ and http://www4.od.nih.gov/oba/rac/PROTOCOL.pdf).

Human immunodeficiency virus 1 (HIV-1) was the first well-characterized lentivirus (3). The identification and characterization of HIV-1 overlapped with the development of retroviral vectors described above; however, extensive characterization of the HIV system occurred somewhat later than the development of the MLV-based systems. Because retroviral vectors were perceived to have safety issues of unknown proportions (4,5), it was not attractive at the time to add to the degree of difficulty by using a known human pathogen as the basis of such vectors. However, it was known (and rediscovered several times) that C-type retroviruses such as MLV do not efficiently transduce nonreplicating cells while lentiviruses can (6), and this property of MLV, although conferring potential specificity, made some desirable applications impossible or, at best, more difficult than anticipated. These desirable applications included ex vivo transduction of cells and in vivo applications, such as delivery to liver, brain, lung, bone marrow, and other tissues (the majority) where there was normally little or no cellular replication.

The first lentiviral vectors were constructed by Sodroski, Haseltine, and their collaborators (7,8) and were based on HIV-1, using natural envelope that conferred tropism for CD4+ T cells. In fact, most of these early vectors were replication competent and were produced in a manner similar to the ''wild-type'' virus. Soon after this, Page et al. (9) described efficient pseudotyping with nonlentiviral envelopes such as the amphotropic MLV envelope, but this was seen as a molecular tool for laboratory use. In the meantime, the use of pseudotyping with the vesicular stomatitis virus G (VSV-G) protein for C-type vectors (10) and, crucially, the ability to easily concentrate these pseudotyped vectors by centrifugation and resuspension (11) were described. This information, and further data from extensive characterization of the HIV system in the mid-1990s, led to the demonstration that VSV-G pseudotyped HIV vectors could be made, concentrated, and used to transduce rat neural tissues in vivo (12). Such transduction led to long-term expression. The ability to use these vectors efficiently and easily in a research lab setting sparked a good deal of activity and initiated the current intense activity in the field of lentiviral vectors.

III. TYPES OF VECTOR—MOLECULAR STRUCTURE AND FUNCTION

A. Different Lentiviruses as the Bases for Vectors

The genome of HIV-1 (3) is shown in Fig. 1, as are those of other lentiviruses [feline immunodeficiency virus (FIV), equine infectious anemia virus (EIAV), simian immunodeficiency virus (SIV), bovine immunodeficiency virus (BIV), caprine arthritis encephalitis virus (CAEV)] that have been used to make vectors (13). The HIV viral genome encodes 9 proteins: the structural proteins, Gag, Gag-Pol, and Env, plus accessory proteins: Tat, Rev, Vif, Vpu, Vpr, and Nef (Table 1). The other viruses have some of the same accessory proteins and some others. All the viruses have a Rev/Rev responsive element (RRE) system that allows export of unspliced or partially spliced viral RNA from the nucleus. All the viruses appear to be able to infect nonreplicating cells. In general, the vectors and packaging systems have moved from the first generation (Helper genome with an envelope deletion) (12) through a second generation that eliminated some of the accessory proteins (14) to third-generation systems (e.g., 15–17), shown in Fig. 2 and realized for HIV and EIAV, where almost all the unnecessary accessory proteins have been removed leaving just Rev, or Rev and Tat only. Further refinements are described below. The most thorough understanding of structure and function is, of course, for HIV-1, and the most commonly used envelope is the VSV-G protein. Vectors from the different systems appear not to differ in potency a great deal, although it is hard to be definite about this because even those experiments that claim to do so may not compare the best of both systems (e.g., 18,19). In general, vectors generated by transient transfection on 293T cells with a VSV-G pseudotype give titers around 10^6 transducing units (TUs)/mL as measured by a β-gal assay in tissue culture on various cell types. If you can achieve this, then you can join the club!

B. Accessory Proteins

The functions of the accessory proteins have been intensively investigated for HIV-1, but remain incompletely understood (see Table 1 and Refs. 3,20,21). It is possible to delete or inactivate all of *vif*, *vpr*, *vpu*, and *nef* and still retain viral replication in tissue culture (21), and so it is believed that most of these play a role in human or animal infection and pathology. The information concerning accessory proteins in other lentiviruses is often derived by analogy from the HIV data. Nevertheless, as shown in Fig. 1, although SIV looks quite similar to HIV, the nonprimate lentiviruses (13,22) are not as similar and do not carry analogs to HIV *vpr*, *vpu*, and *nef*. The Rev, Tat, and Vif proteins and functions appear to be conserved, however, with the exception that EIAV has no Vif protein and FIV has no recognizable Tat, although some tatlike functions are performed by Orf A (23). In addition, the nonprimate lentiviruses carry other genes of unknown function (e.g., S2 in EIAV) and also encode a dUTPase in the Pol polypeptide. This level of complexity is fairly daunting, and the approach of vector makers has been somewhat cavalier, but also apparently successful so far. This approach has been to eliminate these functions from vectors and helper functions as far as possible and current vector systems usually incorporate only *rev*, and then only in the production stage. It is unknown whether expression of such accessory proteins could, under certain circumstances, influence the properties of the vectors in uptake, transduction, and expression in animals or clinical trial subjects. However, it is also true that some of these proteins are toxic, at least in tissue culture, and their functions are incompletely understood, so the expression of these functions adds an unknown level of risk for use in animals and clinical trial subjects. The bottom line is that the vectors appear to be quite potent without the accessory proteins.

C. Integration in Nondividing Cells

As noted in Section I, a key issue has been the ability of these viruses (and the derived vectors) to infect (or transduce) nondividing cells (3,6,12). This is achieved by the passage of the intact preintegration complex of nucleic acid and protein through the nuclear membrane by a mechanism that remains unclear. The preintegration complex appears to be less massive than for C-type viruses because most of the nuclear capsid proteins are removed in the cytoplasm, with the matrix (MA) peptide and reverse transcriptase (RT)/integrase (IN) peptides retained (24,25). Contribution to the nuclear entry function have been mapped to 4 different viral functions in HIV: the MA protein of the nuclear capsid (22,26,27); the IN molecule encoded as part of the reverse transcriptase polypeptide (22,28); the accessory protein, Vpr (22,29); and the central polypurine tract (22,30). It is clear, however, that not all these are needed for the integration to occur in nondividing cells (31–33) and, for example, in some vectors only the MA and IN contributions remain, but integration in nondividing cells proceeds efficiently. The central polypurine tract appears to make the vectors more efficient in some situations but not in all (33). The MA function by itself may not be sufficient to allow the nuclear transport to occur as attempts to transplant the function into MLV vectors allowed infection of replicating, but not of growth-arrested cells (32).

Nevertheless, the lentiviruses and lentiviral vectors do not transduce all cell types by any means, even when equipped with a pantropic envelope such as VSVg, and the efficiency can vary widely. For example, in the initial description of this property (12), it was clear that HIV vectors can transduce human macrophages more efficiently than MLV-based vectors. Nevertheless the efficiency with which this happens (as measured by the effective titer on those cells) is around 1% of the efficiency on replicating tissue culture cells such as HeLa cells (17). Another example for which the entire story is not yet clear is the transduction of liver cells in vivo following intravenous (IV) administration of the vectors to animal models (mainly mice). Some investigators have experienced difficulty transducing hepatocytes in vivo (34), but other pub-

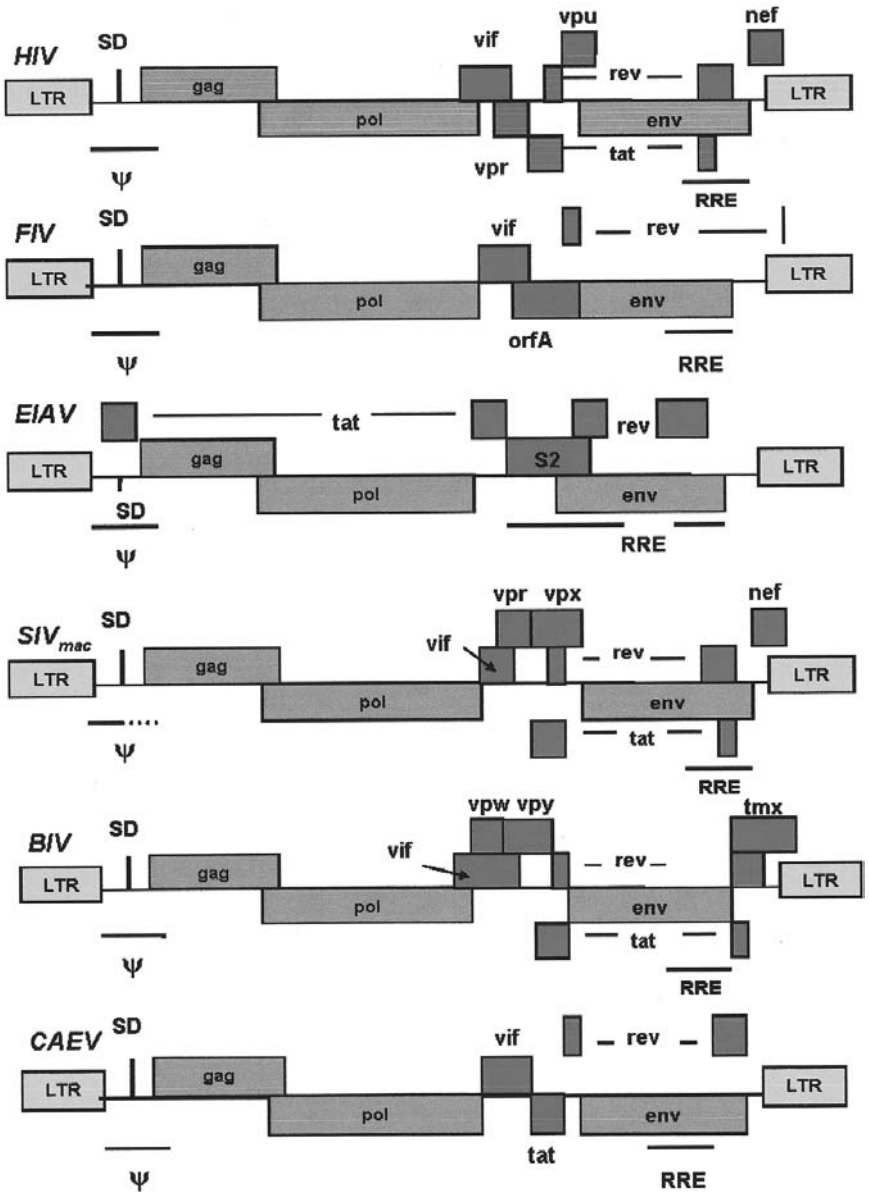

Figure 1 Genomes of lentiviruses that have been used as the bases for vector construction. The genomes are shown with the genes coding for the structural proteins in green, the accessory proteins in light blue, and the long terminal repeats (LTRs) in yellow. Ψ, packaging signal; SD, splice donor; RRE, rev responsive element. The diagram is not to scale. See the color insert for a color version of this figure.

lications do not report such a problem (35). This issue has been difficult to resolve because it is not clear how much exposure the total complement of hepatocytes in mature liver has to vector in the circulation, and therefore what ''efficiency'' to expect. In any case, once again, compared with MLV, the efficiencies of lentiviral vector-mediated transduction are much improved in vivo. This issue is discussed in more detail in Section V. There may be a block to hepatocyte transduction in vivo under some circumstances, but this is likely due to something other than the ability of the vector capsid to penetrate the nuclear membrane. It was originally suggested that the vectors may be better at transducing cells arrested in the cell cycle (G_2) rather than those that are in G_0/G_1 (12) or that have no possibility of replicating, but this

Table 1 Functions of HIV Accessory and Regulatory Proteins

Protein	Function
Tat	Activation of LTR transcription, other postentry functions, able to pass into neighboring cells intact, may set up neighboring cells for infection
Rev	Transport of unspliced or singly spliced message from nucleus to cytoplasm
Vif	Acts during virus assembly to make virus particle competent for subsequent infection—dependent on the cell type
Vpu	Facilitation of release of budding virus particles from surfaces of infected cells—cell-type dependent and not limited to HIV
Vpr	G2 cell-cycle arrest, nuclear transport, suppresses immune activation and apoptosis through regulation of nuclear factor kappa B, positive regulator of viral transcription and infectivity in primary human macrophages
Nef	Facilitates capsid disassembly upon infection, may down-regulate MHC

Source: Refs. 3, 20, and 21.

turned out not to be the case (36,37); in any case, the vectors are very efficient in transducing some postmitotic cells, such as neurons, in vivo (see below).

D. Packaging Signal

The packaging signal is the sequence that allows recognition and packaging of the genomic RNA into the viral capsid before the capsid proceeds to the internal surface of the coated pits where it picks up pieces of cellular membrane and some cellular surface proteins and buds from the cell (38,39). The packaging signal in general contains a set of ''lollipop'' RNA secondary structures that can be varied in sequence as long as the structure is maintained (22,40). This site is the area of the dimerization signal for inclusion of 2 viral genomes in the nascent particle, but this *trans*-interaction also appears to be structurally driven and not sequence specific. The packaging signal is recognized by nucleocapsid structural (NC) peptide from the Gag polyprotein to start formation of the viral capsid (41,42). It seems likely that this occurs through interaction with zinc fingers in the NC peptide.

The original definition of the packaging signal in HIV-1 was the 19 bp deletion between the LTR and the major splice donor by Lever et al. (8). Since then, the packaging signals for HIV-1 and -2, SIV_{mac}, EIAV, FIV, and BIV have been quite well defined (43–49). The packaging signal for these, as for most retroviruses, lies somewhere in the region between the 5′R region and includes the start of the *gag* sequence. It is bipartite, with the area around the splice donor probably being expendable although the spacing between the 2 segments is likely important. It is important to define this area

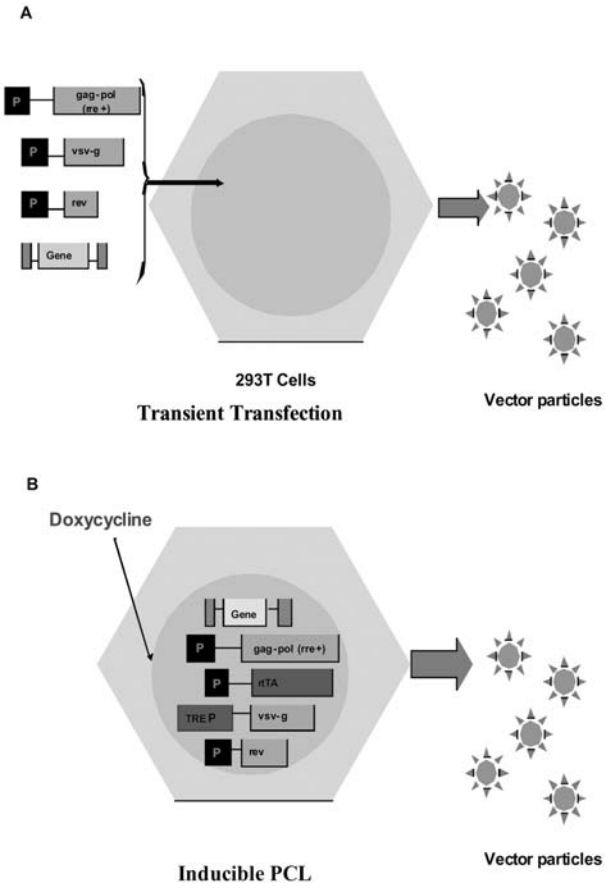

Figure 2 Processes for making vector preparations with third-generation packaging systems. (A) Transient process where the various elements shown are cotransfected into the recipient cell line that is usually 293T cells. This is a typical system that retains the need for Rev to get good expression of the Gag and Gag-Pol proteins, and to boost vector genome production. P, promoter, usually the CMV IE1 promoter. (B) Packaging producer cell line. All the elements necessary to make vector are in the cell line permanently. Doxycycline is used to induce expression of the VSV-G protein through the interaction with the constitutively expressed rtTA transactivator that induces expression from the TRE promoter after interaction with doxycycline or tetracycline. This is the ''tet on'' system designed by Gossen and co workers (117), but other inducible systems can be used. The blue hexagon represents the cell and the brown oval, the nucleus. The yellow box is the gene encoded by the vector, and the vector structure is simplified here with only the LTR regions shown in green. A more detailed diagram of a typical vector is shown in Fig. 3. See the color insert for a color version of this figure.

as closely as possible for 2 major reasons: (1) to obtain as high titers as possible, and (2) to identify and minimize obligate areas of homology between the vectors and the packaging constructs because these have been shown to lead to homologous recombination between these sites.

Homologous recombination reunites elements that were separated during the design of the vector system and could be a first step on the road to generating a replication-competent entity. In general it is easier to define what is necessary (by deletion analysis) than what is sufficient. The latter requires a more complicated molecular manipulation and the results are usually not black and white. From the viruses' point of view, the inclusion of *gag* sequence in the packaging signal makes sense because it allows for selection of full-length unspliced genomic RNA for encapsidation. From the vector makers' point of view, this is a nuisance because the *gag* sequence provides difficult-to-avoid sequence homology to the *gag* sequence in packaging plasmids provided in *trans* during vector production. Parenthetically, HIV-2 (and hence possibly SIV_{mac} because these 2 viruses are closely related) is reported to be an exception and the gag sequence may be a relatively unimportant part of the packaging signal (44). The *gag* recombination issue for vector construction could be addressed by simply leaving out part of the packaging signal, but in general this reduces titers considerably. One effective solution that is now in common use is to build expression vectors for the viral packaging proteins, Gag and Gag-Pol, with optimized/different amino acid coding sequences (50,51). This has several advantages: elimination of homology to the packaging signal as discussed here, potentially higher levels of Gag-Pol expression, and elimination of the dependency of Gag-Pol expression on Rev expression in the packaging system.

E. Gene Expression and RNA Nuclear Export Enhancers

Lentiviral genomes carry a series of elements that, in the virus, ensure the orderly progression of the viral life cycle, but that complicate life for vector makers (22). These include the Tat-mediated control of transcription that renders the HIV LTR a poor promoter in its absence, and the existence of RNA nuclear export inhibitory sequences in *env* and *gag-pol* primary transcripts, which are counteracted by the interaction of the Rev protein with the RRE. This allows export of the messages for the structural proteins and the full-length viral genome to the cytoplasm. These issues are addressed in the ''third-generation'' vector systems (15–17,46,47,52,53).

The Tat dependence of the LTR has been avoided by substituting other promoters (usually the CMV IE1 promoter that is very active in 293 cells) at the 5′ end, while leaving in place those elements that are needed to allow the transcript to be reverse transcribed and integrated (tRNA primer site and R region, packaging signal) (see also Figs. 2 and 3). The Rev dependence has been manipulated by including the RRE in the vector genome, but positioning it so that it is excluded from the transcript of the desired transgene, as it was believed

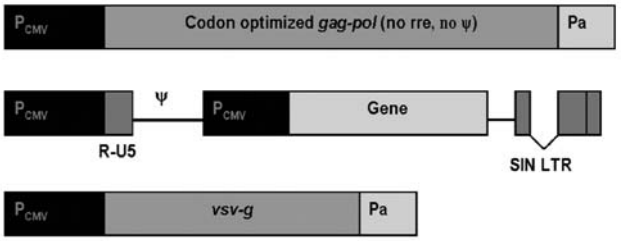

Figure 3 Components of a minimal vector system. The figure shows the 3 components necessary for Rev-independent packaging systems, such as with those designed with codon optimized *gag-pol* genes (50,51). The vector is also expressed without the need for Rev, and is shown in its plasmid configuration. When the transcribed RNA vector genome is packaged into a vector particle, then reverse transcribed and integrated into the genome of a target cell, the 5′CMV promoter disappears and is replaced by the SIN LTR, which has no promoter function. The encoded gene is expressed from the inner CMV promoter. The system shown is used for transient transfection. For a packaging cell line using the VSV-G protein as envelope, the gene encoding VSV-G would need to be inducible. P_{CMV}, CMV IE1 promoter. See the color insert for a color version of this figure.

to be desirable for high-level expression of the vector genomes. The transferred gene itself is expressed from an internal promoter. In most third-generation systems (Fig. 2), Rev is necessary anyway in the packaging cell to obtain good levels of expression of the Gag and Gag-Pol proteins. The packaging cell requirement for rev can be eliminated by the use of codon optimized *gag* and *gag-pol* genes, as noted above (50,51).

There has been benefit in some situations to add extra nucleic acid components to the vector genome to facilitate steps in the transduction cycle. The most commonly used elements include the cPPT element from the virus itself (see Section III.C) (30), which is part of the reverse transcriptase coding sequence and is a start site for viral genome replication (54,55); the Mason-Pfizer monkey virus constitutive transport element or analogs that facilitate export of unspliced RNA by interacting with a cellular activity (56); and the Woodchuck hepatitis virus posttranscriptional regulatory element element (57) that enhances the translation activity of the message in which it is incorporated by several possible mechanisms. All these elements can be shown to be quite potent in enhancing titer or potency of expression in some situations, but are also ineffective in others (e.g., 33). However, they have never been shown to be deleterious and so they or analogs are often included in the design of vectors without significant subsequent proof of their utility in the particular situation.

F. Envelope Proteins and Pseudotyping

The vast majority of lentiviral vectors have been made using the VSV-G pseudotype of the vector particles. This is for 2

main reasons: it works well in almost all vector systems to give high in vitro titer; and the vector produced can be easily concentrated up to about 1000-fold at the research scale, by centrifugation (11). This in turn yields preparations of vector that have titers of around 10^9 TU/mL, which turns out to be what is needed for a number of in vivo applications. However, numerous other pseudotypes (see Table 2 for some examples) have been made to try to provide tissue tropism, explore targetable envelopes, look for a nontoxic protein (as opposed to VSV-G) and hence simplify vector production, provide higher titers and also simply explore what novel properties such pseudotypes might possess. Although many such pseudotypes have been made, there is only preliminary information on the properties of such vector preparations in vivo, where it counts. An intriguing example has been the report of retrograde transport of the vector genome up the axons of neurons to the nucleus with rabies G pseudotyped vectors (58). This raises the possibility of introducing genes into the easily accessible muscle of a clinical subject and transducing the nuclei of neurons in the not-easily-accessible spinal cord, with prospects for treating motor neuron diseases.

Another aspect of the viral/vector life cycle that is beginning to be understood is the manner in which the viral capsid hijacks the endosomal transport pathways in order to travel to the inner side of the cell membrane. How envelope proteins gather there in the area of a coated pit to which the capsid arrives is less understood, as are the rules governing the subsets of the cellular surface proteins that gather there and bud off with the cellular membrane and the envelope protein (71). For example, HIV includes MHC class I and II molecules in the membrane of the particles (72). In MLV-based vectors, the amphotropic envelope probably allows inclusion of the CD55 and CD59 molecules that protect against complement attack in vivo, but VSV-G probably excludes them (73). The rules for such exclusion and inclusion of cellular markers are incompletely understood and have not been investigated in the context of the vectors or the different possible pseudotypes. One obvious consequence is that it is not known, for example, to what extent the vectors are resistant to degradation by human complement.

G. Other Cell and Tissue Tropism Issues

In vector systems, another classic way that does not involve envelope switches to achieve tissue-specific effects is to use a cell type-specific, or environment-specific, promoter and enhancer. This works quite well with lentiviral vectors (e.g., 74) (better, in fact, it seems than with MLV-type vectors), although there is not a large amount of data in vivo where, as noted before, it counts. The ease of accomplishment is related to the fact that ''SIN'' vectors (i.e., those with deletions in the 3′LTR that migrate to the 5′LTR after 1 round of reverse transcription and integration) (75) seem to work better with lentiviral vectors than with MLV-based vectors.

However, in addition to these intentional tissue-targeting issues there are innate tropisms in the vectors themselves that sometimes are unexpectedly observed. The best known of these is probably the failure of many HIV vectors to productively transduce some monkey cells (76). Further investigation shows that this phenomenon is quite common and can apply to nonprimate lentiviral vectors in primates (77). As primates are considered desirable models for human safety studies, and

Table 2 Examples of Various Pseudotypes of Lentiviral Vectors and Their Properties

Vector	Pseudotype	Observed properties	Reference
HIV	Amphotropic (A)-MLV	10-Fold lower titer than VSVg	9,12
FIV	A-MLV	10-Fold lower titer than VSV-G	47
EIAV	Rabies G	Retrograde transport in neuronal axons	58
HIV	Mokola	Titer less than VSV-G	59
HIV	Ebola, LCMV, mokola, A-MLV	Mokola has titer <VSV-G; ebola does not transduce CNS tissue	60
SIV, HIV	Sendai	May target liver cells	61,62
FIV	Alphavirus	Titers apparently better than VSV-G pseudotype	63
HIV	HTLV-1	Low titer ($<10^4$ TU/mL)	64
SIV	Mokola-G, A-MLV, influenza HA, LCMV	All preferentially transduce pigmented epithelial cells	65
HIV	HERV-W	Low titer ($<10^4$ TU/mL)	66
HIV	LCMV	Nontoxic in producer, titer equivalent to VSV-G, spin concentration possible	67
HIV	Avian leukosis-sarcoma virus	Low titer, removing cytoplasmic tail boosts titer	68
HIV	Ecotropic (E)-MLV, A-MLV	E-MLV pseudotype transduces mouse B cells <VSV-G	69
HIV	RD114-MLV, GALV-MLV Hybrids	Moderate titers (>A-MLV), spin concentration possible, resistant to complement	69,70

humans are the ultimate target population, this restriction of virus and vector entry could create problems. The phenomenon is likely akin to the N/B tropism of MLV-based vectors that maps to the capsid. The HIV/SIV restriction in some monkey cells also maps to the capsid (76), and it has recently been reported that the block can be overcome by substituting the cyclophilin A-binding region in the capsid with that from macrophage tropic HIV (78). Another example of unexpected restriction of transduction familiar to this author is that we were unable to transduce muscle tissue from mouse with FIV vectors but were able to easily introduce the same vectors into guinea pig muscle (47). However, it should also be noted that this restriction is generally saturatable, and, for example, HIV vectors have been used very successfully to treat a macaque model of Parkinson's disease (79), where there is a restriction to HIV entry.

Because the knowledge of the virology of these viruses is incomplete, we should expect further unforeseen observations.

IV. METHODS OF PRODUCTION AND TESTING

A. Viral Life Cycle

As for C-type viruses, the life cycle of lentiviruses can be conceptually divided into 2 stages for the purposes of using it as a vector. The entry, reverse transcription, transport into the nucleus and integration correspond to the use of the vector to carry heterologous genes into target cells. The subsequent provirus transcription synthesis of viral proteins, packaging of the viral genome, maturation of the viral particle, and export from the cell correspond to the production of the vector particles.

B. Transient and Stable Vector Producer Systems

There are 2 general categories of vector production procedures at present. These are transient transfection of highly transfectable cells (Fig. 3A), usually 293 or 293T cells with most or all the plasmids encoding the packaging and vector components (15–17,45–49), and production from stable cell lines already carrying some or all the necessary molecular components. The stable cell lines normally carry an inducible expression cassette for the VSV-G protein so that production of vector is triggered by induction of VSV-G expression (Fig. 3B). Because the VSV-G protein is toxic, these types of cells produce vector for at most around 4 days. This contrasts unfavorably with MLV-based packaging cells that use nontoxic envelopes and can produce vector for 2 weeks or more with 1 run.

No publications describe FIV packaging cell lines, although there are investigators working on these. There is 1 report about an early EIA V-based packaging cell (80). Several publications (81–85) have described HIV-1 packaging cell systems along these lines, but they have so far been put to very little use. This is probably the case for several reasons. First, these cell lines at present produce at best equivalent, more often lower, titers than the transient procedures (in the range of 10^5–10^6 TU/mL). Second, the packaging cell lines are more cumbersome to use in the research laboratory because it is likely that cellular clones of producer cell lines, carrying the vector of interest, would need to be isolated and tested, whereas the transient technique allows vector preparation to be rapidly generated. Third, packaging and producer lines usually would offer the prospect of continued harvest of vector for 2 weeks or more, but with inducible VSV-G, producer lines do not last more than a few days. Fourth, the real advantage of producer cell lines lies within the ability to characterize the vector-producing source in detail and this is of real advantage for late preclinical and clinical experiments, not for smaller lab or small animal experiments. It is not clear how much effort has gone into optimizing these systems, and there is certainly scope for some variation in approach. For example, it is known from MLV systems that limited induction of VSV-G is better than high levels (86). An SIV packaging cell line has also been described (87) and performs more or less like the HIV-based lines. In addition, cell lines for making true HIV vectors with HIV envelopes have been described and made in monkey cell lines (88–90), but the titers from these were 10e4/mL or less. One packaging cell line (82) was used in conjunction with a vector that initially is driven by a CMV promoter at the 5′ end, but after 1 round of replication the 5′ end acquires a tetracycline-inducible promoter (from the original 3′LTR). The attraction of this maneuver is that it allows transduction of vector genomes into the packaging cell, rather than transfection, but will also allow an effectively ''SIN'' configuration in target cells with an inactive (uninduced) promoter at the 5′LTR end. It is known from studies in MLV vectors that transduction of the vector, as opposed to transfection, into packaging cells allows higher vector genome expression (a limiting factor in making high titer producer lines) and clean insertion of multiple copies of the genome (91).

The components of the transient transfection system are those shown in Fig. 3a, or some variation thereof. In this situation, the expression of VSV-G does not have to be directed off an inducible promoter system as it is expressed transiently anyway. Because of the need for efficient transfection to make vector, almost all systems use the 293 or 293T (92) cell lines as the cell substrate. The major technical innovations here to make life easier have been the use of sodium butyrate to boost expression (93,94), and the use of standard transfection agents that are sold commercially (e.g., 95,96) to try and avoid the variability inherent in calcium phosphate precipitation methods. However, for clinical use it is likely that the calcium phosphate method will be preferred because, it seems that either most of the transfection agents have undefined components, the components are trade secret, and/or the manufacturer is unwilling to file a master file with the Food and Drug Administration (FDA).

C. Processing and Purification

The most common processing method by far for these vectors is high-speed centrifugation and resuspension (11). Done

once, this can concentrate the vectors about 1000-fold and the resulting preparations show little loss of activity and are surprisingly clean (i.e., the level of obvious contaminants from the tissue culture process such as BSA and DNA are not excessive) and with titers (see below) of around 10^9 TU/mL. This is, in fact, one of the reasons that the use of these vectors has become quite widespread. Such preparations are not toxic to animals in general, and the high potency allows administration to small animals such as mice and to tissues such as the brain and eye (see below), where it is impossible to effectively administer more than a few microliters. The resuspension buffer is typically ''isotonic'' PBS or Tris buffer with a cryoprotectant sugar and sometimes human serum albumin. The formulation of the vector preparations has not received much attention and investigators have usually extrapolated from useful retroviral vector formulations (91). There are no reports of stability studies.

It is possible to reconcentrate the 1000-fold concentrated material by further centrifugation, but beyond about 3000-fold total concentration results have not been good and difficulties in handling the material (viscosity etc.), toxicity, and significant losses begin to occur.

Alternate concentration methods are desirable because (1) centrifugation is a method that is notoriously difficult to scale up and use for manufacturing significant quantities of material for clinical trials and eventual product marketing; (2) alternate purification methods could be used with centrifugation to achieve higher concentrations; and (3) if other envelopes apart from VSV-G are to be used, it is likely that losses from centrifugation will be significant. There is a good deal of guidance for alternate procedures in the retroviral vector literature (e.g., 97) and column chromatography and other methods are starting to be used (98–100)

D. Titering

The titer or potency of vector preparations is typically measured by a dilution series of vector applied to target cells growing on tissue culture plates, allowing the cells to take up and express the vector, then stain for gene expression. This is descended from the classic phage plaque methods originally introduced by Max Delbruck and extended to mammalian viruses by Dulbecco (101). This type of measurement has served the viral and vector community well, but there are several issues with it. First, this works best with a marker that is easy to measure like beta-galactosidase or green fluorescence protein. Second, it is well known that this does not measure all the vector that is supplied to the plate in question, and that a similar ''titer'' can be observed by removing the applied supernatant and applying to a second plate. Third, along the same lines, it is possible to ''increase'' titers by methods such as ''spinoculation'' (102), where the cells are centrifuged during transduction. Fourth, the titer is very dependent on the cells used as target cells, the strain of the particular cell type, and seemingly minor changes in conditions. However, under highly standardized conditions this assay can be used to assess the potency of vector preparations.

For the reasons listed above, plus the fact that most vectors do not encode a gene product that is straightforward to detect in tissue culture, several other assays have been developed and used.

One common assay is the polymerase chain reaction (RT-PCR) measurement of the level of vector RNA in the preparation (103). In this assay, an aliquot of the vector preparation is disrupted and the level of some vector sequence (usually the packaging signal, although care must be taken to avoid competing gag sequences from the packaging construct) is measured by priming with oligomers for a first reverse transcription step followed by regular PCR amplification, usually followed in real time and measuring the number of PCR cycles necessary to observe a signal. Often this is compared in the same experiment to a beta-galactosidase vector preparation and a titer/mL obtained by comparing the two. Alternatively, an internally consistent measurement can be made against a known RNA standard. This assay is simple and rapid and samples the whole aliquot, so it is widely used. The drawbacks are that the relationship to actual in vitro and in vivo potency is not well characterized in general and this is probably vector dependent.

A third assay (the so-called ''DNA transduction'' assay) (96,103,104) is to perform the limiting dilution assay on tissue culture cells, as described above, then measure the level of the vector DNA as compared with cellular DNA directly by PCR (usually by the real-time, PCR cycle-to-detection method used for the RT-PCR assay). This in principle is an absolute measurement and is suitable as a potency assay, but uncertainties around the level of contamination and the rate of disappearance of DNA used in the transient transduction process, have to be dealt with. In addition, it is possible that all the lentiviral vector DNA may not integrate immediately (12), so the timing of the measurement may make a difference.

A fourth assay used with HIV-based vectors is simply to measure the levels of the p24 capsid protein (e.g., 35) using inexpensive widely available commercial kits (used for blood testing). This assay is very robust but measures only the level of p24 in the preparation. The link between this number and actual transduction potency is not obvious, and may be different with different vector preparations. Such assays form part of the basic characterization of vector preparations, but it is recognized that, at present, these preparations have properties that are not necessarily consistent from batch to batch. Such inconsistency may be linked to issues such as the ratio of active to inactive particles, the extent of encapsidation of nonviral RNA, the cell line from which the particles were made, and the variations in the preparation methods in general. Further characterization of these issues is being undertaken and will be necessary as these vectors become more commonly used in the clinic. (See, for example, ''Guidance for Human Somatic Cell and Gene Therapy,'' U.S. Department of Health and Human Services, FDA, Center for Biologics Evaluation and Research, March 1998, http://www.fda.gov/cber/gdlns/somgene.pdf 1998.)

E. Replication-competent Lentivirus and Other Safety Issues in Manufacturing

Biological entities, in terms of FDA definitions of product types, are defined by the process by which they are made, such that robust, reliable manufacturing processes will need to be developed further. However, an important issue that has attracted a good deal of attention is the possibility of regenerating some form of replicating lentiviral entity. This attention was engendered by both the precedent of replication-competent retrovirus being generated in MLV-type production systems and its link to lymphoma in monkeys (5), and the fact that HIV is a well-known and potentially lethal human pathogen. This issue was one force driving the development of the stripped-down, accessory protein-minimized, third-generation production systems. It is likely that these efforts have made generation of replication-competent lentivirus (RCL) (105) in third-generation systems, in the manner seen for MLV type systems, close to impossible, and that any replicating agent may need to use or acquire by recombination, cellular components as well as the viral system machinery. For example, an envelope from a human endogenous retrovirus can pseudotype HIV-1 (66), when the gene is supplied in trans. This potential acquisition of cellular components through some form of nonhomologous recombination will likely need to be even more extensive to generate a hypothetical replicating entity from cells making vectors based on viruses such as FIV and EIAV that are not capable of replication in human cells. Nevertheless this issue is perceived as significant and the likelihood of generating RCI will be judged by the data generated in vector production and testing. Therefore, tests for RCL form a key element of testing of vector preparations. The major difficulty is that, as it is unclear exactly what the properties of the replicating entity would be, designing a reliable test and spike control has been difficult. In general, a putative RCL needs to be able to replicate in amplifier or test cells to be detected. It has been agreed generally that the risk involved to construct, test, and use experimentally some of the postulated hybrids outweighs any possible general benefit to testing of vector preparations. For example, a version of HIV without accessory proteins and a VSV-G type envelope could have extremely unpredictable properties if a human infection occurred. No investigator wants to use this.

Therefore, various test methods have been proposed and developed. These include the use of cell lines that express an envelope and the use of an HIV *gag-pol* vector as the spike with read-out being the production of p24 (84), as well as the use of the ''product-enhanced reverse transcriptase assay'', which assays for the RT activity on a defined template (96), and then amplifies the defined RT product by PCR and detects using real-time PCR cycle-dependent assay. The spike in this case could be almost any replicating retrovirus such as MLV. Both these assays require some cellular passaging to get rid of vector signal and hopefully amplify or conserve the RCL signal. Alternative assays look directly for postulated recombination products by PCR but have the drawbacks that this represents a guess at what the entity would be and also it does not actually test for replicating agents.

V. TARGET TISSUES AND THERAPEUTIC MODELS

Gene therapy techniques, as currently applied to the treatment of disease, tend to develop as follows. A vector is made, tried out in tissue culture and small animal models to see how it performs in terms of tissue tropism, the results assessed and a disease process identified that might be susceptible to modification. This is a perfectly rational way to proceed given the complexity of the technology and disease pathogenesis, but it has the disadvantage that the clinical element arrives late and the choice of clinical target has not always been well made. One of the exciting aspects about lentiviral vectors has been the early clear identification of tissues and disease areas where the technology seems to have great potential and there are large clinical needs. Time will tell if the development of these vectors will, in fact, lead to clinically useful therapies, but there is no doubt about the promise.

One of the first areas identified as a target was the brain. Injection of small amounts of high titer material leads to localized long-lived expression of the encoded genes (12,46,106–111c) (Fig. 4.). This has a seemingly natural fit with the supposed need for chronic therapies for chronic neurodegenerative diseases. The VSV-G pseudotyped material from HIV, FIV, and EIAV vectors have been shown to efficiently transduce neurons in various areas of the brain and express the transgene(s) for as long as anyone has looked so far. Such experiments have been performed in mice, rats, and monkeys. Thus, animal model data for the treatment of lysosomal storage diseases (112,113), Huntington's disease (114), Parkinson's disease (79,115,116), and other diseases have been generated. One prominent example has been the recovery from a model of Parkinson's disease in primates (79) after administration of an HIV vector encoding glial cell derived nerve growth factor. It is hard to see how a protein can be delivered chronically to large numbers of people, as may be needed, without some kind of gene therapy. The flip side of this is that, of course, it is necessary have some control over expression of a growth factor in the brain, and this technology (e.g., 117–120) will also need to be clinically developed. Nevertheless, the results are encouraging enough that several groups are starting to undertake this.

A related area that shows promise is the delivery of genes to the eye for treatment of various types of retinopathies, including macular degeneration and diabetic retinopathy (121–125). This interest springs, largely, from the observation that lentiviral vectors seem to have particular tropism for pigmented retinal epithelial cells in several species. Most proposals center on preventing the disorganized angiogenesis that follows disease onset and try to prevent it as it exacerbates clinical symptoms. There is currently a clinical trial underway using adenoviral vectors encoding the angiogenesis inhibitor pigment derived epithelium factor (126), but presumably len-

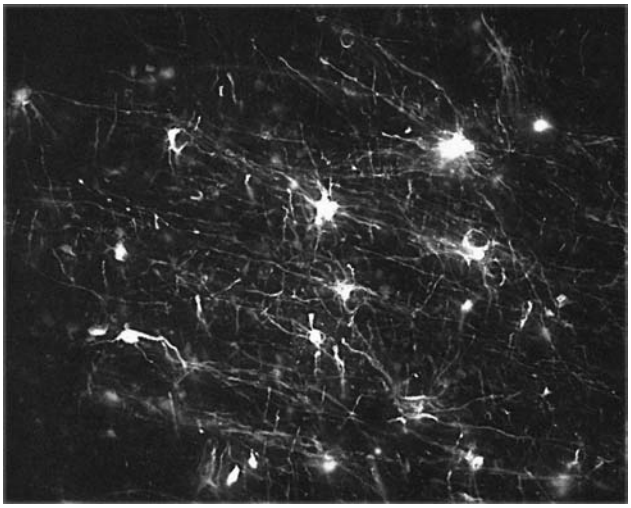

Figure 4 Efficient transduction of neural tissue in vivo with a lentiviral vector. The photomicrograph shows GFP expression in the striatum of a squirrel monkey at 18 days following infusion of 7.5 uL of an EIAV-based VSV-G pseudotyped vector [pSMART(1)G]) encoding GFP (2.4×10^{10} TU/mL) into the right caudate nucleus. Lentiviral vector was infused at a rate of 0.5 uL/min. Extensive expression of GFP can be seen throughout both cell bodies and processes. Cells morphologically similar to both neurons and glia expressed high levels of GFP. See the color insert for a color version of this figure.

tiviral vectors may be a better fit. Once again, however, clinically it would be desirable to be able to switch the gene off. If a VSV-G lentiviral vector is injected intravenously in a mouse, it localizes mainly to the liver, spleen, and bone marrow (74,127,128). The levels decline somewhat over time in the liver and spleen but may stay at the initial level in the marrow. These levels are not completely consistent but are in the 0.1% to 30% range of total cell sampled. This observation points to some other promising target tissues, namely, liver and bone marrow. The spleen observation raised the possibility of inducing immune responses and has not attracted as much attention, except in vaccine-oriented applications.

The ability of lentiviral vectors to transduce liver tissue in mice and rats has been the subject of some debate, and there are definitely some issues that are not fully understood. Some investigators see the need to make the liver cells at least be part of a regenerating or proliferating tissue (34,129,130), whereas others experience no problem in generating therapeutic levels of systemic protein after liver targeted transduction (35,74,131). It seems likely that such differences are due to subtle vector differences or precise details of the delivery method, which have not yet been completely identified. It does seem that explanted primary hepatocytes that are not replicating are efficiently transduced (132), and pseudotyping with Sendai virus envelope has been used to try to target liver cells (61). The indications that are most discussed here are treatments that require systemic protein over long periods of time such as hemophilia A and B.

There is little investigation of transducing bone marrow in vivo but a lot of effort has been devoted to using the vectors to deliver genes to hematopoietic stem cells (HSCs). This is because the transplantation technology is in clinical use and the lentiviral vectors offer the opportunity to transduce the cells in vitro before reimplantation, without the need to make these cells pass through the cell cycle, as has been required for MLV-based vectors. This has been performed in mouse models and in human HSC in immune-deficient mouse models (133,134). Targets here include genetic diseases such as thalassemia (135,136), sickle-cell anemia (137), and chronic granulomatous disease (138). In addition, anti-HIV therapy has been investigated to provide blood cells derived from HSC that are protected from HIV or simply transducing T cells directly (139). Among the anti-HIV strategies are rescuable anti-HIV genes (140), antisense (141), and iRNA (142) to constitutively protect cells (143).

Because of the characteristics of the vector, there has only been a small amount of activity in cancer (e.g., 144,145), a target that has attracted a lot of attention from other vector systems. In addition, there have been attempts to use the vectors for lung application, such as cystic fibrosis (146), where some understanding of the issues around tranducing the apical side of the lung epithelial cells has been developed. Other targets include collagen deficiency (147) and kidney disease (148).

VI. CLINICAL AND CLINICAL SAFETY ISSUES

As this is written, these vectors appear to be on the point of being used in the clinic (see http://www.virxsys.com/PressReleaseFINAL20030213.pdf). The first indication is likely to be for HIV therapy, but it is likely that protocols for neurodegenerative diseases such as Parkinson's disease will follow. In the clinic, the major vector-related safety issues [apart from contamination of vector preparations with adventitious agents (149) such as RCL, and see above) that have been raised relate to recombination or rescue by preexisting (and perhaps unrecognized) infection with HIV (150–152), interaction with endogenous sequences (65) in the trial subject, and more recently insertional mutagenesis (4,153,154) and resultant predilection to development of cancers. The HIV ''rescue'' issue can probably be dealt with by using SIN vectors (75) that are not able to be rescued, although the final answer will come from clinical data. It should also be noted that large numbers of HIV-infected individuals have been treated with MLV vectors without obvious vector-related side effects [see the web site of the National Institutes of Health Office of Biotechnology Activities (OBA) at http://www4.od.nih.gov/oba/rac/SAE_rpts/Mod0902s/Sep02_MODs.htm]. The insertional mutagenesis issue has been prompted by the appearance of treatment-related leukemias in 2 of 11 children treated by bone

marrow transduction and reimplantation (153,154) from X-linked severe combined immunodeficiency disease (X-SCID). The data in the first child suggests some kind of transcriptional activation event of the LMO-2 gene was involved. Interestingly, it has been reported that lentiviral vectors should be less likely to have this kind of effect as they have less read through of the 3′LTR polyadenylation site than vectors based on MLV-type C retrovirus (155). However, lentiviral SIN vectors are as leaky as MLV vectors. The X-SCID trial was performed using MLV-type vectors, and the results were unexpected given the large numbers of other retroviral vector-treated trial patients in unrelated protocols. Nevertheless, the observation will undoubtedly lead to further examination of the probability of such events in other trials using integrating vectors (155). There is no indication, however, from the hundreds or thousands of animals treated with lentiviral vectors so far that this issue will be a significant one in general.

VII. SUMMARY

Lentiviral vector development is at an exciting stage. Groundwork sufficient to allow their clinical use has been laid, although much more remains to be done before such agents become part of a licensed drug. The areas where such agents could be useful have been identified, and it now remains to see how predictive the extensive research and preclinical data are for human patients. Experience suggests that success in the preliminary indications will lead to further areas of use.

I. INTRODUCTION: SKELETAL MUSCLE AS A TARGET TISSUE FOR GENE THERAPY

Human gene therapy—clinical treatments aimed at introducing or repairing genes to provide long-term correction for a defect caused by acquired or inherited disease—has been rapidly shuttled from a realm of theory and speculation into one of impending reality. The first approved protocol for human somatic gene therapy entered clinical trials in 1990 (1); the number of clinical trials worldwide has since burgeoned into the hundreds. Although gene therapy is still in its infancy and has yet to overcome a variety of pitfalls and problems, significant progress has been made. In this chapter, we discuss some advances in developing efficient means of gene delivery and in regulating gene expression to achieve pulsatile protein delivery when desired and avoid toxic levels. Although many of the features of muscle described below make it ideally suited for adenoviral, adeno-associated viral (AAV), lentiviral, and naked DNA delivery, the primary focus of this is ex vivo gene delivery via intramuscular cell implantation. Ex vivo myoblast-mediated gene delivery results in robust, long-term production in skeletal muscle of recombinant proteins ranging from muscle-specific proteins to systemic circulatory factors. This approach holds the advantage over direct viral or DNA delivery that the genetic change occurs outside the body, and the transgenic cells can be screened for potentially deleterious consequences like tumorigenicity before being implanted into a patient. Moreover, problematic immunological effects currently associated with most other methods are avoided with autologous myoblast-mediated delivery.

Of the many preclinical studies past and present, a number of approaches have employed skeletal muscle for delivery of genes in attempts to treat muscle disorders and other types of diseases. Skeletal muscle has been a target of special interest for gene therapy because of inherent properties that set it apart from other tissue types. Among its advantages include the fact that it is a very well-studied and understood tissue. This knowledge is invaluable for engineering strategies of gene delivery, and for assessing and controlling therapeutic protein expression. Skeletal muscle comprises a large percentage of the total body mass and thus is easily accessible to gene delivery. Mature, differentiated myofibers are relatively long lived, providing a lasting substrate for the stable expression of recombinant genes. Myoblasts that are purified and genetically engineered in tissue culture can be reinjected and will then enter host fibers where they are nurtured, properly innervated, and in close proximity to the blood. The multinucleate nature of muscle cells facilitates delivery of 2 or more different vectors that encode products that can meet inside the cell. This is particularly advantageous for vectors with limited capacity, such as AAV, or for introducing gene regulatory systems (see below). Moreover, although rich in contractile apparatus and not obviously suited for secretion, genetically altered skeletal muscle tissue has proven to be a surprisingly efficient factory for the production and delivery of recombinant proteins to the circulation, allowing for the treatment of a broad array of muscle and nonmuscle disorders where cell type-specific expression is not required.

In addition to the ex vivo gene transfer approach, an in vivo method of gene delivery to muscle is currently being tested and developed. In the in vivo approach, a vector harboring a copy of a corrected gene or encoding a product that can remedy a patient's defect is introduced directly into the muscle tissue of the patient. The vector employed may be either viral

or nonviral in nature. Viral vectors that have been examined for their ability to transduce nondividing cells characteristic of muscle tissues include adenovirus, AAV, lentivirus, and herpes simplex type-1 virus (2–4). Although promising, in vivo approaches using viral vectors face several challenges, such as immune reactions elicited against viral elements (2,3). Although the most persistent expression has been seen with AAV (5–9), small capacity limits cDNA size, and difficulties in achieving adequate viral titers necessary for clinical trials have yet to be overcome. New generations of viral vectors characterized by more efficient production, lower immunogenicity and more stable expression are currently being developed that may prove to be powerful tools for muscle-mediated gene therapy.

Nonviral in vivo approaches for gene delivery to skeletal muscle center on intramuscular injection of plasmid DNA vectors. In the early 1990s, studies by Wolff and coworkers demonstrated that direct injection of naked plasmid DNA directly into the muscle tissues of mice led to transfection of skeletal myocytes and persistence of expression for at least 19 months in vivo (10,11). Naked plasmid DNA has also been shown to be taken up and expressed by cardiac muscle and skin (12–15). Plasmid vectors have a number of advantages for muscle-based gene therapy, and efforts to improve the efficiency of delivery appear warranted. These include simplicity of preparation and introduction into the host, and ability to be produced and stored in large quantities. In addition, the vectors are nonviral and are unlikely to be transmitted to other tissues. They also do not integrate into the genomes of host cells, precluding the risk of cancer by activation of a neighboring oncogene. Because achieving high levels of transgene expression using this approach has been problematic, direct plasmid DNA injection has been applied mostly to applications where only very low levels of transgene expression are required. One such application is in using intramuscular injection of plasmid DNA for vaccination purposes (16–19). Plasmids encoding antigenic proteins may be used to generate host antibodies specific to the antigen; because only small amounts of antigen are needed to elicit an immune response, plasmid vectors are well suited for this purpose. Recently, new progress has been made in developing methods for attaining stable, high-level gene expression using plasmid vectors. These include modifying DNA sequences within plasmids to enhance transcriptional efficiency of the vector (20), and combining plasmid DNA injection with the delivery of electric pulses to increase efficiency of myofiber transfection (21,22). Although promising, these methods require further study and development before they can be effectively applied to the therapeutic realm.

Cell-mediated or ex vivo gene delivery may provide a method of drug delivery for the treatment of a wide range of diseases (23). Skeletal muscle cells can be maintained as either proliferating or differentiating cells. The proliferative cells, known as myoblasts, are mononucleate muscle progenitors capable of fusing with each other to form new muscle fibers, or with preexisting myofibers (Fig. 1A). Myoblasts can be readily isolated from muscle and expanded in cell culture.

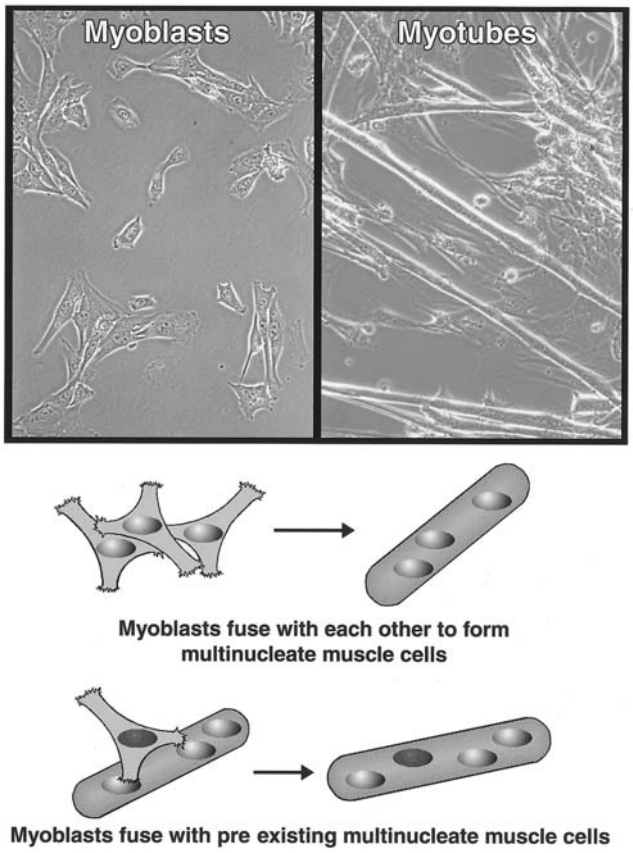

Figure 1 Myoblasts fuse to form multinucleate muscle cells. (A) Myoblasts are mononucleate muscle progenitor cells that can be isolated from muscle tissue and grown in cell culture (left). When provided with appropriate growth conditions, myoblasts fuse with each other in culture to form long, cylindrical, multinucleate myotubes (right). (B) Myoblasts can either fuse with each other to form new muscle cells, or they can fuse with preexisting muscle cells. Myoblasts of one genotype (shown with a dark gray nucleus) can fuse with multinucleate muscle cells of another genotype (shown with a light gray nucleus), thus delivering new genetic information to the preexisting muscle cell.

In vitro, they may be genetically engineered and extensively characterized, and then reimplanted back into muscle, where they stably fuse with myofibers (Fig. 1B). This unique property of skeletal muscle tissue has allowed for the development of myoblast-mediated gene transfer (24–26). Although the ex vivo approach of gene transfer to muscle is currently more cumbersome and costly than the in vivo approach, it provides certain advantages not offered by in vivo methods. Genetically altered myoblasts may be fully characterized in vitro before in vivo injection to ensure secretion of recombinant products of correct size and function at physiologically useful levels. In addition, isolated myoblasts are engineered outside the

body with retroviruses, a process that generally ensures that only the proper cell type is transduced. In contrast, introduction of viral or nonviral vectors directly into muscle could theoretically lead to inadvertent low-level transduction of cells other than those being targeted, for example cells of the germline. Finally, recent studies suggest that a major limitation to ex vivo gene delivery—the requirement that syngeneic myoblasts isolated from 1 patient be reinjected into that same patient to avoid rejection of cells by the immune system—may be overcome. Encapsulation of myoblasts overrides the requirement for a ''tailor-made'' therapy, allowing allogeneic cells that are invisible to the immune system to be used. Myoblasts appear advantageous over other cell types for this purpose because they do not overgrow and die within capsules, but instead differentiate and persist (27–29). Although this procedure prevents myoblasts from fusing into preexisting muscle, it theoretically allows universal donor cells to be derived from muscles of a single patient and implanted at ectopic sites in different patients for delivery of diverse products. All these advantages make ex vivo gene delivery via myoblasts a promising candidate for human gene therapy in the future. The remainder of this chapter focuses on ex vivo gene delivery to skeletal muscle.

II. DEVELOPMENT OF EX VIVO GENE DELIVERY BY MYOBLAST TRANSPLANTATION

A. Evidence for Myogenic Precursor Cells: Myoblasts

Skeletal muscle comprises approximately 10% of the total human body mass and is highly accessible to manipulation. A typical striated mature skeletal muscle cell, known as a myofiber, is large (1–40 mm in length and 10–50 microns wide), cylindrical, and multinucleated (as many as 100 nuclei per cell). Myofibers contain many nuclei because they are formed during development by the fusion of mononucleated precursor cells known as myoblasts. Myoblasts persist in mature muscle tissue as satellite cells, which can be viewed by electron microscopy as being ''wedged'' between the plasma membrane of the myofiber and the surrounding extracellular matrix (30) (Fig. 2). These cells can continue to fuse to neighboring myofibers in mature muscle, aiding in new muscle formation during regeneration following injury (31).

Interest in myoblasts as vehicles for gene delivery arose from studies of muscle cell biology and development. Studies of pattern formation in skeletal muscle showed that myoblasts are greatly influenced by extrinsic factors and become integrated into existing muscle fibers. Mammalian skeletal muscle is composed of a complex pattern of myofibers. Fiber types differ in their rate of contraction (fast and slow), determined in part by the ratio of fast and slow myosin heavy chain (MyHC) isoforms contained in each fiber (32). Although both fiber types occur in all skeletal muscles, the ratio of the 2 classes differs between muscles and even between different regions of a single muscle (33). Whereas lineage and myoblast-intrinsic

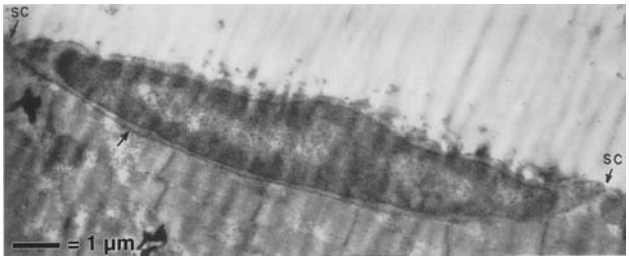

Figure 2 Satellite cell viewed by electron microscopy. Electron micrograph of a satellite cell in frog skeletal muscle, seen in longitudinal view. Extreme poles of the cell are indicated (sc). The arrow marks where the plasma membrane of the satellite cell juxtaposes that of the muscle fiber. (Reproduced from Ref. 30, p. 495, by copyright permission of The Rockefeller University Press.)

properties play a role in muscle fiber patterning, as shown by the finding that myoblasts expressing different slow isoforms are characteristic of different developmental stages (34), a number of experiments suggest that the environment is important in the generation and maintenance of that pattern (35). During early development of human limb muscle when multiple fiber types are forming, virtually all myoblasts, irrespective of the stage of development from which they are taken, give rise to clones expressing slow MyHC upon differentiation in culture. This is seen to be true even when myoblasts are taken from muscle at midgestation, when only 3% of fibers in vivo express slow MyHC. These results suggest that although culture conditions allow for slow MyHC expression in myoblasts, such expression seems to be repressed by extrinsic factors in vivo.

Additional experiments using retroviruses as heritable markers of cell fate in vivo further solidified these findings. When retroviral vectors encoding the reporter gene lacZ were injected directly into muscles of postnatal rats, clusters of multiply labeled fibers arising from progeny of single satellite cells were observed (24). The basal lamina, a connective sheath surrounding each muscle fiber, did not appear to prevent migration of labeled myoblasts into multiple fibers. Moreover, rat myoblast clones were shown to contribute progeny to both slow and fast muscle fiber types in their vicinity in vivo (25). These results demonstrate that mammalian myoblasts fuse randomly with all fiber types encountered, and adopt the pattern of myogenic gene expression characteristic of the host muscle fiber.

Transplantation studies further developed the notion of employing myoblasts for gene delivery, using allografts of minced muscle tissue (36) or pieces of intact muscle (37), and also by injection of muscle precursor cells (38–41). In these studies, isoforms of the enzyme glucose-6-phosphate isomerase were employed as markers to differentiate contributions of donor and host myoblasts to myofibers. The detection of hybrid fibers expressing isoforms containing subunits de-

rived from donor- and host-provided evidence that grafts of muscle precursor cells could alter the genetic makeup of, and contribute muscle proteins to, mature myofibers.

These initial experiments were of importance in establishing that myoblasts can fuse with all muscle fiber types in their vicinity, becoming fully integrated into mature muscle tissue that has access to the circulation and is innervated. In addition, muscle precursor cells of one genotype that are injected into muscle tissue of another genotype fuse to form hybrid muscle fibers, where they are capable of expressing donor genes. These findings paved the way for later studies examining applications of myoblast transplantation for the correction of various diseases.

B. Methodology: Purification, Growth, and Transduction of Primary Myoblasts

The ease of isolating myoblasts from both mouse and human muscle, and purifying, growing, and transducing them in vitro is a major advantage of using myoblasts rather than other cell types for gene transfer. Primary myoblasts can be isolated from any mouse strain—including strains carrying genetic mutations or transgenic strains (42,43)—providing a broad array of genotypes either for study in tissue culture or for transplantation. Moreover, because myoblasts may be isolated from a specific donor for implantation into a syngeneic host, problems of immunoincompatibility are obviated. Although established myoblast cell lines, such as the C2 myogenic cell line, may also be used for implantation, these cells can proliferate and form tumors when implanted into mice (44). In contrast, despite their impressive capacity to proliferate in culture, primary muscle cells do not form tumors upon injection into mouse muscle (44), and in the case of human myoblasts exhibit Hayflick-like senescence but not transformation (45).

Myoblasts can be isolated from muscle tissues from individuals of all ages, although both the yield and number of doublings tend to be higher if obtained from younger donors. Primary cultures are derived from postnatal muscle using mechanical or enzymatic dissociation methods (44,46), and readily obtained from human biopsy or autopsy tissue (47). Because such cultures are composed of a mixture of cell types, the population of myoblasts must be further purified. For primary cultures isolated from mice, this is accomplished using cell culture conditions that favor myoblast growth at the expense of other cell types, such that a pure population of myoblasts can be obtained within 2 weeks of normal growth (26,44). Human myoblasts can be purified by sorting in a fluorescence-activated cell sorter (FACS), employing fluorescent antibodies specific to the muscle surface antigen H31 or neural cell adhesion molecule (NCAM) (46). The cells that are isolated are capable of self-renewal and can undergo at least 40 cell doublings without differentiating (46). This implies that a kilogram of cells for transplantation use may be derived from a 5-mm^3 biopsy. Mouse (48) and rat (49) primary cells have also been isolated by FACS using antibodies to α7 integrin. Thus, a large population of rodent or human myoblasts may be easily obtained, purified, and expanded in cell culture.

Recombinant genes can be stably introduced into isolated and purified myoblasts using a number of methods, including lipofection, calcium-mediated transfection, or (more readily) by retroviral infection. Using conditions optimized for retroviral infection of myoblasts at high efficiency, 99% of primary myoblasts in culture are easily transduced without use of a selectable marker (50). This enables the creation of pure populations of primary myoblasts expressing a gene of interest, free of contamination by most nonexpressing cells. Myoblasts do not lose their ability to mature and differentiate by the process of being genetically altered.

III. APPLICATIONS OF MYOBLAST-MEDIATED EX VIVO GENE DELIVERY

Primary mouse myoblasts stably express recombinant genes following transduction. Myoblasts retrovirally transduced with the bacterial *lacZ* gene and injected into mouse skeletal muscle fuse with muscle fibers and express high levels of β-galactosidase (Fig. 3). The β-galactosidase expression can be observed in hybrid myofibers for at least 6 months (44). Other studies have shown that stable levels of recombinant proteins are produced for at least 10 months (51). Myoblasts that have been genetically engineered to express a recombinant gene may thus be used for stable delivery of that gene into the body (Fig. 4).

Although not widely viewed as a secretory tissue, skeletal muscle is highly vascularized and recombinant proteins secreted from myoblasts readily gain access to circulation. Initial studies using C2C12 myoblasts genetically altered to express human growth hormone (hGH) first demonstrated this to be the case (52,53). hGH was chosen as the gene of interest because it has a very short half-life in mouse serum (4 min) (54), providing a stringent test for sustained production and secretion into the circulation over time. After injection of genetically engineered myoblasts into mouse muscle, stable physiological levels of hGH could be detected for at least 3 months (Fig. 5). These results showed that myoblasts, by fusing with preexisting multinucleated myofibers, can serve as vehicles for systemic delivery of recombinant proteins. Thus, skeletal muscle may be used as a factory for production of a range of secreted gene products for treatment of nonmuscle-related disorders. Because muscle is capable of carrying out posttranslational modifications normally performed by other tissues (e.g., gamma carboxylation essential for production of functional coagulation factors in the liver), such recombinant nonmuscle proteins are biologically active even when produced by muscle (55–58). Applications of myoblast-mediated gene delivery to treat diseases affecting both muscle and other tissues are discussed in the following section.

IV. DISEASE TARGETS FOR MYOBLAST-MEDIATED GENE TRANSFER

A. Muscular Dystrophies

The concept of applying myoblast transplantation to the treatment of disease was a natural outcome of the many studies

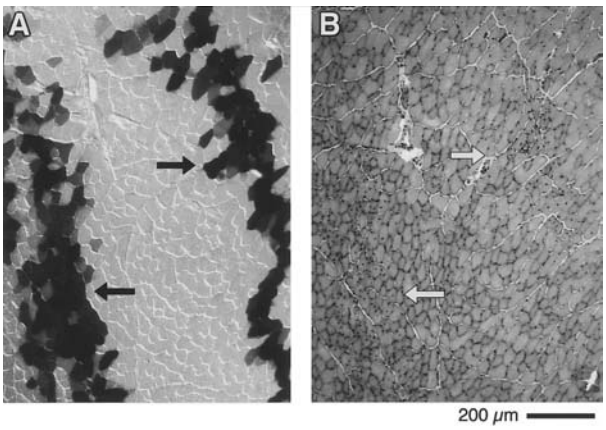

Figure 3 Incorporation of β-galactosidase-expressing myoblasts into skeletal muscle. Primary mouse myoblasts transduced with the reporter gene lacZ, encoding the bacterial β-galactosidase enzyme, were injected into mouse leg skeletal muscle, where they formed hybrid myofibers with host muscle. Injected muscles were isolated and frozen, and cryostat sections were prepared for histological analysis. (A) Hybrid myofibers producing β-galactosidase at the implantation sites can be seen as dark fibers after staining with the enzyme's substrate X-gal. (B) An adjacent section was stained with hematoxylin/eosin to show tissue architecture, and demonstrates that the hybrid fibers are of normal diameter and morphology and are an integral part of the muscle tissue. The centrally located nuclei that can be observed in (B) are indicative of myofibers that have undergone regeneration, and represent a normal response to a needle injection. The arrows denote corresponding regions in the two sections.

establishing myoblasts as potent vehicles for delivering donor genes into host muscle. The first approaches centered on the use of allografts of normal precursor cells to insert donor nuclei, containing a normal genome, into genetically abnormal muscle. Although not technically gene therapy (because donor myoblasts were not genetically engineered in any way), such ''cell therapy'' experiments were important in establishing the utility of myoblast-mediated gene delivery for the treatment of disease, and are the only studies involving myoblast transplantation that have translated into human clinical trials to date. The first disorder to which this therapeutic approach was applied was Duchenne muscular dystrophy (DMD), the most common of heritable human muscular dystrophies. DMD affects 1 in 3000 males and causes progressive muscle weakness beginning in childhood; patients with severe forms rarely survive past early adulthood. DMD is caused by mutations in the gene *dystrophin* (59), a large gene encoding a structural protein involved in anchoring skeletal myofibers to the extracellular matrix. By implanting myoblasts that contained normal copies of the *dystrophin* gene into dystrophin-deficient muscle, researchers hoped to rescue the genetic defect in humans as previously achieved in mdx mice, the mouse model of disease (41). In mdx mice, the implanted myoblasts were able to render host myofibers dystrophin positive while counteracting the characteristic cycle of fiber degeneration and regeneration characteristic of mdx muscle (41,60).

Clinical trials in which donor myoblasts taken from normal human muscle were introduced into DMD patients were initiated at multiple institutions (61–67). All these studies demonstrated that myoblast implantation into humans has no adverse effects. However, all but 1 group reported the disappointing finding that only a very small percentage of host myofibers resulted in normal dystrophin expression. At the protein level, these results could have been due to reversion or occasional expression by mutant host fibers of a truncated dystrophin detectable by antibodies. One group, however, provided definitive evidence that donor dystrophin transcripts were being synthesized by polymerase chain reaction (PCR) (62). Experiments combining fluorescent in situ hybridization (FISH) together with immunohistochemistry were recently conducted to examine the fate of individual myoblasts after implantation into muscles of DMD patients (68,69). This combination of techniques allowed the localization of both the dystrophin protein and the donor nuclei themselves, permitting more quantitative assessment of the efficiency of myoblast transfer. Findings from these studies showed that a large proportion of donor myoblasts successfully integrated into host myofibers in almost every subject; donor nuclei were interspersed with and aligned with host nuclei. Furthermore, these experiments demonstrated that increased dystrophin expression observed in recipient muscle was contributed by the donor nuclei and was not due to spontaneous reversion of the mutated *dystrophin* gene because the antibodies used were specific to the product for the deleted gene regions in the recipient. Moreover, the dystrophin produced by single nuclei spanned regions, including 20 to 30 nuclei. Why only a subset of transduced myofibers expressed dystrophin is still not understood. One hypothesis is that variables related to the DMD disease state itself, such as increased fibrosis with patient age, impaired myoblast access. An alternative hypothesis is that nuclei were not transcriptionally active in regions of fibers undergoing degeneration.

For treatment of muscular dystrophies by gene therapy, a large proportion of muscle fibers must be transduced to produce a beneficial outcome. Furthermore, myoblasts must be implanted into all muscles, some of which are difficult to access, such as the diaphragm and heart. Failure of these latter muscles is the cause of death in patients with DMD. These represent major challenges to myoblast-mediated gene delivery in treating inherited myopathies and suggest that a cell-based method may not be practical. Histochemical staining and enzymatic activity assays of muscle transplanted with β-galactosidase-expressing myoblasts show that the total number of labeled fibers and the total β-galactosidase activity is maximal at the implantation site, and decreases in parallel with increasing distance from the site (70). Although myoblasts were believed to be able to migrate from the circulation to damaged muscle (71), this is certainly not a frequent event. Thus, to target a high percentage of myofibers in multiple

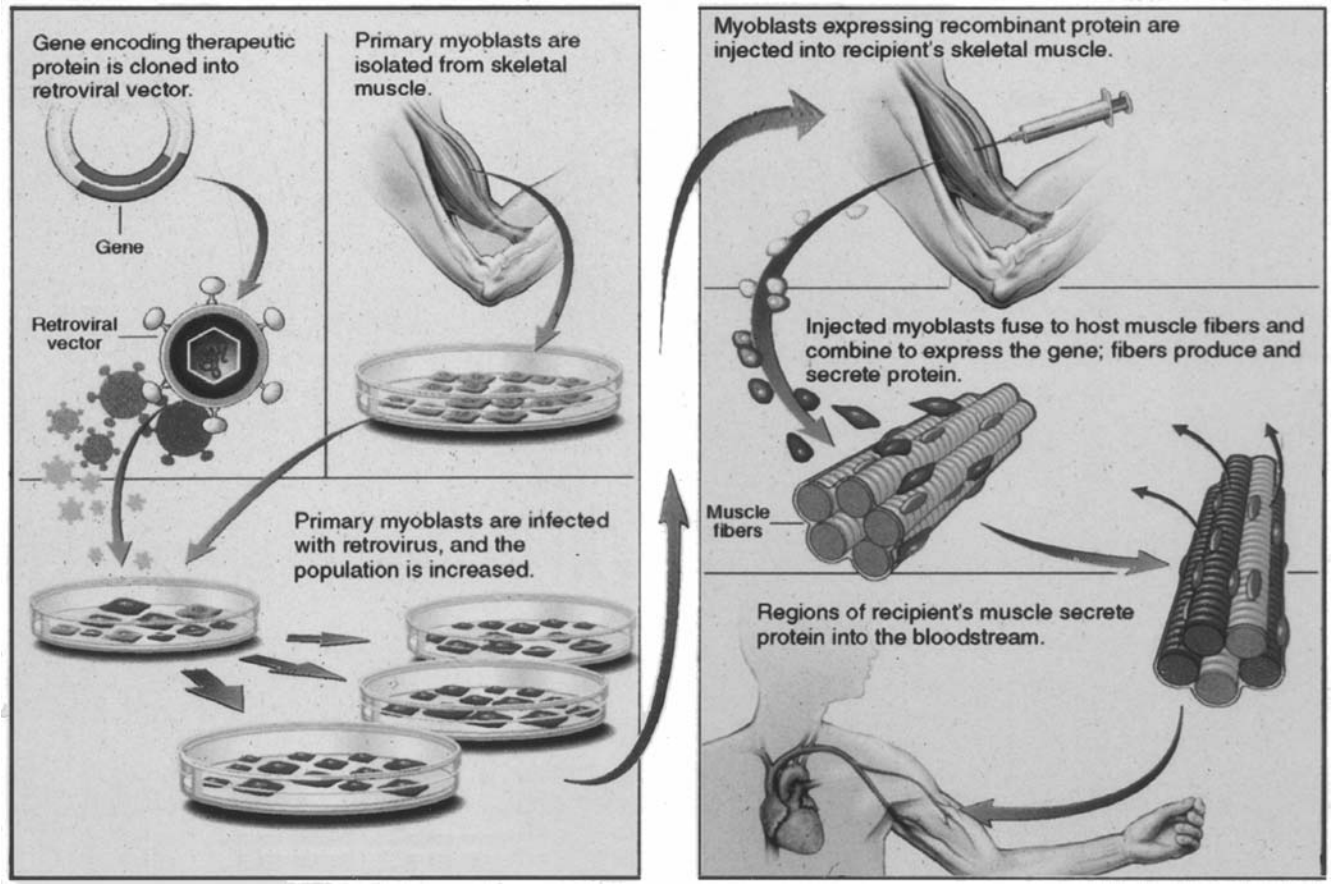

Figure 4 Muscle-mediated gene therapy. Muscle-mediated gene therapy by implantation of genetically engineered myoblasts allows for delivery of diverse therapeutic proteins, either directly to muscle or (as shown) to the systemic circulation. (Adapted with permission from Ref. 23, p. 1555. Copyright © 1995 Massachusetts Medical Society. All rights reserved.)

muscles of large organisms such as humans, delivery of viral vectors and naked DNA encoding either full-length or truncated dystrophin genes (72–74), or in the future the ubiquitous utrophin (75), may be most effective.

B. Lysosomal Storage Diseases and Serum Protein Deficiencies: Treatment by Secreted Circulating Recombinant Proteins

As described above, studies with hGH showed that myofibers efficiently secrete recombinant proteins that readily gain access to the circulation. Myoblast-mediated gene transfer has been further employed to express therapeutic proteins not normally made by muscle (51–53,55–58,76–79). Here we describe in further detail progress made in studies in which genes encoding β-glucuronidase, clotting factor IX, and erythropoietin were transferred to muscle using myoblasts.

Lysosomal storage diseases are a subset of disorders that may be appropriate for muscle-mediated gene therapy (80). These recessive disorders are caused by detrimental buildup of lysosomal enzyme substrates within affected tissues due to a single missing or dysfunctional lysosomal enzyme. Because these enzymes are marked with a specific targeting signal (mannose 6-phosphate) (81), missing lysosomal enzymes manufactured by muscle and delivered to the serum can be internalized by distant tissues and appropriately transported to lysosomes via mannose 6-phosphate receptors. By implanting into muscle genetically engineered primary myoblasts encoding β-glucuronidase, a lysosomal enzyme, 1 group was able to demonstrate in vivo expression of the recombinant protein in adult β-glucuronidase-deficient mice (77). Production and secretion of the missing lysosomal enzyme by muscle led to correction of phenotypic abnormalities in the liver and spleen of treated animals.

A second disorder well suited to myoblast-mediated gene therapy is hemophilia B. Hemophilia B is a blood-clotting disease caused by a deficiency of a protein, clotting factor IX. Because conventional protein replacement therapies face drawbacks, including the necessity for frequently repeated

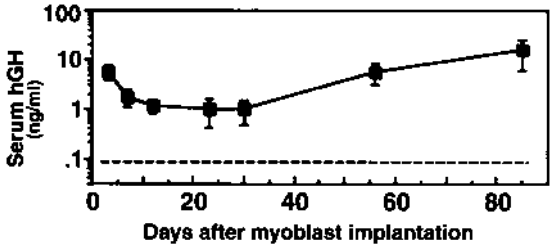

Figure 5 Systemic delivery of human growth hormone. A population of C2C12 myoblasts retrovirally transduced with hGH were implanted into hind limbs of 24 syngeneic mice, and serum hGH levels were monitored by radioimmunoassay of tail blood. Greater than 90% of the implanted cells expressed and secreted hGH as determined by clonal analysis in culture. Each point represents the mean ± SD for 4 to 24 mice; the dashed line shows the mean ± SD for serum samples taken from five uninjected control mice. Expression of hGH by implanted myoblasts persisted for at least 85 days in vivo. (Reprinted with permission from Ref. 53. Copyright © 1991 American Association for the Advancement of Science.)

treatments and the risk of contaminating blood-borne pathogens in plasma-derived factors, gene therapy may provide a safer and more convenient alternative (82). Initial studies in which C2C12 myoblasts were transduced with a gene encoding human factor IX and implanted into immunocompetent mice led to a peak expression of recombinant protein (1 μg/mL) at day 12, and subsequent decline back to basal levels thereafter (55). The drop in human factor IX expression was shown to be due to production of specific antibodies targeted against the protein in wild-type mice. Other experiments (56–58) demonstrated that primary myoblasts engineered to constitutively express factor IX led to stable, low-level production of the protein in immunodeficient nude or SCID mice for many months. Another study (51) achieved stable production of human factor IX at therapeutic levels in SCID mice, using a promoter with muscle creatine enhancers to drive high levels of muscle-specific expression, for at least 8 months. Of importance, recombinant factor IX manufactured in muscle undergoes the gamma carboxylation required for functional activity of the protein (55,56). This finding demonstrates that muscle cells have efficient mechanisms for posttranslational modifications normally carried out by other tissue types such as liver. Moreover, the problems with immunogenicity are likely to affect only a percentage of hemophiliacs, as not all are null mutations but have some, albeit reduced, level of factor IX (83). Until recently, only dog models were available, however, now a mouse model that lacks factor IX has been created by homologous recombination (84), which should facilitate future preclinical gene therapy studies.

A third class of disorders for which myoblast-mediated expression of recombinant proteins into the circulation may be beneficial is in the treatment of erythropoietin (Epo)-responsive anemias. Recombinant Epo replacement therapy has been employed for successful treatment of anemia associated with end-stage renal disease (85) and is being tested as a therapy for a broad array of other anemias (86). Epo is a mammalian hormone that controls the production of erythrocytes, hemoglobin-carrying cells that deliver oxygen to tissues of the body (87). Anemic patients can currently be treated by repeated administration of recombinant Epo; such treatments, however, require frequent hospital visits by patients and are costly. Thus, Epo delivery by gene therapy could provide patients with long-term delivery of the protein, eliminating the need for multiple treatments. However, as with many gene therapies, regulated expression is desirable for Epo, because dosage must be tailored to the particular application and to the individual patient.

Studies of muscle-mediated delivery of Epo by gene therapy appear promising. Epo-secreting primary or C2 myoblasts have been introduced bilaterally into skeletal muscles of mice (77,78). Implantation of engineered cells led to an elevated hematocrit for 3 months, a direct measure of Epo production. At 3 months posttransplantation, implanted myoblasts were observed to have fused and fully differentiated into myofibers (78). Moreover, in an animal model of renal failure in which anemia is induced by nephrectomy of immunocompromised nude mice, injection into muscle of C2 myoblasts secreting human Epo led to reversal of the anemic phenotype (79). Levels of recombinant serum Epo measured by enzyme-linked immunosorbent assay (ELISA) remained elevated for the 2 months during which the animals were assessed following myoblast implantation. These studies lend credibility to using myoblast-mediated expression of recombinant Epo as a viable treatment for anemias.

Thus, myoblast-mediated gene transfer appears to be well suited for expression of recombinant proteins to the circulation. Unlike applications aimed at treating inherited myopathies, not all fibers need to be transduced with the gene of interest to achieve a therapeutic effect. Indeed, such therapies can be highly localized to a particular region of a single muscle. For a variety of disorders where patients may benefit from delivery of a recombinant gene product to the bloodstream, myoblast-mediated gene transfer to muscle tissue appears to be a promising treatment method. Stable, long-term expression of physiological levels can be achieved with therapeutic effects, and because there is no immune response, repeated administration of genetically engineered myoblasts is possible, unlike AAV or adenoviral gene delivery.

C. Vascular Insufficiencies and Cancer

Since the 1990s, a great deal has been learned about growth factors that induce angiogenesis, the sprouting of new blood vessels from preexisting vessels. There has been much interest in the use of angiogenic factors to stimulate new vessels to grow as a treatment for maladies including stroke, peripheral arterial disease, and myocardial infarction. As the genes that encode these proteins have been cloned, the concept of thera-

peutic angiogenesis has moved quickly into the realm of gene therapy and clinical trials are already underway as low levels provide therapeutic effects. Factors produced by genetically engineered myoblasts are continuously produced by contrast with injection of pure proteins, naked DNA, and viral vectors, and may be advantageous.

The angiogenic factor that has received the most attention to date is vascular endothelial growth factor (VEGF), a potent mitogen that was isolated by virtue of its ability to stimulate growth of endothelial cells and to increase permeability in vascular endothelium (hence its other designation, vascular permeability factor) (88–92). VEGF plays an important role in the induction of angiogenesis by tumors (93), and in the angiogenic response of normal tissue to decreased oxygen availability. VEGF is also known to serve as a critical signal during the initial embryonic development of the vasculature by a process known as vasculogenesis, or the *de novo* growth of blood vessels from precursor cells (94,95). In this case, VEGF induces endothelial cell migration via specific receptors. Therefore, VEGF is a crucial regulator of both modes of growth and development of the vasculature pre- and postnatally.

Because of the potential clinical benefits of stimulating new blood vessel growth, much effort in recent years has been invested in the delivery of VEGF to tissues that are insufficiently vascularized. Injection of VEGF protein has resulted in angiogenic sprouting of vessels in muscle that was partially deprived of blood and oxygen, and therefore ischemic (96–98). However, presumably because of vascular permeabilizing and/or vasodilating properties, bolus injections of the protein have been reported to be deleterious, causing hypotension (99,100). As a result, recent investigations have assessed the feasibility of localized delivery of VEGF by gene transfer using plasmid DNA injection or adenoviral vectors. Both of these delivery methods lead to transient production of the recombinant protein, and to angiogenic sprouting from preexisting vessels in matrigel in vitro (101,102), in adipose tissues in vivo (103), as well as in ischemic skeletal or cardiac muscle (104–107). These results have led to clinical trials of VEGF gene delivery for ischemic heart and limb diseases (104,108,109).

The effects of long-term stable production of VEGF were recently investigated using the myoblast-mediated gene transfer techniques described above (110). This resulted in many unexpected findings. Myoblasts were transduced with a retrovirus carrying a murine cDNA encoding the heparin-binding $VEGF_{164}$ and injected into the muscles of SCID mice. A physiological response to VEGF was observed in every mouse that received VEGF-producing cells. At day 11 postimplantation, mice appeared outwardly normal and no differences were observed between VEGF and control muscle upon dissection. However, histological analysis of frozen muscle sections revealed that the implantation sites of VEGF-expressing myoblasts, but not control myoblasts, were invariably associated with regions of infiltrating mononuclear cells, identified by fluorescent antibody staining to multiple markers as endothelial cells and macrophages. By days 44–47, 100% of legs injected with VEGF myoblasts contained large hemangiomas composed of vascular channels and pools of blood, whereas control legs appeared normal (Fig. 6). These results have been reproduced in the heart following myoblast implantation into myocardium (111). However, implantation into muscle of clonal populations of myoblasts that express lower levels of VEGF results in an increased number of vessels without associated hemangioma formation (C. Ozawa et al., submitted). Interestingly, if the implanted cells are a mixture of myoblast clones expressing different levels of VEGF, due to genomic differences in retroviral insertion, the induced vasculature ranges from seemingly normal capillaries to hemangioma-like vascular sacs. This reveals a surprisingly localized response to VEGF on a microscopic scale and shows the importance of not exceeding threshold levels of VEGF, not only on a tissuewide level, but also on a per cell level. These studies demonstrate that myoblast-mediated VEGF gene delivery is extremely potent and provide evidence that this single growth factor can lead to a cascade of events resulting in the formation of complex tissues of multiple cell types. These results also show for the first time that exogenous VEGF expression at high levels or long duration can have deleterious effects, a factor of importance as clinical trials of VEGF gene delivery by plasmid DNA injection or adenoviral-mediated delivery are underway. Moreover, because myoblast implantation affords higher expression levels of longer duration than other gene transfer techniques, a physiological response to VEGF was observed in nonischemic muscle for the first time. Thus, the dose and duration of VEGF expression appear critical in determining a range of effects.

These results point both to the potency of myoblast-mediated gene transfer, and the necessity of regulation of recombinant gene expression for gene therapy applications. In the case of myoblast-mediated delivery of VEGF, too much of a good thing clearly can lead to adverse and unwanted effects. Gene therapy has usually been plagued by insufficient levels of the protein of interest. However, these VEGF results illustrate that current methods of gene delivery can be limited by a lack of ability to control gene expression. Both the ability to increase expression levels if an insufficient amount of a recombinant protein is being produced, and the option to intentionally reduce or cease expression, are likely to be necessary for the health of the patient in many cases.

In addition to studies aimed at triggering the growth of new blood vessels, other experiments are currently geared toward preventing blood vessel development in special circumstances. Because tumor growth and metastasis require persistent new blood vessel growth (112,113), therapies targeted at blocking this growth could lead to an arrest of tumor development. One of the most promising avenues for preventing angiogenesis in tumors may lie in the utilization of recently discovered antiangiogenic agents.

Early in the 20th century, it was first noticed that primary tumors are able to suppress the growth of a second tumor inoculum (114). Resistance to secondary tumor challenge was shown to be inversely proportional to the size of the second tumor inoculum, and directly proportional to the size of the

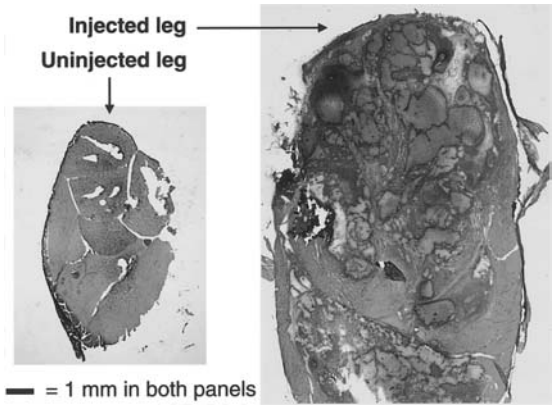

Figure 6 Formation of vascular structures in VEGF-myoblast-implanted legs. Myoblasts expressing the murine $VEGF_{164}$ gene were injected into mouse hindlimb. Histological analysis of injected muscles were conducted at day 44–47 postimplantation using hematoxylin/eosin staining of cryostat sections. Uninjected control legs were normal both in size and in morphology (left panel), whereas legs injected with VEGF myoblasts (right panel) were greater than twice the diameter of control legs, and consisted primarily of hemangioma and pools of blood. Both panels are shown at the same magnification. These results demonstrate the importance of regulating recombinant gene expression in gene therapy applications. (Adapted and reprinted from Ref. 110 with permission, copyright 1998 Cell Press.)

primary tumor (115,116). Moreover, removal of certain tumors can lead to rapid growth of metastases (117). Isolation of fractions taken from serum and urine that were capable of inhibiting endothelial cell proliferation in vitro and metastatic tumor growth in vivo led to the discovery of two antiangiogenic proteins, angiostatin (118) and endostatin (119), proteolytic products of plasminogen and collagen XVIII, respectively. A recent study demonstrated that viral vectors encoding angiostatin cDNA could inhibit endothelial cell proliferation in vitro and glioblastoma growth in vivo (120). An interesting therapy for cancer could be to engineer myoblasts to express these proteins, such that their secretion may inhibit growth of tumors at distant sites. Reconfirmation that desired blood vessel synthesis at sites of injury, for example, is not impaired would be critical. Because angiostatin and endostatin are difficult to produce in adequate amounts in bacteria, gene therapy protocols will be invaluable for discerning their biological function and possible application as anticancer agents in vivo.

V. REGULATABLE RETROVIRAL VECTORS AND THE RETROTET-ART SYSTEM

Until recently, all vectors employed in gene therapy protocols have depended on constitutive promoters to drive expression of the transgene. As made abundantly clear in the recent study of the effects of myoblast-mediated delivery of VEGF on normal adult muscle (110), regulation of gene expression is extremely important for safe treatment of patients. Both delivery by plasmid transfection or adenoviral vectors, the 2 VEGF gene transfer techniques currently being used in clinical trials, typically lead to transient gene expression that may be desirable in the case of angiogenic gene delivery. However, rather than count on inherent but uncontrollable limitations of the gene delivery systems, it may prove better to use a system that delivers sustained and excessive levels, but has been modified with regulatable control elements. This theoretically allows levels and timing of expression to be tailored to those that are deemed optimal on a case-by-case basis. An advantage of retrovirally transduced myoblast implantation is that it allows localized delivery of a recombinant gene at sustained levels; addition of inducible elements to retroviral vectors provides a mechanism for fine-tuning gene expression to the physiological levels required.

There are 4 characteristics that an ''ideal inducible system'' should possess. First, the regulatable system should demonstrate specificity—it should not require endogenous factors for activation, or interfere with cellular regulatory pathways. Second, the system should be efficient—demonstrating induction to high levels of gene expression from starting low basal levels, and the potential for repression back to uninduced levels. Third, it must be dose dependent, responding to its inducer by modulating its expression in a sensitive and homogeneous manner. Last, none of its components should elicit a host immune response or be toxic. To date, there are 4 regulatable systems displaying some or most of these characteristics: the ecdysone, RU486, FK506/rapamycin, and tetracycline-inducible systems. The first 3 systems are derived from members of the nuclear receptor superfamily (for ecdysone and RU486) or immunosuppressant compounds (for FK506/rapamycin) (for review, see (121,122)), and they may have potential effects on host genes in some cases. This section focuses on the attributes and recent advances of the tetracycline system, which has been extensively studied in our laboratory and has already been incorporated into myoblast implantation strategies.

The tetracycline-inducible system was originally developed by Bujard and coworkers (123,124) and has become one of the most widely used methods of regulating gene expression to date. All elements of the system are prokaryotic; thus, pleiotropic effects and endogenous ligands are avoided. In addition, because the inducer becomes an integral part of the transactivator directly responsible for turning on gene expression, there are no intermediate steps in the induction pathway. The tetracycline system thus allows for a more direct correlation between the amount of transcription factor capable of binding DNA, and the concentration of exogenous inducer [tetracycline (tet) or its synthetic analog doxycycline (dox)]. The pharmacokinetics of tet are well understood, and at the levels required for the inducible system, are well known to be safe for human use.

In its original and simplest form, the tet transactivator (tTA) is a hybrid factor comprising a bacterial tetracycline repressor (tetR) and the viral transactivator domain VP16 (123). When bound to tet, tTA is prevented from binding to tet operator sequences juxtaposed to a minimal promoter, and gene expression is turned off. In the absence of tet, tTA is free to bind to the inducible promoter, and gene expression is induced up to 5 or 6 orders of magnitude. A relatively recent modification of the system allows for induction of gene expression in the presence, rather than absence, of tet (124). A second chimeric protein containing a mutated version of tetR was developed and designated as ''reverse'' tTA (rtTA); this transactivator binds to tet operator sequences in the presence of tet. Both tTA and rtTA have been demonstrated to efficiently regulate expression in tissue culture, fruit flies, and mice (125–128).

A major advance in broadening the utility of the tet system was the employment of retroviruses. Retroviral gene delivery is much more rapid and efficient than transfection-using plasmids. Retroviral vectors also do not form concatemers and thus should not form a repressive chromatin environment sometimes associated with plasmids (129). Genes can be introduced into tens of thousands of myoblasts at high efficiency, generating polyclonal populations within a week (50), an advantage over the few stable clones routinely obtained. For these reasons, retroviruses are well suited for delivery of tet-inducible systems to primary cells isolated directly from tissue. Initial studies using tet-regulatable cassettes, however, met with numerous problems. In one case, the inclusion of an autoregulatory feedback loop necessitated high background levels of expression in order to ''jumpstart'' the system (130). In other cases, overcomplexity of transcription and translation units produced low viral titers (131–135).

Bohl and colleagues (136) first overcame this problem by using simplified retroviral vectors in which the necessary elements were dispersed over more than 1 retroviral vector. In this study, 1 retrovirus encoded rtTA, whereas the other contained an inducible Epo cassette. After multiple rounds of infection, primary myoblasts exhibited induction of about 200-fold in expression of the protein. When the engineered myoblasts were transplanted into mice, Epo expression could be repetitively turned on and off over a 5-month period by controlling levels of dox in drinking water. In an improvement of this approach, inclusion of a selectable marker such as green fluorescent protein (GFP) allows for purification by flow cytometry of regulatable populations of cells (128) (Fig. 7).

Recently, 2 additional advancements of the tet system have increased its applicability for gene therapy purposes. The tetR transcriptional elements are modular; one may replace the VP16 transactivator domain of tTA, for instance, with a KRAB transrepressor domain to create a tet-regulated repressor of transcription (137). Expression of 2 tet modulators within the same cell, however, leads to formation of nonfunctional heterodimers because the modulators have identical dimerization domains (Fig. 8) (138). Based on sequence information and known crystal structures of tetR as well as mutational analysis (139–141), mutually distinct dimerization domains deriving from separate classes of Gram negative bacteria have been identified (142,143). The ability to engineer tet modulators with specific dimerization domains allows tet activators and tet repressors to be expressed within the same cell without risk of forming a nonfunctional heterodimer. The development of such a tetracycline-inducible retroviral system, designated the RetroTet-ART (activators and *r*epressors expressed *t*ogether) system (142), allows for gene expression to be completely extinguished or induced in a fully dose-dependent manner—as a result, the dynamic range of gene expression has been greatly increased (Fig. 9). This improvement is a significant advantage in applications where basal expression from the inducible promoter must be extinct. The RetroTet-ART system was demonstrated to be able to reversibly silence expression of p16, a growth arrest protein (142).

In a second modification of the tet-inducible system, the DNA-binding domain of tetR was altered to interact with a modified tet operator sequence (143). The original and adapted binding sequences were engineered into tTA and rtTA proteins harboring distinct dimerization domains. By placing 2 separate genes under control of old and new tet operator sequences and expressing both of the modified tTA and rtTA proteins, Baron and colleagues were able to either repress expression of both genes or express either gene alone simply by changing the dox concentration (Fig. 10) (143). A means of turning on both genes at once has yet to be achieved. Thus, the activity of two different genes can be reversibly controlled in a mutually exclusive manner.

In summary, tet-regulatable retroviral systems are capable of being repressed and expressed in a fully inducible manner both in vitro and in vivo. Tet has been used for decades in humans and animals, and only at higher doses above those required for induction of transgenes have few if any deleterious effects been observed. In addition, when the rtTA protein was delivered to mice by ex vivo gene delivery using myoblasts, no immune response to foreign elements was observed (136). Retroviruses are efficient means of delivering tet-regulatable vectors to large numbers of primary cultures of cells, including myoblasts. Thus, there is much reason to believe that the tet-regulatable retroviral systems, in conjunction with myoblast-mediated gene delivery, may be well suited for gene therapy applications in humans in the future.

VI. FUTURE PROSPECTS FOR MYOBLAST-MEDIATED THERAPIES

A. Inherited Myopathies

As noted earlier, a problem in using the ex vivo delivery approach to treat inherited myopathies is that for such therapies to be effective, a large proportion of skeletal muscle must be targeted. Direct intramuscular implantation of myoblasts leads to fusion of the injected myoblasts to a majority of fibers in the region of the injection site; the number of fibers to which genes are delivered by this approach decreases with increasing distance from the site (70). Thus, for a sufficiently large percentage of fibers to be treated, many closely spaced injections

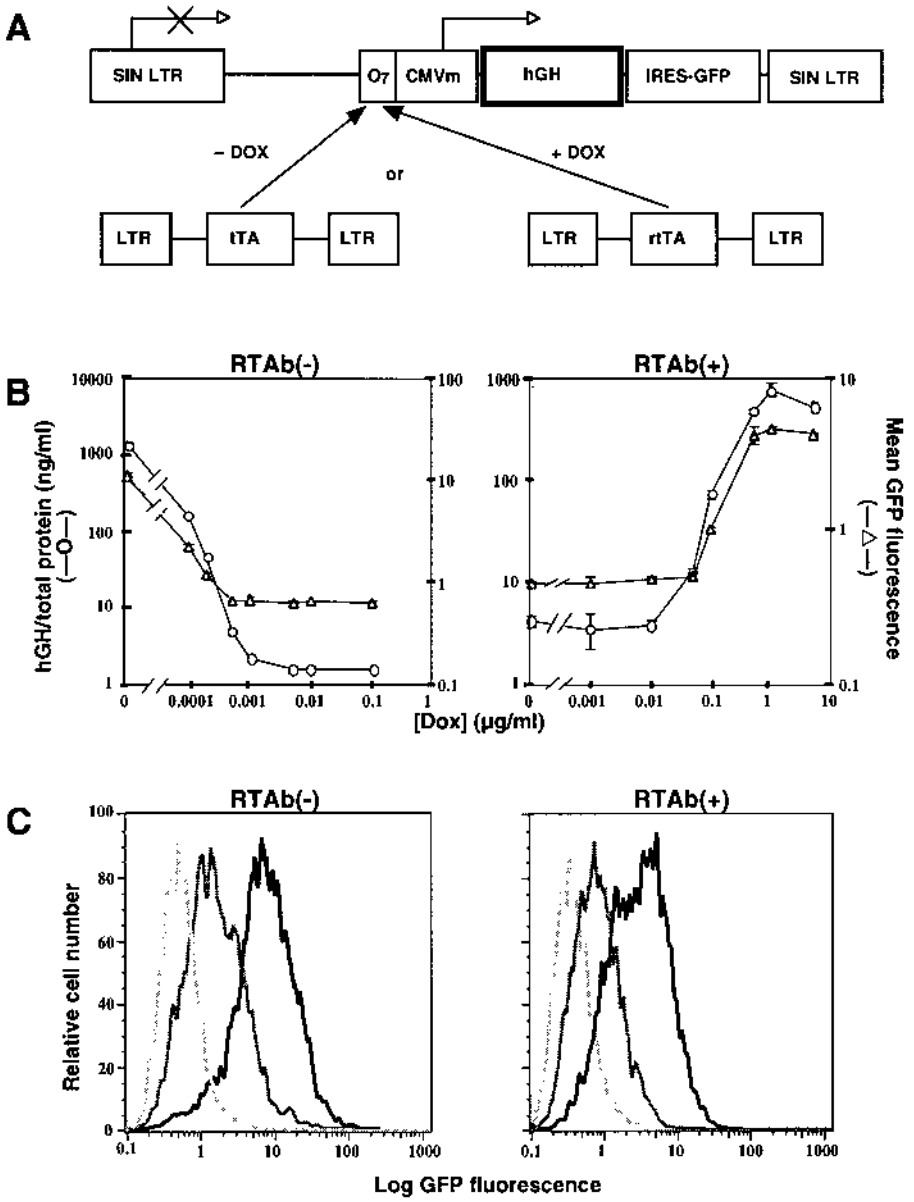

Figure 7 Tetracycline-inducible expression using tTA and rtTA. (A) Schematic of a binary retroviral system allowing tetracycline-inducible expression of both human growth hormone (hGH) and green fluorescent protein (GFP). The expression of both proteins is ensured by the use of an internal ribosomal entry site (IRES), allowing both genes to be encoded within the same mRNA transcript. The reporter virus contains a self-inactivating (SIN) retroviral backbone to avoid interference of the viral long terminal repeat (LTR) with the tet-responsive promoter (O_7-CMVm). The diagram represents the system after integration into the chromosome; hence, the SIN LTR exists in both the 5′ and 3′ positions. Tet-sensitive transactivators (either tTA or rtTA) are provided constitutively from a second retrovirus. (B) Dose response of the binary tet-inducible system shown in (A). RTAb(−) cells transduced with tet reporter virus and tTA virus, and RTAb(+) cells transduced with tet reporter virus and rtTA virus, were assessed for their dox dose response of hGH (○) expression and GFP (Δ) expression. Both systems exhibit concentration dependence over several orders of magnitude. (C) Histogram plots of GFP expression obtained from FACS analysis are shown in overlay at three selected doses [RTAb(−): 0.1 μg/mL (light gray), 0.001 μg/mL (dark gray), and 0 μg/mL (black); RTAb(+): 0 μg/mL (light gray), 0.1 μg/mL (dark gray), and 5 μg/mL (black)]. These plots show that with changing concentrations of dox, populations uniformly shift to intermediate and high levels of expression. (Adapted and reprinted from Ref. 128 with permission of the Proceedings of the National Academy of Sciences USA, 2101 Constitution Ave., NW, Washington, DC 20418. Figure 8 The need for tet modulators with distinct dimerization domains. Coexpression of tetR fusion proteins with different functional domains such as repressor domains (represented in the top row by the ''do not enter'' sign), and activator domains (represented by the ''go'' sign), or DNA-binding domains with distinct specificity (symbolized in the middle row by the light gray and dark gray ''feet''), leads to formation of both functional homodimers and nonfunctional heterodimers. Such nonfunctional heterodimers can be eliminated by engineering distinct dimerization domains into the tetR portion of the tet modulators (symbolized by the dark gray and light gray shaded midsections in the bottom row). (Reprinted from Ref. 138 with permission of the Proceedings of the National Academy of Sciences USA, 2101 Constitution Ave., NW, Washington, DC 20418. Reproduced by permission of the publisher via Copyright Clearance Center, Inc.)

would be necessitated. This requirement imposes a major limitation to the utility of myoblast-mediated gene transfer in treating human muscular dystrophies, which often affect cardiac and diaphragm muscles as well as skeletal muscles. Unless a myoblast population is isolated that can efficiently migrate to damaged or degenerated muscle, this approach seems too inefficient to be useful.

Recent observations that cells originating from bone marrow can become incorporated into regions of induced muscle regeneration has been met with much interest (144–146). This finding was significant because it elucidated the possibility that such bone marrow-derived cells can travel through the circulation and enter into skeletal muscle tissue (147). A possible solution to the problem of targeting skeletal muscles throughout the body may lie in introducing genetically engineered muscle precursor cells to the circulation, where they can reach muscles throughout the entire body. One study has examined the feasibility of intra-arterial delivery of genetically labeled, immortalized L6 myoblasts to skeletal muscle (71). After infusion of these cells into the arterial circulation, a small number of labeled fibers were observed in skeletal leg muscle, showing that the circulation may be capable of delivering muscle precursor cells to differentiated myofibers, although some were also found in the lung. Alternatively, if muscle stem cells of the bone marrow could be isolated, genetically engineered ex vivo and injected back into the patient, they could serve as a continual pool of circulating therapeutic effectors for the treatment of myopathies.

The existence of a muscle stem cell has been suggested from several pieces of evidence. Populations of cells that are capable of self-renewal and that give rise to differentiated cells have been identified both in the myogenic C2 cell line (148), and in clones of human myoblasts (149). In addition, a recent paper showed, using 2 genetic markers with different modes of inheritance to examine the fate of myoblasts transplanted into skeletal muscle, that only a discrete minority of transplanted myoblasts participate in regeneration of host muscle (150). This minority population of cells appears to divide slowly in vitro, but proliferates rapidly in vivo upon transplantation into regenerating muscle (150). If methods for characterizing and isolating this muscle stem cell population could be devised, such cells could be genetically engineered ex vivo and then introduced to patients, either by infusion into the circulation or through introduction to the bone marrow.

B. Circulating Therapeutic Proteins

The utility of myoblast-mediated gene delivery has broadened to include disorders that benefit from long-term secretion of recombinant proteins into the circulation, including treatment of lysosomal storage deficiencies, hemophilia B, anemias, and possibly cancer. For application of myoblasts in delivering genes encoding recombinant secreted proteins, a hurdle limiting its utility in the therapeutic realm is the necessity of using syngeneic cells to avoid immunological rejection of transplanted cells (151). Although myoblasts may be both isolated from and implanted back into the same individual, such procedures are both time consuming and costly. An alternative strategy would be to encapsulate myoblasts in an immunoisolated environment prior to implantation. Using this approach, myoblasts are enclosed within a matrix, for example, an alginate matrix (although other materials may be used), that allows secreted proteins to leave the capsules. The recipient's immune cells are prevented from coming into contact with the myoblasts, obviating the need for a genetically identical donor. This technology has been shown to be effective in delivering myoblasts engineered to secrete mouse growth hormone (27) and human factor IX (28) intraperitoneally. Encapsulated myoblasts were shown to be retrievable as long as 213

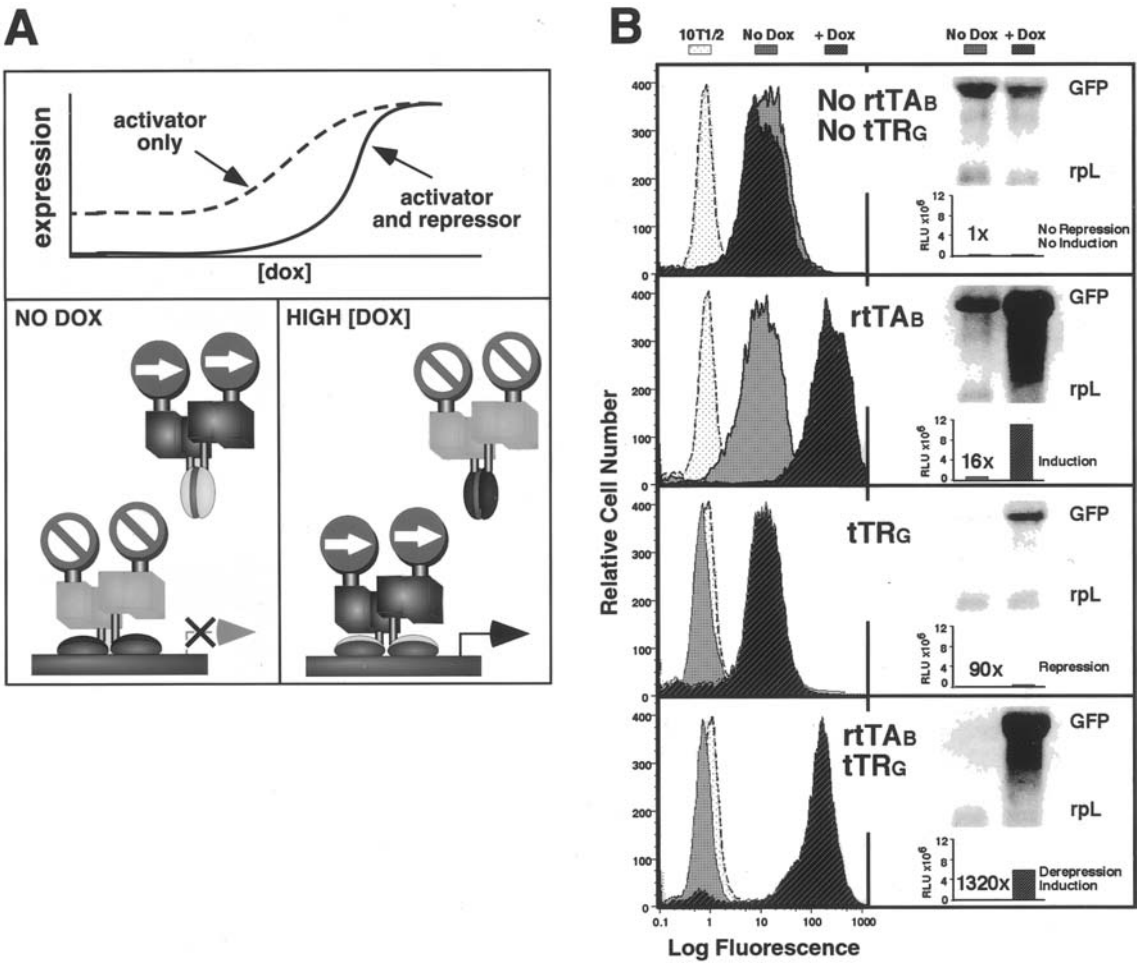

Figure 9 The RetroTet-ART system. (A) By coexpressing in the same cells a repressor and an activator that respond oppositely to dox and that do not heterodimerize because of different dimerization domains, the basal expression level of genes under tet control can be reduced without affecting the fully induced level. The net result is an increase in the dynamic range of the tet system (Reprinted from Ref. 138 with permission of the Proceedings of the National Academy of Sciences USA, 2101 Constitution Ave., NW, Washington, DC 20418. Reproduced by permission of the publisher via Copyright Clearance Center, Inc.). (B) Proof of concept of the RetroTet-ART system is demonstrated by FACS (left) and Northern blot (right) analysis. 10T1/2 fibroblasts were transduced with the GFP reporter retrovirus. Subsequently, cells were transduced with the transactivator retrovirus (b), the transrepressor virus (c), or with both transactivator and transrepressor virus (d). With the addition of both transactivator and transrepressor, the dynamic range of gene expression is increased. Gene expression can be fully extinguished, and induced to maximal levels, as shown in (d). (From Ref. 142 with permission)

days postimplantation. These cells were found to be fully viable and capable of secreting recombinant proteins ex vivo at undiminished rates even at this late time point (28). More recently, encapsulated primary myoblasts were used to deliver VEGF to mice subcutaneously and intraperitoneally, causing an angiogenic response (29). This type of technology provides a promising method of attaining nonautologous gene therapy, in which universal donor cells can be created simply by encapsulation in a benign, immunoprotective environment.

VII. SUMMARY

The types of disorders considered as potential targets for gene therapy has changed with the development of the field. Initially, most studies centered on developing therapies for single gene defect disorders; however, these present the greatest challenges. Thus, increasingly more attention is being paid to complex diseases involving more than 1 gene, such as cardiovascular disease and cancer, because these appear more tractable. In addition, although efforts attempting to correct genes

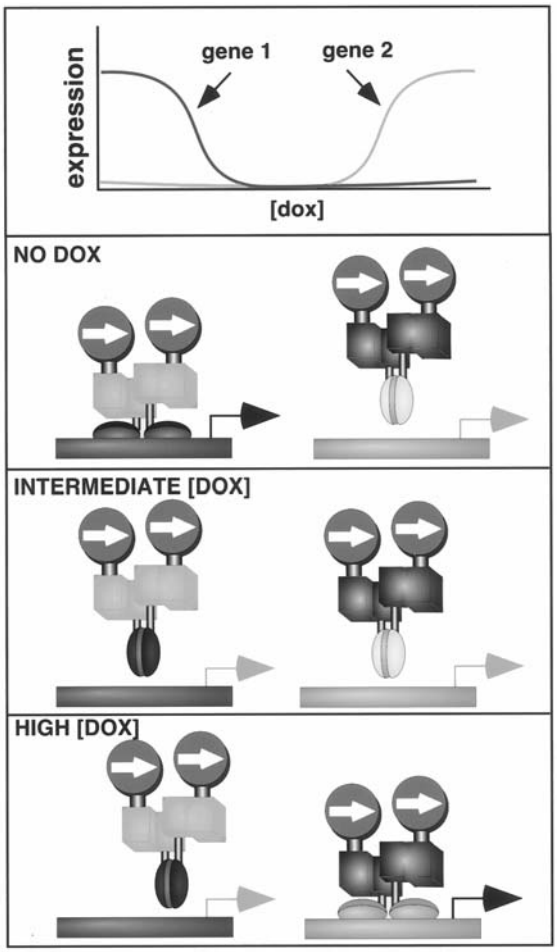

Figure 10 Tet-regulated expression of two separate genes. By coexpressing two tetR-based activators that contain DNA-binding domains with distinct specificity, respond oppositely to dox, and do not heterodimerize, two independent genes can be regulated by the same inducer. Because of the characteristic dose response of the wild-type and ''reverse'' tetR, the expression of each gene can be turned off at an intermediate concentration of dox and activated at markedly different dox concentrations. (Reprinted from Ref. 138 with permission of the Proceedings of the National Academy of Sciences USA, 2101 Constitution Ave., NW, Washington, DC 20418. Reproduced by permission of the publisher via Copyright Clearance Center, Inc.)

that are defective are under development, currently methods for complementing their defects through recombinant expression of related genes are more readily achieved. As the strategies for gene therapy develop in complexity, the methods available for treatment of disorders must also increase in their level of sophistication. Because of its many advantages, myoblast-mediated gene delivery may be a method well suited for addressing these needs for certain types of diseases. Myoblasts can be multiply transduced ex vivo with a variety of retroviral cassettes, each containing separate genes. The availability of improved tet-inducible retroviral vectors allows for fine control of recombinant gene expression levels. The 2 systems together—ex vivo gene transfer using myoblasts and regulatable retroviral vectors for transducing myoblasts—contribute a powerful toolbox with which to develop gene therapies for a number of human diseases. If myogenic stem cells prove to be readily isolated, cultivated, and able to migrate to muscle tissue, a large percentage of muscle could be targeted with relative ease, allowing for broad application in the treatment of both inherited myopathies and nonmuscle-related disorders.

I. INTRODUCTION

Vaccinia virus has been used clinically as a vaccine for smallpox since the late 18th century, and thus is associated with a rich history and extensive clinical experience (1,2). In 1798, Edward Jenner demonstrated protection from smallpox by vaccination with the cowpox virus obtained from infected milk maids. In the early 19th century, this evolved into the use of vaccinia virus (3). The precise origin of vaccinia virus is difficult to identify because the virus has no known natural host, leading some researchers to suggest that it may have arisen from mutations in the cowpox or smallpox viruses (4). However, it is more likely that vaccinia represents a distinct strain that is extinct in its natural host or so rare that it is difficult to identify naturally (5).

Vaccinia virus was widely used as a vaccine for the eradication of smallpox until 1978. Since then, it has been used experimentally as an in vitro gene expression vector and to express foreign genes as a vaccine for infectious agents and cancer (6). Vaccinia has many advantages over other viruses as a vector for gene delivery. Vaccinia has a wide host range. Its genome has been completely sequenced, facilitating the creation of recombinant vectors. It can hold up to 25 kb of foreign DNA without a need for viral deletions (7). Recombinant vectors are easily produced in high titers for use in vivo (8).

Vaccinia virus has also been modified to carry various antigens, cytokines, and immunostimulatory molecules (9). In fact, it has become evident that several properties make it useful as an oncolytic virus for cancer gene therapy (10). Any cell infected with the virus is rapidly killed, and cell-to-cell spread is efficient. Also, a natural tumor tropism exists in animal models. Applications requiring long-term gene expression, however, are not feasible with vaccinia. This chapter reviews the relevant aspects of vaccinia biology necessary for its use as a vector, and reviews the preclinical and clinical development of vaccinia virus as a vector for gene therapy.

II. BIOLOGY OF VACCINIA

Poxviruses are classified into 2 subfamilies, chordopoxvirinae (vertebrate poxviruses) and entomopoxvirinae (insect pox viruses), and at least 46 species (11). The classification scheme is based on host range, sequence homology, and antigenicity. Vaccinia virus is a member of the orthopoxvirus genus. It is genetically distinct from both cowpox virus and variola virus (smallpox). All members of the orthopoxvirus genus have immune cross-reactivity and are genetically stable. This allowed for the complete eradication of variola virus in 1977 (last case of endemic smallpox).

Multiple strains of vaccinia viruses exist (Table 1). As vaccination became widespread throughout the world, numerous centers produced and maintained the vaccine in different ways, resulting in numerous strains, which differ in characteristics, pathogenicity, and host range. The New York City Board of Health strain was obtained from England in 1856 and was originally used for smallpox vaccination in the United States (5). The Western Reserve (WR) strain is a laboratory derivative of this strain and appears to be one of the more virulent strains in laboratory animals and nonhuman primates.

It has not been used in patients to date. Another derivative, the Wyeth strain, was produced by Wyeth as a smallpox vaccine and is the backbone commonly used for experimental vaccines in clinical trials. The modified vaccinia ankara (MVA) strain was developed through multiple rounds of infection in avian cells. This strain is highly attenuated and does not replicate in human cells (12).

As with all poxviruses, the vaccinia virus is a double-stranded DNA virus whose entire life cycle exists within the cytoplasm of eukaryotic cells. The virus contains an outer envelope, as well as an internal membrane, and it carries the enzymes required for initiation of transcription. The genome of the Copenhagen strain of vaccinia virus was completely sequenced and reported in 1990 (13); other strains have been sequenced subsequently (14). The genome consists of double-stranded DNA with inverted terminal repeats and a terminal hairpin loop, which mimics a large, circular, single-stranded DNA. The genome consists of 191,636 base pairs encoding approximately 2063 proteins of 65 or more amino acids in length. It is among the largest viruses in size, averaging 270 $\times$ 350 nm in the shape of a brick (15).

Vaccinia has two infectious forms: the intracellular mature virus (IMV) and the extracellular enveloped virus (EEV) (16). The infectious form responsible for cell-to-cell spread in vivo is the EEV. IMV is the form recovered during viral purification in vitro, as it is released on cellular disruption. Purification of EEV is quite difficult because the EEV envelope is too fragile to withstand the purification process. The process of cell entry by vaccinia is not well understood and is complicated by the fact that there are multiple forms of infectious virus, and multiple cell types and species infected. EEV and IMV bind different but unknown cellular receptors as evidenced by different binding efficiencies among cell lines, and the observations that the enzymatic digestion of cell surface molecules and the binding of specific monoclonal antibodies to cells affects binding of EEV and IMV differentially (17). Consistent with this, confocal microscopy has shown that IMV and EEV enter cells by different mechanisms (18). The IMV contains several proteins on its outer envelope, including A17L, A27L, and D8L (19–25). D8L was one of the first membrane proteins identified in the IMV. It is nonessential in the viral life cycle but may mediate IMV binding to cell surface chondroitin sulfate (23,24). A27L may mediate vaccinia interaction with cell surface heparan sulphate. Virus infection is inhibited by 60% in the presence of soluble heparin

(22). EEVs are believed to be responsible for cell-to-cell spread and long-range transmission of vaccinia virus in vivo (26). Six proteins (encoded by A33R, A34R, A36R, A56R, B5R, and F13L) are EEV specific (11). However, A56R has no effect on infectivity or spread if mutated (27).

It may be possible to circumvent normal receptor requirements by engineering vaccinia virus to bind to alternative cell surface molecules. Consistent with this, expression of an ScFv to erbB2 on the surface of the EEV (created as a fusion with A56R) was shown to bind erbB2 by enzyme-linked immunosorbent assay (27). Creation of a fusion protein between an ScFv and A56R is technically feasible and may direct binding of the EEV to a specific antigen or cell type. Fusions of other surface proteins, including B5R have been reported (28).

The life cycle of vaccinia is illustrated in Fig. 1. Vaccinia virus (as with all poxviruses) spends its entire life cycle in the cytoplasm of the host cell and has never been shown to integrate into the host genome. Vaccinia has very few interactions with host cellular proteins, allowing for rapid, efficient replication without negative effects from host cell defenses. The virus induces a profound cytopathic effect very soon after viral entry, as early viral enzymes completely shut down host cell functions. By 4 to 6 h after infection, there is almost complete inhibition of host protein synthesis. This allows for very efficient expression of viral genes and viral replication. In fact, approximately 10,000 copies of the viral genome are made within 12 h of infection (29). Half of these are incorporated into mature virions and released.

After vaccinia enters the cell, it undergoes a process of DNA uncoating and transcription begins. Three stages of transcription—early, intermediate, and late—have been described, each with its own specific promoters and transcription factors (30). The enzymes required for initiation of transcription are encapsulated in viral particles and released on viral entry. Proteins needed for viral replication are synthesized at the early (prereplicative) stage of infection. A DNA-dependent RNA polymerase is injected with the virus into the cytoplasm leading to the synthesis of early mRNA. Translation of this RNA forms early proteins, which are involved in uncoating of the viral DNA, DNA replication, and intermediate transactivation for transcription of intermediate mRNA. Intermediate mRNA is then expressed, which encodes for late transactivators leading to late mRNA synthesis. Late proteins include structural proteins for membrane formation and early transcription factors to be incorporated into the new virus particle. Only a relatively small number of proteins are required for DNA synthesis, making the system simple and largely autonomous.

Unlike many viruses, which rely on cellular machinery to replicate, vaccinia replicates virtually as an independent unit. Artificial transcriptional control for gene therapy applications is therefore challenging. It is clear, however, that some cellular protein interaction with viral transcription may occur. One group has identified a cellular protein transcription factor YY1, with vaccinia late promoter-binding activity (31). YY1 has been shown to bind the vaccinia ILl late promoter (32).

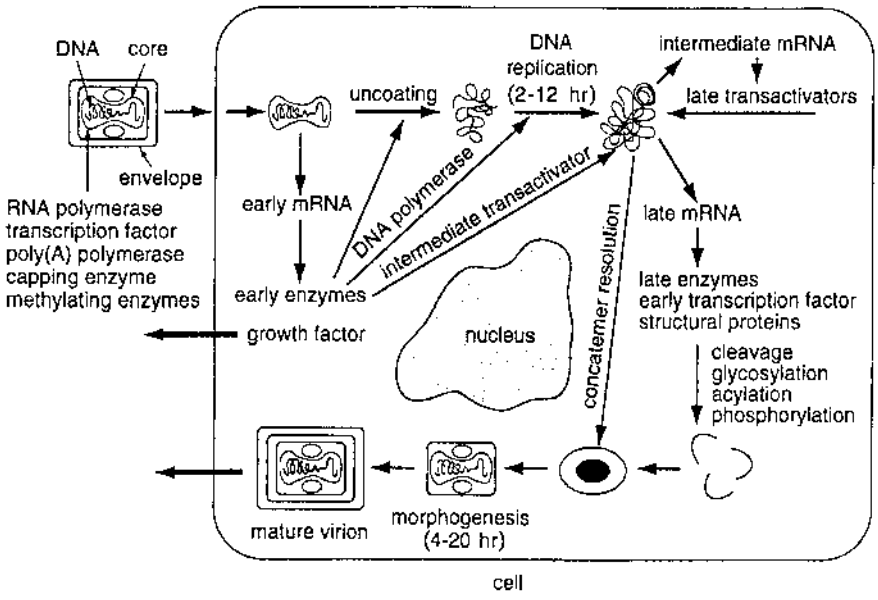

Figure 1 Schematic of vaccinia life cycle. (From Ref. 144.)

The vaccinia double-stranded DNA genome replicates in the cytoplasm, forming multiple concatamers of the genome. These concatamers are then resolved into individual genomes, which are encapsulated along with the early transcription factors into golgi-derived membranes. The first stage in the formation of infectious particles is the development of viral crescents composed of lipid and viral protein. To date, the origin of these crescents is disputed. Currently, the crescent is believed to be composed of a single lipid bilayer without continuity to cellular membranes (33). These crescents then coalesce into immature virus that lack infectivity. Immature virus then matures into IMV by condensation of the core and processing of core proteins (Fig. 2). IMV is transported to sites at which it becomes wrapped with 2 additional membranes. These membranes are derived from trans-golgi network membranes that have been modified by the inclusion of virus-encoded proteins and ultimately become part of the EEV outer envelope. These wrapped intracellular enveloped virus move to the cell surface where the outer membrane fuses with the plasma membrane, exposing the virus on the cell surface. If the virus is retained or reattaches it is called the cell-associated enveloped virus (CEV), but if released, becomes EEV. The A34R gene product plays a role in holding the virus to the cell surface. Mutations in A34R lead to increased EEV released and decreased CEV (34).

This entire life cycle occurs very rapidly. Initial RNA transcripts are detectible within 20 min of infection and DNA replication begins 1 to 2 h after infection. Within 12 h after infection, the majority of mRNA within the cytoplasm is from vaccinia-encoded genes. The entire replication cycle occurs in approximately 12 h (6).

III. CONSTRUCTION OF RECOMBINANT VECTORS

Homologous recombination occurs naturally during the replication of vaccinia virus, thus lending itself toward efficient insertion of foreign DNA. The creation of recombinant vaccinia vectors is relatively simple. The issues to be considered when creating a recombinant vaccinia vector include choosing a site for proposed recombination, a selection method(s), and a promoter for the foreign gene.

A shuttle plasmid is first created where a foreign gene expressed off a vaccinia promoter is flanked by vaccinia DNA sequences. Care must be taken that the foreign gene does not contain vaccinia transcription termination signals for early promoters (TTTTTNT) (35). The most common site of recombination has been the vaccinia thymidine kinase (TK) gene. Insertion of genes into the TK locus eliminates functional viral TK, leading to attenuation of the virus in vivo (36). Recombinations into numerous other loci have been performed, including intergenic segments such that no functional deletion occurs (37,38). The functional analysis of many vaccinia genes has been defined through insertional deletion.

A wide range of vaccinia promoters are available for expression of transgenes. It is necessary to use vaccinia promoters for creation of the recombinant vectors because these are specific for vaccinia polymerase. Eukaryotic promoters will not function in vaccinia infection because the host cell polymerase is not present in the cytoplasm where vaccinia transcription occurs. Several natural and synthetic early and late promoters have been described with various levels of activity (39–41). The native vaccinia promoters are generally very strong and compare favorably to other viral promoters used in other viral vectors. The synthetic early/late promoter described by Chakrabarti et al. (41) has led to consistent, reliable high levels of gene expression in numerous systems tested.

Several methods for selection of recombinant viruses are available. Growth in the presence of the thymidine analog BdUr can be used to select for a TK-negative phenotype in select cells after recombination into the TK locus (42). Others have commonly used the selection gene xanthine-guanine phosphoribosyltransferase, which allows for selective growth in media containing mycophenolic acid (43). Positive selection through replacement of an essential gene previously deleted from a backbone virus grown on permissive cell lines is also available (44). β-galactosidase and green fluorescent protein can aid in selection of recombinants. Once the shuttle plasmid is constructed, it can be transfected into a cell that has been infected with vaccinia. Homologous recombination leads to the insertion of the foreign gene into 0.1% of progeny virus genomes (6). The use of at least 3 rounds of selection ensures that there is no contaminating parental virus.

IV. IN VITRO GENE TRANSFER VECTOR

It has long been recognized that vaccinia is a valuable tool for expression of foreign genes in vitro (45,46). It is relatively easy to make recombinant viruses, and to grow and purify the virus. Large inserts can be accepted in the genome, and strong synthetic promoters lead to high levels of protein expression from infected cells. The virus has a broad tropism, and will infect and replicate in most mammalian cells. The high efficiency of expression with vaccinia obviated the need for other vectors, which permanently integrated into the genome and the cloning of high expressing cells. Infection with recombinant vaccinia leads to high levels of expression of foreign genes that are processed in the appropriate way such that their function can be studied. Vaccinia infection of cells at an multiplicity of infection (MOI) of 1.0 leads to >99% of cells expressing the gene of interest in most cell lines. Rather than make recombinants, simple plasmid transfection in a virally infected cell leads to efficient expression of foreign genes. The gene must be placed under control of a vaccinia promoter. The backdrop of vaccinia infection allows for cytoplasmic transcription, avoiding the inefficient process of trafficking into the nucleus. This leads to >90% of cells expressing foreign genes after simple plasmid transfection (47). This efficient transient expression system has been used for the functional analysis of innumerable foreign proteins over the years. Inactivation of the virus with psoralen and ultraviolet (UV) light can result in an efficient expression vector that does not cause a cytopathic effect (48). This may be important for the functional analysis of some proteins.

V. IN VIVO PATHOGENICITY AND BIODISTRIBUTION

Vaccinia virus has been used as a live vaccine in the smallpox eradication program, and more recently as a vaccine against cancer (49). It has not been widely accepted as a potential tumor-directed gene therapy vector, however, due to concerns regarding the safety of a systemically administered replicating virus. Although it is generally considered to be a relatively safe vector for vaccinations, a defined risk exists for generalized vaccinia, vaccinia-associated encephalitis, vaccinia necrosom, and eczema vaccinatum have been described in infants and the immunosuppressed population, specifically those with deficits in cellular immunity (50–55).

Vaccinia-associated encephalitis is a recognized complication of smallpox vaccination that can lead to death, and vaccinia can be recovered from the central nervous system (54). Classically, vaccinia infection in immunosuppressed patients leads to a progressive necrotic ulcer known as vaccinia necrosum. This ulcer can progress to destroy significant amounts of tissue, leaving exposed bone, requiring tissue grafts or amputation (56) (Fig. 3). Often this dramatic local infection does not lead to systemic viral spread. Patients with eczema, however, can get vaccinia infection of eczematous skin throughout the body (eczema vaccinatum). A large viral load such as this leads to fever and malaise and can lead to death from a ''septic syndrome.'' The exact cause of vaccinia pathogenicity and lethality in animal models is difficult to determine. Mice moribund from wild-type vaccinia infection have demonstrated high levels of circulating inflammatory cytokines, and it is

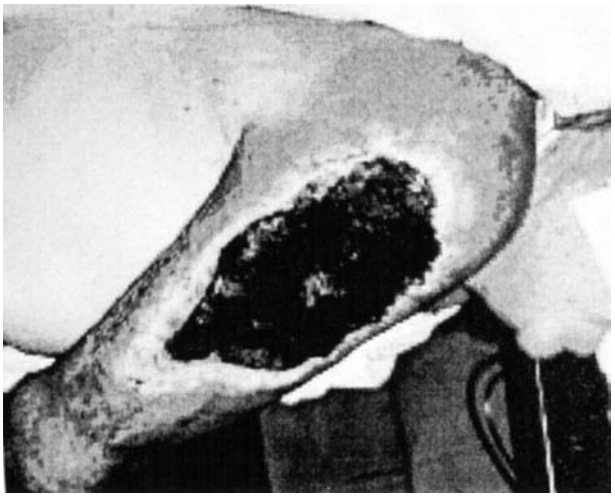

Figure 3 Example of vaccinia necrosum in a 66-year-old male 50 days after vaccination with a vaccinia melanoma cell lysate. The man had chronic lymphocytic leukemia. (From Ref. 145.)

suspected that the systemic inflammatory response syndrome plays a significant role in viral pathogenicity as opposed to specific organ dysfunction (Naiak et al., unpublished data, 1999).

The biodistribution of systemic injection of wild-type and TK-deleted vaccinia virus has been studied extensively in many animal models, including mice, rats, rabbits, and primates (10,57,58). The highest titers of recoverable virus are always from the ovary. Many fold less virus is recoverable from the liver, spleen, lung, and brain. Cutaneous pox lesions, which have high titers of vaccinia, can form. Mutations (e.g., TK deletion), which attenuate the virus by making it less efficient for replication in nondividing cells, are less recoverable from normal organs after systemic injection (59).

VI. HOST IMMUNE RESPONSE TO VACCINIA

The immune response to vaccinia viral vectors serves as our paradoxical friend and foe in attempting to develop them into effective vectors for gene therapy. On the one hand, the vigorous immune response is desirable because we believe that it enhances its potential as a vaccine. On the other hand, the vigorous immune response leads to premature clearance of the virus before adequate levels of replication have occurred, thus decreasing the level of transgene expression and possibly the overall efficacy.

Most viruses that infect human cells are also endemic in the population; therefore, many patients will have circulating antibodies against the viruses and preformed cellular precursors. Vaccinia is unique in that it is not endemic to humans, and because widescale smallpox immunizations terminated in the 1970s, young patients will not have been exposed to the virus. Most cancer patients, however, are older and have been exposed to vaccinia. As with other virus vectors, however, reinfection is possible after prior exposure. Laboratory workers and military personnel who undergo revaccination for smallpox usually form pox vesicles in the skin, despite prior vaccination. This has also been demonstrated in tumor vaccine trials in patients previously immunized (60). Workers at vaccine production plants in the past suffered from repeated skin infections with vaccinia and pox lesions in the skin. Some viruses can avoid circulating antibodies by mutating their coat proteins and changing serotype. This is not seen with vaccinia virus. However, vaccinia has evolved expression of immunosuppressive proteins (61). Viral surface proteins act as complement inhibitors, and the extracellular envelope is known to be almost completely resistant to antibody neutralization (62).

Both cellular immunity and neutralizing antibodies play a role in protection from vaccinia infection. The T cell response to vaccinia seems to be quite potent and is probably more important than antibodies in the primary host resistance to the virus. Progressive vaccinia correlates with a defect in cell-mediated immunity (63). In murine models, in the absence of a functional T cell population vaccinia is able to replicate and express genes within tumor cells at high levels for greater than 30 days (64). In an immunocompetent host, the window of gene expression only lasts for about 8 days with high levels of gene activity lasting approximately 4 days (58).

The success of vaccinia as a gene therapy vector relies on its efficiency in vivo. Vaccinia has developed a wide range of immune evasion strategies in order to survive in vivo (Table 2). Understanding and manipulating these factors may optimize the vector for clinical use. If one examines these factors closely, it is clear that the majority of them encode for proteins that are able to actively suppress both innate immunity and the development T helper 1 (Th1) immune response. For example, vaccinia virus has adopted at least 3 different genes whose product can block the function of the interferon (IFN) family members IFN $\alpha/\beta,\gamma$ (65–67). These factors are secreted by a variety of cells in response to innate danger signals. They can induce an antiviral state and up-regulate adaptive immune functions. Vaccinia also carries genes for multiple inhibitors of chemokines, some of the earliest substances produced during the initiation of an immune response (68–70).

Vaccinia encodes for at least 3 factors that can directly block the function of IFN-γ, one of the most potent Th1 cytokines (71–73). In addition, vaccinia encodes for the recently described IL-18-binding protein (IL-18BP) (74–76). IL-18BP is a naturally produced soluble factor that blocks the binding of IL-18 to its cognate receptor. IL-18BP has been shown to be one of the most potent inhibitors to the development of a Th1-biased immune response (77). Vaccinia virus also encodes for several other immunosuppressive factors, including factors to block complement activation, IL-1β soluble receptor, and soluble tumor necrosis factor receptor antagonist (78–81). These observations suggest that subverting the early innate immune response and slowing the development of Th1

Table 2 Vaccinia Gene Products that Inhibit Immune Response

Vaccinia open reading frame	Function
B13R (SPI-2)	Inhibits IL-1β converting enzyme
E3L	Inhibits PKR activation by dsRNA
K3L	Inhibits phosphorylation of eIF2α by PKR
A53R	Soluble TNF receptor
B8R	Soluble IFN-γ receptor
B18R	Soluble IFN-α/β receptor
B29R	Soluble chemokine-binding protein
C3L	Inhibits complement (C4B, C3B)
B5R	Inhibits complement
B16R	Soluble Il-1β receptor
A44L	Steroid synthesis

responses is important for the efficacy of vaccinia therapy (69,82).

Other studies have confirmed the critical role of Th1 response to clearance of vaccinia viral infection. Van den Broek et al. examined the effect of Th1 (IFN-γ, IL-12) and Th2 (IL-4, IL-10) balance in the clearance of vaccinia virus in mice using cytokine knockouts (KOs) (83). Vaccinia viral replication was enhanced in IL-12 and IFN-γ KO mice, with IL-12-/- demonstrating greater susceptibility to infection than IFN-γ-deficient mice. Interestingly, development of antivaccinia CTL was completely abrogated in IL-12 KO mice but remained normal in IFN-γ-/-. In contrast, IL-4- and IL-10-deficient mice showed marked enhancement of vaccinia viral clearance, suggesting that these cytokines naturally suppress the host response to vaccinia. IL-10-/- mice exhibited greater inhibition of viral replication than IL-4-deficient mice. When the effects of each cytokine on vaccinia infection was examined in recombinant viral constructs, local expression of IL-4 showed a much greater inhibition of host responses. In fact, although the absence of IL-10 resulted in improved clearance of vaccinia virus that was mediated by increased levels of IL-6 and IL-1, the local expression of IL-10 had little to no effect on viral clearance. Similarly, Deonarain et al. showed that IFN alpha/beta KO mice demonstrate markedly enhanced susceptibility to vaccinia viral infection (84).

There are several strategies that have been investigated to circumvent the problem of premature immune clearance. First, one could create a virus that is less recognizable by the immune system. This could be accomplished by mutating the viral coat of the vaccinia virus to make it less cross-reactive with antibodies. However, the poxviridae and, in particular, vaccinia virus is antigenically very complex and it is unlikely that 1 or 2 mutations in viral envelope genes could significantly alter antibody recognition. Further, any mutations in the viral envelope may decrease the infectivity of the virus. Another strategy would be to develop other poxviruses that are able to selectively infect and lyse human tumor cells that do not cross-react with vaccinia. Viruses from the Yatapox genus infect monkeys and secondarily have infected monkey caretakers (85). These viruses do not cross-react with vaccinia, yet they cause human disease and replicate in human cells. The yabalike disease virus is under investigation as another replicating poxvirus for tumor-directed gene therapy (86). Avian poxviruses also do not cross-react with vaccinia virus and have become popular expression vectors (87). They do not replicate in human cells and are less efficient vectors overall.

Another approach to circumventing premature clearance of our vaccinia vector is to create a viral recombinant that actively suppresses host cellular immune responses. Several groups have reported that insertion of Th2-like cytokines such as IL-4 or IL-10 into vaccinia virus increases in vivo viral replication and slows host clearance of infection (83,88,89). However, creation of a virus that is not recognized by the immune system obviously creates serious safety concerns for the population as a whole because unforeseen events could lead to a pathogenic virus that is not immunologically cleared.

A third approach to improving in vivo viral replication involves reversible transient host immunosuppression. Because of the growth of knowledge in solid organ transplantation, we now have available multiple immunosuppressive agents that can very precisely target specific pathways of the host immune response. This knowledge, combined with our growing understanding of the immune response to vaccinia virus, should allow us to reversibly slow the immune response to our vector. This will theoretically allow for more efficient in vivo viral replication in the tumor, higher transgene expression, and greater oncolysis. This will be a feasible approach with vaccinia mutants exhibiting tumor selectivity.

VII. SAFETY CONSIDERATIONS

Safety considerations for cancer gene therapy vectors include direct pathogenicity of the virus, toxicity of the therapeutic gene product, genome insertion with risk for malignant transformation and germ line mutations, teratogenesis, and the ability to recombine with endemic virus or spontaneously mutate to form a more virulent pathogen. Because vaccinia is a cytoplasmic virus, the viral DNA does not transport to the nucleus and therefore integration into the genome is very unlikely. In addition, there is no known latent infection with vaccinia virus and all cells infected by the virus will be killed by the virus. In addition, because poxviruses are not endemic in the population, it is extremely unlikely for recombinations to occur in patients between attenuated strains and wild-type strains, which would result in a more virulent virus with world health implications (90). The stability of the virus has already been proven during vaccination as part of the smallpox eradication program, so it is unlikely for spontaneous mutations to occur which would change the pathogenicity.

However, the properties that make it a useful virus for tumor-directed gene therapy also make it potentially dangerous. It replicates efficiently in human cells, and its pathogenicity as a systemically delivered virus in humans is unknown.

The scarification of the skin during vaccination for smallpox results in viral replication in the dermis, pox formation over 5 to 7 days, and an aggressive immune response against the virus, which eliminates the virus and prevents systemic spread. A permanent scar in the skin results from the infection. It is not difficult to imagine that, if such an infection occurred in an organ such as the brain, this could result in a poor outcome. During vaccination for smallpox, some patients with T cell-deficient immune systems suffered progressive systemic infection and death from vaccinia (63). In vaccine trials for HIV patients, deaths have been attributed to systemic viremia in the setting of an immunocompromised host (91). Although intradermal delivery is quite safe for the vaccine strains, more virulent strains such as WR delivered systemically may be more pathogenic. These viruses need to be carefully examined in preclinical toxicology studies prior to human trials.

Vaccinia and other poxviruses have been identified, designed, or treated such that they no longer replicate in human cells, but still efficiently express genes. These include the MVA strain (attenuated by serial passage in chick embryo fibroblasts, until it is no longer replicated in human cells), NYVAC (life cycle blocked prior to DNA replication in nonavian cells), fowlpoxvirus, and entomopoxviruses (92–94). Vaccinia can also be reliably inactivated using UV light and psoralen such that early genes are still expressed, but no cytopathic effect or replication occurs (95). Also, viral mutants can be constructed with deletions in essential genes preventing replication, except in cell lines where the gene is compensated for by stable integration into the genome. Although all these nonreplicating viruses improve the safety profile, they would not be expected to be efficient for the purpose of tumor-directed gene therapy. Any mutations that result in improved tumor specificity and decreased systemic virulence should be considered. An efficient strain of vaccinia virus such as WR may be mutated to inhibit replication in nondividing cells, but maintain efficient replication in tumor cells. This significantly decreases viral pathogenicity, but maintains vaccinia efficiency as a vector. An enzyme/prodrug approach may inhibit viral replication and provide a switch for turning off infection prior to host toxicity. Treatment with 5-fluorocytosine prolongs survival in a model where mice are administered a lethal dose of vaccinia expressing the cytosine deaminase (CD) gene. This was the original intention of ''suicide genes'' and needs to be explored further in vaccinia (96).

Other strategies toward improving the safety of this vector have been described (36,37,49,97,98). One strategy to attenuate the virus has been the deletion of genes required to evade the host immune response (61). As discussed above, vaccinia expresses several proteins that interfere with the host response to viral infection. These include inhibitors of apoptosis such as the serpins B13R, SPI-1, and SPI-2, inhibitors of cytokines such as interferon, interleukins, tumour necrosis factor, and mechanisms to evade complement (vaccinia complement control protein). Deletions of many of these proteins have led to attenuation of the virus. Safety can also be improved by actively improving the host immune response against the vector. Vaccinia engineered to express inflammatory cytokines are rapidly cleared by the host, leading to decreased pathogenicity. IL-2 expressing vaccinia is rapidly cleared by natural killer cells, leading to marked attenuation. IFN-γ expressing vaccinia was also less virulent (99). Another strategy to attenuate the virus has been the deletion of genes required for viral DNA synthesis. Deletion of the vaccinia TK gene or vaccinia growth factor genes renders the virus dependent on the nucleotide pool of the host cell (36,37). A mutant vaccinia virus with both the TK and vaccinia growth factor (VGF) genes were deleted was highly attenuated in nude mice (100).

VIII. CLINICAL EXPERIENCE

A. Smallpox Vaccination

Extensive clinical experience exists with vaccinia virus as a vaccine for the eradication of smallpox. The most common commercial preparation used in the United States was the Wyeth Dryvax (101). It is the only vaccine available today. The virus was produced by infection of live calves by dermal scarification, followed by physical scraping of the skin. Future vaccines will be produced on cell lines, and ongoing trials are comparing strains for safety and efficacy (56). The vaccine is delivered by scarification of the skin. The lyophilized virus is reconstituted and spread on the skin. A scarification needle is then used to penetrate the dermis through the vaccinia coat in multiple places. Effective vaccination is indicated by the development of pustules 6 to 10 days after vaccination. The pustules represent replicating vaccinia within the dermis. Live virus can be recovered from the pustules from days 3 through 14 after vaccination. There is a direct relationship between the intensity and extent of virus multiplication in the skin and the magnitude and duration of antibody response. The immune protection seems to last a lifetime, including both circulating antibodies and memory T cells (102). The current recommendation, however, is to be boosted with vaccinia every 10 years.

Adverse events occurred in about 1250 per million vaccinations, as described above, including vaccinia necrosum, vaccinia-associated encephalitis, and eczema vaccinatum (102). Aggressive dermal replication occurred almost exclusively in patients who were T cell immunodeficient. The majority of deaths occurred in infants who suffered postvaccinal encephalitis. The risk of complications increased with the more virulent strains of virus used in Austria and Denmark. Despite worldwide use of this live virus vaccine, no reported adverse events related to mutation of the virus to a more aggressive phenotype was ever reported. No viral-induced tumor formation has been reported. Overall, the virus is remarkably safe for use in humans, despite controlled viral replication in the skin of a potentially destructive virus.

B. Other Vaccines

After proven success as a vaccine responsible for the elimination of endemic smallpox in the world, the obvious leap toward using vaccinia as a vaccine for other indications was made, and vaccinia was engineered to express antigens from

other infectious agents. Likewise, as tumor antigens were recognized and defined, vaccinia was used as a cancer vaccine. The size of the vector allows for flexibility in engineering, such that immune-enhancing genes and antigen genes can be recombined together into the genome. In general, these approaches do not rely on targeting of any specific tissues and may not require viral replication, rather they are designed to take advantage of the immune stimulatory effects of the complex viral particle and the efficient transcriptional machinery of the virus. For safety considerations, nonreplicating vaccinia mutants were developed. The known inflammatory response to the vector combined with tumor antigens and immunostimulatory molecules holds promise for cancer therapy. The potential seems great, but controversy exists as to whether complex immunogenic viruses such as vaccinia may be less effective as vaccine vectors against proteins foreign to the virus.

Vaccinia virus has been used in multiple clinical trials as vaccines for treatment of a variety of tumors as well as treatment of infectious diseases such as rabies and HIV (Table 3). Vaccinia virus has been delivered as subcutaneous, intramuscular, intratumoral, and intravesical (bladder) injections in clinical immunotherapy trials without significant vector-related toxicity (60,103,104). Doses of up to 10^9 plaque-forming units (pfu) have been delivered safely. Intravenous injection of fowlpox virus has been performed with no significant toxicity; however, this species does not replicate in human cells. No systemic injection of a replicating vaccinia virus has been performed in human trials.

Allogeneic cell lysate vaccines incorporating vaccinia virus have been explored clinically. In these studies, vaccinia was not used as a vector, but as an immunogen. The virus was not replication competent. A phase 3 randomized, double-blind, multi-institutional trial of an allogeneic vaccinia virus-augmented melanoma cell lysate (VMO) vaccine was performed with 250 patients from 11 centers (105). A 10% survival advantage to VMO-treated patients was detected; however, this was not statistically significant. Hersey et al. in Australia also reported an improved survival in patients treated with an allogeneic vaccinia melanoma cell lysate vaccine (105,106). In many of these trials, DTH response and development of antibodies to tumor antigens correlates with disease-free survival. No vaccinia pathogenicity was observed.

Eder et al. reported a phase I trial of vaccinia expressing prostate-specific antigen in prostate cancer patients (108). The virus was delivered intradermally every 4 weeks for 3 doses. No significant toxicities were related to the virus, which was a Wyeth strain. A cutaneous reaction consistent with viral replication was seen in all patients treated with 2.65×10^7 pfu vaccinia or greater. Fourteen of 19 patients continued to demonstrate cutaneous replication after the third dose. Several patients developed T cell immune responses associated with prolonged stabilization of their cancer. Vaccinia expressing carcinoembryonic antigen (CEA) has been studied clinically as a priming vaccine followed by a boost with avipox expressing CEA (109). This regimen consisted of 1×10^7 pfu Wyeth strain vaccinia injected intradermally, and it was well tolerated. Specific T cell immune responses were generated without clinical responses. A good example of the utility of vaccinia as an immune vector is the development of rV-CEA TRICOM by Greiner et al. (110). This vaccinia expresses a triad of costimulatory molecules: B7.1, ICAM-1, and LFA-3, along with CEA for a vaccine against CEA expressing cancers. This vector demonstrated encouraging preclinical results and is now in clinical trials. Numerous other trials are in varying stages of accrual using vaccinia to express different tumor antigens.

C. Replication Selective Vaccinia "Oncolytic Therapy"

The extent of experience with vaccinia over the years and its proven safety record should lead to acceptance of exploration

Table 3 Recombinant Vaccinia Virus Used in Clinical Trials

First author	Vector	Results
Mastrangelo (60)	Vaccinia-GmCSF	Regression of injected lesions
Marshall (109)	Vaccinia-CEA	No clinical response
Mukherjee (114)	Vaccinia-IL-2	No clinical response
Eder (108)	Vaccinia-PSA	Stabilization of PSA levels
Sanda (126)	Vaccinia-PSA	Stabilization of PSA levels
Conry (127)	Vaccinia-CEA	No clinical response
Tsang (128)	Vaccinia-CEA	No clinical response
Graham (129)	HIVAC-le (gp160)	HIV immunity in healthy controls
Adams (130)	Vaccinia-HPV	Responses in cervical cancer
Kanesa-thasan (131)	NYVAC-JEV	Neutralizing Ab to JEV

Picard (135)	Vaccinia-gp 160	HIV immunity in healthy controls

of this vector in more novel delivery systems in terminal cancer patients. As the field of tumor-directed cancer gene therapy has developed, the study of tumor-selective replicating viruses has become an important endeavor. Because of the known ability of vaccinia to destroy tissue (a complication of smallpox vaccination known as vaccinia necrosom), vaccinia has also been developed as a direct oncolytic virus for cancer therapy. The concept of using replication-competent viruses to selectively destroy tumors is quite appealing. Numerous viruses have been explored as tumor-selective replicating vectors, including adenovirus, herpes simplex virus, reovirus, newcastle disease virus, autonomous parvovirus, and vaccinia virus (111,112). Advantages and disadvantages exist for each of these vectors, and some limitations are common to all vectors.

Vectors are most limited by inefficient replication in vivo, inefficient tumor targeting, and safety concerns. Vaccinia has many characteristics that overcome these limitations:

1. It has a quick, efficient life cycle, forming mature virions in just 6 h after infection;
2. it spreads efficiently cell to cell thus increasing the efficacy of in vivo infection;
3. it has a large genome that can accept over 25 kb of inserted DNA without deletions;
4. vaccinia virus carries its own strong promoters capable of achieving very high levels of transgene expression;
5. it can infect a wide range of human tissues but does not cause any known human disease;
6. there is a large body of knowledge about its biology and extensive experience with it clinically as part of the smallpox vaccination program.

Preclinical development has focused on mutating the WR strain of vaccinia virus to make it replication selective for tumor cells (100,113,114). The WR strain of vaccinia virus appears to be more efficient in vivo than other strains used in vaccination trials. An intradermal injection of 10^6 pfu of a wild-type WR strain of vaccinia in rhesus macaques leads to a necrotic ulcer of 108 cm^2 in diameter in only 8 days, without systemic spread of the virus. This compares with $<$ 1 cm for NYCBH and Wyeth strains (115). This ability to quickly spread, express genes, and destroy tissue to this extent is unique among current vectors in clinical and preclinical development.

We and others have studied the wild-type virus and found that after intravenous injection, the highest amount of virus can be recovered from the tumor, the second highest from the ovary, and minimal to no virus is recovered from other organs (58,100,116,117) (Fig. 4). The natural tropism of this virus to tumor is surprising, and the mechanism of this is not established. This tumor tropism was demonstrated in numerous tumor models, including murine colon cancer and melanoma, rat sarcoma, human colon cancer in nude mice, and rabbit kidney cancer. Historically, smallpox virus was noted to have

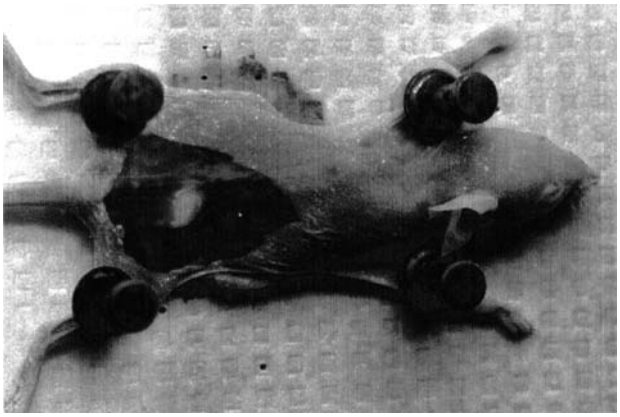

Figure 4 GFP fluorescence is specific for this subcutaneous tumor after intravenous injection of vaccinia-GFP. See the color insert for a color version of this figure.

tropism for injured and irritated skin. This is believed to be secondary to histamine release, leading to leaky vasculature and allowing for transfer of the virus out of the circulation. Vaccinia is a large virus particle (350 nm in diameter) and would require leaky vasculature for extravasation into tissues. Notably, the tumor and ovarian follicles are both known to be sites of vascular endothelial growth factor production and leaky vasculature. As demonstrated by immunohistochemistry, vaccinia tropism to the ovary is specific for ovarian follicles (100).

To develop a tumor-selective vaccinia, the WR strain of vaccinia was mutated such that the VGF and TK genes were deleted (100). The TK gene is important for nucleotide synthesis and DNA replication, and is near essential for replication in nondividing cells where the host nucleotide pool is low. Vaccinia growth factor is a protein that is expressed early by vaccinia virus and is secreted by infected cells. It binds growth factor receptors on surrounding resting cells and stimulates them to proliferate. This increases the available nucleotides in these resting cells, priming them for vaccinia infection. Deleting both the TK and VGF genes leads to near complete abrogation of replication in resting cells, without decreasing the ability of the virus to replicate in the tumor environment. This mutant virus was made and tested, and found to have markedly enhanced tumor specificity (Fig. 5). This virus was tested in rhesus macaques and was found to be completely nonpathogenic when delivered intravenously at doses up to 10^9 pfu (115). Intradermal inoculation at 10^6 pfu demonstrated no viral replication. Nevertheless, 4 days after intravenous virus delivery, equal titers of wild-type and double-deleted virus could be recovered from subcutaneous tumor in mice. This virus can be given systemically at doses of 10^9 pfu to a nude mouse without pathogenicity, and led to marked responses in established subcutaneous tumors (Fig. 6).

One limitation to mutating a virus for selective replication in dividing cells is potential toxicity to other dividing cells in

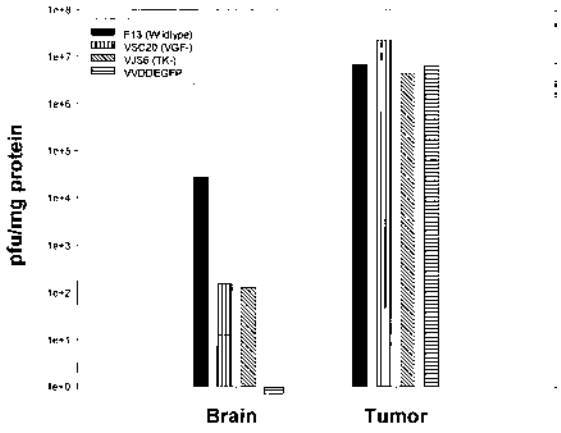

Figure 5 Differential viral recovery (median viral titers) from brain and tumor after systemic injection of 10^7 pfu wild-type, VGF-deleted, TK-deleted, and TK/VGF-deleted vaccinia virus in MC-38 tumor-bearing mice.

vivo. Vaccinia can efficiently infect almost all cell types in vitro, and it is hard to imagine delivering this systemically to animals or humans without significant pathogenicity. Other sites of dividing cells known to suffer toxicity from chemotherapy agents such as bone marrow-derived cells and gastrointestinal mucosa are not affected by systemic vaccinia in murine, rat, rabbit, or primate studies (10). The large virus seems to require a leaky vasculature for extravasation into tissues in addition to proliferating cells. This leaky vasculature is lacking in tissues such as the gastrointestinal mucosa. Despite bone marrow-derived cells having ready access to circulating vaccinia, no bone marrow toxicity is encountered, even

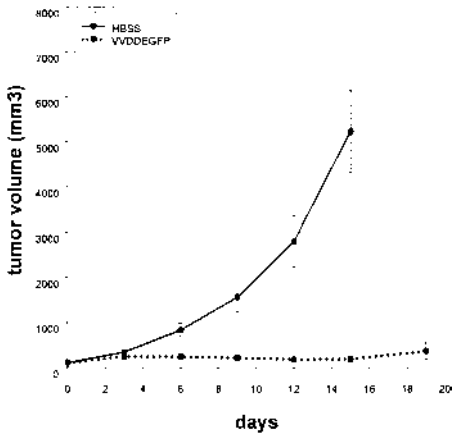

Figure 6 Antitumor response after systemic injection of 10^9 pfu of the TK/VGF-deleted virus in nude mice bearing 5-mm MC-38 tumors. (From Ref. 100.)

in animals succumbing to viral pathogenicity (unpublished observations, 1999). Bone marrow-derived cells are known not to infect well by vaccinia for unknown reasons. The one place that replicating virus is recovered is ovarian follicles. The developing follicle is much like a tumor with developing, leaky vasculature, high levels of VEGF, and replicating cells (118). Immunohistochemistry demonstrates that the double-deleted vaccinia replicates efficiently throughout developing ovarian follicles, without infection or spread through normal ovarian parenchyma.

Although no clinical trials to date have focused directly on the ''oncolytic'' activity of vaccinia virus, intratumoral injections have been explored. In 1974, Roenigk et al. described direct injection of melanoma with vaccinia from standard vialed smallpox vaccine (Wyeth strain) at unknown concentrations in 20 patients at 2-week intervals (119). Numerous interesting antitumor responses of injected lesions were described. Even older studies from the 1960s describe the treatment of warts with direct intralesional vaccinia injection with success (120).

Mastrangelo et al. reported their results of intratumoral injection of a NYCBH vaccinia strain expressing GM-CSF into cutaneous melanoma (60,121). This was a phase I trial of escalating doses up to 2×10^7 pfu per lesion and 8×10^7 pfu per session (multiple lesions injected). Patients were administered twice weekly intratumoral injections over 6 weeks. Systemic toxicity was limited to mild flulike symptoms that resolved within 24 h and local inflammation at the injection site with doses of $\geq 10^7$ pfu per lesion. All patients were vaccinated against vaccinia within weeks prior to receiving the vaccinia-GM-CSF. Interesting responses were seen in 5 of the 7 patients treated. Three patients had mixed responses with complete regression of treated and untreated dermal metastases, 1 patient had a partial response with regression of injected and uninjected regional dermal metastases, and 1 patient with multiple dermal metastases confined to the scalp achieved a complete remission. This group plans to extend their observations with continued clinical trials using this vector.

D. Treatment of Poxvirus Infection

The treatment of orthopoxvirus infections has become of widespread interest recently due to the terroristic threat of biological warfare with smallpox virus. Clinical trials using vaccinia as a gene delivery vector would benefit greatly from a drug or compound that could turn off viral replication. Vaccinia immunoglobulin (VIG) is the only approved product available for treating complications of vaccinia infection. VIG has been owned by the Department of Defense, with a small amount available through the Centers for Disease Control (55). No randomized controlled clinical trials have been performed to evaluate therapeutic efficacy; and prevention therefore, there is doubt as to its effectiveness in established complications from vaccinia. A randomized trial examining comcomitant treatment with vaccinia and VIG demonstrated a significantly lower rate of postvaccinal encephalitis.

Numerous antiviral drugs have been tested in animal models of orthopoxvirus infections (122) (Table 4). Of the

Table 4 Antiviral Compounds Effective In Vivo Against Vaccinia

Animal model	Compound	First author
Vaccinia keratitis in rabbits	Ribavarin	Sidwell (136)
Vaccinia tail lesion formation in mice following IV injection	Interferon	de Clercq (137)
Vaccinia tail lesion formation in mice following IV injection	Polyacrylic acid	de Clercq (137)

Vaccinia tail lesion formation in mice following IV injection	C-c^3 Ado	de Clercq (139)
Vaccinia tail lesion formation in mice following IV injection	3-Deazaneplanocin A, Ara-A	Tseng (140)
Vaccinia tail lesion formation in mice following IV injection	(S)-HPMPA	de Clercq (141)
Vaccinia related death in SCID mice following IV injection	(S)-HPMPC	Neyts (142)
Vaccinia related death in SCID mice following IV injection	H961 (diacetate ester prodrug of S2242)	Neyts (143)

licensed antiviral compounds, cidofovir has the greatest potential for protection against and treatment of vaccinia infections (123,124). Numerous other agents have also been identified that demonstrate efficacy against different poxviruses. The pharmacokinetics and safety profile of these agents have not been defined in humans, so their true utility will have to be determined. Suicide genes engineered into the virus may function to decrease viral replication upon addition of the prodrug. This has been demonstrated experimentally both in vitro and in vivo using a vaccinia expressing CD followed by the addition of 5-FC (64). Prolonged survival after inoculation with a lethal dose of vaccinia in a murine model was achieved with addition of prodrug compared with controls. Future studies with more potent enzyme/prodrug systems may enhance this effect. Combinations of antiviral drugs and prodrugs may improve outcome.

The development of tightly regulated inducible gene expression systems would allow for in vivo induction of genes, which would be toxic to the virus itself and inhibit viral replication. This has been difficult in vaccinia virus, because of its unique transcription system. Nevertheless, Traktman et al. reported on a tetracycline-inducible expression system in vaccinia (125). This system should be explored further to demonstrate the potential for in vivo induction of genes that are self-toxic.

IX. SUMMARY

Vaccinia virus is an interesting gene expression vector, which is worthy of continued exploration as a gene therapy vector. It is an efficient, destructive virus with some element of baseline tumor specificity. Powerful transcription machinery can lead to very high levels of therapeutic gene expression within tumor cells, and its immunogenicity may lead to an improved immunotherapy application. Mutations lead to tumor-specific replication and direct oncolytic applications. Because the vaccinia virus can include multiple genes, it would be possible to simultaneously express toxic genes, multiple suicide genes, cytokine genes, costimulatory genes, HLA genes, and tumor antigens.

Compared with other replicating vectors such as herpes virus and adenovirus, the study of vaccinia as a tumor-directed vector is in its infancy. Over time the advantages of this vector may become more apparent, and its applicability may be more significant as the population ages and more cancer patients have not been vaccinated against smallpox. Further understanding of the biology of the virus will improve our ability to manipulate it to our advantage and enhance its potential as a vector for tumor-directed gene therapy.

I. INTRODUCTION

The great potential of gene therapy has recently been supported by successful treatments of immune deficiency and cancer patients (1,2). However, much remains to be solved before gene therapy becomes a standard procedure. One major obstacle is the low efficiency of gene transfer (3); thus, further development of vectors is necessary. In this context, baculoviruses have raised increasing interest because they have a long history as safe and efficient gene delivery tools in insect cells (4), and the long-lived dogma of incompability with mammalian cells has recently been revised (5–7).

Baculoviruses are common in nature and the food that we consume, and have been known for hundreds of years. Still, no diseases have been linked to baculoviruses in any organism outside the phylum *Arthropoda* (8). Baculoviruses have been studied extensively since the 1950s as biopesticides (9) and, therefore, a lot of data are available about their biology (8) and biosafety (10). The baculovirus expression vector system (BEVS) became a popular choice for recombinant protein production during the late 1980s and 1990s, with a large number of commercially available reagents (4).

It became evident already in early 1980s that baculoviruses can penetrate into nontarget cells, including many human cell lines, but non productively. No viral replication or gene expression could be detected (11,12). However, in 1985, Carbonell et al. (13) reported a successful transduction of mammalian cells by a recombinant baculovirus bearing a promoter active in target cells [Rous sarcoma virus (RSV) long terminal repeat promoter] as part of the recombinant baculovirus genome. In 1995, Hofmann et al. (14) confirmed these results. They were also the first to suggest baculovirus-mediated gene therapy. There was a 10-year gap between these 2 papers probably because Carbonell et al. (15,16) later claimed that their initial findings of low-level gene expression in mammalian cells were due to pseudotransduction. During the late 1990s the concept of baculovirus-mediated gene transfer was further verified and the list of suitable target cells is still continuously increasing.

The fact that baculoviruses are efficiently destroyed by complement (17) delayed the first successful in vivo applications of baculovirus-mediated gene transfer to the beginning of the new millennium (5), although the feasibility of these viruses in an ex vivo perfusion model was reported soon after baculoviruses were suggested as tools for gene therapy (17). Several recent reports have also highlighted the use of baculoviruses in in vivo applications, especially in immune-privileged tissues such as brain or eye (18–20). Indeed, baculoviruses offer many advantages compared with other viral vectors in terms of safety, high capacity for the incorporation of foreign DNA, and easy production (Table 1). This chapter provides a detailed overview of the history as well as current status of baculovirus-mediated gene delivery. Future trends in baculovirus-mediated gene therapy are also discussed. For more detailed background on baculoviruses, the reader can refer to an excellent book, ‘‘The Baculoviruses,’’ edited by Miller (8) and a laboratory manual by O’Reilly et al. (4) de-

Table 1 Properties of Recombinant Baculoviruses that Make Them Suitable for Gene Therapy

Properties	Ref.
Easy to manipulate and produce at high titers ($> 10^{10}$ pfu/mL)	(4,5,18,66,90,106)
High capacity for DNA inserts (>50 kb)	(4,105,106)
Nonreplicative in mammalian cells	(21)
No evidence of viral gene expression	(12–14,140)
Little or low cytotoxicity at high moi	(17,77,80,81,90)
Broad cell-type specificity	(77,80–82,84)

scribing recombinant protein production in insect cells by the BEVS.

II. BACULOVIRUS BIOLOGY

Baculoviruses are a diverse group of rod-shaped viruses having a restricted host range, which is often limited to specific invertebrate species, especially insects (21). Baculoviruses constitute a family of viruses, the *Baculoviridae*, including more than 500 known members (22), which are believed to infect permissively only arthropod hosts. The double-stranded circular DNA genome (80–200 kbp) of baculoviruses (23,24) is condensed into a nucleoprotein structure known as a core (25). The core is located within a flexible rod-shaped capsid, which is 25–50 nm in diameter and 200–320 nm in length (26–28) and can expand relatively freely to accommodate even very large recombinant molecules (29). The core and the capsid are known collectively as a nucleocapsid. The nucleocapsids are made in the nucleus of infected cells, and they acquire membrane envelopes either by budding through the plasma membrane of the cell or by a nuclear envelopment process. Membrane-enveloped nucleocapsids are referred to as virus particles or virions (4).

Baculoviruses are divided into 2 morphologically distinct genera: nuclear polyhedrosis viruses (NPVs), and granulosis viruses (GVs). In the NPV group, virions that obtain an envelope from nuclear membrane are occluded within a paracrystalline protein matrix [occluded viruses, (OVs)], forming large (1–5 μm) polyhedral inclusion bodies (PIBs) containing multiple virions. NPVs are further distinguished on the basis of whether they contain a single nucleocapsid or multiple nucleocapsids per envelope in the polyhedrin matrix (30). In contrast to NPVs, GVs have only a single virion embedded in a very small inclusion body (4).

Baculoviruses have 2 distinct forms involved in their life cycle that play different roles during the natural life cycle of the virus (Fig. 1). OVs are responsible for horizontal transmission between insect hosts, whereas systemic spread within the insect and propagation in tissue culture is dependent on budded viruses (BVs) (8,31,32). Structurally, BVs and OVs differ by the origin and composition of their envelopes (33). They also differ in the mechanisms by which they enter the host cells. BVs enter the cells by adsorptive endocytosis (34), but OVs enter the midgut epithelial cells via direct membrane fusion at the cell surface (35,36). PIBs are formed during late phase of natural infection by embedding the virions in the crystalline protein matrix, which is composed mostly of polyhedrin protein (37). PIBs enable the horizontal infection of larva by contaminating the plant on which the larva feeds (38). The viruses are protected from environmental factors within the PIB, but in the alkaline midgut of the larva the crystalline polyhedrin matrix is solubilized (39) and the released OVs enter the midgut cells by fusion with the membrane of the microvilli (40). During the lytic cycle of infection, the cells release BVs from the basolateral area of the midgut cells (41). The spread of infection within the insect occurs from the midgut to most tissues by hemolymph (42). Eventually the larva dies and the PIBs that are produced in the very late phase of infection are released into the environment, and the cycle begins again. Most of the naturally occurring baculoviruses kill their target host within 4 to 7 days (9).

Baculovirus infection can be divided into early, late, and very late phases. Biologically these phases correspond to reprogramming the cell for virus replication (BV and PIB production). In the early phase (the first 6 h), the virus prepares infected cell for viral DNA replication. This phase is also known as viral synthesis phase. Virus-specific RNAs can be detected in the cells by 30 min postinfection (pi) (43). The late phase extends from 6 h pi to approximately 20 to 24 h pi. During this viral structural phase, late genes are expressed and the production of BVs starts around 12 h pi. Progeny nucleocapsids leave the nucleus and are transported onto the plasma membrane where they acquire their envelope. The occlusion-specific phase begins around 20 h pi. Production of infectious BVs decreases and packaging of virus particles into polyhedrin matrix as OVs begin followed by the cell lysis (4). The packaging into polyhedrin matrix (i.e., production of PIBs) does not take place with BEVS because the polyhedrin gene has been deleted from most baculovirus genomes used in biotechnology procedures.

A. *Autographa californica* Multiple Nuclear Polyhedrosis Virus

The prototype of the family *Baculoviridea* and the most extensively studied NPV-type baculovirus is the *Autographa californica* multiple nuclear polyhedrosis virus (AcMNPV). Its genome (~134 kbp) has been sequenced and predicted to contain 154 open reading frames (44). Although the 3-dimensional structure remains to be determined, the components of its cigar-shaped loosely enveloped virion have been extensively studied by protein chemistry (45). Vp39, p80, and p24 represent the major capsid proteins of the BV form of AcMNPV (Fig. 2). Among them, the vp39 is the most studied and is shown to be randomly distributed over the capsid surface. The major glycoprotein of AcMNPV is gp64, which is the only virus-encoded protein found to be associated with the BV envelope. It is believed to be responsible for the forma-

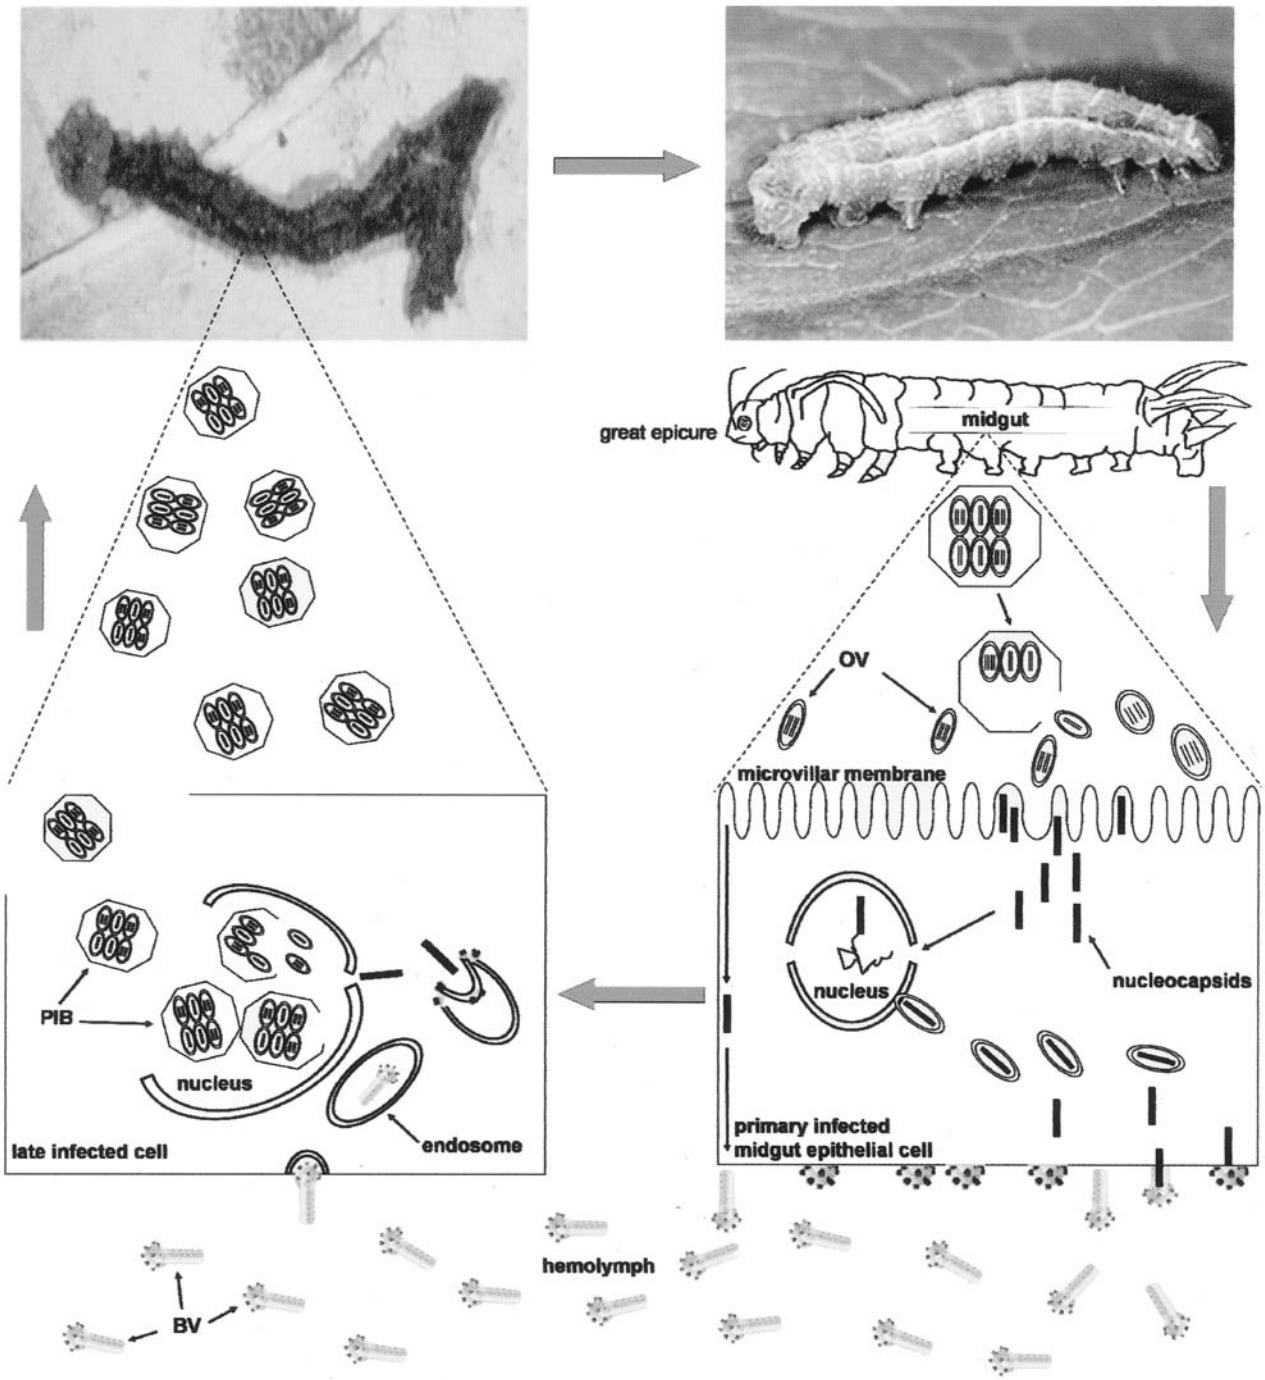

Figure 1 The life cycle of nuclear polyhedrosis virus (AcMNPV). Larva ingests occluded viruses (OVs) containing polyhedral inclusion bodies (PIBs) with their nourishment. In the alkaline environment of the midgut, the PIB break down and the nucleocapsids are released. They infect primarily epithelia of the gut wall. Viruses are fused directly to the plasmalemma of epithelium and the capsids are transported into the nucleus. A minor proportion of viruses may travel through the cells without infecting them in a process called transcytosis. The infection spreads through hemolymph inside the larva via budded viruses (BVs) that contain an essential protein gp64 in their envelopes. Later in the infection, occluded viruses are packed into PIBs inside the nucleus of the infected cells where these particles are released to the environment ready to infect the next hosts (horizontal infection) when cells are lysed and larva dies. , Polyhedral inclusion body; , occluded virus; , budded virus; , gp64 adhesion point in the plasma membrane of infected cells; | nucleocapsid. See the color insert for a color version of this figure.

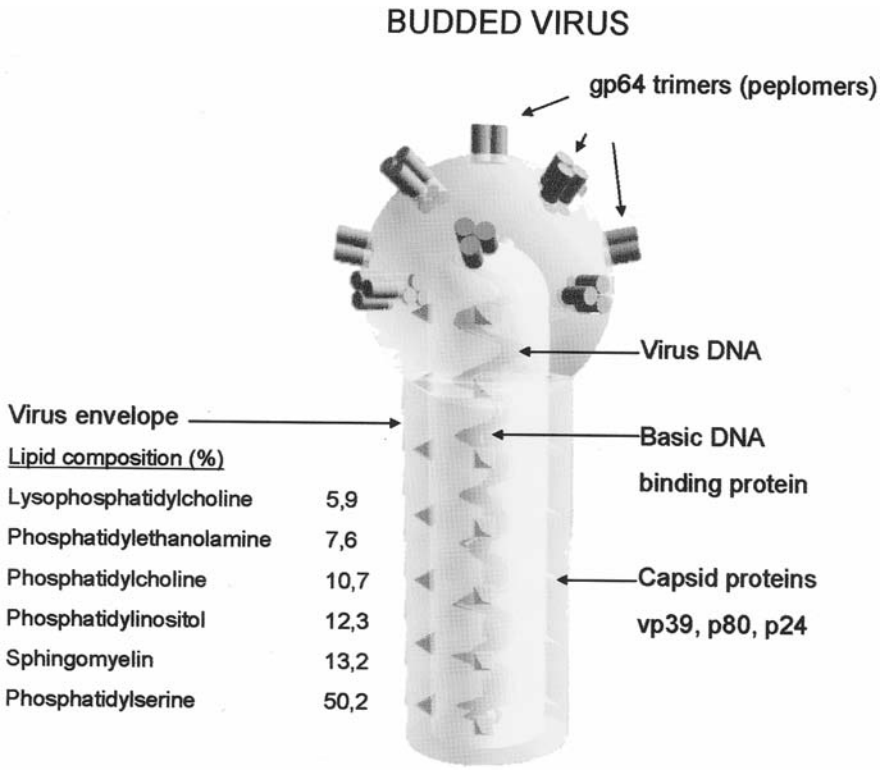

Figure 2 Schematic illustration of the budded form of AcMNPV. (Modified from Ref. 8.) See the color insert for a color version of this figure.

tion of so-called peplomer structure at one end of the virion (Fig. 2). The nucleocapsid of OV and BV are similar, but their envelopes differ in the composition (Fig. 2). The differences in lipid and protein composition of BV and OV envelopes reflect different origin and functions during the virus life cycle (46). Basic DNA-binding protein, p6.9, is shown to be present in the virions of several baculoviruses, including AcMNPV. It may become phosphorylated upon entry into the insect cells, which may result in unpackaging of the viral DNA (47,48).

AcMNPV enters cells by adsorptive endocytosis (34). The role of the major envelope glycoprotein, gp64, is essential for viral entry. It mediates pH-dependent escape of the AcMNPV capsid from the endosomes (49). gp64 is necessary and sufficient for virus preparation because it is needed for efficient virion budding from the insect cells (50). The cellular surface molecules for AcMNPV attachment and entry are not known, but the large range of target cells suggests that the molecules are common cell surface components such as integrins, phospholipids, or heparan sulfate proteoglycans (51–53).

The range of transfer plasmids and parent viruses available for the AcMNPV-based system, and the characteristics (growth, expression level) of the cell lines supporting AcMNPV, have made it a common choice for eukaryotic protein production. The most commonly used cell lines for AcMNPV are Sf-9 and Sf-21AE. They both originate from IPLB-Sf-21 cells, which were derived from *Spodoptera frugiperda* pupal ovarian tissue (54). A new cell line derived from *Trichoplusia ni* egg cell homogenates (BTI-TN-5B1-4 = High Five™), however, has become a popular alternative to Sf cell lines due to the fact that these cells have been shown to produce up to 28-fold more secreted proteins than any other insect cell lines (55–57). These cell lines grow well in both monolayer and suspension cultures, and a serum-free culture medium can be used if desired.

To enable expression of a recombinant protein in insect cells, the gene for the desired protein is usually placed under a strong polyhedrin promoter (*polh*) of AcMNPV (4). For other cells a promoter active in the target cells, such as CMV (cytomegalovirus), RSV, or CAG (chicken β-actin promoter) must be used because *polh* is inactive in these cells. The *polh* is normally responsible for the synthesis of polyhedrin, which can constitute up to 50% of the total protein of the infected cell. Fortunately, polyhedrin is not essential to virus replication or infection in the cell culture (58). However, the use of the *polh* promoter may be restricted in some cases by the fact that it is activated very late in the infection cycle at a point where the host cell machinery for posttranslational modifications is no longer functional. Problems with the *polh* promoter

have been encountered, especially with proteins whose biological activity depends on proper glycosylation (59). In such cases, the use of an alternative strong viral promoter that initiates transcription earlier in the infection cycle (while the host posttranslational modification pathways are still functional) could be useful. Indeed, Chazenbalk and Rapoport (60) were able to produce a more glycosylated and functional form of extracellular domain of the human thyrotropin receptor under a late basic protein promoter (*late*). Other promoters, which will be activated earlier than *polh*, include promoters for the p10 gene (*p10*), the major capsid protein gene (*vp39*), the basic 6.9-kD protein gene (*cor*), and the viral ie1 gene (*ie1*). These promoters are available in a variety of baculovirus plasmids (4,61–63).

B. Preparation of Recombinant Baculoviruses

Due to the large size of baculovirus genome (80 kbp–200 kbp) a homologous recombination procedure was originally adopted to insert foreign genes into baculovirus genome, instead of conventional plasmid cloning techniques (64). In practice, the target gene is subcloned into a transfer vector containing a suitable promoter, flanked by baculovirus DNA derived from a nonessential locus, such as the polyhedrin gene of AcMNPV. The viral DNA and transfer plasmid are then cotransfected into insect cells or yeast cells where the recombination events take place. Typically, 0.1% to 1% of the resulting progeny is recombinant, which complicates their identification. Because the target gene is inserted into the polyhedrin locus, altered plaque morphology of the recombinant viruses can be used for the identification of recombinant viruses. The cells, in which the nuclei do not contain PIBs, contain a recombinant virus. However, the detection of the desired PIB-minus plaque phenotype against the background of greater than 99% wild-type parental viruses is difficult. Viral identification may be facilitated by the introduction of a *lacZ* cassette (β-galactosidase) along with the foreign gene, which enables the detection of the recombinant viruses according to a blue color (4). Drug selection may also be used (65).

Recently, several techniques have been developed to further facilitate and speed up the construction of recombinant baculoviruses (63,66). By using a unique restriction site (Bsu361) at the polyhedrin locus, Kitts and coworkers (67) were able to linearize the double-stranded circular genome of AcMNPV. The linearization reduced the background of wild-type viruses and, as a result, 10% to 25% of the progeny viruses were recombinant. To obtain an even higher proportion of recombinants (85%–99%), Kitts and Possee (68) further modified the AcMNPV genome to enable Bsu361 digestion to also remove an essential gene (ORF 1629) from the AcMNPV genome. Infective viruses will only be reconstituted by recombination with the transfer vector carrying the gene of interest, whereby an intact ORF 1629 will be restored to the genome. The system also enables a blue/white color selection of the recombinant viruses. However, it suffers from the need of time-consuming plaque assays to purify the recombinant virus. A version of this system has been developed in which the target gene is amplified with specific primers using the polymerase chain reaction. This enables the ligase-free coupling of the linearized transfer vector and amplified gene in the mixture, which then can be used directly to transfect insect cells with cut viral DNA. The avoidance of cloning steps in *Escherichia coli* speeds up the construction of the recombinant virus (69). To ease the manipulation of ORF 1629-deleted baculovirus genome, Je et al. (70) recently described a bacmid form of this virus that can be maintained in *E. coli*.

Construction of the recombinant baculovirus genomes by traditional cloning techniques was reported by Ernst and coworkers (71). They introduced the I-*Sce*l meganuclease site into the AcMNPV genome by homologous recombination. The new virus genome, called Ac-omega, can be cut with I-*Sce*l meganuclease, and the target gene bearing compatible ends can be ligated straight to the linearized Ac-omega DNA under a polyhedrin promoter. This method is simple and less time consuming than conventional homologous recombination, but owing to the normal background problems encountered with traditional cloning techniques, the need of plaque purification cannot be entirely avoided. In addition, handling of the large AcMNPV genome (134 kbp) makes the method inconvenient. Another in vitro system based on the preparation of recombinant baculoviruses by versatile Cre-*loxP* recombinase has also been described (72). The advantage of this system is a possibility to recover cloned inserts from baculovirus genome into Cre/*loxP* compatible plasmids. However, only up to 50% of the viral progeny are recombinants.

To avoid laborious and time-consuming plaque purification process, the genetic material can be introduced into the baculovirus genome outside the insect cells. Patel and coworkers (73) reported a novel method of propagating the viral genome by homologous recombination in the yeast *Saccharomyces cerevisae*, where the appropriate recombinants can be more easily selected. Viruses are then obtained by transfecting insect cells. This method is rapid (pure recombinant virus within 10–12 days) and efficient, and it ensures that there is no parental virus background. It also eliminates the need for time-consuming plaque assays, and multiple recombinants can be readily isolated. The major disadvantages of this system are the need of experience in yeast culturing and the incompatibility of traditional transfer vectors with the system. An even faster approach for generating recombinant baculoviruses uses site-specific transposition with Tn7 to insert foreign genes into bacmid DNA (virus genome) propagated in *E. coli* cells. The *E. coli* clones containing recombinant bacmids are selected by color (β-galactosidase), and the DNA purified from a single white colony is used to transfect insect cells (74). The system has the same advantages as the yeast system but is faster (pure recombinant virus within 7–10 days) and easier to work with for those not familiar with the yeast cells. The poor selection features of the original system have been overcome by a modified donor vector (pBV boost) and an improved selection scheme of the baculovirus bacmids in *E. coli* with a mutated lavansucrase gene from *Bacillus amyloliquelaciens*. The new selection schema bypasses the disadvantages

associated with the original transposition-based generation of baculovirus genomes in *E. coli* while retaining the simple, rapid, and convenient virus production (75).

C. Baculoviruses and Nontarget Vertebrate Cells

Baculoviruses have been studied in the past for their ability to infect nontarget cells for safety considerations with regard to their use as biological pesticides. Volkman and Goldsmith demonstrated that baculoviruses were able to enter certain cell lines derived from vertebrate species (12). Thirty-five nontarget host cell lines, 23 of human and 12 of nonhuman vertebrate origin, were exposed to AcMNPV. However, no evidence of viral gene expression was obtained. This study was in accordance with the earlier reports showing uptake of AcMNPV by several vertebrate cell lines with no evidence of viral replication (11,76). Carbonell et al. (13) were the first to show that by constructing a recombinant baculovirus bearing a suitable promoter, marker gene expression in nontarget cells can be detected. Because a low level of marker gene expression was observed in the studied cells, it was claimed that marker protein was carried into the cells with the virus and not actively expressed in the cells (15,16). Several other publications, however, have confirmed Carbonell and coworkers' (13) initial findings and demonstrated that AcMNPVs containing mammalian expression cassettes can enter mammalian cells and express reporter genes under the control of strong viral promoters. Hofmann et al. (14,77) demonstrated that recombinant AcMNPV containing the luciferase gene under a CMV promoter can efficiently infect human hepatocytes (Huh7 and HepG2), as well as primary hepatocytes of human and rabbit origin. Boyce et al. (78) confirmed these results and showed that a virus carrying *lacZ* reporter gene under the control of RSV promoter led to a high-level expression of the marker gene in human hepatocellular carcinoma line HepG2, as well as in primary rat hepatocytes. More recently, primary rat and human hepatic stellate cells (HSCs) were shown to be highly susceptible to baculovirus-mediated gene delivery (79). These findings favor the potential of baculovirus vectors for liver-directed gene therapy.

Further studies have indicated that a high-level expression of marker gene can be achieved not only in hepatic, but also in other cell lines (77,80–84). Shoji et al. (80) transduced a panel of mammalian cells with a baculovirus vector carrying a marker gene in comparison with a replication-defective adenovirus vector. High-level luciferase activity was detected in this study not only in human hepatocytes, but also in other cell lines such as monkey kidney cells (COS7), porcine kidney cells (CPK), and human cervix carcinoma cells (HeLa). Furthermore, the same level of marker gene expression was observed in these cells by both viruses, but as an advantage for the baculovirus, much lower cytotoxicity was associated with it than adenovirus at a high multiplicity of infection (moi). The use of CAG promoter in this study resulted in a 10-fold higher level of luciferace gene activity than in the previous study with a CMV promoter (14). This indicates the importance of the promoter and the expression cassette per se for successful transduction of target cells not only by baculoviruses, but also by any other gene delivery vector (20,85–88). High-level expression of T7 RNA polymerase was also directed by CAG in HepG2 and CPK cells, and lower expression was observed in some other cell lines (81). Condreay et al. (84) demonstrated that recombinant baculoviruses containing green fluorescent protein (GFP) gene under the CMV promoter can transduce a wide range of mammalian cell types originating from different tissues. Cell lines of hepatic origin were transduced efficiently, as described earlier, but notable gene expression was also detected in cell lines derived from kidney tissue (Cos-7, BHK, CV-1, 293) and other nonhepatic hepatic cell lines such as keratinocytes (W12, primary human keratinocytes), bone marrow fibroblasts, and osteosarcoma cells (MG-63). The lowest efficiency of transduction and level of GFP expression was seen in cell lines of hematopoietic origin, such as THP-1, U937, K562, Raw264,7 and P388D1. Efficient gene transfer has also been obtained in primary mouse and human pancreatic islet cells (89). Recombinant baculovirus expressed the glycoprotein gB of pseudorabies virus (PrV) under the CAG promoter in various mammalian cell lines and produced specific antibodies in mice against PrV (90). High levels of expression of PrV gB were observed in many porcine kidney cell lines such as CPK, SK-H, and CPK-NS, and in hamster kidney cells (BHK-21). The potential of baculovirus for therapeutic applications was tested by a virus containing a p53 tumor suppressor gene under the control of the CMV promoter together with an anticancer drug, adriamycin (91). Greater than 95% of Saos-2 cells were killed by the combination of the recombinant virus (moi of 100) and adriamycin (35 ng/mL), suggesting that the combination treatment greatly enhanced apoptosis of the tumor cells. Table 2 summarizes some common cell lines found to be good and poor targets for baculovirus transduction by several independent authors.

Baculoviruses have been pseudotyped by a vesicular stomatitis virus G transmembrane glycoprotein (VSV-G) to further broaden the host range. VSV-G has an extremely broad host range because its entry into the cells seems to not be dependent on the presence of any specific receptor but a phospholipid component of the plasma membrane (92). VSV-G mediates pH-dependent membrane fusion in endosomes (93), and has earlier been used to pseudotype and stabilize other enveloped viruses such as murine retroviruses and lentiviruses (94–96). VSV-G has increased the efficiency of baculovirus transduction in a range of mammalian cells that have been studied (82,97). In these studies, VSV-G was cloned under the control of the *polh* promoter so that it was expressed in infected insect cells but not in mammalian cells. This circumvents the toxicity of VSV-G in mammalian cells. Indeed, the inactivity of baculoviral promoters in mammalian cells is a very useful property of baculovirus vectors. The level of marker gene expression in HepG2 cells treated with a pseudotyped virus was 10-fold higher than in the same cells treated with a wild-type virus. Pieroni et al. (98) showed that VSV-G enhances the transduction efficacy of pseudotyped baculovirus also in vivo. VSV-G can complement the gp64 and there-

Table 2 Common Cell Lines Found to be Good, as Well as Poor Targets for Baculovirus Transduction In Vitro by More Than One Independent Author

Good targets		Poor targets	
Cell lines	Ref.	Cell lines	Ref.
Liver cells		Blood cells	
Huh7	(14,17,20,28,52,77,80–82,84, 97,98,107,112,119,178)	HL-60	(14,77,78)
HepG2	(14,52,77–82,91,97,112,178)

fore allows productive infection, replication, and propagation of the gp64 deleted baculovirus in Sf9 insect cells (99). However, the virus propagation appeared to be inefficient and delayed as compared with the wild-type virus, but virions were similar in morphology to the wild-type viruses. Interestingly, the use of mouse hepatitis virus S protein (MHVS) pseudotyped baculoviruses can also result in a 100- to 500-fold higher marker gene expression than the wild-type virus in many mammalian cells at a low moi (52).

Agents that inhibit histone deacetylation, such as trichostatin A (TSA) and sodium butyrate, can have a significant effect on the gene expression in cells (100,101). The effect is supposed to be mainly due to the more exposed chromatin structure (102). These agents also enhance adenovirus- and retrovirus-mediated transgene expression in vivo and in vitro (5,103,104). Thus, it is not surprising that sodium butyrate and TSA also increase the expression of marker genes significantly in the baculovirus-treated cells in vitro (5,84).

D. Baculovirus Hybrid Vectors

The extraordinary capacity of AcMNPV to carry foreign DNA (no known limit for foreign DNA, but at least 50 kbp tolerated) allows construction of recombinant viruses bearing large expression cassettes (4,105,106). This is a valuable property for many purposes, including hybrid vector construction, as shown by recent reports. Palombo and coworkers (107) constructed a baculovirus-adeno-associated virus (Bac-AAV) hybrid vector to prolong the transient nature of baculovirus-mediated transgene expression. The idea was to use the natural integration capacity of AAV to carry the transgene cassette into a defined region (chromosome 19) of the host cell genome (107). β-galactosidase and hygromycin resistance gene excision from the baculovirus backbone vector and a subsequent integration into the genome of 293 cells was shown to occur with significant frequency. However, integration into the desired region occurred only in a fraction of the clones, and nonspecific integration and multiple insertions of the marker gene were detected.

A system for the production of gutless adenovirus vectors (FD-AdVs) that does not require helper adenoviruses was recently described (106). The helper virus was replaced by the baculovirus-adenovirus hybrid vector (Bac/Ad) containing a Cre recombinase-excisable copy of the packaging-deficient adenovirus genome. 293-Cre cells were transfected with the FD-AdV plasmid containing a transgene cassette, packaging signals, and 2 copies of the inverted terminal repeats, and were followed by transduction by the Bac/Ad. High titer FD-AdV virus preparations (10^8 pfu/mL) were attained. However, the system has to be further improved to avoid generation of replication-competent viruses during a large-scale production.

Yap et al. (81) constructed a recombinant baculovirus carrying a cDNA of the bacteriphage T7 RNA polymerase under the control of the CAG promoter. High-level expression of this enzyme in various mammalian cell lines was observed after the baculovirus transduction. A plasmid bearing the entire poliovirus genome under the T7 promoter yielded a high-titer of infectious poliovirus in the HeLa cells after prior transduction with the baculovirus.

To efficiently propagate and study hepatitis B virus (HBV) and hepatitis C virus (HCV) in cultured cells, recombinant baculoviruses carrying the HBV (108–111) and HCV (105) cDNAs under mammalian promoters have been prepared. The

control of the gene expression in both the HCV minigenome and the full-length HCV construct was also investigated (112). In addition, Tet-off and ecdysome/ponasterone-inducible (pon) systems were compared to control the gene expression. The tetracycline-controlled system gave a low basal activity and was highly inducible in almost 100% of HepG2 cells. Hepatitis-baculovirus hybrid vectors represent a simple and highly flexible system for studying the effects of antivirals and/or cytokines on HBV and HCV production, and for the understanding of their replication and pathogenesis at the molecular level.

To investigate biology of the human cytomegalovirus (HCMV), genes encoding immediate early proteins of the HCMV were cloned into baculoviruses under the CAG promoter (113). These viruses provided a new strategy for efficient isolation of the HCMV viruses with mutations in essential genes.

Finally, a recombinant baculovirus expressing Ebola virus nucleoprotein under the CMV promoter was used to transduce HeLa cells, which were subsequently used as an antigen to detect Ebola virus IgG antibodies from serum samples (114).

E. Entry Mechanisms into the Mammalian Cells

Cell surface receptors responsible for baculovirus attachment and entry are unknown, although the dogma that baculovirus enters the insect cells by an adsorbtive endocytosis has been confirmed by several studies (34). In contrast, the mechanisms involved in the baculovirus entry into mammalian cells are still poorly known. Indeed, several contradictory reports have been published concerning essential cellular motifs responsible for baculovirus uptake into mammalian cells. All these studies, however, agree on that the uptake occurs via an endocytotic route. Early reports suggested that the degree of virus uptake was variable, depending on the cell, incubation time, temperature, and viral phenotype (12). The effect of the titer and virus competition studies in the cell culture have suggested that gene transfer into hepatocytes might be due to the presence of a specific receptor (14). A candidate receptor was postulated to be an asialoglycoprotein receptor. Inhibition tests with choloroquine also indicated that endosomal maturation was essential for virus transport into the nucleus in agreement with the mechanism of virus uptake in the insect cells (Fig. 1) (14,78). Contrary to a supposed specific receptor theory, baculoviruses were reported to enter several cell lines by absorptive endocytosis, which does not require any interaction with a high-affinity receptor but rather interaction with a heterogeneous cell surface motif(s) (51). Electrostatic charges were shown to be important. Neutralization of negatively charged epitopes at the cell membrane appeared to be critical for baculovirus–cell interactions and the subsequent entry. Heparan sulfate proteoglycan seemed to be an important docking motif. Enzymatic removal of heparan sulfate groups from the cell surface caused a significant reduction in transduction (51).

The mode of baculovirus entry into the target mammalian cells has been further studied by constructing recombinant baculoviruses expressing gp64, VSV-G, MHVS, or GFP to compare susceptibility of various cell lines to these recombinant baculoviruses (52). Increased amounts of gp64 or foreign envelope protein (VSV-G, MHVS) on the virus surface (envelope) caused higher expression than the control virus in various mammalian cell lines. Furthermore, this study indicated that phospholipids, such as phosphatidic acid or phosphatidylinositol, on the cell surface played an important role in the transduction of mammalian cells by baculovirus, whereas heparin and heparan sulphate did not.

The basolateral surface has shown to be important in baculovirus-mediated transduction when the hepatocytes acquire intercellular junctions and form islands in the cell culture. Disruption of the cell–cell junctions masking the baculovirus motifs by a calcium chelator, ethylene glycol-bis(β-aminoethylether)-N,N,N′,N′-tetraacetic acid (EGTA), significantly improved the transduction efficiency (115). Baculovirus entry into cells or tissues with tight cellular junctions may thus require transient breakage of intercellular linkages to allow viral contact with the basolateral surface.

Van Loo et al. (28) showed that baculoviruses can also transduce nondividing cells and that the mechanism of the viral capsid transport into the nucleus before uncoating is apparently identical to that of insect cells (Fig. 1) (116). Pig kidney cells (Pk1) were arrested in S phase with aphidicolin, a reversible blocker of DNA polymerase, to show that the arrested cells can be transduced similarly as untreated mitotic cells. An electron microscopy study of the viral uptake showed that baculoviruses enter mammalian cells via endocytosis and are released into the cytoplasm by an acid-induced fusion of the viral envelope with the endosomal membrane in accordance to the entry into the insect cells. Cytochalasin D, which causes reversible depolymerization of actin filaments, inhibited marker gene expression, suggesting that actin filaments are important for viral capsid transport into the nucleus. Similar results were recently obtained also in HepG2 cells and it was further suggested that the transduction block in the nonsusceptible vertebrate cells lies in the cytoplasmic transport or nuclear entry of the virus capsid (117).

F. Gene Delivery In Vivo

Current evidence suggests that baculoviruses also provide an effective tool for in vivo gene delivery. The first attempts of in vivo gene transfer with baculovirus were performed into the liver parenchyma of rats and mice (17). Several attempts were also undertaken to inject baculoviruses directly into systemic and intraportal circulation (17). These experiments resulted in undetectable transgene expression, suggesting that the virus was somehow inactivated by serum components. This led to several studies in immune-compromised animals. When Hofmann et al. (77) injected a β-galactosidase expressing baculovirus directly into the liver parenchyma of C5-deficient immunocompromised mice, a few transduced hepato-

cytes were detected around the injection site. They also injected recombinant baculoviruses into the Huh7-derived human hepatocarcinomas generated in nude mice (T cell deficient) and got low gene transfer efficiency. A systemic baculovirus gene vector delivery into complement deficient Neuro2a tumor-bearing A/J mice resulted in transgene expression primarily in liver, spleen, and kidney, but significant expression was also found in the tumor (118). Injection of decay acceleration factor (DAF)-modified complement-resistant baculovirus vector into the liver parenchyma of complement-sufficient neonatal Wistar rats caused an enhanced expression of the marker gene suggesting that generation of complement-resistant vectors could improve the gene transfer efficiency in vivo (119). However, direct intrahepatic injection of the complement resistant AcMNPV-DAF-βgal vector in adult rats resulted only in single positive cells distant from the injection site.

Delivery methods that allow gene transfer in the absence of serum, or to the sites where viruses are not exposed to the complement, have led to more successful experiments in immune-competent animals. BALB/c mice, nude mice, and Sprague-Dawley rats were injected with recombinant baculovirus directly into the striatum of brain (18,20). Marker gene expression was detected in the striatum, the corpus callosum, and the ependymal layer, indicating the ability of baculoviruses to transduce neural cells in vivo. Transduced cells were identified mainly as astrocytes with only a few positive neurones. No difference was detected between the 3 species or between the cobra venom factor CVF (an inhibitor of the complement system) treated and untreated groups, suggesting immune-privileged nature of the brain. Transduction efficiency, tropism, and biodistribution of the baculoviruses after local delivery into the brain have been studied in comparison to adenoviruses also in BDIX and Wistar rats (18). In this study, baculoviruses were found to transduce cuboid epithelium of the choroid plexus cells very efficiently (76% ± 14). A clear difference was observed with the adenovirus vector when injected into the corpus callosum; adenoviruses did not transduce the choroid plexus cells, whereas ventricular ependymal lining and cells in the corpus callosum were transduced with a high efficacy. Injection into the striatum resulted in an effective transduction near the injection site and in the corpus callosum. Both viruses lead to transgene expression in endothelial cells of brain microvessels throughout the forebrain (18).

In a different approach, carotid arteries of New Zealand White rabbits were successfully transduced by recombinant baculoviruses using a collar device. This system allowed gene delivery with minimal exposure to complement (5). Transient expression in the adventitial cells was observed with an efficacy and duration comparable to adenoviruses. Recombinant baculoviruses have also been tested for direct administration into a mouse eye by subretinal injections. A strong expression of the marker gene in retinal pigment epithelial cells was reported by this study (19). Intravitreal injection of the virus resulted in the marker gene expression in the corneal endothelium, lens, retinal pigment epithelial cells, and retina. The ocular tissue contains areas where antigens are not subjected to the complement pathway and therefore makes it a good target for baculovirus-mediated gene therapy.

Direct injection of recombinant baculoviruses into the quadriceps femoris muscle of BALB/c and C57BL6 mice resulted in a transient expression of β-galactosidase. Expression levels were 5- to 10-fold higher when VSV-G pseudotyped baculoviruses were used (98). The authors also used C5-deficient mice where a higher and more sustained gene expression (up to 178 days) was observed than in BALB/c and C57BL6 mice, suggesting a different gene transfer efficiency between the different mouse strains and the importance of the complement activity.

Baculoviruses have also shown be potentially useful as vaccines. Induction of anti-PrV gB antibody was observed in mice that were inoculated intranasally or intramuscularly. Higher levels of antibodies against PrV gB were detected in serum after intramuscular rather than intranasal inoculation (90). In a related study, Lindley et al. (120) reported a novel use of the baculovirus gp64-display system (121) as a rapid method to produce monoclonal antibodies directed against gp64–fusion proteins. This method might also be useful for vaccination with desired antigens, as suggested by Tami et al. (122). Vaccination with either recombinant baculoviruses or infected cells may prove to be a safe alternative for vaccination approaches (123,124). Table 3 summarizes the current data of the baculovirus-mediated gene transfer studies in vivo.

G. Safety

Since the 1950s, extensive safety testing of baculoviruses has been conducted. These studies have revealed that nuclear polyhedrosis viruses are harmless to and unable to replicate in microorganisms, noninsect invertebrate cell lines, vertebrate cells, vertebrates, plants, and nonarthropod invertebrates. These trials have included long-term carcinogenicity and teratogenicity tests, tests in primates, and tests in humans (10). Ten different mammalian species have been studied, including rats, mice, dogs, guinea pigs, monkeys, and humans. In these tests baculoviruses were administered by a variety of routes, including orally, intravenous injection, intracerebral injection, intramuscular injection, and topically. No toxicity, allergic responses, or pathogenicity associated with the baculoviruses were detected (125). The safety of baculoviruses is also underscored by the fact that we are exposed daily to baculovirus particles present in large numbers in our environment and food. Yet no diseases have been linked to baculoviruses (126).

The safety of baculoviruses is secured at several levels of restrictions in baculovirus infectivity (127). The polyhedrin matrix of OV is essential to horizontal transfer of the virus by protecting it from the environment. The alkaline midgut of insects facilitates the dissolution of OV matrix, leading to primary infection of the larva (Fig. 1). Organisms such as birds and mammals that lack such alkaline conditions in their digestive tract or other potential points of entry, such as respiratory tract, are not infected by OV (128–130). Tissue or cell-

type specificity may create the second level of restriction, although the baculovirus host range does not appear to be limited at the point of entry into the target cells (12,52). This is particularly true for AcMNPV. The subsequent steps following the virus entry by adsorbtive endocytosis may be much more important (28,34,117). Indeed, it was recently suggested that the block in the entry of the AcMNPV into the unsusceptible vertebrate cells lies in the defective transport or entry of the nucleocapsid into the nucleus (117). Although escape from the endosomes certainly creates some barriers, it was found that nucleocapsids seemed to enter into the cytoplasm even in the cells in which no marker gene expression was detected. This is in agreement with the known ability of gp64 to mediate pH-dependent membrane fusion in endosomes (49). Finally, if the nuclecapsid reaches the nucleus, strictly guided molecular mechanisms that cover the expression of the baculovirus genome remain in place. Indeed, baculoviruses propagate only in restricted insect cells and are inherently unable to replicate or express their genes in nontarget mammalian cells (6,131,132). This is a great advantage when baculoviruses are used for gene therapy because risks related to the rise of replication-competent viruses during the virus production can be avoided. Replication-competent viruses are the major concern with most of the current main stream gene delivery vectors based on natural human pathogens (133).

The large size of the baculovirus genome raises a theoretical concern about the possibility of homologous recombination of its genome (or parts of it) into the target cell genome. In the worst case, this might lead to malignancy of the target cell as reported recently in the case of naturally integrating retrovirus and AAV vectors (134–138). Integration of AcMNPV genomic fragments into the mammalian genome has shown to take place in vitro in the presence of selection pressure (84,139). In these studies, Chinese hamster ovary (CHO) cells, which were stably transduced by selection pressure with recombinant baculoviruses, expressed GFP at least 25 passages (84). Analysis of the baculovirus-derived DNA indicated that at least 12 kbp of DNA derived from the viral vector had stably integrated into the transduced CHO cells (84). Integration into the CHO genome occurred as small fragments (5–18 kb) via illegitimate recombination (139). Two of the clonal cell lines maintained starting levels of the GFP expression over a 5-month period with and without selection. The 2 remaining clones, however, showed a loss of the marker gene expression. Baculoviruses can thus be used for the preparation of stable cell lines. However, no evidence of Integration of AcMNPV genomic fragments into the target cell genome has been found without concomitant antibiotic selection pressure (140,141).

One of the biggest challenges in gene therapy is the immune response of the host. The host defense mechanisms function both at the cellular level by generating cytotoxic T cells and at the humoral level by generating antibodies against foreign antigens. Cellular immunity eliminates the transduced cells, whereas humoral immunity protects against the repeated administration of the vector (98,142,143). The host may recognize not only the vector and the transgene product, but also the foreign DNA, which makes the vector design even more challenging (144). However, the eye, brain, and reproductive organs possess immune-privileged regions (145) and therefore may provide good targets for the baculovirus-mediated gene therapy (19,20).

As discussed earlier, immune responses against baculoviruses were suggested as a reason for no detectable transgene expression when mice and rats were treated with systemic, intraportal, or direct injections into the liver parenchyma (17). Therefore, the influence of untreated and heat-inactivated serums from different species was tested for baculovirus transduction efficiency. The results indicated that the classical complement (C) cascade inactivates baculoviruses rapidly and the extent of inactivation varies from one species to another (17,146). Incubation of baculoviruses in the serum of either C3- or C4-deficient guinea pigs did not cause any significant neutralization of the baculovirus, suggesting that C3 and C4 components are essential (17,146). In line with these findings, the direct injection of recombinant baculoviruses into C5-deficient mice resulted in a higher and longer-lasting expression of the marker gene than that in mice, which were not complement deficient (98). In ex vivo experiments that excluded the C system, detectable levels of the marker gene expression were found in human liver segments perfused by the baculovirus vectors (17,77). More detailed investigations have demonstrated that the classical pathway of the C system and assembly of the very late C components are essential for the inactivation of the baculovirus in human serum, indicating the presence of IgM or IgG antibodies against baculoviruses (146). These antibodies are most probably part of the innate self/nonself pattern recognition immune system detecting antigens without a known history of immunization (147,148).

A couple of efforts have been taken to protect baculovirus from inactivation by the complement system (149,150). The treatment of human serum with functional blocking agents (CVF, anti-C5 monoclonal antibodies) against the components of the C-cascade increased vector survival significantly in a dose-dependent manner in vitro (146). Soluble complement receptor type 1, a potent inhibitor of both the classical and alternative C pathways, increased baculovirus survival in human serum in a dose-dependent manner (151). A complete baculovirus survival was achieved by the soluble complement receptor at concentration of 100 μg/mL of serum (151). As mentioned earlier, incorporation of the complement-regulatory protein DAF into the viral envelope was also shown to improve gene transfer efficiency in neonatal Wistar rats in vivo (119).

Baculoviruses have been shown to stimulate antiviral activity in mammalian cells by promoting cytokine production. Baculovirus exposure resulted in the activation of TNF-α, IL-1α, and IL-1β expression in the primary hepatocyte cultures and production of interferons (IFNs) in some mammalian cells (152,153). Kupffer cells were present in the primary hepatocyte cultures and were most probably responsible for the cytokine production (152). The IFN-stimulating activity of the baculoviruses required live virus and was not due to the presence of viral RNA, DNA, or bacterial endotoxin (153). The

detailed mechanism for the observed baculovirus-mediated interleukin induction remains to be studied, but the data suggest a unique process involved in the baculovirus-mediated stimulation of the mammalian IFN. In accordance to these studies, baculovirus-mediated periadventitial gene transfer was found to result in mild immune responses (5). Interestingly, however, only a modest microglia response was seen in rat brain after the baculovirus transduction whereas the adenovirus gene transfer led to a strong microglia response (18).

Despite the profound existing knowledge about the baculovirus safety, further studies are still needed before clinical trials with baculovirus vectors can be launched. Particularly the biodistribution of the virus in vivo is still largely unknown and the immune responses in vivo must be studied more carefully. Further investigations are also required to determine whether some of the viral genes are expressed in mammalian cells. The current data strongly suggest that the AvMNPV genome is strictly silent (6,131,132), but some immediate early genes whose promoters are recognized by host RNA polymerases may well prove to be active (154).

III. FUTURE ASPECTS

Strong evidence now exists to support baculovirus-mediated gene delivery in vitro, and there is very little doubt that this concept is also useful for in vivo. The genuine advantages of baculovirus vector (Table 1) certainly make it a potential new player in gene therapy. However, before this, further studies concerning AcMNPV behavior in mammals, particularly biodistribution and inflammatory issues, need to be studied.

An ideal gene therapy vector should transduce only the desired target cells with a high efficacy. Therefore, a strong interest in developing targeted gene delivery vectors has emerged (155–162). As a first step toward targeted baculovirus transduction, Ojala et al. (163) recently described baculovirus vectors displaying either a functional single chain antibody fragment (scFv) specific for the carcinoembryonic antigen or the synthetic IgG-binding domains derived from protein A of *Staphylococcus aureus*. Display of the targeting moieties on the viral surface was achieved through fusion to the N-terminus of gp64 (Fig. 2) (121). Specific binding of the gp64 fusion viruses to mammalian target cells could be demonstrated by fluorescence and confocal microscopy. However, no enhancement of the viral entry or gene transfer into the mammalian cells could be observed by monitoring GFP expression. Indeed, it is well known that a specific ligand–receptor interaction does not necessarily guarantee efficient transduction of the target cells (161). Internalization, escape from endosomes, and transport of the genetic material into the nucleus are required as well (28,164). The fact that baculoviruses seem to not have any blocks in the entry into the cells (11,12,131,141,165), may make baculovirus targeting

Table 3 Summary of Current Data of Baculovirus-mediated Gene Transfer In Vivo

Study	Target animal	Positive organ/tissue	Positive cell types	Notes
Airenne et al. (5)	Rabbits	Blood vessel, adventitia	Fibroblasts, smooth muscle cells	Collar device used for delivery
Haeseleer et al. (19)	Mice	Retina, corneas	Retinal pigment epithelial cells, retinal inner nuclear layer, corneal endothelial cells, ganglion cell layer, muller cells, lens epithelium, photoreceptor cells	Intravitreal and subretinal injection into eye
Hofmann et al. (77)	C-5 deficient mice	Liver	Hepatocytes	
Hüser et al. (119)	Neonatal Wistar rats	Liver parenchyma	Not determined	Did not work in adult rats
Kirchels et al. (118)	Complement-deficient A/J mice	Liver, spleen, kidney, lungs	Not determined	Systematic delivery through tall vein
Lehtolainen et al. (18)	Normal Wistar rat	Hindbrain, forebrain, spleen, heart, lung	Cupoid epithelium of chorolds plexus endothelial cells in brain microvessels	Intracerebral delivery
Pieroni et al. (98)	DBA/2J, BALB/c, and C57BL/6 mice	Guadriceps, femoris muscle	Myofibers	Best expression of β-gal and the longest expression of EPO in DBA/2J
Sarkis et al. (20)	Nude mice, BALB/c mice, and Sprague-Dawley rats	Brain	Striatum: astrocytes, corpus callosum, ependymal layer neuronal cells	Intracerebral delivery

even more challenging. Further knowledge on molecular mechanisms behind cellular entry will create the basis for further engineering of the baculovirus envelope, allowing better possibilities for cell/tissue-specific entrance. Pseudotyping with known viral surface proteins may also be useful to achieve this goal (52,99,166).

Current baculovirus vectors allow only transient transgene expression, which is desirable in the treatment of cancer or cardiovascular disorders (167). However, more prolonged expression is needed for the treatment of genetic diseases (1). As an attempt to reach this goal, AAV baculovirus hybrid vector was described (107). The strategy to combine elements from known integrating viruses (3) and viruses capable of episomal replication (168) may well prove to be useful. In these kind of vectors, the addition of gene expression control by tetracylin-based system will be desirable (169,170). As time progresses, more baculovirus hybrid vectors will appear to ease the preparation of viruses that are difficult to produce at present (81,105,106,108,171).

A novel system was recently developed where the fusion protein (enhanced GFP) is displayed in large quantities on the surface of the baculovirus capsid without compromising the viral titer or functionality (117). The system is based on the production of the desired peptides or proteins as either C-terminally or N-terminally linked fusion proteins with the baculovirus major capsid protein, vp39 (Fig. 2). This system has many advantages as compared with the baculovirus surface display system, based on baculovirus major envelope glycoprotein, gp64 (Fig. 2) (121,172–174). In vp39, no structural motifs have been recognized either for association with molecules within the stromal matter or for capsid assembly (175). Neither is it responsible for infectivity of the virus. This is important because the major restriction of the (baculo)virus surface display is the fact that displayed proteins may easily destroy the infectivity of the virus in insect cells, leading to low or no titer of the produced virus (176). In addition, immunoelectron microscopy has shown that vp39 is uniformly distributed on the surface of the capsid (175). The baculovirus envelope display system allows fusions only to the N-terminal end of the gp64, whereas the results suggest that vp39 allows the tagging of both termini. Because the length of the capsid can extend relatively freely (29), it is reasonable to expect that this system may be compatible with even larger proteins than GFP. If the penetration of the baculovirus into mammalian cells and the release of the viral capsid into the cytoplasm prove to be a general phenomenon, the concept of baculovirus-mediated therapy may be further extended, with the possibility of using baculovirus capsid as a shuttle to transport therapeutic proteins directly into the cells as an alternative to traditional protein transduction strategies (177).

In conclusion, baculoviruses with many advantages provide an alternative to current gene therapy vectors (Table 1). They are especially useful for large expression constructs allowing the use of multigene strategies. Inherent safety, together with the ease and speed of production of these vectors, creates a powerful concept to test different gene delivery constructs also in a high-throughput manner.

ACKNOWLEDGMENTS

We thank Dr. Tomi Airenne, Mr. Tom Brimelow, Ms. Sari Kukkonen, Ms. Hanna Lesch, Ms. Miia Lind, Ms. Mervi Riekkinen, and Ms. Pernelle Smits for comments regarding the manuscript; Mr. Jani Räty for 3-dimensional graphics of BV in Figures 1 and 2; Dr. Susan E. Rice Mahr for the photograph of infected larva, and Dr. Franklin Dlott for the photograph of healthy Alfalfa looper in Figure 1.

I. INTRODUCTION

Increasing knowledge about molecular characteristics of malignant cells allows the development of gene therapeutic strategies against a variety of human tumors. Diverse approaches have been followed that can be classified into strategies directly aimed at the tumor or tumor cells, as well as strategies aimed toward the immune system of the host. Due to the successive accumulation of gene defects during tumor development, therapies based on direct gene transfer into tumor cells are mainly of destructive rather than of corrective nature. Suicide killing of tumor cells can be achieved by genetically modifying the malignant cells to express bacterial toxins, prodrug activating enzymes, or tumor suppressors (1,2). The expression of such therapeutics has to be highly restricted to the tumor cells to prevent damage of normal tissues. This selectivity can be achieved by the combination of tumor-targeted gene delivery with tumor-targeted gene transcription. Although transcriptional targeting systems for different tumors have been developed during recent years, tumor-restricted gene delivery is still an obstacle that has to be overcome (1,2).

However, tumor destruction via gene therapy is not exclusively dependent on direct gene transfer into the malignant cells, it can also be achieved by genetic strategies directed toward the immune system of the tumor-bearing host. The motivation of such immunotherapeutical approaches is based on findings, mainly obtained during treatment of melanoma patients, which clearly indicated that the immune system can specifically attack the tumor. Spontaneous regression of primary malignancies can be observed. In addition, tumor-infiltrating T lymphocytes that have the capability to specifically recognize and destroy autologous tumor cells can be isolated. A multitude of studies characterizing the immunogenic nature of tumors and immune responses of the host against it, led to the following concept of T cell-dependent antitumor immunity. Tumor cell destruction can be mediated by cytotoxic $CD8^+$ T lymphocytes (CTLs), specifically recognizing epitopes derived from tumor antigens presented by MHC class I molecules on the surface of the malignant cell. CTL effector activity is dependent on helper functions of antigen-specific $CD4^+$ T cells suggesting that an effective antitumor immune response essentially requires cell-mediated adaptive immunity of a Th1-like phenotype (3,4). Based on this model, immunization protocols are developed that trigger the immune system to overcome the hurdles of immunological tolerance against tumor antigens or escape mechanisms of the tumor. In this context, genetic vaccination might prove great potential. Here, vaccination is attained by administering eukaryotic expression plasmid encoding tumor antigens and/or immune stimulatory molecules in order to activate a cellular immune response directed against the malignant cells.

Irrespective of whether the genetic material is targeted to the immune system or to the tumor or tumor cells, efficient DNA delivery is an absolute requirement. Recently, bacteria have been discovered as an efficient tool for gene delivery to mammalian cells (5–7). This chapter focuses on 2 bacterial delivery systems, *Listeria monocytogenes* and *Salmonella typhimurium*, which had already proven their potential as carriers for heterologous antigens and are now employed in the

delivery of expression plasmids to host cells in vitro and in vivo. In this chapter, the potential use of these bacteria as vector systems for tumor gene therapy is highlighted.

II. BACTERIA-MEDIATED DNA TRANSFER INTO MAMMALIAN CELLS

During infection, some bacteria have the capability to invade particular cells of the host. Dependent on their infection cycle, these microorganisms might establish themselves in different compartments of the target cell. Invasive bacteria such as *S. typhimurium* arrest in the phagosome, whereas facultative intracellular bacteria such as *L. monocytogenes* escape from the phagosome into the cytosol of the infected cell. Independent of whether the pathogens arrest in the phagocytic vacuole or in the cytosolic compartment, both have been demonstrated to be capable of transferring plasmid DNA to the nucleus of the mammalian host cell and to induce heterologous gene expression in vitro and in vivo (7).

In 1995/1996, bacteria-mediated gene delivery to in vitro cultured cell lines was first described by Sizemore et al., Courvalin et al., and Powell et al., using auxotrophic mutants of *Shigella flexneri* as a vector vehicle (8–10). These studies led to the following concept of bacteria-mediated gene transfer: the microorganisms have to invade the target cell and escape into its cytosol, where the expression plasmid is liberated due to death of the attenuated pathogen and subsequently directed into the host cell nucleus (Fig. 1A). This hypothesis had to be partially revised when invasive auxotrophic *Salmonella* were demonstrated to be capable of DNA transfer in vitro and in vivo (11), indicating that phagosomal escape was not an essential prerequisite for gene delivery (Fig. 1B). Interestingly, efficient DNA transfer by attenuated *Salmonella* seems to be restricted to primary murine/human macrophages and dendritic cells (DCs), the professional inductors of an innate and adaptive immune response, respectively (11–16). Only 1 recent study described a low rate of *Salmonella*-mediated gene delivery to cells of epithelial origin, which could be increased by engineering the bacteria to escape from the phagosome into the cytosol (17). The molecular mechanism responsible for *Salmonella*-mediated DNA transfer in the host cell and its restriction to primary macrophages/DCs remains to be determined. The specific biology of macrophages and DCs as professional antigen-presenting cells (APCs) might be responsible for this phenomenon. Macromolecule delivery from the endocytic vacuole to the cytosol has been described for such cells (18,19). However, it might also be attributed to the secretory machinery of the pathogen (20).

In contrast to *S. typhimurium*, in vitro gene transfer to a broad range of host cells has been described for *L. monocytogenes*, including cell lines of epithelial origin, murine primary macrophages, macrophage-like cell lines, and human DC (16,17,22–25). For *Listeria*, efficient plasmid delivery seems to be absolutely dependent on bacterial escape from the phagosome into the cytosol of the target cell (24,25). Interestingly, the capability to deliver DNA into mammalian cells can also be transferred to noninvasive bacteria. Courvalin et al. (9) demonstrated that an auxotrophic *Escherichia coli* strain modified with virulence genes from *S. flexneri* became invasive and delivered plasmid DNA from the cytosol to the nucleus of the host cell. Less efficient but detectable gene transfer was still achieved when attenuated *E. coli* were engineered to arrest in the phagosome, comparable to *Salmonella* (26). But in contrast to *Salmonella*, plasmid delivery by *E. coli* exhibited a broad host range (26). The data on gene delivery indicate that its outcome and efficiency is determined by both, the bacterial vector species and the host cell type. In general, in vitro DNA transfer seems to predictably occur when the bacteria have access to and liberate the plasmid into the cytosol of the host. To achieve plasmid liberation, different strategies have been followed. Most studies employed variant strains that were auxotrophic for a component that is not supplied by the host cell (8–11). Alternatively, bacteria were engineered to lyse intracellularly by the expression of a bacteriophage autolysin (21) or were simply killed by antibiotic treatment (24,25). However, recent studies indicated that invasive wild-type bacteria of the genera *Shigella* and *Listeria* are also capable of DNA delivery to epithelial cells and macrophages without induction of microbial death (17,25). This transfer might be due to cytosolic lysis of individual bacteria that have been damaged during their residence in the phagolysosome or that have been attacked by bactericidal host effector molecules (e.g., reactive oxygen, nitrogen intermediates, defensins), thus indicating that gene delivery might also occur spontaneously under natural conditions.

In comparison to other DNA delivery systems, like viruses, gene delivery by bacterial vectors is characterized by several advantages: (1) plasmids of almost unlimited size, allowing the combination of several genes on one DNA molecule, can be easily transferred into bacteria; (2) plasmid-carrying microbes can be produced and stored at low cost; (3) bacterial vectors can be applied mucosally via their natural route of infection; (4) for many bacterial species approved metabolically attenuated vaccine strains are available; and (5) bacterial infection can be controlled by common antibiotics as a safe guard, an important aspect with regard to the in vivo application of such microbial vector systems.

III. ENHANCING IMMUNE RESPONSES TOWARD TUMORS BY BACTERIAL INFECTIONS

The history of using bacteria in tumor therapy has a long record. Already more than 100 years ago, bacteria were employed by William Coley. Based on his observations on the coincidence of spontaneous tumor remissions and bacterial infections, he systematically treated cancer patients with viable infectious agents (Coley's toxin). By the application of different bacteria preparations, he could obtain impressive therapeutic effects including the complete regression of inoperable cancers in several patients (27,28). How can this acci-

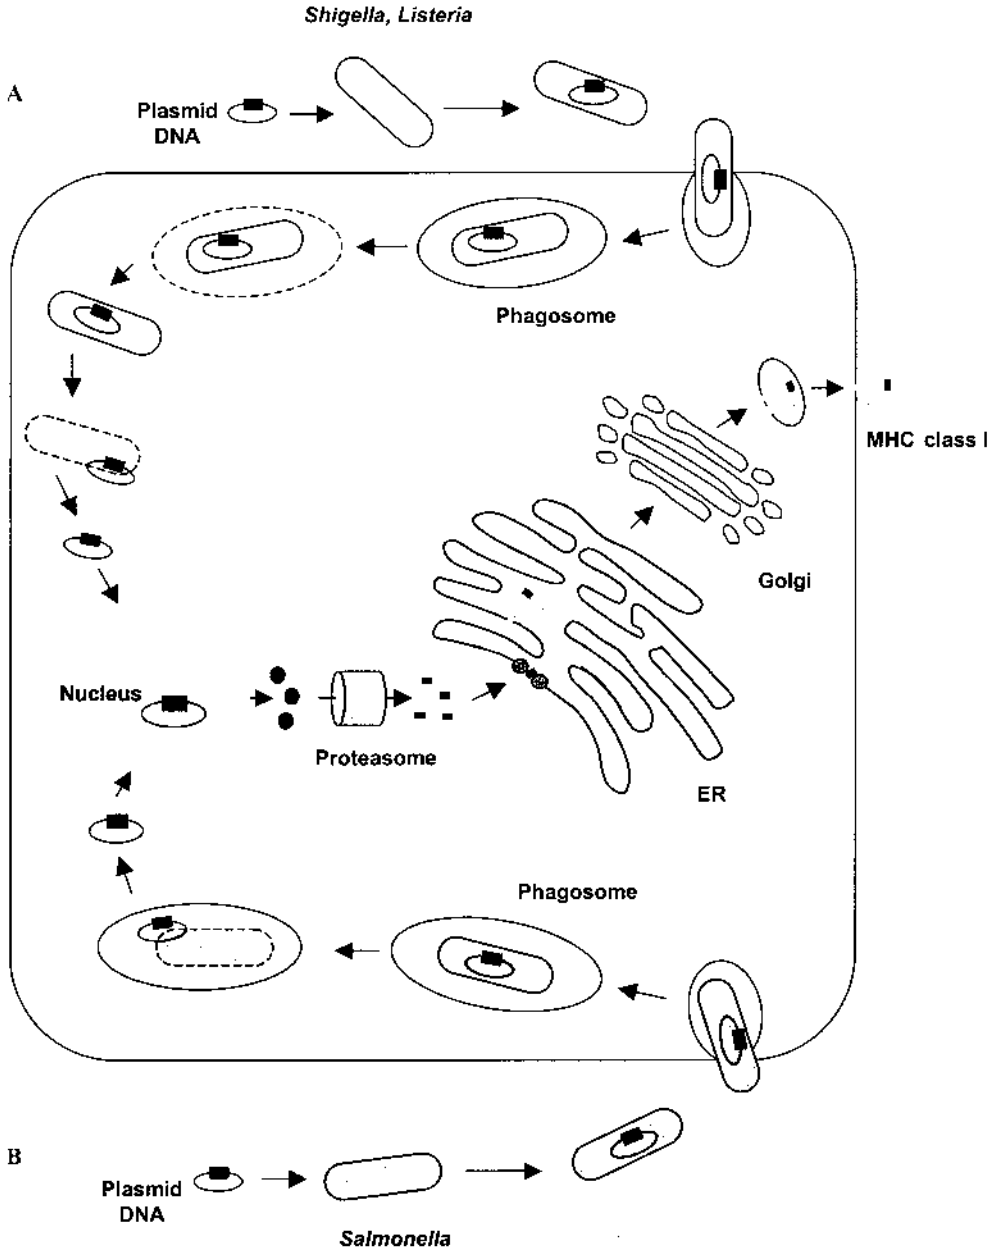

Figure 1 Principles of bacteria-mediated gene transfer. (A) Plasmid DNA encoding the gene of choice is introduced into invasive bacteria such as *Listeria* or *Shigella*. After phagocytic uptake by the target cell, the recombinant bacteria escape from the phagosomal vacuole into the cytosol. The microbes die in the cytosol either due to metabolic auxotrophies, due to genetically engineered autolysins, or by antibiotic treatment. Thereby the plasmid is released, which subsequently obtains access to the nucleus of the infected cells for the foreign gene to be transcribed. The protein antigen is degraded by the proteasome and resulting peptides, containing the appropriate binding motif, are loaded onto MHC class I molecules in the ER (endoplasmatic reticulum). The peptide–MHC class I complex is then transported via the golgi to the cell surface. (B) Facultative intracellular bacteria of the species *Salmonella* are modified with plasmid DNA. The recombinant pathogens invade the host cell and establish themselves in the phagosome. The bacteria die (e.g., due to an auxotrophic attenuation) whereby the plasmid DNA can access the cytosol due to an unknown pathway. Subsequently, the plasmid is transferred to the nucleus of the cell where expression of the gene takes place.

dental finding of a connection between bacterial infections and tumor regressions be explained?

In principle, initiation of antigen-specific immunity is restricted to the lymphoid organs where the target antigens are presented to the T cells by mature dendritic cells. To do so, immature DCs pick up antigens in the periphery. Simultaneous to antigen uptake, DCs have to receive specific environmental signals that induce their activation and maturation. During this maturation process, they obtain migratory capacity toward secondary lymphoid organs and, in addition, become highly stimulatory for T cells by expression of costimulatory molecules. This, leads to antigen-specific T cell activation. With respect to this activation cascade, tumor cells lack the capacity to activate primary T cells, due to the absence of essential stimulatory functions. Although proteins derived from a tumor might be phagocytosed by immature dendritic cells, such DCs normally do not become activated and can therefore not function as inductors of a T cell response. Antigen presentation by immature DC is even considered to result in peripheral tolerance of T cells (Fig. 2). Thus, two opposite functions are attributed to antigen presenting DC depending on their maturation status: they may act as mediators of T cell tolerance or as central players in the induction of adaptive immune responses (29).

How can DC activation be induced? Inflammatory cytokines released in response to tissue damage during infection, as well as highly conserved molecular structures derived from the infectious agent itself, are mediators of DC activation. The latter substances can be considered conserved biochemical patterns that cannot be found in the mammalian host (e.g., unmethylated CpG motifs of bacterial DNA and lipids, such as lipopolysaccharide for Gram negative and lipoteichoic acid for Gram positive bacteria). These molecules bind to Toll-like receptors (TLRs) mainly expressed by cells of the innate immune system and induce their activation (30,31). Several other receptors, such as scavenger receptors, complement receptors, Fc receptors, and the like, might also be involved in the activation process (32). Stimulation via these receptors results in the production of inflammatory cytokines, which in turn might activate additional cell populations, including dendritic cells. Alternatively, DCs themselves can be activated directly by the recognition of pathogen structures through their own pattern recognition receptors. Activated DCs would be the link between the innate immune system and adaptive immunity starting with the activation of T cells of the Th1 type, which might provide essential help for the induction of pathogen-specific CTL (Fig. 2). Thus, the bacterial products are providing strong adjuvant activity that in the context of an antitumor response might be able to break tolerance toward tumor antigens or to circumvent escape mechanisms of the tumor.

One also could envision a scenario where DCs induce a specific immune response against pathogen-derived antigens, while initiating ''bystander activation'' of tumor-specific T cells. When large amounts of tumor antigens are taken up by DCs, this accidental coupling of T cell immunity against microbes and tumor appears to be possible (Fig. 2). This concept might explain the therapeutic effects of Coley's toxin in cancer patients. Nevertheless, despite its effectiveness, this initial immunotherapeutic strategy was ignored for more then half a century, until in the 1960s, when the adjuvant effects of bacterial preparations were rediscovered by the successful use of BCG (*Mycobacterium bovis* strain Calmette-Guerin) in cancer therapy (33).

As a logical consequence, bacteria are now widely used as delivery system for various vaccination strategies, including immunizations against model tumors (34). This was recently extended to genetic vaccination (i.e., bacteria have been used as vehicles for transfer of eukaryotic expression plasmids encoding tumor antigens or immune stimulatory molecules). Obviously, the combination of the adjuvancy of a bacterial carrier and particular features of the antigen expression plasmid should synergize to induce protective antitumor responses. During bacteria-mediated DNA vaccination, DCs might acquire the tumor antigens from the bacterial carrier either by direct infection or via cross-presentation. In the latter case, the infected cell that contains the antigen is phagocytosed by neighboring DCs, which then are activated and represent the original antigens. Both routes, cross-priming and direct priming have been described for specific activation of T cells. In addition to genetic vaccination, bacterial carriers can also be used for gene therapy to improve the performance of the immune system or to directly target inhibitory molecules to the tumor cells.

IV. *L. MONOCYTOGENES* AS DELIVERY VEHICLE FOR EUKARYOTIC EXPRESSION PLASMIDS

The ability of *L. monocytogenes* to transfer eukaryotic expression plasmids into host cells has been mainly explored in vitro so far. However, vast experience exists for the use of such bacteria as a carrier for heterologous antigens, especially in murine tumor systems.

A. L. monocytogenes-mediated DNA Transfer In Vitro

L. monocytogenes infects many cell types in a wide range of different species, including mice and humans. Its intracellular infection cycle, as well as innate and adaptive immune responses against this pathogen in mice, have been extensively studied since the 1970s (35,36). Due to its capacity to induce phagocytosis, *L. monocytogenes* can efficiently infect a variety of cells, including nonphagocytic cells. After its uptake, the bacterium quickly escapes from the phagosome into the cytosol of the host cell, where it replicates. Therefore heterologous plasmid DNA carried by *Listeria* can be delivered directly into the cytosol of the mammalian cell and only has to cross the membrane barrier of the nucleus for expression. Highly efficient plasmid transfer to epithelial cell lines from different species, including fish, mouse, rat, hamster, monkey, and human has been described (16,17,24,25). In addition,

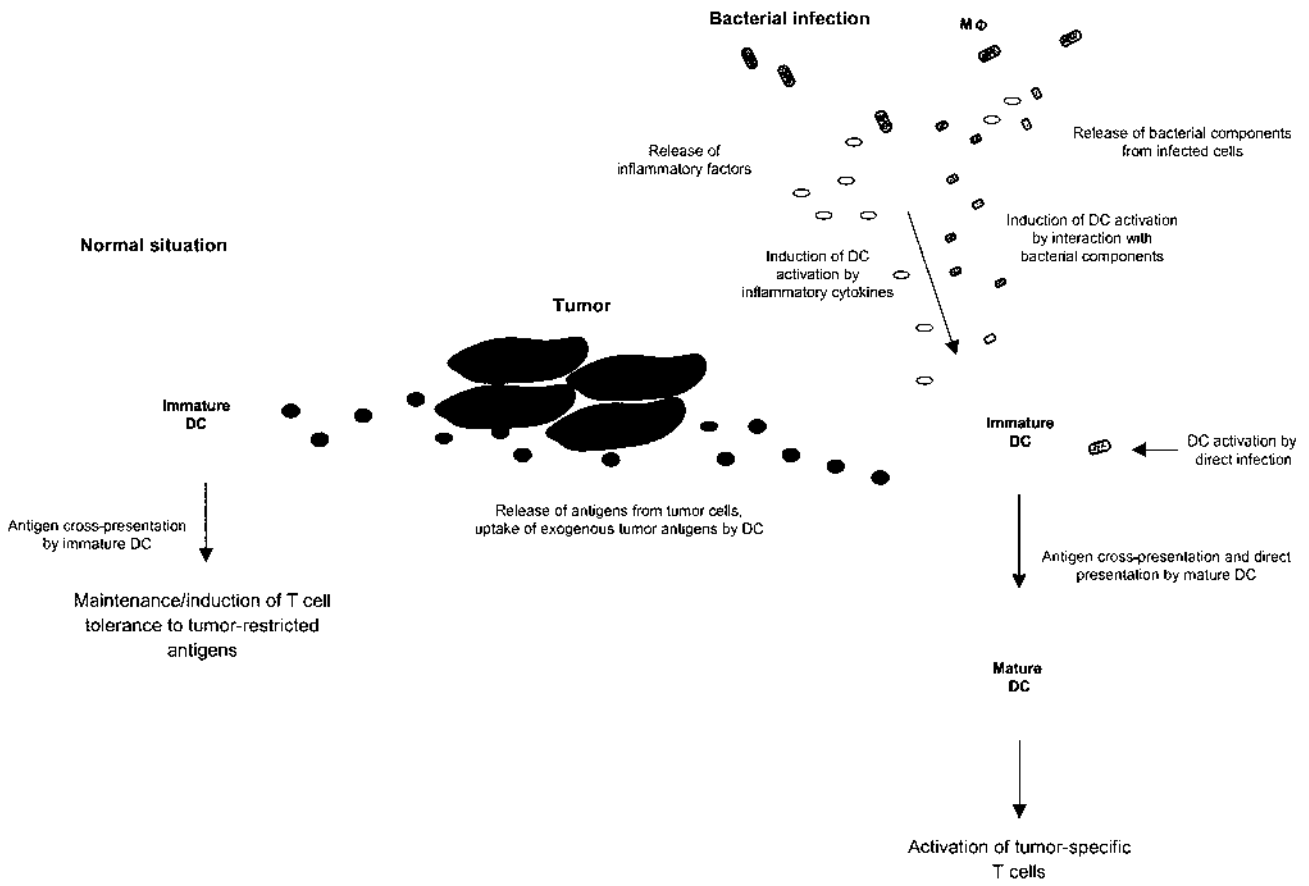

Figure 2 T cell responses to tumors in the presence of bacterial pathogens. Tumors release antigens that are picked up by dendritic cells of the immature phenotype. Presentation of antigens by immature DCs leads to the induction of T cell tolerance. In contrast, bacterial infection is accompanied by the release of inflammatory cytokines, which induce maturation of DCs. In addition, molecules representing conserved pathogen-associated patterns (e.g., unmethylated CpG motifs of bacterial DNA) can be released from infected cells. Alternatively, DCs themselves can be infected and activated. Tumor antigens that are taken up and presented by immature DCs that are activated to mature by the infection will lead to the induction of tumor-specific T cell responses.

professional APC-like murine macrophage-like cell lines, primary macrophages, and human monocyte-derived DCs can be recipients of DNA delivered by *Listeria*, although the frequencies observed vary among studies (17,21–25). This might be due to differences in the experimental settings of infection experiments, but might also be attributed to the mechanism applied to induce bacterial cell death. So far, two strategies have been followed to induce cytosolic plasmid liberation by recombinant *L. monocytogenes*: bacteria were engineered to lyse due to the activity of a bacteriophage autolysin. The expression of this lytic system was under the control of the listerial *actA* promotor and hence was activated preferentially in the cytosol of the host cell (21,23). Alternatively, bacteria were killed by antibiotic treatment of the infected cells (24,25). Interestingly, the way by which an antibiotic interferes with the bacterial metabolism greatly influences the outcome of gene transfer efficiency. Penicillin, an inhibitor of cell wall synthesis, was superior to substances blocking protein synthesis or DNA replication (25). However, gene delivery also occurs using wild-type bacteria without further manipulation, probably as a result of death of the microorganism caused by natural host cell defense activities (17,25).

The efficiency of gene transfer by *L. monocytogenes* is dramatically dependent on the capability of the bacteria to escape from the phagosome into the cytosol of the target cell. Three virulence factors have been demonstrated to be involved in this phagosomal escape—the pore-forming listeriolysin (LLO; encoded by the *hly* gene) and 2 phospholipases (PlcA/PlcB). For some host cells of epithelial origin and for human DC phospholipase activity seems to be sufficient to mediate bacteria entry into the cytosol. In contrast, in the majority of target cells, LLO activity is absolutely required (25,37,38).

However, LLO exhibits severe toxic effects on some cells. Therefore, the bacteria-to-target cell ratios (MOI, multiplicity of infection) normally need to be kept low, which limits the DNA transfer. To overcome this barrier, *Listeria* mutants were constructed that expressed a listeriolysin of reduced cytolytic activity. Indeed, by increasing of the MOI, such strains were able to mediate greatly enhanced plasmid transfer without inducing adverse effects (25).

B. In Vivo Application of *L. monocytogenes* as Vector System

An attenuated strain of *L. monocytogenes*, impaired in intra- and intercellular spreading, has been demonstrated to be capable of plasmid delivery in vivo. Green fluorescent protein (GFP) expressing macrophages could be isolated from cotton rats after intraperitoneal infection with inducible autolyic bacteria that carried a GFP reporter gene plasmid.

Studies exploiting recombinant *Listeria* in gene therapy of cancer have not been published so far, but the therapeutic potential of *Listeria* in tumor therapy was already impressively demonstrated. Wild-type bacteria and attenuated strains of *L. monocytogenes* have been used as an oral vaccine carrier. *Listeria* modified to express β-galactosidase of *E. coli* as surrogate tumor antigen conferred protective immunity in BALB/c mice against a challenge with β-galactosidase (β-gal) expressing fibrosarcoma cells and reduced the growth of established tumors (39).

Even more impressive were the results obtained by the group of Y. Paterson (40,41). In these studies, bacteria were genetically modified with a prokaryotic expression plasmid that integrated into the bacterial chromosome. The plasmid encoded the influenza nucleoprotein (NP) as a model tumor antigen. The NP gene was fused to a deletion variant of the *hly* gene in order to achieve secretion of the LLO-NP gene product. Intraperitoneal (i.p.) immunization of BALB/c mice with LLO-NP expressing *Listeria* conferred complete protection against an otherwise lethal challenge with tumor cells. Colon and renal carcinoma cells that were retrovirally transduced with the NP encoding gene had been used in these studies. In immunized mice, NP-specific $CD8^+$ T cells were identified as main effectors, but $CD4^+$ T cells also contributed to antitumor immunity. The antitumor reactivity was of sufficient potency to even induce regression of macroscopically established tumors (40). In such model systems, tumor protection and regression could also be achieved when LLO-NP expressing bacteria were administered orally (41). Intraperitoneal immunization of C57BL/6 mice with the same bacteria mediated regression of primary tumors and of established lung metastasis by the B16F10 melanoma, when these tumor cells were modified to express the NP gene (42).

Recombinant *Listeria* have also been successfully used to induce protective immunity against viral antigens associated with cancer development. Bacteria, expressing and secreting the E7 protein from the human papilloma virus-16 in the form of an LLO-E7 fusion protein, induced regression of E7-expressing tumors in C57BL/6 mice (43). Similarly, protective and therapeutic immunity against cottontail rabbit papillomavirus induced papillomas, which progress with high frequency to carcinoma, was established when rabbits were immunized with a cocktail of recombinant *L. monocytogenes* expressing and secreting deletion variants of the viral E1 protein (44). Again the efficacy of this carrier system, even in a therapeutical setting, was demonstrated.

Furthermore, recombinant *Listeria* could induce protective immunity against gliomas expressing the nucleoprotein of the lymphocytic choriomeningitis virus (LCMV-NP) as surrogate tumor antigen (45). Subcutaneous administration of bacteria genetically modified to secrete the LCMV-NP conferred antigen-specific $CD8^+$ T cell-dependent protection against a subcutaneous challenge with NP-expressing glioma cells in rats. After tumor rejection, enhanced tumor immunity was observed due to epitope spreading. Such mice were protected against a lethal intracerebral challenge with NP-expressing and parental glioma cells. Parental cells obviously did not express the recombinant surrogate tumor antigen. This indicates that recombinant *Listeria* can initiate antitumor immunity that is even protective within the central nervous system. This anatomical site is considered immunoprivileged (i.e., it is usually not accessible to immunocytes).

Based on these encouraging data an initial clinical safety study of an attenuated *L. monocytogenes* strain in humans has been performed recently (46). Twenty healthy volunteers received orally escalating doses of bacteria that were attenuated by deletions of the *actA* and *plcB* genes. No long-term health sequelae were observed in these studies. This proves the potential applicability of this bacterial carrier system for extended human trials.

V. *SALMONELLA TYPHIMURIUM* AS CARRIER SYSTEM

The gram negative bacterium *S. typhimurium* has been demonstrated to target DNA efficiently to professional antigen presenting cells, whereas transfer in cells of different origin seems to be extremely ineffective (11,17). The original finding that primary macrophages can be transfected to a high degree in vitro using *S. typhimurium* (11) has been further extended. Percentages of transfectants close to 100% have been obtained with murine and human macrophages (13,14). Human dendritic cells have also been shown to be susceptible to transfection by *Salmonella* (16), although the percentage of transfectants obtained was still low. The obvious efficiency of *S. typhimurium* in transferring eukaryotic expression plasmids to APC in vivo and in vitro also has prompted its use for genetic vaccination in tumor systems with extremely promising results in some studies. In addition, the tumor-homing properties of specific attenuated *S. typhimurium* strain variants make them a useful tool for gene delivery to the malignant tissue.

A. Oral DNA Vaccination Against Model Tumors Using Attenuated *S. typhimurium* as Carrier

In a few studies, β-gal of *E. coli* has been used as a surrogate tumor antigen in a prophylactic setting. Partial protective im-

munity could be induced against an aggressive fibrosarcoma by orally administering *Salmonella* carrying a β-gal-encoding plasmid (12). Similarly, using the β-gal expressing murine renal cell carcinoma line RENCA-β-gal, Zoller and Christ have demonstrated superior efficacy in inducing tumor protection when the antigen-encoding plasmids were delivered orally by the *Salmonella* carrier, as opposed to injecting naked DNA intramuscularly (47).

Protective immunity against a challenge with the murine melanoma cell line B16 was achieved using recombinant *Salmonella* for prophylactic vaccination (48). After several administrations of bacteria carrying a plasmid encoding the human gp100 (hgp100) melanoma differentiation antigen, protection of 70% of the mice was observed when challenged with B16 tumor cells transfected with hgp100. Gp100-specific T cells could be detected in the spleen of such mice, and by histology, antigen-expressing dendritic-like cells were found in the mesenteric lymph nodes shortly after intragastric administration of the antitumor vaccine carrier bacteria.

These studies were then extended to autologous tumor antigens. Murine gp100 (mgp100) was used as a tumor antigen in oral *Salmonella*-mediated genetic vaccination. To improve the efficiency of the vaccine mgp100 was fused to the invariant chain, a protein that is intracellularly associated with MHC class II molecules. Therefore, the antigen should be targeted to compartments involved in the MHC class II presentation pathway in order to provide antigen-specific T cell help. In addition, IL-2 was administered subcutaneously around the melanoma location in some of these experiments. The combination of oral DNA vaccination and IL-2 treatment prolonged the survival of the mice and was most effective when the tumor was applied at the same time as the vaccination was started (49). Controversial to the above study, no prophylactic antitumor response could be induced in this work.

The group around R. Reisfeld most consequently developed *Salmonella*-based DNA vaccines against autologous tumor antigens. Extremely promising results were obtained by these experiments. First, they used *Salmonella* that carried minigenes encoding epitopes of the autologous tumor antigens mgp100 and mTRP2 fused to ubiquitin for immunization. This resulted in retardation of growth of the B16 melanoma (15). Because mgp100 and mTRP2 are self-antigens, these results suggest that *Salmonella*-mediated DNA vaccination is able to efficiently break immunological tolerance toward autologous tumor antigens.

These findings were extended to a murine neuroblastoma model. *Salmonella*-mediated DNA vaccination was carried out with a minigene encoding epitopes of tyrosine hydroxylase, an autologous antigen found in this tumor. In addition, the complete protein fused to ubiquitin was tested (50). All recombinant vaccines retarded the growth of subcutaneously applied tumors. The complete protein fused to ubiquitin and the minigene, consisting of several epitopes binding to one of the MHC class I molecules, being the most effective constructs. However, this immunization protocol was not effective against metastases (but see below). Further extension of this work also showed that complete proteins without the ubiquitin fusion partner can be used as antigens. *Salmonella*-mediated DNA vaccination was performed in a mouse that was transgenic for human carcinoembryonic antigen (hCEA), whereby hCEA functioned as a self-antigen. Oral immunization of the transgenic mice with *S. typhimurium* carrying an expression plasmid that encoded the complete hCEA, resulted in the induction of specific cytotoxic T cells (51). In addition, the growth of a colon carcinoma expressing hCEA as tumor antigen was retarded. This response could be strongly improved by additionally administering intravenously IL-2 fused to an antibody that targeted the recombinant cytokine to the tumor. When this combination treatment was applied to a lung metastasis model using the same recombinant hCEA expressing tumors and transgenic mice, most animals remained free of metastases (52).

Similar improvements of protective immune responses were reported by the same group using the original B16 melanoma model described above and the epitopes of mgp100 and mTRP2 fused to ubiquitin as antigens. IL-2 targeted to the tumor was additionally applied as adjuvant shortly after tumor challenge. Targeting of IL-2 to the tumor was achieved via a fusion to an antiganglioside antibody, the antigen of which was found on the tumor. This treatment resulted in complete protection against the melanoma in most mice (53). In these experiments, it could be shown that during the induction phase of the immune response no help from $CD4^+$ T cells was required to induce tumor-specific $CD8^+$ cytotoxic T cells. This is in agreement with the strong adjuvant capacity of the bacterial plasmid carrier.

Additional adjuvant capacity was required for protection against a chemically induced colon adenocarcinoma that expressed the hCEA as transgenic tumor antigen. This was achieved by including CD40 ligand (CD40L) into the vaccine construct. CD40L should support the activation and maturation of antigen-presenting cells. A fusion protein of a trimerizing CD40L was therefore generated with hCEA. Mice transgenic for hCEA were then vaccinated with *S. typhimurium* carrying the CD40L/hCEA fusion construct. The vaccination was also combined with the injection of the IL-2-antibody fusion protein that targets IL-2 to the tumor in vivo. Mice treated this way were completely protected against a tumor challenge by the recombinant adenocarcinoma (54). The application of any of the components of this combination alone only partially protected the mice against the tumor challenge.

An alternative approach to improve vaccination against the neuroblastoma described above was chosen by the same group. Only partial protection against subcutaneous tumors had been observed in this model and no effect was detected against metastases (50,55). The original construct encoding tyrosine hydroxylase fused with ubiquitin was modified to include the posttranscriptional regulatory acting RNA element (PRE) sequence of the woodchuck hepatitis B virus (WPRE). This sequence is known to improve gene expression posttranscriptionally by a still undetermined mechanism. *Salmonella*-mediated DNA vaccination using this construct was very efficient in protecting mice from metastases. Control animals had

uncountable numbers of metastatic foci in their liver when injected intravenously with the neuroblastoma. Vaccination with *Salmonella* carrying the unmodified tyrosine hydroxylase encoding plasmid did not reduce this number, whereas vaccination with bacteria that carried the WPRE modified expression plasmid reduced the number dramatically (55). Only a few mice still exhibited a low number of metastases. Finally, complete protection was achieved when this vaccination protocol was complemented with injections of the tumor-targeted IL-2-antibody fusion protein. This schedule was also most efficient in inducing $CD8^+$ T cells expressing IFN-γ intracellularly and tumor-specific $CD8^+$ T cells. When the mice were treated during the tumor challenge with an antibody that depleted natural killer (NK) cells, protection was completely abolished. It was argued that the IL-2 enhances the activation of $CD8^+$ T cells and NK cells, which then synergize in the protective response against the tumor. Interestingly, when the levels of tyrosine hydroxylase expressed from the unmodified and the WPRE containing plasmid were compared by transfection into COS7 cells, no difference could be observed. This could indicate that in vivo the WPRE sequence has different consequences on expression then in vitro. However, peculiarities of viral sequences could be responsible for such an effect, as has recently been shown for a DNA vaccine that included an alphavirus replicon (56).

Based on the possibility of breaking immunological tolerance by *Salmonella*-mediated DNA vaccination, the Reisfeld group recently attempted to interfere with tumor angiogenesis (57). The rational behind these experiments was that the tumor might be able to escape the immune system by loosing antigens, but it cannot escape the necessity to induce new blood vessels for continuous growth. Therefore, an unmodified eukaryotic expression plasmid was designed that encoded the vascular endothelial growth factor receptor 2 (VEGF-R2). Oral application of this construct using *Salmonella* retarded the growth of various tumors even when the challenge was performed 10 months after vaccination. Similarly, when the primary tumor was removed from mice challenged with D121 small cell Lewis lung carcinoma, the vaccinated mice displayed a low incidence of spontaneous metastases, whereas the controls had a high metastatic score. Even more impressive were the results when vaccination was started 10 days after intravenous administration of CT26. All mice treated therapeutically with the vaccine survived and had only a few small metastatic foci, whereas the controls died between 4 and 5 weeks. Mainly $CD8^+$ T cells were responsible for this protective effect because depletion of such cells resulted in loss of protection. In addition, $CD8^+$ T cells could be found associated with blood vessels in tumors of vaccinated mice and cytotoxicity against cells that expressed VEGF-R2 could also be demonstrated. In vivo assays revealed that angiogenesis in such vaccinated mice was severely impaired. Nevertheless, vaccinated mice were fertile like untreated controls and wound healing was only slightly retarded. Thus, *Salmonella*-mediated oral DNA vaccination has proven its great potential in vaccinations against tumors. It is not only applicable in a prophylactic setting, such as in the case of minimal residual disease, but also acts potentially when tumors or metastases are already established.

In spite of this, one has to bear in mind that the immune system is a double-edged sword. Tinkering with it by immunizing with autologous antigens could induce adverse effects. An example of this was observed in a rat lymphoma system with a splice variant of CD44—CD44v2—as tumor antigen (58). CD44v2 is a self-antigen that it is mainly expressed during fetal development. The lymphoma employed was rendered transgenic for CD44v2. When oral *Salmonella*-mediated DNA vaccination was carried out against CD44v2, cytotoxic and helper T cell responses could be measured. However, upon tumor challenge, the tumor grew faster in vaccinated mice and metastases appeared in the thymus. Histological and cytological analysis revealed expression of the antigen in peritoneal myeloid cells. Surprisingly, however, a few antigen-expressing myeloid cells could also be detected in the thymus. Because CD44 and CD44v2 in particular might be a homing factor for the thymus, this might explain why CD44v2 expressing myeloid cells and CD44v2 expressing tumor cells can be found in the thymus. Unsatisfactorily, however, is the explanation of why only the vaccinated mice exhibited thymic metastases. Tolerance induction against the CD44v2 was observed, at least the specific response initially observed after vaccine administrations declined in rats bearing the tumor. The mechanism of such tolerance induction in immune rats remains unexplained so far.

B. *Salmonella*-mediated Gene Therapy

The obvious efficiency of *S. typhimurium* in transferring eukaryotic expression plasmids to host cells in vivo and in vitro has also prompted its use for applications different than genetic vaccination. Transfection by *Salmonella* was used in vitro to complement a monogenic defect in macrophages from patients with hereditary hemochromatosis by transferring a plasmid encoding the cDNA of the hemochromatosis gene *HFE* (14). In addition, several applications in vivo have been reported. Mice defective in IFN-γ would normally succumb to a challenge with *S. typhimurium* aroA. However, when these bacteria carried an expression plasmid encoding IFN-γ and thus were able to transfer DNA that leads to a complementation of the genetic defect at least in some cells, the mice were able to resist the bacterial challenge (13). Similarly, transfer of IL-12 and GM-CSF encoding cDNA via *S. typhimurium* resulted in measurable levels of the particular recombinant cytokine in the serum of such mice and caused the retardation of subcutaneously applied tumors (59).

In a murine B cell lymphoma model, *Salmonella* were used to transfer a plasmid encoding a soluble form of the human CD40 ligand orally (60). Stimulation of normal APCs with CD40L results in up-regulation of MHC class I and class II as well as costimulatory molecules. In the particular B cell lymphomas employed in these experiments, stimulation via CD40L leads to growth suppression in vitro and in vivo. Oral administration of the recombinant *S. typhimurium* protected mice against a simultaneous challenge with the B cell lym-

phoma. This treatment was still partially effective when the recombinant *Salmonella* were applied 1 week after the challenge and still retarded the tumor growth when administered 2 to 3 weeks after tumor application. CD40L was detectable for several weeks in the serum of such mice. Histological examination demonstrated that, after oral administration of the recombinant *Salmonella*, many cells expressed CD40L in Peyer's patches, whereas only a few such cells could be found in spleen. These findings convincingly demonstrate the high potential of *Salmonella* as carrier for DNA vaccines and gene therapy.

C. Targeting Tumors with Transformed *Salmonella*

An unexpected way of bacteria-mediated gene therapy was discovered recently. This is based on the finding that certain anaerobic bacteria such as *Clostridium beijerinckii* and *Bifidobacterium longum* or facultative anaerobic bacteria such as *S. typhimurium* are able to multiply in tumors after intravenous or even oral application (61–63). This is most likely due to the particular microenviroment supplied within a growing tumor (i.e., low oxygen due to insufficient blood supply and nutrients due to dying cells). Correspondingly, *Clostridia* and *Bifidobacteria* are mainly found in necrotic areas of the tumor, whereas *Salmonella* can be found within the whole tumor. Other organs are usually not infected at all (*Clostridia* and *Bifidobacteria*) or to a much lower degree (*Salmonella*). This tumor specificity of accumulation of such bacteria can be used to carry suicide genes into the tumor, this was most consequently worked out for *S. typhimurium*. First, wild-type bacteria and bacteria that were rendered hyperinvasive by several infection cycles through melanoma cells were made auxotrophic for the purine pathway as attenuation (62). Subsequently, the *mlt* gene that is involved in the lipid biosynthesis was disrupted in such bacteria (64). Thus, an altered lipopolysaccharide is produced and these bacteria no longer induce the secretion of TNF-α in macrophages and human peripheral blood monocytes. Therefore, the risk of toxic shock elicited normally by such bacteria is minimized. Despite this, bacteria of both strains are found to reside preferentially in established tumors as compared with normal tissue. An enrichment ratio between 1400 and 2000 was observed between tumor and liver (64). Using one particular *Salmonella* strain of this series, VNP20009, tumor preference was found for several experimental tumors of mouse or human origin [the latter were tested as xenografts in nude or severe combined immunodeficiency (SCID) mice] and enrichment was also observed in spontaneous mammary gland tumors developing in the c-neu transgenic oncomouse (65).

Finally, a variant strain of VNP20009 was generated, TAPET-CD, carrying the gene for cytosine desaminase that converts 5-fluorocytosine (5-FC), a nontoxic prodrug, to fluorouracil (5-FU), a highly toxic antitumor agent. Mice with established autologous or xenografted tumors were treated with bacteria of this strain, and 3 days later 5-FC was administered (66). Shortly after administration, the 5-FU could only be detected in the tumor and not in other tissues, indicating that the enzymatic activity of cytosine desaminase was almost exclusively restricted to the tumor. In addition, all mice survived the treatment and all the tumors tested regressed almost completely. In contrast, after direct application of 5-FU, the compound was found in serum and all the tissues investigated and several mice died due to its toxic effects. Thus, by using bacteria that carry therapeutic genes and are selected to tumors by the particular conditions the tumor provides, it is possible to target chemotherapeutic drugs to the tumor with little effect on the surrounding tissue. Based on these results, the group of S. Rosenberg initiated a phase I clinical study in which the *S. typhimurium* strain VNP20009 was administered to 25 tumor patients with metastatic disease (67). One renal cell carcinoma and 24 melanoma patients were subdivided into cohorts intravenously receiving escalating doses from 10^6 to 10^9 colony forming units (cfu). Doses of 3×10^8 cfu/m^2 were well tolerated. Bacteria induced a dose-related release of proinflammatory cytokines (e.g., IL1-β, TNF-α, IL-6, IL-12), but focal tumor colonization was only observed in 2 patients without any objective induction of tumor regression. This unfortunate result indicates that additional work has to be done to transfer the tumor-homing properties of the bacterial carrier to the human situation.

VI. CONCLUSION

Within a few years after the discovery of bacteria-mediated gene therapy, the spectrum of its applicability has widened considerable. The results on tumor protection are extremely promising because they are not only restricted to prophylactic vaccination against tumor antigens, but also tumor rejection has been observed when therapeutic treatments were undertaken. Obviously, the strong adjuvant effect of the bacterial carrier allowed the induction of protective immune responses against autologous antigens. In some cases, additional cytokine therapy was required or the expression plasmid needed to be improved. However, this indicates the way for further development to obtain the next generation of vectors and improved strategies. For example, the introduction of a viral element into the expression plasmid that was carried by *Salmonella* enhanced the immune response dramatically—from retarding the growth of subcutaneous applied tumors by the unmodified plasmid to protection of most mice against lung metastasis by the modified plasmid. This was further improved by subtherapeutic doses of a tumor-targeted cytokine. Therefore, it is clear that increasing knowledge on cell interactions and cytokine networks of the immune system, on the one hand, and the improved understanding of the pathogenicity of the bacterial carrier organisms, on the other hand, will soon allow the rational design of even more effective vector systems and treatment protocols.

I. INTRODUCTION

Gene therapy relies on nucleic acid carriers. Viral diversity provides a broad palette of possibilities, thus fulfilling most requirements for gene delivery in clinical situations. However, parallel evolution of viruses and their hosts has made foreign protein particles as well as infected cells effective targets for the immune system. Although the immune response to cells can eventually be turned into therapeutic benefit, immune responses to particles excludes repetitive treatment, which is the only realistic therapeutic approach for a chronic disease. In contrast, artificial carriers can be developed without polypeptide components. They can even be coated with an inert layer, thus escaping most of the immune surveillance. Unfortunately, at best only a few out of a million copies of the gene reach the target cell nucleus. Limited biodistribution and ineffective intracellular trafficking are mainly responsible for this low efficiency.

II. DNA COMPACTION

The routing of a foreign gene to the nucleus of a cell is a complex multistage process that requires a multifunctional vector (Fig. 1). The core of synthetic vectors is invariably a polycation capable of inducing DNA condensation. In effect, conversion of a filiform molecule into a compact particle improves both its chemical stability and physical properties. Plasmid DNA compaction by cationic liposomes or polymers is a quasi-irreversible process that leads to microprecipitates containing hundreds of DNA molecules per particle. For transfection of cells in culture, large complexes are advantageous because they sediment onto the cells. As expected, however, their in vivo transfection properties are weak due (among others) to diffusion hindrance.

Unlike the *poly*cationic species mentioned above, *oligo*cations such as spermine or cationic detergents interact with DNA reversibly. Equilibration ensures comparable sizes for all complexes, and entropy tends to direct the system toward the largest number of condensed DNA particles. As a consequence, each particle will be made of a single plasmid molecule (i.e., the smallest possible particle). Unluckily, the other consequence of reversible binding is that DNA complexes do not withstand dilution or binding to polyanions such as proteoglycans (Fig. 1), and hence cannot be used as DNA vectors (1,2).

A chemical solution to this dilemma was found, based on in situ chemical conversion of the cationic detergent into a cationic lipid (Fig. 2) (3). This 2-step process leading to monomolecular *and* stable DNA particles was validated using cysteine-based cationic detergents as condensing agents, and thiol air oxidation into disulfide as the conversion reaction (4). As shown in Fig. 2, the particles all have the same size (25 nm) that corresponds to the volume of a single molecule of plasmid DNA. Moreover, such particles are capable of moving through an agarose gel in electrophoresis conditions, in contrast to classical cationic lipid/DNA complexes, which remain in the wells. To our surprise, the particles moved even faster than plasmid DNA itself (5) (see also Fig. 5). Improved in vivo diffusion within tissues can thus be expected. Intracellular trafficking may be favored, too, especially as noncondensed plasmid DNA was shown to be immobile in the cytoplasm (6). Finally, the size of the particles remains compatible with active nuclear pore crossing, which may facilitate transfection of postmitotic cells.

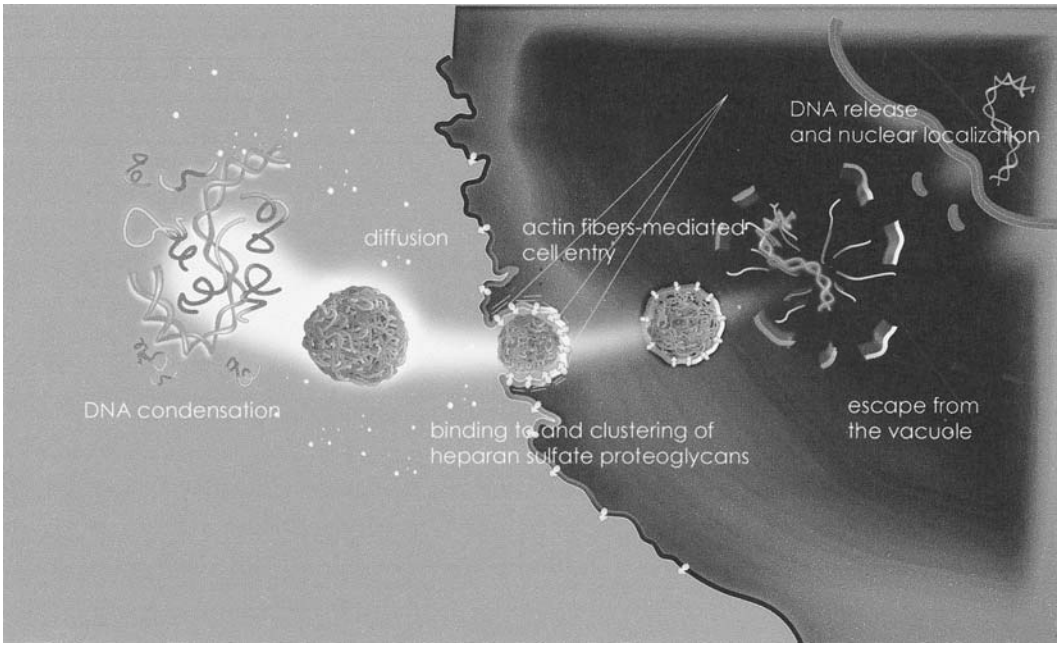

Figure 1 Gene delivery with synthetic vectors is a complex multistep process. See the color insert for a color version of this figure.

III. CELL TARGETING AND ENTRY

To enter their hosts, many viruses and bacteria bind to cell/matrix- or cell/cell-anchoring proteins, such as heparansulfate proteoglycans (HSPGs) and integrins. Anionic HSPGs are involved in cell entry of species with sizes ranging from chlamydia trachomatis (7) to adeno-associated virus (8). Interestingly, condensed DNA particles also require a cationic surface for gene delivery to occur (9), and their cell entry was shown to be mediated by electrostatic interaction with HSPGs (10–12). This is presumably true for all polycationic entities, including calcium phosphate-precipitated DNA.

A common receptor suggests a single mechanism of cell entry. Among ubiquitous HSPGs that may act as receptors are syndecans. This family of transmembrane proteins can cluster to form focal adhesions following individual electrostatic binding to a large polycationic entity. There is evidence (13–15) that syndecans clustering induces their binding to the actin cytoskeleton and eventually the formation of tension fibers. Yet here tension would not provide cell anchoring,

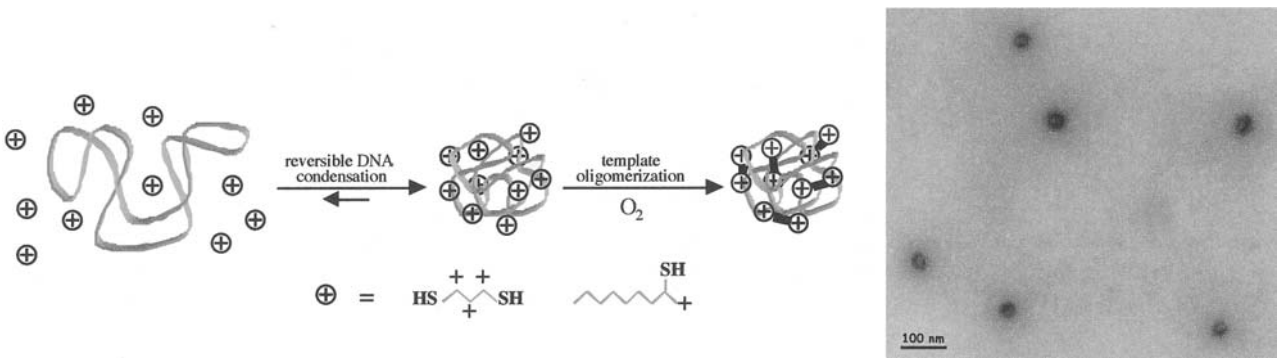

Figure 2 DNA is condensed by thiol-containing oligocations presenting a low binding cooperativity. After equilibration, the particles are ''frozen'' by DNA template-assisted oxidation of thiols into disulfides. Transmission electron microscopy of the particles obtained from a 5.5-kbp plasmid shows a homogeneous population of 25-nm spheres.

but rather a mechanism and the energy to engulf the cationic particle and form an intracellular vacuole (Fig. 1). That cell anchoring and cationic particle binding are competitive processes involving HSPGs may explain why cells have the tendency to detach from their substratum during transfection.

Unfortunately, in vivo a cationic DNA-containing particle will quickly be bound to circulating or extracellular matrix polyanionic proteins. This prevents most particles from reaching their cellular target and eventually releases DNA from the complexes. Therefore, anionic receptors are generally too ubiquitous molecules to serve as targets for synthetic vectors. As mentioned above, integrins share many functional properties with syndecans. Several integrins bind and internalize zwitterionic RGD peptide-presenting particles in vivo (16). The mechanism may be identical to the one described above for HSPGs i.e., mediated by integrin ligation and actin fibers retraction). Imititating adenovirus, RGD peptides have been chemically conjugated to polycations such as polylysine (17,18) or polyethylenimine (PEI) (19,20) and complexed with DNA. The resulting particles were shown to deliver genes to epithelial cells in culture up to 100-fold better than the corresponding polycation–DNA complexes (Fig. 3). Control experiments using RGE-coated particles confirmed the enhanced transfection to be due to $\alpha_v\beta_5$ integrin-mediated cell entry.

IV. STEALTH PARTICLES

An attractive use of RGD-coated DNA particles would be targeting of the neovasculature of metastases following systemic delivery (16). Indeed, resting polarized endothelial cells of normal blood vessels express matrix-binding molecules on their basolateral face, whereas growing and less differentiated blood vessel cells of metastases also express them on the luminal side, hence the targeting. Intravenous injection experiments performed in our laboratory with RGD-PEI–DNA complexes, however, did not target tumors better than the passive accumulation of PEI/DNA or transferrin-PEI–DNA complexes through the leaky vasculature (21). This was presumably due to fast clearance of the complexes. The biodistribution of widely different types of particles has been shown to benefit from coating with a layer of polyethyleneglycol (PEG). This effect is due to the inert nature of the polyether backbone as well as to brush-type polymer crowding, which prevents capture by macrophages. However, the latter property also prevents proper DNA condensation (22,23) and may even interfere with the DNA exchange/release process in the cell. PEI-PEG diblock polymers (22–24–26) or PEG postgrafting strategies (27–29) are being explored as a means to avoid interference with condensation.

As an example of combination of this approach with the monomolecular DNA particle technology discussed above, we currently attempt targeting (30,31) of the high-affinity folic acid receptor, which is overexpressed on many cancer cells. Indeed, folic acid binding was shown to trigger internalization of the complexes (32). To this end, PEG (mw = 3400) was conjugated to a strong DNA-binding moiety one one end, and to folic acid on its distal end (Fig. 4).

Monomolecular plasmid DNA particles were formed with a tetradecane-cysteine-ornithine detergent (C_{14}COrn) (5).

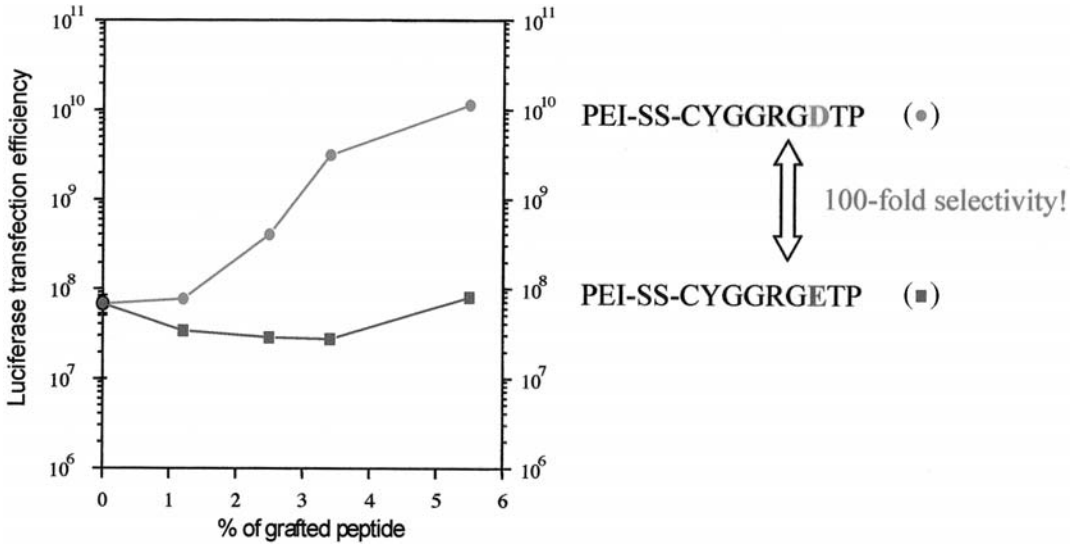

Figure 3 RGD peptide-mediated transfection of HeLa cells expressing $\alpha_v\beta_5$ integrin. Cells were transfected with pCMVluc plasmid complexed to PEI that was grafted with increasing amounts of RGD peptide. Luciferase expression (RLU/mg protein) was measured after 24 h incubation.

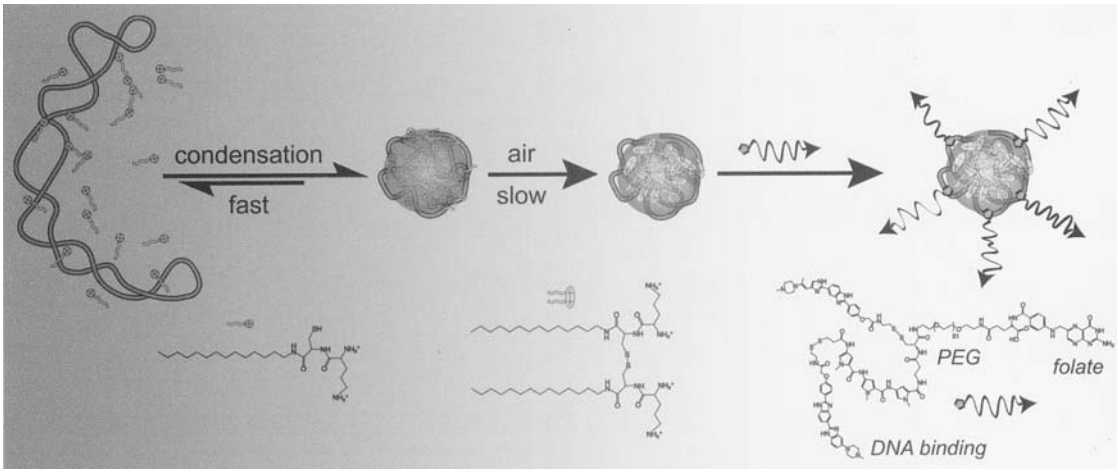

Figure 4 Stepwise assembly of stealth nanometric DNA particles. Plasmid DNA was condensed with a cationic cysteine detergent in aerobic conditions. The resulting gemini lipid/DNA particles were coated with a PEG-folate corona that was anchored to the DNA by a minor groove-binding moiety. See the color insert for a color version of this figure.

Aerobic disulfide bond formation led to stable $(C_{14}COrn)_2$–DNA complexes. Direct binding of PEG-fol to naked DNA as well as PEG-fol grafting onto the surface of the monomolecular DNA particles was monitored by gel electrophoresis (Fig. 5). Electron microscopy showed PEG-coated particles to be compact, monomolecular, and stable in physiological conditions. Finally, cytometry showed them to bind to KB cells (a human nasopharyngeal cancer cell line) when folate receptors are overexpressed (Fig. 6). Targeted gene delivery to cancer cells is being attempted with these complexes.

V. PROTON SPONGE-MEDIATED VACUOLE ESCAPE

After internalization, DNA complexes must escape from the formed intracellular vacuoles (Fig. 1). Many viruses that do not fuse with the plasma membrane exploit endosome acidification as a signal triggering activation of an escape mechanism. This requires sophisticated conformational changes of fusion proteins. In the case of cationic lipids or polymer–DNA complexes, most particles probably remain trapped within vacuoles. DNA being protected within the complexes, this may even be regarded as a ''slow release'' process that sustains gene expression. In effect, cell division, although favoring initial transfection (see below), also leads to loss of the transgene(s) present in the nucleus of a transfected cell. During mitosis of a transfected cell, the intracellular events of gene delivery must thus occur again for that cell to remain transfected, hence the potential importance of slow release. Cationic lipids may possess some intrinsic bilayer-disrupting property, especially when forming nonlamellar phases [e.g., lipopolyamines form direct hexagonal phases (11), DOPE forms an inverted one (33)]. Subsequent vacuole rupture allows charge neutralization of the cationic lipid by intermixing with anionic phosphatidylserine from the vacuole outer leaflet. This may liberate in part the complexed polynucleotide (34).

Cationic polymers possess no fusogenic activity per se. This is why fully cationized polymers such as polylysine require chloroquine, a lysosomotropic drug used to unmask the intravacuolar malaria parasite, to become effective transfection agents. However, some cationic polymers (35), such as polyamine dendrimers (36,37) or PEI(38), share with chloroquine the ability to buffer the acidity of endosomes. Vacuolar pH decrease (39) should therefore coincide with a large ionic concentration increase. Osmotic swelling due to water entry may then burst some of the vacuoles and release the complex into the cytoplasm. This ''proton sponge'' hypothesis (38) proved to be fruitful, as it led to the design of other efficient polymeric vectors (40–42). It was recently supported by the fact that PEI transfection efficiency is 100-fold decreased by bafilomycin A, a specific vacuolar H^+-ATPase inhibitor (43,44).

Over the years, PEI, and especially linear PEI (45–47) has become a versatile vector for in vitro and in vivo gene delivery, with over 300 publications referring to the use of its gene delivery properties. As a leading member of what can be regarded as the second generation of nonviral vectors for gene therapy, in vivo data using PEI deserve a paragraph.

VI. PEI-BASED GENE DELIVERY IN VIVO

As mentioned in the introduction, successful gene delivery and particularly, in vivo delivery, will probably be further optimised with multicomponent approaches. However, despite this caution it is noteworthy that much data on unmodified branched and linear PEIs show them to be efficient, non-

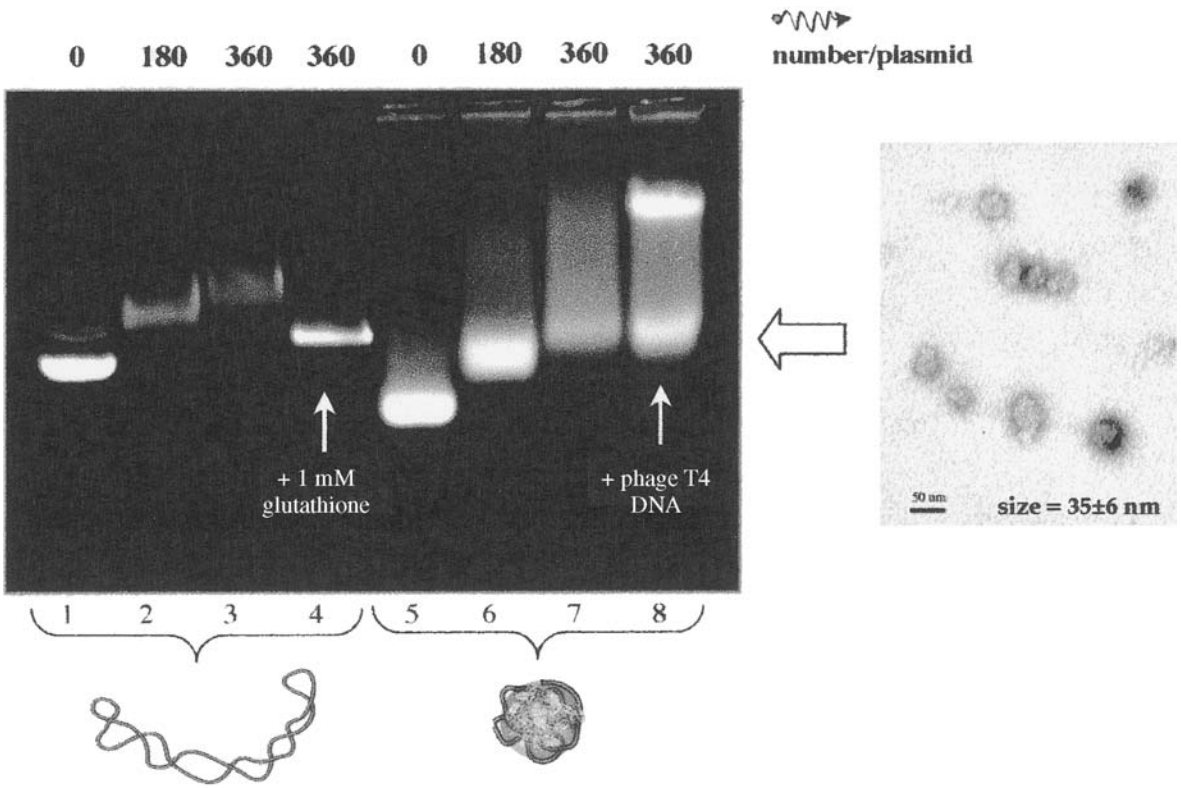

Figure 5 Agarose gel electrophoresis shows complex formation between DNA, cationic detergent, and compound PEG-fol. Plasmid DNA (30 mM bp, lane 1) was mixed with increasing amounts of PEG-fol (1 mM, lane 2 and 2 mM lanes 3, 4); lane 4: DNA–PEG complexes were incubated for 15 min with 1 mM glutation. Lanes 5–8: nanometric $(C_{14}CO)_2$/DNA particles were prepared as in Fig. 4. After overnight incubation, compound PEG-fol (lanes 6–8) was added to the particles; lane 8: 1 h incubation of the complexes with phage T4 DNA. Image: Transmission electron microscopy picture of the final $(C_{14}CO)_2$–DNA–PEG-fol complexes shows monomolecular DNA condensation into compact particles. See the color insert for a color version of this figure.

toxic, and versatile agents for in vivo gene delivery by a number of routes. These commercially available polymers have the added advantage that their relatively high in vivo performance is unhindered by immune effects. Like other synthetic vectors, PEI provides the extra benefit of facility of use for complexing and condensing DNA. This is turn leads to ease of testing DNA constructs and scaling up of protocols. Preclinical data toward gene therapy approaches of AIDS (48), head and neck cancer (49,50), and pancreas (51,52) and ovarian cancer (53) disseminations in the peritoneal cavity are encouraging.

That PEI provides relatively high levels of transfection in a number of target organs, by various delivery routes, prompts a series of questions. Given that the intracellular barriers to delivery are probably similar for in vivo, ex vivo, and in vitro delivery, the main point of inquiry is how DNA–PEI complexes overcome the series of anatomical and physiological barriers that hinder delivery of functional DNA to target cells in vivo. A key point would appear to be the small size of particles obtained when DNA is condensed in a defined medium. PEI–DNA complexes can be formulated that have a size range close to that of viruses (50 nm, Fig. 7) and with a charge ratio that does not hamper biodistribution and yet maintains efficient transfection. According to the choice of formulation solution, small particles can be obtained whether branched (25 kDa) or linear (22 kDa) are chosen. Using linear 22 kDa PEI to complex DNA in salt solutions gives quite large particles ($\geq$1 μm) that work exceedingly well in vitro (47). However, formulation with the same 22 kDa in an equiosmotic but salt-free solution of 5% glucose produces particles with mean size ranging between 30 and 60 nm (54) (Fig. 7). Particles of $<$100 nm with the branched 25-kDa form can be obtained in 150 mM NaCl (23,55). However, despite the roughly similar sizes of particles formulated in appropriate conditions ($<$100 nm), there are quite clear-cut differences in the performances obtained in animal models (47,56) with linear 22-KDa PEI consistently providing the greatest efficiency. Improved transfection of resting cells with linear PEI (46) may be the clue to this observation. The more recent findings on the better performance of the complexes formulated in

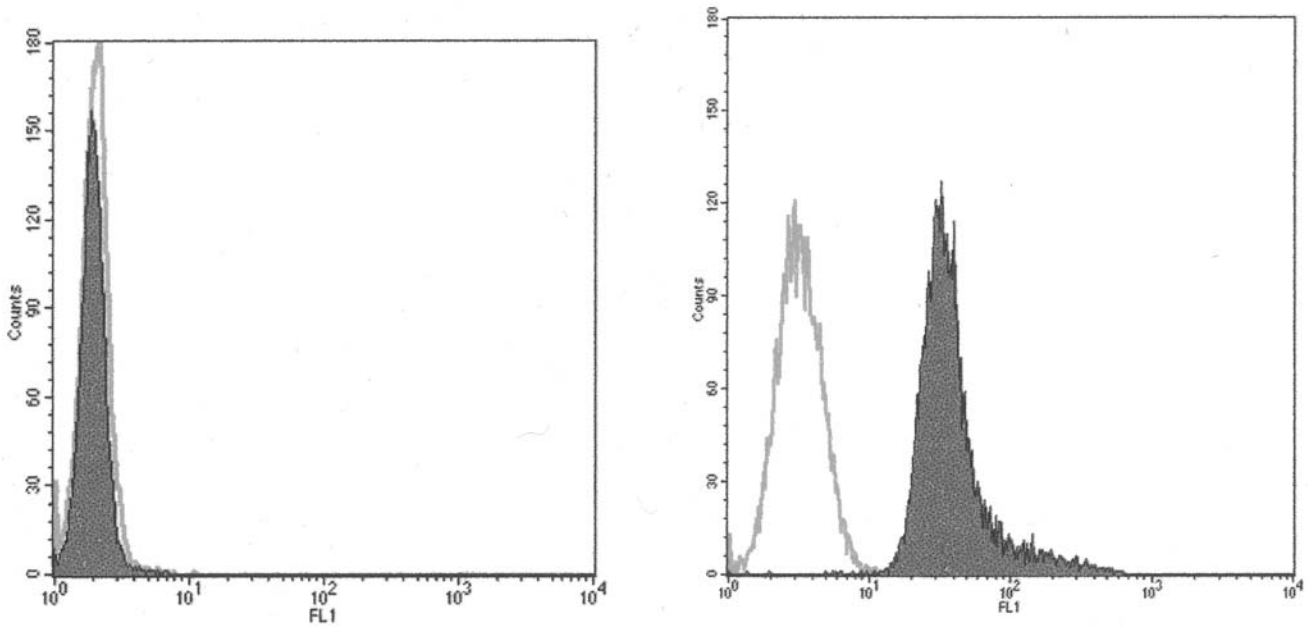

Figure 6 $(C_{14}CO)_2$–DNA–PEG-fol complexes specifically bind to folate receptor-expressing KB cells. Cells were incubated for 3 h with fluorescent DNA complexes and sorted by cytometry according to their fluorescence. Only cells overexpressing the folic acid receptor (right graph) show an increased fluorescence (filled trace) over nontreated cells (hollow trace).

salt-free conditions corroborate early work injecting DNA/PEI particles into the brains of adult mice (57).

The description of the small size of particles formulated in salt-free conditions with 22-KDa PEI was accompanied by the demonstration that these particles were stable in cerebrospinal fluid and led to a large diffusion of active complexes throughout the brain following intraventricular injection (54). This in turn led to the application of the methodology in a number of different settings, including the central nervous system, the respiratory tract, or tumors.

A. Central Nervous System

PEI has been used to deliver DNA into the CNS of rodents both for proof of principle and to analyze physiological functions [for instance, see (58,59)], including regulation of gene expression (promoter studies) and function of proteins (mainly transcription factors and transporter proteins). As concerns the basic optimization of the methodology, keeping concentration of DNA <1 μg/μL increases yield (60). Indeed, in the newborn mouse brain, one can obtain up to 2.10^7 RLU/mg protein when injecting a mere 20 ng DNA. Such conditions also allow for diffusion of particles not only within the intraventricular space, but also through the ependymal cell layer lining the ventricles and through 4 or 5 cells layers beyond it (54). Most recently, using the same intraventricular delivery route, it has been shown that gene delivery with unmodified PEI permits privileged targeting of the neuronal stem cell population in adult mice (61) (Fig. 8).

Similarly, using low DNA concentrations (0.25 μg/μL) and a low charge ratio (3–6 N/P) allowed Marthres and collaborators (62) to obtain increased expression of the dopamine transporter throughout the entire substance nigra (a brain nucleus with a diameter of about 5 mm) in adult rats. Significant increases in binding and uptake were found in all the brain areas receiving neuronal projections from the brain structure transfected (*sustantia nigra*). This finding is important because it underlines the fact that postmitotic neurons can be transfected by this method, in agreement with the related properties of linear PEI (46–63,64). Equivalent results in terms of efficiency of expression in neurons of the adult rat were obtained when injecting plasmids encoding the serotonin transporter into the raphe nucleus of adult rats (65). In this study, effects of modifiying gene expression were also assessed on behavior (sleep/wake cycle), and significant and appropriate changes found for weeks following transfection. Yet another means of gene delivery to the brain with PEI was demonstrated by Wang et al. (66). These authors observed that following injection of PEI–DNA complexes into the tongue muscle of mice, significant reporter gene activity could be found in the brain stem. This finding suggests that PEI–DNA complexes can cross the neuromuscular junction and enter the brain by retrograde axonal transport, thus bypassing the blood–brain

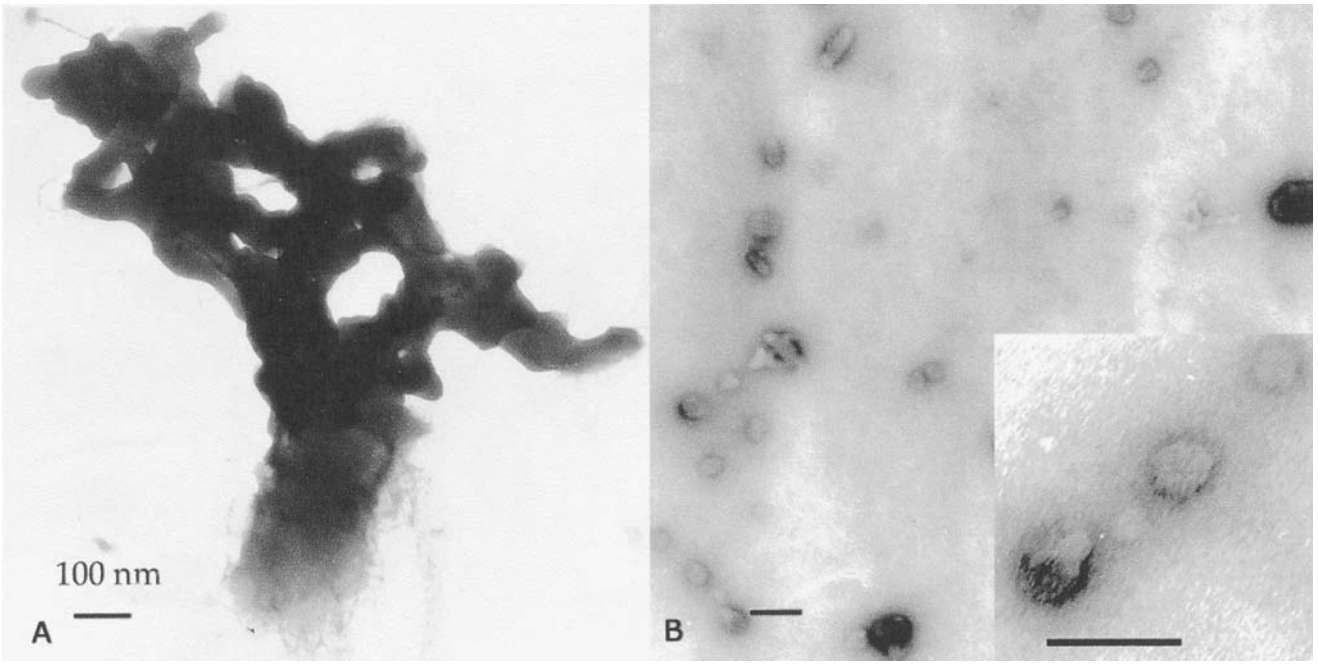

Figure 7 Electron micrographs of PEI 22-kDa–DNA complexes prepared in Nacl 0.15 M (A, N/P = 2) or in 5% (w/w) glucose (B, N/P = 5); bar represent 100 nm.

barrier in a manner similar to vectors based on the proteolytic C fragment of tetanus toxin (TTC peptide) (67).

B. Delivery to Respiratory Tract

Gene therapy to the lung could be exploited for both genetic and acquired diseases. However, like the brain, any therapeutic approach for the respiratory tract must take into account the heterogeneity of the cellular targets in the lung: epithelial cells, alveolar cells, vascular cells, and serous cells in the submucosal glands, etc. Two main routes can be used to introduce genes into pulmonary tissue: via the airways or through the circulation by systemic injection.

Both branched and linear PEIs have been tested with moderate success for delivering DNA by the tracheal route. Branched 25-kDa PEI gave higher levels of transgene expression than fractured polyamidoamine dendrimers especially when DNA–PEI complexes were prepared in water (68). Another group has tried nebulization of PEI–DNA complexes prepared in water (69). Their data show that PEI can protect DNA during nebulization and therefore give enhanced transgene expression. In a further analysis, they show that nebulization with 5% CO_2 improves transfection over that seen with air (70). Yet, in a recent study (71), PEI was shown to give exceptionally high (>1 ng luciferase/mg protein, ca. 1%–5% transfected tracheal cells) and more durable expression (>4 days) following slow instillation of the complexes into the mouse lung.

Following the demonstration that in 5% glucose DNA complexed with 22-KDa PEI provides small particles showing good stability and diffusibility in the brain, it was logical to test whether these particles would be stable enough to provide transfection of various organs following systemic injection. To this end, we analyzed transfection obtained in different tissues of the mouse after injection of varying quantities of DNA complexed with different N/P ratio through the tail vein. It was found that in all cases the lung showed the highest levels of transgene expression with both luciferase and the β-galactosidase genes (72,73). Anatomical analysis revealed pulmonary cells to be transfected and no signs of lesions or toxic effects. This suggested that the particles were crossing the pulmonary capillary barrier, although double labeling was not carried out. Later work showing the transfection of pulmonary cells was confirmed by double immunostaining with appropriate markers and passage of the pulmonary epithelium was shown to be both rapid and nontraumatic (74). Bragonzi et al. (56) used this model with GFP expressing vectors and tagged complexes to further the analysis. They also compared transfection performances of polyplexes formed with branched and linear PEIs to that of two lipoplexes. The most efficient vector for delivery by this route was linear 22 kDa. DOTAP gave reasonable levels of expression with naked DNA, GL-67A, and 25kDa PEI showing negligible transfection.

C. Tumor Targeting

Obviously, another major field of application for gene transfer technology is the treatment of tumors. Unmodified or modified PEI has been used with the aim of targeting lung metasta-

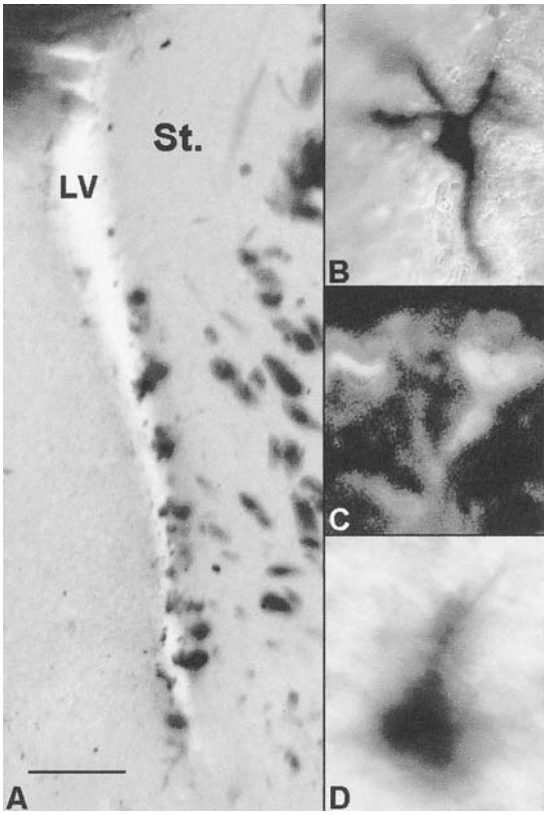

Figure 8 Privileged transfection of neuronal stem cells in adult mice with PEI. (A) In the adult CNS, intraventricular injection of PEI–DNA complexes results in transgene expression (β-gal positive blue cells), mainly on the striatal aspect of the lateral ventricles. (B–D) Identification of the transfected cells revealed a preferential transfection of the adult neural stem cells of the subventricular zone and their immediate progeny. (B) Positive cell with the typical morphology of astrocyte. (C) Confocal microscopy confirm GFP reporter gene expression in GFAP (marker of astrocytes)-positive cells in the subependymal layer. (D) Transfected cells (lacZ-positive cell) in this area also express Nestin, a marker of neural progenitors. Bar: (A) 200 μm; (B–D) 12 μm. St., striatum; LV, lateral ventricle. See the color insert for a color version of this figure.

ses or subcutaneous tumors (75). Various modes of delivery have been tested to this end: direct intratumoral of unmodified 22-kDa PEI (76), intravenous injection of transferrin-conjugated PEI (21) or even aerosolized PEI–DNA complexes to reach lung tumors (70). Interestingly, it is in this field of endeavor that multicomponent approach has yielded the best results. Kircheis et al. (43) shielded either 25-kDa or 22-kDa PEI–DNA complexes by covalently incorporating transferrin and used the complexes for systemic injection of mice bearing subcutaneous tumors. The presence of transferrin on the complexes provided a preferential transfection of the tumors rather than the lung.

VII. NUCLEAR MEMBRANE CROSSING

Whatever the delivery route used, probably the largest barriers to gene delivery are restricted cytoplasmic diffusion and the nuclear membrane (11,77). DNA particles entering fast dividing cells in culture are less hindered by these problems. Indeed, transfection of synchronized cells showed mitosis to be a key event for efficient transfection (78,79). It is therefore possible that, in general, DNA or DNA complexes that are unable to diffuse through the cytoplasm are dragged along with chromosomes and become incidentally sequestered in the nuclei of daughter cells during telophase. This would explain why most transfected cells appear as doublets (Fig. 9). Despite these observations, there are also quite well-documented cases of linear PEI-based transfection of nondividing cells both in vitro and in vivo. Indeed, in vitro transfection of resting (G1) HeLa cells with linear PEI has been shown to occur (46), albeit with 10-fold less efficiency than dividing ones (G_2/M). Lipids or branched PEI were much more dependent on cell division. Moreover, there are a number of studies indicating transfection of mature neurons in vitro and in vivo with linear PEI (62–65,80)

In vivo, even cancer cells can be considered as resting with respect to the lifetime of exogeneous DNA. A vectorial nuclear carrier should therefore be designed. Following the example of some DNA viruses, chemists attempt to divert the endogeneous nuclear import machinery by designing nuclear localization signal peptide (NLS)-bearing vectors (81–86). Unfortunately, cationic vector–DNA complexes are generally

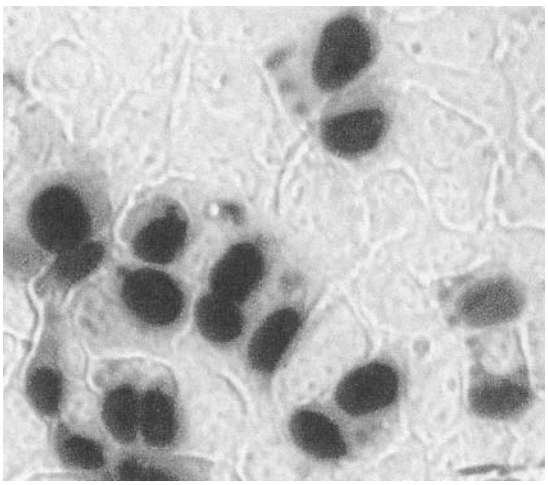

Figure 9 BNL. CI-2 hepatocytes transfected with nuclear LacZ/PEI complexes essentially appear as twins after 24 h. (Courtesy Dr P. Erbacher, Polyplus SAS.) See the color insert for a color version of this figure.

far too large to cross nuclear pores. Assuming the DNA–cationic vector complexes are (at least in part) disassembled in the cytoplasm, we have covalently bound a single NLS peptide to one end of a linear DNA fragment (Fig. 10). This hybrid construction was shown to enhance transgene expression up to 1000-fold in HeLa cells (87). Our working hypothesis was that the 3-nm-wide DNA-NLS molecules present in the cytoplasm would initially be translocated through a nuclear pore by the nuclear import machinery. As DNA would enter the nucleus, it would be condensed into a chromatinlike structure, which would provide the mechanism for threading the remaining wormlike molecule through the pore. Unfortunately, large enhancement factors were only observed for cell lines. Resting primary cells remained refractory, which may indicate that the large intracellular motions that occur during mitosis are required for intracellular trafficking of the DNA-NLS as well.

VIII. CONCLUSION

Following the initial findings over a decade ago that cationic lipids and polymers are able to carry genes into eukaryotic cells, much effort has been dedicated to improving transfection efficiency via structural modifications of the carrier. Exploiting structure–activity relations led to molecules capable of transfecting adherent cell lines in culture at a multiplicity of infection of ca. 10^6 gene copies per cell. In vivo gene delivery, the prerequisite to gene therapy, is still orders of magnitude less effective.

It does not seem reasonable anymore to search for ''the'' molecule able to carry DNA across the numerous barriers. Vectors of the future will be composed, much like viruses, of multifunctional supramolecular systems that self-assemble around DNA. Programmed intracellular disassembly may well be part of a successful story, too, especially for coated or reticulated particles. Each component of the vector is devoted to a particular function. As illustrated above, some functions, such as integrin-mediated cell entry or NLS-directed entry into the nucleus, mime viruses. Some other solutions, such as monomolecular genome condensation *via* detergent dimerization, or endosome release by the proton sponge effect, have obviously not been exploited by the natural cell invaders. The consequences of increased complexity of the vectors on their development as gene medicines (88) are difficult to evaluate at this stage. In any case, the puzzle still has to be assembled prior to ressemblance to an artificial virus (89): this is yet another story.

I. INTRODUCTION

Crucial requirements in gene therapy are a successful delivery of the therapeutic gene into the right target cells and a controlled expression in the transfected cell, at the appropriate levels and over the required period. The current gene delivery systems are not optimal in these aspects. During the last decade increased attention has been given to nonviral gene delivery vehicles, such as naked plasmid DNA, cationic liposome–DNA complexes (lipoplexes), polymer/DNA-based systems (polyplexes), and combinations thereof (1–2). These delivery systems are attractive because of their simplicity (they can be generated from few, defined components), and the flexibility in synthesis and assembly of the gene transfer complex. If desired, they can be designed protein-free/nonimmunogenic and can be very flexible regarding the size of DNA to be transported. However, their efficiency in gene delivery does not meet the requirements for most therapeutic applications.

Evolution has resulted in several mechanisms that enable the transport of molecules into cells that include not only simple diffusion, active transport, phagocytosis, receptor-mediated endocytosis, but also other mechanisms such as those used by various viruses to infect cells, bacterial conjugation, and natural transformation procedures seen in some microorganisms such as Helicobacter pylori (3). These natural pathways can be used in a new, artificial setting as means of a transfer route to deliver nucleic acid into cells. This article describes the nonviral delivery system, which exploits receptor-mediated endocytosis to target and transfer nucleic acids into cells.

The concept of receptor-mediated gene transfer draws its attention from the natural delivery mechanism based on receptor-mediated endocytosis (4,5). There are basically 2 mechanisms of endocytosis: (1) clathrin-dependent receptor-mediated endocytosis (coated pit endocytosis) (6), and (2) clathrin-independent endocytosis (7). Clathrin-dependent receptor-mediated endocytosis involves the binding of a ligand to a specific cell surface receptor, resulting in the clustering of the ligand–receptor complexes in clathrin-coated pits, invagination into the cell and budding off of the coated pits from the cell surface membrane to form intracellular coated vesicles, and maturation (uncoating, fusion of vesicles) into endosomes. Within these endosomes, ligands and receptors are each sorted to their appropriate (intra)cellular destination (e.g., lysosome, golgi apparatus, nucleus, or cell surface membrane). The clathrin-independent mechanisms resulting in uncoated pits include phagocytosis, pinocytosis, and potocytosis. Phagocytosis is a mechanism of internalizing large particles and microorganisms ($>0.5\ \mu m$). This mode of internalization is initiated by receptors on the phagocyte recognizing the particle either directly or indirectly, via opsonization of the particle. Internalization is primarily mediated via pseudopod action rather than pits (invaginations) on the cell surface. The engulfed particle, initially situated in the early phagosome, is eventually destroyed along the endocytosed pathway. Thus, cell capability to recognize particles via receptors and to form pseudopods seems to be a major characteristic mediating phagocytic internalization. Other forms of internalization that do not use clathrin, however, do seem to rely on pits (invaginations) on the cell surface. Such internalization systems include

macropinocytosis, pinocytosis, potocytosis, and transcytosis. Potocytosis and transcytosis may use caveolae as routes for internalization (5,8).

Many receptors contain motifs in their cytoplasmic domains that act as recognition sequences for initiating the process of enhanced intracellular uptake of macromolecules. With ligand interaction, the rate of receptor internalization is increased. Whether the intracellular pathways of the internalized molecule and biochemical consequences is the same between the different forms of endocytosis and ligands remains unclear (9–12).

To describe and elucidate the science of receptor-targeted polyplexes used in gene transfer, special attention is given to the many barriers that need to be overcome for gene transfer to be efficient. Factors such as DNA condensation, particle size of the DNA complex, route of administration, stability of the transferred gene in vivo, physical barriers that need to be overcome in order to reach target sites, and other in vivo confrontations, are discussed. The current concepts on binding of DNA complexes to the cell surface receptor and internalization and intracellular trafficking are reviewed, discussing also strategies for enhanced intracellular vesicular release, cytoplasmic trafficking, and nuclear targeting.

II. POLYPLEXES, CELLULAR TARGETING, AND RECEPTOR-MEDIATED ENDOCYTOSIS

A. DNA-condensing Carrier Molecules and Polyplexes

To transfer DNA safely and efficiently into the cell, it needs to be primarily stabilized. This is achieved by using carrier molecules capable of binding DNA. Such DNA-binding carrier molecules are also used not only to condense and compact the DNA into a size preferred by the target cell for being internalized, but also to neutralize the negative charges of the DNA, hence preventing repulsive forces between the DNA and the cell plasma membrane. In addition, carrier molecules may also protect the DNA from certain undesired affects of the physiological environment. DNA-binding carrier molecules should interact with the genetic material in a reversible, noncovalent, nondamaging manner. Cationic lipid-based systems, formulating DNA into ''lipoplexes,'' and cationic polymers, formulating DNA into ''polyplexes,'' have been used (1). For the majority of the cases, the cationic polymers—polylysine and polyethylenimine (PEI)—have been applied for binding and condensing DNA into polyplexes with sizes of 50 nm up to several hundred nm (13,14), which can be taken up by cells (15–19). A series of other DNA-binding polycations have also been used in polyplexes: polyarginine (20), protamine (13), or nonhistone nuclear proteins such as high-mobility group (HMG) proteins 1 (21), as well as nuclear proteins such as histones H1, H3, or H4 (22).

The cationic portion of the DNA complex can enhance binding to the cell (in addition to ligand-mediated receptor binding), and may also facilitate and mediate the transfer of the DNA to the cytoplasm, such as by disruption of the vesicular membranes. Thus, DNA condensation is essential for efficient transfer into cells; however, not any molecule that binds DNA results in an appropriate condensation.

B. Receptor Ligands for Targeting Specific Cells

Gene transfer vehicles have to fulfill several major delivery tasks: to transfer the therapeutic gene from the site of administration to the surface of the target cells, and to facilitate the internalization of the gene into the cells, trafficking to the nucleus. Incorporation of receptor ligands has been considered to support these tasks [i.e., targeting and enhanced cellular internalization of the transferred (therapeutic) gene, and in some cases, trafficking to and targeting to the nucleus, possibly including intranuclear trafficking]. Furthermore, nonspecific cellular internalization of a DNA–polycation complex via a net positive charge could result in cytotoxic side effects, such as disruption of cell membranes and aggregation of erythrocytes (23). Coupling ligands to the DNA-binding carrier (see Fig. 1) may overcome these obstacles by reducing positive surface charges of DNA complexes, preventing erythrocyte aggregation, and by enabling the complex to target specific cells, binding them strongly by ligand–receptor interactions, and thus minimizing interactions with nontarget cells (23).

Specific cell binding and enhanced cellular uptake can be mediated by 1 ligand, but could also be regarded as 2 separate processes because some ligands might target and bind a specific cell surface receptor, but not necessarily result in enhanced internalization, whereas other ligands have no cell-type specificity, but efficiently mediate uptake. The importance of these 2 points is very clear when working in vitro as well as in vivo. In vitro, targeting the gene of interest to specific cells is not a problem as such because the delivered gene gets in direct contact with the target cells only, and hence, need not seek out specific cells. However, it is necessary to enhance cellular uptake of the transferred gene. This can be achieved by using ligands as intracellular delivery-enhancing elements. For in vivo application, both cellular targeting and enhanced intracellular delivery of the polyplex are crucial for successful gene therapy.

Ligands, internalized via receptor-mediated endocytosis, represent a wide variety of macromolecules with varying physiological activities, including nutrient provision (e.g., low-density lipoprotein, transferrin); modified molecules from the circulation (e.g., ASGP, plasminogen activator inhibitor complexes); growth factors and hormones (e.g., insulin, VEGF, EGF), and some lysosomal enzymes. Some of these ligands may be coupled to DNA complexes (see Fig. 1), targeting them to specific cells. Ligands can be (1) proteins such as transferrin and asialoglycoproteins, and (2) small natural or synthetic molecules such as folic acid, peptides, or sugar derivatives. Examples of ligands that have been used as conjugates with polycationic carriers for targeted gene transfer are shown in Table 1 and references (9–10,13, and 24–87).

A general aspect to be considered in the selection of a ligand to be coupled to the carrier is that certain ligands are very spe-

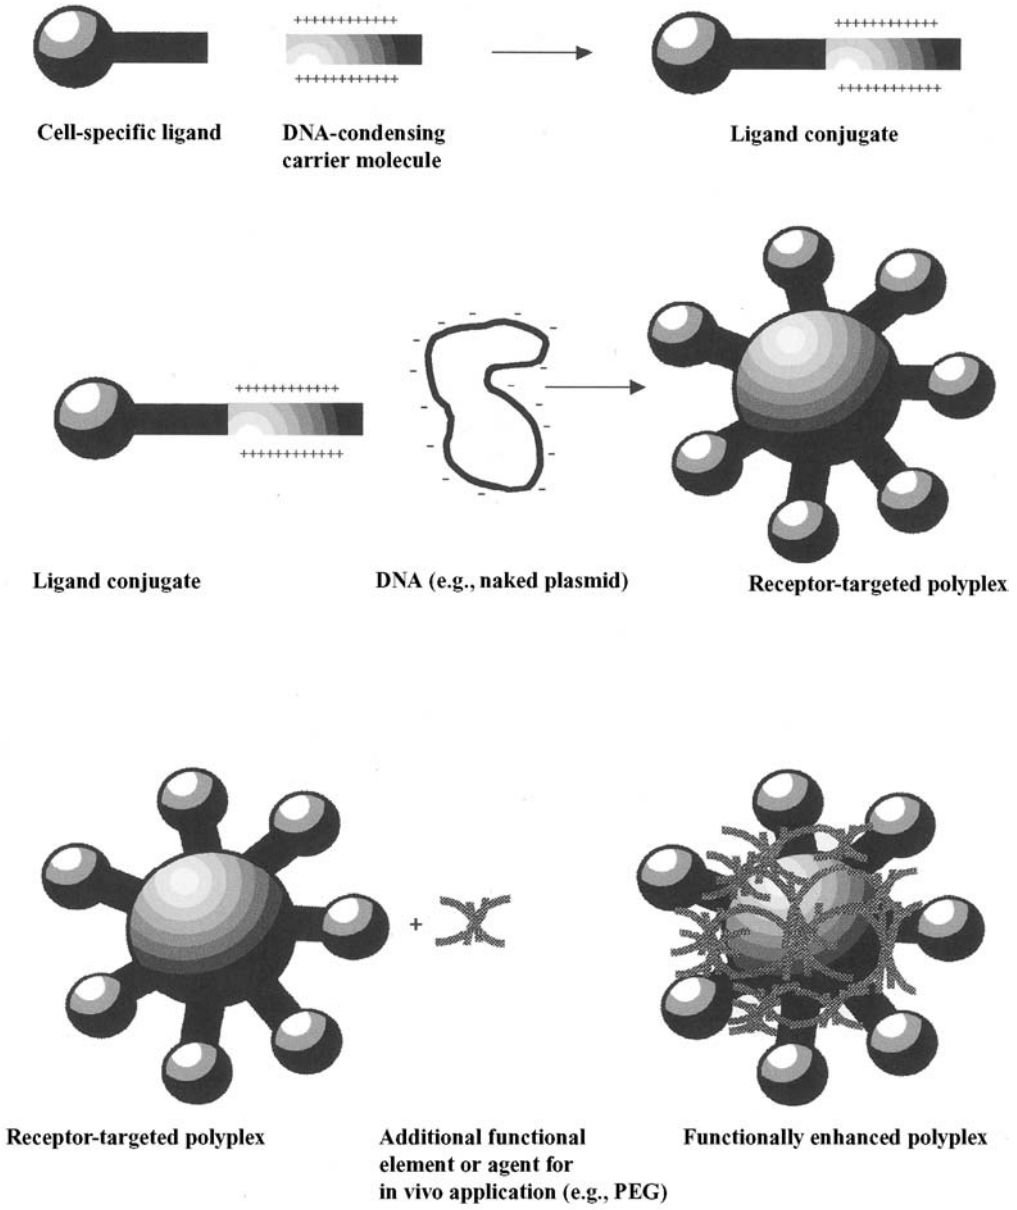

Figure 1 Assembly of DNA complexes (polyplexes).

cific in targeting certain cells or tissues in the body (e.g., asialoglycoproteins/hepatocytes), whereas others are not [e.g., transferrin/iron supply to many cell types]. Some ligands are internalized very efficiently (e.g., transferrin, anti-CD3 antibody bound to the T cell receptor-associated surface molecule CD3), whereas some others may be internalized either very slowly or not at all. Thus, the choice of ligand for efficient gene transfer is fundamental. Regarding this, one may also take advantage of the ligand binding and internalization enhancement as 2 separate processes, using 2 different ligands, 1 for targeting and the other for internalization. Hypothetically, 2 different ligands could also be used, where 1 ligand serves cell binding function only, whereas the other ligand enhances cellular internalization. The target cells need to contain cognate receptors, enabling the ligands to work in concert. Efficient internalization will only take place with cells containing both receptor types, enabling the 2 ligands to work in concert. Furthermore, the biology of specific cell types may also play an important role for efficient targeting. For example, cellular targeting ligand coupled to the DNA complex can be used as an element

Table 1 Ligands Used in Receptor-mediated Gene Transfer

Ligands	Refs.
Alpha2 macroglobulin	24,25
Anti-CD3	26,27
Anti-CD5	28
Anti-CD117	29
Anti-EGF	30
Anti-HER2	31
Anti-IgG	32,33
Antisecretory component Fab	34–36
Anti-Tn	37
Antithrombomodulin	38
Antibody ChCE7	39
Asialoglycoproteins	40–49
EGF	50–52
Fibroblast growth factor 2(FGF2)	9,53
Folate	54–56
Glycosylated synthetic ligands	57–69
IgG (FcR ligand)	32,70
Insulin	10,71
Invasin	72
Lectins	73–75
Malarial circumsporozoite protein	76
RGD-motif (integrin binding)	77
Steel factor (CD117 ligand)	78
Surfactant proteins A and B	79,80
Transferrin	13,81–87

to only target the corresponding cell, whereas internalization can be achieved via phagocytosis. Thus, cells containing the corresponding receptor will be targeted, but internalization will only take place if the cells contain competent phagocytic apparatus.

1. Ligand Conjugates

Cell-targeting ligands can be coupled to the DNA-binding elements (for examples, see Table 1), forming a conjugate capable of interacting with and condensing the DNA, and targeting it to specific cells (Fig. 1). The DNA-binding element (DNA carrier molecule) should be bound to the ligand, without its DNA binding, condensing, and protective functions being affected, and without affecting the cell targeting property of the ligand. Such a molecular conjugate containing both DNA-binding and cell targeting properties can be combined with DNA, forming the conjugate–DNA complex (''polyplex''). This polyplex (1) should contain the DNA in a highly condensed state, with the ligands positioned in a manner, free to interact with the target cell receptors.

Conjugates are commonly synthesized by covalently coupling the ligand to the DNA-binding polymer. Twenty years ago, reports were published describing the concept of exploiting natural endocytosis pathways of ligands for the delivery of DNA macromolecules. A method was published for the covalent coupling of DNA to protein ligands, such as alpha2-macroglobulin, formulating the concept of receptor-mediated endocytosis (24). Alternative approaches use compositions containing DNA associated with the ligand in noncovalent mode, using the ligand linked to liposomes (88). This concept was expanded, with approaches such as modifying proteins (transferrin and asialoglycoprotein) with positively charged N-acylurea groups that enable electrostatic binding to DNA, to generate DNA-binding ligands for receptor-mediated gene transfer (89). A chemically more defined approach involves conjugates of asialo-orosomucoid, and the polycation poly(L)lysine (40). Complexes of these DNA-binding conjugates with DNA plasmids encoding CAT marker genes or therapeutically relevant genes were shown to result in gene expression both in vitro in cultured HepG2 hepatoma cells, and in vivo in the liver of rats or rabbits (40–47). This was the beginning of the era ''receptor-mediated gene transfer'', where ligand–polycation conjugates were complexed with DNA, to condense, target, and transfer the gene into specific cells. Since then, many successful attempts have been performed in synthesizing ligand–conjugates, for example, conjugation of transferrin, folic acid, anti-CD3 antibody, to the DNA-binding elements polylysine, protamines, histones, intercalators, and complexing them with DNA for achieving targeted gene transfer (see Table I).

Taking transferrin as an example, conjugate synthesis involves the modification of transferrin and DNA-binding polycation with bifunctional reagents such as succinimidyl 3-(2-pyridyldithio) propionate (40,81). In the first steps, the activated (succinimidyl) esters can separately react with some amino groups of transferrin and the polycation. Subsequent steps result in disufide bonds (reducible) between the polycation and transferrin. Alternatively, a bifunctional reagent containing a maleimido group has been used (85), resulting in a (nonreducible) thioether linkage. Such an approach is not necessarily specific because the actual site of ligation between transferrin and the polycation is unknown. Conjugate synthesis can also be achieved in a more specific manner (e.g., via ligation through the transferrin carbohydrate moiety) (83). Transferrin contains 2 carbohydrate chains that are attached by N-glycosylation to Asn-413 and Asn-611. The glycan chains have a biantennary structure, composed of a core bearing 2 N-acetylneuraminyl-N-acetyllactosamine units. The glycosylation on the transferrin has no known influence on receptor binding or any other biological function (apart from the clearance of asialotransferin from the plasma). Thus, this site of the transferrin carbohydrate moieties is a good choice for attachment of polylysine and other nucleic acid-binding elements, without disturbing the cell receptor targeting characteristics of transferrin. To couple the transferrin to the amino groups of polylysine, the transferrin carbohydrate groups need to be activated. The terminal point of the transferrin carbohydrate chains consists of sialic acids. The 2 terminal exocyclic carbon atoms of the sialic acids can be selectively removed by periodate oxidation, resulting in the formation of aldehyde groups at the end of the carbohydrate chains.

The concept has been applied to other targeting ligands (Table I). Ideally, the chosen ligand must be recognized by specific cell surface receptors, bound with high affinity and internalized. Most research in this field has been performed by targeting the liver-specific asialoglycoprotein receptor and the ubiquitous transferrin receptor. Other possibilities, such as using antibodies to target specific cells, have been investigated successfully. Anti-CD3 antibody, coupled to carrier-DNA complex has been shown to be very efficient in targeting T cells via binding the CD3 T cell receptor complex (26). Malignant B cells have also been successfully targeted by aids of anti-idiotype antibodies (33). Others have achieved selective targeting of cells by using the ligand folic acid, to target cells that target the folic acid receptor (54–56). It has been demonstrated that the growth factor receptors HER-2 (31), EGF-R (30,51,50), and FGF2-R (9), also highly overexpressed in many human tumors, serve as good targets. Transferring genes into macrophages by mannose/fucose or galactose-specific membrane lectin is another example demonstrating that the receptor characteristics of cells can be exploited to target the cell via an appropriate ligand (57–69).

More recently, the DNA delivery activity of the cationic polymer PEI has been combined with the concept of receptor-mediated gene delivery by incorporating cell-binding ligands (transferrin, anti-CD3 antibody, lactose) by covalent linkage to PEI. Incorporation of cell-binding ligand results in an up to 1000-fold increased transfection efficiency (69,87). This activity was obtained with electroneutral particles, but depends on ligand–receptor interaction, resulting in enhanced cellular internalization. It is important to note that coupling of the ligand did not disturb the DNA condensing and transfer capability of PEI, which is a required aspect in formation of a DNA/conjugate polyplex.

In conclusion, enhancing cellular internalization by incorporating ligands to the carrier, not only enhances cellular internalization, but also avoids problems such as cytotoxicity of positively charged complexes, as well as undesired interactions with other cells and molecules, which would otherwise arise due to the need of a net positive charge of the DNA complex required for efficient (nonligand-mediated) transfection.

Alternative approaches include those that employ DNA-binding domains derived from transcription factors to attach a protein component to plasmid DNA (90). For example, plasmid DNA containing GAL4 recognition motifs can interact with GAL4-containing carrier molecules. Cell-specific ligands can be combined with the GAL4 domain to form a chimeric fusion protein to allow gene delivery to specific cells. For example, GAL4/invasin fusion protein has been shown to transfect target cells in an invasin receptor-dependent manner (91). However, for complex formation, and hence condensation, an additional condensing agent such as polylysine is required.

III. INTRACELLULAR TRAFFICKING AND BARRIERS

Once the cell has been targeted and the DNA has been internalized via receptor-mediated endocytosis, several intracellular barriers (Fig. 2) need to then be overcome for successful foreign gene expression to occur. To tackle the intracellular barriers, a polyplex needs to:

- Escape from the endosome
- Survive the cytoplasmic environment
- Traffick the cytoplasmic environment targeting the nucleus with subsequent nuclear entry
- Be disassembled in the nucleus so it can be recognized by the cell's transcription machinery and be expressed under control in the target tissue population only

Overcoming the intracellular barriers may be achieved via certain DNA carrier molecules (92) and cell targeting ligands, although exploiting other factors such as additional endosomal releasing mechanisms and nuclear localization signals could strongly improve the capacity of a polyplex to overcome intracellular barriers.

A. Endosomal Escape

The first major intracellular barrier that greatly impairs the efficiency of gene transfer is the entrapment and degradation of the DNA complex within intracellular vesicles after budding off of the coated pits from the plasma membrane (Fig. 2). Entrapment and degradation can be regarded as 2 separate barriers because overcoming vesicular degradation would only result in the accumulation of the transferred gene in the vesicles, while still limiting further transport into the nucleus. Thus, after cellular internalization, the transferred gene needs to overcome enzymatic degradation during vesicular fusion into lysosomes, and once this is done, it needs to then be released from the vesicles to traffick the cytoplasm and target the nucleus.

Several strategies have been developed to ensure the protection/release of DNA complexes from intracellular vesicles. The strategies involve incorporation or linkage of vesicular destructive elements to polyplexes, which perturb the integrity of vesicle membranes, allowing the luminal contents to spill into the cytoplasm in a nondamaged manner. The fundamental aspect here is to perturb the vesicular membrane, without damaging the DNA complex and other cellular membranes. Thus, the endosome-releasing mechanisms need to become active within the membraneous vesicle, without rupturing the cellular membraneous structures and organelles.

Application of endosome (vesicular) releasing agents to the transfection process has shown to augment gene transfer. Lysosomotropic agents, glycerol, virus particles, membrane disruptive proteins and peptides, and photosynthesizing compounds possess properties that can reorganize and disrupt vesicular membranes, promoting the release of polyplexes (see below).

1. Lysosomotropic Agents

Lysosomotropic agents are weak-base amines that can inhibit lysosomal function specifically (93,94). Examples of such agents are ammonium chloride and the weakly basic alkylamines, such as methylamine, propylamine, chloroquine, procaine, and spermidine. These agents are termed lysosomotropic

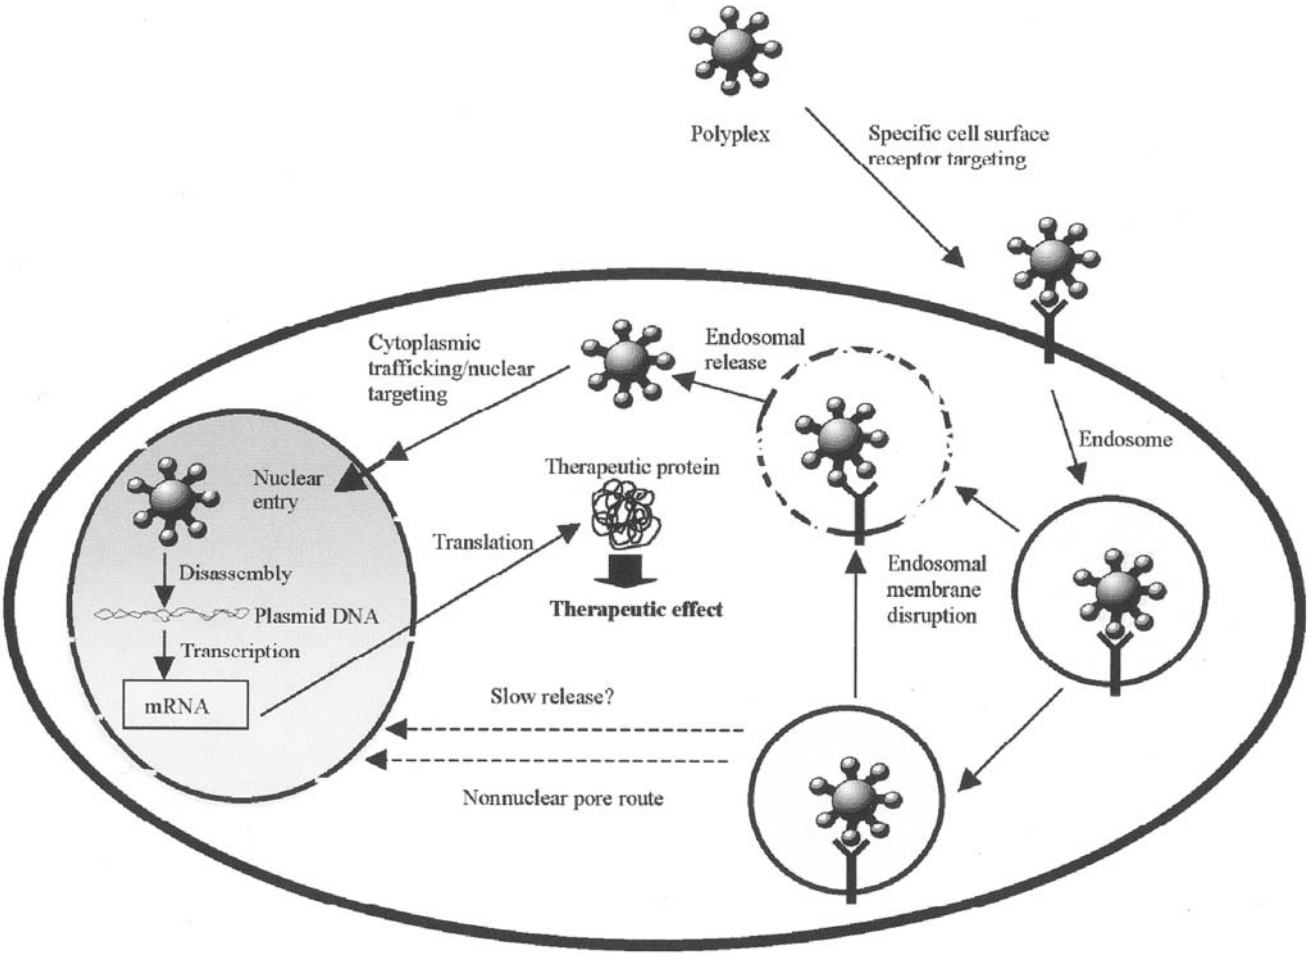

Figure 2 Intracellular release and trafficking of polyplexes.

because they accumulate in the endosomes/lysosomes. This accumulation is partly due to the initially low lysosomal pH, and partly because of the continuous pumping of protons into the endosome/lysosome.

In some cell lines, such as erythroid cell line K562, gene expression is strongly enhanced by adding chloroquine to the transfection medium. This enhancement is primarily due to the prevention of intravesicular (lysosomal) degradation, followed by vesicular membrane disruption triggered by osmotic effects (see below). Chloroquine is also the most commonly used lysosomotropic agent in gene transfer experiments (82). It is believed that chloroquine accumulates in the endosomal/lysosomal compartment, acting osmotically, vacuolarizing and eventually disrupting the vesicle. In this case, the transferred gene is protected and released from intracellular vesicles, bafilomycin or monensin, 2 other agents that also prevent endosomal/lysosomal acidification but do not accumulate or enhance transfection. Regarding chloroquine, its effectiveness in enhancing gene transfer is also dependent on cell type, which ensures vesicular accumulation of the lysosomotropic agent. For example, K562 cells, in comparison to other living cells, have a defect in their vesicular pump system, determining the accumulation of chloroquine in endocytic vesicles (95). The use of chloroquine is limited due to cytotoxic properties.

2. Glycerol

Glycerol is a trihydric sugar alcohol, being the alcoholic component of fats. Several reports describe the interaction of glycerol with cellular membranes (96,97). Incubation of DNA–polylysine complexes in the presence of glycerol has resulted in a substantially enhanced transfection efficiency in primary fibroblasts and some cell lines. Regarding this, glycerol probably acts in intracellular vesicles after DNA complex internalization, rather than at the cellular membrane. The presence of glycerol alone is not sufficient for efficient gene transfer. For glycerol to have its maximum effect, other factors such as DNA complex net positive charge and the type of DNA-binding carrier plays a major role. Thus, a combined action of glycerol and

polylysine on vesicular membrane seems to be responsible for enhancing gene transfer (97). It should, however, be noted that many cell types do not show the strong enhancement by glycerol.

3. Virus Particles

Adenovirus particles are capable of inducing endosomal lysis during the process of adenoviral infection. Upon acidification of the endosome, the capsid proteins (e.g., the penton proteins) undergo conformational changes to an active form, capable of disrupting the endosomal membrane causing release of the contents into the cytoplasm. This observation potentiated the exploration of using adenovirus (viruses that enter cells via receptor-mediated endocytosis) as a means of overcoming vesicular entrapment during gene transfer. Adenovirus has been successfully incorporated in DNA complexes, enhancing transfection efficiency 100- to 1000-fold (48,49,73,84,98–105). Incorporation may be achieved by adding adenovirus freely, where endomolysis action is in trans, or by directly linking the virus to the DNA complex. Various methods of linkage have been applied as an alternative method for ensuring cointernalization of the adenovirus, which is not always the case when the virus is added in trans. The majority of these methods have been investigated with DNA complexes with polylysine as the DNA-binding element. There are several methods of covalently coupling polylysine to the exterior of the adenovirus. Approaches, including an enzymatic transglutaminase method or chemical coupling methods, have been applied successfully. Alternative approaches are those involving noncovalent coupling methods, such as an immunologic linkage strategy, with an anticapsid monoclonal antibody effecting the linkage between the adenovirus and polylysine DNA-binding moiety (antibody bridge), ionic interactions, or biotin-streptavidin bridge. Such complexes consisting of DNA, adenovirus-polylysine, and ligand-polylysine are referred to as ''ternary complex.''

Only the membrane destabilizing function of the adenovirus capsid is required, thus the viral genome can be inactivated with methoxypsoralen plus irradiation, retending endosome disruption properties (99,102). One problem with the inclusion of adenovirus is that the transferred gene may also enter cells via the adenovirus receptor, thus compromising ligand-specific gene transfer. Strategies to inhibit uptake via adenovirus receptor include coupling of polylysine to periodate oxidized adenovirus. This treatment modifies the adenovirus fiber, which is necessary for virus attachment. An alternative approach is to target an antibody against the adenovirus fiber. Ablating binding to adenovirus receptor does not interfere with subsequent endosomolyic activity. In addition to human adenovirus, CELO (chicken adenoviral strain) has also been successfully linked to DNA complexes, enhancing receptor-mediated gene transfer, although not as efficient as adenovirus (73). However, a major drawback in using viruses is their inflammatory response of cells to virus entry per se as well as their immunogenicity.

Because many other viruses also enter cells via the endocytic pathways, they may be used as gene transfer enhancers, provided that they display an endosomolytic function. The use of human rhinoviruses (picornaviruses), which are RNA viruses, has been described and investigated for releasing vesicular-entrapped DNA complexes into the cytoplasm (106). One major drawback of using rhinoviruses is the toxicity to human cells due to host protein synthesis machinery shut off. One way to circumvent the viral-induced drawbacks is to use only the endosomolytic portion of the virus, or synthetic derivatives thereof.

4. Membrane Disruptive Proteins and Peptides

For many biological processes such as entry of viruses and bacterial toxins into cells to be exercised, cellular membrane barriers need to be by passed, and this is usually achieved by membrane reorganization processes. The membrane reorganization process is the result of specific actions of certain membrane-disruptive elements (peptides and proteins). In most cases, the membrane active locate in such elements are peptide domains with amphipathic sequences. Under appropriate conditions the amphipathic sequences can interact with lipid membranes, perturbing them. This characteristic can be specifically used to influence gene transfer; membrane-active peptides can be derived from viral peptide sequences such as the N-terminus of influenza virus hemagglutinin subunit HA-2 or the N-terminus of rhinovirus VP-1, or they may be designed synthetically from the derived peptides by molecular modeling (e.g., GALA, KALA, EGLA, or JTS1) (106–110).

Viruses that enter the cell via the receptor-mediated endocytosis pathway have evolved specific mechanisms that ensure the release of their genome from the intracellular vesicles into the cytoplasm. The mechanisms leading to vesicular release are associated with viral proteins that specifically perturb membranes, either in a disruptive or fusogenic manner. The membrane-disruptive peptides are tools of membrane-free viruses (e.g., adenovirus), whereas the membrane-fusion peptides belong to enveloped viruses (e.g., influenza virus). These fusogenic or endosomolytic protein domains are activated in a pH-dependent manner, and this characteristic can be used to enhance gene transfer (106–110) in a similar manner as whole virus particles, as mentioned above. The virus-derived peptides can be incorporated into polylysine–DNA complexes either by covalently linking to polylysine or via biotinylation of the elements, which allows binding to streptavidinylated polylysine. Simple noncovalent ionic interactions between positively charged polylysine–DNA complex and the negatively charged residues of membrane-destabilizing element is another possibility to achieve linkage. The linkage procedures should be also applicable to other DNA-binding elements. The membrane-destabilizing peptides have shown to enhance receptor-mediated gene transfer up to 1000-fold in cell cultures.

Other larger viral proteins have also been investigated for enhancing transfection by endosomal release. Adenovirus penton proteins have been attached to DNA via a synthetic oligolysine-extended penton-binding adaptor peptide. This complex transfers the DNA into the cell via adenovirus receptor and results in intracellular release (111).

One of the characteristics involved in virulence activity of micro-organism is the formation of substances (toxins, enzymes, and other proteins) that cause damage to the host (112,113). Some of the virulence factors act specifically on cell

membranes. This action can be direct, for example, action of streptolysin O, resulting in cell lysis, or indirect, specifically acting on intracellular vesicular membranes, resulting in the release of entrapped virulence factors, having had entered the cell via an endocytic pathway. Various bacterial lysing proteins (cytolysins) and other toxins have been used as devices to enhance gene transfer. For example, streptolysin O and staphylococcal alpha toxin have been used standardwise as intracellular delivery reagents. Perfringolysin O has also been used to enhance delivery of DNA into cultured cells (114). For this purpose, the biotinylated protein was bound to DNA–polylysine complexes by a streptavidin bridge. Another well-studied exotoxin capable of enhancing gene transfer is the diphtheria toxin. A recombinant transmembrane domain of this toxin has been coupled to polylysine with subsequent incorporation into DNA–asialoorosomucoid-polylysine complexes (115). Also, the bee venom component melittin has been applied for enhancing polyplex-mediated transfection (116).

5. Slow Release from Vesicular Reservoirs

Partial hepatectomy or microtubular disruption by colchicine treatment has shown to prolong gene expression after intravenous injection of DNA–asialoorosomucoid-polylysine complexes (46,47). This prolonged expression is due to the continuous existence and survival of plasmid DNA in cells of treated cells. This survival is due to protection of the DNA complex from the lysosomal or cytoplasmic environment, as a result of DNA complex persistence in the endosomal compartment, and the prolonged gene expression is due to a constant slow supply of plasmid DNA to the nucleus. The slow release is not a direct endosomolytic action. Therefore, how the DNA complex reaches the nucleus in this case remains unclear.

6. Photosensitizing Compounds

A novel technology, named photochemical transfection or photochemical internalization, has been recently developed and is primarily based on photosensitizing compounds, such as tetra(4-sulfonatophenyl)porphine or aluminium phthalocyanine, that localize in the membranes of endosomes and lysosomes (117,118). These become activated upon illumination and induce the formation of reactive oxygen species, destroying endosomal membrane structures releasing endocytosed DNA into the cell cytoplasm. This technology is being currently investigated as a new strategy for cancer therapy (119).

7. Cationic Carriers

In contrast to DNA-binding elements such as polylysine, there are other polycations that possess specific properties enabling them to combine DNA binding and condensing activity with membrane-perturbing capacity, thus, not requiring the presence of endomolytic agents for enhancing transfection. The membrane-perturbing activity of such DNA-binding elements may be associated with their ionic state, or conformational flexibility, resulting in membrane-specific interactions.

PEI and polyamidoamine polymers (''dendrimer'') are efficient transfection agents per se (15–17). Most of these agents possess buffering capacity below physiological pH. This buffering capacity is due to residues of these agents not being protonated at physiological pH, making them efficient ''proton sponges.'' Upon acidification in the intracellular vesicle, the further protonation of the polymers triggers chloride influx, resulting in osmotic swelling (endosome swelling), and thus destabilization (rupture) of the intracellular vesicle membrane, resulting in the escape of the DNA complex. Hence, gene transfer is enhanced in the sense that DNA is free to travel to the nucleus.

Histidinylated polylysine, optionally in combination with zinc ions, was also found to have enhanced transfection property, presumably mediated by a related vesicular escape mechanism (120). Moreover, there are designed cationic peptide carriers that can bind nucleic acids and permeabilize lipid bilayers at the same time. One example is the cationic amphiphilic peptide KALA mentioned above (110).

B. Cytoplasmic Trafficking, Nuclear Targeting, and Entry

Upon receptor-mediated endocytosis and release from the endosome, polyplexes need to then overcome cytoplasmic degradation and traffick to and enter the nucleus. These tasks are only partially fulfilled by certain DNA carrier molecules and cell targeting ligands. Other elements such as nuclear localization signals can be incorporated into polyplexes improving nuclear targeting.

The nucleus is separated from the cytoplasm by the nuclear envelope, which consists of 2 chemically distinct membranes, the inner and outer membrane, with the perinuclear cisterna space in-between. The outer membrane is continuous to the endoplasmic reticulum. Nuclear pore complexes (NPCs) span the nuclear envelope, and transport of macromolecules from the cytoplasm to the nucleus occurs through these complexes. Regarding nuclear import, several major processes need to be distinguished: (1) the steps leading to the import process; that is, signals guiding the protein transport to the nuclear membrane, including cytoplasmic recognition of the import protein by transport factors and nuclear pore targeting; (2) the actual molecular mechanism of translocation of the protein from the cytoplasmic side of NPC to the nuclear side of NPC into the nucleus; the nuclear pores being the site of translocation; (3) release of the import protein into the nucleus; and (4) recycling of transport factors.

There are several distinct nuclear import signals that guide the import of proteins into the nucleus. These signals are part of the primary sequence of the protein destined to be targeted into the nucleus. The best characterized ones are the SV40 LTA ''classical'' nuclear localization signal (NLS) and M9 (an import signal of hnRNP AI protein) import signals.

It has been suggested that shuttling of import receptors may be a major process in nuclear transport of proteins. In this hypothesis, the import receptor binds the protein in the cytoplasm. The molecule is then carried through the NPC into the nucleus, where it is released from the transport receptor. The receptor returns to the cytoplasm, ready for transporting the next molecule into the nucleus. In this model, the binding of the transport

receptor to the molecule may be regulated by the different environments of the nucleus and cytoplasm.

Four major transport factors are required for the NLS-dependent protein import: (1 and 2) importins alpha and beta (karyopherin alpha and beta), (3) GTPase Ran/TC4, and (4) nuclear transport factor 2 (NTF2) (p10). These factors interplay for successful transport of proteins into the nucleus. Proteins (with NLS signal) with sizes up to 25 nm interact in the cytoplasm with soluble NLS receptor (importins alpha and beta). The karyopherin beta 1 (''importin beta'') mediates docking to nucleoporins, the components of the nuclear pore, located at cytoplasmic face and nucleoplasmic face of the NPC. Nucleopore cytoplasmic filaments may also be involved in the nuclear targeting process. GTPase Ran and p10 (NTF2) are required to translocate the docked NLS peptide into the nucleus. The influenza virus nucleoprotein particle is one example that is taken up by this pathway.

The M9 domain of hnRNP A1 contains 38 amino acid residues (M9 import signal) sufficient for import purposes into the nucleus. It bears no sequence similarity to classical NLS. Nuclear import of ribonucleoprotein A1 is mediated by another distinct import pathway, by binding to karyopherin beta 2 (''transportin''—import receptor of the M9 pathway). It also requires Ran.

It is very likely that, in addition to the classical NLS and the M9-type import, more pathways into the nucleus exist. This may be of an advantage in the sense of regulating import of distinct classes of molecules separately (121,122).

The nuclear envelope represents a major barrier for polyplex-mediated gene transfer. In the majority of cell types, transport of DNA into the cell nucleus is inefficient. For example, less than 1% of NIH 3T3 fibroblasts have shown to express β-galactosidase after cytoplasmic injection of reporter gene. However, β-galactosidase has been efficiently expressed when injected into the cytoplasm of primary rat muscle cells. Although how DNA complexes find their way to the nucleus is not fully understood, recent findings suggest that DNA compaction (92), certain physiological ligand pathways such as bFGF-targeted complexes (53), or specific DNA sequences, as demonstrated by intact protein free SV40 DNA (123), may contribute to cytoplasmic trafficking and nuclear targeting of the polyplex.

In dividing cells, DNA may passively enter the nucleus during mitosis when the nuclear membrane is broken down (124). However, many cell types are nondividing with the nuclear membrane staying intact, thus, the transferred gene needs to enter the nucleus differently than in dividing cells. In this case, nuclear entry and trafficking may represent a major interintracellular barrier for successful in vivo gene transfer. When DNA is injected into the muscle cell far from the nuclei, expression decreases. This may be the result of cytoplasmic sequestration, preventing nuclear accumulation of DNA. The movement of DNA toward the nucleus may be inhibited by its binding to cytoplasmic elements, and/or entrapment within the cytoskeletal mesh (125). However, polymers such as PEI and PLL have been suggested to promote gene delivery from the cytoplasm to the nucleus, possibly attributed to intrinsic nuclear targeting activity and protective mechanisms against cytosol nucleases (126,127).

Once the polyplex has trafficked to the nucleus, it then needs to enter through the nuclear membrane into the nucleus. Although rupture of the nuclear envelope (as occurs during cell division) is not a necessity for some PEI polyplexes to penetrate the nucleus (92,128), transfection efficiency of polyplexes in general is critically dependent on cell division (129). High transfection efficacy has been observed when polyplexes are added to cells in late S or G2 phase, and low transfection when polyplexes are added in G1 phase. Thus, transfecting nondividing cells in vivo may be considered as an additional barrier in vivo in terms of nuclear entry of polyplexes.

Thus, understanding the mechanisms of nuclear entry is critical and will be a large step toward designing gene delivery systems, more efficient in transferring the DNA into the cell nucleus.

Expression of transferred DNA has been inhibited by wheat germ agglutinin (WGA), suggesting that DNA may enter the nucleus by the WGA-sensitive process common to large karyophilic proteins and RNA (125) (WGA blocks the NPC machinery because of the presence of N-acetylglucosamin residues on nucleoporins). However, recently it has been shown that nuclear localization of DNA does not require the addition of cytoplasmic protein factors necessary for protein import (130). Nevertheless, DNA entry appears to be regulated by NPC. The NPC accommodates both passive diffusion and active transport. Molecules smaller than 20 nm in diameter passively diffuse through NPC into and out of the nucleus. Larger macromolecules require active transport for nuclear entry. The exact mechanism by which exogeneous DNA passes through the NPC has not yet been determined, although it may be similar to the transport of proteins, larger than 15 Kda, actively into the nucleus.

Certain viruses such as hepatitis B virus also use the active nuclear import mechanism. Viral core particles containing synthesized DNA bind to the nuclear pore complex; the viral polymerase, which is covalently linked to the viral DNA, acts as NLS. Core particles (35 nm) exceed the maximal diameter of the nuclear pores, thus requiring disassembly before the viral genome is internalized.

The efficient transport of DNA complex into the nucleus is an active process that probably requires a nuclear localization signal. Several NLSs have been identified in proteins with a nuclear fate, the sequences being very basic, with >50% of their amino acids being lysine residues [e.g., Phe-Lys-Lys-Lys-Arg-Lys-Val, directing the nuclear import of SV-40 large T antigen, or the NLS (Lys-Lys-Lys-Tyr-Lys-Leu-Lys) within HIV-1 matrix protein]. Substitution of 1 of the lysine residues results in total failure of nuclear import. Thus, it is possible that DNA-binding elements rich in lysine (e.g., polylysine) may play a role in the nuclear import of DNA complexes. Regarding this, injection of DNA–polylysine mixtures into the cytoplasm of mouse ES cells has lead to transgenic animals with about 50% efficiency (compared with intranuclear injection of naked DNA). In contrast, injection of naked DNA into the cytoplasm does not lead to transgenesis. To make the DNA import process more efficient, it may be necessary to direct the transport to the nu-

cleus by incorporating NLSs into the DNA complex. This is strongly supported by recent findings (131) that show that incorporation of a single SV40 LTA NLS into a DNA plasmid molecule can dramatically enhance transfection efficiency.

To sum it up, it would be desirable to engineer DNA complexes with specific nuclear targeting and translocating elements, enabling the DNA complex to be (1) recognized in the cytoplasm by nuclear import receptors (by interacting with transport motifs either directly on the DNA sequence or on a protein from the DNA complex), (2) targeted to the nuclear pore complex, (3) translocated efficiently through the nuclear pore, and (4) released at the nucleoplasmic face of the nuclear pore complex into the appropriate nuclear compartment for subsequent disassembly and expression.

The cell nucleus is crowded, containing large amounts of DNA, RNA, and protein. In addition, nuclear processes such as replication, transcription, translation, and DNA repair processes are constantly active in specific compartments, resulting in a nuclear jam (132,133). Within all the mass of cellular DNA, RNA, and proteins and the nuclear processes, the DNA complex needs to become (either disassembled or reorganized in a suitable fashion) exposed, enabling the nuclear expression machinery to recognize and express it. Premature disassembly and DNA release from the carrier molecule in the cytoplasm may prevent efficient transfer to the nucleus, hence obligerate expression. Polyplexes most likely disassemble in the nucleus, which is a characteristic desirable for successful gene transfer and expression (92).

Furthermore, the anatomical location (intranuclear depot) of polyplexes within the nucleus may be crucial for efficient expression (53). For example, bFGF is believed to be retained in the nucleus within discrete storage depots. Similar distributions have been reported for bFGF-targeted polyplexes with a relatively poor level of specific gene expression, suggesting difficult availability of the DNA for transcription (53). Indeed, intranuclear trafficking of transcription factors contributes to transcriptional control, and thus, has implications for biological control (134,135); hence, it may determine intranuclear trafficking/localization if used as carrier molecules (90,91).

Whether incorporation of intranuclear targeting elements in polyplexes affects nuclear localization and hence, expression, remains to be considered for investigation. Thus, both efficient uncoating and intranuclear trafficking is another challenge to be tackled.

C. Persistence of Gene Expression

Several factors endanger the persistence of transferred DNA within the nucleus: (1) degradation by intranuclear nucleases; (2) DNA loss, mainly during cell division, although DNA may also be rapidly lost even when cells are not dividing; (3) loss of transfected cell because of apoptotic, inflammatory, or immune response; (4) silencing of the introduced gene by transcriptional shut-off; and (5) possibly inefficient intranuclear trafficking.

Protection of DNA may be achieved via the proper ratio of DNA–DNA-binding carrier (e.g., polylysine). Saturating the binding capacity of the DNA backbone with the DNA-binding moiety may avoid the access of DNA to nucleases and increase the stability of the DNA in the nucleus (nuclear retention, resulting in prolonged expression).

DNA loss other than degradative loss can be prevented by including specific sequences to the transferred DNA that ensure either integration of the DNA into host chromosome, or extrachromosomal replication of the transferred DNA with equal segregation to daughter cells. These persistence-ensuring sequences can be derived from certain viruses or from chromosomes.

Retroviruses and adeno-associated virus (AAV) stably insert their genome into host genome. The integration mechanisms have been characterized [retrovirus: LTR sequences, integrase protein; AAV: inverted terminal repeat (ITR) sequences, rep protein], and may be exploited by incorporation of the corresponding nucleic acid and protein elements into a viruslike particle (DNA complex). During its lysogenic cycle, AAV integrates into a specific site, denoted AAVS1, on human chromosome 19 (136). This property has been used to achieve site-specific integration of plasmid DNA in 293 cells. When the AAV-encoded recombinase rep is supplied in cis or trans, plasmids containing the AAV ITRs are integrated at AAVS1. In this way, DNA can be directed to a specific region of a human chromosome, and thus may avoid the problem of random insertional mutations created by integrative vectors such as retroviral vectors.

Other viruses such as herpes virus (e.g., Epstein Barr Virus, EBV) can persist in infected cells without integrating their genome into the host. This persistence is partially due to replicative property of viral DNA via *cis*-acting origin of replication, which is activated by the *trans*-acting gene product of the viral EBNA-1, and additional nuclear retention mechanisms. The viral-persistence mechanisms can be used in designing extrachromosomal-replicating DNA constructs (episomal vectors) by integrating the appropriate sequence elements, recognizable in mammalian cells, into the DNA construct to be transferred (e.g., EBV Ori P, EBNA-1). DNA constructs containing these sequences have the ability to replicate once per cell cycle with nuclear retention without interfering with the host chromosomes. An alternative to using viral origin of replication, human genomic sequences may be used to mediate DNA construct replication (137).

Other origins of replication characterized include those of bovine papilloma virus or SV40 (138). However, these replication origins also require viral proteins for activation, which may have oncogenic or toxic properties. The viral replication origins are species specific and may also replicate more than once per cell cycle, resulting in mutations in the transferred gene.

The next challenge is the generation of artificial chromosomes for maintenance of large genomic sequences. The basic DNA sequence requirements for human chromosome function are believed to be similar to those identified in yeast, which include a centromere, telomeres, and origins of replication. These elements have been used to construct yeast artificial chromosomes (YACs) (139), and their transfer has been demonstrated by spheroblast fusion. Researchers are now trying to construct better artificial chromosomes (140). It is important here to de-

fine the minimal sequence requirements for functional mammalian chromosomal elements.

Human artificial chromosomes (HACs) may serve as valuable DNA constructs, containing the requirements for achieving gene expression persistence. An opening door toward this goal is the recent generation of mitotically and cytogenetically stable artificial chromosome derived from transfecting human HT 1080 cells with alpha satellite plus telomere DNA and genomic carrier DNA, forming *de novo* microchromosomes with functioning centromeres (141). The only sequence that has been shown to form *de novo* centromeres after transfection is alphoid DNA with telomere DNA and genomic carrier DNA. However, centromeric function of human chromosome is not always associated with alphoid repeats. There are other nonalphoid genomic regions characterized by neocentromic activity (sometimes, a centromere can appear at a new position in a chromosome by a process called ''centromere activation''). Transfection experiments with DNA present at the neocentromere should demonstrate whether this DNA can also form centromeres *de novo*.

With advancement, HACs could be used to introduce therapeutic genes into cells. To use HACs for human gene therapy, efficient methods for delivery will be required. The receptor-mediated gene transfer system is a very promising choice capable of targeting and transferring any large DNA construct into cells. Bacterial artificial chromosomes have already been delivered into mammalian cells using psoralen-inactivated adenovirus/PEI carrier (103).

Persistence of the transferred gene is required, but not necessarily sufficient. It does not necessarily mean that gene expression is going to be efficient and long-lasting. A failure of gene therapy in clinical trials may not always be due to gene delivery, but rather due to novel confrontations at the expression level. Specific expression cassettes determine the efficiency of expression after the gene has been transferred and maintained in the nucleus. The major elements of the expression cassette are those that ensure strong, controllable, (switchable), and cell specific (tissue restricted) expression of the therapeutic gene. Previous studies using viral promoters (e.g., cytomegalovirus promoter/enhancer) have observed a transcriptional shut-off (''silencing'') of the introduced expression cassettes. This can be avoided by the use of natural, cell-specific promoter/enhancer sequences. These are also attractive due to the opportunity of transcriptional targeting, as a further filter for specificity (142). Some examples are steroid-inducible promoters, tumor-specific promoters, muscle-specific promoters, hypoxia response elements, hepatitis B virus-derived promoters for liver-specific expression, and multidrug-resistant gene promoter (143). Here lies the attractiveness of nonviral receptor-targeted polyplexes in gene therapy, for the reason that any gene construct regardless of the size may be transferred.

IV. EXTRACELLULAR BARRIERS FOR GENE DELIVERY

For in vivo applications, the development of polyplexes is not only confronted with intracellular barriers, but also with extracellular barriers, which are those prior to reaching the target cells. A schematic diagram of the potential intracellular and extracellular fate of a polyplex is shown in (Fig. 3). Strategies have to be developed in designing polyplexes that enable them to survive blood and other biological fluids, and to escape extracellular physical barriers, in order to reach the target cells. The specific strategies must take into account the physicochemical properties such as size, shape and flexibility, overall charge, charge density, and nonelectrostatic interactions at the surface of the polyplex. Besides considering these physical properties, one could imagine to also use active endogenous cellular transport mechanisms, such as transcytosis (12,144).

In vitro gene delivery and ex vivo gene therapy approaches are predominantly concerned with gene delivery barriers presented by the cell itself. In vivo gene therapy must also be concerned with extracellular barriers, where the route of administration of the therapeutic gene also plays a major role (145). In systemic administration, where the vector is introduced in the body intravenously, the circulatory pathway and environment, as well as various nontarget cells and organs, encountered by the polyplex are major obstacles, determining the fate of the transferred DNA [see, for example, (146)]. However, local administration methods, such as direct injection of the vectors into the target region, are not confronted with the circulation problem, but nevertheless are still confronted with barriers such as extracellular matrix or inflammatory and immune responses.

A. Physical Restrictions of Transfection Particles

Size seems to be a general critical factor for drug targeting (147). Because of size restriction, (several) hundred nm large particles cannot penetrate endothelial and epithelial barriers (148), or extravasate from the vascular to the interstitial space. Particle size is also an important factor when considering organ clearance and intraorgan distribution. For example, particles that are too large to pass through the vascular endothelium to the liver parenchym are engulfed and degraded by liver Kupffer cells (i.e., phagocytic cells residing next to the vascular epithelial cells).

DNA is a negatively charged, flexible molecule, both characteristics that hinder the DNA from being transported efficiently into and across cells, which in this case represent the physical barriers. To overcome these physical drawbacks, the DNA molecule needs to be compacted and the negative charges minimized for efficient gene transfer. These requirements can be achieved by taking advantage of molecules capable of binding and condensing DNA (149). The structure of condensed DNA complexes has been analyzed in several reports, such as (13,150–152,14). DNA–polycation complexes have been characterized by electron microscopy and atomic force microscopy (shape, size), laser light scattering (size), electrophoretic mobility (reflects charge and size of complexes), zeta potential measurements (charge), circular dichroism (conformation of DNA), or centrifugation techniques (molecular weight and condensation). The results give some insight on how to possibly generate DNA complexes sufficiently small to traverse the en-

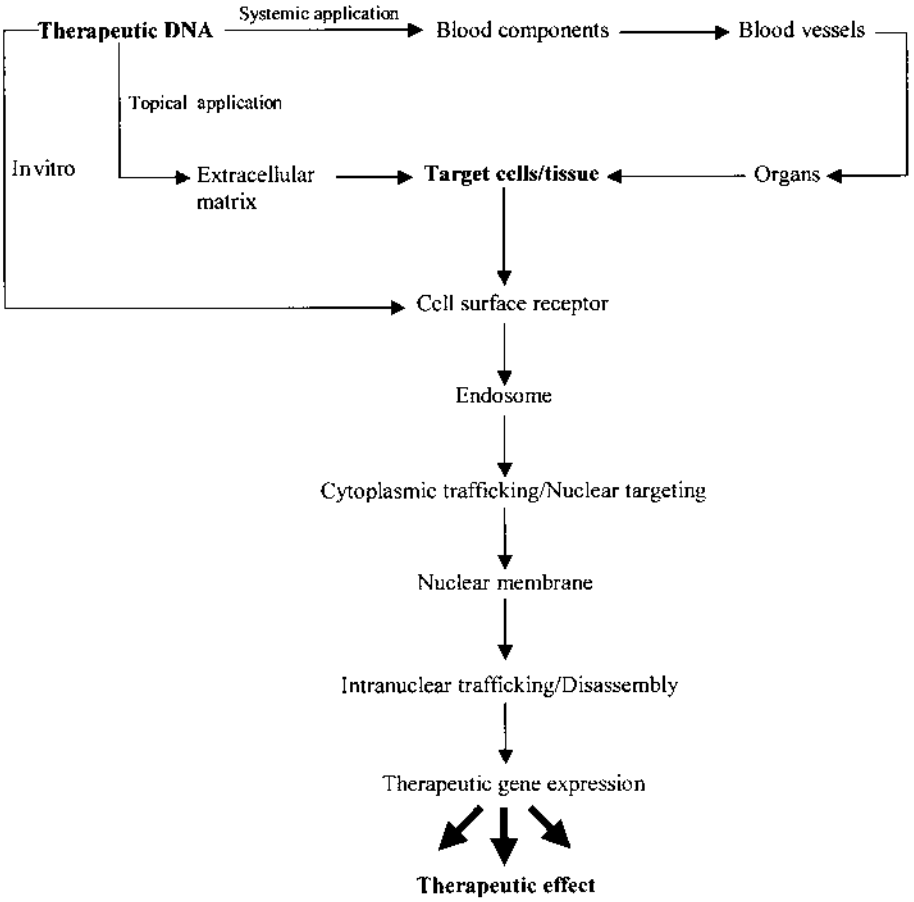

Figure 3 Extracellular and intracellular pathways for gene delivery. In vivo, systemic or local application; in vitro, cultured cells.

dothelial layer, possibly through fenestrations or vesicular transport systems, such as transcytosis (Fig. 4). In addition, the compact DNA complexes are more stable against enzymatic or mechanical degradation, which may take place during DNA transport processes to the target cells/tissue.

However, preparation of effective DNA complex molecules for in vivo delivery of DNA remains a major hurdle. The extent of DNA condensation depends on a number of variables, including the ratio of positively charged DNA-binding element (''cationic carrier'') to negatively charged DNA, the size and modification of the DNA-binding element, size, sequence, and state of the DNA, and also the procedure of complex formation (29), strongly influencing the in vitro and in vivo gene transfer efficiency. The net charge of the DNA–cationic carrier complex affects its solubility. Complexes with either an excess of DNA or positively charged carrier are stabilized in solution by the negative or positive charges. At molar charge ratios [see (1): positive charges of carrier to negative charges of DNA phosphates] close to 1 (i.e., electroneutrality), hydrophobic domains of DNA-binding elements such as polylysine are considered to be responsible for low solubility in water. This may lead to aggregation and precipitation of complexes.

Methods of formulation still have to be improved in generating homogenous and stable complexes capable of overcoming the physical barriers. DNA–polylysine-conjugate complexes have been prepared in several ways. Wu and Wu (40) mixed the compounds at high salt concentration, where electrostatic binding is strongly reduced. Slow reduction of the salt concentration by dialysis into physiological buffer results in a thermodynamically controlled complex formation. Charge ratios of polylysine/DNA smaller than 1 and enhanced hydrophilicity due to the conjugated asialoglycoprotein are presumably essential for the solubility of the complex.

Wagner et al. (13) described a different approach using transferrin-polylysine–DNA complexes. Flash mixing of dilute compounds in physiological phosphate-free buffer results in formation of kinetically controlled complexes. Charge ratios of polylysine/DNA from smaller than 1/2 to larger than 2/1 have been applied. At ratios of electroneutrality or higher, donutlike and rodlike particles of 80 to 120 nm in diameter are formed.

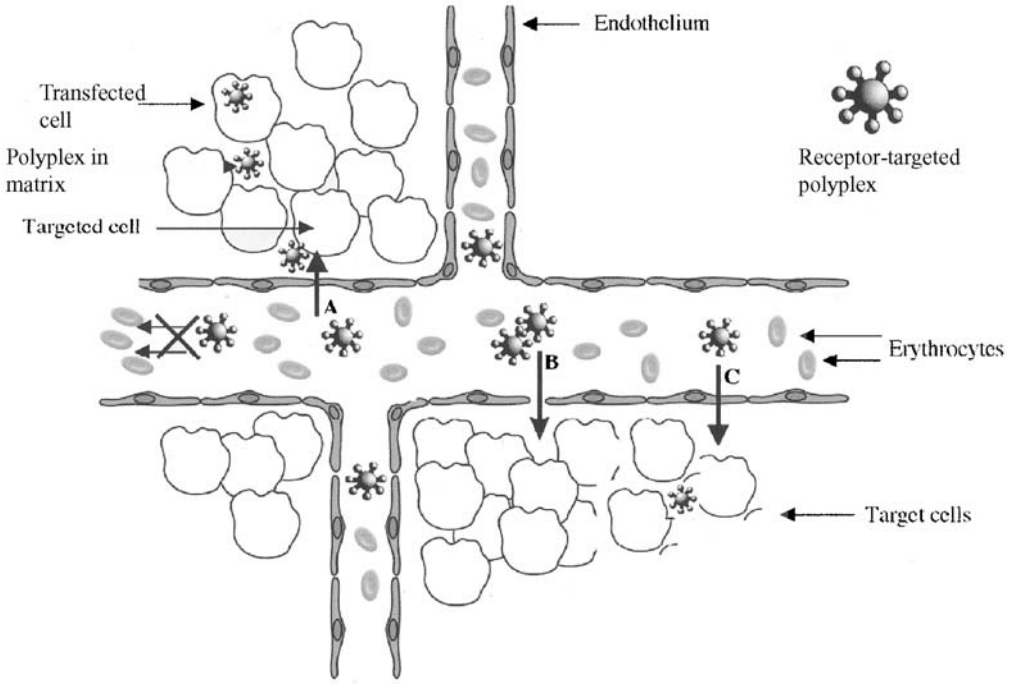

Figure 4 Vascular barrier for gene delivery. See the color insert for a color version of this figure.

Complexes containing transferrin-conjugated polylysine have increased solubility compared with the use of unmodified polylysine.

Interestingly, donuts of similar sizes are formed, independent from whether small or large (up to 48 kbp) and DNA is used in the complex formation. Using a standard expression plasmid of approximately 5 kbp, obviously several DNA molecules are incorporated into 1 particle. In an attempt to generate unimolecular DNA complexes, Perales and colleagues (35,60) added polylysine conjugates slowly, in several small portions, to a vortexing solution of DNA in approx. 0.5 to 0.9 M sodium chloride until a charge ratio of polylysine/DNA of approximately 0.7 is reached. The slow addition of polylysine has been reported to generate monomeric DNA complexes, with sizes of approximately 15 to 30 nm. These complexes aggregate immediately; aggregation is reverted by subsequent addition of salt. The promising findings have been reported to be applicable for in vivo gene transfer applications (35,60).

Recent reports on the size of DNA complexes with PEI or transferrin-PEI describe the strong influence of parameters such as DNA concentration and charge ratio, and also ionic strength of solution, or serum content of culture medium. Mixing DNA–PEI complexes at N/P (PEI nitrogen: DNA phosphate) molar ratios below 6 in 150 mM saline results in rapid aggregation; aggregation can be avoided by complex formation at low ionic strength (25 mM aqueous buffer), generating particles with an average diameter of approximately 40 to 50 nm (14). Incorporation of hydrophilic polyethylene glycol residues into polyplexes also was found to stabilize small polyplexes and prevent their aggregation (153).

B. Undesired Interactions with Plasma, Degradative Enzymes, Matrix, and Nontarget Tissue

Polyplexes, when administered in vivo, are surrounded by a variety of compounds present in blood plasma. Salts, lipids, carbohydrates, proteins, or enzymes contribute to changes in the physicochemical properties of the polyplex. Some of these factors (''opsonins'') may coat the polyplex, causing aggregation, dissociation, or degradation of the DNA complex. This may influence the composition of the complex as well as the bioavailibility. Thus, the DNA complexes, even when reaching the target cells/tissue, may no longer exhibit the physical properties necessary for efficient transfer into cells.

Previous studies have demonstrated the inactivation of polylysine-based DNA complexes by blood components (154). One of the factors was identified as the complement system (155). More recently, the interaction of DNA–PEI complexes with plasma was analyzed on the biochemical level. Upon incubation of the DNA complexes with human plasma, specific proteins (IgM, fibrinogen, fibronectin, and complement C3) bind to the complexes (153). By coating the DNA–PEI complexes with polyethylenglycol (PEG) through covalent coupling to PEI, plasma protein binding was found to be strongly reduced (153).

Another problem encountered in the bloodstream is degradative enzymes. There are nucleases in the bloodstream that degrade extracellular DNA (such as that generated by degradation of invading microorganisms or dead host cells). Cationic DNA-binding elements may serve some protection (45).

Other undesired interactions are the ones with the extracellular matrix and nontarget cells/tissue. There is a complex network of proteins and proteoglycans, termed extracellular matrix that fill the intercellular space (156,157). The matrix helps bind the cells in tissues together and also provides a lattice through which cells can move. Once the DNA complex has traveled across the vascular barrier into the interstitial space, it has to avoid interactions with the extracellular matrix in order to reach and bind the target cells/tissue. Extracellular matrices in animals are composed of different combinations of collagens, proteoglycans, hyaluronic acid, fibronectin, and other glycoproteins. These components could serve as specific barriers by binding the DNA complexes. For example, hyaluronic acid binds cations very effectively. With this in mind, DNA condensed by polycations, resulting in a net-positive charge, could also interact with the extracellular matrix, binding, dissociating, or aggregating the DNA complex. Thus, proper formulations, in preparing the DNA complexes, will be necessary, to avoid such interactions. Optimizing the DNA complexes bearing an overall low-charge ratio close to neutrality is a possibility to avoid such interactions. The problem is that a net-positive charge has been found desirable for interaction with the cellular plasma membrane and entry into the target cell, whereas such positive charge might favor entrapment of the DNA complexes by negatively charged extracellular matrix components.

Interaction with nontarget cells/tissue is another hurdle, complicated to combat. In the previous sections, cellular internalization mechanisms using receptor-specific ligands were presented as a solution to overcome this problem. Ligands may target cells very efficiently, but it has to be kept in mind that they do not inhibit unspecific interactions with nontarget cells, which could result in cellular binding and internalization via any additional process. The unspecific interactions with nontarget cells may be due to factors such as particle size, charge, and in vivo protein coating of the DNA complexes. For example, interaction with nontarget cells may take place due to an excess positive charge of the complex. It has been shown in cell culture that minor changes in the DNA/polylysine-conjugate ratio of the complex, resulting in a positively charged DNA complex, may convert a ligand-specific transfer into a completely unspecific process (29). Ideally, the DNA complex should be masked in a fashion that only allows ligand–receptor interactions with the target cell, and no other interactions with nontarget cells.

C. Inflammatory and Immunological Responses

As a result of introducing foreign molecules into the body, individual immune cells are stimulated to produce antibodies, a process termed humoral immunity. In addition to this humoral response, specific T cells may also be activated (cellular immunity). These 2 processes are the specific immune response. There is, however, also the nonspecific immune response, including phagocytosis, inflammation, and other nonspecific host-resistance mechanisms such as the complement system (158). These nonspecific mechanisms develop immediately against virtually any foreign molecule, even those the host has never encountered. Thus, the nonspecific immune response is a major extracellular barrier for the DNA complex, which in this case is the foreign molecule. The ultimate goal is to formulate and construct polyplexes in a manner, that avoid eliciting any immune response.

Inflammatory response is a major problem for any gene delivery system (159) because it may take place independent from the route of administration and results in a greater access of phagocytes to the foreign molecules, for example, due to an increased capillary permeability caused by retraction of the endothelial cells. During an inflammatory response, leucocytes, particularly neutrophil polymorphs and to a lesser extent macrophages, migrate out of the capillaries into the surrounding tissue. At the site of inflammation, the phagocytes recognize the foreign molecules via receptors on their surface, which allow them to attach nonspecifically and phagocytose-foreign molecules. Attachment is greatly enhanced and specified upon opsonization of foreign molecules, such as by the C3b component of complement. Both neutrophils and macrophages have receptors that specifically bind to C3b, allowing them to recognize their target.

A variety of macromolecules, such as proteins, lipoproteins, some nucleic acids, and many polysaccharides, can act as immunogens under appropriate conditions. Positively charged DNA complexes have the ability to activate the complement system (155). A number of synthetic cationic molecules, frequently used in gene delivery, and their complexes with DNA have recently been examined for their complement-activating properties. Complement activation by polylysine is strongly dependent on chain length and on the charge ratio. Longer chains and greater surface charge density are strong activators of the complement system. The positive charges on the DNA complex are accessible to the complement protein C3b. Opsonization of such particles by C3b leads to the initiation of a cascade of events, presumably resulting in the clearance of DNA complexes by the retinoculoendothelial system. Coating of the positive charges of the DNA complexes with other macromolecules may inhibit interactions with components of complement, hence decreasing complement activation and clearance of the complexes from the blood circulation (160). It has already been demonstrated that modification of the surface of liposomes reduces interaction with blood components (161–163), stabilizes DNA–liposome complexes (164). Coating of polycation–DNA complexes by polyethyleneglycol (PEG) also reduces interaction of DNA complexes with blood components. (153,155).

V. POTENTIAL CLINICAL APPLICATIONS

Although gene transfer via receptor-targeted polyplexes are mainly successful in delivering DNA efficiently in cell culture,

several reports have recently demonstrated the capability of receptor-targeted polyplexes to deliver and transfer DNA to target cells systemically in vivo. This advancement has been enabled by using the various methods to overcome the intra- and extracellular barriers described in the previous sections, but also to a large extent by shielding (or coat) the positive charge of polyplexes, reducing their positive surface charge (zeta potential), hence preventing common interactions with extracellular barriers, such as nonspecific interactions with plasma components or erythrocytes. Shielding methods include those with PEG (153), poly-N-(2-hydroxypropyl)methacrylamide (pHPMA) (165), poloxamer (166), or recently ligand density (23).

A. Receptor-mediated Gene Delivery In Vitro (Ex Vivo)

One approach for performing somatic gene therapy is the ex vivo strategy. In this approach, gene transfer is performed in cell culture (in vitro) and the resulting transfected is transplanted into the organism. Application of receptor-mediated gene transfer to transfect endothelial cells (101,167), fibroblasts, B cells, vessels, and primary tumor cells has potentiated several ex vivo approaches. For example, the clotting factor VIII, which is deficient in hemophilia A, can be produced by transfected primary fibroblasts at levels more than 10-fold higher than those generated by retroviral vectors, enabling factor VIII expressing fibroblast implants for in situ expression of this protein (168).

The highly efficient delivery in vitro has resulted in the development of other ex vivo approaches. For example, treatment for malignant melanoma has been designed by application of gene-modified cancer cell vaccines. DNA complexes are used to deliver immunostimulators genes (e.g., interleukin-2) into melanoma cells in vitro. After irradiation (to block tumor cell growth), the transfected cells are applied in vivo to trigger an antitumor immune response. This treatment has been translated into a medical protocol and is being evaluated in clinical trials (169,170).

B. Receptor-mediated Gene Delivery In Vivo

The first encouraging results for in vivo gene transfer were obtained by targeting, via intravenous injection, the liver asialoglycoprotein receptor using asialoorosomucoid covalently linked to poly(L)lysine carrying the CAT marker gene (42–44,46,47). DNA expression proved to be liver specific. Other organs such as kidney, spleen, and lungs did not produce detectable quantities of CAT activity. Gene expression persistence was improved by applying partial hepatectomy, a procedure for stimulation of hepatic regeneration, and DNA synthesis, beginning 12 h after surgery, resulting in CAT activity up to 11 weeks postsurgery.

Related approaches have been used to target the liver, with different size DNA complexes. Unimolecular, about 12-nm small galactosylated DNA–polylysine complexes encoding human factor IX have been shown to target the hepatic asialoglycoprotein receptor, with up to 140 days of detectable protein in serum of transfected rats (60). This result was achieved without partial hepatectomy. In a related approach, the polymeric immunoglobulin receptor has been targeted by 25-nm DNA complexes bearing antigen-binding fragment of an antibody enabling gene transfer to rat pneumocytes following intravenous administration (35,36). It appears that the procedure in preparing DNA complexes may at least partially determine the success of in vivo gene transfer approaches, by influencing extracellular barriers.

Initially, polyplexes based on polylysine did not demonstrate efficient gene transfer in vivo. However, addition of endosomal disruptive agents, such as adenoviruses (84), to such polyplexes resulted in efficient gene expression in airway epithelium after intratracheal application (171) and in tumors after intratumoral application (172,173). Shielding of the polyplexes and the mode of administration, such as with micropump, have further advanced polyplexes to overcome such barriers as extracellular matrix and interstitial pressure (174), respectively. Local injection of DNA complexes directly into subcutaneously growing tumors produced significant reporter gene expression, with DNA–transferrin-PEI complexes or adenovirus-linked DNA–transferrin-polylysine complexes being 10- to 100-fold more efficient than naked DNA (173).

Recently, the lung has been successfully targeted via systemic tail vein injection of mice by 22-kDa linear PEI/DNA polyplex (175,176). High levels of gene expression were observed in the lungs but lower expression in other major organs, including heart, spleen, kidney, and liver. This observation indicated PEI to be suitable for transfection of the lungs. However, in contrast to the high transfection efficacy observed with PEI in the lungs, systemic gene delivery with PEI/DNA polyplexes to target lung tumors in mice did not result in such an efficient transgene expression (174). Thus, such polyplexes can be classified as nontarget complexes where several parameters may account for the pronounced systemic gene delivery to normal lungs but not to tumors. These include nonspecific interactions of positively charged polyplexes with negatively charged surface structures in the lungs, as well as aggregation of erythrocytes, resulting in lung embolism and severe toxicity (23).

C. Tumor-targeted Polyplexes

The promising results discussed above suggest that receptor-targeted polyplexes might be used to deliver genes systemically in vivo to target tumor-specific receptors or receptors that are differentially expressed on tumors (172).

Intravenous application of standard transferrin-PEI–DNA complexes through the tail vein into tumor-bearing mice (subcutaneous tumors) resulted in gene expression in the tail and lung; there was no expression in the tumor, but serious toxicity (153,173). However, surface shielding the transferrin-linked polyplexes with PEG through covalent coupling to PEI, complexes were stabilized in size, did not bind plasma proteins (153) and did not result in erythrocyte aggregation. These PEGylated PEI polyplexes, when injected into tail vein of syngeneic

mice (see Fig. 5) were far less toxic; gene expression in the tumor was up to 100-fold higher than in other organs (153,173). Similar results were obtained with other transferrin polyplexes with electroneutral surface: shielded optimized adenovirus-linked transferrin-polylysine polyplexes (173) or transferrin-PEI polyplexes with a higher content of transferrin as shielding agent (23).

Because subcutaneous tumors are not directly supplied by main blood vessels, delivery is dependent on peripheral blood supply. Thus, the polyplexes probably target such distant tumors in a combinatorial passive (i.e., overcoming extracellular barriers, EPR = enhanced permeability and retention effect in tumors) and active targeting mechanisms (i.e., specific receptor-targeted endocytosis).

Another recent report demonstrated that intravenous injection of PEGylated EGF-containing DNA–PEI complexes results in a highly specific expression in human hepatocellular carcinoma (HCC) tumors. Following intravenous injection into human HCC xenograft-bearing severe combined immunodeficiency mice, luciferase reporter gene expression was predominantly found in the tumor, with levels up to 2 logs higher than in the liver (52).

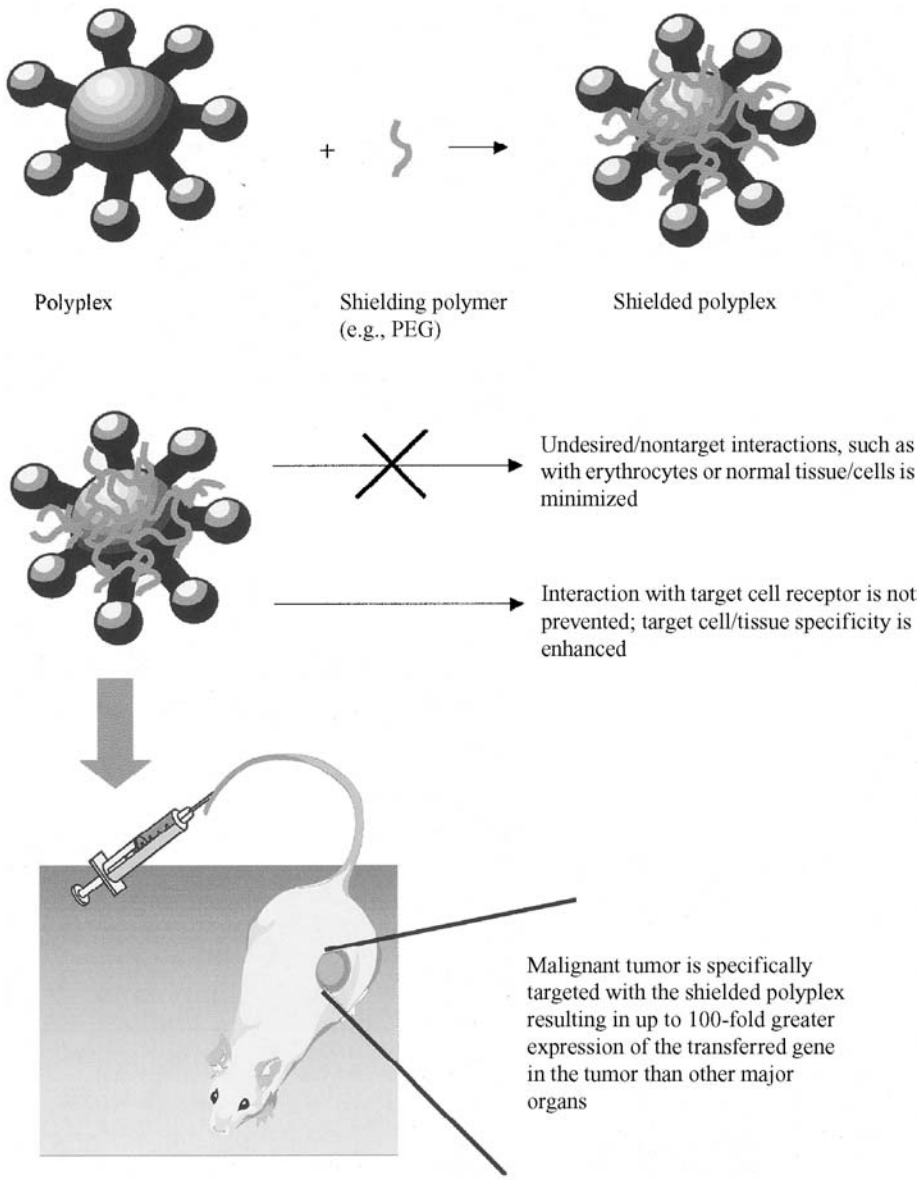

Figure 5 Tumor-targeted gene transfer. See the color insert for a color version of this figure.

Such shielded tumor-targeting polyplexes appear to also have interesting characteristics from a therapeutic perspective. Expression of tumor necrosis factor-α (TNF-α) as the therapeutic gene after systemic application of transferrin- or transferrin-PEG-shielded PEI polyplexes resulted in hemorrhagic necrosis in targeted distant tumors without TNF-α-related systemic toxicity (177,178). These first results are encouraging, and further optimization of tumor-targeting polyplexes should result in the development of potential therapies for human patients.

Electrokinetic Enhancement of Plasmid Delivery In Vivo

Ruxandra Draghia-Akli and Louis C. Smith
Advisys, Inc.
The Woodlands, Texas, U.S.A.

I. INTRODUCTION

An ideal delivery system for in vivo gene transfer should be simple and safe, and provide prolonged expression of transgenes at therapeutic levels. A variety of nonviral delivery systems can be used for gene transfer in different clinical settings (1). Plasmid constructs are attractive candidates for direct injection into organs and tissues because plasmids are well-defined entities that are biochemically stable and have been used successfully for many years (2,3). In a few cases, the relatively low expression levels achieved after simple plasmid injection are sufficient to reach physiologically acceptable levels of bioactivity of secreted peptides (4,5).

One of the most striking recent advances for plasmid delivery in vivo has been that of electropermeabilization, also described as either electroporation or electrokinetic enhancement. This physical process exposes the target tissue to a brief electric field pulse that induces temporary and reversible breakdown of the cell membrane. During the period of membrane destabilization, a variety of molecules, including drugs and plasmids, may gain intracellular access. A scheme of the electroporation process is depicted in Fig. 1. This method of molecule delivery, which is simple, efficient, and reproducible, has become valuable for basic research, with great potential for gene transfer and DNA vaccination (6). Electroporation has been used very successfully to transfect tumor cells after injection of plasmid (7,8) or to deliver the antitumor drug bleomycin to cutaneous and subcutaneous tumors in humans (9,10). Electroporation has been extensively used in mice (11–13), rats (14,15), dogs (16), and pigs (17,18) to deliver therapeutic genes that encode for a variety of hormones, cytokines, enzymes, or antigens. The numerous tissues and organs that have been targeted include liver, skin, eye, testis, cardiac muscle and smooth muscle, tumors at different locations, and skeletal muscle.

II. MECHANISTIC STUDIES OF ELECTROPORATION

The degree of permeabilization of the muscle cells is dependent on the electric field intensity, length of pulses, shape and type of electrodes, and cell size.

A. Electric Field Intensity

The influence of electrode configuration on the electric field distribution has been shown by measuring ^{51}Cr-EDTA uptake in vivo (19,20). These studies indicated two uptake phases in which the membrane permeabilization increases, followed by irreversible membrane damage. Both plate electrodes (18,21) or a pair of wire electrodes (22) have been shown to be effective. The calculated electric field distribution was more homogenous for plate electrodes than for needle electrodes. Also, the needle diameter determines 3 parameters: in rabbit liver, the decrease of the electric field intensity near the electrodes is steeper with smaller electrode diameter; the area covered with a given electric field is smaller with smaller electrodes (23); and there is a more homogenous electric field with larger electrode diameter.

Recently, square-wave electric pulses of different field strength and duration have been evaluated. Data for high-voltage pulses of short duration or low-voltage pulses of long duration are found in Table 1. Despite the large variation in conditions used for the target tissue or organ, the expression achieved in all these cases represents efficacious levels of gene products, some of which are within the range that is necessary to treat human diseases.

Theoretical and practical data also suggest that the cell size in the region perpendicular to the electric field plays a crucial role in determining the permeabilization parameters (24). The larger the ''functional'' size of the cell, the lower is the field strength necessary (25). For example, tissues containing cells

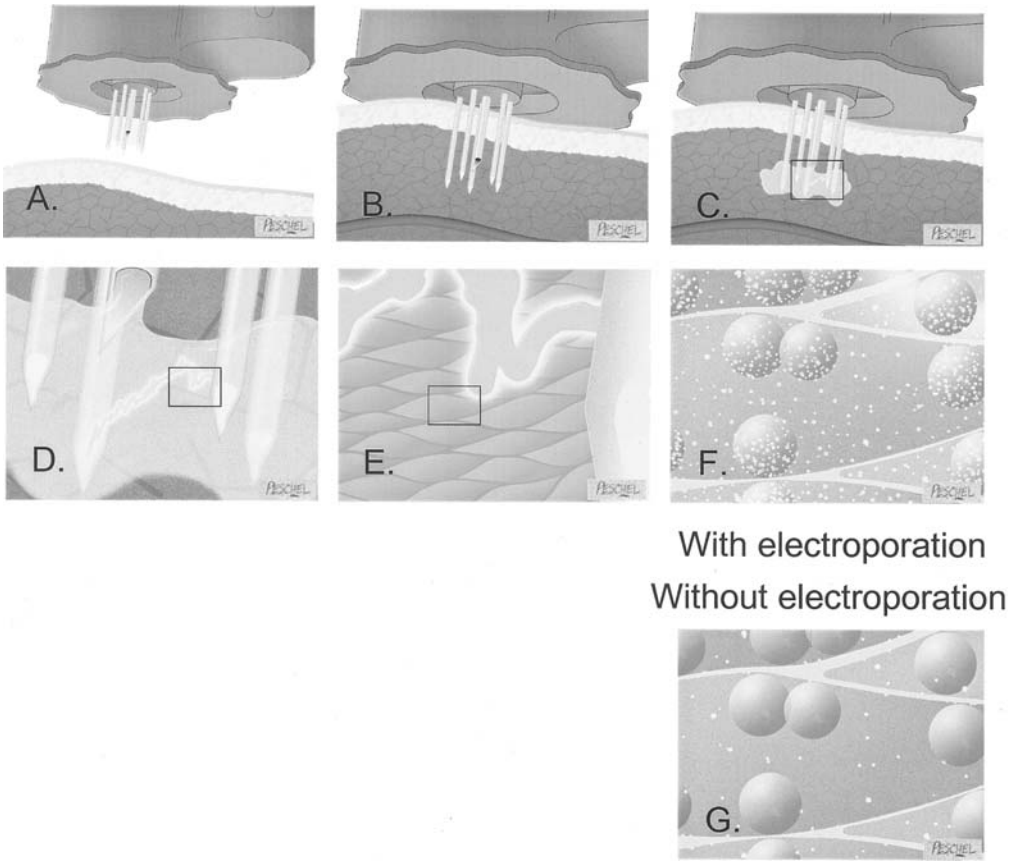

Figure 1 Schematic depiction of the electroporation process in the skeletal muscle using penetrating electrodes. (A) Electroporation system is placed next to the target muscle; (B) the injection needle and the electrodes are inserted into the muscle; (C) plasmid is injected into the target muscle; (D) at a selected time interval after plasmid injection, typically 2 min, a square-wave electric pulse is generated; (E) effect of the electric field at the muscle fiber level; (F) plasmid injection followed by electroporation increases uptake by 10- to 1000-fold into the target muscle; notice the muscle fiber nuclei that contain numerous copies of the injected plasmid; and (G) direct plasmid injection into the skeletal muscle, without electroporation results in a low plasmid copy number uptaken and expressed by the muscle fiber. See the color insert for a color version of this figure.

that communicate through tight gap junctions amplify transmembrane potential changes. Thus, the skeletal muscle can be electroporated at lower field intensities (26) with decreased tissue damage, compared with other tissues.

In studies of the electric field-mediated enhancement of gene and drug delivery, different types of electrodes have been used. These include clamp or caliper, tweezers, paddles, and needle arrays. In large mammals such as pigs, dogs, or humans, the increased resistance of the skin, the thickness of the subcutaneous fat tissue, and the concern for tissue damage that occurs with the proportionally increased intensity of the electric field makes use of some percutaneous electrodes inefficient and impractical. Thus, the electrode design must be adapted to the application, organ, and animal species. For cutaneous and subcutaneous tumors in animals and humans, calipers or needles (27–29) are used. For liver, tweezers, or occasionally needles (23,30–32); for skin, calipers, meander electrode, plate-and-fork electrodes, or small needles (29,33,34); and for the skeletal muscle, calipers or needles (17,18,35) are used.

B. Association with Carrier Molecules

Despite the recent advances in the technology of plasmid transfer into tissues, additional improvements in electroporation techniques and plasmid formulations are needed. For example, the entire electroporation procedure in theory can be completed without causing permanent damage to the cell. However, under some conditions, electroporation procedures inflict fatal stress on some skeletal muscle cells (16,36) and

Table 1 Examples of Square-wave Pulses Electric Field Intensity and Pulse Length

	Species	Tissue	Condition (Ref.)
High voltage	Rat	Skin	10 × 1000 V/cm, 0.1 ms (71)
Short duration	Mouse	Muscle	8 × 1600–2000 V/cm, 0.099 ms (19)
	Mouse	Tumor	6 × 1500 V/cm, 0.099 ms (29)
	Pig, monkey	Skin	6 × 1750 V/cm, 0.1 ms (73)
Low voltage	Mouse	Muscle	6 × 100 V/cm, 20–50 ms (51,102)
Long duration	Dog	Muscle	2 × 375 V/cm, 25 ms (16)
	Pig	Muscle	6 × 200 V/cm, 60 ms (17)
	Monkey, rabbit	Muscle	8 × 200 V/cm, 20 ms (103)
	Rat	Skin	8 × 12–24 V/cm, 50 ms (104)
	Mouse	Liver	10 × 150 V/cm, 50 ms (105)
Combination regimen	Mouse	Muscle	1 × 800 V/cm, 0.01–0.1 ms + 4 × 80 V/cm, 83–100 ms (106,107)

degrade the plasmid (21). As animal models, pigs and dogs have muscle fibers that are quite large (37,38) and consequently are more suitable than rodent muscle for electrokinetic enhancement. Polymers such as polyvinylpyrrolidone (PVP) and poly-(L-glutamate) (PLG) at high or low concentrations or mild surfactants in low concentration such as poloxamer 188 have been used to enhance plasmid uptake, with some reduction in tissue damage. Poloxamer 188 may induce sealing of permeabilized lipid bilayers to rescue cells that were not extensively heat damaged; consequently, the expression levels may rise (21,39). Following electroporation of the skeletal muscle of mice, rats, dogs, or pigs (16,40–42), plasmid formulated with PLG or PVP has been observed to increase gene expression up to 10-fold compared with nonformulated plasmid. In mice, preinjection of the electroporated muscle with hyaluronidase, an enzyme that hydrolyzes hyaluronic acid, a ubiquitous component of the extracellular matrix, increases gene expression up to 5-fold with minimal tissue damage (43).

C. Delivery of Plasmid Fragments

Linear fragments of DNA derived from adeno-associated viral vectors have been delivered to the liver by an intra-arterial high-pressure hydrodynamic method, and have been shown to be efficacious and provide long-term expression of a secreted protein (44). Mice injected with a linear DNA expression cassette encoding human α-1-antitrypsin (hAAT) expressed approximately 10- to 100-fold more serum hAAT than mice injected with closed circular DNA over the length of the study.

We examined the effect of electroporation on expression of plasmid fragments containing expression cassettes, with or without residual plasmid backbone in skeletal muscle. There may be many advantages of delivering DNA fragments in vivo from which the antibiotic resistance gene and/or the bacterial origin of replication have been removed. First, the antibiotic resistance gene could render the host organism resistant to that particular antibiotic. In addition, some antibiotic resistance genes, such as the ampicillin gene, contain multiple CpG motifs, which are known to enhance the immune response in muscle cells (45). A less immunogenic vector can reduce the possibility of immune or toxic responses and increase the therapeutic value of the vector (46). In addition, although undocumented for naked plasmid, the possibility of plasmid replication or recombination in vivo exists. It is possible to redesign plasmids with conditional origins of replication, as in the pCOR plasmids (47) or supercoiled minicircles (48) that lack the bacterial origin of replication. The creation of putatively safer plasmid constructs is difficult and will require sufficient resources for the design and testing of new plasmid systems that exceed the overall yield and performance of existing systems.

The pSEAP2 mammalian reporter vector (Clontech, CA) that contains the human placental secreted alkaline phosphatase (SEAP) gene was used in these studies (Fig. 2A). The strong muscle-specific synthetic promoter SPc5-12 (49) was inserted into the pSEAP2 basic vector to create a pSP-SEAP vector. The SEAP coding sequence is followed by the SV40 late polyadenylation signal. The vector backbone also provides an f1 origin for single-stranded DNA production, a pUC19 (prokaryotic) bacterial origin of replication, and an ampicillin (prokaryotic)-resistant gene for propagation and selection in *Escherichia coli*. Several linear plasmid DNA fragments were generated by specific restriction enzyme digestions of the circular DNA. Electrophoresis was used to separate the linear fragments, which were then extracted from the gel. The SEAP gene is an immunogenic protein in most normal adult mammals (50). To avoid an immune reaction against the transgene, studies of the long-term expression of the different non-circular DNA fragments were conducted in severe combined immunodeficient (SCID) mice. On day 1, the mice ($n = 10$ per group) were weighed. Then, their left tibialis anterior muscles were injected with equivalent molarities of DNA fragments or supercoiled plasmid. Of the 6 groups, 1 received uncut, circular DNA; 4 received specific

plasmid fragments; and 1 control group received an injection of phosphate buffered saline (PBS). The injection was followed within 2 min by electroporation, using external caliper electrodes and conditions of 6 pulses, 100 V/cm, 60 ms. A BTX T820 generator (Genetronics, San Diego, CA) was used to deliver square-wave pulses in all experiments. SEAP values were assayed to 54 days postinjection (Fig. 2B). The SEAP expression levels were not different among the treated groups. These results suggest that, when using the in vivo electroporation technique, gene expression, and probably intracellular bioavailability of the plasmid, is not dependent on the plasmid configuration.

III. TISSUE SPECIFIC EXPRESSION

A. Skeletal Muscle

Since the initial report by Aihara and Miyazaki (51), in vivo electroporation of the skeletal muscle for delivery of therapeutic proteins has become widely used. Table 2 summarizes some of the recent literature reports in which electroporation was used to enhance plasmid delivery to skeletal muscle. Although the devices, conditions, methods, and animal models substantially differ, all studies conclude that plasmid injection followed by electroporation can be successfully used to deliver therapeutic genes. The electrokinetic enhancement of plasmid delivery allows the muscle to be used as a bioreactor for the persistent production and secretion of proteins into the bloodstream. The expression levels are increased by as much as 2 to 3 orders of magnitude over plasmid injection alone, to levels comparable to those of adenoviral-mediated gene delivery and may reach physiological ranges. The applications of intramuscular electroporation gene transfer are innovative and intriguing, and span a large array of pathologies: malignancies, renal disease, anemia, prevention of drug toxicity, etc. Thorough review articles address aspects of these proposed therapies (6,52–54). The duration of gene expression was reported to be at least 9 to 14.5 months after in vivo gene electrotransfer into skeletal muscle (55–57). Collectively, these studies provide the evidence that adequate levels of secreted proteins can be achieved using plasmids in a simple, safe, and efficient manner, with significant potential for gene transfer and vaccination for large animals and humans. Interestingly, more and more scientists are now addressing a new problem, the regulation of gene expression, raised by the *adequate* levels of protein production, to maintain levels of expression in concordance with therapeutic needs (15,18,58,59).

B. Liver

The liver represents one of the primary targets for gene therapeutic treatment of numerous metabolic diseases, cancers, hepatitis, and other pathologies. Although recombinant viral vectors have been widely used to introduce new genes into the liver, their usefulness may be mitigated by side effects and potential safety concerns (60–63). Plasmid delivered to hepatic vasculature (64), by hydrodynamic methods (65,66), or by electroporation constitutes an alternative method to deliver transgenes to the liver. Mechanistic studies to characterize electric field distribution for drug or plasmid administration under different conditions were performed in the liver (23). Electroporation is traditionally performed in conjunction with chemotherapy for different malignancies. This treatment, known as electrochemotherapy, has been successful for liver malignancies in animal models (67). Tumor reduction has been recently achieved by locally injecting DNA to the site of interest in the liver followed by the electric field application (see also Table 4). Long-term expression of bcl-xs and tumor regression has been observed after plasmid delivery and electrotherapy using tweezers electrodes (68). In addition, nutritionally regulated foreign gene expression in vivo is attainable locally in the liver by this method (69). A method for efficient gene transfer to the liver by electroporation following tail vein administration of the naked DNA has been recently described (31). According to the authors, systemic injection has the advantage of delivering genes to more hepatocytes when compared with the local injection of plasmid to the liver. These advances in liver gene delivery may provide powerful tools for basic research or potential clinical application studies.

C. Skin

DNA delivery to skin may be useful for the treatment of skin disorders, DNA vaccinations, and other gene transfer applications requiring local or systemic distribution of a transgene product (33). This choice is facilitated by information that shows that electroporation of skin induces a mild and reversible impairment of the barrier function of the skin, a decrease in skin resistance, and a transient decrease in blood flow. Neither inflammation nor necroses is generally observed (70,71). Reporter genes are expressed in the immediate area surrounding the injection site. After direct plasmid injection into skin, transfected cells are typically restricted to the epidermis. However, in different animal species, when electroporation is applied after the injection, larger numbers of adipocytes and fibroblasts and numerous dendriticlike cells within the dermal and subdermal tissues, as well as lymph nodes draining electropermeabilized sites, are transfected (72–74). Compounds such as aurintricarboxylic acid have been found to enhance plasmid expression in rodent, primate, and pig muscles (73). Therapeutic molecules such as erythropoietin or HBV antigen can be efficiently produced by skin cells and remain functionally active up to 7 weeks (34,72).

D. Tumors

Electrochemotherapy, or enhanced delivery of chemotherapeutic drugs, especially bleomycin, to solid tumors has been used successfully for many years (76,77). Clinical trials using this method for the treatment of solid tumors have been conducted in humans and other species (9,78–80). Recently, investigators focused on plasmid delivery to tumors as a means to increase long-term antitumor immunity successfully (7,81,82), to inhibit angiogenesis (83,84), or to reduce tumor volume (85). Interestingly, in some cases, CpG islands within the plasmid backbone may contribute to the antitumor effect in the absence of therapeutic cDNA expression or eukaryotic sequences (86).

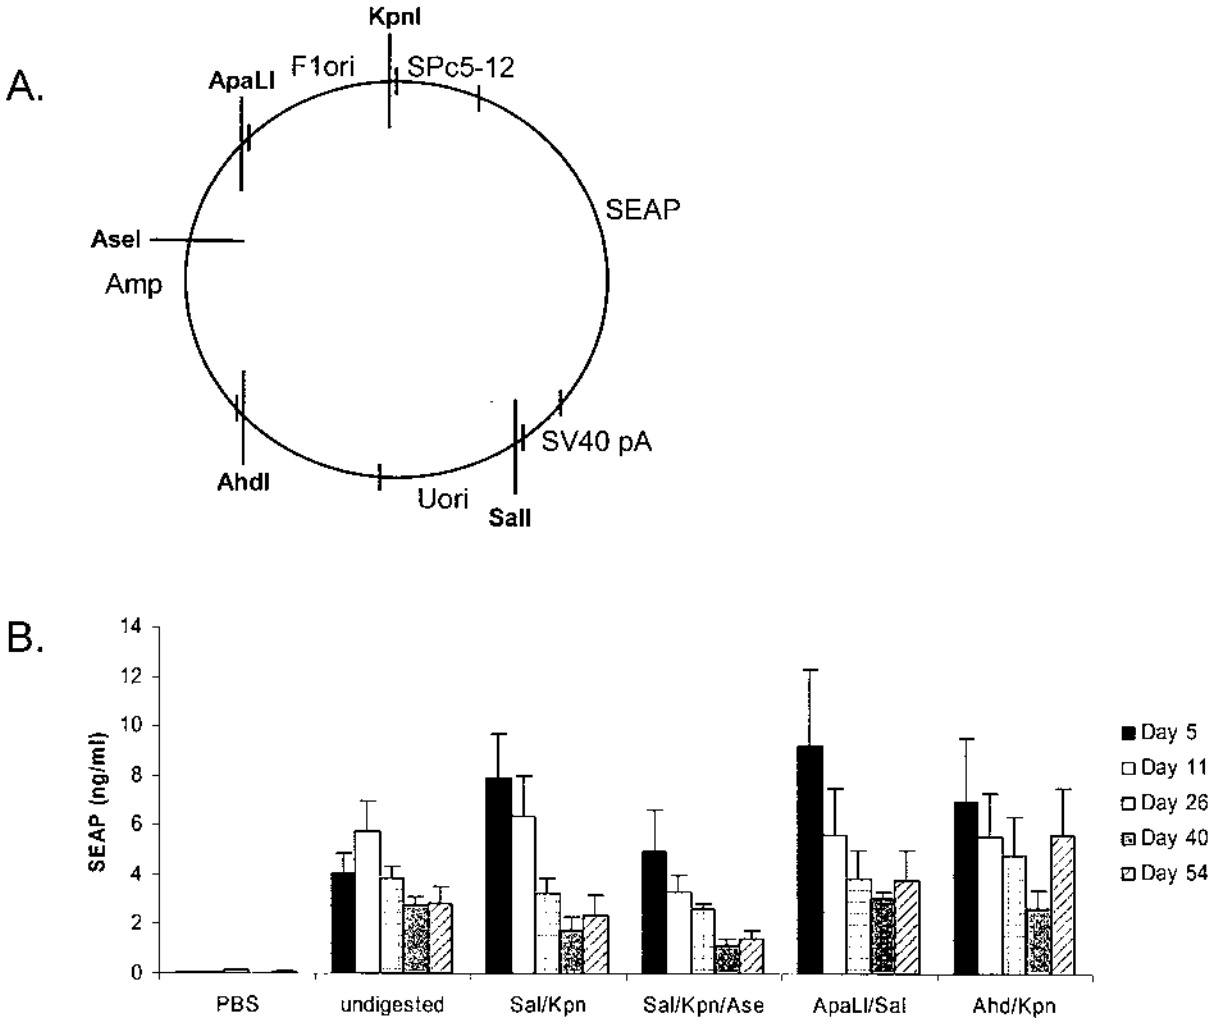

Figure 2 In vivo expression of plasmid fragments delivered by electroporation to the skeletal muscle. (A) The construct pSP-SEAP contains a SPc5-12 synthetic promoter, a human SEAP gene, the SV40 polyadenylation signal (expression cassette), and a plasmid backbone with bacterial replication origin, Uori, an antibiotic resistance gene (ampicillin), and a packaging origin for the SEAP gene, F1ori. Different regions of the plasmid were cut using restriction enzymes to yield the following:

- KpnI/SalI, containing the expression cassette
- KpnI/AhdI, containing the expression cassette and Uori
- ApaLI/SalI, containing the expression cassette and F1 ori
- KpnI/SalI/AseI, containing the expression cassette and other 2 additional fragments of the plasmid backbone.

(B) SCID mice were injected with supercoiled DNA or plasmid fragments. Expression levels were not different among groups.

In a comparative study, 50 micrograms of plasmid was found to be as efficacious as 5×10^9 i.u. adenovirus. Furthermore, adenovirus leakage induced mild to moderate liver damage, while practically no leakage occurred after electroporation (87). Table 3 contains reports that show that improved vectors, delivered using highly effective electroporation methods, may form the basis for future human applications. Updated overviews of the therapeutic perspectives of antitumor drug and DNA electrotransfer are also of significant interest (88,89).

E. Eye

Recently, electric pulse-mediated plasmid transfer has been used to deliver transgenes to cornea in an effort to ensure long-

Matrix metalloproteinase 4	Mouse	Tumor volume, apoptosis	(126)
Neurotrophin 3	Mouse	Latency of sensory nerve action, immunohistochemistry, serum protein levels	(127)
B7-1, peptides	Mouse	Cytotoxicity, immunohistochemistry	(128)
Luciferase, IL-12	Mouse	Relative light units, cytokine levels	(82)
Luciferase, erythropoietin	Mouse	Relative light units, EPO levels, hematocrit, fluorescence microscopy	(56)
Hepatitis C E2 ectodomain with N-terminal fusion with hypervariable region 1 (HVR1) peptide mimic	Mouse	Titers, cytotoxicity, seroconversion	(129)
EGFP-dystrophin fusion proteins	Mouse	Fluorescence microscopy	(130)

Table 2 Continued

Transgene	Species	Endpoint	Ref.
HIV gag, luciferase	Mouse	Luciferase mass, titer	(131)
Luciferase, β-galactosidase	Rat	Histochemistry, relative light units	(132)
β-galactosidase, luciferase	Mouse	Histochemistry, titer, luciferase mass, confocal microscopy	(133)
Hepatitis B surface Ag	Mouse, rabbit, guinea pig	Antigen level, titer, cytotoxicity	(134)
Luciferase	Mouse	Relative light units, ^{51}Cr-EDTA uptake	(106)
Erythropoietin	Rat	RT-PCR, Epo levels, hematocrit	(135)
β-galactosidase, GFP	Rat	Histochemistry, microscopy	(22;55)
Tissue inhibitor of metalloproteinases-4	Mouse	Immunohistochemistry, tumor size, Western blot	(136)
SEAP	Mouse	SEAP levels, antibody titer	(50)
IL-12	Mouse	IL-12 levels, tumor volume, flow cytometry	(137)
Influenza B hemagglutinin, neuraminidase, nucleoprotein	Mouse	Survival, antibody titer, body weight	(138)
MyHC promoter family, luciferase	Mouse	Fold change in relative light units	(139)
Erythropoietin	Mouse	EPO levels, hematocrit	(140)
INF-α, luciferase, SEAP, IL-2, IL-12, endostatin	Mouse	Tumor volume, tumor vascularization, luciferase mass, SEAP mass	(141)
Luciferase (as plasmid and in adenovirus vector)	Mouse, rat	Relative light units, histology	(87)
INF-γR/Fc fusion protein	Mouse	INF-γ levels, survival, IgG subclass levels, BrdU incorporation in T cell subset, immunohistochemistry	(142)
Luciferase, β-galactosidase,	Mouse	Relative light units, histochemistry	(143)
Luciferase, β-galactosidase, FGF1	Mouse, rat, rabbit, Maccaca	Luciferase mass, histochemistry, immunohistochemistry	(103)
Erythropoietin, SEAP, β-galactosidase	Rat, mouse, rabbit	Histochemistry, SEAP, EPO levels, hematocrit, kidney function	(144)
Erythropoietin	Mouse	EPO levels, hematocrit	(59)
gp100, TRP-2	Mouse	Tumor rejection, cytolysis, survival	(145)
Erythropoietin	Rat	Epo levels, hematocrit, platelet count, blood pressure, weight	(104)
LFT3 llgand, GM-CSF	Mouse	LFT-3, GM-CSF levels, splenocytes, splenic DC	(110)
Erythropoietin	Mouse	qPCR, Epo levels, hematocrit, erythrocyte membrane parameters	(146)
Hepatocyte growth factor	Rat	Renal function, histology, immunohistochemistry, plasma HGF levels, HGF mRNA levels	(147)
M. tuberculosis antigens mpb79, ag85b, ag85a, β-galactosidase	Mouse	Antigen-specific $CD4^+$, $CD8^+$ T cells, IFN-γ, IgG subclasses	(148)
Luciferase, β-galactosidase	Mouse	Luciferase mass, histochemistry	(149)
Laminin α2, chimeric dystrophin-EGFP, β-galactosidase	Mouse	Immunohistochemistry, fluorescence microscopy, histochemistry	(130)

lasting expression of a desired protein either for treatment of a local disease or for research purposes. Results of these studies demonstrate that electroporation is an excellent method for delivering genes to multiple cell layers within the cornea with extremely high levels of gene expression and little, if any, inflammatory response or tissue damage (90,91). Retinal ganglion cells have also been targeted. After a first demonstration showing retrograde labeling of up to 41% of the total ganglion cells in the electroinjected area (91), other studies with brain-derived neurotrophic factor (BDNF) gene transferred by in vivo electroporation showed protection of axotomized retinal ganglion cells against apoptosis (91,92).

Table 3 Electroporation for Plasmid Delivery in Tumors

Transgene	Species	Endpoint	Ref. Citation
CpG (luciferase)	Mouse	Tumor volume	(86)
IL-12	Mouse	Tumor volume	(7)
Antisense VEGF, sFlk-1	Mouse	Tumor volume	(83)
GFP	Mouse	Tumor area	(150)
HSV*tk*	Mouse	Tumor volume, histopathology, metastasis incidence	(85)
Tie2 receptor	Mouse	Tumorigenicity with neovascularization	(151)
TRAIL/Apo2L	Mouse	Tumor volume, histopathology, western blotting of serum	(152)
IL-2, GM-CSF	Mouse	Tumor volume	(8)
Luciferase	Mouse	Relative light units	(153)
IL-12	Mouse	Tumor volume	(154)
IL-2, IL-12	Mouse	Tumor volume, protein levels	(155)
IL-12, luciferase	Mouse	Relative light units, serum cytokine levels, tumor volume, histochemistry	(105)
GM-CSF, IL-2	Mouse	Tumor volume	(81)
Luciferase, β-galactosidase	Mouse	Luciferase mass	(156)
Luciferase,	Mouse	Relative light units	(157)
Luciferase, EGFP, diphtheria toxin fragment A	Mouse	Relative light units, histopathology	(158)
HSV-*tk*, GFP, diphtheria toxin fragment A	Mouse	Tumor volume, microscopy, histopathology	(159)
Endostatin, luciferase	Mouse	Relative light units, tumor volume, endostatin levels, number of metastases	(84)
Dominant-negative Stat3	Mouse	Histochemistry, tumor volume, histology	(160)
β-galactosidase	Mouse	Histochemistry	(161)

F. Others—Cardiac Muscle, Vascular Smooth Muscle, and Testes

Investigators have demonstrated the potential application of plasmid electroporation in many other tissues (Table 4). For example, in the cardiac tissue of chicken (93) green fluorescent protein (GFP) levels achieved by electroporation were similar to 10^6 transduction units/mL of adenovirus GFP. Smooth muscle cells in the renal tubulointerstitial compartment were also targeted. Myocyte-enriched calcineurin-interacting protein, (MCIP1), inhibits cardiac hypertrophy in vivo (75). In vivo injection of a plasmid expressing an enzyme for early growth response gene 1 via the urethra followed by tweezer electroporation prevented interstitial fibrosis in a rat model of kidney obstruction (94). Although gene transfer via in vitro fertilization with directly injected oocytes is a widely used method, recent studies suggest that in vivo electroporation technique in conjunction with direct plasmid injection into testes could be used to create transgenic animals or to treat some types of infertility. After testicular injection and electroporation, plasmid is rapidly transferred to epididymal ducts, and incorporated by ductal epithelial cells and epididymal spermatozoa (95). Long-lasting GFP expression can be detected in the spermatogenic cells even 2 months after electroporation. Natural mating with normal adult females revealed that 65% of the transfected males remained fertile and could generate their offspring normally (96). Infertile mice expressed an enhanced green fluorescent protein (EGFP) construct in the Sertoli cells in the testis for at least 35 days (97).

G. Embryo

A major challenge in current developmental biology and neuroscience is to understand the functions and activation sequence of thousands of genes involved in organogenesis, plasticity, physiology, and function. An unexpected tool was provided by the electroporation technique. Using this method, it is now possible to express foreign genes or antisense sequences in either a single cell or population of cells in vivo, by varying the size and type of electrodes or by modifying the pattern of stimulation. Recent advances are summarized in Table 5 and point out that electroporation is one of the most versatile of the nonviral technologies.

IV. FUTURE DIRECTIONS

All the studies presented above describe electroporators and methods based on a predetermined voltage between the electrodes. Because the impedance between electrodes that are

Table 4 Electroporation for Plasmid Delivery in Various Organs

embedded in a tissue can vary from case to case, or tissue to tissue, a predetermined voltage may not necessarily produce a predetermined current (98). As an example, Fig. 3 depicts a direct comparison of the 2 methods in the pig muscle. Notice that a predetermined voltage pulse causes an increase in the current flowing through a porcine muscle tissue during the duration of the pulse with the loss of a perfect square wave; in contrast, a constant current source actually maintains a constant current through a porcine muscle tissue. Thus, in many cases, the experiments do not provide a means to delineate the exact amount of current to which the cells are exposed. For this reason, conventional electroporators may generate amounts of heat in tissues that can easily kill cells (99,100). For example, a typical electronic 50-mS pulse with an average current of 5 Amperes across a typical load impedance of 25 ohms can theoretically raise the temperature in tissue 7.5°C, which is enough to kill cells. The physics of tissue injury caused by electrical shock is reviewed by Lee et al. (101). In contrast, the power dissipation decreases in a constant current system and prevents heating of a tissue, which may reduce tissue damage and contribute to the overall success of the procedure. Thus, there is a need to overcome the technological problems associated with constant voltage electroporation by providing a means to control effectively the amount of electricity delivered to the cells. This can be accomplished by precisely controlling the ionic flux that impinges on the cell membrane conduits. A constant current electrokinetic device has been tested in our laboratory, in collaboration with Robert H. Carpenter, DVM, MS. The paired-needle electrodes that use a predetermined voltage pulse across opposing electrode pairs creates a centralized pattern during an electroporation event in an area where congruent and intersecting overlap points develop. This area can be visualized as an asterisk pattern, as shown in Fig. 3C. However, asymmetrically arranged needle electrodes without opposing pairs will produce a decentralized pattern during an electroporation event in an area in which there are no congruent electroporation overlap points. One example of such symmetry is shown in Fig. 3D, with a decentralized pattern area of electroporation that resembles a pentagon. In this case, plasmids would be stereotactically

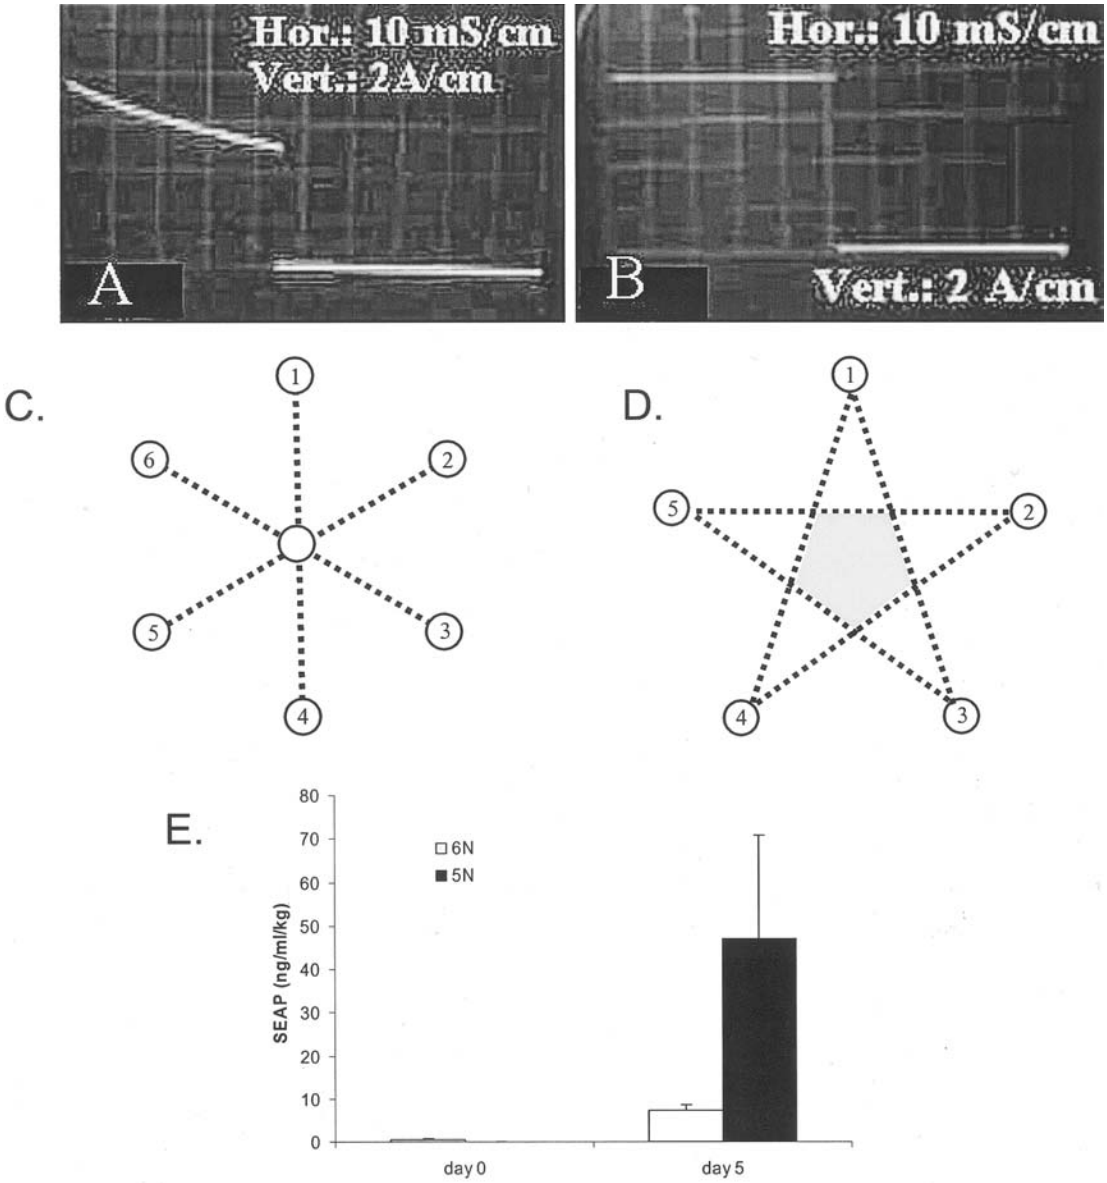

Figure 3 Constant voltage electroporation with paired needles vs. constant current electroporation using a pentagonal electrode array. (A) A predetermined voltage pulse causes an increase in the current flowing through a porcine muscle tissue during the duration of the pulse. In contrast, (B) a constant current source actually maintains a constant current through a porcine muscle tissue. (C) Maximum intensity electric field after constant voltage electroporation using a paired needle array. (D) Diffuse electric field after constant current electroporation using a pentagonal needle array. (E) Comparison of gene expression between the 2 delivery methods using similar electric field intensities.

delivered in-between the internal electrodes, followed by the constant current electric field pulses. A comparison of in vivo results obtained with a classical electroporator and a constant current device with asymmetrically arranged electrodes in adult pigs is depicted in Fig. 3E.

V. SUMMARY

The electrokinetic enhancement of plasmid delivery has become widely used for a variety of academic and preclinical applications. Since 1998, more than 90 transgenes have been

used to achieve quantitatively significant in vivo endpoints in response to the circulating levels of their respective protein products. The full potential of skeletal muscle as a bioreactor for production of therapeutic proteins has yet to be realized. It is well established in animal models that tumor growth can be inhibited by transgenes expressed either locally by expression in tumors or systemically in remote muscles. This technology holds promise for significant advances in treatment of tumors and their associated metastatic disease. Developmental biologists have recognized the experimental power of electroporation to augment plasmid delivery to single cells or populations of cells at stages of development, as selected by the investigator. Electrokinetic enhancement of plasmid delivery, particularly in skeletal muscle and embryos, is a significant advance toward the development of practical uses envisioned for the molecular information contained in the mammalian genomes.

I. INTRODUCTION

Biolistic gene delivery (a.k.a. microparticle injection, ballistic, bioballistic, particle bombardment, etc.) is mediated by devices generally known as ''gene guns'' because these devices literally propel nucleic acids on ''bullets'' to ''shoot'' genes into cells. Chemicals, proteins, mRNA, or DNA are first coated on dense metallic particles of 0.25 to 5 μm in diameter, and these are accelerated into target cells or tissues to deliver these substances directly inside cells. Unlike the cooperative processes needed for gene delivery by viral or nonviral vectors (Fig. 1A), biolistic gene delivery (1) breaks down many of the barriers to transfection by applying kinetic energy to drive macromolecules across cell membranes into the cell interior (Fig. 1B). Direct delivery into the cell cytoplasm avoids the necessity for cell receptor binding, engagement of receptor-mediated endocytosis mechanisms, and escape from endosomes (Fig. 1B). As such, biolistic transfection using gene guns allows for transfection of cells normally refractory to transfection. This method also avoids destruction of nucleic acids by nucleases present in extracellular fluids and in the endosomes (2), thereby allowing gene delivery without the necessity to package nucleic acids into virions or nonviral particles. Given these features, gene guns have become a potent method for gene delivery into cells in vitro and for gene delivery directly into animals and humans, thereby allowing application of simple plasmids for gene therapy and genetic immunization applications.

II. BRIEF HISTORY OF BIOLISTICS AND GENE GUNS

Biolistic technology was originally developed in the area of plant genetics to introduce genes into target cells that were largely refractory to traditional methods of gene delivery (1). Biolistic lore holds that the gene gun was inspired by interactions between edible bonsai plants and squirrels, and the later involvement of an air rifle to control these interactions. Legend has it that in the course of those events, Dr. John Sanford made the pivotal extrapolation that if an air rifle could be used to deliver macrobullets into a macrotarget, perhaps another gun could be used to deliver microbullets into microtargets like living cells. By extension, if a microbullet could be shot into living cells without killing them, could a microbullet also be used to carry nucleic acids into those cells to genetically modify them?

The obvious answer now to this strikingly simple but powerful question is, of course, ''yes.'' However, moving from concept to a practical device that could deliver DNA into cells without killing them required a number of years of work by Sanford's group and several other groups. Sanford's group originally focused on biolistic gene delivery for plant and prokaryotic applications (1,3,4). These efforts developed a wide variety of gene guns, including the precursor to the gunpowder-driven commercially available gene gun from BioRad. Further gene gun development occurred as a collaboration between John Sanford and Stephen Johnston, who did their graduate training together in Bob Hanneman's laboratory at

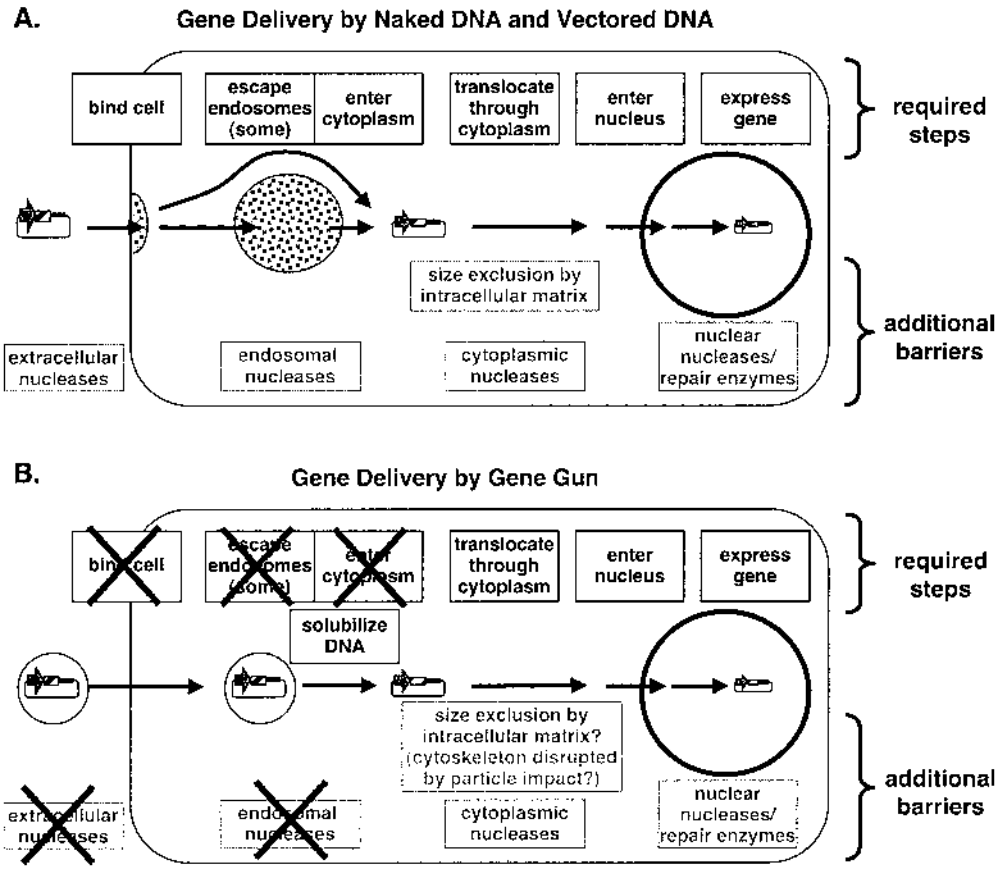

Figure 1 Cartoon of the required events and theoretical barriers to gene delivery in mammalian cells. (A) Gene delivery by naked plasmid DNA and viral or nonviral gene delivery vectors. (B) Gene delivery by gene guns using kinetic energy to overcome some required events and barriers.

the University of Wisconsin. This collaboration between Sanford's group and Johnston's group enabled a number of new gene guns, including a helium-driven vacuum chamber device (Fig. 2A) that was the predecessor of BioRad's helium-driven PDS1000™ for mammalian cell and animal transfection. This collaboration along with Rumsey–Loomis generated several handheld helium-driven guns (Fig. 2B) for animal transfection including the infamous ''bazooka'' and the ''wand'' (Fig. 3). The long-standing Sanford–Johnston collaboration also provided first demonstration of mitochondrial transformation by biolistics, as well as early demonstrations of transfection of mammalian cells and living animals in collaboration with Sandy Williams (5–7).

Following Sanford's first demonstration of gene gun technology (1), several other groups developed parallel or alternate gene gun technologies for biolistic gene delivery [reviewed in (7)]. Most notable of these are the efforts by the group from Agracetus (now Powderject), who developed a series of gene guns, including the electrically driven Accell™ device (8), and an entrainment gene gun (Fig. 2C) that was the ultimate prototype for the commercially available Helios™ device (BioRad).

Commercialization of the Helios gene gun was an important milestone for enabling the use of biolistics for gene therapy because it opened the technology up for those who previously could not engineer their own gun or who could not obtain one of the few spare guns from established groups. This product was also important because each ''home-built'' gene gun was different from every other one, so it was nearly impossible to standardize methods or compare efficiencies between different groups. One final advantage of the Helios gun relative to most home-built guns is that it is a 12-shot ''revolver'' gene gun allowing 12 transfections before the gun needs to be reloaded. In contrast, nearly all other gene guns were single-shot guns requiring reloading after each shot. Because each ''reload'' on older gene guns generally took about 1 minute to perform, the ability to more quickly reload the 12-shooter Helios and perform 12 transfections in a row greatly facilitated transfections of large numbers of cells or animals.

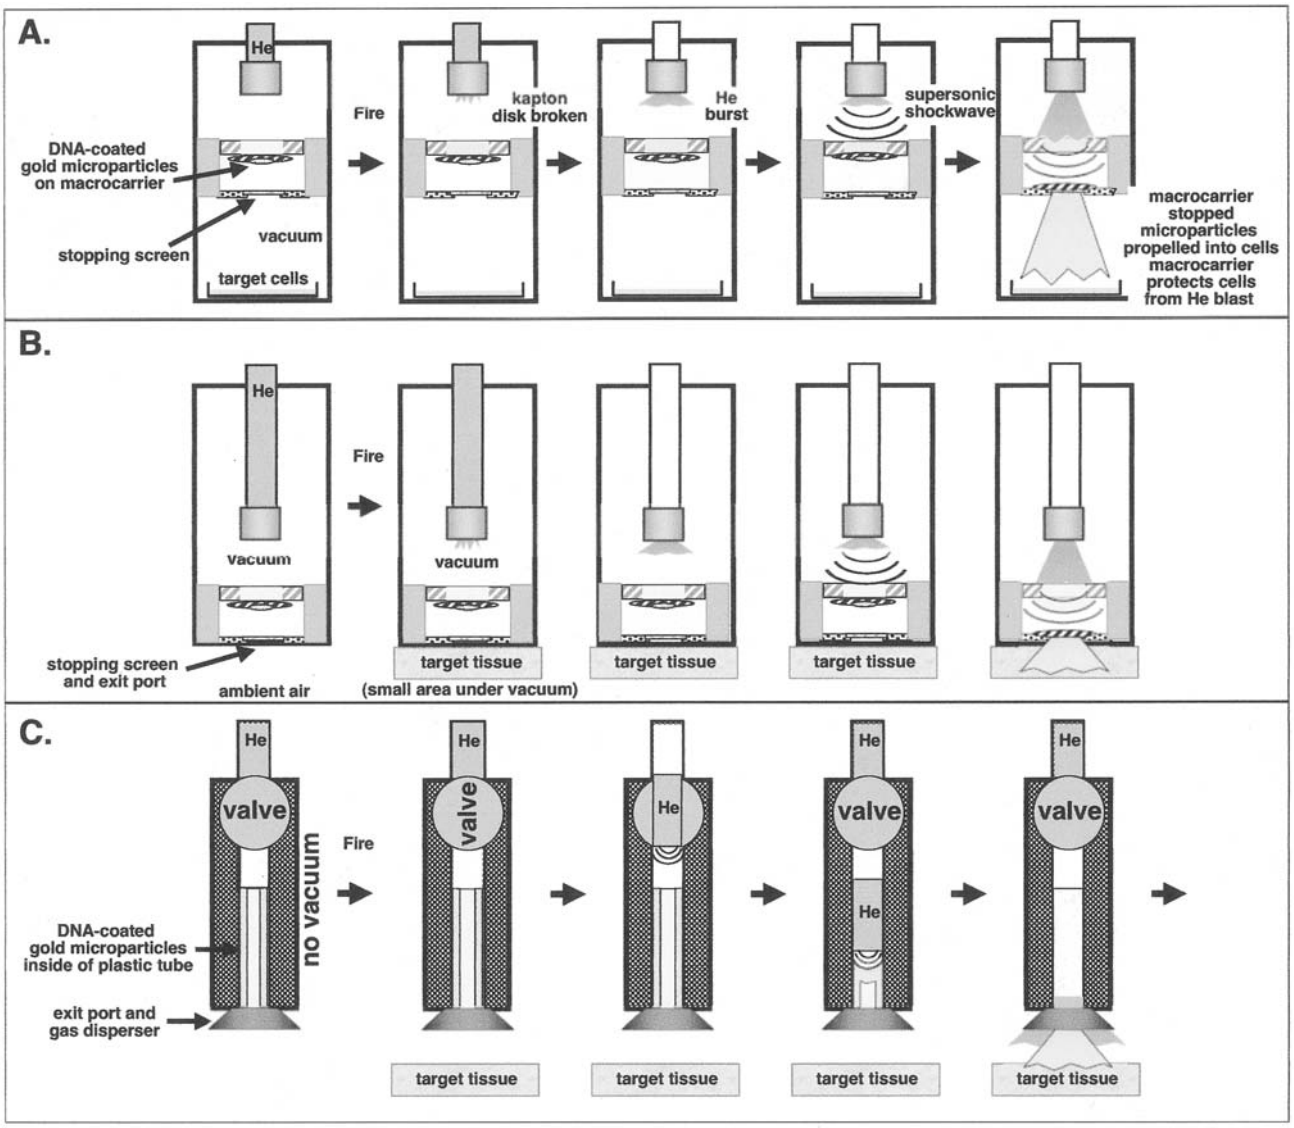

Figure 2 Cartoon of the particle acceleration by different types of gene guns. (A) Helium-driven chambered gene gun under vacuum. (B) Helium-driven handheld gene gun with internal vacuum. (C) Entrainment gene gun. See the color insert for a color version of this figure.

Sanford's pivotal incite that produced the gene gun revolutionized genetic engineering of a number of plant species, including soybeans and corn [reviewed in (9)]. Subsequent work demonstrated that biolistic gene guns could deliver genes not only into plant cells, but also into bacteria, yeast, and fungi [reviewed in (9)]. Biolistics was also the first technology able to genetically modify subcellular organelles, including chloroplasts (10) and mitochondria (11).

This work in other organisms laid the foundation for the application of gene guns for mammalian cells and intact animals. The first published demonstration of mammalian cell modification by biolistics was by Zelenin et al. demonstrating gene delivery into cultured mouse 3T3 cells in 1989 (12). This was followed by in vitro and in vivo gene gun-mediated gene delivery by groups from Agracetus published in 1990 (13) and by the Sanford–Johnston–Williams collaboration in 1991 (14). In the 1980s, these efforts to deliver plasmid DNA into living animals by gene gun occurred parallel to efforts by Jon Wolff's group to deliver plasmids as naked DNA into skeletal muscle by injection, which were published in 1990 (15). Prior to these observations, in vivo gene delivery could routinely be performed only by use of complex nonviral or viral vectors

Figure 3 Prototype handheld gene guns developed in the Johnston Laboratory. (A) The bazooka. (B) The wand.

for gene delivery. The ability to deliver simple plasmids into living cells in living animals by gene gun and by naked DNA injection were pivotal technological advances that enabled a variety of gene therapy applications. They particularly allowed one to transfect living animals or humans with vectors that were unencumbered vector chemicals or antigens.

III. THE MECHANICS AND BIOLOGY OF BIOLISTIC TRANSFECTION

A. Microparticles

The need for ''bullets'' or microparticles in this technology relates to the fact that kinetic energy depends on both mass and velocity ($p = m \times v$). Therefore, applying velocity to a low mass nucleic acid has a low likelihood of imparting sufficient kinetic energy to the molecule to drive it through the membrane and protein structures of a living cell. To circumvent this, nucleic acids and proteins are attached to dense carriers usually in the form of microparticles or ''microbullets'' with diameters from 0.25 to 5 μm (1). Metal microparticles are the carrier of choice for biolistic gene delivery because they have unparalleled density to maximize cell and tissue penetration while minimizing the size of particle needed to achieve this mass. A variety of metals including tungsten and depleted uranium, have been used for biolistics (1,5–7,14). Although any metal could theoretically be used, gold is the favored microparticle material for most mammalian applications because this metal is both dense and inherently biocompatible. For most applications, particles of 1 to 3 μm are used because these are sufficiently small relative to most mammalian cells to allow the particle to fit in the cytoplasm, but they are also sufficiently large to penetrate through 10 to 20 cell layers when applied in vivo (13,14). For the cornified epithelium of the skin, this size of particle can penetrate into the epidermis and dermis, although efficient gene delivery is usually observed only in the epithelial layers (Fig. 4). Although larger particles can be used, these typically do not bind DNA well and frequently cause more tissue damage than transfection and so are generally not used.

The gold microparticles used for biolistics are usually not made for this specific application, but are made as a by-product of other manufacturing processes. As such, obtaining ''good'' particles of the right size has historically been difficult and required screening of each batch of particles to (1) confirm they were the correct size, (2) that they were spherical and monodisperse, (3) that they could efficiently bind DNA, and (4) that they mediated transfection. Generally, if the particles satisfied the first 3 requirements, they would function well for transfection. Transfection efficiency generally correlates with the ability of the particles to bind DNA. Particles that bind 50% less DNA per particle generally mediate 50% less transfection. In practice, DNA binding after precipitation in high calcium varies substantially between different gold particles from different vendors. Given this, investigators would usually screen a small batch of a given lot and then buy as much of that lot as they could afford with typical costs on the order of $300 to $400 per gram. BioRad supplies gold particles that they have screened for activity for the gene gun. These cost considerably more per unit gold, but do save the investigator the necessity to screen and buy large amounts of particles.

B. Precipitation of DNA onto Microparticles

Nucleic acids and proteins do not inherently bind to gold particles. A number of methods have been tested to attach nucleic

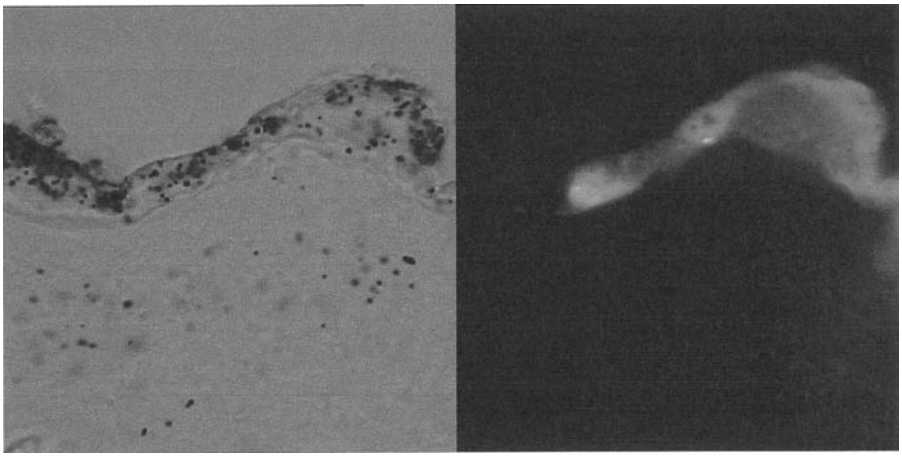

Figure 4 Cross-section of mouse skin transfected with the gene gun. The panel on the left in black and white shows the tissue and locations of the particles as dark dots. The panel on the right shows epidermal expression of green fluorescent protein (GFP) after delivery of its gene on the particles. Note, expression is restricted to the epidermis, despite the fact that particles have penetrated deeper into the dermis. See the color insert for a color version of this figure.

acids and proteins to particles. Although one could covalently attach DNA or RNA to particles or use very strong noncovalent methods, the most common method involves preciptation of DNA onto the particles using high concentrations of calcium in the presence of polyamines or polymers to protect the DNA (1,5,6). Simple precipitation is ideal for this approach due to the need for ''reversibility'' when delivering nucleic acids by any method. Producing a vector or a gene gun particle that is essentially like a rock might provide robust protection from physical or nuclease damage, but a nucleic acid ''rock'' is unlikely to mediate transfection because it would remain trapped after entry into the cell. For most nonviral vectors, this need for reversibility is solved by relying heavily on charge interactions to assemble negatively charged nucleic acids with positively charged chemicals such as a cationic lipids or peptides. For the gene gun, a gold particle has little charge or binding affinity for nucleic acids. Therefore, to satisfy the attachment need and the reversibility problem, the simplest and most robust solution is to precipitate the DNA in the presence of 1.5 M $CaCl_2$ in the presence of spermidine or another polymer. By this approach, the nucleic acid becomes insoluble in the high calcium and precipitates onto the gold particles in suspension. The DNA-calcium precipitate is ''sticky,'' so it adsorbs to the particles efficiently. As the particles are loaded with precipitate, they tend to settle out of solution faster than unloaded particles. The gold particles are big enough that they will settle out of suspension normally, but this is accelerated when they are coated with nucleic acids. A good indication that nucleic acids have successfully attached to the particles is that they will have a tendency to stick together somewhat and will need to be triturated (pipetted repeatedly) to be brought back into a state that is easily resuspended. A good indication that the ratio of nucleic acid to particles is too high is that the particles will form a fairly solid ''clump'' at the bottom of the tube. If observed, too much DNA was added. If not too far gone, the clumps can in some cases be broken apart by trituration, although the resulting particles will likely consist of aggregates of multiple particles that are more likely to cause cell/tissue damage. The particles are then washed in 70% ethanol, then dried in 100% ethanol. The microparticles are then transferred to a macrocarrier, such as a plastic bullet (1) or a plastic disc (7,8), or they can be coated on the inside of a tube for entrained delivery (3) (Fig. 2) in dry 100% ethanol. For macrocarrier-driven guns, transfer of the particles in dry 100% ethanol allows the ethanol to evaporate off the suspension (in a dessicator box) such that the nucleic acid slurry dries and adsorbs to the macrocarrier with sufficient adhesion to remain attached while at rest, but with low enough adhesion that they will release when impacting a stopping plate or screen (Fig. 2A). Working out the minute variations that allowed nucleic acid adhesion to particles and particle adhesion to macrocarriers required substantial effort by early investigators and were pivotal to enabling the gene gun technology.

C. The Effects of Humidity

One critical aspect to the preparation of DNA-coated microparticles is performing DNA precipitation and storage in a low-humidity environment. For the Sanford–Johnston group, this parameter was discovered only after a few years of frustration where they observed that they could get efficient gene delivery for 6 months and then transfection efficiency would drop for the next 6 months. This cycle continued until they realized that the gun worked well in the winter, but poorly during the humid summers in North Carolina at Duke Univer-

sity (Stephen Johnston, personal communication). The poor transfection appeared to be due to the fact that DNA-coated microparticles loaded on macrocarriers in a humid environment did not release or ''unstick'' from the macrocarrier efficiently, whereas particles prepared in a dessicator with dry reagents released well and mediated efficient transfection. This humidity variable was unobserved prior to this because Sanford's work was performed in upstate New York, with a considerably lower humidity than North Carolina in the summer. Once only dry reagents were used (e.g., 100% ethanol stored in a dessicator), and macrocarriers and DNA-coated particles were prepared in a dessicator flooded with dry helium gas, efficient transfection was routine at any time of the year.

Particle preparation guidelines for the Helios device are similar to those described with the exception that polyvinyl pyrolidone (PVP) is added to the precipitation reaction to increase the ability of the particles to stick to the inside of the plastic tube for this entrained mode of particle acceleration (Fig. 2C). For this system, the use of too much PVP gives the same problem as humidity in which the particles will not release efficiently from the tube. Although BioRad holds that humidity does not affect their system, in Houston, Texas (which is probably even more humid than Duke), we observed variations in the release of particles from the Helios that may be due to humidity effects. Given this, we prepare and store particles for the Helios using dessicated 100% ethanol, dry the particles with dry N_2 gas, and store them in a dessicator.

D. Particle Acceleration

Once particles are attached to their macrocarrier or lined on the inside of their tube for entrainment, they are ready to be accelerated. Kinetic energy can be applied to the macrocarrier or the microparticles directly from a variety of sources, including gun powder (1), and high-pressure gases, including nitrogen (12), air (16), and helium (7), and by electrical discharge to vaporize a droplet of water explosively (8). Efficient acceleration of microparticles for most guns does not occur simply by ''blowing'' the particles into the target tissue, but appears to require the production of a supersonic shockwave by the explosive release of gases, whether the energy source is gunpowder, gas, or electrical [(7) and Figs. 2A and B]. Shockwave efficiency appears to increase with decreasing molecular weight of the gas. For this reason, helium is the current propellant of choice for most gene guns. Although hydrogen might be more efficient than helium, the risk of combustion and explosion by this gas precludes its use.

Creating a supersonic shockwave requires the explosive release of gas or vapor. Generating this much force with helium generally employs gas pressures of 1000 to 2000 psi to create sufficient explosive energy to produce shockwaves. Release of this much gas is comparable to the force generated by a high-powered rifle and, if unrestrained, this gas blast will deafen anyone the room. This amount of gas will also destroy any cells in the path of the blast. Given this, much of the early development of gene guns involved a balancing act of generating sufficient force to produce a shockwave, while engineering a robust mechanism to protect the target from the gas blast used to produce the shockwave. One part of the solution to this problem was to generate the gas blast in a vacuum (Figs. 2A and B). Shooting in a vacuum not only improved shockwave production, but also absorbed some of the gas blast after gene gun firing. In addition, removal of ambient air prior to firing also increased the final velocity of the particles because the gas molecules in air are sufficiently large to create drag on the flying particles. Accelerating the particles in a vacuum also necessitates that the target cells be under vacuum. Fortunately, mammalian cells can tolerate transient vacuum of 25 in. of mercury for long enough to allow transfection by gene guns like the PDS1000. Unfortunately, the same cannot be said for intact animals, who would likely explode if exposed to high vacuum. To protect animals from the required vacuum, the initial solution was to design an adaptor that could be placed in the vacuum chamber of the PDS1000 that would allow exposure of only a small area of skin or organ to the vacuum of the gun (14). The subsequent solution for the vacuum problem was the design of ''handheld'' gene guns (Fig. 3), in which the vacuum was internal to the gun and only a small area of tissue was exposed to vacuum via a small exit port (Fig. 2B). Intact tissues like the skin and liver are resilient to the application of vacuum levels of 30 to 20 in. of Hg, respectively, through the exit port of the gene gun (7). Even relatively fragile structures like the eye will tolerate vacuum levels of 5 in. Hg (17,18).

The second key feature that enabled the shockwave-generating gene guns was the use of kapton or mylar plastic disks as macrocarriers (7,8). These incredibly tough plastics are sufficiently durable to be struck by a supersonic shockwave and also hold up to the gas blast that creates the shockwave. The tough nature of these macrocarriers allowed the disks to perform several critical roles in the gene gun. Their primary function was to carry the microparticles as a ''flying disk'' macrocarrier that could be accelerated by the shockwave, fly to and impact with the stopping screen (Fig. 2A). When the macrocarrier impacts the stopping screen, the disk is stopped but the loosely held microparticles on the front of the disk do not stop and fly through the screen to impact the target cells below (Fig. 2A). The shockwave that is the driving force for particle acceleration travels at a speed greater than the speed of sound. The helium blast that produced the shockwave is chasing after the wave at the speed of sound. If this blast reaches the target cells or tissue, the target will be destroyed by the gas impact. To protect the target cells from this blast, the macrocarrier plays its final role upon impact with the stopping screen, where it seals the upper chamber with the helium away from the lower chamber containing the target cells. The helium blast chasing after the shockwave therefore bounces off the macrocarrier on the stopping screen and the excess pressure is absorbed by the vacuum pump (Fig. 2A). Thus, the flying disc macrocarrier not only carries the particles, but also shields the target from the gas blast that is the driving force of the gun.

Particle acceleration by entrainment differs substantially from shockwave-mediated gene guns. For entrainment, the

microparticles are literally ''blown'' out of a tube by high-pressure helium without any supersonic shockwave production in a manner analogous to blowing powder out of a straw (Fig. 2C). This entrainment approach originally described by Sanford did not become practical until gas valves could be used in the gene guns that could open and close rapidly enough to create a sharp gas accelerant burst. The entrainment approach to particle acceleration was first demonstrated by the group from Agracetus and later applied commercially in the Helios gene gun. Because a supersonic shockwave is not required for entrainment, much lower helium pressures (i.e., 200–400 psi) can be used for these types of gene guns. This approach also allows particle acceleration to occur in the absence of a vacuum. Although the gas pressure is lower, it is still sufficient to shred target tissues if not deflected. To deflect the helium, these guns typically use deflectors or a ''horn'' that dissipates the gas to the sides of the shot site using Bernouli's law (Fig. 2C). These guns are therefore easier to use than shockwave gene guns because entrained guns do not require vacuum or very high pressures of gas. They are, however, more prone to aerosolizing DNA or target materials into the environment because the helium surge is blown to the sides of the gun. One should be aware of the potential for aerosols with this type of gun, particularly when shooting potentially biohazardous materials on the particles or when addressing a biohazardous target (e.g., an infected cell culture, animal, or person). It is advisable to perform the shooting with this type of gun (or any gun) in a biosafety cabinet designed for personnel protection to avoid distribution of random agents into the air. The shockwave gene guns largely avoid aerosolization problems by applying shots under vacuum, but are more cumbersome to use than the Helios gene gun. Regardless of which gene gun is used, one should always consider the production of aerosols, how potential contaminants are released from the gun in the laboratory, and effective methods to decontaminate the gun after use.

E. Particle–Cell Interactions

Gene guns use kinetic energy to deliver nucleic acids, proteins, and chemicals directly into cells. As such, gene guns have the capacity to modify cells that are generally refractory to vectored gene delivery. For example, differentiated skeletal myotubes have historically been difficult to transfect with nonviral or viral vectors (19) due in part to lower receptor-mediated uptake by myotubes, as well as mismatch between the receptors of the cell and the ligands of the vectors (20). Although we could not transfect differentiated myotubes with liposomes or other vectors, these cells could be transfected by the gene gun (Fig. 5). Similarly, more complex targets such as whole mouse embryos can be transfected by the gene gun ex vivo with little damage to the organism (Fig. 6). Therefore, refractory cells can be addressed by the gun using kinetic energy to deliver the DNA directly into the cytoplasm of the cell, thereby avoiding the need to cooperatively bind a cell receptor, enter an endosome, and escape into the cytoplasm (Fig. 1).

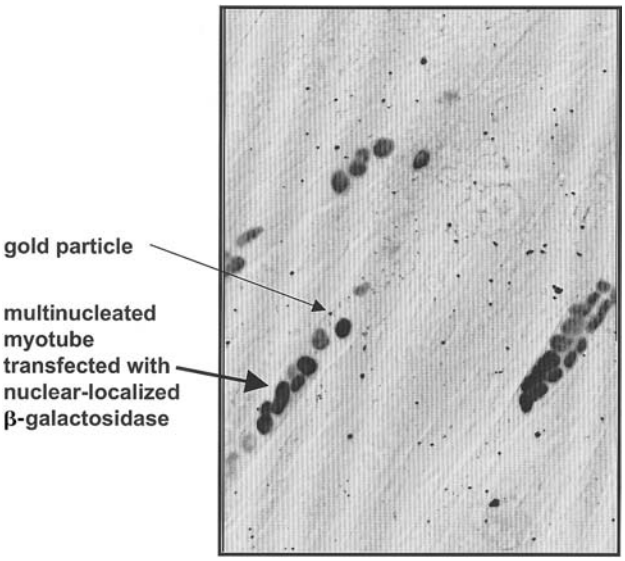

Figure 5 Gene gun-mediated transfection of terminally differentiated skeletal myotubes. Cells were cultured and differentiated and transfected with 1 to 3 μm gold particles coated with nuclear-localized β-galactosidase gene. One day later, the cells were fixed and stained with X-gal. The large dark circles are the β-galactosidase-positive nuclei of the multinucleated myotubes.

When tissues or cells in culture are examined to determine the location of the particles in the cells, they are in most cases found in the cytoplasm of the transfected cell, not in the nucleus (Fig. 5 and data not shown). Experiments using fluorescently labeled DNA have demonstrated that immediately after impact in the cytoplasm, DNA on the particles comes back

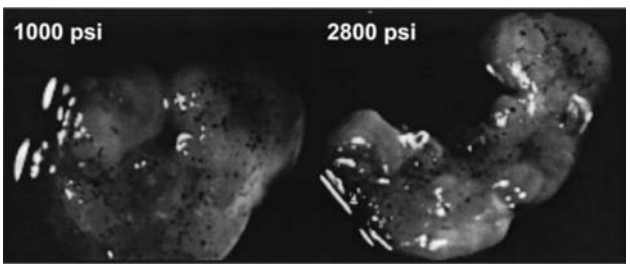

Figure 6 Gene gun-mediated transfection of living mouse embryos. Day 9.5 embryos were transfected in vitro with 1 to 3 μm gold particles coated with nuclear-localized β-galactosidase gene. One day later, the embryos were fixed and stained with X-gal. The dark dots under this low magnification are the β-galactosidase-positive cells.

into solution and rapidly ''streams'' into the nucleus of the cells (Stephen Johnston, personal communication). This observation has several implications. First, DNA is not delivered by direct particle delivery into the nucleus. Instead, the DNA is initially delivered into the cytoplasm where it engages endogenous host cell nuclear uptake machinery for translocation into the nucleus (Fig. 1B). This active uptake into the nucleus after gene gun delivery is quite different than that observed after microinjection of DNA into the cytoplasm were little uptake is observed (21–23). This difference could occur by a number of mechanisms. The first difference is related to how much DNA is introduced and how biologically relevant that amount of DNA is. For example, cytoplasmic microinjection delivers approximately 10 to 1000 femtograms of DNA in picoliter volumes (21–23). This amount of cytoplasmic DNA equals approximately 15,000 to 1,500,000 plasmids per cell. Given that each cell only has approximately 30 femtograms of cellular DNA, it is not surprising that the nuclear uptake machinery of the cell might be overwhelmed and disabled by the delivery of whole genome amounts (or more) of injected DNA. In contrast, the gene gun typically delivers 1 particle per cell where each particle carries approximately 100 copies of plasmid (0.006 femtograms of DNA). Therefore, under this condition of delivering a low number of plasmids to the cell in amounts that normally occur during transfection, DNA uptake by the nucleus is observed, whereas when massive amounts of DNA are delivered to the cytoplasm, the system is overwhelmed and nuclear uptake of DNA is inefficient. An alternate mechanism may involve a secondary effect of using kinetic energy to deliver particles and DNA to cells. In this mechanism, the velocity of the microparticles not only punches the particle through the plasma membrane, but also the impact of the particle with the cell may shatter this complex network of the cytoskeleton (Fig. 1B). This could disrupt the ''size exclusion'' or ''sieving'' effect of the cytoskeletal network that is speculated to impede movement of DNA through the cell (Fig. 1A). If this occurs, then the delivered DNA might be more easily translocated to the nuclear pore and into the nucleus than if DNA is simply injected into the cytoplasm. Another mechanism to explain more efficient nuclear uptake after gene gun delivery involves the use of the polyamines like spermidine to protect DNA when it is loaded onto the microparticles. In this case, the polyamine that is normally found in the nucleus bound to DNA may itself act as a nuclear localization signal to increase localization of the DNA to the nuclear pore and/or to increase uptake into the nucleus through the pore. For the gene gun, nuclear uptake does not appear to require nuclear membrane breakdown during mitosis (21) because one can effectively transfect a number of postmitotic cells, including the epidermis of the skin (14) and terminally differentiated myotubes (Fig. 5). These mechanisms (and others) may act alone or in concert to produce differences in the efficiency of DNA uptake into the nucleus by various gene delivery methods. Robust head-to-head comparisons using biologically relevant amounts of DNA are needed to extract the true biology at work.

F. Efficiency of Gene Gun Delivery

Although gene guns can address cells that are refractory to cooperative vectored gene delivery, the gene gun is limited in the total number of cells that are typically transfected in each shot. In most cases, the total number of cells addressed by this technology is typically 5% to 10% of cells within 10 to 20 cell layers of a target site (14). This limited capacity to transfect many cells at a time limits the gene therapy applications for which this technology will be effective. For example, the gene gun is clearly unsuited to gene therapy that requires that most if not all cells be modified (e.g., in Duchenne muscular dystrophy) because only a small fraction of target cells can be addressed. Likewise, the gene gun is unsuitable for therapeutic applications to tissues that are difficult to expose, such as the inner structures of the brain or the lumen of the lung. In contrast, the gene gun is suitable for addressing targets in culture, targets that are at the surface of the body [e.g., the skin (13,14), the eye (17,18)], or internal organs/tissues that can be exposed surgically [e.g., the liver (13,14), the muscle (13,24), the spleen (25)].

IV. APPLICATIONS OF GENE GUNS IN THE IMMUNE SYSTEM

Gene gun technologies are most potent when applied to easily exposed targets and when expressing gene products that have high-specific activity or whose biological effects engage systems that amplify the protein's effects. The most potent amplification system in the body is the immune system because this has evolved to detect a small number of infectious agents and amplify a response that may involve millions of cells and billions of effector molecules. Given this, some of the most potent application areas of the gene gun stimulate the immune system by delivering either antigens, cytokines, or both to the host organism. Current applications of the gene gun for immunological applications fall into the following categories:

1. Genetic immunization to provoke cellular and humoral immune responses by delivering antigen genes from pathogens or cancers to the immune system
2. Genetic immunization to divert problematic allergic or autoimmune responses by delivering antigens from the allergen or autoreactive immune cell or by delivery of cytokine genes to skew the T helper-type response
3. Cancer gene therapy to amplify weak responses to self- or mutant antigens present in tumors by delivering genes encoding immunostimulatory or immune presentation proteins

A. Genetic Immunization to Increase Immune Responses

The gene gun and naked DNA injection approaches for in vivo transfection with plasmids in mammals were developed

essentially in parallel in the 1980s. With the advent of these approaches, it became theoretically possible to use them to deliver antigen genes into the cells of a host to provoke immune responses. Genetic immunization is performed by introducing the gene(s) for protein antigens into the host animal rather than introducing the antigen itself. Once the plasmid is delivered into the host cell, the gene is expressed and produces the antigen intracellularly. The process therefore essentially uses the host animal itself as a bioreactor to generate its own vaccine antigens to drive both antibody and cellular immune responses.

1. History

The first published demonstration of this novel approach to immunization was by Stephen Johnston's group (26). In this first paper published in 1992, the ''wand'' gene gun (Fig. 3B) was used to deliver plasmids encoding human growth hormone and human α1-antitrypsin into the skin of mice. This in situ gene delivery allowed the host cells to produce these secreted proteins such that they were recognized by the immune system and provoked potent antibody responses against these foreign antigens. The authors coined the term ''genetic immunization'' to describe this process of using genes to immunize a host. Subsequent publications have called the technology ''DNA-based immunization,'' ''DNA vaccines,'' and ''polynucleotide vaccines.'' Recent terminology seems to have settled toward calling the process ''genetic immunization'' and the application a ''genetic vaccine,'' a ''DNA vaccine,'' or a ''gene-based vaccine.''

This first publication by Johnston's group was interestingly delayed by over a year and half by a number of short-sighted and erroneous reviews that produced comments such as ''*···this is cute at best···*'' and ''*···this will induce tolerance···*''. Even later reviews were skeptical about the utility of this technology with titles such as: ''*Genetic immunization—the biological equivalent of cold fusion*?'' (27). These reviewer comments were obviously off the mark in predicting the impact of the approach because Johnston's paper has been referenced more than 600 times since 1992, and there are now more than 350 publications in the PubMed database using the approach.

2. Antibody Production

Genetic immunization can elicit antibody responses against encoded antigens to make polyclonal and monoclonal antibodies in the laboratory (26,28). This application is particularly useful for raising antibodies against proteins that cannot be purified directly or that cannot be readily expressed in *Escherichia coli*, provided the gene for the protein is available. Antibody production is a practical nonvaccine application of the technology that is particularly useful in this genomic era of biology, when an investigator is more likely to possess the gene that encodes a protein before they will actually have the protein itself. As such, genetic immunization is a simple approach that allows the gene to be used to make antibody tools to analyze proteins and bridge the gap between genomics and proteomics. Given this, a number of companies now make their antibodies only by genetic immunization and a few offer this service commercially to investigators.

3. Vaccine Applications

Johnston's paper demonstrated that genetic immunization could be used to produce antibodies with a gene gun (26). Wolff's observation that muscle injection of naked DNA could transfect host cells (15) prompted several other investigators to explore whether plasmids could be used for vaccination against infectious agents, including influenza and human immunodeficiency virus 1 (HIV-1) (29–31). This approach was theoretically attractive for vaccine applications because these technologies allowed proteins to be produced intracellularly in living animals, such that they could be presented by major histocompatibility complex (MHC) class I molecules to stimulate T cell responses. Therefore, a cell would look infected to the immune response without actually having to be infected with a biohazardous agent. The feasibility of generating cellular immune responses by genetic immunization was first published in 1993 by Margaret Liu's group at Merck, where they demonstrated the production of cytotoxic T lymphocyte (CTL) responses against the nucleoprotein of influenza virus (29). In this same publication and in one published the same year by Harriet Robinson's group, both demonstrated that genetic immunization could be used to vaccinate animals and protect them from infection (31).

These observations provided excellent proof of principle for the application of genetic immunization for vaccine approaches driving both humoral and cellular immune responses. Prior to this, combined antibody and cellular responses could only generally be achieved using attenuated forms of the pathogen itself or by use of infectious viral vaccines that carry considerable biosafety baggage. In contrast, genetic immunization generated qualitatively similar immune responses as these whole pathogen or whole virus vaccines, but in the form of a single plasmid without any vector antigens. This meant that a genetic vaccine could provoke immune responses against its encoded genes without generating immune responses against itself, so multiple immunizations with the same vector were feasible. Likewise, since a genetic vaccine typically carries only 1 or a few genes from a pathogen, this type of vaccine could not cause the infection it is intended to prevent (32). This contrasts with potent whole pathogen vaccines such as that for poliovirus that can infrequently escape attenuation and actually cause the disease they should repel (33).

These benefits and others (Fig. 7) have led to the application of genetic vaccines against a growing list of infectious agents and against cancer for prophylactic and therapeutic immunization. The gene gun has been applied for vaccination against HIV, simian immunodeficiency virus (SIV), and feline immuno deficiency virus (FIV) (34–53), hepatitis (54–58), schistosoma (59), rabies and pseudorabies (60,61), encephalitis viruses (62–67), foot and mouth disease virus (68), rubella virus (69), infectious hematopoietic virus (70), papilloma virus (71,72), herpesviruses (73), pseudomonas aeruginosa

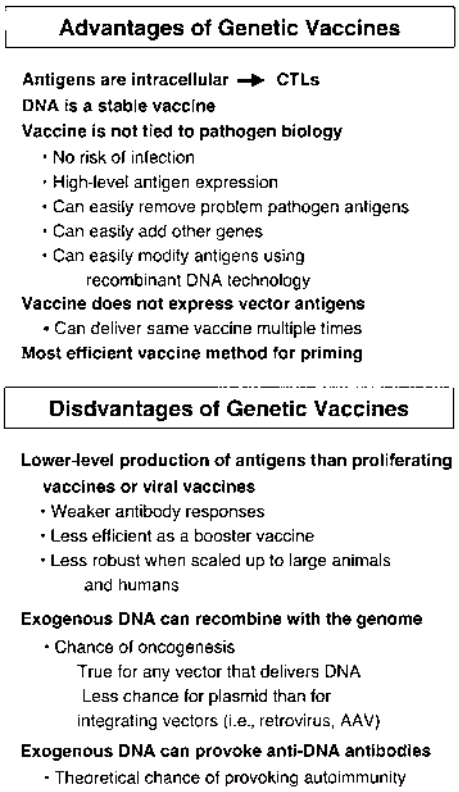

Figure 7 Advantages and disadvantages of genetic vaccines.

(74), chlamydia (75), and cancer (51,76–81). Beyond these demonstrations of genetic immunization for prophylactic vaccination, notable examples of gene gun applications of genetic vaccines are for biodefense [e.g., ebola virus (82), anthrax (83)], for emerging pathogens [e.g., ebola virus (82) and hanta virus (32)], and for unique vaccine applications [e.g., control of gingivitis (84)]. The gene gun has been applied for vaccination predominantly in mice, but also in rabbits (39,85), rats (86), chickens (31), cats (53), cattle (73,87), sheep (87), fish (70), nonhuman primates (35), and humans (58).

4. Genetic Immunization Allows Combinatorial Delivery of Antigen Genes for Multivalent Vaccines and Vaccine Discovery

In most applications against infectious agents, genetic immunization is performed to deliver a specific antigen gene from the pathogen to provoke protective cellular or humoral responses. Early genetic vaccines generally delivered single antigen genes to the host for immunization (29,30). Subsequent applications have included multiple genes to provoke multivalent immune responses (88). Another approach is to deliver whole genomes of pathogen genes by Expression Library Immunization (ELI) (50,89,90). The ELI approach can be applied to screen whole pathogen genomes to identify vaccine genes where none existed previously or can be used as an approach to delivery all or many antigens from a pathogen to provoke many immune responses simultaneously (50,89,90).

5. Reengineering Antigens

Unlike other vaccines, genetic vaccines are simple plasmids. Therefore, any recombinant technique can be applied to these vaccines to fundamentally manipulate how the vaccine is expressed and how it interacts with the immune system. Recombinant engineering of pathogen and nonpathogen plasmids has utility to increase antigen expression and boost the level of immune responses against these antigens. For example, antigens can be codon-optimized by rebuilding whole genes from oligonucleotides to replace poorly translated codons of pathogen genes with well-translated ones optimized for mammalian expression (91). Other approaches involve fusing poorly translated antigen genes to well-expressed mammalian proteins to increase translation *in cis*(92).

For pathogen vaccines, reengineering the antigen may be a necessity because many pathogens have evolved potent methods to hide not only themselves, but also their antigens from the immune system. As such, reengineering antigens in genetic vaccines provides an approach to break down immune evasion mechanisms that are built into the structure of pathogen proteins. Antigens can be reengineered to increase antibody responses by fusing them to secretory leaders or whole secreted proteins (89,93). $CD8^+$ CTL responses can be increased in genetic vaccines by fusing antigens to proteasome targeting proteins such as ubiquitin (89) or by fusing them to cytokine domains such as Flt-3 ligand (94). $CD4^+$ T helper responses can be increased by fusing antigens to lysosomal targeting proteins like LAMP-1 for intracellular targeting (95) and to proteins like the Fc domain of immunoglobulin for extracellular targeting to antigen-presenting cells (APCs) (96). Likewise, proteins can be delivered as a cocktail of plasmids, each expressing an overlapping fragment of the protein to break down secondary structures in the antigen that prevent processing by the proteasome and that hide subdominant epitopes (97). Fragmenting pathogen antigens also has the benefit of inactivating the function of proteins that may be frankly toxic or that inhibit immune presentation of pathogen antigens. By these methods, one can engineer vaccines that are markedly more potent than the pathogen or cancer itself.

6. Amplifying Genetic Vaccine Potency

Genetic vaccines have demonstrated robust protection against a wide variety of pathogens. In most cases, proof of principle has been demonstrated in mouse models where the amounts of DNA delivered could mediate high-level immune responses. Although many vaccines mediate protective levels of immune responses in large animals or humans, other genetic vaccines have failed this scale-up when translated into larger animals (36,37). This has been a particular problem for human immunodeficiency virus (HIV-1), simian immunodeficiency virus (SIV), and shiv chimeric (SHIV) vaccines aimed at testing in nonhuman primates, where initial genetic vaccines failed to mediate protection (36) or mediated only partial protection (37). These weaker responses in larger animals are likely due

to the fact that genetic vaccines generally produce nanogram to microgram amounts of antigen, levels that may be inadequate to effectively stimulate potent immune responses in a large mammal. A number of approaches are being tested to amplify genetic vaccine immune response for human applications, including (1) codon optimization, (2) coadministration of cytokine genes, and (3) use of heterologous vaccines to boost genetic vaccine priming.

7. Codon Optimization

Early work using genetic immunization with HIV-1 envelope plasmids generally raised weak antibody responses (98–100). This problem appears to be due in part to the poor codonbias of HIV genes that makes their expression in mammalian drastically reduced compared with other genes (91). The level of expression of envelope can be increased more that 100-fold by codonoptimization in which codons that are poorly represented by mammalian tRNAs can be replaced by codons from highly expressed mammalian genes. This increased expression by codonoptimization produces recombinant HIV genes that mediate substantially better immune responses after genetic immunization (101). Given this, most current genetic vaccine trials in primates or humans now use antigen genes that have been completely reengineered by codonoptimization strategies (102).

8. Coadministration of Cytokine Genes

In some cases, cytokine-expressing plasmids have been added to the plasmid mixture as genetic adjuvants to augment immune responses against pathogens (103–105). However, most genetic vaccine approaches against pathogens are directed at delivering antigen genes rather than cytokine genes. This contrasts with most gene gun applications for cancer, where it is more typical to deliver cytokines into tumors or tumor cells (106) because, in many cases, cancer antigens and their genes are unknown. Combining genetic vaccines with cytokine plasmids as genetic adjuvants is a robust method to increase immune responses (104,107,108). This approach has recently been quite effective at amplifying not only CTL responses, but also increasing control of pathogenic viruses in rhesus macaques (102). In this case, a relatively simple genetic vaccine expressing codon-optimized SIV gag and HIV env was used to immunize rhesus macaques by intramuscular (i.m.) injection. This work demonstrated control of viremia in the macaques only when IL-2-Ig plasmid (a more stable IL-2 protein) was inoculated with the genetic vaccines (102). This highlights the application of cytokine genetic adjuvant to rescue genetic vaccine responses and also highlights the need to provide robust T helper cell support for vaccines aimed at driving CD8 T cell responses.

9. Use of Heterologous Vaccines for Boosting

An alternate approach to amplify immune responses has been to boost genetic vaccines with heterologous vaccines such as recombinant protein vaccines or recombinant viruses (109,110). The improved responses observed with protein or viral vector boosting are likely related to the larger amounts of antigen that are delivered by these methods. Although these protein or viral vaccines are useful for boosting, in most cases, they are not as potent as genetic vaccines for immune priming, perhaps by the ability of DNA vaccines to directly transfect dendritic cells (111) or to cross-prime antigens to dendritic cells (112). Genetic vaccines are also useful for priming, because they do not encode vector-specific antigens. In contrast, viral vectors such as vaccinia or adenovirus generate immune responses against the intended vaccine antigen and also against proteins of the viral carrier. Therefore, when viral vectors are used, they generate immune responses against themselves that preclude their effective readminstration. In contrast, genetic vaccines express only the vaccine antigen. Thus, they impart no immunological memory against the vector itself and can be readministered multiple times or used to prime antigen-specific responses for later amplification by viral vectors with more robust antigen production. Given these observations, a number of protocols intended for humans involve DNA priming with a heterologous vaccine for boosting. One good example of this is a combined DNA and modified vaccinia ankara (MVA) poxvirus vaccine that is now being developed for a phase III clinical trial in Africa as a candidate acquired immune deficiency syndrome (AIDS) vaccine (113). Similarly, Merck is pursuing a DNA prime and adenoviral vector boost strategy to amplify responses (reviewed in (61)).

10. Genetic Immunization of Humans

Although the gene gun has been applied to many types of animals, only 1 pathogen-directed application has been reported in the literature in humans. In this trial, Powderject Vaccines is testing a hepatitis B virus genetic vaccine using the gene gun to immunize healthy volunteers (58). Three groups of 4 people were immunized epidermally by gene gun with 1, 2, or 4 μg of plasmid-encoding hepatitis B virus surface antigen. The immunization was well tolerated and provoked CD8 T cell responses as well as protective levels of antibodies in all volunteers. The amount of DNA used in this gene gun trial contrasts with other trials using naked DNA injection that use 0.1 to 1.8 milligrams of DNA (114–119).

It should be noted that China is well ahead of the United States in transferring genetic vaccines into humans as demonstrated by the fact that, since 1997, the primary clinical vaccine against hepatitis B in China is a genetic vaccine (120). Although not a gene gun approach, this large scale application of genetic vaccines in China is a fundamental milestone in this vaccine technology.

11. Gene Guns Versus Naked DNA Injection for Genetic Vaccines

Investigators in genetic immunization tend to fall into two camps: those that use gene guns and those that use naked DNA injection. Prior to commercialization of the Helios, most investigators could not obtain a gene gun unless they built one themselves or entered into a research collaboration with companies making guns. Even now when one can buy a gene gun commercially, the cost of the instrument runs in excess of $15,000 for academics, making it prohibitive to many investigators. Given these parameters, the vast majority of ge-

netic vaccine research has been performed using a syringe and needle to inject large amounts of plasmids as naked DNA in saline. Based on Wolff's results (15), most work has involved naked DNA injection into skeletal muscle. Raz's group subsequently demonstrated that intradermal injection could also be used for genetic immunization (121). At least in mice, the site of intradermal injection has marked effects on the efficiency of transfection, where injection into the rigid structure of the tail can generate 10- to 100-fold higher transfection than i.m. injection or injection at other dermal sites (2). This may be due to the ability to produce higher pressures upon injection into the tough tail versus generating lower pressures in other sites that can expand upon injection. Indeed, the fact that injections in small animals work substantially better than in large primates may be due to the fact that injections into mouse muscle deliver 25 to 50 μL of volume into a tissue that may itself only normally be 50 to 500 μL in volume. In contrast, injections into primates and humans are never delivered with same relative volumes as in mice. Given that high-pressure injection into a number of tissues including muscle increases transfection efficiency (122,123), it is likely that the poor scale-up of naked DNA injection large animals and humans is in part due to the use of too small of volumes into the muscle and dermis.

In many applications, the gene gun and naked DNA injection yield comparable immune responses when both are applied under optimal conditions. However, the fundamental mechanisms by which cells are transfected by the 2 approaches are quite different and can yield qualitatively different immune responses.

12. Gene Guns Transfect Dendritic Cells and Non-APCs, Naked DNA Injection Transfects Non-APCs

The gene gun is typically applied for genetic immunzation by directly transfecting epidermal cells of the skin. As such, the gene gun can not only transfect nonantigen-presenting keratinocytes, but the gun also transfects Langerhans dendritic cells directly in vivo (111). In contrast, naked DNA injection predominantly transfects non-APCs when applied in the skeletal muscle. Therefore, in i.m. injection, the vast majority of antigen presentation to T cells occurs by transfer of antigens from the transfected muscle cells to host APCs for cross-presentation (124). In contrast, the gene gun may drive immune presentation either by cross-presentation or by direct transfection of dendritic cells, allowing these transfected APCs to express and present antigens themselves. Although some work delivering antigen plasmids under the control of tissue-specific promoters has suggested that gene gun-mediated immune responses occur only by cross-presentation (125), the promoters used were somewhat mismatched for the biology of epidermal cells and were not directly validated by in vivo reporter activity. Other work has compared the efficiency of gene gun modified Langerhans cells that were transfected either directly in vivo or in vitro and then reintroduced into the animals (126). In this case, the investigators found that transfection of as few as 500 dendritic cells in vitro in the absence of non-APC transfection-generated immune responses comparable to that by direct gene gun delivery. Although direct transfection of dendritic cells in vivo by the gene gun appears promising, it is conceivable that this transfection may actually render the cells less efficient at presentation, or they may only inefficiently present their antigens expressed in an autocrine fashion. Further work is required to determine which transfected cells is driving immune responses after gene gun transfection.

13. Gene Gun Delivery Is More Efficient and Consistent Than Naked DNA Injection

The gene gun is inherently more consistent shot to shot than i.m. injection (108). Increasing the amount of DNA in an i.m. injection increases the ''hit'' rate, but does not obviate animals that fail to respond (Fig. 8). To reduce the likelihood that an animal will be ''missed'' by i.m. injection in a given immunization round, it is advisable to inject each animal in four separate sites. To achieve the same level of antigen production, one typically needs to deliver 50 to 100 times as much plasmid by naked DNA injection than by gene gun (31,108). Typical delivery amounts for the gene gun are 1 to 2.5 μg per shot. For i.m. naked DNA injection, they are typically 50 to 100 μg per shot in a mouse. This difference in efficiency is likely related to the ability of the gun to deliver plasmids directly into the cytoplasm of cells, whereas syringe injection delivers DNA extracellularly where more than 99% of the injected DNA is rapidly degraded into nonexpressible DNA fragments by the action of extracellular nucleases (2).

14. T Helper Cell Bias for Gene Guns and Naked DNA Injection

Depending on the pathogen, protection can be mediated antibody responses, cellular responses, or a combination of both. For some infectious agents, antibodies are able to neutralize incoming pathogen. For other pathogens, $CD8^+$ T cell responses are advantageous because these can kill or inactivate infected or neoplastic cells. Fortunately for viral and cancer vaccines, the plasmid DNA used for genetic vaccines is inherently biased toward generating $CD8^+$ T cell by virtue of the fact that it is quite potent at biasing T helper responses toward a T_{H1} phenotype. This bias occurs because the bacterial plasmid DNA bears unmethylated CpG motifs that stimulate IFN-γ and IL-12 production from natural killer (NK) cells and macrophages (127). This production of cytokines biases immune responses toward the T_{H1} phenotype against any antigen present after injection, whether it is encoded by the DNA itself or delivered as a protein (128).

Because naked DNA injection delivers 50 to 100 times as much DNA as the gene gun, i.m. and intradermal (i.d.) injection has a stronger T_{H1} bias than the gene gun [(24) and Fig. 8]. Both methods of gene delivery are able to drive T_{H1} responses at the early phases of responses as evidenced by interferon (IFN)-γ production by T helper cells, but the gene gun appears to have increased T_{H2} character (at least for some antigens) later in the T helper responses, as evidenced by increases in interleukin (IL)-4 production after IFN-γ re-

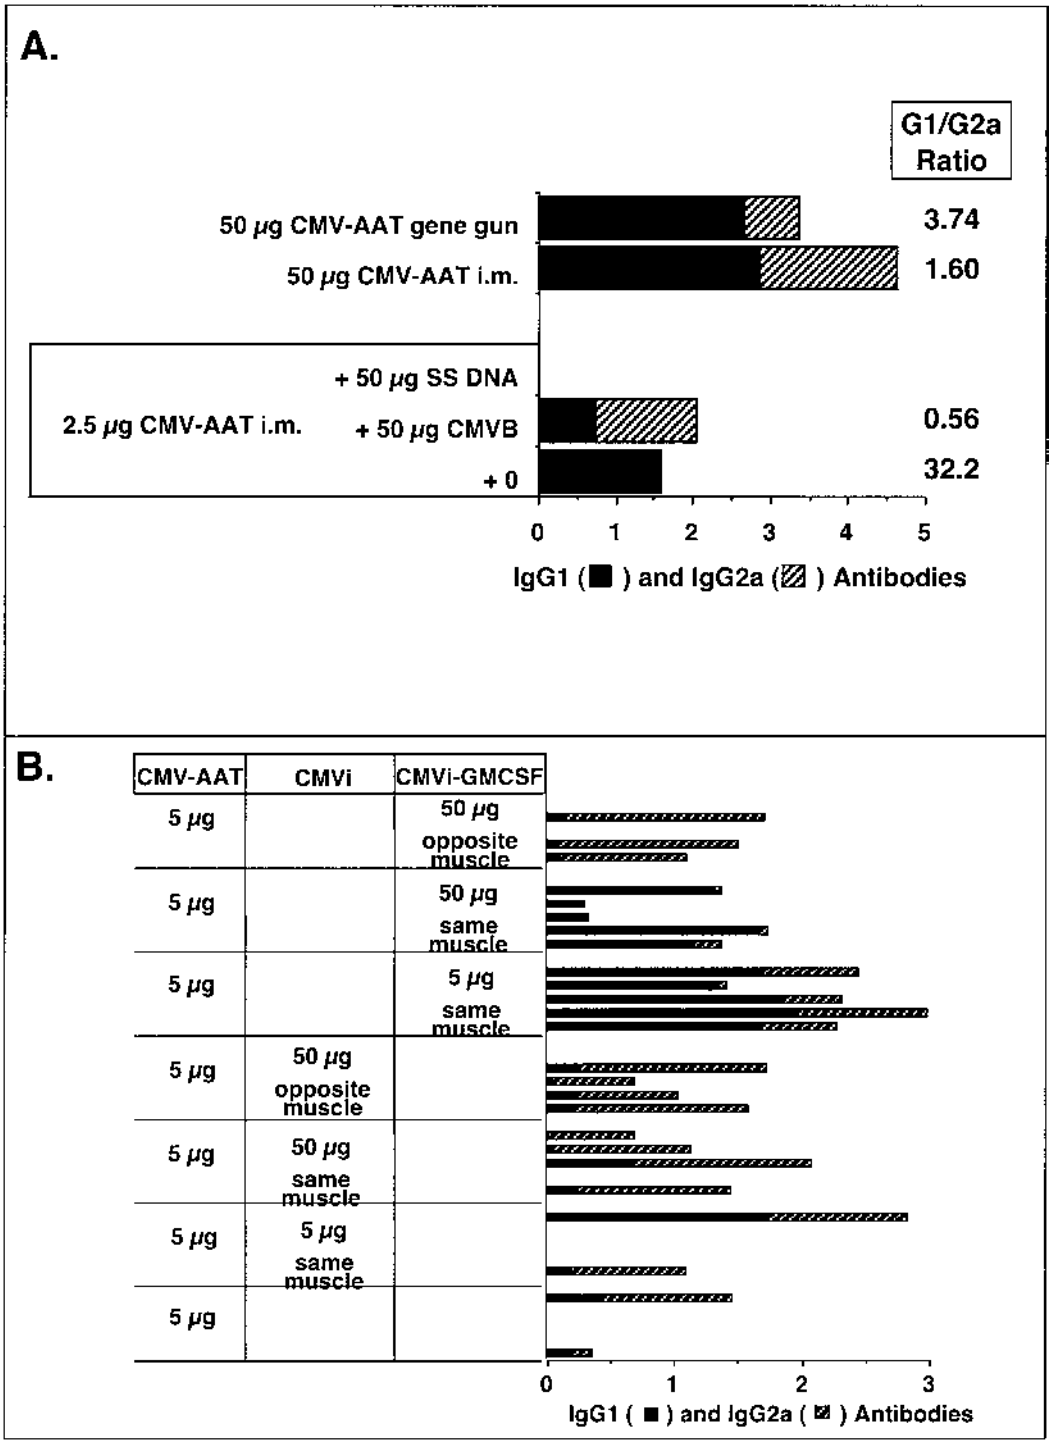

Figure 8 T_{H1} skewing by excess plasmid DNA after gene gun and i.m. injection. BALB/c mice were immunized a single time as indicated, and their antibody responses were evaluated by isotype-specific ELISA against α1-antitrypsin (AAT). (A) Comparison of the effects of large amounts of antigen-coding plasmid (CMV-AAT), noncoding plasmid (CMVB), and eukaryotic DNA (SS DNA) on antibody levels and isotype. (B) Comparison of the effects of noncoding excess DNA and GM-CSF expressing plasmid on antibody boosting and isotype when delivered into the same site as the antigen plasmid or the contralateral muscle.

sponses wane (129). Because of this, the gene gun fairs worse in controlling some pathogens that are highly dependent on potent $CD8^+$ T cell responses for protection (130). Conversely, the T_{H2} bias is the likely explanation for why the gene gun is generally more robust at generating antibody responses than i.m. injection in mice (131) and in primates (132). Therefore, the gun has better utility for protection requiring neutralizing antibodies [e.g., hepatitis B (58)]

Although many investigators call i.m. injection ''T_{H1}'' and the gene gun ''T_{H2}'', this is inaccurate. It is more accurate to say that both can produce mixed T_{H1}/T_{H2} responses and that i.m. injection skews responses toward T_{H1}, whereas the gene gun skews responses toward T_{H2}. The T_{H2} bias of the gun is not absolute because the gene gun can provoke quite potent T_{H1}-driven CD8+ T cell responses with nanogram amounts of plasmid (131) and even after single immunization (50). Further, the T_{H2} bias of the gene gun can be converted to more of a T_{H1} responses by coimmunization with cytokines like IFN-α or IL-12 (133).

Each antigen has its own T_{H1} or T_{H2} bias and the different delivery methods retain the inherent bias or skew it in one direction or the other. For example, protein immunization with human α1-antitrypsin (AAT) in mice produces IgG_1 antibodies. If a 2.5 μg of a plasmid-encoding AAT is delivered by either gene gun or i.m. injection, antibody responses are still predominantly IgG_1 (Fig. 8 and data not shown). T_{H1} skewing (as evidenced by increased IgG_{2a} antibodies) only occurs when more bacterial DNA is added in the i.m. injection (either more AAT plasmid or a nonexpressing plasmid) (Fig. 8A). A similar mixed response involving combined IgG_1/IgG_{2a} antibodies is observed if 1 gene guns 50 μg of DNA. If 2.5 μg AAT plasmid plus 47.5 μg more AAT plasmid is introduced by i.m. injection, the response is still predominantly IgG_1. In contrast, if one adds 2.5 μg AAT plasmid plus 47.5 μg of a nonexpressing plasmid (supplies cytosine-guanosine dinucleotides (CpGs), but not more antigen), then stronger skewing toward IgG_{2a} responses is observed after i.m. injection (Fig. 8). Therefore, for AAT, the default antibody response is IgG_1. Adding more CpGs by gun or i.m. injection skews this toward a T_{H1} response as evidenced by increased (but not only) IgG_{2a} antibodies.

The CpG effects by plasmid DNA appears to be a systemic one given that increased responses can be observed, whether the large amounts of plasmid is injected into the same site as the antigen-expression plasmid or into a contralateral muscle (Fig. 8B). Increased levels of response as well as increased numbers of animals that respond are observed, whether large amounts of plasmid DNA is injected in the same site or an alternate site to where the antigen plasmid is injected. This site effect is quite different than that observed when using cytokine genes as genetic adjuvants. For example, low-level antibody responses after i.m. injection of suboptimal amounts of α1-antitrypsin (AAT) plasmid can be amplified if a granulocyte-macrophage colony stimulating factor (GM-CSF) plasmid is coinjected in the same site, but not if the cytokine plasmid is injected in another muscle (Fig. 8B). Note also, that unlike the CpG effect, the GM-CSF antibody boost retains the normal T_H-bias of AAT by producing predominantly IgG_1 antibodies. Interestingly, if GM-CSF plasmid is delivered into a nonmuscle site (e.g., the skin), this can actually antagonize the immune response (unpublished observations), suggesting the cytokine may attract APCs away from the site of antigen production to the wrong location.

In summary, the gene gun tends to bias responses toward a T_{H2} phenotype. Naked DNA injection biases responses toward the T_{H1} phenotype due to delivery of large amounts of unmethylated CpG motifs. Both approaches have the capacity to drive mixed T_{H1} and T_{H2} responses, and both can be skewed toward one response or the other by delivery of cytokine plasmids. The T_H bias of the antigen is a primary factor in the character of responses. One should be aware that differences in responses are usually highly antigen and model specific, so the approaches with generally need to be compared for each investigator's own system.

B. Genetic Immunization to Reduce or Skew Immune Responses

Allergy and autoimmune diseases represent immunological diseases in which aberrant immune responses occur against exogenous allergens or against self-antigens, respectively. Genetic immunization has been applied in these situations to inactivate or skew the existing immune response to one that does not support cause the disease. Genetic immunization prevents allergic responses when the allergen antigen gene is delivered with CpG-rich DNA to skew the T_{H2}-driven allergic response to a nonproblematic T_{H1} response. This approach has been applied successfully to prevent allergic responses against peanut (134), pollen (135), and milk antigens (136). For diseases like autoimmune diabetes, there are autoimmune T cell responses against antigens associated with pancreatic β cells. In NOD mice, the diabetes is mediated by responses against glutamic acid decarboxylase. Genetic immunization with a plasmid-encoding glutamic acid decarboxylase was able to prevent spontaneous diabetes in the NOD mice, demonstrating that the skewed responses could disrupt disease progression (137). An alternate approach is to generate immune responses against the antigen receptors of T cells that target self-antigens. Proof of principle for this approach was demonstrated for autoimmune encephalitis by expressing the genes encoding T cell receptor specific to the self-antigen myelin basic protein (138). This report was notable because the vaccine approach not only ablated the autoimmune disease prophylactically, but was also able to attenuate established autoimmunity. These reports on both allergy and autoimmune applications hold great promise for the application of genetic immunization for not only inducing new immune responses, but also ablating problematic immune responses.

C. Gene Gun Applications for Cancer

The use of gene guns and genetic immunization for cancer is usually quite different than for vaccination against pathogens. First, for most pathogens, candidate vaccine antigens are already known and can be applied in the genetic vaccine. For

those pathogens that lack candidate genes, ELI can be applied to screen the whole genome to find these candidates (89). In contrast, the proteins that could act as protective antigens against cancer cells are (1) usually unknown, (2) are usually specific to 1 type of cancer, and (3) may in some cases be specific to the individual patient. For those few cancers associated with or caused by infectious agents, one can vaccinate with genes from the pathogen that are associated with the tumor cell. Good examples of this are the use of the gene gun to vaccinate against papillomavirus antigens (139,140). Whole genome searches for antigens by ELI and other techniques is a staggering task for cancer as compared with viral or bacterial pathogens because the mammalian genome is 1000- to 10,000-fold larger than the genomes of most pathogens. To combat this size issue, most investigators use cDNA libraries, rather than unbiased genome libraries, to reduce the complexity of their search. Although feasible, screening cDNA libraries for cancer antigens introduces a potent bias in the antigens that are searched because representation in the library is directly proportional to the expression level of the message in the cancer cells. Despite these considerable difficulties, investigators have identified several promising cancer antigens. Given this, the gene gun has been applied to deliver melanoma antigens gp100 (80) and tyrosinase-related protein 2 (81), preprocalcitonin has been applied for medullary thyroid carcinoma (77), and alpha-fetoprotein has been applied for genetic vaccination against hepatocellular carcinoma (76).

The vast majority of gene gun applications for cancer are directed at generating cancer vaccines. In this application, the gun is used to transfect cancer cells either in vitro or in vivo, with plasmids encoding immunostimulatory proteins to amplify weak anticancer responses. By this approach, the cancer cell provides the antigens and the gene gun provides gene products to increase immune reactions against these antigens. One of the earliest approaches using gene guns for this application was by Kam Hui's group in Singapore, where they engineered their own gene gun and used this to transfect cancer cells with the genes for allogeneic MHC I proteins (78,141). Other applications have delivered genes encoding HLA-A, HLA-DR, and B7 costimulatory molecules (51). In most applications, the gene gun has been used to deliver cytokine genes to explanted tumors or tumor cell lines ex vivo (51,142–144). The advantage of the gene gun in these applications is that it mediated gene delivery without biohazardous viruses and without the need for cancer cells to be cycling or cultured for long periods of time. Alternate applications have delivered cytokines to the skin immediately above subcutaneous tumors (145–150), taking advantage of the ease in addressing the epidermis with the gun. Cytokines, including IL-2, IL-12, pro-IL-18, IFN-α, GM-CSF, and tumor necrosis factor (TNF)-α, have been delivered either alone or in combination to modulate cellular immune responses against the cancer cells. In the case of IL-12, direct transfection of the skin above intradermal sarcomas in mice mediated comparable protection to treament with recombinant IL-12 protein (151). However, an advantage associated with the localized delivery and production of IL-12 by the gene gun is that this avoided many of the toxic side effects associated with systemic IL-12 therapy (151). Further, transfection with cytokine genes by gene gun is substantially less expensive than systemic delivery of recombinant cytokine proteins.

Although the vast majority of gene gun testing for cancer has occurred in mouse models, 3 trials have been performed or are underway in humans. In 1 trial, melanoma and sarcoma explants from patients are to be transfected by the gene gun with a plasmid-encoding human GM-CSF and the cells were injected intradermally back into the patients as an autologous cancer vaccine (79). In 2 other trials, IL-7 or IL-12 plasmids were delivered by gene gun into melanoma cells and injected subcutaneously back into patients (152,153). Patients immunized with autologous IL-7-modified cells demonstrated little toxicity, increased CTL levels against the tumor, and 2 of the 6 patient demonstrated minor clinical responses (152). In the IL-12 trial, mild fever was the only side effect of the therapy and increases were observed in cytotoxic T cells (153). One of the 6 patients had a minor clinical response that was associated with infiltration of CD4 and CD8 T cells into metastatic sites distant from the vaccination site. From these phase I trials, the gene gun holds some promise for human tumor applications, particularly when it is applied to deliver known tumor antigens or when it is used to deliver cytokine genes for local production to augment immune responses against unknown tumor antigens.

V. GENE GUN-MEDIATED GENE THERAPY IN OTHER SYSTEMS

A. Gene Gun Applications for Wounds and Burns

The gene gun is most useful in applications on exposed tissues. Given this, a number of investigators are testing gene guns for their ability to increase repair of wounds or burns as well as to reduce pain signaling at sites of tissue injury [reviewed in (154)]. Examples of repair applications include delivery of keratinocyte growth factor (155), platelet-derived growth factor (156), and epidermal growth factor receptor (157) to speed wound healing. Examples of approaches to limit pain are delivery of semaphorin A (18) and delivery of the gene for pro-opiomelanocortin (158).

B. Gene Gun Applications in the Eye

Given that the eye is exposed on the surface of the body, this tissue is a natural target for gene gun applications. The first demonstration of transfection by the gene gun was in the delivery of plasmids encoding the green fluorescent protein to corneal epithelial cells (17). In this work in rabbits, it was demonstrated that gene gun particle penetration could be readily titrated by changing the helium pressure driving particle acceleration and that little corneal damage was observed after particle bombardment. This work was followed by a true gene therapy approach where the gene for semaphorin A was delivered into the eye to modulate neuronal growth and architecture

(18). This was a good example of a gene therapy approach that avoids immunogenicity problems because (1) the transgene product is already present in the host, but is being increased locally; and (2) the gene gun delivers simple plasmids encoding only the therapeutic transgene protein and no vector-specific antigens. This contrasts with viral methods of gene delivery to the eye that can provoke strong immune responses even in this ''immunopriviledged'' site (159).

Subsequent approaches using the gene gun in the eye have delivered fluorescent tracer chemicals and the genes for fluorescent proteins to the eye to characterize morphology (120,160,161) and to characterize eye-specific regulatory elements in enhancer/promoters of genes (162). Another interesting gene therapy application of the gene gun in the eye was to deliver genes encoding immunosuppressive proteins like IL-4 and CTLA4 into the cornea after an allotypic corneal transplant (163). In this case, gene gun delivery was able to prolong allogeneic graft survival in mice. This interesting application, like that for semaphorin A, delivers an endogenous gene product by simple plasmid to avoid immune responses against the transgene proteins. This work also provides proof of principle for the use of the gene gun to genetically modify a variety of tissues to increase transplant survival.

One limitation of the gene gun is that transfection generally occurs within 10 to 20 cells of the surface that is bombarded. As such, the gene gun will likely have utility in applications to genetically modify the surface of the eye, including the corneal epithelium and the conjuctiva. In contrast, applications in the retina or other buried structures of the eye will likely be out of reach of this technology.

C. Neuronal Gene Gun Applications

Most gene gun applications in neuronal systems have been performed for basic research studies to characterize the biology of these cells. The gun provides the unique ability to deliver substances directly into not only neuronal cells in culture (164,165), but also into whole brain slices (120,166). The gene gun has been used to deliver not only DNA, but also fluorescent tracer molecules to track neuronal phenotype and survival (165). Direct gene gun delivery into the brain in vivo has been reported for transfection of the lamprey brain neurons and glia in the exposed floor of the fourth ventricle (167), and for direct transfection of the exposed brain in live mice (168). An alternate in vivo approach of gene guns has been to manipulate neuron behavior, but not to directly transfect the neurons themselves. In this case, the gene for semaphorin A was delivered into corneal epidermal cells of rabbits (18). In this model, local production of semaphorin A after gene gun transfection effectively repelled established and growing A-delta and C-fiber trigeminal sensory afferents. This application provided proof of principle for gene therapy applications to repel pain-sensing neurons from locals to attenuate chronic pain or prevent problematic pain responses in surgical fields.

D. Gene Gun Applications in Other Organs

Although the gene gun is most easily applied to exposed tissues such as the skin or the eye, the original demonstrations of gene gun transfections in animals showed that internal tissues could be surgically exposed to allow gene gun delivery (13,14). Therefore, any tissue that can be surgically exposed can also be transfected by the gene gun. Applications to date on internal organs include the liver (13,14), the muscle (13,24), the spleen (25), the bladder (169), and the heart (170,171). In many cases, the gene gun has been used to probe the biology of cells or genes in these organs. In particular, the gene gun has been used to deliver genes to analyze the specificity and level of gene expression by different enhancer/promoter constructs into the liver (172) and into cardiomyocytes (173). In other cases, preclinical approaches are being tested to deliver antigen genes directly into the liver to prevent the liver stage of malaria (174). Future applications of the gene gun in deep tissues may be focused not only on understanding the biology of genes and tissues, but also for direct gene therapy. One interesting future application in organs will be to test whether the gene gun can effectively protect transplanted tissue from immune rejection. The work in corneal transplantation protection in the eye (163) provides good proof of principle for the use of the gene gun to modify tissues after removal without the need for immunogenic viral vectors or the need for prolonged culture ex vivo.

VI. OTHER PRACTICAL APPLICATIONS OF GENE GUNS

Beyond true gene therapy applications, the gene gun has a number of practical uses in the laboratory for basic science research or to enable other therapeutics. First, the gene gun has utility as a simple method to deliver enhancer/promoter constructs into cells to analyze gene regulation. The gene gun can also deliver gene-encoding proteins that interact with other proteins to assess pathway function. The gene gun is unique in these applications in that it can easily transfect a number of tissues in living embryos (Fig. 6) or living animals [(162,175) and Fig. 4]. Further, because the gun delivers plasmids, investigators do not have to go through the laborious process of engineering a new viral vector for each new enhancer, new intron, new poly A signal, or each new gene to be tested (Fig. 9). Because approximately 100 plasmids are complexed on each particle, each transfected cell receives multiple copies of plasmid. Because of this, the gene gun is efficient cotransfection of cells (6,176). This allows more efficient control of multigene systems, such as drug-regulated expression systems, than mediated by other vectors when applied in vivo. Finally, when applied for genetic immunization, the gene gun is a potent method to generate polyclonal and monoclonal antibodies (28) for laboratory and clinical applications.

VII. SUMMARY

Gene guns are a unique method of gene delivery that employs kinetic energy to overcome transfection bottlenecks to deliver chemicals, proteins, mRNA, or genes directly into cells on

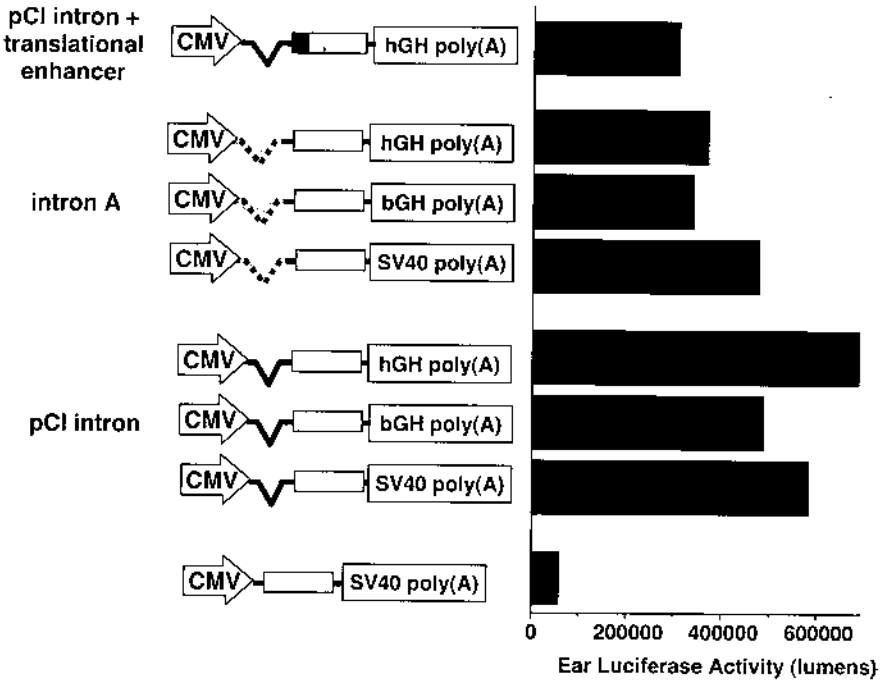

Figure 9 Rapid in vivo expression screening of different introns and poly adenylation sequences by gene gun delivery into the skin. Plasmids bearing the indicated sequences driving luciferase expression were delivered into the skin of the ears of BALB/c amice by gene gun. Expression comparison was performed the next day by luciferase assay on the shot skin.

microparticle ''bullets.'' Gene guns can transfect many tissues that are refractory to vectored gene delivery, and are also quite efficient at direct delivery of plasmids into living animals and humans. This approach allows simple plasmids to be delivered into the host that encode only the gene of interest. This avoids problematic immune responses against vector antigens that can prevent multiple administration. Although gene guns can modify both dividing and nondividing tissues in vitro and in vivo, they do not modify a massive number or percent of cells in a given transfection event. Therefore, gene guns are best applied to systems that amplify the effects of a small amount of transgene product. Gene guns therefore have great utility in the delivery of antigen or cytokine genes into the immune system to stimulate or block immune responses. Gene guns also have utility in surgical settings to repulse neurons to reduce pain and for the delivery of transgene proteins to enhance wound and burn repair.

Optimization of Nonviral Gene Therapeutics

Nancy Smyth Templeton
Baylor College of Medicine
Houston, Texas, U.S.A.

I. INTRODUCTION

Many investigators are focused on the production of effective nonviral gene therapeutics and on creating improved delivery systems that mix viral and nonviral vectors. Use of improved liposome formulations for delivery in vivo is valuable for gene therapy and would avoid several problems associated with viral delivery. Delivery of nucleic acids using liposomes is promising as a safe and nonimmunogenic approach to gene therapy. Furthermore, gene therapeutics composed of artificial reagents can be standardized and regulated as drugs rather than as biologics. Cationic lipids have been used for efficient delivery of nucleic acids to cells in tissue culture for several years (1,2). Much effort has also been directed toward developing cationic liposomes for efficient delivery of nucleic acids in animals and in humans (3–12). Most frequently, the formulations that are best to use for transfection of a broad range of cell types in culture are not optimal for achieving efficacy in small and large animal disease models.

Much effort has been devoted to the development of nonviral delivery vehicles due to the numerous disadvantages of viral vectors that have been used for gene therapy. Following viral delivery in vivo, (1) immune responses are generated to expressed viral proteins that subsequently kill the target cells required to produce the therapeutic gene product, (2) an innate humoral immune response can be produced to certain viral vectors due to previous exposure to the naturally occurring virus, (3) random integration of some viral vectors into the host chromosome could occur and cause activation of proto-oncogenes resulting in tumor formation, (4) clearance of viral vectors delivered systemically by complement activation can occur, (5) viral vectors can be inactivated upon readministration by the humoral immune response, and (6) potential for recombination of the viral vector with DNA sequences in the host chromosome that generates a replication-competent infectious virus also exists. Specific delivery of viral vectors to target cells can be difficult because 2 distinct steps in engineering viral envelopes or capsids must be achieved. First, the virus envelope or capsid must be changed to inactivate the natural tropism of the virus to enter specific cell types. Then sequences must be introduced that allow the new viral vector to bind and internalize through a different cell surface receptor. Other disadvantages of viral vectors include the inability to administer certain viral vectors more than once, the high costs for producing large amounts of high-titer viral stocks for use in the clinic, and the limited size of the nucleic acid that can be packaged and used for viral gene therapy. Attempts are being made to overcome the immune responses produced by viral vectors after administration in immune-competent animals and in humans, such as the use of gutted adenoviral vectors or encapsulation of viral vectors in liposomes (13). However, complete elimination of all immune responses to viral vectors may be impossible.

Use of liposomes for gene therapy provides several advantages. A major advantage is the lack of immunogenicity after in vivo administration, including systemic injections. Therefore, the nucleic acid–liposome complexes can be readministered without harm to the patient and without compromising the efficacy of the nonviral gene therapeutic. Improved formulations of nucleic acid–liposome complexes can also evade complement inactivation after in vivo administration. Nucleic acids of unlimited size can be delivered ranging from single nucleotides to large mammalian artificial chromosomes. Furthermore, different types of nucleic acids can be delivered, including plasmid DNA, RNA, oligonucleotides, DNA-RNA chimeras, synthetic ribozymes, antisense molecules, RNAi, viral nucleic acids, and others. Certain cationic formulations can also encapsulate and deliver viruses (13), proteins or par-

tial proteins with a low isoelectric point (pI), and mixtures of nucleic acids and proteins of any pI. Creation of nonviral vectors for targeted delivery to specific cell types, organs, or tissues is relatively simple. Targeted delivery involves elimination of nonspecific charge interactions with nontarget cells, as well as addition of ligands for binding and internalization through target cell surface receptors. Other advantages of nonviral vectors include the low cost and relative ease in producing nucleic acid–liposome complexes in large scale for use in the clinic. In addition, greater safety for patients is provided using nonviral delivery vehicles due to few or no viral sequences present in the nucleic acids used for delivery, thereby precluding generation of an infectious virus. The disadvantage of nonviral delivery systems had been the low levels of delivery and gene expression produced by ''first-generation'' complexes. However, recent advances have dramatically improved transfection efficiencies and efficacy of liposomal vectors (14–18). Reviews of other in vivo delivery systems and improvements using cationic liposomes have been published recently (19,20).

Cationic liposome–nucleic acid complexes can be administered via numerous delivery routes in vivo. Routes of delivery include direct injection (e.g., intratumoral), intravenous, intraperitoneal, intra-arterial, intrasplenic, mucosal (nasal, vaginal, rectal), intramuscular, subcutaneous, transdermal, intradermal, subretinal, intratracheal, intracranial, and others. Much interest has focused on noninvasive intravenous administration because many investigators believe that this route of delivery is the ''holy grail'' for the treatment or cure of cancer, cardiovascular, and other inherited or acquired diseases. Particularly for the treatment of metastatic cancer, therapeutics must reach not only the primary tumor but also the distant metastases.

Optimization of cationic liposomal complexes for in vivo applications and therapeutics is complex, involving many distinct components. These components include nucleic acid purification, plasmid design, formulation of the delivery vehicle, administration route and schedule, dosing, detection of gene expression, and others. Often I make the analogy of liposome optimization to a functional car. Of course, the engine of the car, analogous to the liposome delivery vehicle, is extremely important. However, if the car does not have wheels, adequate tires, etc., the motorist will not be able to drive the vehicle to its destination. This chapter focuses on optimization of these distinct components for use in a variety of in vivo applications. Optimizing all components of the delivery system will allow broad use of liposomal complexes to treat or cure human diseases or disorders.

II. OPTIMIZATION OF CATIONIC LIPOSOME FORMULATIONS FOR USE IN VIVO

Much research has been directed toward the synthesis of new cationic lipids. Some new formulations led to the discovery of more efficient transfection agents for cells in culture. However, their efficiency measured in vitro did not correlate with their ability to deliver DNA after administration in animals. Functional properties defined in vitro do not assess the stability of the complexes in plasma or their pharmacokinetics and biodistribution, all of which are essential for optimal activity in vivo. Colloidal properties of the complexes in addition to the physicochemical properties of their component lipids also determine these parameters. In particular, in addition to efficient transfection of target cells, nucleic acid–liposome complexes must be able to traverse tight barriers in vivo and penetrate throughout the target tissue to produce efficacy for the treatment of disease. These are not issues for achieving efficient transfection of cells in culture with the exception of polarized tissue culture cells. Therefore, we are not surprised that optimized liposomal delivery vehicles for use in vivo may be different than those used for efficient delivery to cells in culture.

In summary, in vivo nucleic acid–liposome complexes that produce efficacy in animal models of disease have extended half-life in the circulation, are stable in serum, have broad biodistribution, efficiently encapsulate various sizes of nucleic acids, are targetable to specific organs and cell types, penetrate across tight barriers in several organs, penetrate evenly throughout the target tissue, are optimized for nucleic acid : lipid ratio and colloidal suspension in vivo, can be size fractionated to produce a totally homogenous population of complexes prior to injection, and can be repeatedly administered. Recently, we demonstrated efficacy of a robust liposomal delivery system in small and large animal models for lung (15), breast (17), head and neck (Hung and Templeton, 2002), and pancreatic cancers (16), and for hepatitis B and C (Clawson and Templeton, 2000). Based on efficacy in these animal studies, this liposomal delivery system will be used in upcoming clinical trials to treat these cancers. Our studies demonstrated broad efficacy in the use of liposomes to treat disease and have dispelled several myths that exist concerning the use of liposomal systems.

III. LIPOSOME MORPHOLOGY AND EFFECTS ON GENE DELIVERY AND EXPRESSION

Efficient in vivo nucleic acid–liposome complexes have unique features, including their morphology, mechanisms for crossing the cell membrane and entry into the nucleus, ability to be targeted for delivery to specific cell surface receptors, and ability to penetrate across tight barriers and throughout target tissues. Liposomes have different morphologies based on their composition and the formulation method. Furthermore, the morphology of complexes can contribute to their ability to deliver nucleic acids in vivo. Formulations frequently used for the delivery of nucleic acids are lamellar structures, including small unilamellar vesicles (SUVs), multilamellar vesicles (MLVs), or bilamellar invaginated vesicles (BIVs), recently developed in our laboratory (Fig. 1). Several investigators developed liposomal delivery systems using hexagonal structures; however,

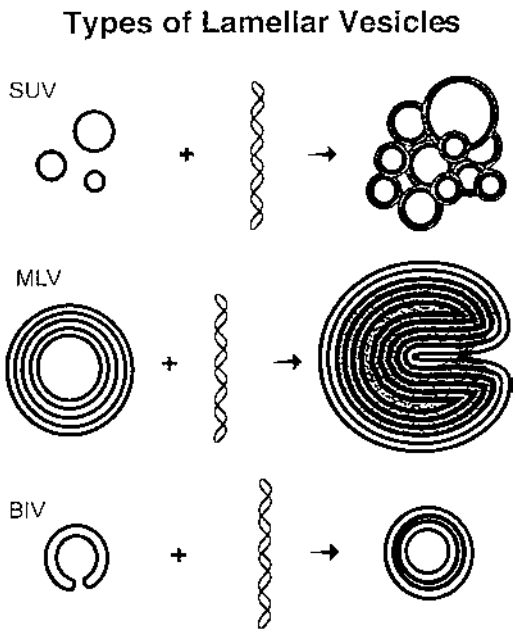

Figure 1 Diagrams drawn from cryoelectron micrographs of cross-sections through vitrified films of various types of liposomes and DNA–liposome complexes. SUVs condense nucleic acids on the surface and produce ''spaghetti and meatballs'' structures. MLVs appear as ''Swiss rolls'' after mixing with DNA. BIVs are produced using a formulation developed in our laboratory (14). Nucleic acids are efficiently encapsulated between 2 BIVs.

they demonstrated efficiency primarily for the transfection of some cell types in culture and not for in vivo delivery. SUVs condense nucleic acids on the surface and form ''spaghetti and meatballs'' structures (21). DNA–liposome complexes made using SUVs produce little or no gene expression upon systemic delivery, although these complexes transfect numerous cell types efficiently in vitro (1,2). Furthermore, SUV liposome–DNA complexes cannot be targeted efficiently. SUV liposome–DNA complexes also have a short half-life within the circulation, generally about 5 to 10 min. Polyethylene glycol (PEG) has been added to liposome formulations to extend their half-life (22–24); however, PEGylation created other problems that have not been resolved. PEG seems to hinder delivery of cationic liposomes into cells due to its sterically hindering ionic interactions, and it interferes with optimal condensation of nucleic acids onto the cationic delivery vehicle. Furthermore, extremely long half-life in the circulation (e.g., several days) has caused problems for patients because the bulk of the PEGylated liposomal formulation doxil that encapsulates the cytotoxic agent, doxorubicin, accumulates in the skin, hands, and feet. For example, patients contract mucositis and hand and foot syndrome (25,26) that cause extreme discomfort to the patient. Attempts to add ligands to doxil for delivery to specific cell surface receptors has not resulted in much cell-specific delivery, and the majority of the injected targeted formulation still accumulates in the skin, hands, and feet. Addition of PEG into formulations developed in our laboratory also caused steric hindrance in the bilamellar invaginated structures that did not encapsulate DNA efficiently, and gene expression was substantially diminished.

Some investigators have loaded nucleic acids within SUVs using a variety of methods; however, the bulk of the DNA does not load or stay within the liposomes. Furthermore, most of the processes used for loading nucleic acids within liposomes are extremely time consuming and not cost effective. Therefore, SUVs are not the ideal liposomes for creating nonviral vehicles for targeted delivery.

Complexes made using MLVs appear as ''Swiss rolls'' when viewing cross-sections by cryoelectron microscopy (27). These complexes can become too large for systemic administration or deliver nucleic acids inefficiently into cells due to inability to ''unravel'' at the cell surface. Addition of ligands onto MLV liposome–DNA complexes further aggravates these problems. Therefore, MLVs are not useful for the development of targeted delivery of nucleic acids.

Using a formulation developed in our laboratory, nucleic acids are efficiently encapsulated between 2 BIVs (14). We created these unique structures using 1,2-bis(oleoyloxy)-3-(trimethylammino)propane (DOTAP) and cholesterol (Chol), and a novel formulation procedure. This procedure is different because it includes a brief, low-frequency sonication, followed by manual extrusion through filters of decreasing pore size. The 0.1- and 0.2-um filters used are made of aluminum oxide and not polycarbonate, which is typically used by other protocols. Aluminum oxide membranes contain more pores per surface area, evenly spaced and sized pores, and pores with straight channels. During the manual extrusion process, the liposomes are passed through each of 4 different-size filters only once. This process produces 88% invaginated liposomes. Use of high-frequency sonication and/or mechanical extrusion produces only SUVs.

The BIVs produced condense unusually large amounts of nucleic acids of any size (Fig. 2) or viruses (Fig. 3). Furthermore, addition of other DNA-condensing agents including polymers is not necessary. For example, condensation of plasmid DNA onto polymers first before encapsulation in the BIVs did not increase condensation or subsequent gene expression after transfection in vitro or in vivo. Encapsulation of nucleic acids by these BIVs alone is spontaneous and immediate, and therefore, cost effective, requiring only 1 step of simple mixing. The extruded DOTAP : Chol–nucleic acid complexes are also large enough that they are not cleared rapidly by Kupffer cells in the liver, and yet extravasate across tight barriers, including the endothelial cell barrier of the lungs in a normal mouse, and diffuse through target organs efficiently (15). Our recent work demonstrating efficacy for treatment of nonsmall cell lung cancer (15) showed that only BIV DOTAP : Chol–p53 DNA liposome complexes produced efficacy, and SUV DOTAP:Chol–p53 DNA liposome complexes produced no efficacy. Therefore, the choice of lipids alone is

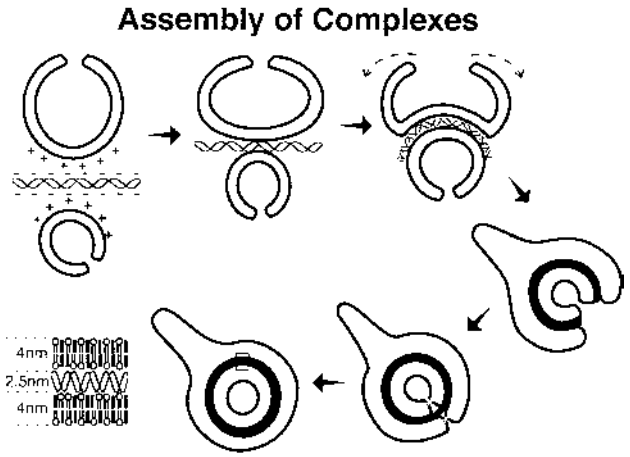

Figure 2 Proposed model showing cross-sections of extruded DOTAP:Chol liposomes (BIVs) interacting with nucleic acids. Nucleic acids adsorb onto a BIV via electrostatic interactions. Attraction of a second BIV to this complex results in further charge neutralization. Expanding electrostatic interactions with nucleic acids cause inversion of the larger BIV and total encapsulation of the nucleic acids. Inversion can occur in these liposomes because of their excess surface area, which allows them to accommodate the stress created by the nucleic acid–lipid interactions. Nucleic acid binding reduces the surface area of the outer leaflet of the bilayer and induces the negative curvature due to lipid ordering and reduction of charge repulsion between cationic lipid headgroups. Condensation of the internalized nucleic acid-lipid sandwich expands the space between the bilayers and may induce membrane fusion to generate the apparently closed structures. The enlarged area shows the arrangement of nucleic acids condensed between two 4-nm bilayers of extruded DOTAP:Chol.

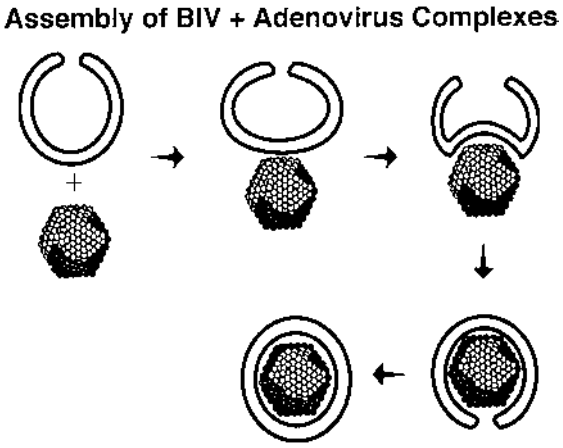

Figure 3 Proposed model showing cross-sections of an extruded DOTAP:Chol liposome (BIV) interacting with adenovirus. Adenovirus interacts with a BIV, causing negative curvature and wrapping around the virus particle.

not sufficient for optimal DNA delivery, and the morphology of the complexes is essential.

IV. OPTIMAL LIPIDS AND LIPOSOME MORPHOLOGY: EFFECTS ON GENE DELIVERY AND EXPRESSION

Choosing the best cationic lipids and neutral lipids are also essential for producing the optimal in vivo formulation. For example, using our novel manual extrusion procedure does not produce BIVs using the cationic lipid dimethyldioctadecylammonium bromide (DDAB). Furthermore, DOTAP is biodegradable, whereas DDAB is not biodegradable. Use of biodegradable lipids is preferred for use in humans. Furthermore, only DOTAP and not DDAB-containing liposomes produced highly efficient gene expression in vivo (14). DDAB did not produce BIVs and was unable to encapsulate nucleic acids. Apparently, DDAB- and DOTAP-containing SUVs produce similar efficiency of gene delivery in vivo; however, these SUVs are not as efficient as BIV DOTAP:Chol (14). In addition, use of L-α-dioleoyl phosphatidylethanolamine (DOPE) as a neutral lipid creates liposomes that cannot wrap or encapsulate nucleic acids. Several investigators have reported efficient transfection of cells in culture using DOPE in liposomal formulations. However, our data showed that formulations consisting of DOPE were not efficient for producing gene expression in vivo (14).

Investigators must also consider the source and lot of certain lipids purchased from companies. For example, different lots of cholesterol from the same vendor can vary dramatically and will affect the formulation of liposomes. Recently, we are using synthetic cholesterol (Sigma, St. Louis, MO). Synthetic cholesterol, instead of natural cholesterol purified from the wool of sheep, is preferred by the Food and Drug Administration for use in producing therapeutics for injection into humans.

Our BIV formulations are also stable for a few years as liquid suspensions. Freeze-dried formulations that are stable indefinitely even at room temperature can also be made. Stability of liposomes and liposomal complexes is also essential, particularly for the commercial development of human therapeutics.

V. LIPOSOME ENCAPSULATION, FLEXIBILITY, AND OPTIMAL COLLOIDAL SUSPENSIONS

A common belief is that artificial vehicles must be 100 nm or smaller to be effective for systemic delivery. However, this belief is most likely true only for large, inflexible delivery vehicles. Blood cells are several microns (up to 7000 nm) in size and yet have no difficulty circulating in the blood, includ-

ing through the smallest capillaries. However, sickle-cell blood cells, which are rigid, do have problems in the circulation. Therefore, we believe that flexibility is a more important issue than small size. In fact, BIV DNA–liposome complexes in the size range of 200 to 450 nm produced the highest levels of gene expression in all tissues after intravenous injection (14). Delivery vehicles, including nonviral vectors and viruses, which are not PEGylated and are smaller than 200 nm, are cleared quickly by the Kupffer cells in the liver. Therefore, increased size of liposomal complexes could extend their circulation time, particularly when combined with injection of high colloidal suspensions. BIVs are able to encapsulate nucleic acids and viruses, apparently due to the presence of cholesterol in the bilayer (Fig. 4). Whereas formulations including DOPE instead of cholesterol could not assemble nucleic acids by a ''wrapping type'' of mechanism (Fig. 5), and produced little gene expression in the lungs and no expression in other tissues after intravenous injections. Because the extruded DOTAP:Chol BIV complexes are flexible and not rigid, are stable in high concentrations of serum, and have extended half-life, they do not have difficulty circulating efficiently in the bloodstream.

We believe that colloidal properties of nucleic acid–liposome complexes also determine the levels of gene expression produced after in vivo delivery (14,28). These properties include the DNA:lipid ratio that determines the overall charge density of the complexes and the colloidal suspension that is monitored by its turbidity. Complex size and shape, lipid composition and formulation, and encapsulation efficiency of nucleic acids by the liposomes also contribute to the colloidal properties of the complexes. The colloidal properties affect serum stability, protection from nuclease degradation, blood circulation time, and biodistribution of the complexes.

Our in vivo transfection data showed that an adequate amount of colloids in suspension was required to produce efficient gene expression in all tissues examined (14). The colloidal suspension is assessed by measurement of adsorbance at 400 nm using a spectrophotometer optimized to measure turbidity. Our data showed that transfection efficiency in all tissues corresponded to OD400 of the complexes measured prior to intravenous injection.

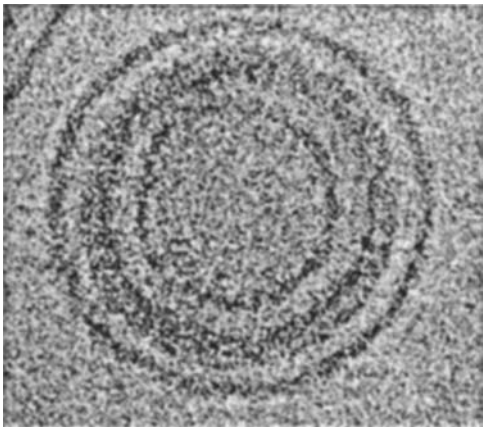

Figure 4 Cryoelectron micrograph of BIV DOTAP:Chol–DNA liposome complexes. The plasmid DNA is encapsulated between 2 BIVs.

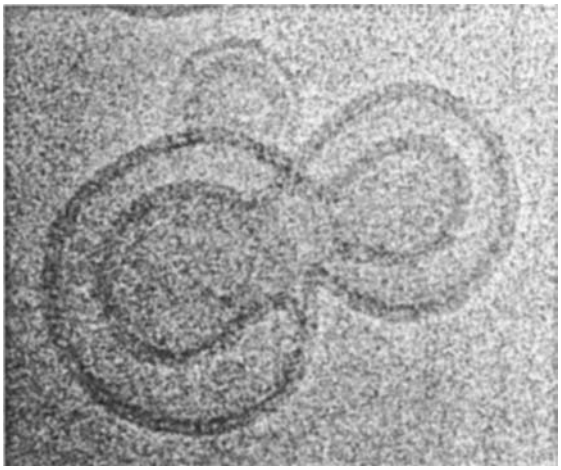

Figure 5 Cryoelectron micrograph of extruded DOTAP:DOPE liposomes complexed to plasmid DNA. Although these liposomes were prepared by the same protocol that produces BIV DOTAP:Chol, these vesicles cannot wrap and encapsulate nucleic acids. The DNA condenses on the surfaces of the liposomes shown.

VI. OVERALL CHARGE OF COMPLEXES AND ENTRY INTO THE CELL

In addition, our delivery system is efficient because the complexes deliver DNA into cells by fusion with the cell membrane and avoid the endocytic pathway (Fig. 6). Cells are negatively charged on the surface, and specific cell types vary in their density of negative charge. These differences in charge density can influence the ability of cells to be transfected. Cationic complexes have nonspecific ionic charge interactions with cell surfaces. Efficient transfection of cells by cationic complexes is, in part, contributed by adequate charge interactions. In addition, recent publications report that certain viruses have a partial positive charge around key subunits of viral proteins on the virus surface responsible for binding to and internalization through target cell surface receptors. Therefore, this partial positive charge is required for virus entry into the cell. Thus, maintenance of adequate positive charge on the surface of targeted liposome complexes is essential for optimal delivery into the cell. Different formulations of liposomes interact with cell surfaces via a variety of mechanisms. Two major pathways for interaction are by endocytosis or by direct fusion with the cell membrane (27,29–34). Preliminary data suggest that nucleic acids delivered in vitro and

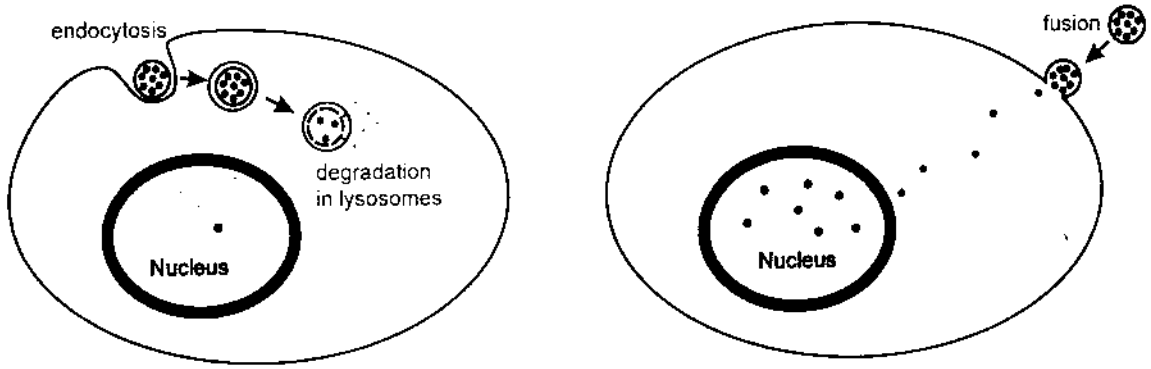

Figure 6 Mechanisms for cell entry of nucleic acid–liposome complexes. Two major pathways for interaction are by endocytosis or by direct fusion with the cell membrane. Complexes that enter the cell by direct fusion allow delivery of more nucleic acids to the nucleus because the bulk of the nucleic acids do not enter endosomes.

in vivo using complexes developed in our lab enter the cell by direct fusion (Fig. 6). Apparently, the bulk of the nucleic acids do not enter endosomes, and therefore, far more nucleic acid enters the nucleus. Cell transfection by direct fusion produced orders of magnitude, increased levels of gene expression, and numbers of cells transfected vs. cells transfected through the endocytic pathway.

We believe that maintenance of adequate positive charge on the surface of complexes is essential to drive cell entry by direct fusion. Therefore, we create targeted delivery of our complexes in vivo without the use of PEG. These ligand-coated complexes also reexpose the overall positive charge of the complexes as they approach the target cells. Through ionic interactions or covalent attachments, we have added monoclonal antibodies, Fab fragments, proteins, partial proteins, peptides, peptide mimetics, small molecules, and drugs to the surface of our complexes after mixing. These ligands efficiently bind to the target cell surface receptor, and maintain entry into the cell by direct fusion. Using novel methods for addition of ligands to the complexes for targeted delivery results in further increased gene expression in the target cells after transfection. Therefore, we design targeted liposomal delivery systems that retain predominant entry into cells by direct fusion vs. the endocytic pathway. Figure 7 shows our optimized strategy to achieve targeted delivery, deshielding, fusion with the cell membrane, entry of nucleic acids into the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid.

VII. SERUM STABILITY OF OPTIMIZED NUCLEIC ACID–LIPOSOME COMPLEXES FOR USE IN VIVO

Serum stability of cationic complexes is complicated and cannot be assessed by simply performing studies at a random concentration of serum. Figure 8 shows results from serum stability studies of DNA–liposome complexes that have been optimized in our laboratory for systemic delivery. Serum stability of these complexes was studied at 37°C out to 24 h at concentrations of serum ranging from 0% to 100%. Two different serum stability assays were performed. The first assay measured the OD400 of BIV DOTAP:Chol–DNA liposome complexes added into tubes containing a different concentration of serum in each tube, ranging from 0% to 100%. The tubes were incubated at 37°C, and small aliquots from each tube were removed at various time points out to 24 h. The OD400 of each aliquot was measured on a spectrophotometer calibrated to accurately measure turbidity. Previous work in our laboratory demonstrated that the OD400 predicted both the stability of the complexes and the transfection efficiency results obtained for multiple organs after intravenous injections (14,28). Percent stability for this assay is defined as the transfection efficiency that is obtained at a particular OD400 of the complexes used for intravenous injections. Therefore, this assay is rigorous because slight declines in OD400 of these complexes result in obtaining no transfection in vivo. Declines in the OD400 also measure precipitation of the complexes.

A second assay was performed to support the results obtained from the OD400 measurements described above. A different concentration of serum, ranging from 0% to 100%, was placed into each well of a 96-well microtiter dish. BIV DOTAP:Chol–DNA liposome complexes were added to the serum in the wells, and the plate was incubated at 37°C. The plate was removed at various time points out to 24 h and complexes in the wells were observed under the microscope. Precipitation of complexes in the wells was assessed. Stability (100%) was set at no precipitation observed. Results from this assay were compared with those obtained in the first assay. Stability (100%) of complexes was set at no decline of OD400 in assay #1 and no observed precipitation in assay #2 at each % serum concentration, and the results were plotted (Fig. 8).

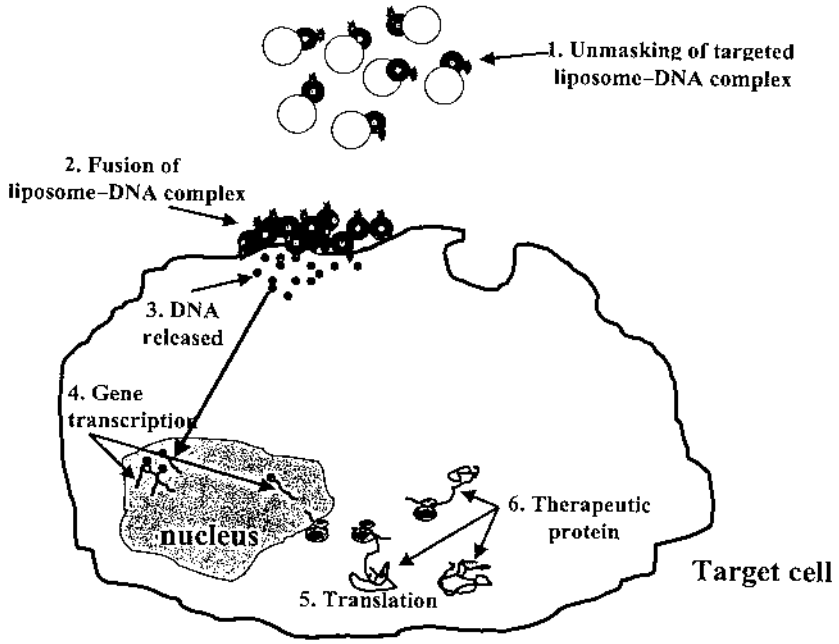

Figure 7 Optimized strategy for delivery and gene expression in the target cell. Optimization of many steps is required to achieve targeted delivery, deshielding, fusion with the cell membrane, entry of nucleic acids into the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid.

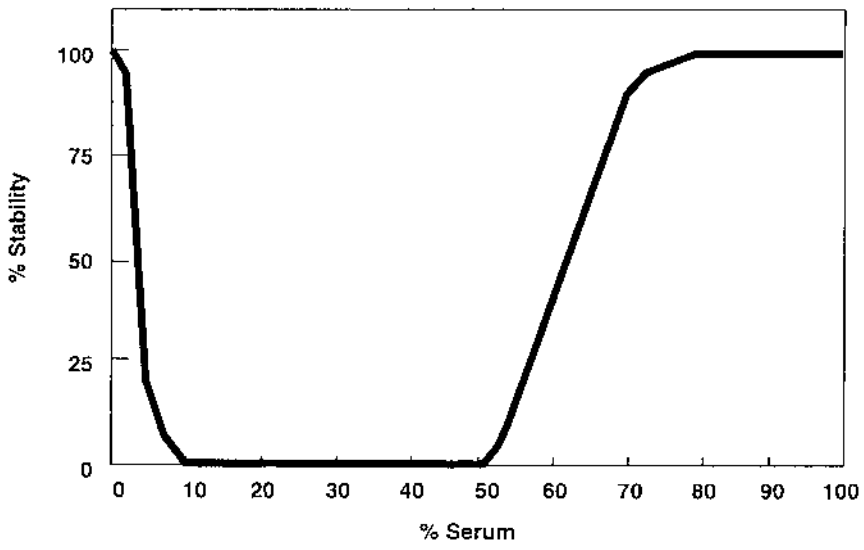

Figure 8 Serum stability profile for DNA–liposome complexes optimized for systemic delivery. Serum stability of these complexes was studied at 37°C out to 24 h at concentrations of serum ranging from 0% to 100%. Serum stability at the highest concentrations of serum, about 70% to 100%, that are physiological concentrations of serum found in the bloodstream is required.

The results showed serum stability at the highest concentrations of serum, about 70% to 100%, that are physiological concentrations of serum found in the bloodstream. In addition, these complexes were also stable in no or low concentrations of serum, whereas the complexes were unstable at 10% to 50% serum, perhaps due to salt bridging. Therefore, in vitro optimization of serum stability for formulations of cationic complexes must be performed over a broad range of serum concentration to be useful for applications in vivo.

VIII. OPTIMIZED HALF-LIFE IN THE CIRCULATION

As stated above, the extruded BIV DOTAP:Chol–nucleic acid complexes are large enough so that they are not cleared rapidly by Kupffer cells in the liver and yet extravasate across tight barriers and diffuse through the target organ efficiently. Further addition of ligands to the surface of extruded BIV DOTAP:Chol–nucleic acid complexes does not significantly increase the mean particle size. Extravasation and penetration through the target organ and gene expression produced after transfection are not diminished. These modified formulations are positively charged and deliver nucleic acids efficiently into cells in vitro and in vivo. Because extruded BIV DOTAP:Chol–nucleic acid complexes with or without ligands have a 5-h half-life in the circulation, these complexes do not accumulate in the skin, hands, or feet. Extended half-life in the circulation is provided primarily by the formulation, preparation method, injection of optimal colloidal suspensions, and optimal nucleic acid:lipid ratio used for mixing complexes, serum stability, and size (200–450 nm). Therefore, these BIVs are ideal for use in the development of effective, targeted nonviral delivery systems that clearly require encapsulation of nucleic acids.

IX. BROAD BIODISTRIBUTION OF OPTIMIZED LIPOSOME FORMULATIONS

Our ''generic'' BIV nucleic acid–liposome formulation transfects many organs and tissues efficiently after intravenous injection (14) and has demonstrated efficacy in animal models for lung cancer (15), pancreatic cancer (17), breast cancer (16), hepatitis B and C (Clawson and Templeton, 2000), and cardiovascular diseases (35). Therefore, optimization of the morphology of the complexes, the lipids used, flexibility of the liposomes and complexes, colloidal suspension, overall charge, serum stability, and half-life in circulation allows for efficient delivery and gene expression in many organs and tissues other than the lung. Apparently, these extruded DOTAP:Chol BIV nucleic acid–liposome complexes can overcome the tendency to be adsorbed only by the endothelial cells lining the circulation surrounding the lungs described by other investigators (36). However, as discussed above and below, we can further direct delivery to specific target tissues or cells by our targeted delivery strategies in combination with reversible masking used to bypass nonspecific transfection.

X. OPTIMIZATION OF TARGETED DELIVERY

Much effort has been made to specifically deliver nucleic acid–liposome complexes to target organs, tissues, and/or cells. Ligands that bind to cell surface receptors are usually attached to PEG and then attached to the cationic or anionic delivery vehicle. Due to shielding the positive charge of cationic complexes by PEG, delivery to the specific cell surface receptor can be accomplished by only a small fraction of complexes injected systemically. Furthermore, delivery of PEGylated complexes into the cell occurs predominantly through the endocytic pathway, and subsequent degradation of the bulk of the nucleic acid occurs in the lysosomes. Thus, gene expression is generally lower in the target cell than using the nonspecific delivery of highly efficient cationic complexes.

As discussed above, the vast majority of the injected PEGylated complexes bypasses the target cell. Apparently, the PEGylated complexes cannot use critical charge interactions for optimal transfection into cells by direct fusion. Inability to expose positive charge on the surface of optimized complexes results in the transfection of fewer cells. PEGylation was first used to increase the half-life of complexes in the circulation and to avoid uptake in the lung. However, this technology also destroys the ability to efficiently transfect cells. We were able to increase the half-life in circulation of BIVs to 5 h without the use of PEG. Because the extended half-life of BIVs is not too long, this delivery system does not result in the accumulation of complexes in nontarget tissues that circulate for 1 to 3 days. Some investigators have now reported targeted delivery that produces increased gene expression in the target cell over their nontargeted complexes. However, these nontargeted and targeted delivery systems are inefficient (37) compared with efficient delivery systems such as the BIVs.

In using the extruded BIV DOTAP:Chol nucleic acid:liposome complexes, we produced an optimal half-life in the circulation without the use of PEG (14). Extended half-life was produced primarily by the formulation, preparation method, injection of optimal colloidal suspensions, serum stability, and optimal nucleic acid:lipid ratio used for mixing complexes, and size (200–450 nm). Furthermore, we avoid uptake in the lungs using the negative charge of the ligands and ''shielding/deshielding compounds'' that can be added to the complexes used for targeting just prior to injection or administration in vivo. Our strategy to bypass nonspecific transfection is called reversible masking. By adding ligands using the novel approaches that we developed, adequate overall positive charge on the surface of complexes is preserved. In summary, we achieve optimal circulation time of the complexes, reach and deliver to the target organ, avoid uptake in nontarget tissues, and efficiently interact with the cell surface to produce optimal transfection.

XI. EFFICIENT DISSEMINATION THROUGHOUT TARGET TISSUES AND MIGRATION ACROSS TIGHT BARRIERS

A primary goal for efficient in vivo delivery is to achieve extravasation into and penetration throughout the target organ/tissue ideally by noninvasive systemic administration. Without these events therapeutic efficacy is highly compromised for any treatment including gene and drug therapies. Achieving this goal is difficult due to the many tight barriers that exist in animals and people. Furthermore, many of these barriers become tighter in the transition from neonates to becoming adults. Penetration throughout an entire tumor is further hindered due to the increased interstitial pressure within most tumors (38–40). We believe that nonviral systems can play a pivotal role in achieving target organ extravasation and penetration needed to treat or cure certain diseases. Our preliminary studies have shown that extruded BIV DOTAP:Chol nucleic acid:liposome complexes can extravasate across tight barriers and penetrate evenly throughout entire target organs, and viral vectors cannot cross identical barriers. These barriers include the endothelial cell barrier in a normal mouse, the posterior blood retinal barrier in adult mouse eyes, complete and even diffusion throughout large tumors (15), and penetration through several tight layers of smooth muscle cells in the arteries of pigs (35). Diffusion throughout large tumors was measured by expression of β-galactosidase or the proapoptotic gene p53 in about half of the p53-null tumor cells after a single injection of BIV DOTAP:Chol–DNA liposome complexes into the center of a tumor. Transfected cells were evenly spread throughout the tumors. Tumors injected with complexes encapsulating plasmid DNA encoding p53 showed apoptosis in almost all the tumor cells by TUNEL staining. Tumor cells expressing p53 mediate a bystander effect on neighboring cells perhaps due to up-regulation by Fas ligand that causes nontransfected tumor cells to undergo apoptosis. Currently, we are investigating the mechanisms used by extruded DOTAP:Chol nucleic acid:liposome complexes to cross-barriers and penetrate throughout target organs. By knowing more about these mechanisms, we hope to develop more robust nonviral gene therapeutics.

XII. OPTIMIZATION OF PLASMIDS FOR IN VIVO GENE EXPRESSION

Delivery of DNA and subsequent gene expression may be poorly correlated (18,41). Investigators may focus solely on the delivery formulation as the source of poor gene expression. In many cases, however, the delivery of DNA into the nucleus of a particular cell type may be efficient, although little or no gene expression is achieved. The causes of poor gene expression can be numerous. The following issues should be considered independent of the delivery formulation, including suboptimal promoter enhancers in the plasmid, poor preparation of plasmid DNA, and insensitive detection of gene expression.

Plasmid expression cassettes typically have not been optimized for animal studies. For example, many plasmids lack a full-length cytomegalovirus (CMV) promoter enhancer. Over 100 variations of the CMV promoter enhancer exist, and some variations produce greatly reduced or no gene expression in certain cell types (18). Even commercially available plasmids contain suboptimal CMV promoters enhancers, although these plasmids are advertised for use in animals. Furthermore, upon checking the company data for these plasmids, one would discover that these plasmids have never been tested in animals and have been tested in only 1 or 2 cultured cell lines. Conversely, plasmids that have been optimized for overall efficiency in animals may not be best for transfection of certain cell types in vitro or in vivo. For example, many investigators have shown that optimal CMV promoters enhancers produce gene expression at levels several orders of magnitude less in certain cell types. In addition, one cannot assume that a CMV promoter that expresses well within the context of a viral vector, such as adenovirus, will function as well in a plasmid-based transfection system for the same cell context. Virus proteins produced by the viral vector are required for producing high levels of mRNA by the CMV promoter in specific cell nuclei.

Ideally, investigators design custom promoter enhancer chimeras that produce the highest levels of gene expression in their target cells of interest. Recently, we designed a systematic approach for customizing plasmids used for breast cancer gene therapy using expression profiling (18). Gene therapy clinical trials for cancer frequently produce inconsistent results. We believe that some of this variability could result from differences in transcriptional regulation that limit expression of therapeutic genes in specific cancers. Our systemic liposomal delivery of a nonviral plasmid DNA showed efficacy in animal models for several cancers. However, we observed large differences in the levels of gene expression from a CMV promoter enhancer between lung and breast cancers. To optimize gene expression in breast cancer cells in vitro and in vivo, we created a new promoter enhancer chimera to regulate gene expression. Serial analyses of gene expression data from a panel of breast carcinomas and normal breast cells predicted promoters that are highly active in breast cancers [e.g., the glyceraldehyde 3-phosphate dehydrogenase (GAPDH) promoter]. Furthermore, GAPDH is up-regulated by hypoxia, which is common in tumors. We added the GAPDH promoter, including the hypoxia enhancer sequences, to our in vivo gene expression plasmid. The novel CMV-GAPDH promoter enhancer showed up to 70-fold increased gene expression in breast tumors compared with the optimized CMV promoter enhancer alone. No significant increase in gene expression was observed in other tissues. These data demonstrate tissue-specific effects on gene expression after nonviral delivery and suggest that gene delivery systems may require plasmid modifications for the treatment of different tumor types. Furthermore, expression profiling can facilitate the design of optimal expression plasmids for use in specific cancers.

Several reviews have stated that nonviral systems are intrinsically inefficient compared with viral systems. However, as discussed above, one must separate issues of the delivery

vehicle vs. the plasmid that is delivered. Case in point, we have shown that our extruded liposomes optimized for systemic delivery could out-compete delivery using a lentivirus. For example, we have compared SIVmac239, a highly noninfectious virus, with nonviral delivery of SIVmac239 DNA complexed to BIVs in adult rhesus macaques after injection into the saphenous vein of the leg. Our data showed that the monkeys injected with SIV DNA encapsulated in DOTAP:Chol BIVs were infected 4 days postinjection, and high levels of infection were produced in these monkeys at 14 days postinjection. Furthermore, higher levels of SIV RNA in the blood were produced using our BIV liposomes for delivery vs. using the SIV virus. CD4 counts were measured before and after injections. CD4 levels dropped in all monkeys to the lowest levels ever detected in the macaques in any experiment by 28 days postinjection, the first time point at which these counts were measured postinjection. All monkeys had clinical SIV infections and lost significant weight by day 28. These results were surprising because SIVmac239 is not highly infectious, and monkeys become sick with SIV infection only after several months or years postinjection with SIVmac239 virus. Therefore, we were able to induce SIV infection faster using our nonviral delivery of SIV plasmid DNA. In this case, we delivered a replication-competent plasmid so that gene expression increased over time posttransfection. Our delivery system was highly efficient and exceeded that of the lentivirus. The critical feature in this nonviral experiment was the plasmid DNA that was delivered.

Plasmids can be engineered to provide for specific or long-term gene expression, replication, or integration. Persistence elements, such as the inverted terminal repeats from adenovirus or adeno-associated virus, have been added to plasmids to prolong gene expression in vitro and in vivo. Apparently, these elements bind to the nuclear matrix, thereby retaining the plasmid in cell nuclei. For regulated gene expression, many different inducible promoters are used that promote expression only in the presence of a positive regulator or in the absence of a negative regulator. Tissue-specific promoters have been used for the production of gene expression exclusively in the target cells. As discussed in the previous paragraph, replication-competent plasmids or plasmids containing sequences for autonomous replication can be included that provide prolonged gene expression. Other plasmid-based strategies produce site-specific integration or homologous recombination within the host cell genome [reviewed in (42)]. Integration of a cDNA into a specific ''silent site'' in the genome could provide long-term gene expression without disruption of normal cellular functions. Homologous recombination could correct genetic mutations upon integration of wild-type sequences that replace mutations in the genome. Plasmids that contain fewer bacterial sequences and that produce high yield upon growth in *Escherichia coli* are also desirable.

XIII. OPTIMIZATION OF PLASMID DNA PREPARATIONS

The transfection quality of plasmid DNA is dependent on the preparation protocol and training of the person preparing the DNA. For example, we performed a blinded study asking 3 people to make DNA preparations of the same plasmid from the same box of a Qiagen Endo-Free Plasmid Preparation kit. One person then mixed all the DNA–liposome complexes on the same morning using a single vial of liposomes. One person performed all tail vein injections, harvesting of tissues, preparation of extracts from tissues, and reporter gene assays on the tissue extracts. In vivo gene expression differed 30-fold among these 3 plasmid DNA preparations.

One source for this variability is that optimized methods to detect and remove contaminants from plasmid DNA preparations have not been available. We have identified large amounts of contaminants that exist in laboratory and clinical grade preparations of plasmid DNA. These contaminants copurify with DNA by anion exchange chromatography and by cesium chloride density gradient centrifugation. Endotoxin removal does not remove these contaminants. High-performance liquid chromatography cannot detect these contaminants. Therefore, we developed 3 proprietary methods for the detection of these contaminants in plasmid DNA preparations. We can now make clinical grade (GMP) DNA that does not contain these contaminants. To provide the greatest efficacy and levels of safety, these contaminants must be assessed and removed from plasmid DNA preparations. These contaminants belong to a class of molecules known to inhibit both DNA and RNA polymerase activities. Therefore, gene expression posttransfection can be increased by orders of magnitude if these contaminants are removed from DNA preparations. The presence of these contaminants in DNA also precludes high-dose delivery of DNA–liposome complexes intravenously. Our group and other investigators have shown that intravenous injections of high doses of improved liposomes alone cause no adverse effects in small and large animals.

Some investigators have removed the majority of CpG sequences from their plasmids and report reduced toxicity after intravenous injections of cationic liposomes complexed to these plasmids (43). However, only low doses containing up to 16.5 μg of DNA per injection into each mouse were shown to reduce toxicity. To achieve efficacy for cancer metastases, particularly in mice bearing aggressive tumors, most investigators are interested in injecting higher doses in the range of 50 to 150 μg of DNA per mouse. Therefore, removal of CpG sequences from plasmid-based gene therapy vectors will not be useful for these applications because no difference in toxicity was shown after intravenous injections of these higher doses of plasmids, with or without reduced CpG sequences, complexed to liposomes (43). Therefore, we believe that removal of the other contaminants in current DNA preparations, discussed above, is the major block to the safe intravenous injection of high doses of DNA–liposome complexes.

XIV. DETECTION OF GENE EXPRESSION

Thought should also be given to choosing the most sensitive detection method for every application of nonviral delivery rather than using the method that seems most simple. For

example, detection of β-galactosidase expression is far more sensitive than that for the green fluorescent protein (GFP). Specifically, 500 molecules of β-galactosidase (β-gal) per cell are required for detection using X-gal staining, whereas about 1 million molecules of GFP per cell are required for direct detection. Furthermore, detection of GFP may be impossible if the fluorescence background of the target cell or tissue is too high. Detection of chloramphenicol acetyltransferase (CAT) is extremely sensitive with little or no background detected in untransfected cells. Often, assays for CAT expression can provide more useful information than using β-gal or GFP as reporter genes.

Few molecules of luciferase in a cell can be detected by luminescence assays of cell or tissue extracts posttransfection. The sensitivity of these assays is highly dependent on the type of instrument used to measure luminescence. However, luciferase results may not predict the therapeutic potential of a nonviral delivery system. For example, if several hundred or thousand molecules per cell of a therapeutic gene are required to produce efficacy for a certain disease, then production of only few molecules will not be adequate. If only few molecules of luciferase are produced in the target cell using a specific nonviral delivery system, then the investigator may be misled in using this system for therapeutic applications.

Furthermore, noninvasive detection of luciferase expression in vivo is not as sensitive as luminescence assays of cell or tissue extracts posttransfection. Recently, my colleagues tried cooled charge-coupled device (CCD) camera imaging on live mice after intravenous injection of other cationic liposomes complexed to plasmid DNA-encoding luciferase, and they were not able to detect any transfection. However, these liposomal delivery systems had been used to detect luciferase by luminescence assays of organ extracts. My colleagues detected luciferase expression by CCD imaging after intravenous injections of BIV DOTAP:Chol–luciferase DNA–liposome complexes (44). Because the luciferase protein is short-lived, maximal expression was detected at 5 h posttransfection, whereas detection of herpes simplex virus-thymidine kinase (HSV-TK) gene expression using microPET imaging in the same mice was highest at 24 h posttransfection. In contrast to luciferase, the CAT protein accumulates over time, and therefore, the investigator is not restricted to a narrow time frame for assaying gene expression. Furthermore, detection of CAT seems to be more sensitive than CCD imaging of luciferase following intravenous injections of DNA–liposome complexes. However, the animals must be sacrificed in order to perform CAT assays on tissue or organ extracts. In summary, further work is still needed to develop in vivo detection systems that have high sensitivity and low background.

XV. OPTIMIZATION OF DOSE AND FREQUENCY OF ADMINISTRATION

To establish the maximal efficacy for the treatment of certain diseases or for the creation of robust vaccines, injections, or administrations of the nonviral gene therapeutic, etc., via different routes may be required. For particular treatments, one should not assume that one delivery route is superior to others without performing the appropriate animal experiments. In addition, people with the appropriate expertise should perform the injections and administrations. In our experience, only a minority of people who claim expertise in performing tail vein injections can actually perform optimal injections.

The optimal dose should be determined for each therapeutic gene or other nucleic acid that is administered. The investigator should not assume that the highest tolerable dose is optimal for producing maximal efficacy. The optimal administration schedule should also be determined for each therapeutic gene or other nucleic acid. To progress faster, some investigators have simply used the same administration schedule that they used for chemotherapeutics, for example. The investigator should perform in vivo experiments to determine when gene expression and/or efficacy drops significantly. Most likely, readministration of the nonviral gene therapeutic is not necessary until this drop occurs. Loss of the therapeutic gene product will vary with the half-life of the protein produced. Therefore, if a therapeutic protein has a longer half-life, then the gene therapy could be administered less frequently.

XVI. SUMMARY

Overcoming some hurdles remain in the broad application of nonviral delivery, however, we are confident that we will successfully accomplish the remaining challenges soon. Furthermore, we predict that eventually the majority of gene therapies will use artificial reagents that can be standardized and regulated as drugs rather than biologics. We will continue to incorporate the molecular mechanisms of viral delivery that produce efficient delivery to cells into artificial systems. Therefore, the artificial systems, including liposomal delivery vehicles, will be further engineered to mimic the most beneficial parts of the viral delivery systems while circumventing their limitations. We will also maintain the numerous benefits of the liposomal delivery systems discussed in this chapter.

ACKNOWLEDGMENT

I thank Dr. David D. Roberts at the National Cancer Institute, National Institutes of Health, Bethesda, MD, for preparation of the figures.

I. INTRODUCTION

Designed by nature for information and valued by molecular biologists for manipulation, DNA is also a favorite of physical chemists and physicists (1). Its mechanical properties (2), its interactions with other molecules (3), and its modes of packing (4) present tractable but challenging problems whose answers have in vivo and in vitro consequences. In the context of DNA transfection and gene therapy (5), what has been learned about molecular mechanics, interaction, and packing might teach us how to package DNA for more effective gene transfer. Among these modes of in vitro packaging are association with proteins, treatment with natural or synthetic cationic ''condensing agents,'' and combination with synthetic positively charged lipids (6).

In vivo, DNA is tightly held, not at all like the dilute solution form often studied in vitro (Fig. 1). This tight assembly necessarily incurs huge energetic costs of confinement, costs that create a tension under which DNA is expected to ravel or unravel its message. Through direct measurement of forces between DNA molecules (7) and direct observation of its modes of packing (8), we might see not only how to use concomitant energies to design better DNA transfer systems, but also how to better understand the sequences of events by which DNA is read in cells.

What binds these structures? To first approximation, for large, flexible biological macromolecules, the relevant interactions resemble those found among colloidal particles (9), where the size of the molecule (e.g., DNA molecules, lipid membranes, actin bundles) distinguishes it from simpler, smaller species (e.g., small solutes or salt ions). On the colloidal scale of tens of nanometers [1 nm $= 10^{-9}$m], only the interactions between macromolecules are evaluated explicitly, whereas the small molecular species only ''dress'' the large molecules and drive the interactions between them.

The electrical charge patterns of multivalent ions such as Mn^{+2}, Co^{3+}, or spermine^{+4} cation binding to negative DNA create attractive electrostatic and/or solvation forces that move DNA double helices to finite separations, despite the steric knock of DNA thermal Brownian motion (10). Solvation patterns about the cation-dressed structures create solvation forces: DNA–DNA repulsion because of water clinging to the surface, and attraction from the release of solvent (11). Positively charged histones will spool DNA into carefully distributed skeins, themselves arrayed for systematic unraveling and reading (12). Viral capsids will encase DNA, stuffed against its own DNA–DNA electrostatic and solvation repulsion, to keep it under pressure for release upon infection (13). In artificial preparations, the glue of positively charged and

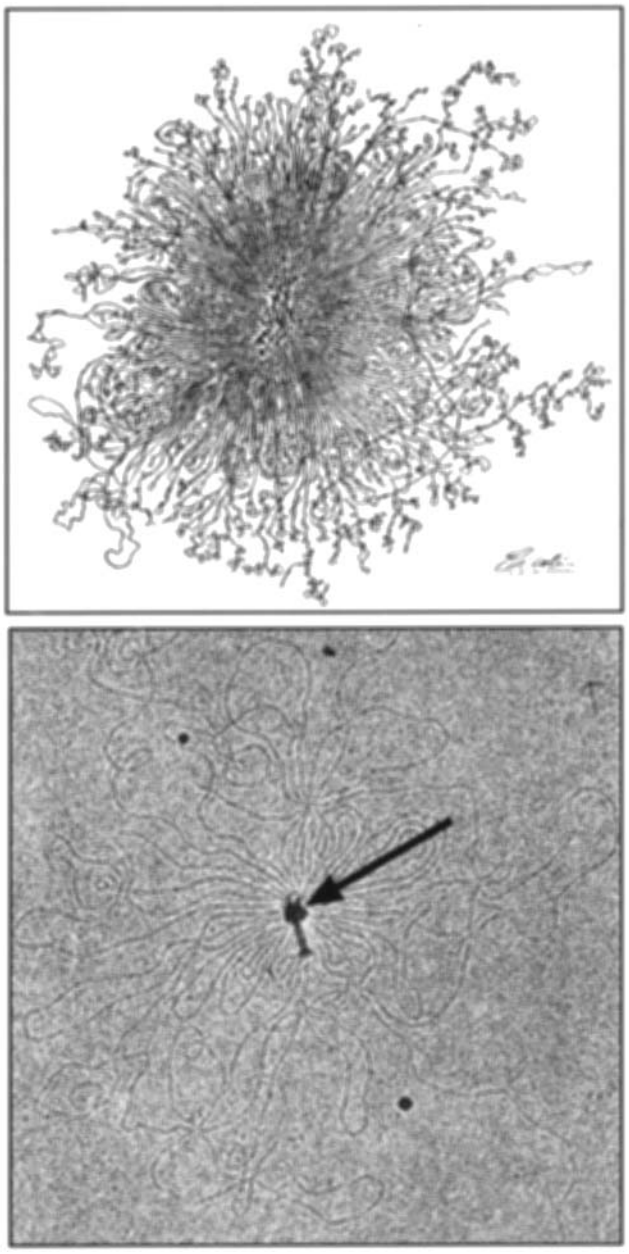

Figure 1 In vivo DNA is highly compacted. The figure shows *E. coli* DNA and T2 bacteriophage DNA after an osmotic shock in distilled water that has allowed them to expand from their much more compacted in vivo configurations. (*E. coli* picture courtesy of Ruth Kavenoff, Bluegenes, Inc., Los Angeles (1994); T2 picture from Kleinschmidt et al. BBA **61** (1962) 252.)

neutral lipids can lump negative DNA into ordered structures that can move through lipids and water solutions (14).

Changes in the suspending medium can modulate intermolecular forces. One example is the change in van der Waals charge fluctuation forces (see below) between lipid bilayers when small sugars modifying the dielectric dispersion properties of water are added to the solution (15). More dramatic, the addition of salt to water can substantially reduce electrostatic interactions between charged molecules such as DNA or other charged macromolecules bathed by an aqueous solution (16). These changes can modify the behavior of macromolecules quantitatively or induce qualitatively new features into their repertoire among these, most notably, precipitation of DNA by addition of organic polycations to the solution (10).

Similar observations can be made about the small molecules essential to practically every aspect of interaction between macromolecules. Through the dielectric constant or dielectric permittivity, it enters electrostatic interactions; through pH, it enters charging equilibria; and through its fundamental molecular geometry, it enters the hydrogen bond network topology around simple solutes. This is, of course, the water molecule (17). In what follows, we limit ourselves to only three basic properties of macromolecules—charge, polarity (solubility), and conformational flexibility—that appear to govern the plethora of forces encountered in biological milieu. It is no surprise that the highly ordered biological structures, such as the quasicrystalline spooling of DNA in viral heads or the multilamellar stacking of lipid membranes in visual receptor cells (Fig. 2), can be explained through the properties of a small number of fundamental forces acting between macromolecules. Detailed experimental as well as theoretical investigations have identified hydration, electrostatic, van der Waals or dispersion, and conformational fluctuation forces as the most fundamental interactions governing the fate of biological macromolecules.

Our intent here is to sketch the measurements of these operative forces and to dwell on concepts that rationalize them. It is from these concepts, with their insight into what controls organizing forces, that we expect people to learn to manipulate and package DNA in more rewarding ways.

II. MOLECULAR FORCES

A. The Origin and Measurement of Molecular Forces

We divide these forces into two broad categories, both of which can be either attractive or repulsive. First, there are interactions that are connected with fields emanating from sources within or on the macromolecules themselves (16) (e.g., electrostatic fields pointing from the fixed-charge distributions on macromolecules into the surrounding space, fields of connectivity of hydrogen bond networks extending from the macromolecular surfaces into the bulk solution that are seen in hydration interactions). Second, there are forces due to fluctuations that originate either in thermal Brownian motion or quantum jitter (15). Consequent interactions include the van der Waals or dispersion forces that originate from

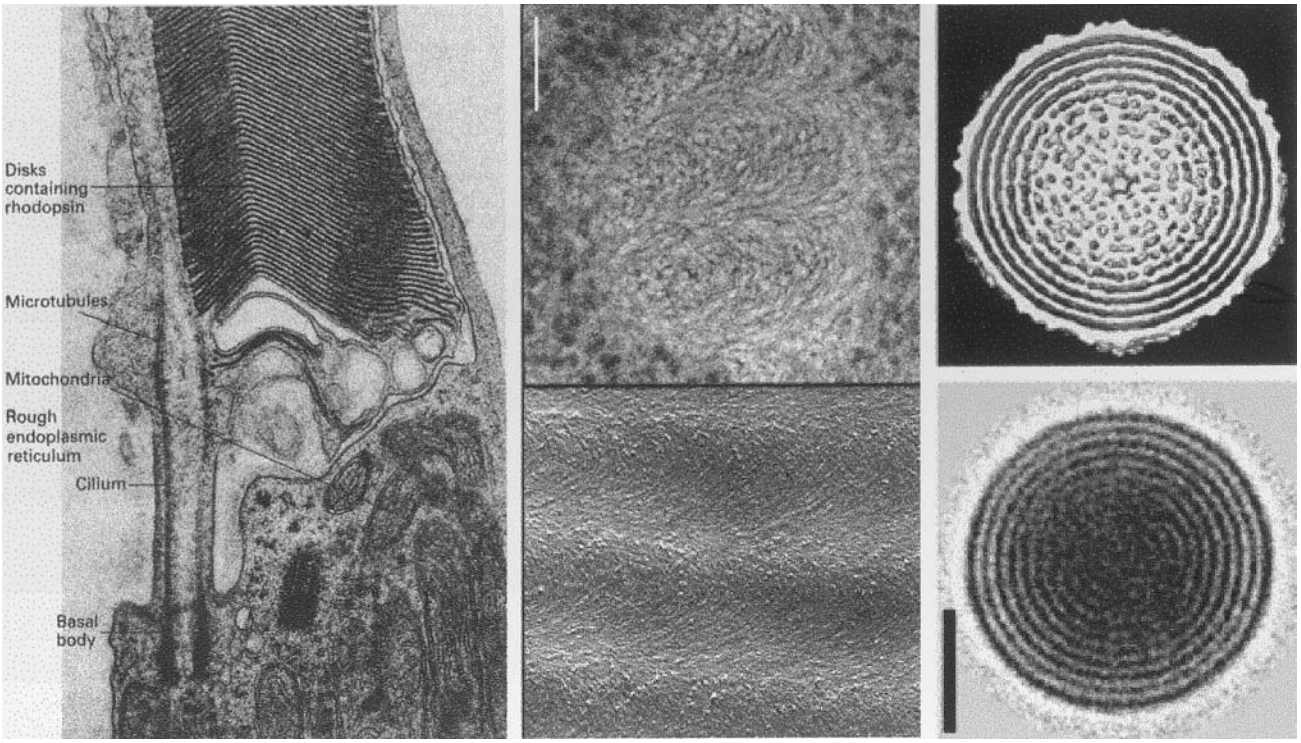

Figure 2 Highly ordered assemblies, ubiquitous among biological structures, can be explained through the properties of a very small number of fundamental forces acting between macromolecules. On the left-hand side, electron micrograph of a part of a human eye rod cell showing multilamellar bilayer aggregate. (From Kessel RG, Kardon RH. Tissues and Organs. San Francisco: W.H. Freeman and Co, 1979.) In the middle, electron micrograph of an in vivo cholesteric phase of a wild-type *E. coli* DNA. (Adapted from D. Frankiel–Krispin et al. EMBO J **20** (2001) 1184–1191.) For comparison we show the same type of structure for DNA in vitro below. (Adapted from A. Leforestier and F. Livolant, Biophys. J **65** (1993) 56–72.) On the right-hand side, cryomicrographs and computer-processed images of T7 phage heads showing ordered DNA spooling within the viral heads. (From Ref. 13.)

thermal as well as quantum mechanical fluctuations of electromagnetic fields in the space between and within the interacting molecules; conformation-fluctuation forces from thermal gyrations by the macromolecule when thermal agitation pushes against the elastic energy resistance of the molecule and confinement imposed by neighboring macromolecules (16).

There are many ways to detect interactions between macromolecules. Here we consider only macromolecules interacting in ordered arrays that are particularly relevant for investigations of the packing and energetics of DNA–lipid complexes.

A fundamental concept in macromolecular arrays is that of osmotic pressure (Fig. 3). It is equal to the pressure needed to hold a macromolecular array together against the forces acting between its constituent macromolecules. It can be applied either mechanically across a semipermeable membrane or via the osmotic stress of a high molecular weight (e.g., PEG (polyethyleneglycol), PVP (polyvinylpyrrolidone), dextrane) polymer solution. At chemical equilibrium, the osmotic pressure of one solution (macromolecular array) balances that of another (the bathing polymer solution). The chemical equilibrium can be maintained either via a semipermeable membrane or simply because the bathing polymer solution phase separates from the macromolecular array, as is many times the case with PEGs, PVP, and dextrane. This osmotical balancing of different molecular solutions is the basis of the ''osmotic stress method'' of measuring the equation of state of macromolecular arrays (18).

The equation of state of a macromolecular solution is defined as the dependence of its osmotic pressure on the density of the array (Fig. 4). By equilibrating the macromolecular array vs. a solution of high molecular weight polymer with a known osmotic pressure, one can set the osmotic pressure in the macromolecular array itself (18). If in addition the concurrent density of the macromolecular array is measured, either via X-ray scattering or direct densitometry, one gets the dependence of the osmotic pressure of the array on its density (i.e., its equation of state). This is the essence of the osmotic stress method.

1. Hydration Force

The hydration force is connected with a simple observation that it takes increasing amounts of work to remove water from

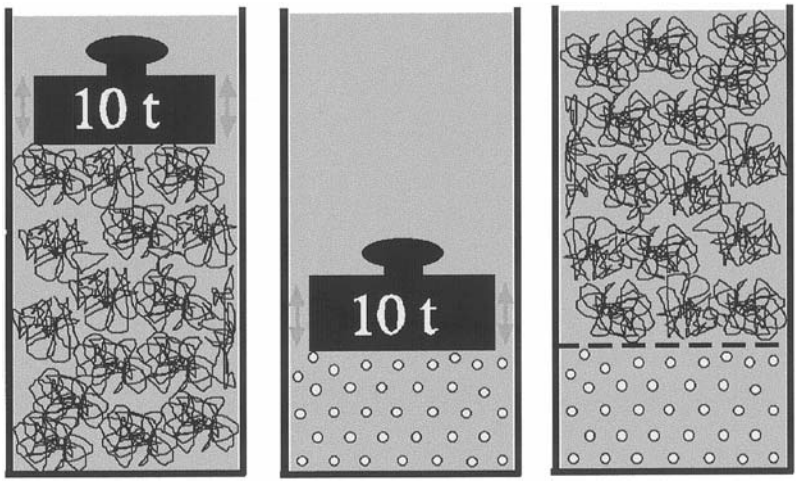

Figure 3 Osmotic pressure in macromolecular arrays. Dissolved polymers such as PEG exert an osmotic pressure on the the part of the solution from which they are excluded (shown schematically by the weight). Instead of exerting directly a pressure on the macromolecular subphase such as DNA or lipid arrays (small circles), one can equilibrate it with a solution of PEG at a set concentration (what amounts to the same thing: a set osmotic pressure) and PEG itself will exert osmotic stress on the macromolecular subphase. Osmotic weighing of polymers one against the other (the one with the known, set osmotic pressure against the unknown one) is the essence of the osmotic stress technique of measuring interactions in macromolecular solutions. See the color insert for a color version of this figure.

between electrically neutral lipids in multilamellar arrays, or from between ordered arrays of polymers at large polymer concentrations (18). Direct measurements of this work strongly suggest that it increases exponentially with the diminishing separation between colloid surfaces with a certain decay length that depends as much on the bulk properties of the solvent as on the detailed characteristics of the interacting surfaces. There is nevertheless some profound universality in the interactions between macromolecular surfaces at close distances (Fig. 5), whether they are charged, zwitterionic, or uncharged, that strongly suggest that water is essential in maintaining the stability of biological matter at high densities.

Hydration forces can be understood in different terms with no consensus yet on mechanism (11). Marčelja and coworkers (19) first proposed the idea that colloid surfaces perturb the vicinal water and that the exponential decay of the hydration force is due to the weakening of the perturbation of the solvent as a function of the distance between the interacting surfaces (Fig. 6). They introduced an order parameter $P(z)$ as a function of the transverse coordinate z, between the surfaces located at $z = D/2$ and $z = -D/2$, that would capture the local condition, or local ordering of solvent molecules between the surfaces. The detailed physical nature of this order parameter is left unspecified, but because the theory builds on general principles of symmetry and perturbation expansions molecular details are not needed. All one needs to know about P is that within the bulk water $P = 0$ and close to a macromolecular surface P remains nonzero. As a mnemonic, one can envision P as an arrow associated with each water molecule. In the bulk, the arrows point in all directions with equal probability. Close to a bounding macromolecular surface, they point preferentially toward or away from the surface (Fig. 6), depending on the surface-orienting fields.

If we envisage solvent molecules between two perturbing surfaces, we can decompose the total free energy F of their configuration into its energy W and entropy S parts via the well-known thermodynamic definition $F = W - TS$, where T is the temperature. Energetically it would be most favorable for the surface-induced order to persist away from the surfaces, but that would create conflict between the apposing surfaces (Fig. 3). Entropy fights any type of ordering and wants to eliminate all orderly configurations between the two surfaces, creating a homogeneous state of molecular disorder characterized by $P = 0$. Energy and entropy compromise to create a nonuniform profile of the order parameter between the surfaces; surface-induced order propagates but progressively decreases away from the surfaces.

From the free energy, we can derive the repulsive hydration osmotic pressure p acting between the surfaces because by definition it is proportional to the derivative of the free energy with respect to the separation D. Osmotic pressure between two apposed lipid surfaces has been measured extensively for different lipids (20) and has been measured to have the form $p = p_0 \exp(-D/\lambda_H)$, consistent with previously theoretically derived form of the hydration free energy if one assumes that $p_0 \sim P^2(z = D/2)$. Here λ_H is the hydration decay length of 0.1–0.4 nm measuring the spatial extent of water perturbation. From these experiments, one can deduce the magnitude of the prefactor p_0, which for a great variety of lipids and lipid mixtures can be found within an interval 10^{12} to 10^{10} dynes/cm^2. This ratio also

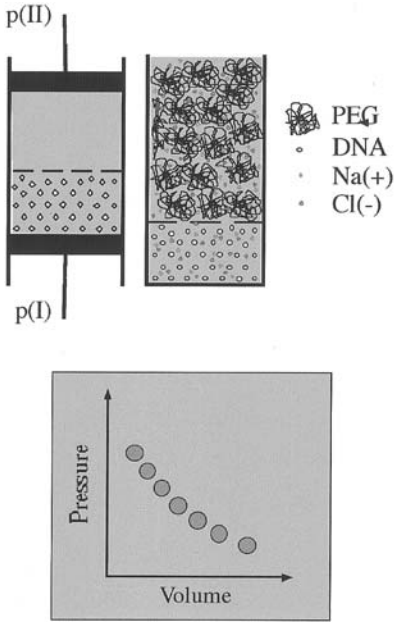

Figure 4 The osmotic stress method (18). DNA liquid crystals are equilibrated against solutions of a neutral polymer (e.g., PEG or PVP, depicted as disordered coils). These solutions are of known osmotic pressure, pH, temperature and ionic composition (54). Equilibration of DNA under the osmotic stress of external polymer solution is effectively the same as exerting mechanical pressure on the DNA subphase with a piston that passes water and small solutes but not DNA. After equilibration under this known stress, DNA separation is measured either by X-ray scattering, if the DNA subphase is sufficiently ordered, or by densitometry (55). DNA density and osmotic stress thus determined immediately provide an equation of state (osmotic pressure as a function of the density of the DNA subphase) to be codified in analytical form over an entire phase diagram. See the color insert for a color version of this figure.

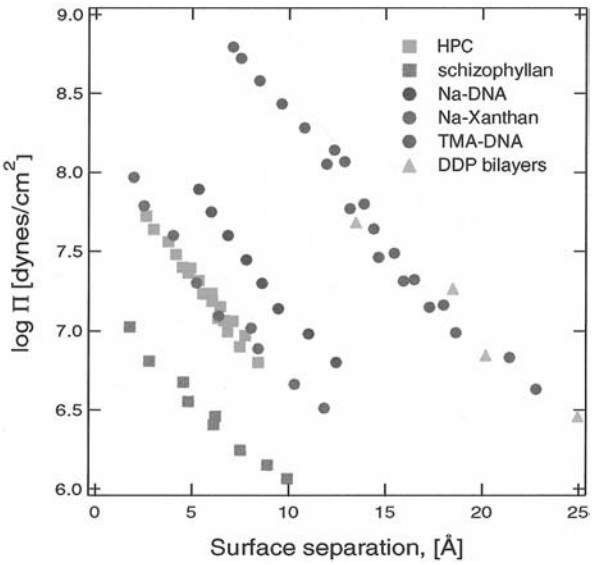

Figure 5 Interactions between biological macromolecules show pronounced universality at close surface-to-surface separations (or equivalently at very large densities). Hydroxypropyl cellulose, schizophillan, different DNA salts, xanthan, and DDP bilayers at small intermolecular separations (given in terms of the separation between effective molecular surfaces of the interacting molecules) all show strong repulsive interactions decaying with about the same characteristic decay length. The log-linear plot is thus more or less a straight line. (Composite data courtesy of D. C. Rau.) See the color insert for a color version of this figure.

determines the absolute magnitude of the hydration repulsion, which can be in the hundreds of atmospheres.

As already noted in this simple theoretical approach, the hydration decay length depends only on the bulk properties of the solvent, and not on the properties of the surface. To generalize this simplification, Kornyshev and Leikin (21) formulated a variant of the hydration force theory to also take into account explicitly the nature of surface ordering. They derive a modified hydration decay length that clearly shows how the surface order couples with the bare hydration decay length. Without going too deeply into this theory, we note that if the interacting surfaces have 2-dimensional ordering patterns characterized by a wave vector $Q = 2/\lambda$, where λ is the characteristic scale of the spatial variations of these patterns, then the effective hydration force decay length would be $\lambda_{KL} = \frac{1}{2}\, l_H\, (1 + 4^2(\lambda_H/\lambda)^2)^{-1/2}$. Inserting numbers for the case of DNA, where the ''surface'' structure has a characteristic scale of 1 to 2 Å, we realize that the hydration decay length in this case would be almost entirely determined by the surface structure and not the bulk solvent properties. Given the experimentally determined variety of forces between phospholipids (20), it is indeed quite possible that even in the simplest cases the measured decay lengths are not only those of the water solvent itself, but also include the surface properties via the characteristic scale of the surface ordering l_H.

The other important facet of this theory is that it predicts that in certain circumstances the hydration forces can become attractive (11). This is particularly important in the case of interacting DNA molecules where this hydration attraction connected with condensing agents can hold DNAs into an ordered array, even though the van der Waals forces themselves would be unable to accomplish that (22). This attraction is always an outcome of nonhomogeneous surface ordering and arises in situations where apposing surfaces have complementary checkerboard-like order (11). Unfortunately, in this situation, many mechanisms can contribute to attractions; therefore, it is difficult to argue for one strongest contribution.

2. Electrostatic Forces

Electrostatic forces between charged colloid bodies are among the key components of the force equilibria in (bio)colloid sys-

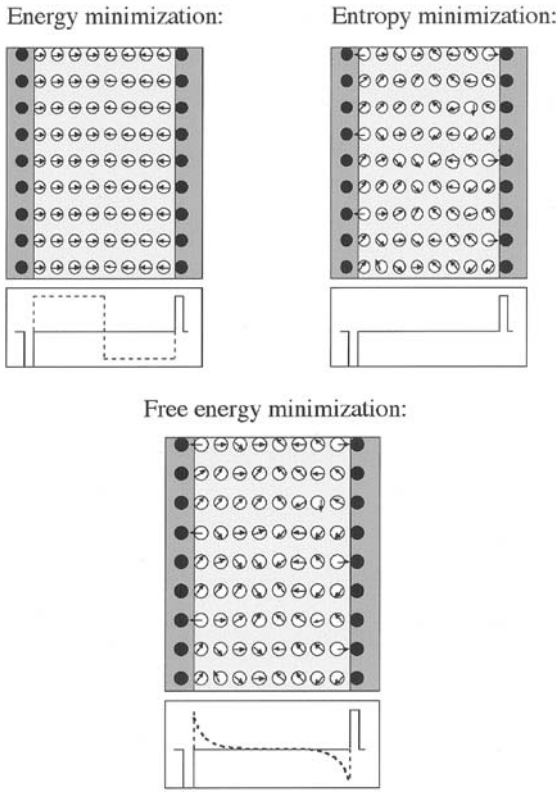

Figure 6 The hydration force. Marcelja and Radic (19) introduced an order parameter P that would capture the local condition, or local ordering, of solvent molecules between the surfaces. We represent it as an arrow (that has magnitude and direction) on each water molecule that is trapped between the two apposing surfaces and is being acted upon by the surface fields, depicted schematically with a bold line below each of the three drawings. Minimizing the energy corresponding to a spatial profile of P, leads to a configuration where P points (for example) away from both surfaces, and there is thus mismatch at the midplane (the dotted line below the leftmost drawing). The entropy would favor completely disordered configurations with no net value of P (the dotted line below the rightmost drawing). The free energy strikes a compromise between the two extrema, leading to a smooth profile of P, varying continuously as one goes from one surface to the other (the dotted line below the bottom drawing). As the two surfaces approach the nonmonotonic profile of the order parameter P leads to repulsive forces between them. See the color insert for a color version of this figure.

tems (23). At larger separations, they are the only forces that can counteract van der Waals attractions and thus stabilize colloid assembly. The crucial role of the electrostatic interactions in (bio)colloid systems is well documented and explored, following the seminal realization of Bernal and Fankuchen (24) that electrostatic interaction is the stabilizing force in tobacco mosaic virus (TMV) arrays.

Although the salient features of electrostatic interactions of fixed charges in a sea of mobile countercharges and salt ions are intuitively straightforward to understand, they are difficult to evaluate. These difficulties are clearly displayed by the early ambiguities in the sign of electrostatic interactions between two equally charged bodies that were first claimed to be attractive (Levine), then repulsive (Verwey-Overbeek), and finally that they were usually repulsive except if the counterions or the salt ions are of higher valency (25).

Here we introduce the electrostatic interaction on an intuitive footing (Fig. 7). Assume we have two equally charged bodies with counterions in-between. Clearly the minimum of electrostatic energy W_E (28), which for the electrostatic field configuration at the spatial position r, $E(r)$, is proportional to the integral of $E^2(r)$ over the whole space where one has nonzero electrostatic field, would correspond to adsorption of counterions to the charges leading to their complete neutralization. The equilibrium electrostatic field would thus be entirely concentrated next to the surface. However, at finite temperatures, it is not the electrostatic energy but rather the free energy (26), $F = W_E - TS$, also containing the entropy S of the counterion distribution, that should be minimized. The entropy of the mobile particles with the local density $\rho_i(r)$ [we assume there are more than 1 species of mobile particles, (e.g., counterions and salt ions) tracked through the index i] is taken as an ideal gas entropy (26), which is proportional to the volume integral of $\Sigma_i[\rho_i(r)\ln(\rho_i(r)/_{i0}) - (\rho_i(r)\text{-}\rho_{i0})]$, where ρ_{i0} is the density of the mobile charges in a reservoir that is in chemical equilibrium with the confined system under investigation. Entropy by itself would clearly lead to a uniform distribution of counterions between the charged bodies, $\rho_i(r) = \rho_{i0}$, whereas together with the electrostatic energy it obviously leads to a nonmonotonic profile of the mobile charge distribution between the surfaces, minimizing the total free energy of the mobile ions.

The above discussion, although far from being rigorous, contains the important theoretical underpinnings known as the Poisson–Boltzmann theory (27). To arrive at the central equation corresponding to the core of this theory, one simply has to formally minimize the free energy $F = W_E - TS$, just as in the case of structural interactions, together with the basic electrostatic equation (28) (the Poisson equation) that connects the sources of the electrostatic field with the charge densities of different ionic species. The standard procedure is now to minimize the free energy, take into account the Poisson equation, and what follows is the well-known Poisson–Boltzmann equation, the solution of which gives the nonuniform profile of the mobile charges between the surfaces with fixed charges. This equation can be solved explicitly for some particularly simple geometries (27). For two charged planar surfaces, the solution gives a screened electrostatic potential that decays exponentially away from the walls. It is thus smallest in the middle of the region between the surfaces and largest at the surfaces. The spatial variation of the electrostatic interaction is just as in the case of structural interactions described with a characteristic decay length, dubbed the Debye length in this case, which for uni-uni valent salts assumes the value

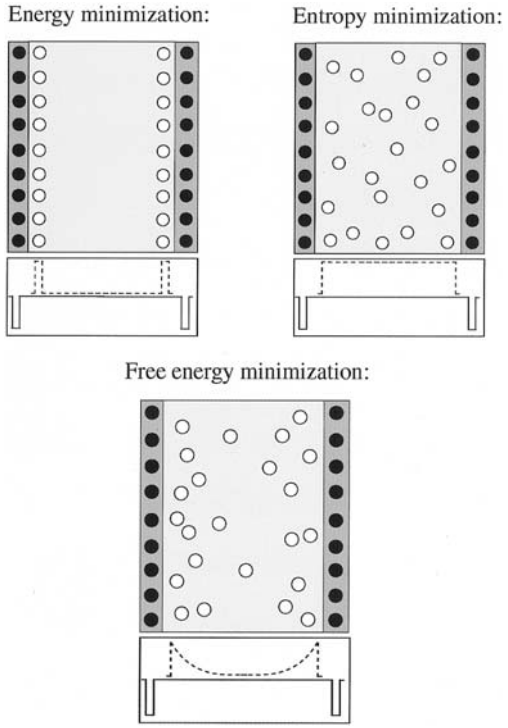

Figure 7 A pictorial exposition of the main ideas behind the Poisson–Boltzmann theory of electrostatic interactions between (bio)colloidal surfaces. Electrostatic energy by itself would favor adsorption of counterions (white circles) to the oppositely charged surfaces (black circles). The equilibrium profile of the counterions in this case is presented by the dotted line below the leftmost drawing. Entropy, to the contrary, favors a completely disordered configuration (i.e., a uniform distribution of counterions between the surfaces), presented by the dotted line below the rightmost drawing. The free energy works a compromise between the two principles leading to a nonmonotonic profile of the counterion density (25), varying smoothly in the intersurface region. As the two surfaces are brought close, the overlapping counterion distributions originating at the fixed charge at the surfaces (the bold line below each drawing) create repulsive forces between them. See the color insert for a color version of this figure.

of $\lambda_D = 3$ Å$/\sqrt{I}$, where I is the ionic strength of the salt in moles per liter. A 0.1 molar solution of uni-uni valent salt, such as NaCl, would thus have the characteristic decay length of about 9.5 Å. Beyond this separation, the charged bodies no longer feel each other. By adding or removing salt from the bathing solution, we are thus able to regulate the range of electrostatic interactions.

The exponential decay of the electrostatic field away from the charged surfaces with a characteristic length, independent (to the lowest order) of the surface charge, is one of the most important results of the Poisson–Boltzmann theory.

Obviously, as the surfaces come closer together, their decaying electrostatic potentials begin to interpenetrate (25). The consequence of this interpenetration is a repulsive force between the surfaces that again decays exponentially with the intersurface separation and a characteristic length again equal to the Debye length. For two planar surfaces at a separation D, bearing sufficiently small charges, characterized by the surface charge density σ, so that the ensuing electrostatic potential is never larger than k_BT/e, where k_B is Boltzmann's constant and e is the elementary electron charge, one can derive (27) for the interaction free energy per unit surface area $F(D)$ the expression $F(D) \sim \sigma^2 \exp(-D/\lambda_D)$. Obviously the typical magnitude of the electrostatic interaction in different systems depends on the magnitude of the surface charge. It would not be unusual in lipids to have surface charge densities in the range of 1 elementary charge per 50 to 100 Å^2 surface area (29). For this range of surface charge densitities, the constant prefactor in the expression for the osmotic pressure would be of the order 0.4 to 1.2×10^7 N/m.

The same type of analysis would also apply to two charged cylindrical bodies (e.g., two molecules of DNA) interacting across an electrolyte solution. What one evaluates in this case is the interaction free energy per unit length of the cylinders (30), $g(R)$, where R is the separation between the cylinders that can be obtained in the approximate form $g(R) \sim \mu^2 \exp(-R/\lambda_D)$. It is actually possible to also get an explicit form (30) of the interaction energy between two cylinders even if they are skewed by an angle θ between them. In this case, the relevant quantity is the interaction free energy itself (if θ is nonzero, then the interaction energy does not scale with the length of the molecules) that can be obtained in a closed form as $F(R,\theta) \sim \mu^2 \lambda_D R^{1/2} \exp(-R/\lambda_D)/\sin(\theta)$.

The predictions for the forces between charged colloid bodies have been reasonably well borne out for electrolyte solutions of uni-uni valent salts (31). In that case, there is near quantitative agreement between theory and experiment. However, for higher valency salts, the Poisson–Boltzmann theory does not only give the wrong numerical values for the strength of the electrostatic interactions, but also misses their sign. In higher valency salts, the correlations among mobile charges between charged colloid bodies due to thermal fluctuations in their mean concentration lead effectively to attractive interactions (32) that are in many respects similar to the van der Waals forces that are analyzed next.

3. van der Waals Forces

van der Waals charge fluctuation forces are special in the sense that they are a consequence of thermodynamic and quantum mechanical fluctuations of the electromagnetic fields (15). They exist even if the average charge, dipole moment, or higher multipole moments on the colloid bodies are zero. This is in stark contrast to electrostatic forces that require a net charge or a net polarization to drive the interaction. This also signifies that the van der Waals forces are much more general and ubiquitous than any other force between colloid bodies (9).

There are many different approaches to the van der Waals forces (15,33). For interacting molecules, one can distinguish different contributions to the van der Waals force, stemming from thermally averaged dipole–dipole potentials (the Keesom interaction), dipole-induced dipole interactions (the Debye interaction), and induced dipole-induced dipole interactions (the London interaction) (34). They are all attractive and their respective interaction energy decays as the sixth power of the separation between the interacting molecules. The magnitude of the interaction energy depends on the electromagnetic absorption (dispersion) spectrum of interacting bodies, thus also the term dispersion forces.

For large colloidal bodies composed of many molecules, the calculation of the total van der Waals interactions is no trivial matter (15), even if we know the interactions between individual molecules composing the bodies. Hamaker assumed that one can simply add the interactions between composing molecules in a pairwise manner. It turned out that this was a very crude and simplistic approach to van der Waals forces in colloidal systems because it does not take into account the highly nonlinear nature of the van der Waals interactions in condensed media. Molecules in a condensed body interact among themselves, thus changing their properties (c.f. their dispersion spectrum) that in their turn modify the van der Waals forces between them.

Lifshitz, following work of Casimir (9,15), realized how to circumvent this difficulty and formulated the theory of van der Waals forces in a way that already includes all these nonlinearities. The main assumption of this theory is that the presence of dielectric discontinuities as in colloid surfaces, modifies the spectrum of electromagnetic field modes between these surfaces (Fig. 8). As the separation between colloid bodies varies, so do the eigenmode frequencies of the electromagnetic field between and within the colloid bodies. It is possible to deduce the change in the free energy of the electromagnetic modes due to the changes in the separation between colloid bodies coupled to their dispersion spectral characteristics (35).

Based on the work of Lifshitz, it is now clear that the van der Waals interaction energy is just the change of the free energy of field harmonic oscillators at a particular eigenmode frequency ω as a function of the separation between the interacting bodies D and temperature T, $\omega = \omega(D,T)$. With this equivalence in mind, it is quite straightforward to calculate the van der Waals interaction free energy between two planar surfaces at a separation D and temperature T; the dielectric permittivity between the two surfaces, ε and within the surfaces, ε', must both be known as a function of the frequency of the electromagnetic field (35). This is a consequence of the fact that, in general, the dielectric media comprising the surfaces as well as the space between them are dispersive, meaning that their dielectric permittivities depend on frequency of the electromagnetic field [i.e., $\varepsilon = \varepsilon(\omega)$]. With this in mind one can derive the interaction free energy per unit surface area of the interacting surfaces in the form $F(D) = A/12\pi D^2$, where the s.c. Hamaker coefficient A depends on the difference between the dielectric permittivities of the interacting materials at different imaginary frequencies. It can be in general split into two terms: the first term in the Hamaker coefficient is due to thermodynamic fluctuations, such as Brownian rotations of the dipoles of the molecules composing the media or the averaged dipole-induced dipole forces and depends on the static ($\omega = 0$) dielectric response of the interacting media, whereas the second term is purely quantum mechanical in nature (15). The imaginary argument of the dielectric constants is not that odd because $\varepsilon(\iota\zeta)$ is an even function of ζ, which makes $\varepsilon(\iota\zeta)$ also a purely real quantity (35).

To evaluate the magnitude of the van der Waals forces, one thus has to know the dielectric dispersion $\varepsilon(\omega)$ of all the media involved. This is no simple task and can be accomplished only for very few materials (34). Experiments seem to be a much more straightforward way to proceed. The values for the Hamaker coefficients of different materials interacting

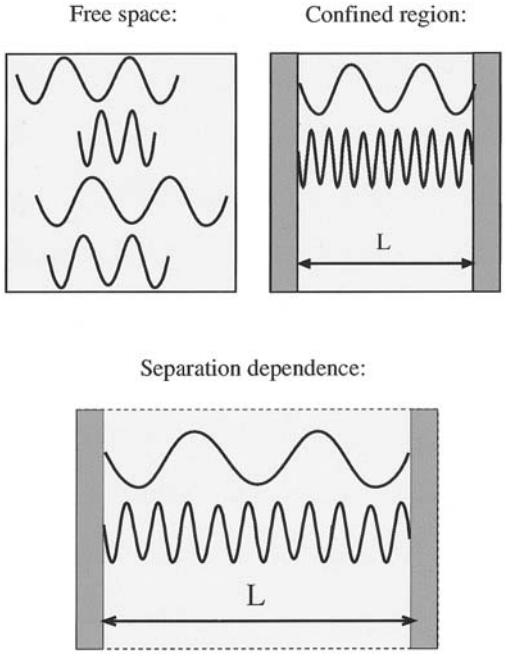

Figure 8 A pictorial introduction to the theory of Lifshitz–van der Waals forces between colloid bodies. Empty space is alive with electromagnetic (EM) field modes that are excited by thermal as well as quantum mechanical fluctuations. Their frequency is unconstrained and follows the black body radiation law. Between dielectric bodies, only those EM modes survive that can fit into a confined geometry. As the width of the space between the bodies varies, so do the allowed EM mode frequencies. Every mode can be treated as a separate harmonic oscillator, each contributing to the free energy of the system. Because this free energy depends on the frequency of the modes, that in turn depend on the separation between the bodies, the total free energy of the EM modes depends on the separation between the bodies. This is an intuitive description of the Lifshitz–van der Waals force (15). See the color insert for a color version of this figure.

across water are between 0.3 and 2.0 $\times$ 10^{-20} J. Specifically for lipids, the Hamaker constants are quite close to theoretical expectations except for the phosphatidylethanolamines that show much larger attractive interactions probably due to headgroup alignment (31). Evidence from direct measurements of attractive contact energies as well as direct force measurements suggest that van der Waals forces are more than adequate to provide attraction between bilayers for them to form multilamellar systems (36).

For cylinders the same type of argument applies, except that due to the geometry the calculations are a bit more tedious (37). Here the relevant quantity is not the free energy per unit area but the interaction free energy per unit length of the two cylinders of radius a, $g(R)$, considered to be parallel at a separation R. The calculation (38) leads to the following form $g(R) \sim A\ a^4/R^5$, where the constant A again depends on the differences between dielectric permittivities $\varepsilon_{\parallel}$, the parallel, and $\varepsilon_{\perp}$, the perpendicular components of the dielectric permittivity of the dielectric material of the cylinders, and ε_m, the dielectric permittivity of the bathing medium.

If, however, the 2 interacting cylinders are skewed, then the interaction free energy $G(R, \theta)$, this time not per length, is obtained (38) in the form $G(R) \sim (A + B\cos^2\theta)(a^4/R^4\sin\theta.)$ The constants A and B describe the dielectric mismatch between the cylinder and the bathing medium at different imaginary frequencies. The same correspondence between the thermodynamic and quantum mechanical parts of the interactions as for two parallel cylinders also applies to this case. Clearly, the van der Waals force between two cylinders has a profound angular dependence that in general creates torques between the two interacting molecules.

Taking the numerical values of the dielectric permittivities for two interacting DNA molecules, one can calculate that the van der Waals forces are quite small, typically 1 to 2 orders of magnitude smaller than the electrostatic repulsions between them, and in general cannot hold the DNAs together in an ordered array. Other forces, leading to condensation phenomena in DNA (10) clearly have to be added to the total force balance in order to get a stable array. There is as yet still no consensus on the exact nature of these additional attractions. It seems that they are due to the fluctuations of counterion atmosphere close to the molecules.

4. The DLVO Model

The popular Derjaguin-Landau-Verwey-Overbeek (DLVO) (9,25) model assumes that electrostatic double-layer and van der Waals interactions govern colloid stability. Applied with a piety not anticipated by its founders, this model actually does work rather well in surprisingly many cases. Direct osmotic stress measurements of forces between lipid bilayers show that at separations less than $\sim$10 Å there are qualitative deviations from DLVO thinking (39). For micron-size objects and for macromolecules at greater separations, electrostatic double-layer forces and sometimes van der Waals forces tell us what we need to know about interactions governing movement and packing.

5. Geometric Effects

Forces between macromolecular surfaces are most easily analyzed in plane parallel geometry. Because most of the interacting colloid surfaces are not planar, one has either to evaluate molecular interactions for each particular geometry or to devise a way to connect the forces between planar surfaces with forces between surfaces of a more general shape. The Derjaguin approximation (9) assumes that interactions between curved bodies can be decomposed into interactions between small plane-parallel sections of the curved bodies (Fig. 9). The total interaction between curved bodies would be thus equal to a sum where each term corresponds to a partial interaction between quasi-plane-parallel sections of the two bodies. This idea can be given a completely rigorous form and leads to a connection between the interaction free energy per unit area of two interacting planar surfaces, $F(D)$, and the force acting between two spheres at minimal separation D, $f(D)$, 1 with the mean radius of curvature R_1 and the other 1 with R_2. The formal equivalence can be written as follows, $f(D) = 2\pi (R_1R_2/(R_1 + R_2))\ F(D)$. A similar equation can also be obtained for 2 cylinders in the form, $f(D) = 2\pi(R_1R_2)^{1/2}\ F(D)$.

These approximate relations clearly make the problem of calculating interactions between bodies of general shape tractable. The only caveat here is that the radii of curvature should be much larger than the proximal separation between the two interacting bodies, effectively limiting the Derjaguin approximation to sufficiently small separations.

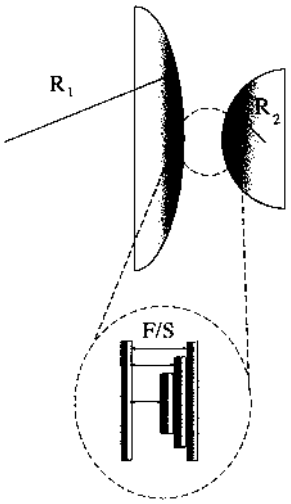

Figure 9 The Derjaguin approximation. To formulate forces between oppositely curved bodies (e.g., cylinders, spheres, etc.) is very difficult, but it is often possible to use an approximate procedure. Two curved bodies (two spheres of unequal radii in this case) are approximated by a succession of planar sections, interactions between which can be calculated relatively easy. The total interaction between curved bodies is obtained through a summation over these planar sections.

Using the Derjaguin formula or evaluating the interaction energy explicitly for those geometries for which this indeed is not an insurmountable task, one can now obtain a whole zoo of DLVO expressions for different interaction geometries (Fig. 10). The salient features of all these expressions are that the total interaction free energy always has a primary minimum, that can only be eliminated by strong short-range hydration forces, and a secondary minimum due to the compensation of screened electrostatic repulsion and van der Waals–Lifshitz attraction. The position of the secondary minimum depends as much on the parameters of the forces (Hamaker constant, fixed charges, and ionic strength) as on the interaction geometry. Generally, the range of interaction between the bodies of different shapes is inversely proportional to their radii of curvature.

Thus, the longest-range forces are observed between planar bodies, and the shortest between small (pointlike) bodies.

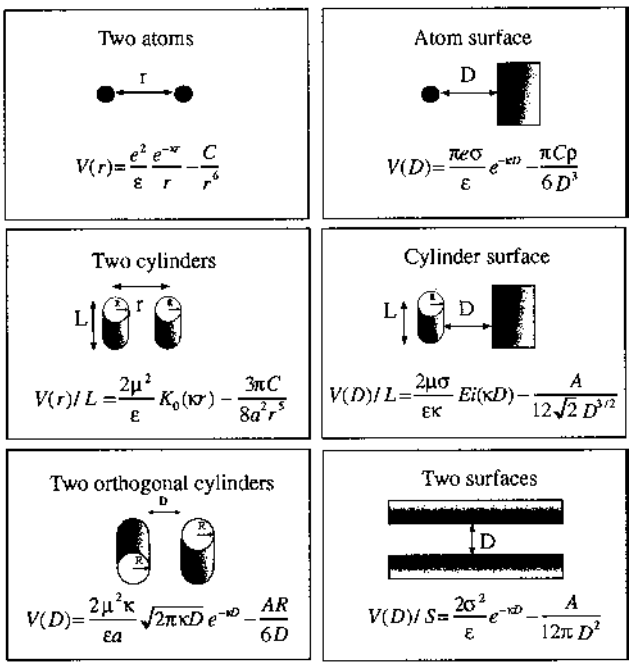

Figure 10 A menagerie of DLVO interaction expressions for different geometries most commonly encountered in biological milieu. Two small particles, a particle and a wall, 2 parallel cylinders, a cylinder close to a wall, 2 skewed cylinders and 2 walls. The DLVO interaction free energy is always composed of a repulsive electrostatic part (calculated from a linearized Poisson–Boltzmann theory) and an attractive van der Waals part. Charge: e, charge per unit length of a cylinder: μ, charge per unit surface area of a wall: σ, C is a geometry-dependent constant, ε the dielectric constant, κ the inverse Debye length, and ρ the density of the wall material. The functions $K_0(x)$ (the Bessel function K_0) and $Ei(x)$ (the exponential integral function) both depend essentially exponentially on their respective argument.

What we have not indicated in Fig. 7 is that the interaction energy between two cylindrical bodies, skewed at a general angle θ and not just for parallel or crossed configurations, can be obtained in an explicit form. It follows simply from these results that the configuration of two interacting rods with minimal interaction energy is the one corresponding to $\theta=\pi/2$ (i.e., corresponding to crossed rods).

6. Fluctuation Forces

The term ''fluctuation forces'' is a bit misleading in this context because clearly van der Waals forces are already fluctuation forces. What we have in mind is thus a generalization of the van der Waals forces to situations where the fluctuating quantities are not electromagnetic fields but other quantities subject to thermal fluctuations. No general observation as to the sign of these interactions can be made, they can be either repulsive or attractive and are as a rule of thumb comparable in magnitude to the van der Waals forces.

The most important and ubiquitous force in this category is the undulation or Helfrich force (41). It has a very simple origin and operates among any type of deformable bodies as long as their curvature moduli are small enough (comparable to thermal energies). It was shown to be important for multilamellar lipid arrays (41) as well as in hexagonal polyelectrolyte arrays (42) (Fig. 11).

The mechanism is simple. The shape of deformable bodies fluctuates because of thermal agitation (Brownian motion) (26). If the bodies are close to each other, the conformational fluctuations of one will be constrained by the fluctuations of its neighbors. Thermal motion makes the bodies bump into each other, which creates spikes of repulsive force between them. The average of this force is smooth and decays continuously with the mean separation between the bodies.

One can estimate this steric interaction for multilamellar lipid systems and for condensed arrays of cylindrical polymers (Fig. 11). The only quantity entering this calculation is the elastic energy of a single bilayer that can be written as the square of the average curvature of the surface, summed over the whole area of the surface, multiplied by the elastic modulus of the membrane, K_C. K_C is usually between 10 and 50 k_BT (43) for different lipid membranes. If the instantaneous deviation of the membrane from its overall planar shape in the plane is now introduced as u, the presence of neighboring membranes introduces a constraint on the fluctuations of u that basically demands, that the average of the square of u must be proportional to D^2, where D is the average separation between the membranes in a multilamellar stack. Thus, we should have $u^2 \sim D^2$. The free energy associated with this constraint can now be derived in the form (40) $F(D) \sim (k_BT)^2/(K_CD^2)$, and is seen to decay in inverse proportion to the separation between bilayers squared.

It has thus obviously the same dependence on D as the van der Waals force. This is, however, not a general feature of undulation interactions as the next example clearly shows. Also, we only indicated the general proportionality of the interaction energy. Calculation of the prefactors can be a difficult (44), especially because the elastic bodies usually do not

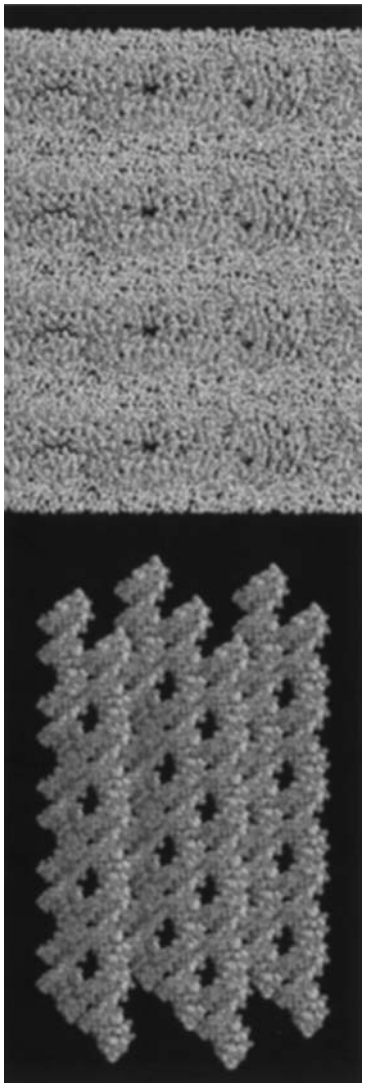

Figure 11 Thermally excited conformational fluctuations in a multilamellar membrane array (small molecules are waters and long-chain molecules are phospholipids) or in a tightly packed polyelectrolyte chain array (the figure represents a hexagonally packed DNA array) lead to collisions between membranes or polyelectrolyte chains. These collisions contribute an additional repulsive contribution to the total osmotic pressure in the array, a repulsion that depends on the average spacing between the fluctuating objects. See the color insert for a color version of this figure.

interact with idealized hard repulsions but rather through soft potentials that have both attractive as well as repulsive regimes.

The same line of thought can now be applied to flexible polymers in a condensed array (42). This system is a 1-dimensional analog of the multilamellar membrane system. For polymers, the elastic energy can be written similarly to the membrane case as the square of the local curvature of the polymer, multiplied by the elastic modulus of the polymer, integrated over its whole length. The elastic modulus K_c is usually expressed through a persistence length $L_p = K_c/(k_BT)$. The value of the persistence length tells us how long a polymer can be before the thermal motion forces it to fluctuate wildly. For DNA, this length is about 50 nm. However, it spans the whole range of values between about 10 nm for hyaluronic acid, all the way to 3 mm for microtubules. Using the same constraint for the average fluctuations of the polymer away from the straight axis, one derives for the free energy change due to this constraint the relationship $F(D) \sim (k_BT)/(L_p{}^{1/3}D^{2/3})$ (42).

Clearly, the D dependence for this geometry is much different from the one for van der Waals force, which would be D^{-5}. There is thus no general connection between the van der Waals force and the undulation fluctuation force. Here again, one has to indicate that if the interaction potential between fluctuating bodies is described by a soft potential, with no discernible hard core, the fluctuation interaction can have a profoundly different dependence on the mean separation (42).

Apart from the undulation fluctuation force, there are other fluctuation forces. The most important among them appears to be the monopolar charge fluctuation force (45), recently investigated in the context of DNA condensation. It arises from transient charge fluctuations along the DNA molecule due to constant statistical redistributions of the counterion atmosphere.

The theory of charge fluctuation forces is quite intricate and mathematically demanding (46). Let us just quote a rather interesting result, viz. if two point charges interact via a ''bare'' potential $V_0(R)$, where R is the separation between them, then the effect of the thermal fluctuations in the number of counterions surrounding these charges would lead to an effective interaction of the form $V(R) \sim - k_BTV_0{}^2(R)$. The fluctuation interaction in this case would thus be attractive and proportional to the square of the bare interaction.

This simple result already shows one of the salient features of the interaction potential for monopolar charge fluctuation forces, viz. it is screened with half the Debye screening length [because of $V_0{}^2(R)$]. If there is no screening, however, the monopolar charge fluctuation force becomes the strongest and longest ranged among all fluctuation forces. It is however much less general than the related van der Waals force, and it is still not clear what the detailed conditions should be for its appearance, the main difficulty being the question of whether charge fluctuations in the counterion atmosphere are constrained.

7. Lessons

Molecular forces apparently convey a variety that is surprising considering that they are all to some extent or another just a variant of electrostatic interactions. Quantum and thermal fluctuations apparently modify the underlying electrostatics, leading to qualitatively novel and unexpected features. The

zoo of forces obtained in this way is what one has to deal with and understand when trying to make them work for us.

III. DNA MESOPHASES

A. Polyelectrolyte Properties of DNA

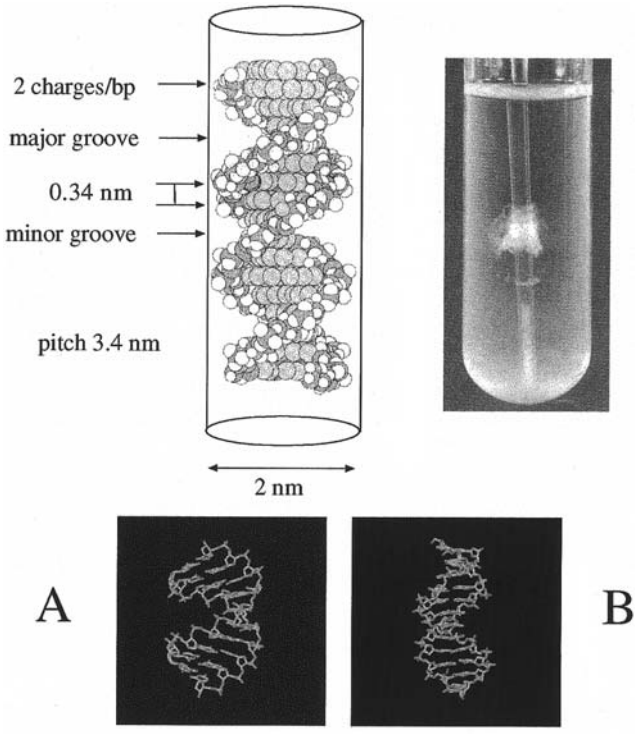
We can define several levels of DNA organization similarly to (1). Its primary structure is the sequence of base pairs. Its secondary structure is the famous double helix that can exist in several conformations. In solution, the B-helical structure dominates (47). The bases are perpendicular to the axis of the molecule and are 0.34 nm apart, and 10 of them make 1 turn of the helix. These parameters can vary for DNA in solution where up to 10.5 base pairs can make a whole turn of the double helix (48). In the A structure, the bases are tilted with respect to the direction of the helix, and this arrangement yields an internal hole, wider diameter, and closer packing (Fig. 12). Other conformations, such as the left-handed Z form, are rare. In solution, DNA's tertiary structure includes the many bent and twisted conformations in 3 dimensions.

DNA lengths can reach macroscopic dimensions. For instance, the human genome is coded in approximately 3 billion base pairs with a collective linear stretch on the order of a meter. Obviously, this molecule must undergo extensive compaction in order to fit in the cell nucleus. In natural environments, DNA is packaged by basic proteins, which form chromatin structures to keep DNA organized. In the test tube, DNA can be packaged into very tight and dense structures as well, primarily by various ''condensing'' agents. Their addition typically induces a random coil to globule transition. At large concentrations, DNA molecules, like lipids, form ordered liquid crystalline phases (10) that have been studied extensively at different solution conditions (8).

In vitro, at concentrations above a critical value (49), polyelectrolyte DNA self-organizes in highly ordered mesophases (8). In this respect, it is a lyotropic liquid crystal. But contrary to the case of lipid mesophases, where the shape of constituent molecules plays a determining role, the organization of DNA in condensed phases is primarily a consequence of its relatively large stiffness (8). The orientational ordering of DNA at high concentrations is promoted mostly by the interplay between entropically favored disorder or misalignment and the consequent price in terms of the high interaction energy. The mechanism of orientational ordering is thus the same as in standard short nematogens (50). The main difference being due to the large length of polymeric chains. The discussion that follows concentrates mostly on very long, on the order of 1000 persistence lengths thus microns long, DNA molecules.

B. Flexibility of DNA Molecules in Solution

In isotropic solutions, DNA can be in one of several forms. For linear DNA, individual molecules are effectively straight over the span of a persistence length that can also be defined as the exponential decay length for the loss of angular correlation between 2 positions along the molecule, while for longer



Polymer	Solvent	Persistence length [nm]

Figure 12 Structural parameters of a DNA molecule. The two relevant configurations of the DNA backbone: A-DNA, common at small hydrations or high DNA densities, and B-DNA common in solution at large hydrations and lower DNA densities. The test tube holds ethanol-precipitated DNA in solution. Its milky color is due to the light scattering by thermal conformational fluctuations in the hexatic phase (see main text). Box: typical persistence lengths for different (bio)polymer chains in nm. See the color insert for a color version of this figure.

lengths they form a wormlike random coil. The persistence length of DNA is about 50 nm (1). The persistence length has been determined by measuring the diffusion coefficient of different-length DNA molecules using dynamic light scattering and by enzymatic cyclization reactions (51). It depends only weakly on the base-pair sequence and ionic strength.

DNA can also be circular as in the case of a plasmid. The closed form of a plasmid introduces an additional topological constraint on the conformation that is given by the linking number Lk (2). The linking number gives the number of heli-

cal turns along a circular DNA molecule. Because plasmid DNA is closed, Lk has to be an integer number. By convention, Lk of a closed right-handed DNA helix is positive. The most frequent DNA conformation for plasmids in cells is negatively supercoiled. This means that for such plasmids Lk is less than it would be for a torsionally relaxed DNA circle—negatively supercoiled DNA is underwound. This is a general phenomenon with important biological consequences. It seems that free energy of negative supercoiling catalyzes processes that depend on DNA untwisting, such as DNA replication and transcription, which rely on DNA (52). Although the sequence of bases in exons determine the nature of proteins synthesized, it is possible that such structural features dictate the temporal and spatial evolution of DNA-encoded information.

C. Liquid Crystals

The fact that DNA is intrinsically stiff makes it form liquid crystals at high concentration (8). Known for about 100 years, the simplest liquid crystals are formed by rodlike molecules. Solutions of rods exhibit a transition from an isotropic phase with no preferential orientation to a nematic phase, a fluid in which the axes of all molecules point on average in 1 direction (Fig. 11). The unit vector in which the molecules point is called the nematic director n. Nematic order is orientational order (50), in contrast to positional order that distinguishes between fluid and crystalline phases. Polymers with intrinsic stiffness can also form liquid crystals. This is because a long polymer with persistence length L_p acts much like a solution of individual rods that are all one persistence length long, thus the term ''polymer nematics'' (53).

If the molecules that comprise the liquid crystal are chiral, have a natural twist such as double-helical DNA, then their orientational order tends to twist. This twist originates from the interaction between two molecules that are both of the same handedness. This chiral interaction is illustrated in Fig. 13 for two helical or screwlike molecules. For steric reasons, two helices pack best when tilted with respect to each other. Instead of a nematic phase chiral molecules form a cholesteric phase (50). The cholesteric phase is a twisted nematic phase in which the nematic director twists continuously around the so-called cholesteric axis as shown in Fig. 13. Using the same arguments as for plain polymers, chiral polymers will form polymer cholesterics.

Both cholesteric and hexagonal liquid crystalline DNA phases were identified in the 1960s. This discovery was especially exciting because both phases were also found in biological systems. The hexagonal liquid crystalline phase can be seen in bacterial phages, and the cholesteric phase can be seen in cell nuclei of dinoflagellates (8).

D. Measurements of Forces Between DNA Molecules

Liquid crystalline order lets us measure intermolecular forces directly. With the osmotic stress method, DNA liquid crystals

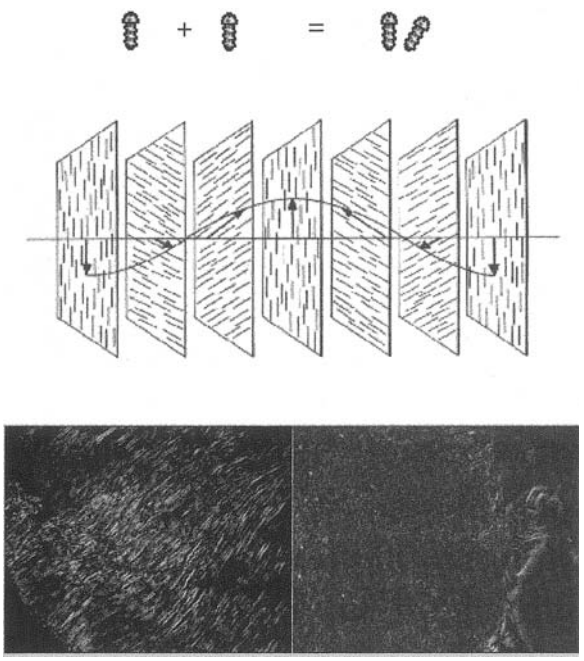

Figure 13 Chiral interaction for two helical or screwlike molecules. For steric reasons, two helices just as two screws (depicted on the figure) pack best when slightly tilted with respect to each other. Because of DNA's double-stranded, helical nature, it is a type of molecular screw and exhibits chiral interactions. Instead of a nematic phase depicted on Fig. 11, characterized by the average constant direction of molecules, chiral molecules form a cholesteric phase (50). The cholesteric phase is a twisted nematic phase in which the nematic director twists continuously around a ''cholesteric axis'' depicted on the middle drawing. Under crossed polarizers (bottom), the DNA cholesteric phase creates a characteristic striated texture. For long DNA molecules, the striations appear disordered.

are equilibrated against neutral polymer (e.g., PEG or PVP) solutions of known osmotic pressure, pH, temperature, and ionic composition (54). Equilibration of DNA under osmotic stress of external polymer solution is effectively the same as exerting mechanical pressure on the DNA subphase with a piston [see Fig. 4]. In this respect, the osmotic stress technique is formally much similar to the Boyle experiment where one compresses a gas with mechanical pistons and measures the ensuing pressure. After equilibration under this known stress, DNA separation is measured either by X-ray scattering, if the DNA subphase is sufficiently ordered, or by straightforward densitometry (55). Known DNA density and osmotic stress immediately provide an equation of state (osmotic pressure as a function of the density of the DNA subphase) to be codified in analytical form for the entire phase diagram. Then, with the local packing symmetry derived from X-ray scatter-

ing (7,54), and sometimes to correct for DNA motion (42), it is possible to extract the bare interaxial forces between molecules that can be compared with theoretical predictions as developed in Chapter 2. In vivo observation of DNA liquid crystals (56) shows that the amount of stress needed for compaction and liquid crystalline ordering is the same as for DNA in vitro.

E. Interactions Between DNA Molecules

Performed on DNA in univalent salt solutions, direct force measurements reveal two types of purely repulsive interactions between DNA double helices (4):

1. At interaxial separations less than ~3 nm (surface separation ~1 nm), an exponentially varying ''hydration'' repulsion believed to originate from partially ordered water near the DNA surface.
2. At surface separations greater than 1 nm, measured interactions reveal electrostatic double-layer repulsion, presumably from negative phosphates along the DNA backbone.

Measurements give no evidence for a significant DNA–DNA attraction expected on theoretical grounds (57). Although charge fluctuation forces must certainly occur, they appear to be negligible at least for liquid crystal formation in monovalent-ion solutions. At these larger separations, the double-layer repulsion often couples with configurational fluctuations to create exponentially decaying forces whose decay length is significantly larger than the expected Debye screening length (42).

Bare short-range molecular interactions between DNA molecules appear to be insensitive to the amount of added salt. This has been taken as evidence that they are not electrostatic in origin, as attested also by similar interactions between completely uncharged polymers such as schizophilline (Fig. 5). The term hydration force associates these forces with perturbations of the water structure around DNA surface (54). Alternatively, short-range repulsion has been viewed as a consequence of the electrostatic force specific to high DNA density and counterion concentration (58).

F. High-density DNA Mesophases

Ordering of DNA can be induced by two alternative mechanisms. First of all, attractive interactions between different DNA segments can be enhanced by adding multivalent counterions believed to promote either counterion correlation forces (59) or electrostatic (60) and hydration attraction (22). In these cases, DNA aggregates spontaneously. Alternatively, one can add neutral crowding polymers to the bathing solution that phase separate from DNA and exert osmotic stress on the DNA subphase (61). In this case the intersegment repulsions in DNA are simply counteracted by the large externally applied osmotic pressure. DNA is forced in this case to condense under externally imposed constraints. This latter case is formally (but only formally) analogous to a Boyle gas pressure experiment but with osmotic pressure playing the role of ordinary pressure. The main difference being that ordinary pressure is set mechanically, whereas osmotic pressure has to be set through the chemical potential of water, which is in turn controlled by the amount of neutral crowding polymers (e.g., PEG, PVP, dextran) in the bathing solution (55).

At very high DNA densities, where the osmotic pressure exceeds 160 atm, DNA can exist only in a (poly)crystalline state (62). Nearest neighbors in such an array are all oriented in parallel and show correlated (nucleotide) base stacking between neighboring duplexes (Figs. 11 and 14). This means that there is a long-range correlation in the positions of the backbone phosphates between different DNA molecules in the crystal. The local symmetry of the lattice is monoclinic. Because of the high osmotic pressure, DNA is actually forced to be in an A conformation characterized by a somewhat larger outer diameter as well as a somewhat smaller pitch than in the canonical B conformation (see Fig. 12), which persists at smaller densities. If the osmotic pressure of such a crystal is increased above 400 atm, the helix begins to crack and the sample loses structural homogeneity (62).

Lowering the osmotic pressure does not have a pronounced effect on the DNA crystal until it is down to ~160 atm. Then the crystal as a whole simultaneously expands while individual DNA molecules undergo an A-B conformational transition (see Fig. 14) (62). This phase transformation is thus first order, and besides being a conformational transition for single DNAs, is connected also with the melting of the base stacking as well as positional order of the helices in the lattice. The ensuing low-density mesophase, where DNA is in the B conformation, is therefore characterized by short range base stacking order, short range 2-dimensional positional order and long-range bond orientational order (Fig. 15) (63). This order is connected with the spatial direction of the nearest neighbors (64). It is for this reason that the phase has been termed a ''line hexatic'' phase. Hexatics usually occur only in 2-dimensional systems. They have crystalline bond orientational order but liquidlike positional order. There might be a hexatic-hexagonal columnar transition somewhere along the hexatic line, though a direct experimental proof is lacking.

The difference between the 2 phases is that the hexagonal columnar phase has also a crystalline positional order and is thus a real 2-dimensional crystal (see Fig. 15) (65). It is the long-range bond orientational order that gives the line hexatic phase some crystalline character (66). The DNA duplexes are still packed in parallel, while the local symmetry perpendicular to the long axes of the molecules is changed to hexagonal. The directions of the nearest neighbors persist through macroscopic dimensions (on the order of mm) while their positions tend to become disordered already after several (typically 5 to 10) lattice spacings. This mesophase has a characteristic X-ray scattering fingerprint (see Fig. 15). If the X-ray beam is directed parallel to the long axis of the molecules, it will show a hexagonally symmetric diffraction pattern of broad liquidlike peaks (67).

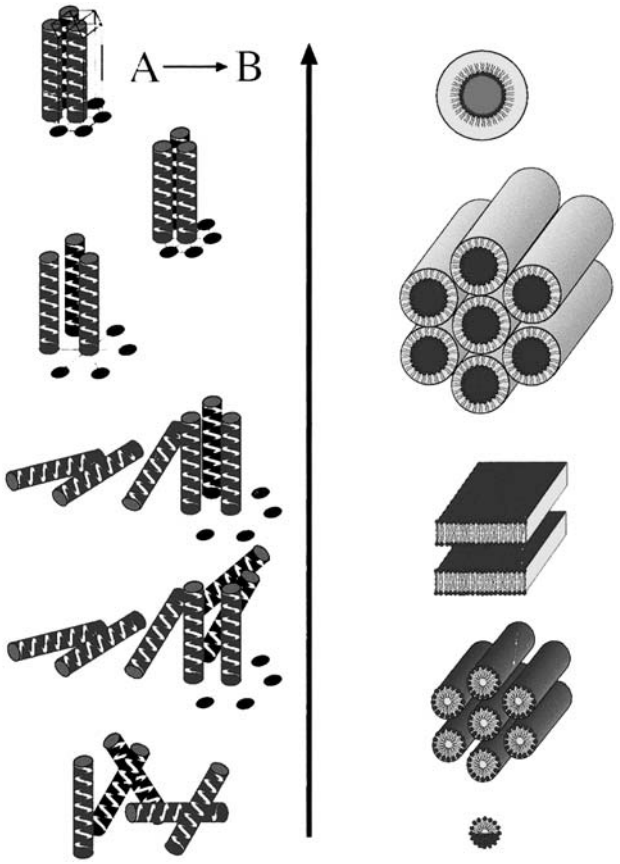

Figure 14 Schematic phase diagrams for DNA (left) and lipids (right). In both cases, the arrow indicates increasing density in both cases. DNA starts (bottom) as a completely disordered solution. It progresses through a sequence of blue phases characterized by cholesteric pitch in two perpendicular directions (68), then to a cholesteric phase with pitch in only one direction. At still larger densities, this second cholesteric phase is succeeded by a hexatic phase, characterized by short-range, liquidlike positional order and long-range, crystallike bond orientational (or hexatic order, indicated by lines). At highest densities, there is a crystalline phase characterized by long-range positional order of the molecules and long-range base stacking order in the direction of the long axes of the molecules. Between the hexatic and the crystalline forms, there might exist a hexagonal columnar liquid-crystalline phase, that is similar to a crystal, but with base stacking order only on short scales. The lipid-phase diagram (77) is a composite of results obtained for different lipids. It starts from a micellar solution and progresses through a phase of lipid tubes to a multilamellar phase of lipid bilayers. This is followed by an inverted hexagonal columnar phase of water cylinders and possibly goes to an inverted micellar phase. Most lipids show only a subset of these possibilities. Boundaries between the phases shown here might contain exotic cubic phases not included in this picture. See the color insert for a color version of this figure.

Typical lattice spacings in the line hexatic phase are between 25 and 35 Å (i.e., between 600 and 300 mg/mL of DNA) (63). The free energy in this mesophase is mostly a consequence of the large hydration forces stemming from removal of water from the phosphates of the DNA backbone. Typically independent of the ionic strength of the bathing solution, these hydration forces (54) depend exponentially on the interhelical separation and decay with a decay length of about 3 Å (11) at these large densities. This value of the hydration decay length seems to indicate that it is determined solely by the bulk properties of the solvent (i.e., water).

It is interesting to note that the behavior of short-fragment DNA in this range of concentrations is different from the long DNA (65). The short-fragment DNA, typically the nucleosomal DNA fragment of 146 bp, makes a 2-dimesional hexagonal phase at interaxial spacing of ~30 Å, that progressively orders into a 3-dimensional hexagonal phase on decrease of the interaxial spacing to ~23 Å (65). At still larger concentrations, the short-fragment DNA makes a 3-dimensional orthorhombic crystal, with a deformed hexagonal unit cell perpendicular to the *c*-axis. Concurrently to this symmetry transformation, the helical pitch of the condensed phase decreases continuously from 34.6 to 30.2 Å (65). The reasons for this fundamental difference between the behavior of long as opposed to short-fragment DNA is still not well understood.

When the osmotic pressure is lowered to about 10 atm (corresponding to interaxial spacing of about 35 Å, or DNA density of about 300 mg/mL), the characteristic hexagonal X-ray diffraction fingerprint of the line hexatic mesophase disappears continuously. This disappearance suggests the presence of a continuous, second-order transition into a low-density cholesteric (63). It is characterized by short-range (or effectively no) base stacking order, short-range positional order, short-range bond orientational order, but long-range cholesteric order, manifested in a continuing rotation of the long axis of the molecules in a preferred direction. In this sense, the cholesteric DNA mesophase would retain the symmetry of a 1-dimensional crystal. X-ray diffraction pattern of the DNA in the cholesteric phase is isotropic and has the form of a ring. Crossed polarizers, however, reveal the existence of long-range cholesteric order just as in the case of short chiral molecules. The texture of small drops of DNA cholesteric phase (spherulites) under crossed polarizers (Fig. 16) reveals the intricacies of orientational packing of DNA, where its local orientation is set by a compromise between interaction forces and macroscopic geometry of a spherulite. It is thus only at these low densities that the chiral character of the DNA finally makes an impact on the symmetry of the mesophase. It is not yet fully understood why the chiral order is effectively screened from the high-density DNA mesophases.

At still smaller DNA densities, the predominance of the chiral interactions in the behavior of the system remains. Recent work on the behavior of low-density DNA mesophases indicates (68) that the cholesteric part of the phase diagram might end with a sequence of blue phases that would emerge as a consequence of the loosened packing constraints coupled to the chiral character of the DNA molecule. At DNA density

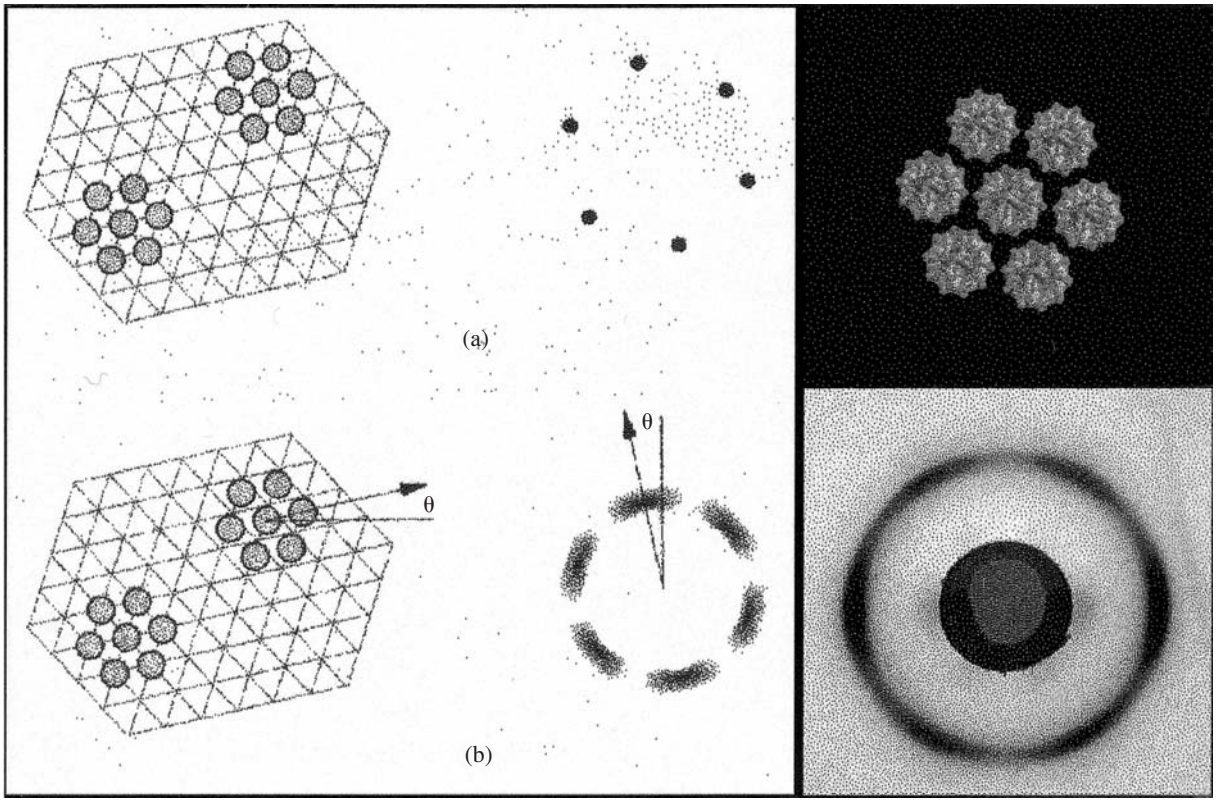

Figure 15 Bond orientational or hexatic order. With a real crystal if one translates part of the crystal by a lattice vector, the new position of the atoms completely coincides with those already there. (Adapted from ref. 67.) In a hexatic phase the directions to the nearest neighbors (bond orientations) coincide (after rotation by 60°), but the positions of the atoms do not coincide after displacement in 1 of the 6 directions! Consequently, a real crystal gives a series of very sharp Bragg peaks in X-ray scattering (upper half of box), whereas a hexatic gives hexagonally positioned broad spots. The pattern of X-ray scattering by high- density DNA samples gives a fingerprint of a hexatic phase. The densitogram of the scattering intensity (right half of figure) shows 6 pronounced peaks that can be Fourier decomposed with a marked sixth-order Fourier coefficient, another sign that that the scattering is due to long-range bond orientational order (63). See the color insert for a color version of this figure.

of about 10 mg/mL, the cholesteric phase line would end with DNA reentering the isotropic liquid solution where it remains at all subsequent densities, except perhaps at very small ionic strengths (69).

G. DNA Equation of State

The free energy of the DNA cholesteric mesophase appears to be dominated by the large elastic shape fluctuations of its constituent DNA molecules (70) that leave their imprint in the very broad X-ray diffraction peak (55). Instead of showing the expected exponential decay characteristic of screened electrostatic interactions (71), where the decay length is equal to the Debye length, it shows a fluctuation-enhanced repulsion similar to the Helfrich force existing in the flexible smectic multilamellar arrays (41). Fluctuations not only boost the magnitude of the existing screened electrostatic repulsion, but also extend its range through a modified decay length equal to 4 times the Debye length. The factor-of-4 enhancement in the range of the repulsive force is a consequence of the coupling between the bare electrostatic repulsions of exponential type and the thermally driven elastic shape fluctuations described through elastic curvature energy that is proportional to the square of the second derivative of the local helix position (42). In the last instance, it is a consequence of the fact that DNAs in the array interact via an extended, soft-screened electrostatic potential and not through hard bumps as assumed in the simple derivation in Chapter 2.

The similarity of the free energy behavior of the smectic arrays with repulsive interactions of Helfrich type and the DNA arrays in the cholesteric phase that can also be understood in the framework of the Helfrich-type-enhanced repulsion satisfies a consistency test for our understanding of flexible supermolecular arrays.

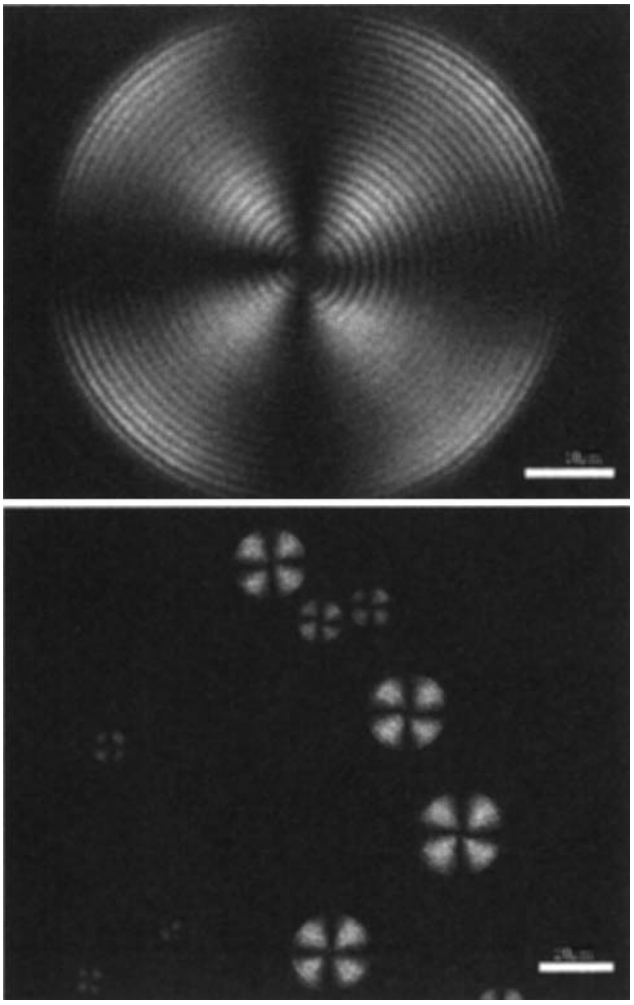

Figure 16 Texture of small drops of DNA cholesteric phase (spherulites) in a PEG solution under crossed polarizers. These patterns reveal the intricacies of DNA orientational packing when its local orientation is set by a compromise between interaction forces and the macroscopic geometry of a spherulite. The change from a bright to a dark stripe indicates that the orientation of the DNA molecule has changed by 90 degrees.

IV. LIPID MESOPHASES

A. Aggregation of Lipids in Aqueous Solutions

Single-molecule solutions of biological lipids exist only over a negligible range of concentrations; virtually all interesting lipid properties are those of aggregate mesophases such as bilayers and micelles. Lipid molecules cluster into ordered structures to maximize hydrophilic and minimize hydrophobic interactions (72,73). These interactions include negative free energy contribution from the solvation of polar heads and van der Waals interactions of hydrocarbon chains, competing with positive contributions such as steric, hydration, and electrostatic repulsions between polar heads. The ''hydrophobic effect,'' which causes segregation of polar and nonpolar groups, is said to be driven by the increase of the entropy of the surrounding medium.

Intrinsic to the identity of surfactant lipids is the tension between water-soluble polar groups and lipid-soluble hydrocarbon chains. There is no surprise then that the amount of water available to an amphiphile is a parameter pertinent to its modes of packing and to its ability to incorporate foreign bodies.

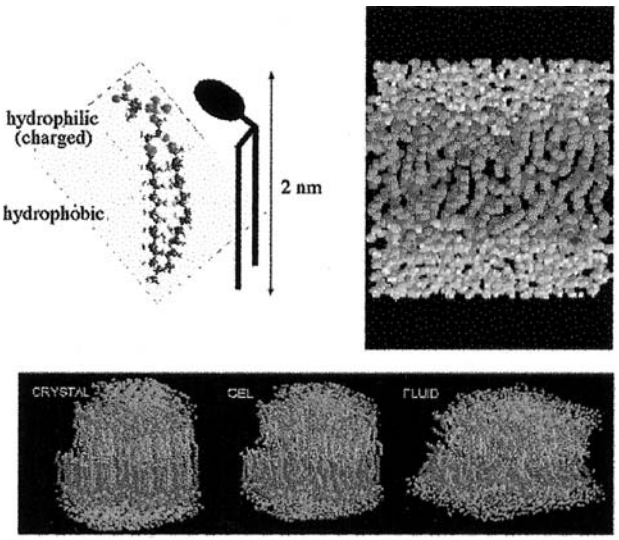
These interactions therefore force lipid molecules to self-assemble into different ordered microscopic structures, such as bilayers, micelles (spherical, ellipsoidal, rodlike, or disk-like), which can, especially at higher concentrations, pack into macroscopically ordered phases, such as lamellar, hexagonal, inverted hexagonal, and cubic. The morphology of these macroscopic phases changes with the balance between attractive van der Waals and ion correlation forces vs. electrostatic, steric, hydration, and undulation repulsion (74).

B. The Lipid Bilayer

The workhorse of all lipid aggregates is the bilayer (Fig. 17) (73). This sandwich of two monolayers, with nonpolar hydrocarbon chains tucked in toward each other and polar groups facing water solution, is only about 20 to 30 Å thick. Yet it has the physical resilience and the electrical resistance to form the plasma membrane that divides ''in'' from ''out'' in all biological cells. Its mechanical properties have been measured in terms of bending and stretching moduli. These strengths together with measured interactions between bilayers in multilamellar stacks have taught us to think quantitatively about the ways in which bilayers are formed and maintain their remarkable stability.

With some lipids, such as double-chain phospholipids, when there is the need to encompass hydrocarbon components voluminous compared with the size of polar groups, the small surface-to-volume ratio of spheres, ellipsoids, or even cylinders cannot suffice even at extreme dilution. Bilayers in this case are the aggregate form of choice. These may occur as single ''unilamellar'' vesicles, as onionlike multilayer vesicles, or multilamellar phases of indefinite extent. In vivo, bilayer-forming phospholipids create the flexible but tightly sealed plasma-membrane matrix that defines the inside from the outside of a cell. In vitro, multilayers are often chosen as a matrix of choice for the incorporation of polymers. Specifically, there are tight associations between positively charged lipids that merge with negatively charged DNA in a variety of forms (see below).

The organization of lipid molecules in the bilayer itself can vary (73). At low enough temperatures or dry enough conditions the lipid tails are frozen in an all-trans conformation that minimizes the energy of molecular bonds in the alkyl tails of the lipids. Also, the positions of the lipid heads along the surface of the bilayer are frozen in 2-dimensional positional order, making the overall conformation of the lipids in



Lipid	Bending rigidity [10^{-19}J]	Area compression [mN/m]
DMPC	1.15	145
SOPC	0.9	200
EggPC	0.4-2	
Plasma membrane	0.2-2	700
Red Blood Cell	0.13 - 0.3	450

Figure 17 The lipid bilayer. A lipid molecule has a hydrophilic and a hydrophobic part (here shown is the phosphatidylserine molecule that has a charged headgroup). At high-enough densities, lipid molecules assemble into a lipid bilayer. Together with membrane proteins as its most important component the lipid bilayer is the underlying structural component of biological membranes. The degree of order of the lipids in a bilayer depends drastically on temperature and goes through a sequence of phases (see main text): crystalline, gel, and fluid, depicted in the middle drawing. The box at bottom gives sample values of bilayer bending rigidity and area compressibility for some biologically relevant lipids and one well-studied cell membrane. See the color insert for a color version of this figure.

the bilayer crystal (L_C). The chains can either be oriented perpendicular to the bilayer surface (L_β and $L_{\beta'}$) or be tilted (crystalline phase L_C or ripple phase P_β). Such a crystalline bilayer cannot exist by itself but assembles with others to make a real 3-dimensional crystal.

Upon heating, various rearrangements in the 2-dimensional crystalline bilayers occur, first the positional order of the headgroups melts leading to a loss of 2-dimensional order ($L_{\beta'}$) and tilt (L_β), then, at the gel–liquid crystal phase transition the untilted or rippled (P_β phase) bilayer changes into a bilayer membrane with disordered polar heads in 2 dimensions and conformationaly frozen hydrocarbon chains, allowing them to spin around the long axes of the molecules, the so-called L_α phase. At still higher temperatures, the thermal disorder finally also destroys the ordered configuration of the alkyl chains, leading to a fluidlike bilayer phase. The fluid bilayer phase creates the fundamental matrix that according to the fluid mosaic model (72) contains different other ingredients of biological membranes (e.g., membrane proteins, channels, etc.).

Not only bilayers in multilamellar arrays but also liposome bilayers can undergo such phase transitions; electron microscopy has revealed fluid phase, rippled, and crystalline phase in which spherical liposomes transform into polyhedra due to very high values of bending elasticity of crystallized bilayers (75).

The fluid phase of the lipid bilayer is highly flexible. This flexibility makes it prone to pronounced thermal fluctuations, resulting in large excursions away from a planar shape. This flexibility of the bilayer is essential for understanding the zoo of equilibrium shapes that can arise in closed bilayer (vesicles) systems (76). Also, just as in the case of flexible DNA, it eventually leads to configurational entropic interactions between bilayers that have been crammed together (41). Bilayers and linear polyelectrolytes thus share a substantial amount of fundamentally similar physics that allows us to analyze their behavior in the same framework.

C. Lipid Polymorphism

Low temperature phases (77) are normally lamellar with frozen hydrocarbon chains tilted (crystalline phase L_C or ripple phase P_β) or nontilted (L_β and $L_{\beta'}$ form three-, two-, or one-D crystalline or gel phases) with respect to the plane of the lipid bilayers. Terminology from thermotropic liquid crystals phenomenology (50) can be used efficiently in this context: these phases are smectic, and SmA describes 2-dimensional fluid with no tilt while a variety of SmC phases with various indices encompass tilted phases with various degrees of 2-dimensional order. Upon melting, liquid crystalline phases with 1- (lamellar L_α), 2- (hexagonal II), or 3-dimensional (cubic) positional order can form.

The most frequently formed phases are micellar, lamellar, and hexagonal (Fig. 14). Normal hexagonal phase consists of long cylindrical micelles ordered in a hexagonal array, while in the inverse hexagonal II (H_{II}) phase water channels of inverse micelles are packed hexagonally with lipid tails filling the interstices. In excess water, such arrays are coated by a lipid monolayer. The morphology of these phases can be maintained upon their (mechanical) dispersal into colloidal dispersions. Despite that energy has to be used to generate dispersed mesophases relatively stable colloidal dispersions of particles with lamellar, hexagonal, or cubic symmetry can be formed.

Many phospholipids found in lamellar cell membranes, after extraction, purification, and resuspension, prefer an inverted hexagonal geometry (Fig. 18) (77). Under excess-water conditions different lipids will assume different most-favored spontaneous radii for the water cylinder of this inverted phase (78). An immediate implication is that different lipids are strained to different degrees when forced into lamellar pack-

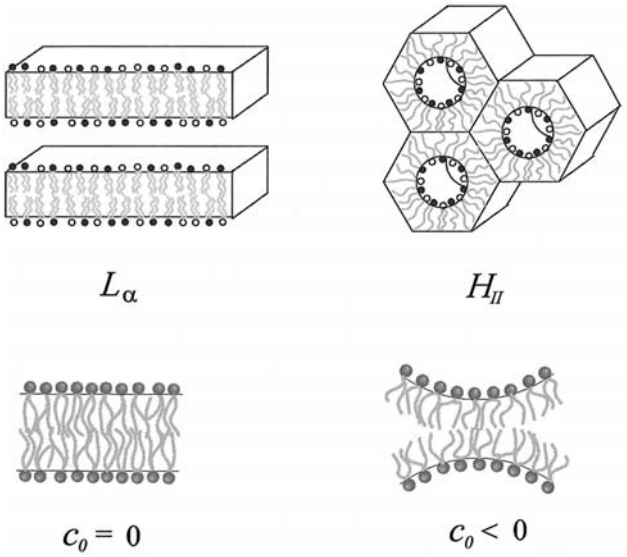


Figure 18 Different lipids are strained to different degrees when forced into lamellar packing. Relaxation of this strain contributes to the conditions for lamellar–to–inverted hexagonal phase transitions that depend on temperature, hydration, and salt concentration (for charged lipids). See the color insert for a color version of this figure.

ing. There are lamellar-inverted hexagonal phase transitions that occur with varied temperature, hydration, and salt concentration (for charged lipids) that form in order to alleviate this strain (see Fig. 18).

In the presence of an immiscible organic phase emulsion, droplets can assemble (79). In regions of phase diagram that are rich in water, oil-in-water emulsions and microemulsions ($c > 0$) can be formed, while in oil-rich regions these spherical particles have negative curvature and are therefore water-in-oil emulsions. The intermediate phase between the two is a bicontinuous emulsion that has zero average curvature and an anomalously low value of the surface tension (usually brought about the use of different cosurfactants) between the two immiscible components. Only microemulsions can form spontaneously (analogously to micelle formation) while for the formation of a homogeneous emulsion some energy has to be dissipated into the system.

The detailed structure of these phases as well as the size and shape of colloidal particles are probably dominated by:

- The average molecular geometry of lipid molecules
- Their aqueous solubility and effective charge
- Weaker interactions such as intra- and intermolecular hydrogen bonds
- Stereoisomerism as well as interactions within the medium

All depend on the temperature, lipid concentration, and electrostatic and van der Waals interactions with the solvent and solutes. With charged lipids, counterions, especially anions, may also be important. Ionotropic transitions have been observed with negatively charged phospholipids in the presence of metal ions leading to aggregation and fusion (80). In cationic amphiphiles, it was shown that simple exchange of counterions can induce micelle-vesicle transition. Lipid polymorphism is very rich and even single-component lipid systems can form a variety of other phases, including ribbonlike phases, coexisting regions and various stacks of micelles of different shapes.

D. Forces in Multilamellar Bilayer Arrays

Except for differences in dimensionality, forces between bilayers are remarkably similar to those between DNA. At very great separations between lamellae, the sheetlike structures flex and ''crumple'' because of (thermal) Brownian motion (41). Just as an isolated flexible linear polymer can escape from its 1 linear dimension into the 3 dimensions of the volume in which it is bathed, so can 2-dimensional flexible sheets. In the most dilute solution, biological phospholipids will typically form huge floppy closed vesicles; these vesicles enjoy flexibility while satisfying the need to keep all greasy nonpolar chains comfortably covered by polar groups rather than exposed at open edges. For this reason, in very dilute solution, the interactions between phospholipid bilayers are usually space wars of collision and volume occupation. This steric competition is always seen for neutral lipids; it is not always true for charged lipids (74).

Especially in the absence of any added salt, planar surfaces emit far-ranging electrostatic fields (27) that couple to thermally excited elastic excursions to create very long-range repulsion (44,83). As with DNA, this repulsion is a mixture of direct electrostatic forces and soft collisions mediated by electrostatic forces rather than by actual bilayer contact. In some cases electrostatic repulsion is strong enough to snuff out bilayer bending when bilayers form ordered arrays with periodicities as high as hundreds of Å (82).

Almost always bilayers align into well-formed stacks when their concentration approaches ~50 to 60 weight percent and their separation is brought down to a few tens of Å. In this region charged layers are quite orderly with little lamellar undulation. In fact, bilayers of many neutral phospholipids often spontaneously fall out of dilute suspension to form arrays with bilayer separations between 20 and 30 Å. These spontaneous spacings are believed to reflect a balance between van der Waals attraction and undulation-enhanced hydration repulsion (74). One way to test for the presence of van der Waals forces has been to add solutes such as ethylene glycol, glucose, or sucrose to the bathing solutions. It is possible then to correlate the changes in spacing with changes in van der Waals forces due to the changes in dielectric susceptibility as described above (83). More convincing, there have been direct measurements of the work to pull apart bilayers that sit at spontaneously assumed spacings. This work of separation is of the magnitude expected for van der Waals attraction. (84).

Similar to DNA, multilayers of charged or neutral lipids subjected to strong osmotic stress reveal exponential variation in osmotic pressure vs. bilayer separation (74). Typically at separations between dry ''contact'' and 20 Å, exponential decay lengths are 2 to 3 Å in distilled water or in salt solution, whether phospholipids are charged or neutral. Lipid bilayer repulsion in this range is believed to be due to the work of polar group dehydration sometimes enhanced by lamellar collisions from thermal agitation (85). Normalized per area of interacting surface the strength of hydration force acting in lamellar lipid arrays and DNA arrays is directly comparable.

Given excess water, neutral lipids will usually find the above-mentioned separation of 20 to 30 Å at which this hydration repulsion is balanced by van der Waals attraction. Charged lipids, unless placed in solutions of high salt concentration, will swell to take up indefinitely high amounts of water. Stiff charged bilayers will repel with exponentially varying electrostatic double layer interactions, but most charged bilayers will undulate at separations where direct electrostatic repulsion has weakened. In that case, similar to what has been described for DNA, electrostatic repulsion is enhanced by thermal undulations (86).

E. Equation of State of Lipid Mesophases

Lipid polymorphism shows much less universality that DNA. This is of course expected because lipid molecules come in many different varieties (73) with strong idiosyncrasies in terms of the detailed nature of their phase diagrams. One thus can not achieve the same degree of generality and universality in the description of lipid phase diagram and consequent equations of state as was the case for DNA.

Nevertheless, recent extremely careful and detailed work on PCs by J. Nagle and his group (87) points strongly to the conclusion that at least in the lamellar part of the phase diagram of neutral lipids the main features of the DNA and lipid membrane assembly physics indeed is the same (85). This statement however demands qualification. The physics is the same, provided one first disregards the dimensionality of the aggregates—1 dimensional in the case of DNA and 2 dimensional in the case of lipid membranes—and takes into account the fact that while van der Waals forces in DNA arrays are negligible, they are essential in lipid membrane force equilibria. One of the reasons for this state of affairs is the large difference, unlike in the case of DNA, between the static dielectric constant of hydrophobic bilayer interior, composed of alkyl lipid tails, and the aqueous solution bathing the aggregate.

We have already pointed out that in the case of DNA arrays quantitative agreement between theory, based on hydration and electrostatic forces augmented by thermal undulation forces, and experiment has been obtained and extensively tested (7,42). The work on neutral lipids (85) claims that the same level of quantitative accuracy can be achieved also in lipid membrane assemblies if one takes into account hydration and van der Waals forces again augmented by thermal undulations. Of course, the nature of the fluctuations in the 2 systems is different and is set by the dimensionality of the fluctuating aggregates—1- vs. 2-dimensional.

The case of lipids adds an additional twist to the quantitative link between theory and experiments. DNA in the line hexatic as well as cholesteric phases (where reliable data for the equation of state exist) is essentially fluid as far as positional order is concerned and thus has unbounded positional fluctuations. Lipid membranes in the smectic multilamellar phase are quite different in this respect. They are not really fluid as far as positional order is concerned but show something called quasilong range (QLR) order, meaning that they are in certain respects somewhere between a crystal and a fluid (50,67). The quasi long-range positional order makes itself recognizable through the shape of the X-ray diffraction peaks in the form of persistent (Caille) tails (67).

In a crystal one would ideally expect infinitely sharp peaks with Gaussian broadening only because of finite accuracy of the experimental setup. Lipid multilamellar phases, however, show peaks with very broad, non-Gaussian, and extended tails that are one of the consequences of QLR positional order. The thickness of these peaks for different orders of X-ray reflexions varies in a characteristic way with the order of the reflexion (67). It is this property that allows us to measure not only the average spacing between the molecules, but also the amount of fluctuation around this average spacing. Luckily, the theory also predicts that and without any free parameters (all of them being already determined from the equation of state) the comparison between predicted and measured magnitude in positional fluctuations of membranes in a multilamellar assembly is more than satisfactory (85).

In summing up, the level of understanding of the equation of state reached for DNA and neutral lipid membrane arrays is pleasing.

V. DNA–LIPID INTERACTIONS

Mixed in solution with cationic lipids (CLs), DNA spontaneously forms CL-DNA aggregates of submicron size. These DNA-lipid aggregates, sometimes called ''lipoplexes,'' (88) are routinely used for cell transfection in vitro. More important, they are used primarily as potential gene delivery vehicles for in vivo gene therapy [for recent reviews, see (89–94) and references therein]. Under appropriate conditions these aggregates reveal complex underlying thermodynamic phase behavior. There is a practical paradox here. We use stable equilibrium structures to reveal the forces that cause aggregation and assembly; we use this knowledge of forces to create the unstable preparations likely to be most efficient in transfection.

Lipoplexes for transfection were first proposed by Felgner and coworkers (95,96). The guiding idea was to overcome the electrostatic repulsion between cell membranes (containing negatively charged lipids) and negative DNA by complexing DNA with positively charged CL. Preliminary experimental data showed that at least some lipoplexes deliver DNA through direct fusion with the cell membrane (97). More often,

however, lipoplex internalization probably proceeds through endocytosis after initial interaction with the cell's membrane.

Prior to the attempts to use lipoplexes for transfection, studies of DNA aggregated with multivalent cations and coated with negatively charged liposomes were also explored as possible vectors. It was hoped that CL-DNA complexes would no longer require an additional complexing agent, and that also, the transfection efficiency would be higher. The complex's lipid coating could protect the tightly packed DNA cargo during its passage to the target cells.

Although not confronted with the immunological response, risked by the alternative viral vector strategy, the use of lipoplexes in gene therapy is still hampered by toxicity of the CL and low in vivo tranfection efficiency, despite the in vitro efficiency of some CL formulations. This discrepancy can be attributed to the multistage and multibarrier process the complexes must endure before transfection is achieved. These steps typically include passage in the serum, interaction with target and other cells, internalization, complex disintegration in the cytoplasm, transport of DNA into the nucleus, and ultimately expression.

In the search for increasingly more potent gene delivery vectors, the intimate relationship between the lipoplex's phase structure (or morphology) and its transfection efficiency probably serves as the greatest motivation for their study. How is transfection affected by lipoplex morphology? How may this structure be controlled? Experiment and theory of the past decade shed some light on such fundamental questions. They may give perspective for future strategies to design CL-based nonviral vectors.

To this end, we present our current understanding of the structure and phase behavior of CL-DNA complexes. We review the relation of structure to transfection efficiency and, more specifically, to the way the complex formation overcomes one barrier to DNA release into the cytoplasm.

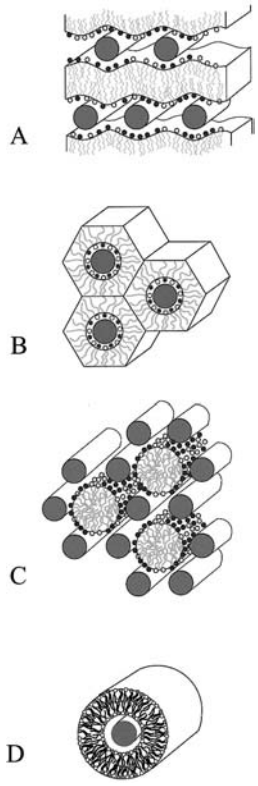

Figure 19 Schematic illustration of some possible structures of DNA–mixed lipid (cationic/nonionic) complexes. (A) The sandwichlike (L_α^c) lamellar complex composed of parallel DNA molecules intercalated between lipid bilayers. (B) The honeycomblike (H_{II}^c) hexagonal complex, composed of a hexagonally packed bundle of monolayer-coated DNA strands. (C) Two interpenetrating hexagonal lattices, one of DNA, the other of micelles. (D) Spaghetti-like complex, composed of bilayer-coated DNA. A. Structure of CL-DNA Complexes

In general, the structures of CL-DNA composite phases can be viewed as morphological hybrids of familiar pure-lipid and pure-DNA phases. A first example is the lamellarlike structure initially proposed by Lasic at al. (99,100). The first comprehensive and unambiguous evidence for this structure came from a series of studies by Rädler et al. (101–105). From high-resolution synchrotron X-ray diffraction and optical microscopy, they reported the existence of novel lamellar CL-DNA phase morphologies. In particular, one complex structure was shown to consist of lamellar multilayer. In this case smecticlike stacks of mixed bilayers, each composed of a mixture of CL—for example, dioleoyltrimethylammonium propane (DOTAP)—and neutral ''helper'' lipid—for example, dioleoylphosphatidylcholin (DOPC)—with monolayers of DNA strands intercalated within the intervening water gaps (Fig. 19A), like a multilipid bilayer L_α phase (106). Helper lipids are often added for their fusogenic properties. Dioleoylphosphatidylethanol amine (DOPE), for example, is conjectured to promote transfection. In addition, because pure (synthetically derived) cationic lipids often tend to form micelles in solution, helper lipids facilitate the formation of membranes.

In this L_α^c complex geometry, the DNA strands within each gallery are parallel to each other, exhibiting a well-defined repeat distance d. While d depends on the CL/DNA and CL/HL concentration ratios, the spacing between two apposed lipid monolayers is nearly constant at ~26 Å, corresponding to the diameter of double-stranded B-DNA, ca. 20 Å, surrounded by a thin hydration shell. This L_α^c lamellar (''sandwich'') complex is stabilized by the electrostatic attraction between the negatively charged DNA and the cationic lipid bilayer. Because of strong electrostatic repulsion between the charged bilayers (particularly at low salt conditions), the lamellar lipid phase is unstable without DNA.

Quite different equilibrium ordered phase morphologies were found to occur from other choices of neutral helper lipid (HL). In the case of DOPE, or lecithin, for example, inverted hexagonal (''honeycomb'' or H_{II}^{c}) organization of the lipid, with stretches of double-stranded DNA lying in the aqueous solution regions, were found to form, see Fig. 19B (95,102,107). The H_{II}^{c} structure may be regarded as the inverse-hexagonal (H_{II}) lipid phase, with DNA strands wrapped within its water tubes. Here, too, the diameter of the water tubes is only slightly larger than the diameter of the DNA ''rods.'' The presence of DNA is crucial for stabilizing the hexagonal structure. Without it, strong electrostatic repulsion will generally drive the lipids to organize themselves into planar bilayers. In fact, the most abundant aggregate structure of pure CL and HL mixtures, from which hexagonal complexes are subsequently formed, is single-bilayer liposomes.

Other CL-DNA phases have also been observed. One of the earliest studies probing the structure of lipoplexes showed some evidence for an hexagonal arrangement of rodlike micelles intercalated between hexagonally packed DNA, Fig. 19C (108,109). The number of possibilities is even larger if one also considers metastable intermediates. The ''spaghetti'' structure (see Fig. 19D), observed using freeze-fracture electron microscopy, has been predicted by theory to probably be one such metastable morphology (110,111). Here, each (possibly supercoiled) DNA strand is coated by a cylindrical bilayer of the CL/HL lipid mixture (112,113). Early proposed models of the CL-DNA complexes suggested a ''beads on a string'' type complex, in which the DNA is wrapped around or in between lipid vesicles (and even spherical micelles). Although this may not turn out to be an equilibrium structure, such aggregates are sometimes found, and may also serve as unstable intermediates (114–116). Other structures, such as the bilamellar invaginated liposomes (BIV) made of DOTAP-Chol, have been proposed and demonstrated to be efficient vectors (97,117). These structures resemble to some degree the L_{α}^{c} phase. However, formed from extruded liposomes, the BIVs are most probably metastable.

What factors determine which of these phases (or possibly several coexisting structures) actually form in solution? To what degree can we control and predict them? Control can first be achieved through the choice of type of CL and HL, and the ratio between the 2 used in forming liposomes. This in turn will determine such basic properties as the lipid bilayer's bending rigidity, spontaneous curvature, and surface charge density of the water–lipid aggregate interface. An additional experimentally controllable parameter is the ratio between the lipid and DNA content in solution. Both these parameters, we show, have significant effects on the phases that are formed.

B. Counterion Release

From the start, it was realized that the expected condensation of DNA with oppositely charged lipids could be used to package and send DNA to transfect targeted cells. The expectation that the DNA and lipids would aggregate was intuitively based on the notion that oppositely charged bodies attract. Early experiments confirmed the aggregation of DNA and lipids. However, the mechanism by which CL and DNA were found to associate—previously termed in the context of macromolecular association ''counterion release'' (118)—is more intricate than the ''opposites attract'' mechanism that may be naively expected.

Prior to association, DNA and lipids are bathed in the aqueous solutions containing their respective counterions, so that the solutions are overall electrostatically neutral. The counterions are attracted to the oppositely charged macromolecules, thus gaining electrostatic energy. Here, in addition to DNA, we also refer to the preformed CL liposomes as a ''macromolecules'' because they typically retain their integrity in solution, even upon association with other charged macromolecules. The counterions are therefore confined to the vicinity of the oppositely charged macromolecules at the compromise of greater translational entropy in solution.

Upon association, the 2 oppositely charged macromolecules condense to form CL-DNA complexes (Fig. 20). Many (possibly all) previously confined counterions can now be expelled into the bulk solution from the lipoplex interior, thus gaining translational entropy. Although the translational entropy of the paired macromolecules is reduced by (typically) only a few k_BTs (due to loss of conformational and translational entropy), many released counterions can now favorably contribute to a gain in entropy, each by a comparable amount. For this reason it is sometimes stated that the DNA–lipid condensation is ''entropically driven.'' The electrostatic en-

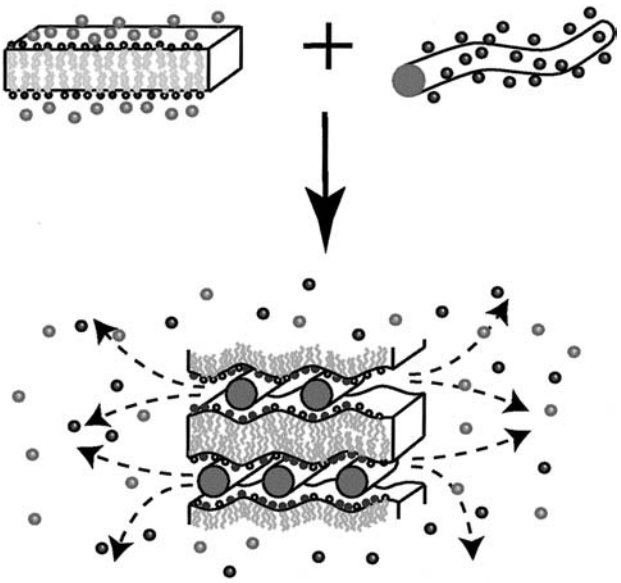

Figure 20 Schematic illustration of the condensation of DNA and lipid bilayers (liposomes) into CL-DNA complexes. In the process, the previously confined counterions are released into the bathing solution, thereby gaining translational entropy. See the color insert for a color version of this figure.

ergy can also contribute somewhat to stabilizing the lipoplexes. However, it has been well argued, both experimentally and theoretically, that the cardinal contribution to the association free energy of CL–DNA complexes is the entropy gain associated with counterion release (119,120).

Further support was given by counting released ions, using conductivity measurements of the supernatant. It was possible to determine that a maximal number of counterions were released when the number of ''fixed'' charges on the DNA and lipid were exactly equal.

Calorimetric measurements confirm this finding and find furthermore that the association could in fact be endothermic, so that it is only favorable for entropic reasons (121,122). The special point at which the number of positive and negative fixed charges is equal has been termed the ''isoelectric point.'' At this point, the (charging) free energy of the complex is minimal: the fixed charges of opposite signs fully compensate each other, thus allowing essentially all the counterions to be released into solution. Note, that by ''counterions'' we do not refer here to added salt ions. Ions of added salt will span the entire solution, including the lipoplex interior. Thus, the salt content changes the thermodynamic phase behavior and the value of the adsorption free energy, mainly because a high ambient salt concentration lowers the entropic gain associated with releasing a counterion.

Theoretical predictions and estimates from calorimetry show that for a salt solution of concentration $n^0 = 4$ mM, and a 1:1 CL/HL mole ratio, the gain in free energy upon adsorption at the isoelectric point is a bemusingly large ~7.5 k_BT per fixed charge pair (DNA and CL) (120–122). This value translates to over 2000 k_BT when considering the energy per persistence length of DNA (about 50 nm), carrying approximately 300 charges.

C. Lamellar DNA–lipid Complexes

Many degrees of freedom with competing contributions are expected to ultimately determine the free energy minimum for equilibrium DNA/membrane structures. Typically, these include (but are not limited to) electrostatic energy, elastic bending, solvation, van der Waals, ion mixing, and lipid mixing. Therefore, considering the lipoplex phase behavior, we begin for simplicity by discussing systems where only L_α^c complexes are found. This can be expected when the lipid membranes are rather rigid, such as in the case of mixtures of DOTAP/DOPC (89,102) or DMPC/DC-Chol (123). The main structural parameter for the L_α^c phase is the DNA–DNA distance, reflecting the DNA packing density within the complex. A series of X-ray measurements by Rädler et al. revealed how the DNA–DNA spacings d vary with the ratio ρ of the number of lipid charges to the total number of charges on DNA. The measurements were repeated for each of several different lipid compositions defined by the ratio of charged to overall number of lipids, ϕ. It was found that for a lipid mixture of a given composition ϕ, the spacings are constant throughout the low ρ range where the complex coexists with excess DNA. In the high ρ range, where the complex coexists with excess lipid, the spacings are also nearly constant. Inbetween these limits there exists a ''single-phase'' region, where all the DNA and lipids participate in forming lipoplexes. This region is generally found to include the isoelectric point where, by definition, $\rho = 1$ (Fig. 21).

Several theoretical studies have been proposed to account for this phase behavior (119,124,125). It was found that it is possible to account for most of the experimental observations within the scope of the nonlinear Poisson–Boltzmann equation (125). In this theoretical model, elastic deformations of

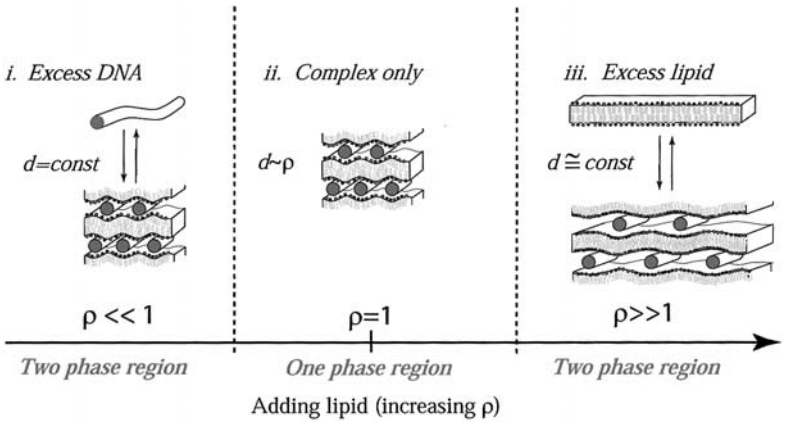

Figure 21 Schematic illustration of the phase evolution of the L_α^c complexes for a constant lipid composition (cationic to nonionic lipid ratio). As lipid is added (ρ increases), the systems evolve from a 2-phase (complex and excess DNA) region through a 1-phase (complex only) region, and finally to a 2-phase (complex and excess lipid) region. The isoelectric point is generally contained within the 1-phase region. See the color insert for a color version of this figure.

the DNA and lipid bilayers were neglected, treating them as rigid macromolecules. On the other hand the lipid's lateral (in plane) mobility in the membrane layer was explicitly taken into account. This turns out to be an important degree of freedom in mixed fluid bilayers, enabling the system to greatly enhance the free energy gain upon complexation, with respect to the case where no lipid mobility is allowed. This adds to the stability of the L_α^c complex. Generally, it was found that lipid mobility favors optimal (local) charge matching of the apposed DNA and lipid membrane. This is the state in which a maximal number of mobile counterions are expelled from the interaction zone, implying a maximal gain in free energy upon complex formation (126). However, the tendency for charge matching (hence migration of lipid to and from the region of proximity) is opposed by an unfavorable local lipid demixing entropy loss. This entropic penalty will somewhat suppress the membrane's tendency to polarize in the vicinity of the DNA molecule. The extent to which the membrane will polarize is determined by the intricate balance between the electrostatic and lipid-mixing entropy contributions to the free energy of the complex. The contribution of lipid demixing to the stabilization of the complex is most pronounced when the membrane's average composition is far from that of the DNA, namely, for low ϕ. Here, the system can gain most out of the polarization so as to come close to local charge matching.

The tendency of charged lipids to segregate in the vicinity of adsorbed rigid macromolecules has gained some experimental support from nuclear magnetic resonance (NMR) studies (127), although many systems may display a more complex behavior. Molecular dynamic simulations of L_α^c complexes, for a lipid mixture of DMTAP and DMPC, showed evidence for a favorable pairing of DMPC and DMTAP lipid molecules through the (partial) negative charge on DOPC, and an interaction of the (remaining) positive charge of the zwiterionic DOPC with the DNA. In contrast to the model discussed above, this implies a nonideal lipid demixing: these lipid molecules preferentially move in pairs (128). This may be anticipated because it is well known that lipids do not generally mix ideally, even in free (unassociated) membranes (129). Furthermore, there is evidence that to some extent neutral lipids also interact directly with DNA (133).

Figure 22 shows the experimental results and theoretical calculations for the dependence of d on ρ for several values of ϕ. For a specific value of ϕ (say $\phi = 0.5$), the 3-phase regimes can clearly be seen. As ρ increases, d changes from ≈ 35 Å (in the excess DNA regime, $\rho << 1$) to ≈ 47 Å (in the excess lipid regime, $\rho >> 1$). Both theory and experiment show that for a wide range of lipid composition, ϕ, there exists a 1-phase, complex-only region at ρ values somewhat larger and smaller than the isoelectric point. This implies that complexes may become either negatively or positively ''overcharged,'' so that the total number of fixed positive and negative charges is not equal. Hence, the complex accommodates either an excess number of lipids or else an excess amount of DNA. The complex's free energy is thus not at its minimum, which occurs at isoelectricity ($\rho = 1$). The interplay between possible phases to minimize the total system's free energy dictates that the complex move away from its minimal free

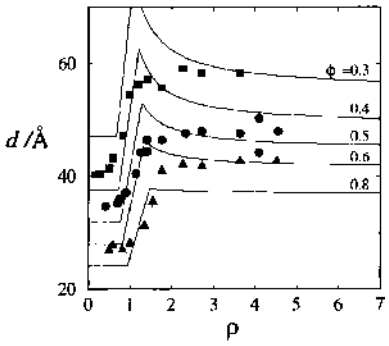

Figure 22 DNA–DNA spacing as a function of ρ in a series of theoretical and experimental results. The theoretical results correspond to (top to bottom) $\phi = 0.3$, 0.4, 0.5, 0.6, and 0.8; all results are presented for a screening length of 50 Å (corresponding to ca. 4 nm of bathing salt solution). The experimental results correspond to $\phi = 0.3$ (squares), 0.5 (circles), and 0.7 (triangles), and were performed with no added salt. (Theoretical results adapted from Refs. (125) and (145); experimental results adapted from Ref. 101.)

energy. The alternative would be to expel the excess lipid ($\rho > 1$) or excess DNA ($\rho < 1$) into solution. The charge densities on these ''free'' unneutralized macromolecules would be very large, rendering this scenario highly unfavorable. Using a simple model based on this overcharging phenomenon, it was possible to account for the considerable extent of this one phase region (125). Within this model, only the uncompensated charges on apposed (DNA–DNA or bilayer–bilayer) surfaces of an L_α^c unit cell (''box'') were considered in estimating the complex's free energy. Figure 22 also shows that as the membrane becomes enriched in CL (ϕ increases) the DNA–DNA distance is systematically reduced, reflecting the fact that smaller amounts of lipid membrane are needed to achieve isoelectricity.

Salt has a significant effect on the phase behavior. In general, added salt causes a significant decrease in d, presumably due to a screening of the repulsive DNA–DNA interaction. This effect is most pronounced when divalent salts are added in increasing amounts. A sharp decrease in the d value is observed for a certain salt molar concentration, resulting in very highly condensed DNA in each gallery (89,130). Another interesting observation is that the identity of the CL's counterion used changes considerably the (endothermic) association enthalpy, particularly in the excess DNA region (121). This probably reflects the nonelectrostatic interaction energies of different ions with membranes, which may influence the thermotropic behavior of the lipid membranes (131,132).

D. DNA Adsorption on Lipid Membranes

Further insight into the in-plane DNA ordering in L_α^c complexes has been gained through the atomic force microscopy

(AFM) study by Fang and Yang (133,134) of DNA adsorption on supported lipid bilayers. In these experiments, DNA was first adsorbed on dipalmitoyldimethylammoniumylpropane (DPDAP) or distearoyl-DAP (DSDAP) CL bilayers, assumed to be in the gel phase. After equilibration and saturation of the surface, the DNA bulk solution was removed, and the surface was put in contact with solution of various concentrations of NaCl. After further equilibration, the salt solution was removed and the surface imaged by AFM. Plasmid and linear DNA similarly treated showed similar results.

Striking, fingerprint-like images of DNA adsorbed on the surface were revealed (Fig. 23). The typical domain size for the aligned, smecticlike order is usually several hundred Angstroms, reflecting the DNA's intrinsic persistence length. These structures are expected to be like those found in L_α^c complexes: the domain size, inferred from x-ray scattering is quite similar (103–104). Furthermore, it was found that the surfaces are often overcharged when DNA is adsorbed, (i.e., the number of DNA fixed charges exceeds the number of lipid charges). This can be anticipated on the basis of theoretical studies of a similar problem: adsorption of charged globular proteins (yet another macroion) on oppositely charged membranes (135). In both cases the driving force for adsorption is similar to that driving lipoplex formation, namely, counterion release. In L_α^c complex formation, much of the DNA can interact with the 2 sandwiching bilayers. In contrast, topology dictates that adsorbates on a single lipid bilayer will always possess a part proximal and a part distal to the interaction zone. If both parts are charged, as is the case with DNA, complete counterion release cannot be achieved because the distal part does not interact significantly with the underlying bilayer. Therefore, although charges on the lipid membrane are fully cancelled by charges on adsorbed DNA macroions, still the portion of DNA away from the contact zone imparts a net surface charge (i.e., overcharging of the DNA-covered membrane).

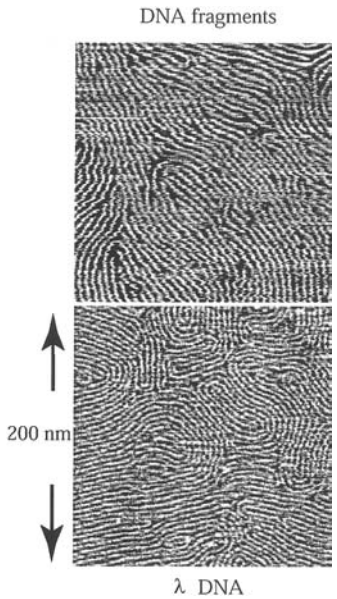

Figure 23 Atomic force microscopy images of DNA from different sources (see figure for details) condensed on DPDAP bilayers at room temperature in 20 mM NaCl. Striking fingerprint-like order is apparent, with a domain size of the order of the persistence length (ca. 50 nm). (Courtesy of J. Yang.)

Yet another interesting feature is the dependence of the DNA–DNA distance on salt concentration. As the NaCl concentration was varied between 20 and 1000 mM, this distance grew from around 45 Å to almost 60 Å. At first this may seem baffling: adding salt should be expected to decrease the DNA–DNA electrostatic repulsion, and hence lower the distance between neighboring interacting strands. This is indeed the general trend that has been observed in L_α^c complexes (101,125). However, because the DNA was primarily allowed to saturate the surface and only subsequently treated with the salt solution (which was later also washed away), adsorption here was not at equilibrium. In fact, when faced with a neat salt solution the adsorbed DNA can only detach, it will not generally readsorb onto the surface. It is therefore hard to give full theoretical reasoning for the trend.

Theoretical explanations have previously been offered to account for this salt-dependent behavior, based on a balance between membrane-mediated effective attraction (that may be the result of the DNA perturbation of the lipid bilayer) and electrostatic repulsion between DNA strands (136). The predicted DNA–DNA spacing as a function of screening length is nonmonotonic: increasing first for low screening lengths and decreasing for high values. An alternative to this approach is related to the free energy gain upon adsorption, and how it changes with the addition of salt. In the presence of added salt, the adsorption free energy can be expected to be lower because the gain in entropy upon release of counterions becomes very small when releasing an ion from an adsorbed layer into a bathing solution with a comparable concentration. Assuming that unbinding would occur when the free energy gain per persistence length is $\approx k_BT$, we can estimate from a simple model that the thickness of the confined layer is $l_{eff} \approx$ 5 Å, rather close to the screening length in solution (3–4 Å) (120–122). Thus, the lower binding free energy may cause some of the DNA strands to dissociate from the lipid surface once the system is exposed to salt. Allowing DNA to rearrange on the surface would then lead to an increase in the average DNA–DNA distance.

When multivalent salt is used, a crowding of DNA molecules is first observed as salt is added (in accordance with the observations in the L_α^c complexes), and then starts to grow for higher concentrations (89,137). This may be a manifestation of the 2 competing forces as salt is added: lessened repulsion between strands vs. weakened adsorption energy.

E. From Lamellar to Hexagonal Complexes

So far, we have discussed the L_α^c lipoplexes formed from lipid membranes that are rigid (bending rigidity much greater than

k_BT) and tend to a planar geometry. Other lipoplex structures may ensue when the lipids possess a spontaneous curvature that is nonplanar, or when the membranes are soft enough to be deformed under the influence of the apposed macroion. The lipid membrane thus responds to the presence of DNA by deforming elastically and by locally changing its composition ϕ.

Membrane elasticity may be varied substantially either by changing the lipid CL/HL composition, changing the lipid species, or by adding other agents, such as alcohols, to the membrane (138,139). In contrast, double-stranded DNA generally remains rather stiff, with a typical persistence length of $\approx$ 500 Å. Hence, the lipoplex geometries are restricted to structures in which DNA remains linear on these large-length scales. Usually, it is the interplay between the elastic (spontaneous curvature and bending rigidity) and electrostatic (charge density) properties of the membrane that will determine the optimum lipoplex geometry at equilibrium.

Often, the membrane elasticity and electrostatic contribution to the free energy display opposing tendencies. For example, the hexagonal H_{II}^c complex, is electrostatically favored due to the cylindrical wrapping of the DNA by the lipid monolayer. This allows better contact between the 2 macromolecular charged surfaces. However, the highly curved lipid geometry may incur a substantial elastic (curvature deformation) energy fee. The price to pay will be lower when the lipid (monolayer's) spontaneous curvature matches closely the DNA intrinsic (negative) curvature or when it has low bending rigidity. Under such conditions, the H_{II}^c complex may become more stable than the L_α^c phase. Usually, a neutral HL is used for adjusting the spontaneous curvature to the required negative curvature because pure CLs typically tend to form uncurved or positively curved aggregates. Use of more HL in the mixed membranes may on the one hand lower the elastic penalty, while on the other hand lower the monolayer's charge density, compromising the electrostatic energy gain upon association.

These qualitative notions were elegantly demonstrated by experiments in which the elastic properties of the lipid monolayers were controlled by changing the nature of the lipid mixture. The spontaneous curvature of the lipid bilayer was modified by changing the identity of HL. It was found that when using a mixture of DOTAP/DOPE, H_{II}^c was the preferred structure, while DOTAP/DOPC mixtures promoted the formation of the L_α^c phase. This is consistent with the fact that pure DOPE forms the inverted hexagonal phase, H_{II}, due to its high negative spontaneous curvature (140–142), while DOPC self-assembles into planar bilayer. In addition, by adding hexanol to the DOTAP/DOPC–DNA lipid mixture, the bending rigidity could be diminished by about 1 order of magnitude (138,139). This induced a clear first order $L_\alpha^c \rightarrow H_{\mathrm{II}}^c$ phase transition (102).

Additional complexity can be expected when accounting for the coexistence of more than 1 phase in solution. A theoretical study of the phase equilibrium took into account the bare lipid phases L_α and H_{II}, the naked DNA and the complex L_α^c and H_{II}^c phases (143). The phase diagram of the system

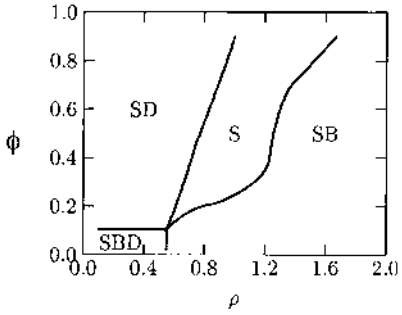

Figure 24 The phase diagram of a lipid–DNA mixture, for lipids that self-assemble into rigid planar membranes. The phase diagram was calculated for membranes characterized by a bending rigidity in the range of $4 < \mathrm{K}_c < \infty\ k_BT$ and a spontaneous curvature of $c = 0\ \mathrm{Å}^{-1}$ for both helper and cationic lipid. The symbols *S*, *B*, and *D* denote, respectively, the L_α^c, L_α, and uncomplexed (naked) DNA phases. (Reprinted by permission from Ref. 143, Biophysical Society.)

was evaluated by minimization of the total free energy, which included electrostatic, elastic, and lipid-demixing contributions. Several systems of different compositions were considered. Figure 24 shows the predicted phase coexistence corresponding to the simplest case already discussed of rigid planar membranes. Results are presented for lipid membranes with a bending rigidity of $\mathrm{K}_c = 10k_BT$ per monolayer and spontaneous curvature $c = 0\ \mathrm{Å}^{-1}$ [typical for many bilayer-forming lipids (106)] for which only lamellar complexes are expected to form. As the overall lipid composition is enriched in CL (higher ϕ) the 1 phase persists over a wider range of ρ. This indicates that for higher CL content, the complex may be expected to be more stable toward addition of either DNA or lipid (hence moving away from the isoelectric point).

The Gibbs phase rule allows for up to three phases to coexist concomitantly for this 3-component (DNA, HL and CL) system. Figure 25 shows the theoretical prediction for the phase diagram for a system in which the HL has a strong negative spontaneous curvature ($\mathrm{K}_c = 10k_BT$ and $c = 1/25\ \mathrm{Å}^{-1}$)(143). For high ϕ values, the phase behavior resembles that of the previously discussed system. However, for lower values of ϕ, a multitude of regions of (up to 3) different phases coexisting together can be found. In some regions, lamellar and hexagonal complexes appear coexisting side by side. A similarly complex diagram results when the membranes are soft (bending rigidity of $\approx k_BT$) as might be expected for membranes with added alcohols (143).

A more subtle demonstration of the underlying balance of forces can be found within the realm of the L_α^c complex. Thus far, the theoretical models considered for the lipid membranes in this lamellar phase assumed them to be perfectly planar slabs. However, this need not be so. When membranes are sufficiently soft (yet not soft enough to favor the H_{II}^c phase) or if one of the CL/HL has a propensity to form curved sur-

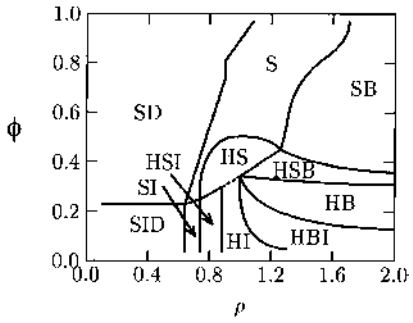

Figure 25 The phase diagram of a lipid–DNA mixture involving ''curvature-loving'' helper lipid. The spontaneous curvature of the helper lipid is $c = -1/25$ Å^{-1}. For the cationic lipid, the spontaneous curvature taken is $c = 0$ Å^{-1}. The bending rigidity for both lipids is $K_c = 10\ k_BT$. The symbols *S*, *H*, *B*, *I*, and *D* denote, respectively, the L_α^c, H_{II}^c, L_α, H_{II}, and uncomplexed (naked) DNA phases. The broken line marks the single H_{II}^c phase. (Reprinted by permission from Ref. 143, Biophysical Society.)

faces, the membrane may corrugate so as to optimize its contact with DNA (see Fig. 19A). If the membrane is further softened, finally, a transition may occur to the H_{II}^c phase. In this respect, the membrane corrugation in the L_α^c complex may be regarded as a further stabilization of the lamellar complex, and a delay to the onset of the $L_\alpha^c \rightarrow H_{II}^c$ transition.

A possible consequence of membrane corrugation in the L_α^c phase is an induced locking between neighboring galleries. This follows the formation of ''troughs'' in a gallery, induced by the interaction of the membrane with DNA in adjacent galleries. This imposes ''adsorption sites'' for the DNA in the 2 neighboring galleries, which propagates the order on. The formation of these troughs, as well as a very weak electrostatic interaction between galleries, may thus correlate between the positions of DNA in different galleries (128,144,145). Limited experimental evidence supports this notion. In cryotransmission electron microscopy (cryo-TEM) studies of the L_α^c phase, spatial correlations were found between DNA strands in different galleries (146). In another series of X-ray studies, the corrugation and charge density modulation in an L_α^c-like complex, in which the membranes are in the gel phase, were measured (147). Further support for the possible formation of corrugations is gained from computer simulations of lipid–DNA complexes (128).

In order to assess the extent of membrane corrugation, a balance of forces between many degrees of freedom should be taken into account. The free energy minimum now depends on the local membrane composition—dictating membrane properties such as local charge density, spontaneous curvature and bending elasticity—and the extent of local deformation around the DNA. Theoretical predictions show that for a wide range of conditions, both stiff and soft membranes can show corrugations that are stable with respect to thermal undulations of the membranes (145). The spacings between galleries and between DNA molecules are also predicted to change somewhat with respect to the case where no corrugations are allowed (144). For the conditions in which the troughs are shallow or absent altogether, one may anticipate the formation of phases where DNA in different galleries are positionally uncorrelated, while orientational order is preserved. These structures were predicted theoretically and termed ''sliding phases'' (103,104,148–150,146).

F. Lipoplex Structure and Transfection Efficiency

In recent years a large number of CL–DNA formulations have been proposed as vectors. However, the fate of the CL–DNA complex once administered, its interaction with the cell membrane, and entry into the cell and subsequently into the cell nucleus, is likely complex and largely unresolved. The poorly understood process of DNA release once in the cell interior must be important (151–153). For example, it has been shown from action in the nucleus that DNA expression is diminished when it is tightly complexed with lipids (156). Hints to the mechanism of the intracellular release of lipoplexes come from experimental evidence in vitro, showing that other added polyelectrolytes may compete with DNA and subsequently replace it in the complex (154). This kind of replacement, by natural polyelectrolytes, may be one way in which DNA is released in cells (155). Another possible mechanism is the fusion of complex lipids with lipid membranes in the cell (89,104).

Only a limited number of experiments have probed the relationship between the structure of CL–DNA complexes and the transfection efficiency. One emergent theme attributes an important role to complex frustration and destabilization in promoting transfection.

Experimental studies show that the 2 ordered complex structures, L_α^c and H_{II}^c, behave differently inside living cells. Furthermore, a correlation was found between the structure of the lipoplexes formed and the transfection efficiency. The structure formed depends in turn on the specific choice and relative amount of HL, CL, and DNA. The H_{II}^c complex was found (in the studied cases) to be a more potent vector than L_α^c (157). Further information is gained from fluorescence studies of cell cultures with both complex types internalized in fibroblast L cells. These indicate that the L_α^c complex is more stable inside the cells, while the H_{II}^c more readily disintegrates—its lipids fusing with the cell's own (endosomal or plasma) membranes—resulting in DNA release. This is in accord with the theoretical findings that the L_α^c complex structure is rather flexible toward changes in the system's compositional parameters, due to its ability to tune both the membrane composition and the DNA–DNA spacing, while this tuning is more limited in the H_{II}^c phase.

The picture is further substantiated by a series of studies by Barenholtz and coworkers (90,152,153,158). In general it was shown that maximal transfection efficiency could be achieved in complexes that were formed in the excess lipid regime (with ρ in the range of 2–5). This correlated well with the point of maximal size heterogeneity of the complexes.

These instabilities were shown to occur concomitantly with an increase in the amount of membrane defects that were in turn mainly attributed to the appearance of several coexisting structures in solution (e.g., H_{II}^{c} and L_{α}^{c} in DOTAP/DOPE lipoplexes, or micellar and lamellar phases in DOSPA/DOPE-based lipoplexes). This is in accordance with the theoretical prediction that the regions of most phase diversity and the largest number of coexisting phases occurs at high ρ (and low ϕ) values (see Fig. 25) (90,114,140).

Other evidence seems to agree with these notions. For example, some successful formulations, such as BIV, are also probably metastable (97,99,110). This may suggest that it is in fact their instability that helps them to release their DNA cargo once they are inside the cell. Attempts have also been made to destabilize lipoplexes more specifically only once they are already internalized in the cells (rather than en route in the serum). Reduction-sensitive cationic lipids were designed, and the subsequent lipoplexes that are formed were shown to undergo large structural changes when exposed to the cytoplasmic reductive systems. The lipoplexes are thus destabilized and the previously packaged DNA is released into the cytosol (92,159–161). A decrease in the toxicity of the CL and increased transfection efficiency are thus achieved (162).

Destabilizing lipoplexes is not the only barrier to transfection. For example, entry of DNA into the nucleus through the nuclear pore complex is inefficient for large pieces of DNA. It has been shown that the cell own nuclear import machinery may be used to increase transfection efficiency dramatically, by attaching a peptide containing a nuclear localization signal (NLS) to the DNA (163,164). Furthermore, the size of the complexes also seems to play a crucial role in determining transfection efficiencies (90,91,97,99). Here, the repulsive interaction between like-surface charge of the complex due to over/undercharging (excess lipid or DNA) can aid in stabilizing the complexes, once they are formed, from fusing further. Another strategy to controlling the interaction between aggregates and the stability of the aggregate in vivo is to modify the composition of the outer wrapping sheath of the lipoplex. The caveat is that the lipoplexes are not stabilized to such a degree that they can no longer disintegrate once inside the cells. For example, short-chain lipids possessing a PEG headgroup (or a derivative thereof) have been used to increase the stability of the lipoplexes in the bloodstream, while not interfering with the endosomal unwrapping once the lipoplexes are internalized in cells (165).

More generally, we can expect that understanding how to control and manipulate the formation of specific phases on the one hand, while better understanding the multistage transfection mechanism and the parameters (conditions) affecting it on the other, should aid in the design of more potent lipid-based gene delivery vectors in the future. These, together with control over the coating and targeting of the complexes, may render these vectors as useful vehicles in gene therapy.

VI. RETROSPECT AND PROSPECT

Structural elucidation of the DNA–cationic lipid complexes and realization of the extent to which they share the structural features of pure DNA or pure lipid polymorphism have advanced notably in the past few years. Some old questions have been answered and new questions raised. It is these new questions that challenge our knowledge of the intricacies of interactions between macromolecules.

The DNA–lipid complexes found so far are only a sample of the much wider set of structures that will be seen on a full DNA–lipid phase diagram. We argue that this larger set of possibilities be approached by firmly established methods to measure the energies of these structures at the same time that they are determined and located on a phase diagram. Built on principles of direct molecular interactions, recognizing the consequences of thermal agitation, this line of observation and analysis can lead to an understanding of the energetic ''whys'' and preparative ''hows'' of complex structures.

Forces so delineated are already knowledgeably applied in new preparations. Precisely how the structure of DNA–lipid aggregates will affect their efficacy in transfection remains to be seen. So far, the ideas we have are too general and have been learned from studying analytically tractable but technically inadequate preparations. General principles do not lead to specific results. Molecules are too interesting to allow easy success in clinical design. Still there is little doubt of a practical link between the energy and structure of these complexes and their viability in a technological application.

Even the present general understanding of forces, even the cartoon ideas of the directions in which forces act in macromolecular complexes can tutor the bench scientist on how to improve preparations. There is enough known for a healthy iteration between experimental attempt and theoretical reason. Experimental successes and failures become the data for molecule force analyses. Various DNA–lipid assemblies reflect the various actions of competing forces. Molecular theorists can define and delineate these forces as they act to create each form; they can provide a logic to design variations in preparation. Basic scientists and clinicians are already in a position to help each other to improve their ways.

ACKNOWLEDGMENTS

We want to thank Milan Hodoscek for his help with molecular graphics in preparing some of the figures. We also want to thank John Nagle and Stephanie Tristram-Nagle for their comments on an earlier version of this chapter.

Gene Therapy Applications of Ribozymes

Bruce A. Sullenger, Lynn Milich, and J. P. Jones III

Durham, North Carolina, U.S.A.

I. INTRODUCTION

Since their discovery in the early 1980s, RNA enzymes or ribozymes have been the subject of much investigation. Numerous studies have been performed to elucidate the biochemistry of how certain RNA molecules can fold into complex tertiary structures to form active sites and perform catalysis. Other studies have focused on identifying the roles that RNA enzymes play in cell biology. More recently, even more attention has been focused on the study of ribozymes because it was recognized that these RNA enzymes can potentially be quite useful for a variety of gene therapy applications.

The first discovered ribozyme was the self-splicing group I intron from *Tetrahymena thermophila*. The reaction mediated by this RNA enzyme has now been extensively characterized and the mechanism by which it excises itself from precursor ribosomal RNAs (pre-rRNA) without the aid of proteins is well understood (1–3). The second ribozyme to be recognized was the RNA subunit of RNase P. RNase P catalyzes the removal of upstream sequences on precursor-tRNAs to produce mature 5′ ends on tRNA molecules in a wide variety of cell types (3,4).

Several other catalytic RNA motifs have been discovered that are naturally associated with plant and human pathogens. The hammerhead and hairpin ribozymes are derived from satellite RNAs from plant viroid and virusoids, and the hepatitis delta virus (HDV) ribozyme is derived from a short single-stranded RNA virus found in some patients with hepatitis B virus. Each of these small RNA enzymes catalyzes a self-cleavage reaction that is believed to play a major role in the replication of these single-stranded RNA pathogens (5).

All these self-cleaving ribozymes have been reengineered so that they can cleave other target RNA molecules in trans in a sequence-specific manner.(6) This ability to specifically cleave targeted RNAs has led to much speculation about the potential utility of trans-cleaving ribozymes as inhibitors of gene expression (7–11). In addition, the group I self-splicing ribozyme from *Tetrahymena* can be reengineered to perform splicing on a targeted RNA molecule in trans. It has been argued that such trans-splicing ribozymes may prove to be effective at repairing mutant cellular transcripts by cleaving off mutant nucleotides and ligating on functional RNA sequences (12–14).

The purpose of this chapter is not to provide an extensive review of the enzymology of ribozymes or to catalog the published results demonstrating that ribozymes may become useful reagents for gene therapy applications. Both of these topics have been extensively reviewed elsewhere (2–14). Moreover, we do not discuss the use of synthetic ribozymes, and leave the description of various gene transfer and expression systems that can be employed to deploy ribozymes to the other chapters in this book. Rather, we attempt to present a focused account of the potential utility of catalytic RNAs for gene therapy by first presenting an overview of the basic biochemistry of well-characterized ribozymes and then discussing how trans-cleaving and trans-splicing ribozymes may be employed for a variety of gene therapy applications. Our hope is that this approach will enhance the reader's understanding of the potential utility of ribozymes for both gene inhibition and genetic repair.

II. CATALYTIC RNAs

Five classes of catalytic RNAs have been extensively characterized. Each class of ribozyme adopts a characteristic secondary and tertiary structure that is required to assemble a catalytic center and perform catalysis (Fig. 1) (6). In addition, these classes of ribozymes differ in size, and the mechanism

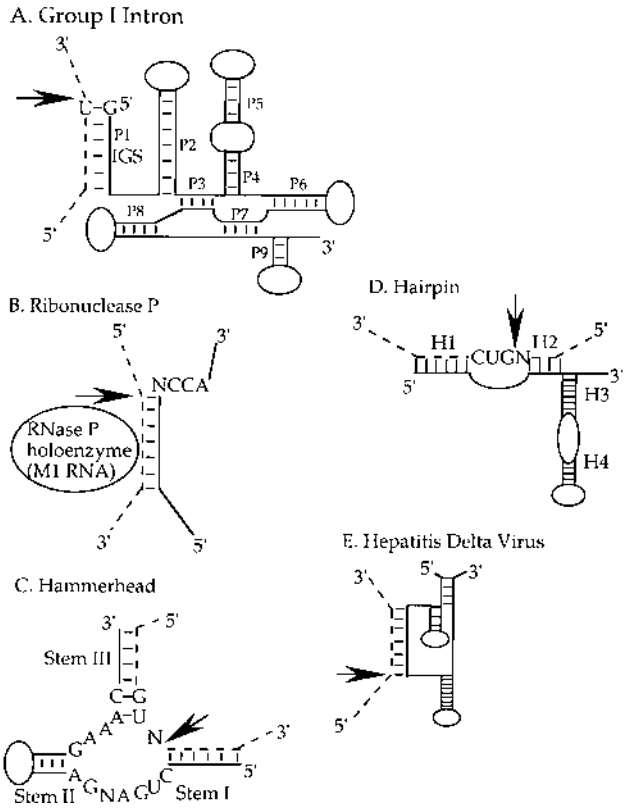

Figure 1 Secondary structures of five classes of ribozymes. All 5 ribozymes, shown in solid black lines, have been engineered to cleave specific target RNAs, shown as dashed lines. The base pairing formed between the ribozymes and their target RNAs are shown and the site of cleavage of the substrate RNAs is indicated by an arrow. (A) The group I ribozyme. P1 through P9 represent the conserved based paired regions found in group I introns. The internal guide sequence (IGS) is shown paired to a target RNA. The substrate is cleaved just 3′ of the conserved G-U wobble base pair. (B) RNase P. RNase P holoenzyme is depicted as a cartoon and contains an RNA subunit as well as a protein cofactor. The substrate for RNase P cleavage is indicated bound to an external guide sequence (EGS) just 5′ of a free 5′-NCCA-3′ sequence. Cleavage of the targeted RNA occurs just across from the end of the EGS-target duplex. (C) The hammerhead ribozyme. The hammerhead ribozyme is shown bound to a target RNA through base pairing interactions formed by stems I and III. The-single-stranded regions encompass the catalytic core of the ribozyme. Cleavage of the substrate RNA occurs at an unpaired residue positioned between stems I and III. (D) The hairpin ribozyme. The hairpin binds its target RNA through 2 base pairing regions called helix 1 (H1) and helix 2 (H2). Cleavage of the target RNA occurs between the N and G nucleotides on the substrate as indicated. (E) The HDV ribozyme. The HDV ribozyme forms 7 or 8 base pairs with its target RNA and cleavage occurs just 5′ of this base pairing interaction.

that each employs to perform catalysis varies. Hammerhead, hairpin, and the HDV ribozymes are only 30 to 80 nucleotides in length and form cleavage products with 2′,3′ cyclic phosphate and 5′-hydroxyl termini. By contrast, catalytic RNAs derived from group I introns and RNase P are typically greater than 200 nucleotides in length and both cleave target RNAs to generate products with 3′-hydroxyl and 5′-phosphate termini. Each class of ribozyme is discussed in more detail below.

A. The Group I Intron from *T. thermophila*

The intervening sequence (IVS) found in nuclear precursor rRNA transcripts from *T. thermophila* is one of the most well-characterized catalytic RNAs. This IVS is a member of a growing family of group I introns that have common structural and functional features. The *Tetrahymena* intron is naturally 413-nucleotides long and is found in the middle of the 26S rRNA gene. The IVS is transcribed as part of the rRNA precursor and excises itself by performing a cleavage and a ligation reaction to form a functional rRNA without the aid of proteins (1,15). Prior to the discovery of this self-splicing reaction, RNA was believed to be only a carrier of genetic information or a scaffold for protein binding and not able to perform catalysis on it own.

B. The Self-splicing Reaction of the *Tetrahymena* Group I Intron

Comparative sequence analysis of several group I introns (16,17) as well as mutational analyses (18–26) have been employed to develop a phylogenetically conserved prediction of the secondary structure of group I introns consisting of a set of paired regions, P1–P9. More recently, X-ray crystallography and chemical probing studies have revealed that the *Tetrahymena* intron adopts a particular 3- dimensional structure using several tertiary interactions (27–34) and contains a catalytic core surrounded by a close-packed layer of RNA helices (32–34). Several studies have shown that this folded RNA structure participates directly in self-splicing (35,36).

The *Tetrahymena* intron excises itself and ligates together its flanking exons by performing 2 consecutive transesterification reactions (2,15). The first step of splicing is a cleavage reaction that is initiated by a free guanosine that is bound by the intron. This guanosine serves as a nucleophile attacking the 5′ splice site and is covalently attached to the 5′ end of the intron (Fig. 2A). The recognition element that defines the exact site of guanosine attack is a G-U wobble base pair that is highly conserved among group I introns. The G-U base pair is part of a short duplex called P1. The P1 duplex includes base pairing between the last 6 nucleotides of the 5′ exon and sequences within the intron called the internal guide sequence (IGS) or the 5′ exon-binding site. In the second step of splicing, the newly generated 3′-hydroxyl group, at the 3′ end of the cleaved 5′ exon, attacks the phosphorous atom at the 3′ splice site, resulting in the ligation of the 5′ and 3′ exons and the excision of

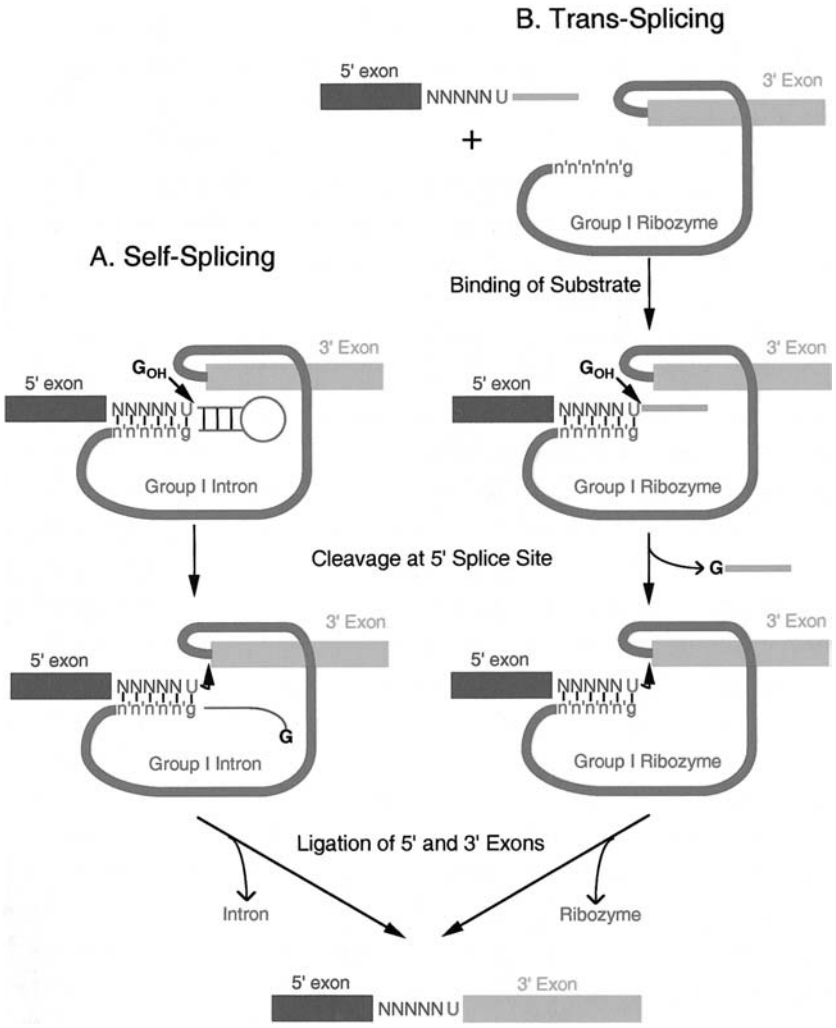

Figure 2 Group I ribozyme-mediated self- and trans-splicing. (A) Self-splicing is initiated by the attack of the 5′ splice site by an intronbound guanosine. This cleavage occurs just 3′ of the uridine shown in red that is involved in a G-U wobble base pair. The group I intron (green) holds onto the 5′ cleavage product via base pairs formed between the internal guide sequence of the ribozyme and the 3′ end of the 5′ exon. In the second step of splicing, the intron attaches the cleaved 5′ exon (blue) onto the 3′ exon (yellow) and liberates itself. (B) During trans-splicing, the ribozyme binds to a sequence in a target RNA (5′-NNNNNU-3′) via base pairing through its internal guide sequence (5′-gn′n′n′n′n′-3′). The ribozyme cleaves the target RNA at the reactive uridine (red), releases the downstream cleavage product (light blue) and ligates a 3′ exon (yellow) onto the upstream cleavage product (dark blue). See the color insert for a color version of this figure.

the intron. The excised group I intron maintains its ability to make and break phosphodiester bonds. However, because the group I intron is not regenerated in its original form following self-splicing, this catalytic RNA is not a true enzyme in the strictest sense (37). Subsequently, shortened forms of the *Tetrahymena* group I intron that lack exon sequences were generated that fulfill the definition of a true enzyme in that they can perform multiple turnover reactions without being modified in the process (38).

C. The Trans-cleaving Reaction of the *Tetrahymena* Ribozyme

Shortened versions of the intervening sequence from *Tetrahymena* that lack the first 19 or 21 nucleotides (called L-19 or L-21) can catalyze the cleavage of oligonucleotide substrates with multiple turnover (38). Moreover, the rate enhancement achieved by this shortened form of the intron is within the range of values achieved by protein enzymes, such as EcoRI,

that catalyze sequence-specific cleavage of nucleic acids. The catalytic mechanism employed by the shortened form of the *Tetrahymena* ribozyme in this trans-cleavage reaction is quite similar to that used by the full-length intron in the cleavage step of self-splicing with a few exceptions (39). First, the 5′ exon sequences preceding the IGS have been removed in the shortened form of the intron. Therefore, the ribozyme must bind to a target RNA that is present in trans (Fig. 2B). As in the case of the self-splicing reaction, a wobble G-U base pair is required at the cleavage site and the IGS of the ribozyme must be complementary to the sequence found on the substrate RNA just 5′ of the reactive uridine residue (40). For the wild-type IGS (5′-GGAGGG-3′), binding would occur at nucleotides 5′-CCCUCU-3′ within the substrate RNA. Cleavage occurs just 3′ of the uridine residue on the substrate RNA at the reconstructed G-U base pair (Fig. 2B).

As noted, substrate recognition and trans-cleavage require base pairing between the IGS on the ribozyme and the RNA substrate. Substrate specificity can be manipulated by altering the sequence of the ribozyme's IGS to make it complementary to any target RNA molecule (40–42). Moreover, no specific sequence requirements exist for the IGS, except that it must contain a guanosine residue at the reaction site. Thus, by altering the guide sequence of the L-21 version of the *Tetrahymena* catalytic RNA, a ribozyme can be created that can be employed to recognize and cleave a target RNA following any uridine residue (Fig. 2B).

The L-21 form of the *Tetrahymena* ribozyme binds to a 6-nucleotide long substrate RNA 10^3- to 10^4-fold tighter than would be predicted by base pairing binding energy alone (43–45). Studies on the L-21 ribozyme, as well as the self-splicing form of the intron, suggest that tertiary interactions contribute to the ribozyme substrate-binding energy. Specific tertiary interactions have been identified that involve 2′-hydroxyl groups on the ribose backbone of the substrate and the intron (46–49). This tight binding between the ribozyme and RNA substrate limits the substrate specificity of the *Tetrahymena* ribozyme because both matched substrates, which are only 6 nucleotides long, and substrates that form single base pair mismatches with the IGS serve as excellent substrates for the ribozyme (44,45). Under conditions of saturating guanosine and 10 mM $MgCl_2$, such RNA substrates are bound so tightly that the ribozyme goes on to cleave essentially every RNA that it binds. Therefore, the substrate specificity of this ribozyme will probably have to be improved if it is to become useful for gene therapy because any 6 nucleotide sequence would be expected to be present in many cellular RNAs. Fortunately, several logical approaches exist that can potentially be employed to enhance the substrate specificity of the *Tetrahymena* ribozyme (50,51).

If the specificity of the group I ribozyme proves very difficult to improve, then trans-cleaving ribozymes derived from group II introns may represent an alternative catalytic RNA motif that may be able to achieve the high levels of substrate specificity that might be required for gene therapy applications. At least some of these group II autocatalytic RNAs, which are present in organelles of plants, lower eukaryotes, and prokaryotes, do not appear to form additional tertiary interactions with their substrates (52). Thus, group II introns may be particularly adept at recognizing only the intended RNA sequence in the pool of cellular transcripts.

D. The Trans-splicing Reaction of the *Tetrahymena* Ribozyme

In addition to performing a trans-cleavage reaction, the *Tetrahymena* ribozyme can also mediate targeted trans-splicing by employing intermolecular cleavage and ligation reactions (41,53). During trans-splicing, a ribozyme with a 3′ exon attached to its 3′ end recognizes a target RNA (5′ exon) by complementary base pairing as in trans-cleavage (Fig. 2B). The ribozyme then cleaves its target RNA as usual at a site immediately 3′ of a conserved G-U base pair formed between a guanosine nucleotide at the 5′ end of the IGS and a uridine nucleotide within the substrate RNA. The sequences downstream of the cleavage site (3′ cleavage product) are then released by the ribozyme. The 3′ end of the 5′ cleavage product is then attached to the 3′ exon, which is originally appended to the ribozyme, to generate the ligated product (Fig. 2B).

As with the trans-cleavage reaction, targeted trans-splicing is very malleable. In principle, any uridine residue in an RNA molecule can be targeted for trans-splicing by simply making the nucleotides in the ribozyme's IGS complementary to the nucleotides that precede an available uridine residue in a targeted RNA. No specific sequence requirements for the 3′ exon are know to exist for this splicing reaction. Thus, essentially any RNA sequence can be employed as a 3′ exon in this reaction and spliced onto a targeted 5′ exon as long as the 3′ exon sequences do not inhibit the ribozyme from folding into a catalytically competent conformation.

E. The RNase P Ribozyme

RNase P, unlike the other 4 ribozymes discussed in this chapter, is the only catalytic RNA that is naturally a true enzyme. RNase P is found in both prokaryotic and eukaryotic cells, where it catalyzes the removal of the 5′ leader sequences from the variety of precursor tRNAs (3,4). This catalytic RNA is naturally part of a ribonucleoprotein (RNP) and in the case of RNase P isolated from *Escherichia coli* the RNP consist of a 377-nucleotide RNA subunit (M1) and a 119-amino acid protein (Fig. 1B). Although it was initially believed that the holoenzyme was required to perform catalysis in vitro, M1 RNA preparations from *E. coli* (54) as well as in vitro-transcribed versions of M1 RNA (55) are able to cleave tRNA precursors with multiple turnover in the presence of high concentrations of magnesium in the test tube. RNase P cleaves substrate RNA by hydrolysis to generate 5′-phosphate and 3′-hydroxyl termini. Although the RNA subunit of RNase P alone is catalytic, the protein cofactor facilitates the RNA processing reaction and allows it to proceed efficiently under physiologically relevant conditions (55).

When processing its natural pre-tRNA substrate, RNase P removes the 5′ leader sequences from the end of the precursor

transcript. Cleavage occurs specifically and accurately just 5′ of the first nucleotide in the mature tRNA, even though only a small degree of sequence conservation exists between different pre-tRNA species. This observation suggested that some facet of the 3-dimensional structure of the precursor tRNAs is the feature of the transcript that is recognized by RNase P. Mutagenesis studies supported this hypothesis because disruption of tRNA folding was shown to decrease the rate of RNase P-mediated cleavage of substrate RNAs. However, the full tertiary structure of tRNA is not required for RNase P recognition and RNA processing (56). Rather the ribozyme appears to recognize a short RNA duplex similar to the acceptor stem of a tRNA just upstream of an unpaired CCA sequence found on the 3′ end of partially processed tRNA transcripts (56). The structure recognized by RNase P can be approximated by a short RNA fragment, termed the external guide sequence or EGS, that is complementary to a substrate (Fig. 1B). RNase P will cleave single-stranded 5′ leader sequences adjacent to any double-stranded RNA duplex as long as the unpaired CCA nucleotides are present at the 3′end of the EGS (Fig. 1B) (56). Thus, through the use of EGS oligonucleotides, RNase P can in principle be targeted to cleave any target RNA.

F. The Hammerhead Ribozyme

The hammerhead ribozyme is a catalytic RNA motif that was originally derived by comparing the self-cleavage domains from a number of naturally occurring viroid and satellite RNAs that replicate in plants (5). The self-cleaving consensus domain consists of a highly conserved catalytic region and 3 helices, and has been shown to have sequence-specific ribonuclease activity (Fig. 1C). Subsequently, a hammerhead domain of less than 60 nucleotides was shown to be sufficient for cleavage (57,58), and two separate oligonucleotides that assembled into a hammerhead structure were shown to mediate a trans-cleavage reaction (59,60).

Crystallographic studies of the hammerhead ribozyme have demonstrated that the tertiary structure of the hammerhead appears to be ''Y shaped'' or like that of a ''wishbone'' (61,62). Helices I and II are in close juxtaposition, whereas helix III is at the bottom of the molecule. However, all 3 are A-form helices. As shown in Fig. 1C, the minimal structural requirements for hammerhead-catalyzed cleavage include two single-stranded regions that contain 9 highly conserved nucleotide sequences, 3 helices, and the nucleotides GUN immediately 5′ of the cleavage site in the substrate RNA. Results of mutagenesis and kinetic studies suggest that the conserved residues comprise the catalytic core of the ribozyme and are required for cleavage (63,64). Helices I and III, which flank the cleavage site, are formed by base pairing with the substrate. This base pairing interaction is extremely important not only because it holds the ribozyme and substrate together, but also because it precisely positions the ribozyme relative to the cleavage site. The most efficient cleavage has been observed with GUC, GUA, or GUU at the cleavage site although some cleavage also occurs after CUC, UUC, and AUC. The hammerhead catalyzes transesterification of the 3′, 5′phosphodiester bond at the cleavage site, which results in the production of RNA with 2′, 3′ cyclic phosphate and 5′-hydroxyl termini.

Much effort has been focused on developing hammerhead ribozymes into useful therapeutic agents. The hammerhead's small size and simple secondary structure, containing helices I and III, which can be made to base pair with virtually any substrate RNA, has allowed a great number of investigators to design hammerhead ribozymes to target any RNA molecule for cleavage and destruction (discussed in detail below). In particular, efforts have been directed at optimizing the interaction between the ribozyme and its substrate because both the length and base composition of complementary helices I and III can affect substrate specificity, ribozyme substrate affinity, and rate of reaction turnover.

G. The Hairpin Ribozyme

As is the case for the hammerhead ribozyme, the hairpin ribozyme represents a catalytic RNA motif that is derived from RNA associated with a plant pathogen (5). This small catalytic RNA was discovered in the 359-nucleotide long negative strand satellite RNA of Tobacco Ringspot virus [(−)sTRSV], which was shown to mediate a self-catalyzed cleavage reaction as part of its replication pathway (57,65).

A minimal catalytic domain for this RNA molecule has been identified (66,67), which consists of a 50-base RNA catalyst that efficiently cleaves an RNA substrate containing 14 bases of satellite RNA sequence (68). Features of secondary structure within this domain, defined from minimum energy RNA folding calculations and supported by mutagenesis studies, include 4 helices, 2 of which are formed by base pairing between the RNA catalyst and the substrate (Fig. 1D) (69). These 2 helices form part of the substrate recognition site and flank a 4-base loop within the substrate (5′-AGUC-3′) containing the cleavage site. For the wild-type (−)sTRSV, cleavage occurs between the nucleotides, A and G, by transesterification generating a 5′ fragment with 2′, 3′ cyclic phosphate termini and a 3′ fragment with a 5′-hydroxyl termini. Trans-cleavage has also been observed in vitro with multiple turnover when substrate RNAs are added to the hairpin ribozyme as separate transcripts (68,69).

The hairpin catalytic RNA motif can be designed to target a great variety of RNA molecules for cleavage because only 2 sequence requirements exist for this reaction. First, to maintain catalytic activity complementary base pairing between the ribozyme and substrate must occur. Single base pair mismatches at the 10 positions included in the 2 flanking helices can result in the loss of catalytic activity (69), although single base pair mismatches distal to the cleavage site appear to be tolerated (70). In addition, it has been noted that the composition of base paired substitutions in these helices can have a wide range of affects on the kinetic properties of the ribozyme (69), suggesting that base pair substitutions should be optimized for each application. The second sequence requirement for the hairpin cleavage reaction involves the nucleotides that compose the target site. Optimal substrate cleavage occurs with the nucleotides GUC immediately 3′ of the cleavage site.

The guanosine residue appears to be essential and is believed to be directly involved in catalysis (71). Moreover, catalytic activity has been shown to vary widely when nucleotide substitutions are made at the other 3 positions (71).

H. The HDV Ribozyme

HDV is a 1700-nucleotide, covalently closed circular RNA that is associated with hepatitis B virus infection in certain patients. This animal RNA virus undergoes autocatalytic self-cleavage as part of its replication cycle (5). A minimal self-cleaving RNA motif have been determined for the HDV catalytic RNA (72,73), which includes approximately 85 nucleotides from both the genomic (74) and antigenomic RNAs (75). Features of secondary structure were proposed based on nuclease probing and/or site-directed mutagenesis, and were found to be similar for both the genomic and antigenomic self-cleaving sequence elements (75). More recently, X-ray crystal structure studies have been employed to solve the 3-dimensional structure of the genomic HDV ribozyme (76). Such analysis demonstrates that the ribozyme forms 4 stems, 2 of which (stems I and II) generate a tertiary interaction called a pseudoknot (Fig. 1E) (75,76). Stems II, III, and IV appear to be important for stabilizing the catalytic form of the ribozyme, whereas formation of stem I is required for efficient cleavage (75).

The self-cleavage reaction mediated by the HDV ribozyme occurs by transesterification and is dependent on divalent cations. Cleavage products have 5′-hydroxyl and 2′,3′ cyclic phosphate termini. The rates of HDV self-cleavage in vitro using either in vitro-transcribed HDV RNA or HDV RNA isolated from infected tissue appears to be very slow. However, addition of urea or formamide has been shown to increase the rate of cleavage as much as 50-fold, suggesting that these denaturants may be mimicking a viral or cellular RNA-binding or unwinding factor that facilitates cleavage in vivo (77). A derivative of the catalytic RNA motif from HDV has been engineered to catalyze cleavage reactions in *trans* with multiple turn over (78,79). Target site recognition is dependent on the formation of 7 to 8 base pairs formed between the target RNA and the HDV ribozyme 3′ of the cleavage site (79).

III. THERAPEUTIC APPLICATIONS OF TRANS-CLEAVING AND TRANS-SPLICING RIBOZYMES

Ribozymes have the potential to become useful therapeutic agents, and currently they are being developed for a wide variety of clinical applications. The vast majority of effort has been expended in the development of trans-cleaving hammerhead and hairpin ribozymes as inhibitors of viral gene expression. In particular, these ribozymes have been targeted to cleave and destroy HIV-1 RNAs to inhibit viral replication in infected cells. The effectiveness of ribozymes as inhibitors of cellular gene expression in both prokaryotes and eukaryotes has been examined, and in a number of studies hammerhead ribozymes have been used to reveal particular gene functions. Trans-cleaving ribozymes are also being developed to target transcripts encoding oncogenes, such as the *bcr/abl* and c-Ha-*ras*. As mentioned earlier, new ribozyme applications are being developed for the group I trans-splicing ribozyme from *T. thermophila*, which can be used to repair defective cellular RNAs and to revise viral transcripts to give them antiviral activity. In the following section, we discuss the therapeutic applications of trans-cleaving and trans-splicing ribozymes. Because so much effort has been devoted to developing trans-cleaving ribozymes that target HIV-1 RNA, a more a detailed summary of the work performed in this area is presented.

A. Inhibition of Gene Expression by Trans-cleaving Ribozymes

1. Inhibition of HIV Replication by Ribozymes

Several different approaches have been described that employ RNA molecules to render cells resistant to HIV replication, including the use of antisense RNA and RNA decoys (80). Although these and other approaches have been reported to be effective in suppressing HIV replication in infected cells, ribozymes have 2 theoretical advantages as compared with other RNA-based HIV inhibition strategies: (1) cleavage of viral transcripts results in the direct, irreversible inactivation of the target RNA; and (2) fewer ribozymes may be required to inhibit a given target gene effectively because a single ribozyme can catalyze multiple cleavage reactions and thus destroy multiple viral transcripts. However, like many other antivirals, ribozymes may also be sensitive to HIV sequence heterogeneity and effective inhibition may require the use of a combination of these strategies.

Ribozymes may be able to cleave viral target RNAs at a number of stages in the viral life cycle. Potential RNA targets include incoming genomic RNAs, early viral mRNAs, late viral mRNAs, and full-length genomic RNAs that are being encapsidated into virion (Fig. 3). Although cleavage of incoming RNAs would prevent viral integration and therefore be highly effective in protecting cells, the fact that HIV genomic RNAs are encapsidated within a viral core may make these transcripts difficult to access by ribozymes. Moreover, the viral polymerase may initiate reverse transcription before the ribozyme can base pair with and cleave the target sequence, setting up a race between the ribozyme and the reverse transcriptase machinery. Nevertheless, several reports suggest that ribozymes may be able to inhibit the initial step of the viral life cycle by cleaving incoming HIV genomic RNAs. However, in most these HIV inhibition studies, cleavage of incoming genomic RNAs has been assessed only semiquantitatively. Differences in the amount of proviral DNA (81) or gag mRNA (82) in ribozyme-expressing cells and controls cells has been only analyzed by PCR amplification reactions, which were not internally controlled. Unfortunately, no system has been developed to date that allows for the direct detection of cleavage products of incoming HIV genomic RNAs in mammalian cells.

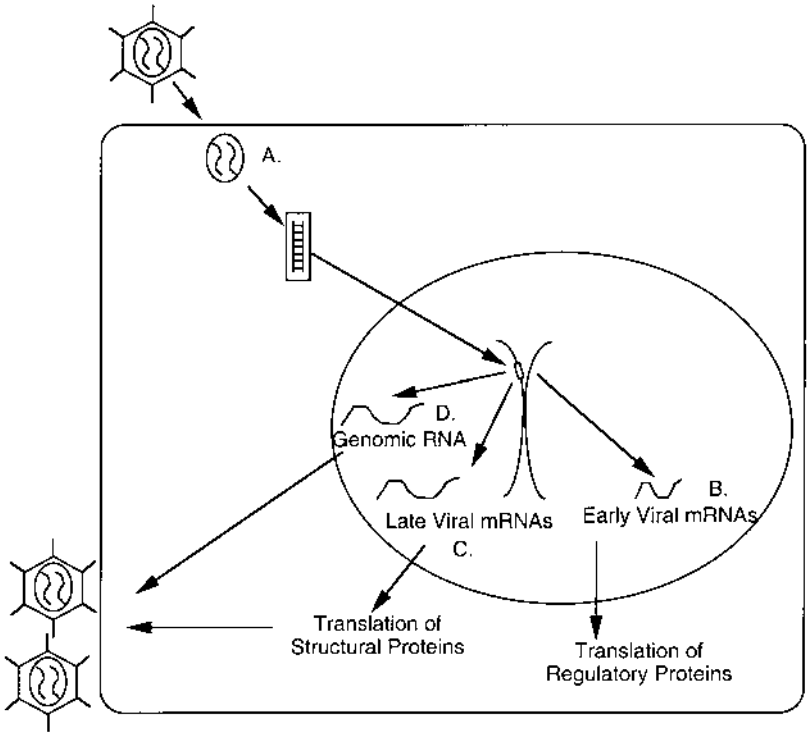

Figure 3 HIV RNAs in the context of the viral life cycle. Trans-cleaving ribozymes can potentially inhibit HIV replication by cleaving and destroying viral RNA at a number of steps in the HIV life cycle. (A) Viral genomic RNAs can be targeted prior to reverse transcription into dsDNA and proviral integration. (B) During early gene expression, messenger RNAs encoding regulatory proteins are made. (C) During late gene expression, mRNAs encoding structural proteins are produced. (D) Full-length genomic RNAs are expressed for packaging into viral particles budding from the cell surface.

Early viral transcripts may prove to be the most attractive targets for conferring resistance to HIV-1 (Fig. 3). Viral RNAs expressed at this stage of the HIV-1 life cycle, such as those encoding tat, rev, and nef proteins, are not very abundant. Thus, fewer catalytic RNAs may be required to be protective. Cleavage of early transcripts that inhibit the expression of regulatory proteins such as rev should also result in the inhibition late gene expression.

Ribozyme-mediated cleavage of late viral transcripts may not be effective in inhibiting HIV replication. Although these RNAs may be accessible for ribozyme cleavage, their shear abundance would probably require that extremely high levels of ribozyme be expressed to reduce their levels in infected cells. In addition, the detrimental affects mediated by early viral regulatory proteins would not be inhibited, even if late viral gene function was eliminated. An alternative strategy may be to target highly conserved sequences in the long terminal repeats present in all viral RNAs. This approach could result in the inhibition of both early and late gene expression.

As mentioned above, much work has been performed to develop ribozymes for HIV gene therapy strategies. Hammerhead and hairpin ribozymes are particularly well suited for this purpose because of their small size, simple secondary structure, and the ease with which they can be manipulated to target specific HIV substrate RNAs for cleavage. In the first application of this approach to inhibit HIV replication, an anti-*gag* hammerhead ribozyme was generated that specifically cleaved gag-encoding RNAs in vitro and inhibited HIV-1 replication in a human T cell line (82). Subsequently, such trans-cleaving ribozymes have been designed to target a variety of highly conserved sequences throughout the HIV-1 genome and have been shown to inhibit HIV replication to varying degrees in a number of tissue culture studies [for extensive review, see (83,84)]. Moreover, certain trans-cleaving ribozymes have been shown to be able to inhibit the replication of diverse viral strains as well as clinical isolates in primary T cell cultures (81,83–85). Comparisons between catalytically active and inactive forms of these anti-HIV ribozymes have demonstrated that maximal inhibition of virus replication is usually associated with catalytic activity and not simply due to the antisense property of these anti-HIV ribozymes (86–88).

To assess the activity of ribozymes in more clinically relevant settings, human peripheral blood lymphocytes have been stably transduced with a hairpin ribozyme targeting U5 region

of the HIV-1 genome. These cells were shown to resist challenge by both HIV-1 molecular clones and clinical isolates (89). More recently, macrophage-like cells, which were differentiated from hematopoietic stem/progenitor cells from fetal cord blood and which were stably transduced with a hairpin ribozyme targeted at the 5′ leader sequence, resisted infection by a macrophage-tropic virus (90). Transduction of pluripotent hematopoietic stem cells with HIV-resistance genes may represent an avenue to continually generate cells that are resistant to HIV infection. Such stem cells differentiate into monocytes and macrophages, the major targets of HIV-1 infection.

The generation of sequence variants during HIV-1 replication has posed a major problem for immunization strategies and anti-HIV-1 drug therapies designed to suppress viral replication in infected patients. Frequent substitution of amino acids within the variable domains of the HIV-1 *env* gene has resulted in the emergence of neutralization escape mutants both in cell culture and in vivo. Similarly, the rapid emergence of resistant viral strains has limited the effectiveness of both nucleoside and nonnucleoside analog reverse transcriptase inhibitors. Selection for variants resistant to anti-HIV-1 ribozymes is also likely to occur because a single-point mutation at the cleavage site on the substrate RNA could inhibit ribozyme-mediated cleavage of viral transcripts. Unlike small molecule drugs that require substitutions at the protein level, even a silent-point mutation can generate a ribozyme-resistant strain. The affect of single-point mutations at the cleavage site of hairpin (5′N/\GHY3′, where H = U, C, or A, and Y = C or U) and hammerhead (5′NUX/\3′, where X = C, U, or A) ribozymes has not been studied, but the more stringent sequence requirement at the cleavage site of the hairpin ribozyme could enhance its sensitivity to mutations. Approaches that have been suggested to overcome sequence heterogeneity among HIV isolates include the development of multitargeted ribozymes that cleave a given RNA at multiple sites and to target either single or multiple ribozymes to highly conserved sequences within the HIV genome.

In summary, several studies have suggested that ribozymes can inhibit HIV replication in cell culture experiments when cells are challenged with very low innoculums of HIV. It remains to be tested if this first generation of ribozymes can also inhibit virus replication in HIV-infected patients under conditions of active viremia and where a multitude of quasispecies of the virus preexist. Ultimately, this question will be answered as ribozymes begin to be evaluated in clinical trials in HIV-infected individuals (91–93).

2. Inhibition of Hepatitis C Virus by Ribozymes

In addition to its use as an anti-HIV-1 antiviral, hammerhead ribozymes are also being used to target hepatitis C virus (HCV) infection (94). Fifteen different hammerhead ribozymes were designed to target different sites in the conserved 5′ untranslated region (UTR) present in all HCV RNAs, and tested for their ability to reduce expression of a luciferase reporter gene downstream of the HCV 5′ UTR. Cotransfection of OST7 cells with target and ribozyme plasmids resulted in a 40% to 80% reduction in luciferase activity. In a more realistic setting, inhibition of polio viral replication in HeLa cells was ascertained by a chimeric construct that contains the HCV 5′UTR fused to the polio virus. Several HCV 5′ UTR targeted ribozymes inhibited the chimeric HCV-PV replication by 90%, suggesting that hammerhead ribozymes may be useful in reducing viral burden in HCV infection.

3. Inhibition of Tumor Growth and Metastasis by Ribozymes

The use of hammerhead ribozymes targeted to vascular endothelial growth factor (VEGF) receptors was investigated to prevent angiogenesis and subsequent tumor growth and metastasis in vivo (95). Ribozymes targeted to Flt-1 (VEGF-1) and KDR (VEGF-2) receptors reduced tumor growth in a metastatic variant of Lewis lung carcinoma, but only the ribozyme targeted to Flt-1 inhibited lung metastasis. In addition, ribozyme inhibition of Flt-1 mRNA expression also reduced liver metastasis in a human metastatic colorectal cancer model. These data suggest that ribozyme inhibition of gene expression in vivo is possible and that inhibition of VEGF receptor expression can reduce tumor growth and metastasis.

B. Trans-cleavage of mRNAs Encoding Dominant Oncogenes

Neoplastic transformation is often associated with the expression of mutant oncogenes. Because ribozymes can be designed to inhibit the expression of specific gene products, their potential as antineoplastic agents is currently being evaluated. For example, hammerhead ribozymes have been reported to be able to suppress the tumorigenic properties of cells harboring an activated human *ras* gene (96–98). More recently, the *bcr/abl* fusion transcript has been the target of many ribozyme studies (99–102). This abnormal mRNA is transcribed from the Philadelphia chromosome, which is present in 95% of patients with chronic myelogenous leukemia (CML) and in many patients with acute lymphocytic leukemia (ALL). In vitro experiments have shown that the 8500-nucleotide long *bcr/abl* transcript was efficiently cleaved by an anti-*bcr/abl* ribozyme. In CML blast crisis cell lines, expression of ribozymes targeted at *bcr/abl* mRNA was reported to be able to reduce the production of $p210^{bcr/abl}$, and *bcr/abl* transcripts and reduce cell proliferation.

C. RNA Revision by Trans-splicing Ribozymes

Recently, it has been argued that ribozymes may also be able to alter the sequence of targeted RNAs not just destroy them and that such RNA revision may be useful for treating a variety of diseases via gene therapy (12). As described earlier, the *Tetrahymena* group I ribozyme can catalyze a trans-splicing reaction (20,53). Such targeted trans-splicing can potentially be used to repair mutant transcripts and to alter viral RNAs to give them antiviral activity.

In the targeted trans-splicing reaction, the *Tetrahymena* ribozyme recognizes and binds to its substrate RNA (the 5′ exon) by base pairing between the IGS and a sequence in the substrate. Following cleavage, the ribozyme splices its 3′ exon onto the cleaved substrate RNA (Fig. 2c). Because the ribozyme cleaves after the sequence N_5U, the only sequence requirement for the substrate is to have a uridine residue preceding the cleavage site. Thus, any uridine nucleotide in an RNA molecule can in principle serve as a target for the ribozyme if the target sequence is accessible for ribozyme binding. Moreover, because there are no sequence requirements for the 3′ exon in the trans-splicing reaction (2), almost any sequence can be spliced onto the 5′ target transcript.

The lack of sequence requirements for the 3′ exon suggests that it could be manipulated so that trans-splicing can be employed to replace a defective portion of an RNA transcript with a functional sequence (Fig. 4). Trans-splicing ribozymes could be designed that would cleave defective transcripts upstream of point mutations or small insertions or deletions. A 3′ exon consisting of the wild-type sequence could then be spliced onto the cleaved target, resulting in a corrected mRNA. Trans-splicing ribozymes can be employed to repair defective RNA messages. In the first example of this application, the group I ribozyme from *T. thermophila* was reengineered to repair truncated *lacZ* transcripts via targeted trans-splicing in *E. coli* (103) and in mammalian cells (104). In both settings, the ribozyme was shown to be able to splice restorative sequences onto mutant *lacZ* target RNAs with high fidelity and thus maintain the open reading frame for translation of the repaired transcripts. In a subsequent study, the efficiency of RNA repair was monitored and the ribozyme was shown to be able to revise up to 50% of the truncated *lacZ* transcripts when ribozyme and *lacZ* substrate- encoding plasmids were cotransfected into mammalian fibroblasts (105).

More recently, several groups have demonstrated that group I ribozymes can be employed to amend faulty transcripts that are associated with common genetic diseases. Phylactou et al. demonstrated that a trans-splicing ribozyme could be employed to amend transcripts associated with myotonic dystrophy (106), Lan et al. employed this RNA repair approach to correct mRNAs associated with sickle-cell disease (Fig. 4) (107), Watanabe et al. corrected mutant p53 transcripts,(108) and Rogers et al. repaired mutant canine skeletal muscle chloride channel (109). In the myotonic dystrophy case, a trans-splicing ribozyme was employed to shorten the trinucleotide repeat expansion found in the 3′ untranslated region of the human myotonic dystrophy protein kinase transcript in cell culture studies (106). In the sickle-cell experiments, trans-splicing was employed to convert sickle β-globin transcripts into γ-globin-encoding mRNAs in erythrocyte precursors isolated from patients with sickle-cell disease (107). In both studies, sequence analysis of the amended RNAs demonstrated that the ribozyme had accomplished such repair with high fidelity, forming the proper splice junctions between the targeted transcript and the corrective sequences. In addition, a trans-splicing ribozyme was employed to repair mutant p53 in human cancer cells. After trans-splicing, repaired functional p53 was monitored by the induction of luciferase gene under the control of a p53-dependent promoter (108). These data suggest that ribozyme repaired mRNAs are translated in mammalian cells and retain wild-type activity. Finally, Rogers et. al. used a trans-splicing ribozyme to correct a mutant canine skeletal muscle chloride channel (cCIC-1). Although repair efficiency was low (1.2%) when ascertained by quantitative reverse transcription and polymerase chain reaction (RT-PCR) in a population of cells, patch-clamp analysis of individual cells yielded a wide range of repair efficiency with 18% of cells showing some restoration and several cells showing complete restoration of wild-type function (109).

Trans-splicing ribozymes have recently been employed to deliver new gene activities to *E. coli* (110), yeast (111), and mammalian cells (112). Kohler et al. (110) designed a trans-splicing ribozymes that contain a 3′ LacZ exon and targets either chloramphenicol acetyltransferase, HIV-1, or cucumber mosaic virus sequences. After induction of target and ribozyme expression in *E. coli*, trans-splicing was monitored by LacZ expression. In addition, Ayre et al. (111) investigated the utility of using a ribozyme that targets the coat protein of cucumber mosaic virus to inhibit viral propagation while selectively destroying virally infected cells. A trans-splicing ribozyme was developed that contains the diptheria toxin A chain (DTA) as a 3′ exon, which is spliced in frame to the viral target sequence. After trans-splicing, yeast cells that express the spliced viral target RNA fail to grow. Finally, this new genetic approach was developed to combat HVC infection in human cells (112). A trans-splicing ribozyme was targeted to a site in the HCV internal ribosome entry site (IRES) present in all viral RNAs and used for cap-independent translation of viral genes in mammalian cells. The 3′ exon contained the IRES sequence after the splice site fused in-frame to the DTA. After trans-splicing and IRES-mediated translation of the DTA, virally infected cells were destroyed by apoptosis. These data suggest that trans-splicing ribozymes can be used specifically and selectively to deliver new gene activities to a variety of cell types.

These results demonstrate that a trans-splicing group I ribozyme can be employed to repair pathogenic transcripts in clinically relevant, cellular settings. However, as with the development of almost every novel therapeutic approach, several technical issues must be addressed before ribozyme-mediated repair of mutant RNAs can become useful in the clinic. First, it remains to be determined whether repair of any pathogenic transcript can proceed efficiently enough in primary human cells to be therapeutically beneficial. In the case of sickle-cell disease, conversion of as little as 5% to 10% of the sickle β-globin transcripts into mRNAs encoding γ-globin is expected to greatly reduce cell sickling and thus the severity of the disease. Whether this relatively modest level of repair can be achieved in erythrocyte precursors from individuals with sickle cell disease is unclear but results demonstrating that 50% of the mutant *lacZ* transcripts expressed in mammalian cells can be revised by ribozymes (105) is at least encouraging in this regard. Second, the specificity of trans-splicing may have to be increased because in mammalian cell experiments the *Tetrahymena*

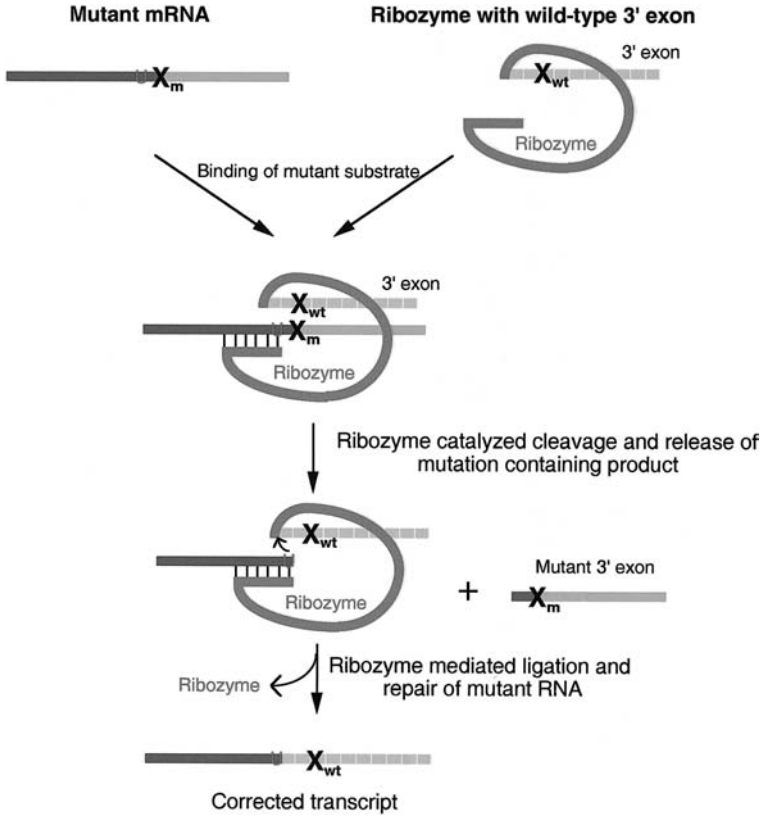

Figure 4 Ribozyme-mediated repair of mutant transcripts. A trans-splicing ribozyme (green) binds to a mutant RNA transcript that contains a point mutation, deletion, or insertion. The IGS on the ribozyme recognizes a uridine residue (red) 5′ of the mutation (indicated by Xm). The ribozyme cleaves the mutant RNA and releases the downstream, mutation-containing cleavage product (light blue). Next, the ribozyme ligates the wild-type sequence (Xwt and yellow) of the target RNA onto the upstream cleavage product to yield a repaired transcript. See the color insert for a color version of this figure.

group I ribozyme was shown to react not only with intended *lacZ* target RNAs, but also with other cellular transcripts (104). Such limited reaction specificity is fully anticipated from knowledge about the energetics of substrate binding by this ribozyme. This biochemical knowledge is now being used to redesign the ribozyme to enhance its specificity (51).

In summary, the ability to employ trans-splicing ribozymes to revise genetic instructions embedded in targeted RNAs represents a broad new approach to genetic therapy. Because defective RNAs can only be repaired in the cells in which they are present and only when they are expressed, RNA repair may become an effective means of recapitulating the natural expression pattern of therapeutic genes. Moreover, RNA repair may be especially useful in the treatment of genetic disorders that are associated with the expression of dominant or deleterious mutant RNAs and proteins. In these cases, RNA repair should simultaneously engender wild-type protein production and eliminate production of the deleterious gene product. For these reasons, the concept of RNA repair is likely to continue to attract increased interest from gene therapists.

IV. CONCLUSION

Trans-cleaving and trans-splicing ribozymes either alone or in combination with other therapeutic agents have the potential to restore genetic information or to eliminate it. The information presented in this chapter describes how ribozymes can be employed to mediate repair of defective transcripts or the destruction of pathogenic RNAs. Although the results from the first generation of therapeutic ribozyme experiments are in general quite encouraging, the long-term utility of catalytic RNAs is still unclear. Many factors may limit the efficacy of ribozymes in the clinic. Thus, it will be essential to evaluate RNA catalysis in clinically relevant settings and to use knowledge gained from such experiments to aid in the design of therapeutic ribozymes. Once adequately developed, catalytic RNAs should become new and useful weapons in the wars being waged on a great number of devastating diseases.

I. INTRODUCTION

Antisense oligonucleotides are short synthetic oligonucleotides, usually between 15 and 25 bases in length designed to hybridize to RNA through Watson–Crick base pairing (Fig. 1). Upon binding to the target RNA, the oligonucleotide prevents expression of the encoded protein product in a sequence-specific manner. As the rules for Watson-Crick base pairing are well characterized (1), antisense oligonucleotides represent, in principal, a simple method for rationally designing drugs. In practice, exploitation of antisense oligonucleotides for therapies has presented a unique set of challenges, some anticipated and others unanticipated. Nevertheless, antisense oligonucleotides are showing promise as therapeutic agents broadly applicable for the treatment of human diseases. Currently, there is 1 approved antisense product in the market and at least 20 agents currently in clinical trials, several of which are in advanced stages of development (Table 1). In this chapter, we summarize the properties of antisense oligonucleotides in terms of their application as therapeutic agents. As expected, there is significantly more information regarding first-generation phosphorothioate oligodeoxynucleotides; this serves as a good benchmark for comparison with some of the newer modified oligonucleotides. One antisense mechanism that we do not discuss in this chapter are ribozymes, as they are covered elsewhere in this volume.

II. ANTISENSE MECHANISM OF ACTION

Antisense oligonucleotides are small synthetic oligonucleotides that are designed to bind to mRNA through Watson–Crick hybridization. Upon binding to the RNA, the oligonucleotide may inhibit expression of the encoded gene product through either inducing cleavage of the RNA by RNases such as RNase H or by occupancy of critical regulatory sites on the RNA (Fig. 2). Several studies have documented that phosphorothioate oligodeoxynucleotides promote cleavage of the targeted RNA by a mechanism consistent with RNase H cleavage (2–6). RNase H is a ubiquitously expressed enzyme that cleaves the RNA strand of an RNA–DNA heteroduplex (6,7). If the antisense oligonucleotide use DNA chemistry, it will direct RNase H to specifically cleave the target RNA upon binding.

Another RNase-dependent antisense mechanism that has recently received much attention is interference RNA or RNAi (8–13). Introduction of long double-stranded RNA (dsRNA) into eukaryotic cells leads to the sequence-specific degradation of homologous gene transcripts. The long dsRNA molecules are metabolized to small 21 to 23 nucleotide interfering RNAs (siRNAs) by the action of an endogenous ribonuclease, Dicer (14–16). The siRNA molecules bind to a protein complex, termed RNA-induced silencing complex (RISC), which contains a helicase activity that unwinds the 2 strands of RNA molecules, allowing the antisense strand to bind to the targeted RNA molecule (12,17). The RISC is also believed to contain an endonuclease activity, which hydrolyzes the target RNA at the site where the antisense strand is bound. It is unknown whether the antisense RNA molecule is also hydrolyzed or recycles and binds to another RNA molecule. Therefore, RNA interference is an antisense mechanism of action, as ultimately a single- strand RNA molecule binds to the target RNA molecule by Watson–Crick base pairing rules and recruits a ribonuclease that degrades the target RNA.

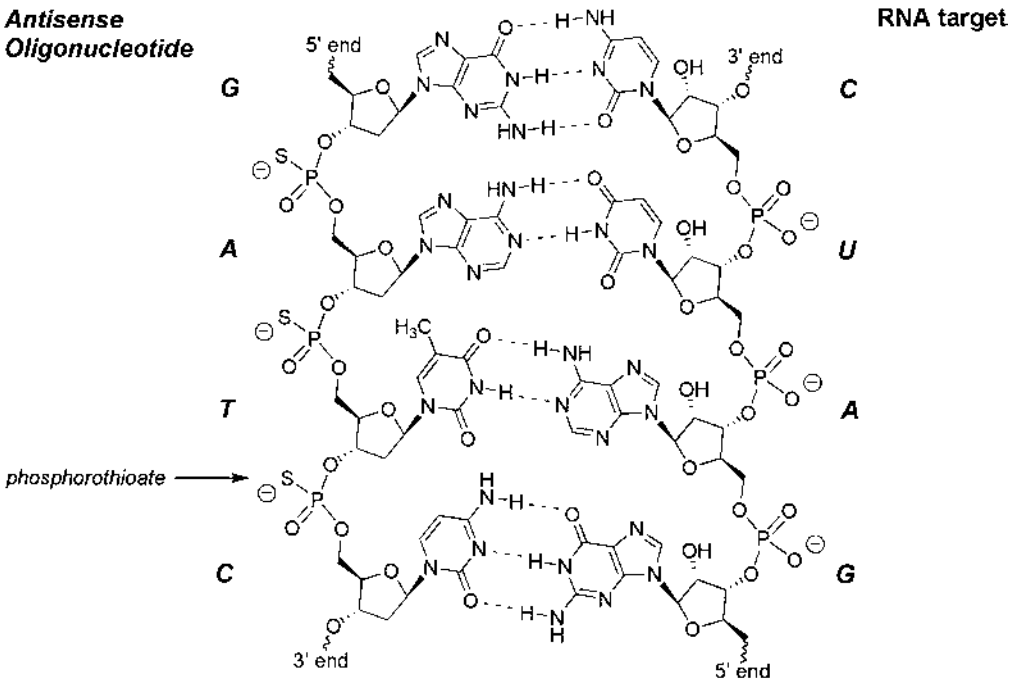

Figure 1 Phosphorothioate antisense oligodeoxynucleotide targeting an RNA receptor. Watson–Crick base pairing rules are indicated: nucleobase adenosine hydrogen bonds to nucleobase uracil, nucleobase cytosine hydrogen bonds to nucleobase guanine.

In mammalian cells, long double-stranded RNA molecules were found to promote a global change in gene expression, obscuring any gene-specific silencing (18,19). This reduction in global gene expression is believed to be mediated in part, through activation of double-stranded RNA-activated protein kinase (PKR), which phosphorylates and inactivates the translation factor eIF2α (20). Recently, it has been shown that transfection of synthetic 21-nucleotide siRNA duplexes into mammalian cells does not elicit the PKR response, allowing effective inhibition of endogenous genes in a sequence-specific manner (21,22). These siRNAs are too short to trigger the nonspecific dsRNA responses, but they still promote degradation of complementary RNA sequences (21–23). We have directly compared the activity of optimized oligonucleotides that work by RNase H mechanism with those that work by an RNAi mechanism in human cells (24). The potency, maximal efficacy, duration of action, selectivity and efficiency for identification of leads was similar for both mechanisms in cell-based assays. The one noted difference between the 2 mechanisms, is that RNase H oligonucleotides are able to cleave pre-mRNA in the nucleus, whereas siRNA oligonucleotides appear to only be able to interact with mature mRNA in the cytoplasm. These results suggest that both mechanisms are equally valid for inhibition of gene expression in mammalian cells.

There are other RNases present in cells that may be exploited in a manner similar to RNase H or the dsRNase associated with RNAi. As an example, Wu et al., reported that single-stranded, phosphorothioate-modified oligoribonucleotides can promote selective loss of ha-ras mRNA in human cells (25). The RNA oligonucleotides could be partially modified with 2′-O-methyl nucleosides and still support enzyme activity. The enzyme activity is consistent with a RNase III type enzyme. RNase III activity is present in both cytosolic and nuclear extracts (25). It is unclear if this enzyme activity is the same RNase III used for siRNA oligonucleotides. Recent work has demonstrated that single-stranded RNA oligonucleotides can interact with the RISC and promote selective degradation of targeted RNA, consistent with RNAi activity, albeit not as efficiently as double-stranded RNA (26,27). Another RNase enzyme that has been exploited for antisense applications is RNase L (28). RNase L is ribonuclease activated by 2′-5′-linked oligoadenylates generated in response to interferon activation. Selectively, linkage of 2′-5′ oligoadenylate to an antisense oligonucleotide has been reported to promote selective cleavage of the targeted mRNA (28–30).

It should be noted that not all oligonucleotide designed to hybridize to a target RNA effectively inhibit target gene expression (2,31–33). This is believed to be due to inaccessibility of some regions of the RNA to the oligonucleotide due to secondary or tertiary structure or to protein interactions with the RNA. At this time, there are no good predictive algorithms for predicting antisense oligonucleotide-binding sites

Table 1 Antisense Oligonucleotides Approved or Currently in Clinical Development

Oligonucleotide	Molecular target	Disease indication	Chemistry	Route of administration	Status	Sponsor
Vitravene (fomivirsen, ISIS 2922)	Human CMV IE-2 gene	CMV retinitis	Phosphorothioate oligodeoxynucleotide	Intravitreal	Marketed	Novartis Ophthalmic/ISIS Pharmaceuticals

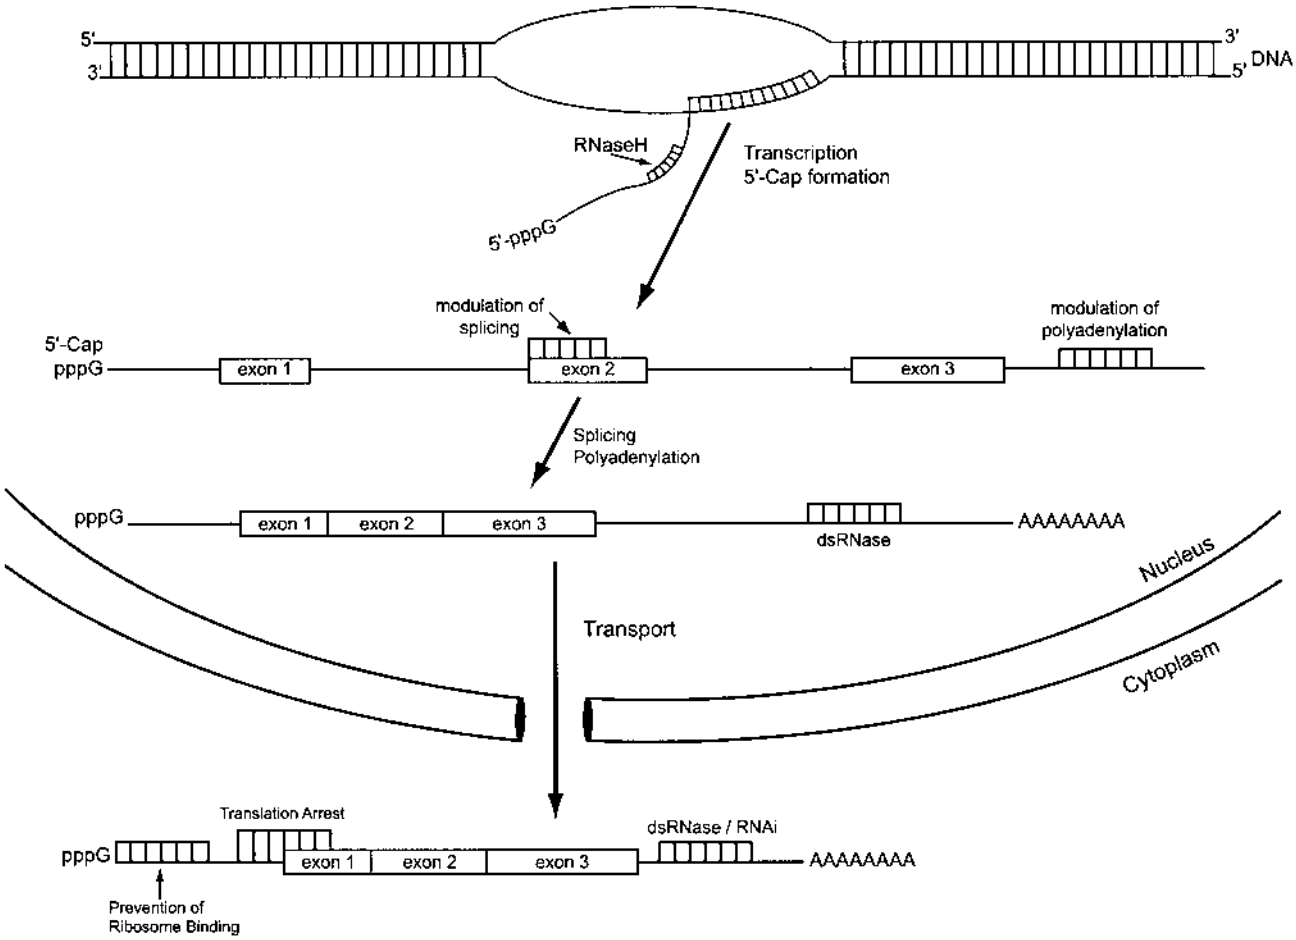

Figure 2 Antisense mechanisms of action. Cartoon depicting 3 different mechanisms by which an antisense oligonucleotide can inhibit expression of a targeted gene product by hybridization to the mRNA, or pre-mRNA which codes for the gene product.

on a target RNA. In our experience, we have found active oligonucleotides that work through an RNase H-dependent mechanism can hybridize to any region on the mRNA or pre-mRNA. Thus, some serendipity is still involved in the process of identifying and optimizing potent and effective antisense inhibitors.

Early on it was believed that occupancy of the RNA (the receptor for the antisense oligonucleotide) by the oligonucleotide would be sufficient to block translation of the RNA (i.e., translation arrest) (34). Subsequent studies have documented that oligonucleotides are not efficient at blocking translation of mRNA if they bind 3′ to the AUG translation initiation codon. Furthermore, we have found that only certain sites in the 5′-untranslated region of a mRNA are effective target sites for an antisense oligonucleotide. In particular, the 5′-terminus of a transcript appears to be a good target site for oligonucleotides for some molecular targets in that occupancy of this region prevents assembly of the ribosome on the RNA (35). It should be noted that occupancy of the receptor (RNA) and steric blocking of factor binding by high-affinity oligonucleotides can be an efficient mechanism for blocking gene expression. For the example cited above, the steric blocking oligonucleotide was approximately 10-fold more potent than an oligonucleotide that supports RNase H activity. These results suggest that catalytic turnover of the target RNA is not the rate-limiting step for antisense oligonucleotides.

Another process that noncatalytic oligonucleotides can use to alter gene expression is through regulating RNA processing. Most mammalian RNAs undergo multiple post- or cotranscriptional processing steps, including addition of a 5′-cap structure, splicing, and polyadenylation. Because single-stranded antisense oligonucleotides localize to the cell nucleus (36–39), they have the potential of regulating these processes.

Several studies have been published documenting that antisense oligonucleotides can be used to regulate RNA splicing in both cell-based assays and in rodent tissues (40–47). Oligonucleotides can be used to modulate alternative splicing by promoting use of cryptic splice sites as was exemplified for β thalassemia (40,41), or by enhancing use of an alternative splice site. Oligonucleotide binding to the pre-mRNA can also be exploited to mask polyadenylation signals on the pre-mRNA, forcing the cell to use alternative poly A sites (48). Finally, oligonucleotides, in principle, can regulate RNA function by sterically preventing factors from binding or changing the structure of the RNA such that it is no longer recognized by the factor. Thus, there are multiple mechanisms by which oligonucleotides can be use to inhibit or modulate expression of a target gene product. No single mechanism is far superior to other mechanisms, thus one should tailor the mechanism for the specific biological application.

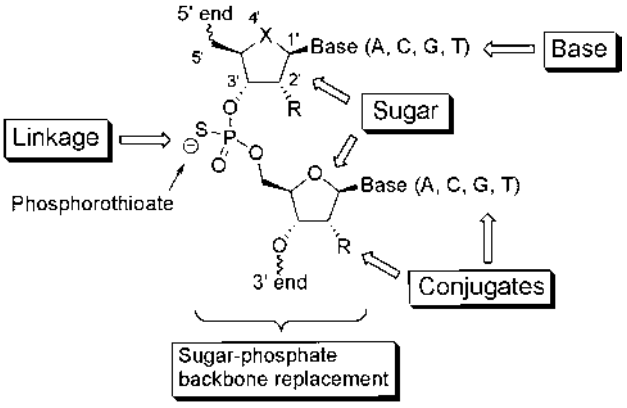

Figure 3 Positions that have been chemically modified for antisense oligonucleotides.

III. ANTISENSE OLIGONUCLEOTIDE CHEMISTRY

The most advanced oligonucleotide chemistry used for antisense drugs is phosphorothioate oligodeoxynucleotides. These differ from natural DNA in that 1 of the nonbridging oxygen atoms in phosphodiester linkage is substituted with sulfur (Fig. 1). Phosphorothioate oligodeoxynucleotides are commercially available, easily synthesized, support RNase H activity, exhibit acceptable pharmacokinetics for systemic and local delivery, and have not exhibited major toxicities that would prevent their use in humans. There have been significant resources employed to identify chemical modifications that further improve upon the properties of phosphorothioate oligodeoxynucleotides. The primary objectives of the effort are similar to medicinal chemistry efforts for other types of pharmacological agents (i.e., to increase potency, improve pharmacokinetics, and decrease toxicity).

A dimer of an oligonucleotide depicting subunits that may be modified to enhance oligonucleotide drug properties is depicted in Fig. 3. In naturally occurring nucleic acids, these subunits are composed of heterocycles, carbohydrate sugars, and phosphodiester-based linkages between the sugars. The combination of the carbohydrate sugar (ribose in RNA, 2′-deoxyribose in DNA) and the linkage provides the backbone of the oligonucleotide polymer. Many modifications have been made on the individual base, sugar, and linkage subunits, and the sugar-phosphate backbone has been completely replaced with an appropriate substitute. In Addition, many diverse moieties have been conjugated to various positions in the subunits, mainly in an attempt to alter the biophysical properties of the polymer. Finally, prodrug modifications may be employed to enhance drug properties. Most of the positions available in a nucleoside dimer (approximately 25 positions for each dimer that do not directly interfere with Watson–Crick base pair–hydrogen bonding) have been modified and studied for their effects on the properties of the resulting oligonucleotides.

The nucleobases or heterocycles of nucleic acids provide the recognition points for the Watson–Crick base pairing rules and any oligonucleotide modification must maintain these specific hydrogen-bonding interactions. Thus, the scope of heterocyclic modifications is somewhat limited. The relevant heterocyclic modifications can be grouped into 2 structural classes: (1) those that enhance base stacking, and (2) those that provide additional hydrogen bonding. The primary objective of heterocyclic modifications being to enhance hybridization, resulting in increased affinity (Fig. 4). Modifications that enhance base stacking by expanding the π-electron cloud are represented by lipophilic modifications in the 5-position of pyrimidines, such as propynes, hexynes, azoles, and a simple methyl group (49–52) and the 7 position of 7-deaza-purines position, including iodo, propynyl, and cyano groups (53–55). Investigators have continued to build out of the 5-position of cytosine by going from the propynes to 5-membered heterocycles to tricyclic fused systems emanating from the 4 and 5-positions of (Fig. 4) (56–59). A second type of heterocycle modification is represented by the 2-aminoadenine (Fig. 4), where the additional amino group provides another hydrogen bond in the A-T base pair, analogous to the 3 hydrogen bonds in a G-C base pair. Heterocycle modifications providing a combination of effects are represented by 2-amino-7-deaza-7-modified A (55) and the G-clamp, a tricyclic cytosine analog having hydrogen-bonding capabilities in the major groove of heteroduplexes (58) (Fig. 4). Furthermore, N2-modified 2-amino purine oligonucleotides have exhibited interesting binding properties (60,61). All these modification are positioned to lie in the major or minor groove of the heteroduplex, do not affect sugar conformation of the heteroduplex, and provide little nuclease resistances, but will generally support an RNase H cleavage mechanism.

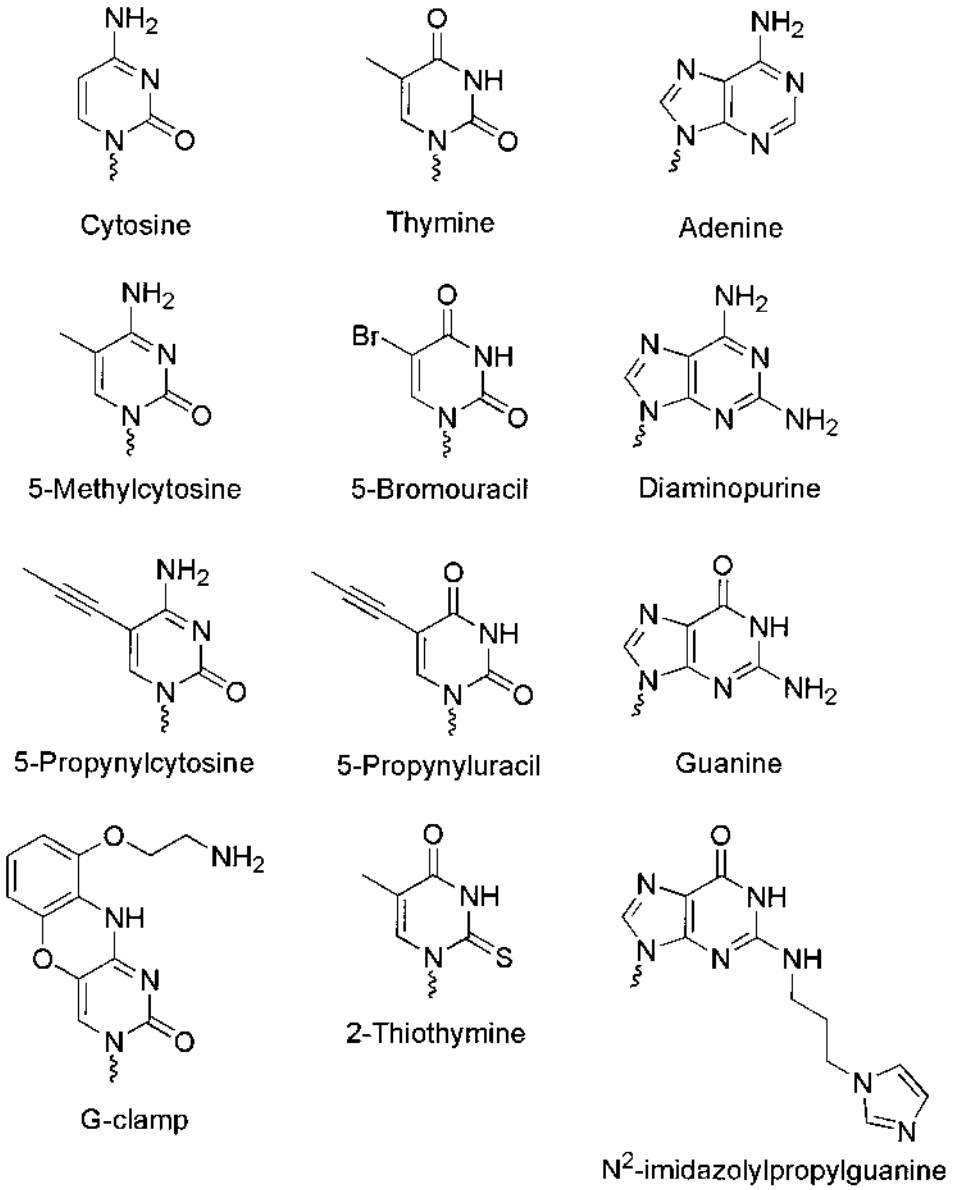

Figure 4 Examples of different heterocycle modifications that support antisense activity.

Modifications in the ribofuranosyl moiety have provided the most value in the quest to enhance oligonucleotide drug properties (Fig. 5). In particular, certain 2′-*O*- modifications have greatly increased binding affinity and nuclease resistance, altered pharmacokinetics, and are potentially less toxic (62). Preorganization of the sugar into a 3′-*endo* pucker conformation is responsible for the increased binding affinity (63–65). The 2′-*O*-methoxyethoxy (MOE) and 2′-*O*-methyl modifications (Fig. 5) are the most advanced of the 2′-modified series, and have entered clinical trials. The cationic 2′-*O*-aminopropyl (66) and 2′-*O*-(dimethylaminooxyethyl) (67,68) have shown favorable binding affinity, with dramatically improved nuclease resistance. In an attempt to extend on the increased nuclease resistance of these cationic modifications to the high affinity seen with MOE, a dimethylaminoethyl version (DMAEOE) was prepared. This modification displays hybridization properties equal to or superior to those of MOE, and nuclease resistance equal to that of the 2′-*O*-aminopropyl modification. The modification showing the largest known improvement in binding affinity is a bicyclic

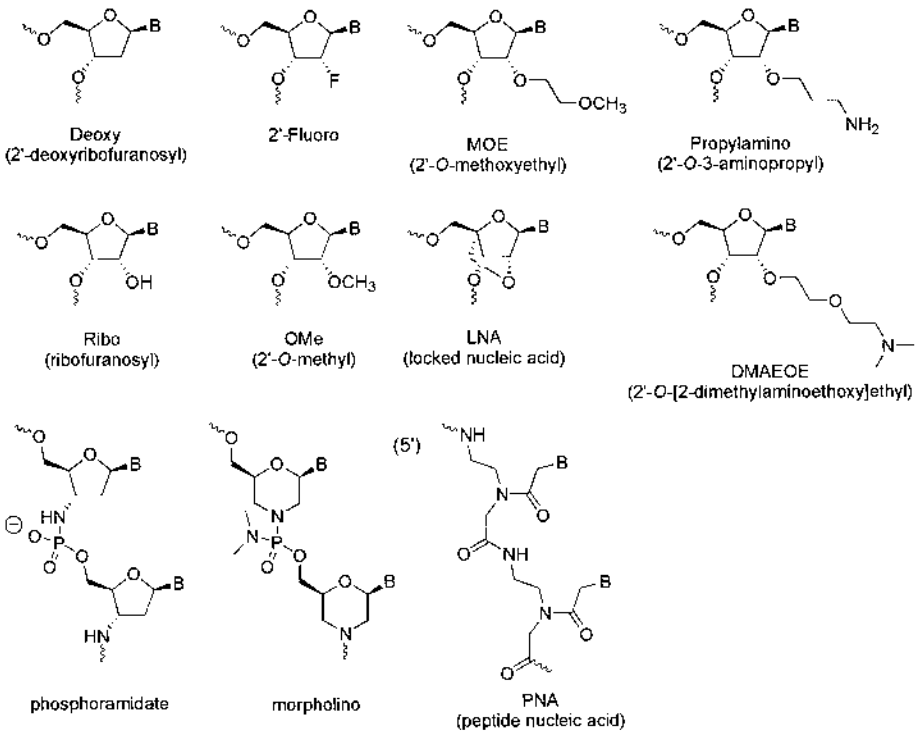

Figure 5 Examples of different sugar and backbone modifications that support antisense activity.

system having the 4′-carbon tethered to the 2′-hydroxyl group. As this modification ''locks'' the conformation of the ribose sugar into an RNA-like (3′-*endo*) conformation, it is referred to as locked nucleic acid (LNA) (69,70). LNA shows dramatically improved hybridization properties with regard to a reference DNA:RNA duplex, and has extremely high nuclease resistance. Although extremely promising from early biophysical and in vitro data, whether these properties will translate into improved efficacy in vivo remains to be seen.

It is now well known that uniformly 2′-*O*-modified oligonucleotides do not support an RNase H mechanism (71). The heteroduplex formed has been shown to present a structural conformation that is recognized by the enzyme, but cleavage is not supported (72–74). Thus, uniformly modified, ''RNA–like'' oligonucleotides (3′-*endo* sugar conformation) will be unable to effect cleavage of the target mRNA, and must therefore exert their effects via other means. This has led to the development of a chimeric strategy (3,71,75–77), which focuses on the design of high-affinity, nuclease-resistant antisense oligonucleotides that contain a ''gap'' of contiguous phosphorothioate- modified oligodeoxynucleotides (Fig. 6). On hybridization to target RNA, a heteroduplex is presented that supports an RNase H-mediated cleavage of the RNA strand via interaction with the 2′-deoxy gap region. The stretch of the modified oligonucleotide–RNA heteroduplex, which is recognized by RNase H may be placed anywhere within the modified oligonucleotide. The modifications in the flanking regions of the gap should not only provide nuclease resistance to exo- and endonucleases, but also not compromise binding affinity and base pair specificity. There are several types of structures that have been successfully developed (Fig. 6), with the most advance being ''gapmers,'' having a 7- to 10-base oligodeoxynucleotide gap flanked by 2 regions of 2′-modified nucleosides. These oligomers, in particular, 2′-MOE modified, show reduced toxicity, increased potency, and superior pharmacokinetics relative to the parent unmodified 20-mer phosphorothioate oligodeoxynucleotide (77–81).

Several possible mechanisms exist for uniformly modified, non-RNase H activating oligonucleotides to show efficacy, such as prevention of assembly of the ribosome through binding in the 5′-UTR, ''translation arrest,'' or ribosome stalling by blocking the reading of the mRNA ribosome, and modulation of splicing events by binding to splice junctions. Although all these strategies have been pursued, no uniformly modified oligonucleotides have advanced beyond gapmer oligonucleotides. However, much recent progress has been made with non-RNase H active oligonucleotides, and there remains much potential for these modifications. LNA and MOE have been used in a uniform context in addition to the gapmer strategy, and early studies show promise. Another interesting uniform

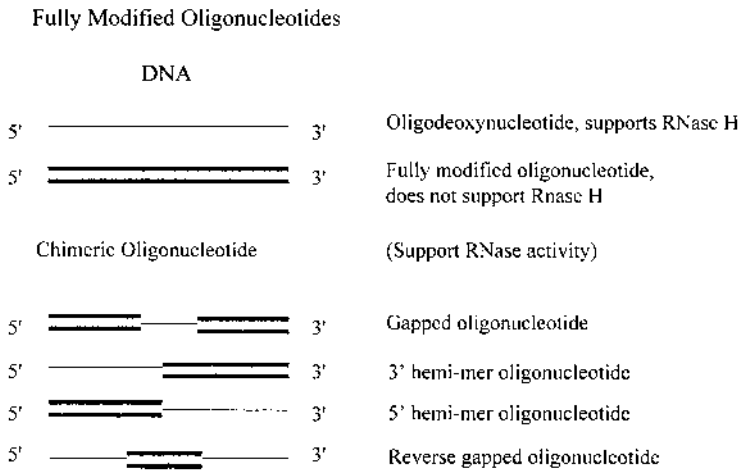

Figure 6 Examples of different oligonucleotide structures.

modification is the phosphoramidiate modification, which substitutes an amino group for the 3′ oxygen atom of the deoxyribose sugar of DNA. This results in a preference for the RNA-like (3′ endo) sugar conformation, and results in increased affinity as is seen with the 2′-*O*-alkyl modifications (82,83).

One of the most intriguing backbone oligonucleotide modifications is peptide nucleic acid (PNA). PNA is unique in that the sugar-phosphate backbone is completely replaced with a peptide-based backbone (Fig. 5) (84). This results in a polymer with a neutral backbone that has high affinity for complimentary nucleic acids. PNA has been extensively investigated as an antisense agent, but these efforts have generally been frustrated by the poor cellular penetration and in vivo pharmacokinetic properties of PNA (85). Recently, a 4-lysine peptide conjugated to a PNA was found to provide robust in vivo activity when targeted to a splice junction (47). These data are highly encouraging because they may provide a path to realizing the promise of PNA as an antisense therapeutic agent.

The most advanced uniform modification is the ''morpholino'' modification (Fig. 5), which is currently in phase II clinical trials for restenosis, cancer, and polycystic kidney disease. The morpholino modification simultaneously replaces the ribofuranosyl sugar with a morpholine ring, and the negatively charged phosphate ester with a neutral phosphorodiamidate linkage (86,87). Morpholinos are generally used around the translation initiation start codon, and are believed to function via translation arrest. A morpholino oligonucleotide has shown in vivo activity (88), as well as oral bioavailability in rats (89), which would be a major advance if studies proved general and translated to larger mammalian species.

In addition to heterocycle, backbone, and sugar modification discussed above, various pendant groups have been attached to oligonucleotides, such as cholesterol, folic acid, fatty acids, etc., to alter pharmacokinetic properties (90,91). The reader is referred to several recent reviews that discuss the chemistry of oligonucleotides in more detail (92–95). It should be noted that there is no single modification that covers all the desired properties for a modified oligonucleotide. Modifications have been identified that increase hybridization affinity of the oligonucleotide for its target RNA, increase nuclease resistance, decrease toxicity, and alter the pharmacokinetics (Table 2). Furthermore, the ideal oligonucleotide will differ for different applications. Therefore, it is important to be able to mix and match the various modifications to obtain the optimal oligonucleotide for the task at hand.

Table 2 Attributes of Various Modified Oligonucleotides

Attribute	Examples
Increased affinity for RNA	2′-*O*-methyl, 2′-fluoro, MOE, DMAEOE, LNA, 5-MeC, 5-propynyl, phenoxazine G-clamp, PNA, phosphoramidate, others
Increased nuclease resistance	MOE, DMAEOE, LNA, PNA, phosphoramidate, morpholino, others
Alter tissue distribution	MOE, PNA, cholesterol conjugate, phosphoramidate, morpholino, others
Decrease toxicity	2′-*O*-methyl, MOE, 5-MeC, morpholino, others

IV. PHARMACOKINETICS OF OLIGONUCLEOTIDES

A. Cellular Pharmacokinetics

Cellular uptake of phosphorothioate oligonucleotides has been documented to occur in most mammalian cells (96–103). Cellular uptake of oligonucleotide is time and temperature dependent. It is also influenced by cell type, cell culture conditions and media, and the length/sequence of the oligonucleotide itself (96). No obvious correlation between the lineage of cell, whether the cells are transformed or virally infected, and uptake has been identified. Cellular uptake appears to be an active process (i.e., oligonucleotide) will accumulate in greater concentration intracellular than in the medium and is energy dependent. Despite the fact that mammalian cells in culture will readily accumulate oligonucleotides, it has been necessary to further facilitate cytosolic delivery for many, but not all, cells with transfection agents such as cationic lipids, dendrimers, fusogenic peptides, electroporation, etc., (38,46,104–108). In the absence of these facilitators, it has been difficult to demonstrate true antisense effects in cultured cells., although there are some exceptions. However, in vivo, this is not the case. It has become apparent that in vitro cell uptake studies do not predict in vivo cell uptake and pharmacokinetics of oligonucleotides (96,109–113). Our understanding of cellular and subcellular uptake has evolved as superior analytical tools have been developed. These advances include development of immunohistochemical techniques use oligonucleotide-specific antibodies (114), and in situ perfusion of whole organs followed by cell sorting and subcellular separation techniques coupled with capillary gel electrophoresis (110).

Our understanding of cellular and subcellular distribution and pharmacokinetics of oligonucleotides in whole animals is emerging. In our laboratories, we use more specific tools for qualification and even quantification of intact oligonucleotide (110,114–116). Phosphorothioate oligonucleotides rapidly distribute to whole tissue with distribution half-lives range from 30 to 60 min in vivo. Approximately half of the oligonucleotide associated with the liver (as an example) is intracellular in both parenchymal and nonparenchymal cells by 4 h after intravenous administration (110,117). The other half of the organ-associated oligonucleotide appears to be associated with extracellular matrix or interstitium, or loosely bound to the cell membrane. Consistent with this observation, others have shown that phosphorothioates have been localized to connective tissue and can bind to various proteins within these matrices, such as laminin and fibronectin (114,118,119). Some of this matrix- associated oligonucleotide will diffuse to cells over time or be lost to efflux from the organ (114). It is likely that both of these processes are functioning up to 24 h after administration of oligonucleotide. By 24 h after injection of phosphorothioate oligonucleotide, little is seen to be associated with extracellular matrix (114). Thus, it is likely that whole organ pharmacokinetic evaluation after 24 h will parallel cellular clearance kinetics.

Although the in vitro studies fail to predict well which cell types will take up oligonucleotide in vivo, the general trend of variability from cell type to cell type continues to be observed in vivo (114). Based on these results, one would not expect to uniformly inhibit expression of a targeted gene product within a tissue or whole organism, resulting in differential sensitivity of different tissues and cells within tissue to the antisense effect. Subcellular distribution has been shown to be broad, and the extent of cytosolic and nuclear distribution differs between cells (110). In general, the total number of oligonucleotide molecules is greatest in the cytosol. However, because of the much smaller volume of the nucleus, the nucleus may often contain a higher concentration of oligonucleotide than the cytosol.

Nuclease metabolism has been shown to account for the clearance of phosphorothioate oligonucleotide from organs of distribution. Within the cells, the pattern of metabolites appears to be quite similar between cell types and the subcellular compartments (membrane associated, cytosolic, and nuclear). Increasing doses from 5 to 50 mg/kg only moderately decreased metabolism intracellularly, consistent with whole organ data (110).

Several studies have suggested that active uptake processes, including receptor-mediated endocytosis and pinocytosis, are involved in uptake of oligonucleotides in vivo. At very low doses (less than 1 mg/kg), competition of binding for scavenger receptors in vivo altered the whole organ distribution of oligonucleotides in liver but not in kidney (120–122). However, distribution studies conducted in scavenger receptor knockout mice did not show significantly altered intracellular and whole organ distribution of phosphorothioate oligonucleotides (123).

Distribution in the kidney has been more thoroughly studied, and drug has been shown to be present in Bowman's capsule, the proximal convoluted tubule, the brush border membrane, and the renal tubular epithelial cells (114,124). These data suggested that the oligonucleotides are filtered by the glomerulus and then reabsorbed by the proximal convoluted tubule epithelial cells. Moreover, the authors identified a specific protein in the brush border that may mediate uptake. In subsequent studies, the authors have purified the 45-kDa protein, reconstituted it in phospholipid vesicles and demonstrated that it served as a channel allowing nucleic acid to pass through phospholipid bilayers (125). In separate studies, other investigators have shown that, although some oligonucleotide is taken up from the tubular lumen brush border, the distribution to the tubule epithelial cells is predominantly from the capillary serosal side (126). The uptake from capillary circulation may not be receptor mediated. In summary, it is likely that there are multiple processes involved in the uptake of oligonucleotides into cells in vivo. Additional research will be required to further elucidate these mechanisms.

B. Whole Animal Oligonucleotide Pharmacokinetics

1. Phosphorothioate Oligodeoxynucleotides

The plasma pharmacokinetics of phosphorothioate oligodeoxynucleotides are characterized by rapid and dose-dependent

clearance (30–60 min half-life) driven primarily by distribution to tissue and secondarily by metabolism. Urinary and fecal excretion are minor pathways for elimination of phosphorothioate oligonucleotides. Dose-dependent clearance from plasma is predominantly a function of saturable tissue distribution (127,128). Metabolism has been shown to be unchanged in plasma over a large dose range (1–50 mg/kg) and after repeated administration up to 1 month, suggesting that metabolism is neither inhibited or induced by repeat administration (129).

The plasma pharmacokinetics are quite similar between animals and man, and they scale from one species to the next on the basis of body weight, not surface area (129–133). For example, it is possible to show that, when dosed on the basis of body weight, the concentrations of oligonucleotides in plasma administered by a 2-h constant intravenous infusion are similar between humans and monkeys. Thus, it has been possible to predict plasma concentrations in humans from nonclinical pharmacokinetic data.

Phosphorothioate oligonucleotides bind to circulating plasma proteins such as albumin and α-2 macroglobulin (134). The apparent affinity for human serum albumin is low (10–30 μM). Therefore, plasma protein binding provides a repository for these drugs preventing rapid renal excretion. Because serum protein binding is saturable at high concentrations, intact oligonucleotide may be found in urine in increasing amounts as dose rate and/or amount is increased (129, 135,136).

Phosphorothioate oligonucleotides are rapidly and extensively absorbed after intradermal, subcutaneous, intramuscular, or intraperitoneal administration (109,127,137,138). Nonparenteral absorption has been characterized for pulmonary and oral routes of administration. Estimates of bioavailability range from 3% to 20% following intranasal dosing and $< 1\%$ by the oral route (139,140). Although it is likely that permeability in the intestine is low, stability of these compounds in the intestine (prior to absorption) may be a rate-limiting factor to oral absorption (141,142). As discussed below, some chemical modifications to the oligonucleotide enhance oral absorption. The metabolic half-life of a 20-mer phosphorothioate oligonucleotide in the rat intestine (in vivo) is less than 1 h (data shown in Section VI).

Phosphorothioates are broadly distributed to all peripheral tissues. Highest concentrations of oligonucleotides are found in the liver, kidney, spleen, lymph nodes, and bone marrow with no measurable distribution to the brain (109,127,129, 135,141). Many other tissues take up smaller amounts of oligonucleotide, resulting in lower tissue concentrations. Phosphorothioate oligonucleotides are primarily cleared from tissues by nuclease metabolism. Rate of clearance differs between tissues with the spleen, lymph nodes, and liver, generally clearing more rapidly than kidney, for example. In general, the clearance rates result in half-lives of elimination ranging from 2 to 5 days in rodents and primates (128,133).

In summary, pharmacokinetic studies of phosphorothioate oligonucleotides demonstrate that they are well absorbed from parenteral sites, distribute broadly to all peripheral tissues, do not cross the blood–brain barrier, and are eliminated primarily by slow metabolism. In short, once-a-day or every-other-day systemic dosing should be feasible. In general, the pharmacokinetic properties of this class of compounds appear to be largely driven by chemistry rather than sequence. Additional studies are required to determine whether there are subtle sequence-specific effects on the pharmacokinetic profile of this class of drugs.

2. Second-generation Oligonucleotides

The plasma pharmacokinetics of 2′-*O*-methyl-, 2′-*O*-propyl-, or 2′-*O*-methoxyethyl-modified oligonucleotides do not differ significantly from their oligodeoxynucleotide congeners (79,80,143,144). Because metabolism plays only a minor role in the plasma distribution kinetics, this modification is expected to do little to alter the distribution and excretion kinetics. Early studies in our laboratory indicate that the binding affinity to serum albumin may be somewhat lessened by 2′-ribose sugar modifications, but the overall capacity of the plasma proteins to bind these oligonucleotides is not significantly changed (Table 3). Therefore, urinary excretion remains a minor route of elimination, and these compounds are broadly distributed to peripheral tissues.

Several of the 2′-ribose sugar modification produces enough of an increase in nuclease resistance that it is possible

Table 3 Serum Albumin Affinity, Whole Plasma Fraction Bound to Proteins (F_b), and Fraction of Dose Excreted in Urine ($f_{excreted}$, 0–24 h) Following Intravenous Administration at 3 mg/kg—Comparison of First- and Second-Generation Chemistries

Compound no.	Chemistry	Kd (μM)	$F_{b\,(\%)}$	$f_{excreted}$
ISIS 2302	PS ODN[a]	17.7	99.2	0.003
ISIS 11159	PS 2′-MOE[b]	29.3	95.5	0.032
ISIS 16952	PO 2′-MOE[c]	>500	79.6	0.45

[a]PS ODN, phosphorothioate oligodeoxynucleotide.
[b]PS 2′-MOE, 2′-O-methoxyethyl ribose modified phosphorothioate (all nucleotides were modified).
[c]PO 2′-MOE, 2′-O-methoxyethyl ribose modified phosphodiester (all nucleotides were modified).

to produce relatively stable oligonucleotides with phosphodiester linkages (Table 2). Thus, this modification allows for elimination or reduction in the number of sulfurs contained in the internucleotide bridge, but these compounds are less stable than their 2′-modified phosphorothioate congeners (145). In addition, as sulfur is removed, plasma protein binding is greatly decreased and rapid removal from plasma by filtration in the kidney increases significantly. This pharmacokinetic characteristic may limit the use of phosphodiester second-generation modified oligonucleotides intended for treatment of systemic disease (79). Alternatively, this pharmacokinetic profile may be ideal for locally administered oligonucleotides because it limits the accumulation of systemically absorbed drug.

Absorption for parenterally administered modified oligonucleotides is consistently rapid and nearly complete. Some of the second-generation modified oligonucleotides have exhibited improved intestinal permeability (141) as well as significantly improved stability in the intestine (142). It is likely this combination of improved biochemical characteristics have led to the observation of improved oral bioavailability (141) for this class of oligonucleotide compounds.

The distribution pattern of the 2′-ribose-modified phosphorothioate oligonucleotides are similar to first-generation phosphorothioates and similarly not altered by changes in sequence. Kidney, liver, spleen, bone marrow, and lymph nodes are the major sites of distribution. The most exciting difference in pharmacokinetics is, not surprisingly, manifested in prolonged terminal elimination half-lives from tissues of distribution. The elimination half-lives appear to be increased nearly 5 to 10-fold, suggesting that once-weekly systemic dosing may be feasible (Table 4).

In summary, pharmacokinetic studies of 2′-modified ribose phosphorothioate oligonucleotides demonstrate that they are well absorbed from parenteral sites, may have improved oral absorption attributes, and distribute broadly to all peripheral tissues. Although stability has been greatly enhanced, nuclease metabolism is likely the primary mechanism for ultimate elimination of these modified oligonucleotides. In short, once-a-week systemic dosing should be feasible and oral administration may be possible in the near future. Additional studies are required to determine whether there are substantial sequence-specific effects on the pharmacokinetic profile of this class of drugs.

Table 4 Summary of Observed Organ Clearance Half-lives (in days) Comparing Second- and First-Generation Chemistries

Organ	2′-Modified phosphorothioate oligonucleotide	Phosphorothioate oligodeoxynucleotide
Kidney cortex	21.7	5.0
Kidney medulla	10.4	3.1
Liver	7.7	2.8
Spleen	8.1	3.3
Lymph nodes	16.5	0.9
Bone marrow	11.5	1.3

V. TOXICOLOGY OF OLIGONUCLEOTIDES

Phosphorothioate oligodeoxynucleotides have been examined extensively in a full range of acute, chronic, and reproductive studies in rodents, lagomorphs, and primates. At high doses, there is a distinctive pattern of toxicity that is common to all phosphorothioate oligodeoxynucleotides (146–149). The remarkable similarity in toxicity with different phosphorothioate oligodeoxynucleotides suggests that, for this class of antisense compounds, toxicity is independent of sequence and is the result of nonantisense-mediated mechanisms. The most probable mechanism of the observed toxicities is the binding of oligodeoxynucleotides to proteins. These nonantisense-mediated pathways are believed to be responsible for most, if not all, of the toxicities associated with the administration of these compounds to laboratory animals. This conclusion is strengthened by studies in which little or no differences in toxicity are observed between pharmacologically active and inactive sequences. Different patterns of toxicity exist between rodents and primates. Understanding the mechanisms behind these differences is crucial to understanding which species best predicts the potential human effects. A comparison of the toxicological profiles of phosphorothioate oligodeoxynucleotides with that of the next generation of phosphorothioate oligonucleotides suggests that some of the chemical class-related toxicities of phosphorothioate oligodeoxynucleotides can be ameliorated by chemical modification.

A number of phosphorothioate oligodeoxynucleotides have been examined in 1 or more of the following battery of genotoxicity assays: Ames test, in vitro chromosomal aberrations, in vitro mammalian mutation (HGPRT locus and mouse lymphoma), in vitro unscheduled DNA synthesis tests, and in vivo mouse micronucleus. In all these assays, the results were negative and there was no evidence of mutagenicity or clastogenicity of these compounds (150).

A. Acute Toxicities

In rodents, the acute toxicity of phosphorothioate oligodeoxynucleotides has been characterized as part of an effort to determine the maximum tolerated dose for in vivo genotoxicity assays. The doses of 3 phosphorothioate oligodeoxynucleotides required to produce 50% lethality (LD50) were estimated to be approximately 750 mg/kg (150).

In primates, the acute dose-limiting toxicities are a transient inhibition of the clotting cascade and the activation of the complement cascade (146,151,152). Both of these toxicities are believed to be related to the polyanionic nature of the molecules and the binding of these compounds to specific protein factors in plasma.

Prolongation of clotting times following administration of different phosphorothioate oligodeoxynucleotides is charac-

terized by a concentration-dependent prolongation of activated partial thromboplastin times (aPTT) (149,153–155). The prolongation of aPTT is highly transient and directly proportional to plasma concentrations of oligodeoxynucleotide and therefore parallels the plasma drug concentration curves with various dose regimens. As drug is cleared from plasma, the inhibition diminishes such that there is complete reversal within hours of dosing. With repeated administration, there is no evidence of residual inhibition. Prolongation of aPTT has been observed in all species examined to date, including human, monkey, and rat. The mechanism of prolongation of aPTT by phosphorothioate oligodeoxynucleotides is believed to be a result of the interaction of the oligonucleotides with proteins. It is well known that polyanions are inhibitors of clotting, and phosphorothioate oligodeoxynucleotides may act through similar mechanisms. If these oligonucleotides inhibit the clotting cascade as a result of their polyanionic properties, then binding and inhibition of thrombin would be a likely mechanism of action. However, the greater sensitivity of the intrinsic pathway to inhibition by phosphorothioate oligodeoxynucleotides suggests that there are other clotting factors specific to this pathway that may also be inhibited. Recent data suggest that there is a specific allosteric inhibition of the tenase complex as well as binding to thrombin (152,156).

In clinical trials with ISIS 2302, normal volunteers and patients were dosed with 2 mg/kg infused over 2 h. This regimen produced total oligonucleotide concentrations of 10 to 15 μg/mL and a concomitant increase in aPTT of approximately 50% (130), which correlates well with in vitro human and animal data. The transient and reversible nature of aPTT prolongation, combined with the relatively small magnitude of the change, makes these effects clinically insignificant for the current treatment doses and regimens.

Activation of the complement cascade by phosphorothioate oligodeoxynucleotides has the potential to produce the most profound acute toxicological effects. In primates, treatment with high doses over short infusion times resulted in marked hematological effects and marked hemodynamic changes that are believed to be secondary to complement activation. Hematological changes are characterized by transient reduction in neutrophil counts, presumably due to margination, followed by neutrophilia with abundant immature, nonsegmented neutrophils (147,151). In a small fraction of monkeys, complement activation was accompanied by marked reductions in heart rate, blood pressure, and subsequently cardiac output. In some animals, these hemodynamic changes were lethal (146,151,157).

There is an association between cardiovascular collapse and complement activation. That is, all monkeys demonstrating some degree of cardiovascular collapse or hemodynamic changes had markedly elevated levels of complement split products. However, the converse is not true, in that only a fraction of the animals with activated complement had cardiovascular functional changes (150). Thus, this observation suggests that there may be sensitive subpopulations or predisposing factors within individual animals that make them susceptible to the physiological sequelae of complement activation. Because of these observed hemodynamic changes, primate studies to monitor for these effects have become part of the normal evaluation of these compounds (158,159). Although complement activation at high doses is consistent and predictable between animals, there is currently little appreciation for the variability in the severity of the associated hemodynamic changes. Although the split product Bb can be used to monitor complement activation, it is C5a (complement split product) that is the most biologically active split product. Preliminary data obtained relating response to complement split product levels indicate that C5a levels are elevated more significantly in some of the more affected animals (150).

The goal of toxicity studies is to characterize the toxicity of compounds and to establish a framework upon which clinical safety studies can be designed. In this regard, it is useful to examine the relationship between plasma concentrations of oligonucleotides and the activation of complement. When Bb concentrations were plotted against the concurrent plasma concentrations of oligodeoxynucleotides in primates, it was apparent that complement was only activated at concentrations of phosphorothioate oligodeoxynucleotides that exceed a threshold value of 40 to 50 μg/mL (151). Bb levels remained unchanged from control values at plasma concentrations below the threshold. Remarkably, this threshold concentration is similar for three 20-mer phosphorothioate oligodeoxynucleotides and for an 8-mer phosphorothioate oligodeoxynucleotide that forms a tetrad complex (160,161). Recent data demonstrate that human serum may be less sensitive to activation than monkey serum, suggesting a species difference in sensitivity. Regardless of small differences, it is clear that clinical dose regimens should be designed to avoid plasma oligodeoxynucleotide concentrations that exceed 40 to 50 μg/mL. To this end, the similarities in plasma pharmacokinetics between monkeys and humans have allowed the design of dose regimens that achieve desired plasma concentration profiles.

The most direct approach for staying below the plasma thresholds for complement activation is to reduce the dose rate by substituting prolonged infusions for bolus injections. In clinical trials with phosphorothioate oligodeoxynucleotides, the drugs are administered either as 2-h infusions or as constant 24-h infusions. At a rate of infusion of 2 mg/kg over 2 h, the Cmax was 8 to 15 μg/mL, still well below the threshold for complement activation (130). Phosphorothioate oligodeoxynucleotides have been administered by intravenous infusion to more than 3000 patients and volunteers without any significant indication of activation of the alternative complement cascade.

1. Modified Oligonucleotides

Chemical modifications to phosphorothioate oligodeoxynucleotides may reduce the potential to activate complement. In one study, cynomolgus monkeys were administered an intravenous infusion over a 10-min period with a 5, 20, or 50 mg/kg dose of a 17-mer phosphodiester oligodeoxynucleotide, Ar177, that had phosphorothioate caps on the 3′ and 5′ termini (154,162). This oligonucleotide is known to have a complex secondary structure. In this experiment, although there was

a dose-related increase in plasma concentrations of Bb, the magnitude of the increases were small in comparison to the known activity of full-phosphorothioate oligodeoxynucleotides (162). Whether this diminished potential to activate the complement cascade is related to the reduction of phosphorothioate linkages or whether it is due to the complex secondary structure of this particular oligodeoxynucleotide was not established by these experiments. Some insight into this question was obtained in a second series of experiments performed with oligonucleotides that contained 2′-*O*-methoxyethyl modifications of the ribose sugar in 12 of the 20 nucleotides (149,150). Cynomolgus monkeys were treated by 10-min intravenous infusion with single doses of 1, 5, or 20 mg/kg of this 20-mer oligonucleotide that was either fully modified phosphorothioate linkages (ISIS 13650) or had phosphodiester wings and a central region of phosphorothioate linkages (9 linkages, ISIS 12854). The termini of both compounds contained six 2′-modified nucleotides. A third unmodified phosphorothioate oligodeoxynucleotide, ISIS 1082, was included as a positive control. The unmodified compound produced marked increases in Bb and severe cardiovascular effect at the dose of 5 mg/kg (30- to 60-fold over baseline). At 5 mg/kg, the aPTT values were 41 and 33 sec for the fully phosphorothioate and partially phosphorothioate 2′-modified oligonucleotides, respectively. In contrast, the unmodified phosphorothioate oligodeoxynucleotide produced an aPTT of 72 sec at the same dose. These data suggest that reduction in the number of phosphorothioate linkages reduced the inhibitory effects on aPTT and the activation of the complement cascade. However, the more important difference was that both 2′-*O*-methoxyethyl compounds were markedly less potent in activating complement than an unmodified oligodeoxynucleotide (D.K. Monteith, P.L. Nicklin, and A.A. Levin, unpublished observations, 1997). Although the safety profile of phosphorothioate oligodeoxynucleotides has proven satisfactory, the acute safety profile of the next generation of oligonucleotides may be improved by modification of the 2′-position of the ribose sugar with an alkoxy such as 2′-*O*-methyl or 2′-*O*-methoxyethyl and by reductions in phosphorothioate linkages.

B. Toxicological Effects Associated with Chronic Exposure

One of the characteristic toxicities observed with repeated exposure of rodents to phosphorothioate oligodeoxynucleotides is a profile of effects that can be described as immune stimulation. The profile is characterized by splenomegaly, lymphoid hyperplasia, and diffuse multiorgan mixed mononuclear cell infiltrates (149). The severity of these changes is dose dependent and most notable at doses equal to or exceeding 10 mg/kg. The mixed mononuclear cell infiltrates consisted of monocytes, lymphocytes, and fibroblasts and were particularly notable in liver, kidney, heart, lung, thymus, pancreas, and periadrenal tissues (148,163–165).

Although immune stimulation in rodents is believed to be a class effect of phosphorothioate oligodeoxynucleotides and not dependent on hybridization, sequence is an important factor in determining immunostimulatory potential (166–169). Immunostimulatory motifs have been described in the literature and involve palindromic sequences and CpG (cytosine-guanosine) motifs (169).

Among the most remarkable features of oligodeoxynucleotide-induced immune stimulation are the species differences. Rodents are highly susceptible to this generalized immune stimulation, whereas primates appear to be relatively insensitive to the effect at equivalent doses. Even 6 months of treatment of cynomolgus monkeys with 10 mg/kg of a 20-mer oligodeoxynucleotide, ISIS 2302, given every other day produced only a relatively mild increase in B cell numbers in spleen and lymph nodes of the primates with no change in organ weights. The mixed mononuclear cellular infiltrates in liver and other organs that are so characteristic of the response in rodents are absent even after long-term exposure in monkeys (149). It is known that rodents are more susceptible to the stimulatory effects of lipopolysaccharides, and much of the immune stimulation produced by oligodeoxynucleotides shares characteristics with lipopolysaccharide stimulation. Assuming results obtained in monkeys can be used to predict stimulation in humans, then the immunostimulatory effects may not be a prominent adverse effect in humans.

It is evident that there are both species and sequence differences involved in immune stimulation and that specific sequences should, if possible, be excluded from oligodeoxynucleotides. In long-term toxicity studies in rodents, the constant cell proliferation associated with immune stimulation may have promoter-like effects and may thus complicate the interpretation of rodent carcinogenicity studies. At this time, there are no reports of toxicity studies longer than 6 months, and the long-term sequelae of immune stimulation in rodents are at present merely speculation. More important, immune stimulation following systemic administration of phosphorothioate oligodeoxynucleotides does not appear to be clinically relevant.

Morphologic changes in the bone marrow of mice were observed after 2 weeks of treatment (3 doses/week) with 100 to 150 mg/kg phosphorothioate oligodeoxynucleotide There was reduction in number of megakaryocytes that was accompanied by a reduction of approximately 50% in circulating platelet counts (164). Reductions in platelets have been observed in rats treated with 21.7 mg/kg ISIS 2105 given every other day (148), but were not observed in primates administered 10 mg/kg. Similarly, a reduction in platelets was observed in mice, but not in monkeys treated for 4 weeks with ISIS 2302 at doses of 100 and 50 mg/kg every other day, respectively. Similar observations were made for ISIS 5132 with reductions in platelets at 20 and 100 mg/kg in mice and no observed effect in monkeys up to 10 mg/kg (163). These data suggest that the mouse may be more sensitive to these subchronic effects on platelets than nonhuman primates. However, in acute studies in primates, transient reductions in platelets are occasionally observed. These transient reductions in platelets occur acutely during 2-h infusions at doses of 10 mg/kg, reverse after completion of the infusion, and have not been associated with any measurable change in platelet number 24

to 48 h after subchronic or chronic treatment regimens (150). Thrombocytopenia has been reported in AIDS patients treated with GEM 91, a 27-mer phosphorothioate oligodeoxynucleotide (170).

Tissue distribution studies have shown that the liver and kidney are major sites of deposition of phosphorothioate oligodeoxynucleotide. In toxicity studies with phosphorothioate oligodeoxynucleotides, a variety of hepatic changes have been observed. The immune-mediated cellular infiltrates in rodent livers were discussed above. With high-dose administration of oligodeoxynucleotides in all species examined, there was a hypertrophic change in Kupffer cells accompanied by inclusions of basophilic material that was observed with hematoxylin and eosin staining. These basophilic granules have been identified as inclusions of oligodeoxynucleotide (114). Furthermore, it was demonstrated that the presence of these inclusions was related to dose.

Hepatocellular changes were not a prominent feature of toxicity in primates. In cynomolgus monkeys, 50 mg ISIS 2302 per kg administered every other day for 4 weeks by intravenous injection produced no morphologic indication of liver toxicity, although there was a slight (1.5-fold) increase in AST in this group (171). Following subcutaneous doses of ISIS 3521 and ISIS 5132 of up to 80 mg/kg every other day for 4 doses, there was Kupffer cell hypertrophy and periportal cell vacuolation, but no indication of necrosis and only a very slight increase in ALT (150). After 4 weeks of alternate-day dosing with 10 mg/kg via 2-h intravenous infusion of either ISIS 3521 or ISIS 5132, there were no alterations in AST or ALT, suggesting that at clinically relevant doses of these compounds, there was no evidence for hepatic pathology or tansaminemia. In clinical trials with ISIS 2302, ISIS 3521, and ISIS 5132 at doses of 2 mg/kg administered by 2-h infusion on alternate days for 3 to 4 weeks, there was no indication of hepatic dysfunction, nor was there any evidence of transaminemia.

Like Kupffer cells in the liver, renal proximal tubule epithelial cells take up oligodeoxynucleotide, as demonstrated by autoradiographic studies and immunohistochemistry as discussed previously (114,118,172,173) and by the use of special histologic stains (147). The appearance of basophilic inclusions is dose dependent in proximal tubule cells. Significant renal toxicity can be induced by extremely high doses. Doses of 80 mg/kg in rats and monkeys have induced both histologic and serum chemistry changes in the kidney (174). At clinically relevant doses, however, there was no indication of renal dysfunction. In 4-week or 6-month toxicity studies with phosphorothioate oligodeoxynucleotides, we observed a much more subtle type of morphologic change in the kidney. At a dose of 10 mg/kg on alternate days, here was a decrease in the height of the brush border and enlarged nuclei in some proximal tubule cells. These changes have been characterized as minimal to mild tubular atrophic and regenerative changes. At a dose of 3 mg/kg and below, these changes were only infrequently observed, if at all.

An important aspect of dose-dependent effects is characterization of exposure concentrations and their relationship to morphological changes. To assess exposure, concentrations of oligodeoxynucleotides have been measured in the renal cortex obtained in subchronic and chronic toxicity studies. Renal concentrations increase with increasing doses. The concentration of total oligodeoxynucleotide in the renal cortex associated with minimal to mild (although not clinically relevant) renal tubular atrophy or regenerative changes is approximately 1000 μg/g of tissue. The cortex concentrations of total oligodeoxynucleotide that are associated with moderate degenerative changes after subcutaneous doses of 40 to 80 mg/kg are greater than 2000 μg/g. At a clinically relevant dose of 3 mg/kg every other day, the steady-state concentration of total oligodeoxynucleotide in the kidney is in the range of 400 to 500 μg/g, thus demonstrating a significant margin of safety between the clinical doses and those doses associated with even the most minimal morphologic renal changes. Application of clearance and steady- state pharmacokinetic models suggests that continued administration of oligodeoxynucleotide at this dose should never achieve the renal concentrations associated with dysfunction (129). These models have been confirmed in 6-month chronic toxicology studies, where tissue concentrations measured at the end of 6 months of every-other-day dosing was no different than levels observed after 4 weeks of dosing at a similar or equivalent dose.

C. Chemical Modification of Oligodeoxynucleotides

Chemical modifications of oligodeoxynucleotides have been shown to reduce the potency of immune stimulation. The simplest modification with remarkable activity for reducing the immunostimulatory effects of oligodeoxynucleotides is the replacement of cytosine with 5-methyl cytosine. The methylation of a single cytosine residue in a CpG motif reduced [^{3}H]uridine incorporation and IgM secretion by mouse splenocytes. Methylation of a cytosine not in a CpG motif did not reduce the immunostimulatory potential (175). In our experience with mice, when sequences with 5-methyl cytosine are compared with the same sequence without methylation, the methylated sequence has a lower potency for inducing immune stimulation, as determined by spleen weights and immune cell activation (176,177).

Substitution of methylphosphonate linkages for phosphorothioate linkages on each of the 3′ and 5′ termini have also been reported to reduce the proliferative effects and the secretion of IgG and IgM compared 2 with the full phosphorothioate analog (178). This suggests that that this modification can also be used to ameliorate immune stimulation. The addition of 2′-*O*-methyl substituents also reduced immunostimulatory potential (178). The relative contribution of the uridine substitution and the 2′-methoxy substitution could not be differentiated in this experiment. The effect of 2′-alkoxy modifications on immunostimulatory potential needs further investigation. Finally, the effects of chemical modifications of phosphorothioate oligonucleotides on renal and hepatotoxicity are currently being investigated.

VI. OLIGONUCLEOTIDE FORMULATIONS

A. Physical-chemical Properties

Due to the presence of a mixture of diastereisomers, phosphorothioate oligodeoxynucleotides are amorphous solids possessing the expected physical properties of hygroscopicity, low-bulk density, electrostatic charge pick up, and poorly defined melting point prior to decomposition. Their good chemical stability allows storage in the form of a lyophilized powder, spray-dried powder or a concentrated, sterile solution; more than 3 years of storage is possible at refrigerated temperatures.

Due to their polyanionic nature, phosphorothioate oligodeoxynucleotides are readily soluble in neutral and basic conditions. Drug-product concentrations are limited (in select applications) only by an increase in solution viscosity. The counter ion composition, ionic strength, and pH also influence the apparent solubility. Phosphorothioate oligodeoxynucleotides have an apparent pKa in the vicinity of 2 and will come out of solution in acidic environments (i.e., the stomach). This precipitation is readily reversible with increasing pH or by acid-mediated hydrolysis.

Instability of phosphorothioate oligodeoxynucleotides have been primarily attributed to 2 degradation mechanisms: oxidation and acid-catalyzed hydrolysis. Oxidation of the (P = S) bond in the backbone has been observed at elevated temperatures and under intense ultraviolet light, leading to partial phosphodiesters (still pharmacologically active) and are readily monitored by anion-exchange high-performance liquid chromatography. Under acidic conditions, hydrolysis reactions followed by chain-shortening depurination reactions have been documented by length-sensitive electrophoretic techniques.

B. Parenteral Injections

Given the excellent solution stability and solubility possessed by phosphorothioate oligodeoxynucleotides, it has been relatively straightforward to formulate the first-generation drug products in support of early clinical trials. Simple, buffered solutions have been successfully used in clinical studies by intravenous, intradermal, and subcutaneous injections. Recently, the intravitreal route was approved for the first antisense drug application.

C. Topical Delivery for Diseases of the Skin

The barrier properties of human skin have been an area of multidisciplinary research for a long time. Skin is one of the most difficult biological membrane to penetrate, primarily due to the presence of stratum corneum (SC), which is composed of corneocytes laid in a brick-and-mortar arrangement with layers of lipid. The corneocytes are partially dehydrated, anuclear, metabolically active cells completely filled with bundles of keratin with a thick and insoluble envelope replacing the cell membrane (179). The primary lipids in the SC are ceramides, free sterols, free fatty acids, and triglycerides (180), which form lamellar lipid sheets between the corneocytes. These unique structural features of SC provide an excellent barrier to penetration of most molecules.

Therefore, as the primary barrier to transport of molecules to the skin, physical alteration in SC can result in improved skin penetration. Tape stripping and abrasion by repeated brushing reduced the SC barrier sufficiently to allow penetration of naked plasmid DNA and produced gene expression in skin at a level comparable to that after intradermal injection of naked plasmid DNA (181). Other studies have also shown an increase in oligonucleotide penetration upon physical removal of SC barrier (182–184).

1. Altering the Thermodynamic Properties of the Molecules

Increasing lipid partitioning to improve skin penetration has been evaluated using 2 techniques that alter the thermodynamic properties of oligonucleotide molecules. A complex of phosphorothioate oligonucleotide with hydrophobic cations such as benzalkonium chloride resulted in increased penetration through isolated hairless mouse skin that was explained on the basis of greater partitioning in lipid phase (184). Chemical modification of oligonucleotides to eliminate the negative charges also resulted in a size-dependent increase in the penetration of oligonucleotide into the skin when used with chemical penetration enhancers such as ethanol and dimethyl sulfoxide (183).

2. Electrical Field for Alteration of Skin Permeability

Iontophoresis, which involves application of electric field across the skin to induce electrochemical transport of charged molecules, is studied extensively for transdermal delivery of phosphorothioate oligonucleotides (185,186). The transdermal delivery was shown to be size dependent with steady-state flux values ranging from 2 to 26 pmol/cm^2 in isolated hairless mice skin. The steady-state flux also depended on the sequence, and not just the base composition, of the oligonucleotide. Molecular structure, therefore, is a key contributor to iontophoretically assisted transport of oligonucleotides (187–189). Electroporation a technique using much higher voltage than iontophoresis to cause formation of transient aqueous pathway in skin lipids, provides therapeutic levels (> 1 μM) of oligonucleotides in the viable tissues of the skin (190).

3. Formulations for the Alteration of Skin Permeability

Chemical penetration enhancers have recently been studied for increasing transdermal delivery of oligonucleotides or other polar macromolecules. Chemical-induced transdermal penetration results from a transient reduction in the resistance of the SC barrier properties. The reduction may be attributed to a variety of factors such as opening of intercellular junctions due to hydration (191), solubilization of SC lipids (192,193) or increased lipid bilayer fluidization (194). Types of chemicals known to be penetration enhancers include alkyl esters (195),

phospholipids (196), terpenes (197), nonionic surfactants (198), and laurocapram (Azone) (199). A combination of various surfactants and cosolvents can be used to achieve skin penetration with therapeutically relevant concentration of phosphorothioate oligonucleotides in the viable epidermis and dermis (200). The topical formulations produced significantly higher epidermal and dermal levels of oligonucleotide than those achieved by an intravenous injection at highest tolerated doses. This suggests that the topical route is more efficient in reaching all layers of the skin than systemic administration of phosphorothioate oligonucleotides.

Liposomes have been studied to transport oligonucleotides into the skin. They can increase the fluidity of skin lipid layers (similar to chemical enhancers) to facilitate transdermal permeation and can also carry encapsulated molecules through appendageal pathway (201,202). Mixture of a phosphorothioate oligodeoxynucleotide with a suspension of anionic or neutral lipids resulted in a slight increase in accumulation in epidermis and dermis (R. Mehta, unpublished, 1999). Using a combination of different delivery techniques and formulations, it appears to be feasible to deliver a therapeutically relevant amount of antisense oligonucleotide to the skin. In addition, preliminary results in our laboratory show a dose-dependent pharmacological effect consistent with the antisense mechanism of action of an ICAM-1 antisense oligonucleotide, ISIS 2302 (200). Studies are also underway to assess pharmacology and tissue kinetics of ISIS 2302 in human disease models.

D. Oral Delivery

Of the numerous barriers proposed by Nicklin and others (138) to the oral delivery of oligonucleotides, our experience has confirmed that 2 stand out as critical: instability in the gastrointestinal (GI) tract and low permeability across the intestinal mucosa. Given the formidable nature of these 2 barriers, it is not surprising that oral delivery of oligonucleotides has been considered impossible, or at best, difficult—as is the case with proteins, which has necessitated the latter's nonenteral administration in order to achieve systemic concentrations considered therapeutic. Nevertheless, progress has been made to address and/or understand each barrier with respect to oligonucleotides. (P = S)-oligonucleotides have a distinct advantage over proteins in that the former does not rely on secondary structure for activity. This provides freedom from concern over secondary structure destabilization and allows for (P = S)-oligonucleotide structural modifications to address both presystemic and systemic metabolism.

Natural DNA and RNA are rapidly digested by the ubiquitous nucleases found within the gut. As a consequence, oligonucleotides need to be stabilized in order to achieve a reasonable GI residence time to allow for absorption to occur. Surprisingly, phosphorothioate oligodeoxynucleotides were found to be rapidly degraded by nucleases found in the GI tract; therefore, additional protection from nuclease degradation is required to achieve significant oral bioavailability. Oligonucleotides that are uniformly modified or modified on the 3′-end (gapmers or 3′-hemimers) (Fig. 6) with nuclease-resistant modification have the potential to exhibit increased oral bioavailability. This was demonstrated for both backbone modifications (methylphosphonates) and for sugar-modified (2′-*O*-methyl) oligonucleotides (141,203). We have found that 2′-*O*-methoxyethyl-modified oligonucleotides also exhibit increased oral absorption compared with phosphorothioate oligodeoxynucleotides (80,142).

The physicochemical properties of phosphorothioate oligodeoxynucleotides present a significant barrier to their GI absorption into the systemic circulation or the lymphatics. These factors include their large size and molecular weight (i.e., up to 6.5 kDa for 20-mers), hydrophilic nature (log $D_{o/w}$approximating -3.5) and multiple ionization pk_as (e.g., G. Hardee, 1999, unpublished titration data, using a Sirius GlpKa instrument on a 20-mer sequence, noted over 17 pk_as for phosphorothioate oligodeoxynucleotide and over 32 pk_as for the 2′-*O*-methoxyethyl hemi-mer form). The use of formulations can improve upon GI permeability. Oligonucleotide drug formulations designed to improve oral bioavailability need to consider the mechanism of oligonucleotide absorption—either paracellular via the epithelial tight junctions, or transcellular via direct passage through the lipid membrane bilayer. By using paracellular and transcellular models appropriate for water-soluble, hydrophilic macromolecules, it was determined that oligonucleotides predominantly traverse GI epithelium via the paracellular route. In this regard, formulation design considerations involve the selection of those penetration enhancers (PEs) that facilitate paracellular transport and meet other formulation criteria, including suitable biopharmaceutics, safety considerations, manufacturability, physical and chemical stability, and practicality of the product configuration (i.e., regarding production costs, dosing regimen, and patient compliance, etc.). Work is in progress, optimizing oligonucleotide chemistry with various permeation enhancers (142,204,205). Preliminary data are encouraging and support continued investment of resources on this endeavor.

E. Liposome Formulations

Liposome formulations of antisense oligonucleotides offer several potential advantages over saline phosphorothioate oligodeoxynucleotides, such as decreased toxicity, altered tissue and cellular distribution, and more convenient dose schedule for the patient. Interesting progress has been reported regarding the passive targeting of oligonucleotides to specific tissues using liposome-encapsulated therapeutics. Accumulation at sites of infection, inflammation, and tumor growth has been attributed to increased circulation times of these materials and the leaky vasculatures associated with these processes (206,207). One caution regarding these observations is worth noting. Because the mononuclear phagocyte system (MPS) is largely responsible for clearing these materials from circulation, misleading data regarding circulation time may be obtained in species with less-evolved systems (i.e., rodents).

Cationic liposomes bind to oligonucleotides due to the electrostatic interaction between positively charged head

groups on lipids and negatively charged phosphates on oligonucleotides. Using the technique of complexation, all the oligonucleotide can be entrapped and purification is not required. The utility of in vivo delivery of oligonucleotide using cationic lipid is limited due to sequestration of material in lung and the RES system (144,208). In addition, interaction of the complex with blood components leads to serum sensitivity and cytotoxicity (209,210).

There are few examples of oligonucleotide delivery by anionic or charge-neutral liposomes. Oligonucleotides encapsulated into cardiolipin-containing anionic liposomes were shown to be taken up 7 to 18-fold more in human T leukemia and ovarian carcinoma cells in vitro. The intracellular release of oligonucleotides was also facilitated and the majority of oligonucleotide was delivered into liposomes (211,212). Methylphosphonate analogs were incorporated into DPPC-containing liposomes and targeted against the Bcr-abl neogene found in chronic myelogenous leukemia (CML). The liposomal- encapsulated oligonucleotides inhibited the growth of CML cells (213). Cellular uptake of oligonucleotides against epidermal growth factor (EGF) encapsulated in DPPC:CHOL liposome containing folate was 9 times higher than nonfolate liposomes and 16 times higher than unencapsulated liposomes (214). There are 2 limitations to intracellular delivery of oligonucleotides by anionic or neutral liposomes: (1) not all cells take up particulate matter, and (2) these liposomes have low encapsulation efficiency.

There is only 1 report of using anionic liposomes in vivo to deliver oligonucleotides. Ponnappa et al. described liposomes consisting DPPC:CHOL:DMPG targeted toward Kupffer cells (215). In this study, greater than 65% of the liver-associated oligonucleotide was found in Kupffer cells.

Conjugation of antibodies to liposomes have been used for targeting of oligonucleotides to specific targets (216–220). Problems with the approach include the inhibition of cellular uptake by the high molecular weight antibody, cost, and poor encapsulation efficiency.

The primary mechanism for cell internalization of neutral liposomes is by endocytosis with the vesicles and their contents delivered to lysozomes (221). pH-sensitive liposomes have been designed to fuse with the endosomes at low endosomal pH and empty their content into cytosol. These pH-sensitive liposomes have been used to deliver antisense oligonucleotides. pH-sensitive liposomes composed of oleic acid: DOPE:Chol-encapsulating antisense oligonucleotide targeted against friend retrovirus inhibited the viral spreading, whereas free oligonucleotide and non pH-sensitive liposomes were ineffective (222,223). pH-sensitive liposomes encapsulating the anti-env oligonucleotide were found to inhibit viral spread at low concentration in infected Dunni cells (224). The major limitation of pH-sensitive liposomes in vivo is their instability in plasma (225,226). This problem was overcome by adding polyethylene glycol-phosphatidylethanolamine (PEG-PE) into the formulation (227). PEG-PE is believed to coat the surface of liposomes, thereby preventing the interaction of liposomes with blood components. This reduced interaction leads to increased stability and plasma half-life of liposomes. The pH-sensitive liposomes composed of CHEMS:DOPE: PEG-PE, when injected intravenously into rats, had similar pharmacokinetics parameters as non pH-sensitive sterically stabilized liposomes. The regular pH-sensitive liposomes without PEG-PE were cleared rapidly from the circulation.

Looking past the question of uptake, a novel approach to releasing endosomal contents into the cytoplasm after uptake has been recently reported (228–230). A 58-kDa protein isolated from Listeria monocytogenes was incorporated into pH-sensitive fluorescent dye. It could be determined that as soon as the endosome began to acidify, the liposome/endosome contents were released into the cytosol. As with the other delivery systems mentioned above, the eventual usefulness of a particular approach will be determined in the near future as we further define the mechanisms and governing restrictions for the inter- and intracellular trafficking of oligonucleotides.

VII. CLINICAL EXPERIENCE WITH ANTISENSE OLIGONUCLEOTIDES

More than 20 different antisense oligonucleotides are currently in clinical trials or approved for use in humans (Table 1). Similar to any other class of drugs, it can be expected that there will be failures in the clinic due to a variety of reasons, such as selection of the wrong molecular target resulting in lack of efficacy, incorrect dosing, marketing consideration, toxicity, etc. It is hoped that because of the generic pharmacokinetics and chemical class-specific toxicity that the failure rates for antisense oligonucleotides will be lower than other classes of agents. However, this remains to be seen.

A. Use of Antisense Oligonucleotides as Antiviral Therapy

The most advanced antisense product is Vitravene™ (fomivirsen, ISIS 2922), which is marketed in the United States for the treatment of patients with cytomegalovirus (CMV) retinitis. Fomivirsen was identified from a screen of a series of phosphorothioate oligodeoxynucleotides targeting human cytomegalovirus (HCMV) DNA polymerase gene, or to RNA transcripts of the major immediate-early regions 1 and 2 (IE1 and IE2) (231). Fomivirsen is a 21-mer phosphorothioate oligodeoxynucleotide targeting the coding region of the immediate early 2 gene. Fomivirsen inhibits viral protein expression, as measured by an enzyme-linked immunosorlent assay detecting an HCMV late protein product, in fibroblasts with an EC_{50} value of 0.1 μM. Noncomplementary phosphorothioate oligodeoxynucleotides exhibit an EC_{50} value of 2 μM, 20-fold higher than fomivirsen. In a plaque reduction assay, fomivirsen exhibited an IC_{70} value of 0.1 μM, whereas a control oligonucleotide exhibited an IC_{70} value of 2 μM. These data suggest that HCMV infection of human dermal fibroblast can be inhibited nonspecifically by higher concentrations of phosphorothioate oligodeoxynucleotides: however, fomivirsen is approximately 20-fold more effective than nonspecific oligonucleotides. Fomivirsen reduced IE1 and IE2 proteins in in-

fected cells, as did control oligonucleotides at 10-fold higher concentrations. As the IE1 and IE2 gene products arise from a common pre-mRNA, these results suggest that the oligonucleotide hybridizes to the pre-mRNA. Deletion of sequences from the 5′- and/or 3′-end of the oligonucleotides reduced antiviral activity, whereas introduction of mismatches in the interior of the oligonucleotide did not significantly reduce antiviral activity, although they did reduce hybridization to the target RNA. These data suggest that the antiviral activity of fomivirsen may not be due entirely to an antisense effect. To address this issue in more detail, U373 cells permanently transfected with the IE72 or IE55 polypeptides (derived from the IE1 and IE2 genes, respectively) were treated with fomivirsen (232). Fomivirsen reduced IE55 but not IE72 protein and RNA levels in a sequence-specific manner, suggesting that reduction of IE55 expression occurs by an RNase H-dependent mechanism. As the construct used to express IE72 protein does not contain the fomivirsen-binding site, these data would support that fomivirsen reduces IE55 expression by an antisense mechanism of action. The antiviral activity of fomivirsen was not due to immune stimulation by the CpG motifs in the oligonucleotide (167), as methylation of all the cytosines or only 2 cytosines in the CpG motifs did not reduce antiviral activity. These studies in aggregate suggest that fomivirsen is a potent inhibitor of CMV replication, which is capable of inhibiting viral gene expression by an antisense mechanism of action, but also may inhibit viral replication by a nonantisense mechanism of action at higher concentrations. Whether both mechanism of action are operational in the clinic remains to be elucidated.

Fomivirsen is approved for the local treatment of CMV retinitis in patients with acquired immunodeficiency syndrome, who are intolerant of or have a contraindication to other treatments of CMV retinitis (233,234). The recommended dose is 330 μg every other week for 2 doses and then a maintenance dose administered every 4 weeks given as an intravitreal injection. The most frequently observed adverse event reported for fomivirsen is ocular inflammation (uveitis), including iritis and vitritis (235). Ocular inflammation has been reported to occur in approximately 25% of the patients. Topical corticosteroids have been useful in treating the ocular inflammation. Open-label, controlled clinical studies have been performed, evaluating the safety and efficacy of fomivirsen in newly diagnosed CMV retinitis patients. Based on assessment of fundus photographs, the median time to progression was approximately 80 days for patients treated with fomivirsen, compared with 2 weeks for patients not receiving treatment (234). Although the market for CMV retinitis is relatively small, this drug represents an important validation for the technology.

Gem 132, a second-generation chimeric molecule targeting the HCMV UL36 gene product, is a 20-mer oligonucleotide containing two 2′-*O*-methyl nucleosides on the 5′-end of the molecule and four 2′-*O*-methyl nucleosides on the 3′-end, with the center 14 residues being oligodeoxynucleotides (236). The 2′-*O*-methyl residues also confer increased hybridization affinity and increased nuclease resistance, whereas the center oligodeoxynucleotide residues support RNase H activity. Gem 132 is being evaluated in CMV retinitis patients as both an intravenous infusion and as a direct intravitreal injection. In healthy volunteers, single 2-h infusions of GEM 132 were administered at doses ranging from 0.125 mg/kg to 0.5 mg/kg. Similar to phosphorothioate oligodeoxynucleotides, the plasma pharmacokinetics of GEM 132 were nonlinear with respect to dose. As a single dose up to 0.5 mg/kg, GEM 132 was well tolerated in normal volunteers, with headache being the most frequently reported side effect (237).

Gem 91, a 25-mer phosphorothioate oligodeoxynucleotide designed to hybridize to a conserved region of *gag* human immunodeficiency virus region of (HIV) RNA (238). GEM 91 inhibits viral replication in short-term viral assays in a concentration-dependent manner, whereas a 4- to 5-fold higher concentration of a random mixture of 25-mer phosphorothioate oligodeoxynucleotides (complexity = 4^{25} unique molecules) was required to inhibit viral replication to a similar extent (239). Other studies have demonstrated that acute HIV viral assays are particularly sensitive to the nonantisense effect of phosphorothioate oligodeoxynucleotides (240–243). In chronic HIV assays, GEM91 suppressed viral replication for greater than 30 days, whereas the random mixture of oligodeoxynucleotides only suppressed viral replication for 10 days. GEM 91 was found to be effective against several viral isolates in primary lymphocytes and macrophages, and exhibited selectivity in comparison to the random mixture. In that a random mixture of 4^{25} sequences was used as a control, it is difficult to conclude that GEM 91 inhibits viral replication in a sequence-specific manner. Based on these data, it is likely that at least part of the antiviral activity exhibited by GEM 91 is due to a nonantisense effect.

Phase I/II clinical studies were initiated for GEM 91 in the United States and France (236). The study performed in the United States was a randomized double-blind, placebo-controlled, dose-escalating study in which GEM 91 was administered as a continuous intravenous infusion for 2 weeks, whereas in the French study, GEM 91 was given as a 2-h intravenous infusion every other day for 28 days. Dose levels up to 4.4 mg/kg/day were achieved in the continuous infusion trials, whereas dose levels of 3.0 mg/kg/day were reported for the intermittent infusion trial. Plasma half-lives for GEM 91 were biphasic with mean half-lives of 0.18 h and 26.7 h (236,244). Hybridon recently announced the termination of clinical studies with GEM 91 based on lack of efficacy as measured by viral burden and the development of thrombocytopenia in some of the patients.

ISIS 14803 is a phosphorothioate oligodeoxynucleotide targeting the translation initiation codon of hepatitis C virus (245,246). ISIS 14803 differs from previous phosphorothioate oligodeoxynucleotides in that the cytosines were modified to 5 methyl cytosines, which further increases binding affinity for RNA and reduces the potential for immune stimulation (247). The oligonucleotide caused a reduction in target RNA, consistent with an RNase H mechanism of action and inhibited the production of hepatitis C viral proteins in hepatocyte cells transfected with a partial HCV genome containing the 5′-non-

coding region, core protein region, and the majority of the envelope region. HCV animal models were not readily available when this compound was being investigated preclinically. Therefore, a surrogate model was used to evaluate the potential in vivo efficacy of this oligonucleotide. A vaccinia virus model was used in which the HCV 5′-noncoding region, containing the IRES, and a portion of the core protein sequence was fused to firefly luciferase gene. Intraperitoneal injection of the recombinant vaccinia virus into mice, produced high levels of luciferase activity in livers. ISIS 14803 selectively inhibited luciferase expression in the livers isolated from infected mice (246). ISIS 14803 is currently in phase II trials, administered as an intravenous infusion, alone or in combination with interferon and ribavirin (248).

B. Use of Antisense Oligonucleotides for Cancer Therapy

An antisense oligonucleotide directed to p53 was one of the first antisense oligonucleotides to be administered systemically to patients. Preclinical studies with OL(1)p53, a 20-mer phosphorothioate oligodeoxynucleotide complementary to a portion in exon 10 of the p53 mRNA, inhibited proliferation of acute myelogenous leukemia cells in cell culture (136,249). Correspondingly, OL(1) p53 was found to reduce the level of p53 in leukemic cells, whereas a reverse sequence control failed to do so (136). A phase 1 study was conducted at the University of Nebraska Medical Center in which OL(1)p53 was infused at doses ranging from 0.05 mg/kg/h to 0.25 mg/kg/h for 10 days into patients with hematological malignancies. There were no apparent toxicities that could be directly attributed to the oligonucleotide. Two patients experienced a transient increase in hepatic transaminase concurrent with administration of the drug. In contrast to observations made with other phosphorothioate oligodeoxynucleotides, 17% to 59% of intact drug was detected in urine in this group of patients. There was an inverse correlation between plasma concentrations of oligonucleotide and cumulative leukemic growth of long-term marrow cultures. However, this correlation was not observed clinically as there were no morphological complete responses. These results provide evidence that OL(1)p53 was tolerated in leukemic patients; however, OL(1)p53 is no longer in active development.

Overexpression of *bcl*-2 is common in several cancers, in particular, non-Hodgkin lymphoma, and may contribute to decreased sensitivity to chemotherapeutic agents (250,251). An 18-mer phosphorothioate antisense oligodeoxynucleotide targeting the translation initiation codon of the *bcl*-2 gene was shown to inhibit the growth of lymphoma cells in severe combined immunodeficient (SCID) mice (252). Follow-up studies demonstrated that oblimersen inhibited growth of lymphoma cells in severely immunocompromised SCID and nonobese diabetic/SCID mice, suggesting that the activity of the oligonucleotide was not secondary to an immunostimulatory effect (253). The drug has also demonstrated antitumor activity in preclinical models of various other cancers such as melanoma, prostate cancer, and gastric cancer (252). Webb et al. conducted a phase 1 clinical trial of this oligonucleotide (Genta 3139, oblimersen) at the Royal Marsden Hospital in London. Genta 3139 was administered as a daily subcutaneous infusion for 14 days to patients with BCL-2 positive non-Hodgkin lymphoma. The dose of the drug given ranged from 4.6 mg/m^2 to 73.6 mg/m^2. Other than local inflammation at the site of infusion, no treatment-related side effects were noted. In 2 patients, tomography scans revealed reductions in tumor size with one complete response. In 2 additional patients, the number of circulating lymphoma cells decreased during treatment. Reduced levels of *bcl*-2 protein expression in circulating lymphoma cells were detected in 2 out of 5 patients. These findings again demonstrate that phosphorothioate oligodeoxynucleotides can be safely administered to patients and also provide preliminary efficacy data with a *bcl*-2 antisense oligonucleotide. Several other phase I/II studies on oblimersen have been performed, including studies in prostate cancer, breast cancer, colorectal cancer, AML, CML, multiple myeloma, and malignant melanoma (254,255). Side effects associated with the use of oblimersen included thrombocytopenia, hypotension, fever, and hypoglycemia (255). Promising clinical activity was seen in several of the studies, warranting continued investigation of the drug. The bcl-2 antisense oligonucleotide is currently in phase III trials for the treatment of melanoma, chronic lymphocytic leukemia, multiple myeloma, and non-small lung cancer, and in several additional phase II trials (255).

Protein kinase C (PKC) was originally identified as a serine/threonine kinase involved in mediating intracellular responses to a variety of growth factors, hormones, and neurotransmitters (256). Molecular cloning studies have revealed that PKC exists as a family of at least 11 closely related isozymes, which are subdivided on the basis of certain structural and biochemical similarities (257–260). Considerable experimental evidence exists for a role of PKC in some abnormal cellular process, such as inflammation, tumor promotion, and carcinogenesis (260–262). Antisense oligonucleotides have been identified that target individual members of the PKC family, both as research tools and as potential drugs (32,111,263,264). Protein kinase C-α has been implicated as a signaling molecule for a number of growth factors, and has been shown to regulate cell motility and apoptotic processes in human cells (265–271). To determine if inhibitors of protein kinase C-α could have potential value in the treatment of malignancies, we have identified an antisense oligonucleotide that specifically inhibit expression of PKC-α either in mouse or human cell lines (32,77,111). These antisense oligonucleotides have been used to identify cellular processes that are governed by this PKC isozyme (32,272–275).

The effects of the human-specific PKC-α phosphorothioate oligodeoxynucleotide, ISIS 3521/LY900003, has been examined on the growth of human tumor xenografts in nude mice. Analysis of PKC-α expression in the tumor tissue by immunohistochemistry revealed positive staining present in the cytoplasm and occasionally in the nuclei of tumor cells in animals treated with either saline or a scrambled control phosphorothioate oligodeoxynucleotide. In contrast, tumors treated with

ISIS 3521/LY900003 showed much reduced staining for PKC-α (276). In a second series of independent studies, ISIS 3521/LY900003 has been used to suppress the growth of U-87 glioblastoma tumor cells in nude mice (272). This cell line was chosen for study because it has previously been shown to be sensitive to growth inhibition by transfection with an antisense PKC-α cDNA. ISIS 3521/LY900003 reduced the growth of these tumor cells when implanted both subcutaneously and intracranially, whereas the scrambled control compound failed to inhibit tumor growth. This resulted in a doubling in median survival time of the animals with intracranially implanted tumors, with 40% long-term survivors of the treated animals. Levels of both ISIS 3521/LY90003 and the scrambled control oligodeoxynucleotide within tumor tissue were determined by capillary gel electrophoresis and found to both be about 2 μM after 21 daily intraperitoneal doses of 20-mg/kg oligodeoxynucleotide. ISIS 3521/LY900003 also reduced the expression of PKC-α in the tumor tissue, but not PKC-ε or PKC-ζ.

Based on the available biological evidence implicating PKC in the pathogenesis of certain tumor types and the broad spectrum of antitumor activity of ISIS 3521/LY90003 in the nude mouse xenograft implant model, clinical trials were initiated. A variety of tumors have been evaluated in phase I/II trials (277–280). In one trial, ISIS 3521/LY900003 was administered as a continuous 21-day infusion, then rested for 7 days. The cycle could be repeated if the treatments were tolerated and the tumor did not progress (277). The dose-limiting toxicities of ISIS 3521/LY90003 were thrombocytopenia and fatigue at a dose of 3.0 mg/kg/day. Pharmacokinetic measurements showed rapid plasma clearance and dose-dependent steady-state concentrations of ISIS 3521. Evidence of tumor response lasting up to 11 months was observed in 3 of 4 patients with ovarian cancer. There were no grade 3 or grade 4 toxicities reported. One patient displayed transient thrombocytopenia and 1 patient exhibited leukopenia. In a second phase I study, ISIS 3521/LY900003 was administered as a 2-h infusion 3 times per week for 3 consecutive weeks (278). A total of 36 patients received 99 cycles of the drug. Apparent drug-related toxicities included thrombocytopenia, nausea, vomiting, fever, chills, and fatigue. Dose escalation was stopped at a dose of 6 mg/kg because of concerns that peak plasma concentrations would approach those correlated with complement activation in monkeys (151). Most of the cancer patients had elevated baseline complement C3a. Following infusion of ISIS 3521/LY90003, several patients had a further increase in C3a; however, no clinical sequelae were attributed to the modest increases observed. Two non-Hodgkin lymphoma patients achieved complete responses, and 8 other patients showed stabilization of disease. Isis Pharmaceuticals, Inc., has completed several phase II trials including non-small cell lung carcinoma. Based on the phase II results, ISIS 3521/LY900003 is currently in 2 phase III trials for non-small cell lung carcinoma, one in combination with carboplatin and paclitaxel, and the second in combination with gemcitabine and taxol. ISIS 3521/LY9200003 is also being evaluated in additional phase II trials.

The discovery of viral oncogenes in the mid-1960s was a major breakthrough in understanding the molecular origins of cancer and directly led to the identification of the first human oncogene in 1982, ras (281). An antisense oligonucleotide targeting ha-ras gene product has initiated clinical trials. ISIS 2503 targets the AUG translation initiation codon for ha-ras gene product (282). Although the frequency of mutations in human cancers is significantly higher for the ki-ras gene product, we have found that antisense oligonucleotides targeting ha-ras gene exhibit broader antitumor effects when evaluated in human tumor xenograft models. In fact, the ha-ras antisense oligonucleotide was effective against human tumor xenografts known to contain a mutation in the ki-ras gene. A multicenter phase I trial against a broad spectrum of cancers has been completed (283). Patients received ISIS 2503 as a continuos intravenous infusion for 2 weeks, followed by a 1-week drug-free period. Patients will repeat the cycle as long as they tolerate the drug or when tumors fail to respond to therapies. In a second study, the drug was administered in a more convenient schedule (i.e., a weekly 24-hour infusion of ISIS 2503). Similar to the PKC-α and C-raf kinase antisense oligonucleotides, the drug was tolerated and exhibited enough, encouraging activity to warrant continuing phase II trials. Thus, a first-generation phosphorothioate oligodeoxynucleotide targeted to normal ha-*ras* is the first selective inhibitor of ras function to enter clinical trials.

Alterations in cellular cAMP concentrations have been associated with changes in cellular proliferation states. There are two isoforms of the major cAMP receptors, cAMP-dependent protein kinases I and II that are distinguished by different regulatory subunits (RI and RII). Increased expression of the RI subunit of PKA I correlates with cellular proliferation and cellular transformation, whereas a decrease in the RI subunit and an increase in the RII subunit correlates with growth inhibition and cellular differentiation (284). To directly address the role of the RI subunit in cell growth and differentiation, an antisense oligonucleotide targeting the RI subunit was designed. This oligonucleotide at concentration of 15 to 30 μM inhibited growth of several human cell lines without signs of cytotoxicity (285–287). As expected, the phosphorothioate oligodeoxynucleotide was more effective than the phosphodiester version. A single injection of the RI subunit phosphorothioate oligodeoxynucleotide suppressed growth of a human colon carcinoma xenograft for a week (286). Tumors exhibited normal growth rates when treated with a control oligonucleotide. Examining levels of PKA-I activity in the tumor xenografts provided further support of an antisense mechanism. The antisense oligonucleotide-treated tumors exhibited loss of enzyme activity 24 h after treatment. More recently, a second-generation, 2-*O*-methyl chimeric oligonucleotide (GEM231) targeting human PKA RI subunit has been described (288–290). This oligonucleotide was more effective than the first-generation oligonucleotide in suppressing growth of human tumor xenografts and has shown enhanced activity when combined with various chemotherapeutic agents. Clinical trials have been initiated with a 2′-*O*-methyl

chimeric PKA RI subunit antisense oligonucleotide (GEM 231) in the treatment of solid tumors.

C. Use of Antisense Oligonucleotides for Treatment of Inflammatory Diseases

In addition to targeting gene products implicated in viral replication or cancer, antisense oligonucleotides have been used to inhibit the expression of gene products, which may have utility for the treatment of inflammatory diseases. Intercellular adhesion molecule 1 (ICAM-1) is a member of the immunoglobulin gene family expressed at low levels on resting endothelial cells and can be markedly up-regulated in response to inflammatory mediators, such as TNF-α, interleukin 1, and interferon-γ on a variety of cell types. ICAM-1 plays a role in the extravasation of leukocytes from the vasculature to inflamed tissue and activation of leukocytes in the inflamed tissue (291–294). Alicaforsen (ISIS 2302) was identified out of a screen of multiple first-generation phosphorothioate oligodeoxynucleotides targeting various regions of the human ICAM-1 (2,295). Alicaforsen inhibits ICAM-1 expression by an RNase H-dependent mechanism of action (295). Alicaforsen will selectively inhibit ICAM-1 expression in a variety of cell types (295–297). Both sense and a variety of scrambled control oligonucleotides fail to inhibit ICAM-1 expression, including a 2-base mismatch control. Treatment of endothelial cells with alicaforsen blocked adhesion of leukocytes, demonstrating that blocking expression of ICAM-1 will attenuate adhesion of leukocytes to activated endothelial cells (295). ISIS 2302 also blocked a 1-way mixed lymphocyte reaction when the antigen-presenting cell was pretreated with ISIS 2302 to down-regulate ICAM-1 expression prior to exposure to the lymphocyte (Vickers et al., 1996 unpublished data). Thus, alicaforsen is capable of blocking both leukocyte adhesion to activated endothelial cells and costimulatory signals to T lymphocytes, both activities were predicted based on previous studies with monoclonal antibodies to ICAM-1.

To test the pharmacology of the human-specific antisense oligonucleotide, we have used experimental models in which immunocompromised mice contain human tissue xenografts. In one model, we were able to demonstrate a role for ICAM-1 in metastasis of human melanoma cells to the lung of mice (296). A second study addressed the role of ICAM-1 in production of cytotoxic dermatitis (lichen planus) in SCID mice containing human skin xenografts (298). Upon engraftment of the human tissue, heterologous lymphocytes injected into the graft migrate into the epidermis (epidermaltropism), and produced a cytotoxic interaction between effector lymphocytes and epidermal cells. Systemic administration of alicaforsen inhibited ICAM-1 expression in the human graft, decreased the migration of lymphocytes into the epidermis, and prevented subsequent lesion formation. A sense control oligodeoxynucleotide failed to attenuate the responses. These data demonstrate that an ICAM-1 antisense oligonucleotide administered systemically can attenuate an inflammatory response in the skin.

ISIS 3082 and ISIS 9125 are 20-base phosphorothioate oligodeoxynucleotides that hybridize to an analogous region in the 3′-untranslated region of murine and rat ICAM-1 mRNA, respectively (299,300). Similar to alicaforsen, ISIS 3082 and ISIS 9125 selectively inhibit ICAM-1 expression in mouse or rat cells by an RNase H-dependent mechanism. Rodent ICAM-1 antisense oligonucleotides have demonstrated activity in a mouse heterotopic heart transplant model (299), mouse pancreatic islet transplant model (301), and rat heart and kidney transplants (300). The murine ICAM-1 antisense oligonucleotide has also shown activity in mouse models of pneumonia, colitis, and arthritis (165,302). Haller et al. independently used an ICAM-1 antisense oligonucleotide to decrease acute renal injury following ischemia in rats (303).

Alicaforsen, which targets human ICAM-1, is currently being developed by Isis Pharmaceuticals, Inc., for the treatment of Crohn's disease and ulcerative colitis. Safety and pharmacokinetics of alicaforsen was established in a phase I study performed at Guy's hospital in normal volunteers (130). Volunteers were either infused over a 2-h period with escalating single doses or multiple doses given of alicaforsen or saline in a double-blinded trial. Brief dose-dependent increases in aPTT were seen at the time of peak plasma concentration and clinically insignificant increases in C3a were seen after repeated 2.0 mg/kg doses. C5a, blood pressure, and pulse were unaffected by administration of alicaforsen. No other adverse events or laboratory abnormalities related to the administration of the drug were noted. The Cmax was linearly related to dose and occurred at the end of infusion. Plasma half-life was approximately 53 min. Nonlinear changes in AUC and volume of distribution were noted with increasing dose, suggesting that oligonucleotide disposition might have a saturable component. These data suggest that ISIS 2302 was well tolerated in normal volunteers and that the pharmacokinetics in man was similar to that observed in nonhuman primates and rodents.

Alicaforsen was evaluated in a series of small phase IIa studies (20–40 patients in each trial) in rheumatoid arthritis, psoriasis, Crohn's disease, ulcerative colitis, and renal transplant. With the exception of the psoriasis study, the trials were placebo-controlled, double-blinded trials in which the drug is administered as a 2-h intravenous infusion. In all trials, the drug was well tolerated. In the rheumatoid arthritis trial, alicaforsen failed to produce significant efficacy but showed positive trends (304). The small sample size of the trial, 43 patients, did not allow definitive conclusions to be drawn.

In the phase IIa Crohn's disease study, conducted by Dr. Bruce Yacyshyn at the University of Edmonton, patients were administered 0.5 mg/kg, 1.0 mg/kg, and 2.0 mg/kg ISIS 2302 every other day for a total of 26 days (305). The response of the patients was not dose dependent, probably due to the narrow dose range investigated and the small number of patients in the lower dose groups (3 each). Therefore, all ISIS 2302-treated patients were analyzed as 1 group. Complete response, defined as Crohn's disease activity index (CDAI) score less than 150, was observed in 7 of 15 patients treated with ISIS 2302 and 0 of 4 of the placebo patients (305). At the end of

the study (6 months), 5 of the 7 patients were still in remission and 1 patient had a CDAI score of 156. During the treatment phase of the study, steroid doses were fixed, afterward the physician was allowed to adjust steroid dose based on symptoms. There was a statistically significant decrease in steroid use in patients treated with ISIS 2302 compared with placebo-treated patients at the end of the study. Other than expected increase in aPTT and mild facial flushing at the end of infusion in 1 patient, the drug was well tolerated. Based on these promising data, a large multicenter phase IIb trial of ISIS 2302 in Crohn's disease has been initiated. Thus, ICAM-1 antisense oligonucleotides may have therapeutic utility for the treatment of Crohn's disease.

The pilot trial in Crohn's disease was followed with a larger 299-patient, placebo-controlled, multicenter trial (306). Alicaforsen was administered intravenously 3 times per week at a dose of 2 mg/kg for either 2 weeks or 4 weeks. Patients were treated in months 1 and 3, with steroid withdrawal attempted by week 10. The primary endpoint of the trial was a CDAI less than 150 and off steroids at the end of week 14. Of the patients completing week 14, 64% of placebo patients had discontinued steroids and 78% of the alicaforsen-treated patients had successfully stopped steroid use ($p = 0.032$) (306). The number of patients achieving steroid-free remissions was similar in all 3 treatment arms. Pharmacodynamic analysis revealed that there was a strong correlation between drug exposure as measured by plasma AUC levels and response to alicaforsen treatment. Remissions increased from 13.0% (7/54) for the lowest AUC group to 55.6% (5/9) for the highest AUC group. One patient in the trial developed an IgM antibody to alicaforsen, without clinical sequelae. Adverse events reported in the trial were minimal with 2% of the patients exhibiting hypersensitive reactions. Anticipated increase in aPTT without bleeding episodes were noted and transient facial flushing during infusion were also noted. Although the trial was not positive, the correlation between exposure and clinical response warranted further investigation. As such, a 22-patient safety and pharmacokinetic trial was recently completed examining 250, 300, and 350 mg doses of alicaforsen. Doses were based on body weight. Infusion-related reactions of fever, chills, headache, nausea, emesis, and arthralgias were reported in 41% of the patients. Infusion-related reactions appear to be less frequent in patients receiving background steroids. The pharmacokinetic data suggest that patients receiving 300 to 350 mg of alicaforsen achieved adequate drug exposure, and this dose is currently under evaluation in a phase III trial.

Inhibitors of TNF-α have proven clinically useful for the treatment of rheumatoid arthritis, psoriasis, and Crohn's disease (307–311). Antisense oligonucleotides to TNF-α have demonstrated positive effects in mouse colitis models and a mouse model of stroke (312,313). ISIS 104803 is a second-generation chimeric, 2′-*O*-methoxyethyl/oligodeoxynucleotide targeting human TNF-α (116). A phase I study of ISIS 104803 has been completed in healthy males (116). The drug was dosed from 0.1 to 6.0 mg/kg given either intravenously of subcutaneously, with up to 4 doses given. Transient prolongation in aPTT was observed, similar to first-generation phosphorothioate oligodeoxynucleotides. Two patients experienced a rash, 1 a reversible platelet decrease, and tenderness was noted at the site of a subcutaneous injection. A decrease in TNF-α production was noted in peripheral blood leukocytes activated ex vivo with endotoxin in subjects treated with ISIS 104803. ISIS 104803 is currently under investigation in phase II trials for rheumatoid arthritis and psoriasis.

VIII. CONCLUSION

As is to be expected with first-generation technology, undesirable properties have been identified for phosphorothioate oligodeoxynucleotides (149,150,314,315). Despite these limitations, it is possible to use phosphorothioate oligodeoxynucleotides to selectively inhibit the expression of a targeted RNA in cell culture and in vivo. The pharmacokinetics of phosphorothioate oligodeoxynucleotides are similar across species and do not appear to exhibit major sequence-specific differences. When dosed at high levels, it is possible to identify toxicities in rodents and primates. However, at doses currently under evaluation in the clinic, phosphorothioate oligodeoxynucleotides have been well tolerated. In addition, there is evidence that phosphorothioate oligodeoxynucleotides provide clinical benefits to patients with viral infections, cancer, and inflammatory diseases. There are several phosphorothioate oligodeoxynucleotides in late-stage clinical trials, which will hopefully deliver more effective therapies for patients suffering from life-threatening or very debilitating diseases.

Extensive medicinal chemistry efforts have been successfully focused on identifying improved antisense oligonucleotides, which address some of these issues. There are at least 4 areas in which chemistry can add value to first-generation drugs: increase potency, decrease toxicity, alter pharmacokinetics, and lower costs. As an example, numerous modified oligonucleotides have been identified that have a higher affinity for target RNA than phosphorothioate oligodeoxynucleotides (84,87,91–93,316). Oligonucleotide modifications have been identified that exhibit increased resistance to serum and cellular nucleases, enabling use of oligonucleotides that do not have phosphorothioate linkages. The tissue distribution of oligonucleotides may be altered with either chemical modifications or formulations (79,134,140,141,143,144,181,200,203). Preliminary data also suggest that oral delivery of antisense oligonucleotides may be feasible (141). Finally, a number of modified oligonucleotides have been described that potentially exhibited less toxicities than first-generation phosphorothioate oligodeoxynucleotides (78,149,178)]. However, as experience with these modified oligonucleotides is rather limited, it remains to be seen whether they will have a distinct toxicity profile.

In conclusion, first-generation phosphorothioate oligodeoxynucleotides have proven to be valuable pharmacological tools for the researcher and have produced new therapies for the patient. Identification of improved second-and third-generation oligonucleotides with novel formulation should better

therapies for patients. Although tremendous progress has been made for antisense technology during the past 14 years, there are many more questions that remain for the technology.

Suicide Gene Therapy

Bert W. O'Malley, Jr.
The University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania, U.S.A.

I. INTRODUCTION

Despite decades of scientific advancements and new developments in surgery, radiation therapy, and chemotherapy, human cancer continues to be a major and growing cause of death in the world today. For most solid tumors, surgical excision is the primary mode of treatment and is frequently combined with radiation or chemotherapy for maximal efficacy. Radiation is capable of destroying both normal and abnormal tissues, but has a preferential effect on dividing malignant cells. Chemotherapy involves the use of cytotoxic drugs, which also have a preferential effect on rapidly dividing cells. Chemotherapeutic drugs are often used in combination because tumors have shown greater susceptibility to multiple agents that attack tumor cells by different mechanisms. Progress with these standard modalities for treating cancer continues while a new field of cancer research and treatment is evolving at a rapid pace. This new field is ''gene therapy'' and is founded on the premise that specific genes can be introduced into tumor cells to cause either a direct or indirect antitumor effect.

At first consideration, cancer does not appear to be a suitable target for ''classic gene therapy.'' That is, the original concept of gene therapy stemmed from the observation that certain diseases are caused by the inheritance of a single defective gene. Such diseases with monogenic defects such as adenosine deaminase deficiency and Gaucher's disease could theoretically be treated by effective insertion and expression of a normal gene into the defective host cells or even the bone marrow stem cell population (1,2). However, our recent understanding of cancer is that it develops via a multistep process whereby a series of genetic alterations or mutations occur within 1 cell (3). This 1 cell then looses regulatory control and proliferates abnormally to produce a population of malignant cells that may also continue to mutate and lead to cancer spread or metastases. Given the complexity of this genetic progression of cancer and the still many unknown abnormalities within any given tumor type, the idea of replacing all the abnormal genes with normal copies using gene therapy would be prohibitive. Also, with the limitations of delivery vehicles or ''vectors'' currently available for gene therapy, it would be equally prohibitive to effectively deliver the normal genes to every defective cancer cell.

Cancer gene therapy, however, is moving in directions that attempt to circumvent these apparent limitations. On such direction is the development of prodrug or ''suicide gene therapy'' strategies that involve specific gene transfer into tumor cells that enables intracellular conversion of a ''nontoxic'' prodrug into an active cytotoxic drug. Following effective suicide gene transfer and systemic or oral administration of the prodrug, an enzyme encoded by the therapeutic gene converts the prodrug into toxic anabolites or metabolites that inhibit or disrupt DNA synthesis. The tumor cells subsequently die via necrosis or apoptotic pathways. The most common suicide gene used in preclinical and human clinical investigation is the gene encoding herpes simplex virus thymidine kinase (HSV-tk). A major advantage of many suicide gene therapy strategies is that not only are the tumor cells that have incorporated the gene destroyed, but also surrounding ''nontransduced'' cells are killed (4). The mechanism by which nontransduced neighboring tumor cells are killed is known as the ''bystander effect,'' which is discussed in more detail later in the chapter. The many facets of the bystander effect significantly strengthen suicide gene therapy as a whole and add to its versatility.

Although the identification and selection of specific suicide genes that may induce both direct and/or indirect antitumor effects is a very important area in gene therapy research, equally important to the success of such strategies is the grow-

ing arena of vector or delivery vehicle development. The choice of delivery vehicle greatly influences the overall outcome and efficiency of the therapeutic strategy. Even with the beneficial bystander effect, the effects of suicide gene therapy are linearly related to the efficiency of gene transfer. New investigations and advances in both viral and nonviral gene therapy technologies should also prove valuable in overcoming many of the obstacles in the application of gene therapy to cancer. One such recent advance is the application of replication-selective oncolytic viruses. These viruses have been engineered to selectively infect and replicate in targeted tumor cells that have inherent genetic defects, such as loss of p53 gene expression. Tumor cells that lack p53 expression allow select viral replication, which kills the host tumor cell, and then subsequent spread and infection of surrounding tumor cells results in further tumor kill. This modification of classic suicide gene therapy into suicide viral therapy may prove a key advance in overcoming limitations of gene transfer efficiency in the presently available replication-incompetent adenoviral vectors.

This chapter describes the various suicide gene therapy strategies, including a brief overview of replication-selective oncolytic virotherapy for treating solid tumors, and provides an overview of advantages and disadvantages of viral vs. nonviral methods of delivering these genes. The 2 basic approaches for suicide gene delivery ''in vivo and ex vivo'' are also reviewed, and an update on the status of human clinical trials is provided.

II. GENERAL PRINCIPLES AND SAFETY ISSUES

The principle of suicide gene therapy stems from the long history of drug discovery and development focusing on the treatment of microbial infections. The enyzmes encoded by suicide genes are important components in metabolic conversion pathways within bacteria, viruses, or fungi (5). The effect of a prodrug on human cells that have been transduced with a suicide gene therefore parallels the effect of an antibiotic on a human bacterial infection. The microbial origin of these enzymes provide 2 important safety and specificity features of suicide gene–prodrug therapy that are similar or identical to the features of antibiotic or antiviral therapy. First, the enyzmes and the associated metabolic pathway may be completely specific to microbial cells and not found in mammalian cells. Because mammalian cells lack the enzyme encoded by the suicide gene, systemic administration of the prodrug has no toxic effect on any human tissue or cell that has not been engineered to express the selected suicide gene (6). Second, certain mammalian cells may actually express the enyzme, but the specific prodrug chose may be a poor substrate for the mammalian form of the enzyme and an excellent substrate for the bacterial or viral form. Again in this scenario, administration of the prodrug would be harmless to the mammalian cell that has not been engineered to overexpress the nonmammalian enzyme. The prodrug is therefore similar to or may actually be a form of antibiotic or antiviral medicine. Systemic administrations of the prodrug will produce effects limited to cells expressing the suicide gene and the microenvironment surrounding these cells and would not cause significant systemic toxicity.

Another general safety feature for suicide gene therapy lies within the actual mechanism of cytotoxicity that results from the conversion of the prodrug to a toxic metabolite. Because the majority of these metabolites inhibit cellular nucleic acid synthesis pathways, the delivery of the suicide gene and administration of the prodrug would have a preferential cytotoxic affect on actively dividing cells. With respect to tumor cell populations vs. normal mammalian cells, the tumor would be more susceptible to the effects of suicide gene therapy. Some suicide gene therapy systems do not show preference for dividing cells, which raises a safety issue. Surrounding normal tissue may be inadvertently injured after exposure and subsequent transduction by the suicide gene. Selection and application of gene delivery techniques are therefore important in targeting the tumor while minimizing exposure to normal or systemic tissues to the suicide gene.

III. SUICIDE GENE THERAPY STRATEGIES

A key issue in the success of a suicide gene therapy strategy is the interaction between the enzyme produced and the prodrug administered. The selection of the enzyme and prodrug combination is influenced by certain variables critical to enyzme-substrate kinetics. Two important variables exist for the enzyme. The first is the speed of activation of the prodrug. The most effective suicide genes will express enzymes that rapidly activate the prodrug. Enzymes that are slower in their activation will be dependent on either higher concentrations of the prodrug or prolonged administration. Issues such as half-life and intracellular degradation and clearance mechanisms will also limit the presence of the prodrug. The second variable is the efficiency of prodrug activation. Enzymes that are highly efficient in converting the prodrug substrate into its toxic metabolite should prove advantageous because of known variances in the levels of effective gene transfer and gene expression (enzyme production) inherent to in vivo suicide gene transfer. Regarding the prodrug, it should be at least 100 times more cytotoxic than the preactivated form upon enzyme activation (7). Because many different types of prodrugs can be designed to achieve maximal activation, the most important and probably most limiting factor is the enzyme and therefore choice of suicide gene. Table 1 depicts the more commonly used suicide genes and corresponding prodrug combinations under investigation for gene therapy application. Table 2 shows the mechanisms of toxicity for selected genes that are presently being investigated in both preclinical and clinical studies.

Despite choosing a generally efficient enzyme–prodrug combination that proves successful with in vitro experimentation, there may not be a paralleled success after the transition to in vivo application against established tumors. In vivo effi-

Table 1 Selected Suicide Gene Therapy Strategies

Gene/enzyme	Prodrug	Initial toxic metabolite
Herpes simples virus thymidine kinase (HSV-tk)	Ganciclovir (GCV)	Ganciclovir monophosphate
Cytosine deaminase (CD)	5-Fluorocytosine (5-FC)	5-Fluorouracil (5-FU)
Varicella zoster virus thymldine kinase (VZV-tk)	6-Methoxypurine arabinonucleoside (araM)	Adenine arabinonucleoside monophosphate
Escherichia coli nitroreductase (NTR)	5-(Aziridin-1-yl)-2, 4-dinitrobenzamide (CB 1954)	5-(Aziridin-1-yl)-4-hydroxyamino-2-nitrobenzamide
Cytochrome P450 B1 (CYP2B1)	Cyclophosphamide (CPA)	4-Hydroxy-cyclophosphamide (4-HCPA)
Carboxypeptidase G2 (CPG2)	Benzoic acid mustard gluonuridebenzoic acid mustard (CMDA)	
E. coli gtp (XGPRT)	6-Thioxanthine (6-TX)	6-Thioxanthine monophosphate (6-XMP)
E. coli Deo (PNP)	6-Methyl purine deopxyriobside (MePdR)	6-Methylpurine (MeP)

cacy may also vary among different types or classes of tumors for any one given enzyme–prodrug combination. An example of this is found within the HSV-tk gene therapy strategy, the most widely used suicide gene in both preclinical investigation and human clinical trials. Although HSV-tk has proven effective in many different solid tumors, it is generally less effective against hematopoietic malignancies (8). It has been hypothesized that HSV-tk is down-regulated or lost more quickly in hematopoietic tumors such as leukemia, which results in ineffective or insufficient conversion of the prodrug to achieve antitumor effects (9).

A. HSV-tk

HSV-tk has shown the greatest potential to date for human application across a broad range of malignancies, and for this reason it is the most popular and widely studied suicide gene therapy strategy. The importance of HSV-tk gene transfer centers on its ability to render cells sensitive to the acyclic guanosine analog ganciclovir (GCV) (10,11). HSV-tk is a prototype ''suicide gene'' because it encodes a viral enzyme that is foreign to mammalian cells and will convert an inactive and relatively nontoxic prodrug to a toxic product. Upon effective HSV-tk gene transfer and expression, the prodrug GCV is monophosphorylated by the enzyme. Intracellular host kinases then metabolize this monophosphorylated nucleoside analog into di- and triphosphates (12). The triphosphate form of GCV is then incorporated into the replicating DNA chain in dividing cells and inhibits DNA polymerase. Inhibition of DNA polymerase results in chain termination, disruption of DNA synthesis, and cell death. The phosporylation of GCV impairs its ability to cross the cell membrane and, as a result, the half-life increases by 6-fold to 18 to 24 h (13,14). The extended half-life of the phosphorylated GCV strengthens the overall anticancer effect of this HSV-tk strategy. With respect to sensitivity, viral thymidine kinase is approximately 1000 times more efficient in phosphorylating GCV than its mammalian counterpart (13). Because GCV is an excellent substrate for

Table 2 Mechanisms of Cytotoxicity of Select Suicide Gene Therapy Strategies

Gene	Final toxic metabolite(s)	Direct cytotoxic effect	Bystander effect
HSV-tk	GCV-triphosphate	Disrupts DNA synthesis	Present
CD	5-FU-mono/tripohosphate	Disrupts DNA and RNA synthesis	Present
VZV-tk	Ara-ATP	Disrupts DNA synthesis	Unknown
NTR	4-Hydroxylamine metabolite of CB 1954	Cross-links DNA (direct DNA breaks; disrupts synthesis)	Unknown
CYP2B1	Phosphoramide mustard DNA acrolein	Alkylation (cross-links DNA) covatently links cellular proteins	Present
CPG2	Benzoic acid mustard	DNA alkylation (cross-links DNA)	Present
XGPRT	6-Thioguanine monophosphate (6-GMP)	Disrupts DNA synthesis	Presumed
PNP	6-Methylpurine (MeP)	Direct toxin/cellular necrosis	Present

viral thymidine kinases and a poor substrate for mammalian thymidine kinases, concentrations can be achieved that are lethal to cells expressing HSV-tk but are nontoxic to normal mammalian cells (10,11,15).

Culver et al. demonstrated the first in vivo application of suicide gene therapy for cancer using retroviral-mediated HSV-tk gene transfer via fibroblast packaging cells injected into brain tumors in mice (16,17). Since this initial study, HSV-tk suicide gene therapy has been applied and investigated in multiple tumor types, including thoracic, head and neck, and ovarian cancer (18–20). Critical to the tumor response described in these early studies was the observation that not all the tumor cells must express the HSV-tk gene for a complete or extensive tumoricidal effect. The term bystander effect has been attributed to the regression of noninfected surrounding tumor cells after HSV-tk delivery and GCV administration. There are both direct and indirect mechanisms driving the bystander effect that are discussed in more detail later in the chapter. Briefly, the direct effect is an exchange of toxic metabolites between HSV-tk infected tumor cells and neighboring noninfected cells (21,22). The indirect effect stems from antitumor immune responses add to the versatility of this suicide gene therapy strategy (23,24).

A potential disadvantage of the HSV-tk strategy is that it requires S-phase cell cycle activity and thus targets only dividing cells. At any given time, not all malignant cells within a tumor are cycling and different tumor types display different rates of cell doubling both in vitro and in vivo. Conditions must therefore be worked out that provide adequate HSV-tk gene expression and administration of GCV over long enough time to account for variability in cell cycling within a designated tumor. Although the bystander effect helps augment the antitumor effects, there is likely a threshold of HSV-tk transfer and expression and persistence of the enzyme that must be achieved to generate or sustain a significant therapeutic effect.

Although a potential disadvantage, the requirement for cell division may also be an advantage for both safety and tumor targeting for the HSV-tk strategy. Normal mammalian cells in general divide at much slower rates than tumor cells within an established malignancy. This differential in S-phase activity allows for design of HSV-tk delivery and expression that would preferentially kill tumor cells while minimizing or eliminating direct toxicity to surrounding or systemic normal tissues that may incorporate the gene and express the enzyme.

B. Cytosine Deaminase

The enzyme cytosine deaminase (CD) is found in a variety of fungi and bacteria, but is not found in mammalian cells. In these microbes, CD is activated during nutritional stress and normally catalyzes the deamination of cytosine to produce uracil. CD is also capable of converting the nontoxic prodrug 5-fluorocytosine (5-FC) into the metabolite 5-fluorouracil (5-FU) (24–26). In a second metabolic conversion process, intracellular enyzmes present in both microbial and mammalian cells then act on 5-FU to produce 5-fluorouridine 5′-triphosphate and 5-fluoro-2′-deoxyuridine 5′-monophosphate. These toxic phosporylated metabolites disrupt both RNA and DNA synthesis resulting in direct cellular cytotoxicity. Because of the natural specificity of CD to fungi and relative lack of toxicity of 5-FC in human tissues at routine dosing, 5-FC has been developed as an antifungal agent. However, because 5-FU is also converted to toxic metabolites in mammalian cells, this compound has been developed and widely applied as a chemotherapeutic agent for cancer.

The original application of CD for cancer therapy involved implanting a capsule containing the enzyme into an established rat tumor whereupon the enzyme diffused into the tumor cells. The animals were subsequently treated with 5-FC, which resulted in an antitumor response (27). Upon the cloning of the gene and building on these early animal investigations, CD suicide gene therapy became a feasible strategy (24). Aside from the direct cytotoxicity with this system, a significant bystander effect has also been identified with this system. The CD system is different from the HSV-tk system and may have a bystander advantage because of the initial production of 5-FU. Because the initial conversion to a ''toxic metabolite'' (5-FC to 5-FU) does not involve phosporylation, the 5-FU produced within the cytoplasm may readily cross the cell membrane and enter surrounding tumor cells. Also, the phosphorylated toxic metabolites of 5-FU that disrupt DNA and RNA synthesis may also be transferred to surrounding cells via intercellular communication or similar mechanisms as reported for the HSV-tk system. In effect, the multiple conversion steps provide 2 possible means of bystander activity that theoretically provide an enhanced overall antitumor and bystander effect as compared with the HSV-tk system. The full efficiency of the CD strategy and its bystander effect, however, has not been elucidated and further preclinical investigations are needed to discern any significant bystander advantages.

The lack of natural CD within mammalian cells and safety of 5-FC dosing makes this enzyme–prodrug combination a natural choice for human cancer investigation. CD is presently the second most common suicide gene under preclinical and clinical investigation; however, it has certain limitations that may affect successful application of this strategy. The toxicity of 5-FU is not S-phase cell-cycle specific, but it does depend on cell proliferation for its effect. As with the HSV-tk system, the CD strategy preferentially affects tumor cells that have a higher rate of proliferation. Although this provides some inherent safety and tumor targeting specificity, heterogenous tumor cell populations with variable levels of cellular proliferation may reduce the overall therapeutic effect. To achieve substantial tumor cell toxicity, high doses of 5-FU at the cellular level are generally required. The need for high cellular levels of 5-FU requires both efficient CD gene transfer and expression followed by adequate systemic dosing of 5-FC. The need for higher doses of 5-FC prodrug introduces the potential for systemic intestinal toxicity. The reason for this potential intestinal side effect is that residing enterobacteria present in normal human gastrointestinal tissues produce CD. These normal intestinal bacteria thus are able to convert 5-FC to 5-FU and produce local cellular injury. Another major

limiting factor is that 5-FU is only active for a maximum of 10 min. Thus, prolonged systemic treatment with 5-FC after CD gene transfer is required to maintain the production of intracellular 5-FU. Possibly the most limiting factor is the complexity of the metabolic conversion pathway itself. A multistep complex pathway provides many opportunities for tumor cells to acquire resistance to the actual therapy (28).

C. Varicella Zoster Virus Thymidine Kinase

The varicella zoster virus is also capable of expressing a unique thymidine kinase (VZV-tk) whose substrate specificity is distinct from both mammalian cellular kinases and the HSV-tk enyzme. Upon gene transfer of VSV-tk into recipient cells, cytotoxicity is induced by administration of the prodrug 9-(b-D-arabinofuranosyl)-6-methoxy-9H-purine, also known as araM (29). VZV-tk enyzme initially phosphorylates araM that is further metabolized by natural cellular enzymes (AMP deaminase, AMP kinase, nucleoside diphosphate kinase, and adenylosucinate synthestase lysase) into adenine arabinonucleoside triphosphate (araATP). ara-ATP is highly toxic and therefore only small quantities of ara-M in the range of 1 to 100 μm are required to directly kill cells that contain the VZV-tk enzyme (29). As with GCV in the HSV-tk system, araM is an excellent substrate for VZV-tk but not mammalian nucleoside kinases. Normal mammalian cells are able to withstand over 1500 μm of ara-M exposure. The overall sensitivity of a transduced cell to the ara-M prodrug is directly proportional to level of the VZ-tk activity.

This system is still relatively new for preclinical investigation, and the presence of a bystander effect remains to be proven. The disadvantages of VZV-tk suicide gene therapy are similar to those of HSV-tk, and further experimentation is required to define the efficacy and safety rationale for selecting between these two strategies.

D. *Escherichia coli* Nitroreductase

The NTR enzyme activates the relatively nontoxic prodrug dintrophenylaziridine CB1954 through a reduction process that generates a 4-hydroxylamine metabolite. This intermediate molecule further reacts with intracellular thioesters such as acetyl-CoA to produce a highly cytotoxic alkylating agent that is 10,000 times more toxic than the original prodrug (30).

There are a few proposed mechanisms by which CB1954 mediates its cellular toxicity after reduction by nitroreductase (NTR). The most commonly reported mechanism is through cross-linking DNA strands causing disruption of synthesis and DNA breaks that are directly cytotoxic to both dividing and nondividing cells (31). Some investigators have reported increased apoptosis after delivery of NTR and CB1954 to targeted cells (32) which was presumed to be a result of the DNA alterations incurred. It appears that CD1954 acts more rapidly than other prodrugs such as GCV in the HSV-tk system, with reports of cytolytic activity as early as 4 h after prodrug administration (31,33). One explanation for this comparatively rapid response is that the NTR strategy does not require cells to be in the S phase of growth.

This lack of specificity for dividing cells may prove advantageous in achieving maximal antitumor efficacy; however, it raises a significant safety concern regarding normal surrounding tissues. A critical issue in the future application of this system will be the development of tumor-specific targeting so that normal somatic cells will not be exposed to the cytotoxic effects of the enzyme and prodrug. Another potential drawback to the CB1954/NTR system is that a bystander effect has not been identified to date (32). These 2 limitations may preclude the clinical application and benefit of this system until increased efficiency of gene transfer and tumor-specific targeting is achieved.

E. Cytochrome P450 2B1

The hepatic enzyme cytochrome P450 B1 (CYP2B1) will convert the inert lipophilic prodrug cyclophosphamide (CPA) into an effective anticancer agent (34). CPA is initially converted into 4-hydroxy-cyclophosphamide (4-HCPA), which is naturally unstable and will spontaneously decompose into 2 toxic metabolites, acrolein and phosphoramide mustard (PM). Acrolein will promote covalent links in cellular proteins and PM induces DNA alyklation and results in DNA strand breaks during replication. The importance of acrolein in causing tumor cytotoxicity in vivo has yet to be proven; therefore, the major anticancer metabolite appears to be PM. The cytotoxicity of PM affects both dividing and nondividing cells and so may prove useful for tumors that have low levels of S-phase activity such as the glioblastoma brain tumor (35).

Tumor cells usually express low levels of CYP2B1 but the liver expresses higher levels. Systemic exposure to CPA at concentrations that would prove effective in killing tumor cells will result in high levels of toxic metabolites produced in normal liver tissue. These high levels of toxic metabolites not only injure normal liver tissue, but also are released into the circulation. Systemic toxicity has therefore limited the ability to use these prodrugs alone as cancer chemotherapeutic agents. Gene transfer of the CYP2B1 gene and the resulting upregulated expression of the enzyme, however, will allow for administration of smaller systemic levels of CPA prodrug to maintain tumor cytotoxicity while minimizing systemic toxicity.

One important advantage of this system is that the intermediate metabolite 4-HCPA is lipophilic and so can pass through cellular membranes (36). Diffusion of these metabolites throughout the nontransduced tumor cells results in a strong bystander effect. Despite this apparent augmentation of overall antitumor effects, the free diffusion of 4-HCPA and the fact that the CYP2B1 gene therapy strategy does not require cell division also carries the disadvantage of possible toxicity in surrounding normal tissue.

F. Carboxypeptidase G2

The bacterial enzyme carboxypeptidase G2, (CPG2) has no mammalian homolog and has been shown to activate the pro-

drug 4-[(2-chloroethyl)(2-mesyloxyehtyl0amino]bensoyl-L-glutamic acid (CMDA), which is a derivative of a benzoic acid mustard. The CPG2 enzyme removes the glutamic acid moiety from the CMDA prodrug and releases a toxic benzoic acid mustard (37), which requires no further enzymatic or decomposition process. The benzoic acid mustard is a strong alkylating agent and cross-links DNA, thus imparting toxicity to both dividing and nondividing transduced cells.

The single-step process of converting CMDA to the toxic mustard metabolite offers an advantage over other suicide gene therapy strategies that have intermediate metabolites and multistep conversion processes within a targeted tumor cell. If the cellular enzymes that are responsible for the second phase or multistep activation process become defective or deficient in the tumor cell, a significant resistance to the prodrug could develop (38). However, when the toxic metabolite is released directly from the initial step or prodrug cleavage, there is much less chance of developing resistance to the suicide gene therapy. Also, mustard alkylating agents such as benzoic acid mustard have the advantage that their cytotoxicity is dose related. This important factor further reduces the chances of resistance.

As mentioned with other suicide gene therapy strategies above, this broad killing is beneficial for tumors with significant number of cells in Go at the time of gene transfer and prodrug administration. However, the potential continues to exist for direct toxicity to surrounding normal tissues that are transduced with this suicide gene.

A substantial bystander effect has been documented with the CPG2 strategy in vitro when as few as 3.7% of the tumor cells were expressing CPG2 (39). This is one of the strongest reported bystander effects and serves as an advantage for this strategy.

G. *E. coli* gtp

The *gtp* gene encodes the enzyme xanthine guanine phophoribosyltransferase known as XGPRT. This enzyme converts the xanthine analog, 6-thioxanthine (6-TX) into a weakly toxic purine analog that is subsequently phosphorylated into 6-thioxanthine monophosphate (6-XMP) by the same XGPRT enzyme. 6-XMP is then converted into the very toxic 6-thioguanine monophosphate (6-GMP). This suicide gene therapy has been studied in a retrovirus-mediated gene transfer strategy in sarcoma and glioma tumor cell line and animal model experiments (39a,39b). XGPRT may also prove valuable in adenovirus-mediated gene transfer strategies.

H. *E. coli* Deo

When the *Deo* gene is expressed in target cells, the enyzme purine nucleoside phosphorylase (PNP) is produced. The PNP enzyme is not found in human cells, thus giving this system a level of selectivity and safety with respect to application in human tumors. PNP converts the prodrug 6-methyl purine deoxyriboside (MePdR) into a very toxic metabolite, 6-methyl purine (MeP). MePp is directly toxic to tumor cells and has a strong bystander effect. The main reason for its strong bystander effect is its ability to freely diffuse through cell membranes and travel into surrounding tumor cells. Significant tumor necrosis has been demonstrated when as little as 1 in 100 to 1000 tumor cells have been effectively trasduced with viral vectors carrying the *E. coli Deo* gene. This strong suicide gene therapy effect and corresponding bystander effect has been studied in human colon, glioma, and melanoma cell lines in vitro and ovarian and glioma cell lines in vivo (39c,39d).

IV. THE BYSTANDER EFFECT

Although present to variable degrees for each suicide gene therapy strategy, the bystander effect provides a major advantage for these systems. The advantage of a bystander effect is obvious when considering that present gene transfer approaches provide relatively poor transduction efficiencies of tumors in vivo. Given that only a fraction of any targeted tumor can be effectively transduced, a supplemental antitumor effect that does not require exposure or uptake of the therapeutic gene is critical to the success of suicide gene therapy. As mentioned previously, the bystander effect is a phenomenon whereby neighboring nontransduced tumor cells are killed in conjunction with direct killing of transduced cells (Fig. 1). Multiple theories have been investigated and proposed as an explanation for this effect.

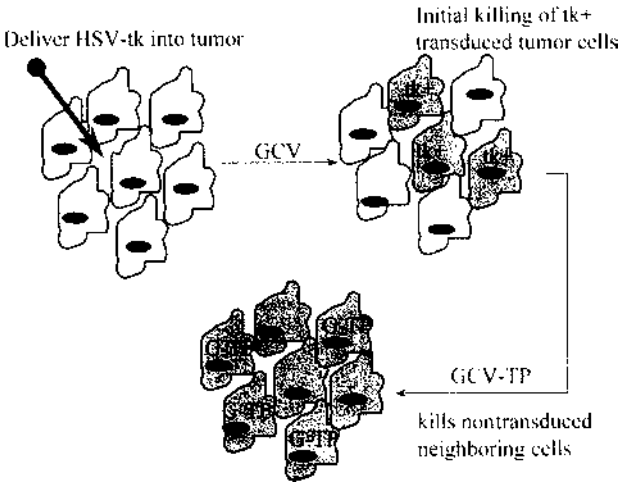

Figure 1 The bystander effect. The HSV-tk gene is delivered to a solid tumor resulting in effective transduction and gene expression in only a percentage of the tumor (shaded cells). Subsequent systemic treatment with ganciclovir (GCV) causes DNA disruption, cell death, and production of toxic metabolites. The toxic metabolites are then passed to surrounding nontransduced cells via gap junctions resulting in cell death.

A. Metabolic Cooperation and Gap Junctions

The most investigated and widely accepted theory to date is that toxic prodrug metabolites are passed between tumor cells through gap junctions. Gap junctions are small hexameric structures (2 nm) in the cell membrane that form part of a communication network between cells. This transfer of toxic metabolites via gap junctional intercelluar communication is founded in the principle of ''metabolic cooperation,'' which was first described by Subak-Sharpe et al. in 1966 (40). Metabolic cooperation is the process whereby low molecular weight molecules (<1000 Daltons) are passed between cells that are in contact. Subsequent to these early studies, it was established that cells with gap junctions were ionically coupled and participated in metabolic cooperation (41). Cells that lacked gap junctions did not participate in this event.

The importance of cell contact in a suicide gene therapy system was identified by Moolten and colleagues who demonstrated bystander killing of nontransduced cells after HSV-tk gene transfer and GCV administration in vitro (10). Although the GCV prodrug can readily and passively diffuse across a cell membrane, the toxic phosphorylated metabolite is not a permeable molecule. However, phosphorylated GCV is approximately 400 Daltons in size and is well within the size limit for metabolic cooperation to occur via gap junctions (42). Subsequent to these early studies with the HSV-tk suicide gene therapy system, Bi et al. introduced the concept that the bystander effect was a result of metabolic cooperation (22). It was demonstrated that labeled phosphorylated GCV was able to enter adjacent contacting tumor cells and resulted in cell death. Gene transfer and expression of a much larger molecule such as β-galactosidase, however, was not transferred to nontransduced contacting tumor cells.

Gap junctional communication is believed to be mediated by a family of proteins called connexins of which 12 genes have been cloned (43). Definitive proof that gap junctional intercelluar communication and connexin activity played a major role in the bystander effect came from the investigations of Mensil et al. (44). In their experiments, HeLa cells were chosen because they exhibit very little gap junctional communication and have no detectable expression of known connexin genes (45). Upon gene delivery of HSV-tk to cultured HeLa cells, only the actual HSV-tk transfected cells were killed despite different levels of cell density or contact. When HeLa cells were transfected with a gene encoding the gap junctional protein connexin 43, both HSV-tk positive and nontransfected surrounding cells in contact were killed. This effect was abrogated when HSV-tk positive and negative HeLa cells were cocultured without cell–cell contact.

B. Transfer of Toxic Metabolites via Apoptotic Vesicles or Direct Transmembrane Diffusion

Another reported mechanism of bystander effect activity is the release of apoptotic vesicles by dying tumor cells after suicide gene therapy. Freeman and colleagues noted that HSV-tk-positive tumor cells exhibited characteristics of apoptosis when dying in culture (21). Microscopic analyses revealed cell shrinkage and detachments as well as chromatin condensation and vesicle formation. Further ultrastructural evaluation using transmission electron microscopy identified features consistent with apoptosis. Apoptotic vesicles released form HSV-tk- and GCV-treated tumor cells could transfer the toxic phosphorylated GCV metabolite or even the HSV-tk gene itself. The mechanism of transfer would involve phagocytoses of these vesicles by surrounding viable tumor cells. This presumed transfer of apoptotic vesicles was demonstrated using a fluorescent tracking dye and fluorescence microscopy and flow cytometry. Nontransfected tumor cells were able to phagocytose the labeled apoptotic vesicles generated from dying HSV-tk transfected cells. Further studies on the importance of this finding in mediating the extent of bystander activity are required before this principle is substantiated and accepted.

Certain toxic metabolites such as 5-FU and 6-methyl purine (MeP) do not require gap junctions or the phagocytoses of apoptotic vesicles in order to enter surrounding tumor cells. 5-FU and MeP are permeable to most cellular membranes and thus can freely diffuse throughout the tumor, resulting in a strong bystander effect that is not restricted by tumor cell-dependent numbers of gap junctions or phagocytotic capabilities.

C. Local Antitumor Immune Responses

Although metabolic cooperation via gap junctions has been consider the major mechanism of the bystander effect, there is a growing interest in the role of the immune system in this phenomenon (Fig. 2). A number of studies have reported the presence of an inflammatory infiltrate in dying or regressing tumors after both HSV-tk and CD gene therapy (46,47). Other investigations have described a lessened response to HSV-tk and GCV therapy for tumors grown in nude mice as compared with immunocompetent animals (23,48). The decreased effect in these athymic and therefore T cell-deficient mice suggests that a T cell-mediated immune response plays some role in tumor regression. In these studies, nude mice and sublethally irradiated mice failed to demonstrate subcutaneous tumor regression when the tumor cell population consisted of 50% HSV-tk-transduced cells. The same experiments in immunocompetent mice, however, did show tumor rejection with the 50% proportion of HSV-tk-transduced cells.

More specific immune and cytokine analyses were subsequently performed using an intraperitoneal tumor model (49). Upon treatment of established tumors with HSV-tk-transduced cells, the peritoneal exudate was analyzed for the presence of various cytokines. Expression of tumor necrosis factor-alpha (TNF-α), interleukin 1-alpha (IL-1α), and IL-6 was identified at 24 h after tumor treatment with HSV-tk-positive cells. After 48 h interferon gamma (INF-γ) was identified and at 96 h, granulocyte-macrophage colony-stimulating factor (GM-CSF) was produced. There appeared to be a defined cascade of cytokine production that was specific to the HSV-

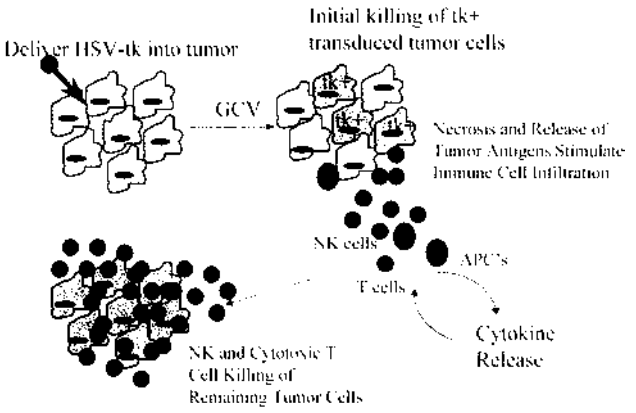

Figure 2 Immune component to the bystander effect. As tumor cells are killed by the suicide gene therapy, there is a release of cellular debris and tumor antigens within the local tumor environment. The cell necrosis and antigen load stimulates recruitment and activation of tumor-specific immune cells. The immune cells attack the local-regional tumor and also initiate a systemic response that may target and kill metastatic disease or prevent recurrence.

tk-treated tumors. Immunohistochemical staining identified immune infiltrates consisting of macrophages and T lymphocytes that were predominantly in and surrounding regressing tumors subsequent to HSV-tk therapy. These representative studies as well as others have established a role for local immune responses in generating killing of both transduced and nontransduced tumor cells. The generation of an antitumor immune response against both transduced and nontransduced tumor cells greatly enhances the power of suicide gene therapy and its associated bystander effect.

D. Systemic Antitumor Immune Responses

There is increasing evidence that not only a direct local immune response but also a systemic immune response is generated from suicide gene therapy. The development of a systemic immunity has been demonstrated for both the HSV-tk and CD strategies. In animal studies with HSV-tk-expressing tumor cells, administration of GCV resulted in both direct tumor cell killing and an ''initial'' protection against a second challenge of wild-type tumor cells (23,50). This effect could not be sustained and eventually tumors grew at the site of second challenge. This initial antitumor immunity was not generated against a second local challenge of syngeneic but heterologous (antigen distinct) tumor cells. Using the same tumor strategy in T cell-deficient nude mice, the antitumor effects and initial systemic immunity against a second-site tumor challenge was greatly reduced. These findings again support the importance of a T cell-mediated tumor-specific immune response. This initial systemic antitumor immunity has been documented in multiple tumor cell types for the HSV-tk strategy, although the extent and period of immune effect has been variable among studies.

Although most of the work centering on immune responses and suicide gene therapy has centered on HSV-tk therapy, the immune component to the bystander effect has also been identified in the CD scheme. Both fibrosarcoma and adenocarcinoma cells that were retrovirally transduced to express CD showed variable levels of resistance to second wild-type tumor challenges subsequent to systemic administration of the prodrug 5-FC (51). Second tumor challenges with antigen distinct tumor lines from the same murine background, however, displayed normal tumor growth, indicating a tumor specificity to the immune response. These findings parallel the results noted in the HSV-tk system.

In the previous investigations, the fibrosarcoma and adenocarcinoma cell lines were generated via carcinogen induction. Subsequent studies have confirmed both a local and systemic protective immune responses after CD and 5-FC therapy in a spontaneously occurring mammary carcinoma (49). Antibody depletion against specific lymphocytes was performed in the animal tumor model system to further define specific components to these immune responses. Upon antibody depletion of CD8-positive T lymphocytes in vivo, a significantly decreased level of local tumor regression and even increased tumor growth was noted in CD-expressing tumors that were treated with 5-FC. Antibody depletion of granulocytes also appeared to limit the antitumor responses. Deletion of CD4 T lymphocytes had no significant effect on local tumor regression from the CD and 5-FC treatment. Interestingly, depletion of CD4-positive T lymphocytes dramatically reduced or in some cases eliminated the systemic immunity against a second local challenge of wild-type tumor. Depletion of CD8 T lymphocytes also appeared to limit the systemic antitumor bystander effects of a second challenge of wild-type tumor. Overall, these studies support the ability of suicide gene therapy to generate some level of systemic immunity. The systemic protection, however, was present at variable levels and only short-term systemic immunity was evaluated.

Although systemic immune responses can be generated against second tumor challenges after suicide gene therapy, could it be possible to induce regression of existing tumor metastases after treatment of the primary tumor? Original murine studies in multiple tumor types evaluating responses against an established subcutaneous wild-type tumor at a second site were not encouraging. Tumor killing and regression identified in subcutaneous flank tumors that expressed CD or HSV-tk did not induce a significant effect on wild-type (nontransduced) tumors growing on the opposite flank (21,26,51). This apparent lack of effect on the presence of established tumors at a distant site suggested that the immune bystander effect was not going to be effective against gross metastases present at the time of primary tumor therapy.

Further studies involving orthotopic metastases, however, have defined some role of this immune bystander effect in the treatment of metastatic disease. Consalvo et al. demonstrated regression of lung metastases in 20% of mice whose primary CD-expressing subcutaneous tumors regressed after 5-FC ad-

ministration (47). Up to 90% regression of HSV-tk-negative liver metastases was also described after elimination of HSV-tk-expressing tumors growing intraperitoneal in a murine colon adenocarcinoma model (52). Immunohistochemical studies confirmed the presence of increased inflammatory infiltrates in these regressing metastases as compared with controls. These representative studies support the concept that a systemic antitumor immunity or bystander effect is capable of generating variable levels of tumor regression in distant metastases.

The issue has not been resolved as to why established second site wild-type tumors are not affected by suicide gene therapy directed at the primary tumor but metastatic lung and liver tumors show some regression. Excluding possibilities such as natural antigenicity of various tumor types and inherent differences among animal tumor models, there are a few hypotheses to explain this somewhat contradictory finding. The first hypothesis is that anatomic location of second site or metastatic disease is an important issue in generating effective immune-mediated regression after primary tumor therapy. The lung and liver have an increased number of cells from the reticuloendothelial system as compared with the subcutaneous tissues. The increased reticuloendothelial cells surrounding the metastases may facilitate or enhance antitumor immune activity generated from the initial primary tumor treatment. Also, this environment within the lung or liver may promote increased or more efficient antigen presentation. The second hypothesis may be related to gross tumor burden. Although in multiple animal models a second site established tumor has not regressed after primary tumor treatment with suicide genes, an initial protection against repeat tumor challenges has been well documented. The second hypothesis is based on this finding. It is possible that the systemic immune response generated from the initial tumor treatment is not strong enough to manage the gross tumor burden of an established tumor but can handle the smaller tumorigenic doses given for a second challenge. Further experiments to evaluate this consideration of tumor burden or rate of cell division within the metastatic lung and liver models may help to answer this question.

V. COMBINATION SUICIDE GENE AND CYTOKINE GENE THERAPY

Based on the initial immune responses generated after suicide gene therapy, there has been a recent interest in combining this strategy with cytokine gene therapy. Cyotokine gene therapy has arisen because of the growing opinion that tumor-specific antigens are expressed in many if not all human tumors, but the immune system fails to generate an adequate immune response against these antigens (53). Designing or discovering a means to augment baseline immune activity or generate tumor-specific responses would greatly enhance any cancer treatment strategy. Systemic infusions of cytokines has demonstrated tumor regression in both animal tumor models and some human clinical trials; however, the severe toxicity associated with the high concentrations required to achieve antitumor efficacy significantly limits this strategy (54–56). Cytokine gene therapy may circumvent the toxicity of systemic infusions and provide both larger and sustained local concentrations of cytokine within the tumor environment. This augmentation of the immune response with cytokine production may also be synergistically enhanced by the addition of suicide gene therapy.

Upon treatment of a tumor with suicide gene, direct cytotoxicity and tumor cell death occurs. This tumor killing releases large amounts of tumor antigens as well as other cellular proteins and debris. As has been demonstrated previously, this results in variable levels of immune activity in and of itself. The suicide gene therapy not only reduces the gross tumor burden, but also primes the local tumor immune environment for the beneficial effects of cytokine production. In addition, the actual suicide gene proteins themselves are believed to be immunogenic and may act as superantigens for both nonspecific and tumor-specific lymphocyte activation. By introducing high levels of local cytokine production using combined gene transfer techniques, this overall antitumor immune response may be greatly magnified.

Pioneering this area has been Chen and Woo et al. who investigated the effects of combination HSV-tk and IL-2 gene therapy for colorectal cancer liver metastases (57). Upon injecting the liver metastases with a combination of HSV-tk and IL-2, a significantly increased level of tumor regression was noted as compared with either HSV-tk or IL-2 alone. A long-term survival benefit was not seen. The combination treatment did generate an initial systemic immunity against a second challenge of wild-type tumor at a distant site. This response was tumor specific, but was not sustained. Immune studies revealed a predominantly CD8-positive T lymphocyte response. Interestingly, the treatment of the liver metastases with HSV-tk alone did not demonstrate a significant effect with respect to protection against a second- site tumor challenge. When applied to a head and neck orthotopic squamous cell carcinoma model, the combination of HSV-tk and IL-2 gene therapy demonstrated both a synergistic antitumor response and increased survival as compared with single gene therapy (58). The combination of HSV-tk and IL-2 in this head and neck cancer model also generated an immediate systemic immunity and protection against a second-site challenge of wild-type tumor (53). Immunohistochemical analyses local tumor environments revealed a predominance of CD8-positive T cell infiltration, but also CD4-positive T cells were identified.

Further investigations with the combination of HSV-tk, IL-2, and GM-CSF have demonstrated both enhanced tumor regression and animal survival. Also, this triple combination has shown that systemic immunity can be sustained as long-term protection against second wild-type tumor challenges could be generated (59). It is hypothesized that the addition of GM-CSF not only stimulates antigen presentation cells within the local tumor environment, but induces a long-term antitumor memory that is mediated by CD4-positive T cells (60) However, not all tumors respond to triple combination therapy, and there may inherent factors within the tumor type

or even the anatomical region of the body that influences such responses to the addition of GM-CSF (60a).

Given the low in vivo gene transfer efficiency of many viral vectors, certain strategies have been studied that may circumvent these limitations. VP22 is a protein normally produced by the HSV-1 virus and has a unique capability of achieving intercellular spread (60b). The VP22 protein is actively exported from the cytoplasm of cells producing the protein, and then it is subsequently transported across neighboring cell membranes where it is delivered to the cell nucleus. VP-22 fusion proteins and genes fused with VP22 (i.e., VP22-tk, VP22-p53, CD-VP22) are able to retain these intercellular transport properties (60c,60d). Wybranietz et al. demonstrated a significant benefit of adenovirus-mediated CD-VP22 fusion gene delivery vs. adenovirus CD suicide gene therapy alone in multiple tumor cell lines. Gene therapy strategies employing VP22 fusion proteins present new horizons for improving the efficiency and overall efficacy of suicide gene therapy strategies.

Another possibility for improved suicide gene therapy is to combine two powerful suicide genes into one delivery vehicle or viral vector. Various studies have investigated the potential for adenovirus-mediated HSV-Tk and CD double suicide gene therapy in both preclinical and clinical investigations (60e). Moriuchi et al. did not identify a benefit of HSV-TK and CD double suicide gene therapy with respect to killing of glioma tumor cells (insert reference Moriuchi S). A replication-defective adenovirus vector was used in these experiments. A number of investigators, however, have demonstrated in preclinical studies the benefit of double suicide gene therapy strategies in combination with radiation for various tumors cell lines (60f,60g). The application of double suicide gene therapy in human clinical trials are discussed at the end of the chapter.

VI. CLASSIC METHODS FOR SUICIDE GENE TRANSFER
