There are 2 classic areas of investigation regarding the application of suicide genes for the treatment of solid malignancies. The first area focuses on the development of suitable vehicles for introducing suicide genes into targeted tumor cells. The second area is the discovery and development of new suicide genes or gene combinations that will provide the greatest antitumor response while maintaining margins of safety. Regarding the area of gene transfer, 2 general classes of vehicles and transfer methods can be distinguished. *DNA-mediated gene transfer* involves the administration of DNA in the form of a circular double-stranded plasmid directly to the tumor. The vehicles for introducing therapeutic DNA into tumor cells are many. They include both mechanical methods and a more promising method that uses a wide variety of lipid or polymer formulations that are designed to maximize gene uptake and expression within the tumor cells. *Viral-mediated gene transfer* involves packaging a therapeutic gene into a replication-defective virus particle and using the natural process of viral infection to introduce the gene. The purpose of viral-mediated gene transfer is to exploit the efficient and often complex mechanisms that viruses have evolved to introduce their viral genes into human cells during infections. DNA-mediated transfer, while being less efficient than viral transfer, does not carry the risks of wild-type virus contamination and other known viral-associated toxicity. Furthermore, treatment limiting immune responses are more prevalent with the use of viral vectors, in general, than DNA transfer systems that may allow repeat gene delivery over a long period of time.

A. DNA-mediated Gene Transfer

DNA-mediated gene transfer is commonly called transfection. The therapeutic gene is typically contained within a circular molecule of DNA (plasmid), which contains various additional genetic elements required to achieve expression of the gene product. Important components to these plasmids are special promoters and enhancers that direct gene expression. There may also be other specific elements that have been engineered to direct the processing and persistence of genetic material within the cell.

There are many methods for delivering plasmid DNA into tumor cells, but only a few are clinically applicable at present. A classic means of introducing DNA into cells in vitro is through electroporation, where cultured cells are exposed to DNA in the presence of a strong electrical pulse (61). The electrical pulse creates pores in the tumor cell membrane, allowing entry of DNA into the cell. A recent technical advance using a similar principle has been the development of the ''gene gun.'' This mechanical device uses electrical currents and magnetic properties to project gold-coated DNA vectors into the tumor cells (62). At present, it is limited to cases where direct visualization and broad access to the tumor is possible.

It is possible to effectively introduce genes into muscle (63) or thyroid (64) simply by directly injecting DNA in saline solution into these tissues, whereupon the process of endocytosis enables cellular uptake. The use of saline as a gene transfer vehicle, however, is extremely inefficient for solid tumors and generally not applicable for cancer suicide gene therapy. The state of the art technology for DNA-mediated gene transfer into solid tumors is the use of liposomes or cationic lipid complexes. These lipid formulations are specifically designed to enhance DNA uptake and may be modified to provide higher levels of gene delivery to different histologic tumor cell types. (65). The use of lipid or liposome formulation gene transfer is becoming a major focus for clinically applied cancer gene therapy.

There are two limiting factors with respect to DNA-mediated gene transfer in general. First, the overall efficiency of gene transfer is low with in vivo expression levels of 1% to 3% at best even with cationic lipid or polymer formulations. Although suicide gene therapy strategies do not require gene transfer into all or even a majority of tumor cells for effective

killing, there is a correlation between levels of gene expression and antitumor effects. This correlation affects both the direct cytotoxicity and the bystander effect. In general, levels of transduction lower than 10% of the tumor population in vivo have very limited effects on either tumor regression or delay in tumor progression. The second limiting factor for DNA-mediated gene transfer is that the therapeutic gene usually resides or functions transiently in the targeted cell, regardless of the formulation. Subsequent to DNA-mediated gene transfer the therapeutic genes are degraded and eliminated from the tumor cell over a short period of time. This factor may be less important for suicide gene therapy as the targeted tumor cells are generally killed within days to a week after initiating prodrug administration. It is also possible to perform repeat dosing with DNA-mediated gene transfer. Sugaya et al. reported antitumor effects of 10 serial DNA-mediated HSV-tk treatments for colon adenocarcinoma with each injection providing only a maximal of 1% to 2% in vivo transduction efficiency (66).

Permanent incorporation of genes into cells occurs rarely after DNA-mediated gene transfer in cultured cells ($<1:10^5$ cells); however, this phenomenon has not been observed in vivo. Although the transient expression of the therapeutic gene may be a disadvantage in certain treatment schemes, there are also may advantages to this property. Because DNA vectors do no integrate into a host cells chromosomes (i.e., in the case of normal tissue surrounding a tumor cell), they do no carry the risk of permanent alteration of a normal tissues genome. The transient nature may also limit toxicity associated with any gene therapy system. The lack of significant immune responses against the DNA vector also allows repetitive administration of the therapeutic gene into persistent or recurrent tumors. The ability to perform repeat treatments may overcome the potential limiting aspect of transient gene expression.

B. Retrovirus-mediated Gene Transfer

The majority of suicide gene therapy preclinical and human trial research to date has centered on the use of viruses as gene delivery vehicles or vectors. The original prototypes for viral-mediated gene transfer are retroviral vectors derived from the Moloney murine leukemia virus (67,68). Retroviral vectors were chosen as vehicles because of several useful properties. First, ''defective'' virus particles can be constructed that contain therapeutic genes and are capable of infecting cells, but which contain no viral genes and express no pathogenic viral gene products. Second, retroviral vectors are capable of integrating the therapeutic genes they carry into the chromosomes of the target cell resulting in long-term gene expression. Third, modifications can be made in retroviral vectors and in the cell lines producing vectors, which result in enhanced safety features.

There are certain limitations to consider regarding the application of retroviruses in gene therapy for cancer. Retroviruses will only integrate into actively dividing cells. Because most tumors have heterogenous populations of dividing and nondividing cells, many tumor cells that are exposed to the retrovirus vehicle may never take up the therapeutic gene. Moreover, the currently achievable viral titers (10^7) are relatively low and the overall efficiency of retroviral infection of tumors in vivo is low. Because of this low level of in vivo transduction, the retrovirus must be delivered to the tumor via its murine or human packaging cell line. Also, serum complement can inactivate retroviruses that are produced from packaging cell lines that are not of human origin (69). Another important limitation is the variable receptivity of host cells to retroviral infection. Finally, under large-scale retrovirus production there is a risk of producing replication-competent viruses. These last 2 limitations are being addressed through modifications of the packaging cell lines (70,71).

C. Adenovirus-mediated Gene Transfer

A recent focus of gene therapy has been the development of adenovirus vectors as powerful and effective vehicles for gene transfer. Adenoviral vectors differ from retroviral vectors in that they do not integrate their genes into the target cell's chromosome. Compared with retroviral vectors, adenoviral vectors can be produced at much higher titers (10^{11} or greater) and can efficiently transduce a wide variety of both dividing and nondividing cells in vitro and in vivo (72). Hematopoietic cells are the only cells that have demonstrated significant resistance to adenovirus infection thus far. Effective therapeutic gene expression is transient after adenovirus gene transfer and typically lasts for 1 to several weeks. There are both advantages and disadvantages to this last characteristic. Although the safety of adenoviral vectors for gene therapy has not been studied as extensively as retroviral vectors, there is considerable experience with the use of attenuated adenovirus in animal models and in human subjects indicating a high margin of safety (73,74).

The disadvantages with the adenovirus system must be considered when designing and applying gene therapy strategies. Although the adenovirus vector is replication defective, it will express certain viral gene products or antigens that are capable of inducing an inflammatory response and subsequent lysis of the transduced cell (75). This inflammatory response could result in injury to normal surrounding tissues or even distant tissues that have been infected with the adenovirus vector. The generation of antibodies against the adenovirus vector may severely limit repeat adenovirus gene therapy treatments. Also, the transient level of gene expression may limit the desired therapeutic effect. As has been mentioned previously, transient gene expression may not be a significant disadvantage with a suicide gene therapy strategy. The potential disadvantages of transient gene expression and limiting inflammatory responses have been addressed with further manipulation of the adenovirus genetic backbone. New ''second-generation'' vectors, which remain for months in the target cell, express less viral proteins, and have greatly reduced inflammatory responses, are now available and under continued modification and development (76,77).

D. Other Viral Vectors

There exist other viruses that exhibit properties that may be useful to exploit for suicide gene therapy or other gene therapy strategies. The adeno-associated virus can provide a completely defective vector with the majority of the viral genome replaced by the therapeutic gene (78). As a result, this virus appears to generate less immune responses and has a longer period of therapeutic gene expression than the classic adenovirus vector. Unlike retrovirus, the adeno-associated virus integrates in a specific location on chromosome 19, thereby reducing the risk associated with randomly integrating vectors. Although a theoretical advantage, recombinant adeno-associated virus appears to have lost this predictable integration advantage (79). Another disadvantage of the adeno-associated virus is the requirement for wild-type ''helper virus'' in the vector production process. The ''safe'' recombinant vector must then be purified from the wild-type helper virus prior to amplification and in vivo application. Also, the viral titers are low for adeno-associated virus (10^4), in part because of the inefficient production process. Further investigation is required to define the role and safety of adeno-associated virus in clinical application.

The herpes simplex virus is capable of infecting cells and persisting indefinitely in a latent state. Vectors using the herpes virus have been constructed which are replication defective and capable of expressing recombinant genes for prolonged periods of time in animal models (80). These viruses are not completely defective and continue to express many viral proteins that can be cytopathic, a property that severely limits the herpes virus for present gene therapy applications.

Other viruses, including the human papilloma virus, vaccinia virus, avipox virus, and baclovirus, are under investigation for gene therapy application. The improvements and continued refinements of presently available viral vectors as well as the development of new vectors should greatly expand the efficacy and applicability of suicide gene therapy.

VII. GENERAL STRATEGIES FOR SUICIDE GENE THERAPY

Two basic strategies exist for cancer gene therapy. The first conceived strategy is ''ex vivo'' gene therapy in which a tumor or fibrous tissue biopsy is taken from a cancer patient whereupon individual tumor cells or fibroblasts are isolated and grown in vitro (Fig. 3). Therapeutic genes are then inserted into these cells typically using retroviral vector infection in tissue culture. The cells are subsequently irradiated and then reimplanted into the original tumor site or distant to the tumor site by autologous transplantation. The level of irradiation is controlled so as not to immediately kill the cells but to prevent growth and allow only a short period of survival after reimplantation. This strategy has been more commonly applied to classic cancer vaccine and cytokine gene therapy strategies. Although this approach is feasible with suicide gene therapy, the predominant tumor response would come from a metabolic cooperation or immune bystander effect subsequent to prodrug

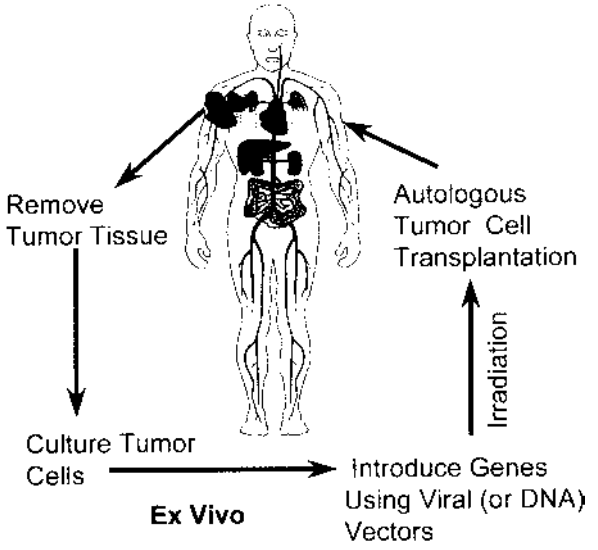

Figure 3 Diagram of the ''ex vivo'' strategy for suicide gene therapy.

administration and killing of the reimplanted transduced tumor cells. The inefficiency of such a system in general supports the predominant research and clinical focus on in vivo approaches for suicide gene therapy.

The second is basic strategy for cancer gene therapy is ''in vivo'' gene therapy where DNA, viral vectors alone, or packaging cell lines producing viral vectors are administered directly to a cancer patient (Fig. 4). The most common route of delivery is via direct injection of the delivery vehicle and gene or the packaging cell line into the tumor. Systemic injection is possible, but with present technology, results in limited exposure of the tumors to the vehicle. Tumors within tissues that have a large amount of blood flow or act as filters such as the lung or liver may prove more amenable to systemic delivery. As gene transfer technology continues to advance, the development of vehicles with tumor- or tissue-specific receptor uptake or promotor activity may allow for systemic administration of the DNA or viral vector carrying the suicide gene.

A. REPLICATION-COMPETENT VIRAL THERAPY: A FORM OF ''SUICIDE THERAPY''

Until very recently, viral vectors used in all gene therapy strategies were replication incompetent. Although this design was intended to introduce safety measures, it does not take advantage of the powerful ability of viruses to infect target cells and replicate and release viral particles, thereby killing target cells and spreading to surrounding target cells. Continued research and investigation in the fields of molecular biology and the genetics of cancer have led to a greater under-

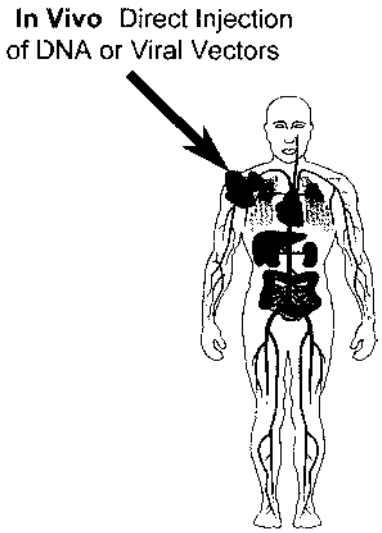

Figure 4 Diagram of the ''in vivo'' strategy for suicide gene therapy.

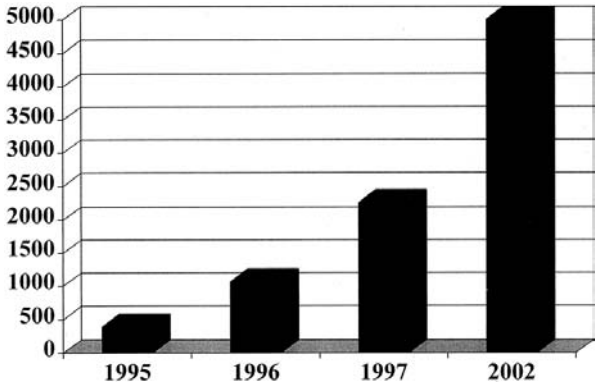

Figure 5 Trend for patient enrollment for human gene therapy trials.

standing of the principles of viral replication and the genetics of carcinogenesis. This greater understanding has allowed the development of replication-selective oncolytic viruses for use as novel anticancer therapies.

The first replication-selective viral vector to move from preclinical studies to human cancer clinical trials was the Onyx-015 adenovirus, also known as dl1520 (81,82). The key alteration that made this adenovirus replication selective was the deletion of the gene that codes for the p53-binding protein, E1B-55kDa. Typically, the adenovirus achieves replication in part through a process by which the E1B-55kDa protein binds a host cells p53, thereby allowing the cell to enter the S-phase of cell-cycle activity. The dl1520 adenovirus with its deletion of the E1B gene will not express the E1B-55kDa p53-binding protein upon infection of a target cell. The lack of E1B-55kDa expression will inhibit viral replication. However, in target cells that lack normal p53 expression, the dl1520 virus will maintain its ability to replicate, lyse a target cell, and spread to nearby cells. Because the majority of cancers have a loss of normal p53 function, cancer cells are the ideal target for a E1B-deleted replication-selective adenovirus therapy. There are many other evolving strategies for oncolytic viral vector therapy, and it is not the purpose of this chapter to discuss the present state of this novel therapy in detail. However, it is important to mention replication-selective oncolytic viral therapy because it may be thought of as a type of gene-dependent suicide therapy.

VIII. CLINICAL TRIAL SUMMARY FOR SUICIDE GENE THERAPY STRATEGIES

As of July 2002, there were 636 human gene therapy clinical trials that were either initiated or completed worldwide with an estimated patient enrollment of 5000 (83,84). A summary of the progression of patient enrollment is depicted in Fig. 5, and a breakdown of the trials by diseases in Fig. 6. Of these human clinical trials, approximately 505 have been or are being conducted in the United States with the next highest number of trials at 43 for the United Kingdom. Of these total human clinical trials, 403 are directed at cancer and 55 of these cancer trials are evaluating suicide gene therapy.

With respect to the vectors being used, Fig. 7 showns the distribution to date. The retrovirus remains the most commonly studied vector at approximately 34% of all trials. The adenovirus has advanced to a close second at 27% of all trials. The largest increase over the past 5 years has been in the strategy of nonviral gene delivery with approximately 23% of all trials focusing on this method. The distribution within nonviral trials is evenly split between lipid-mediated and naked plasmid-mediated gene transfer.

The ongoing or completed clinical trials for suicide gene therapy and cancer overall have provided a few important points for human gene therapy investigation. The first point is that retroviral, adenoviral, and DNA-mediated vectors are at present overall safe vehicles for gene transfer. Except for the

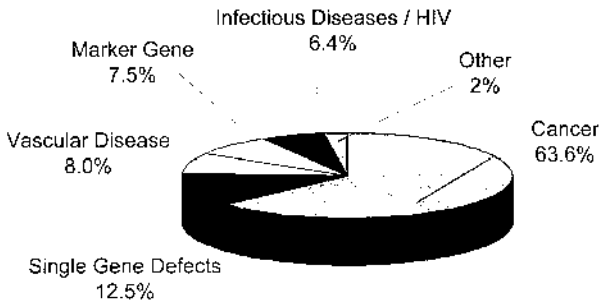

Figure 6 Distribution of human clinical trials by disease state.

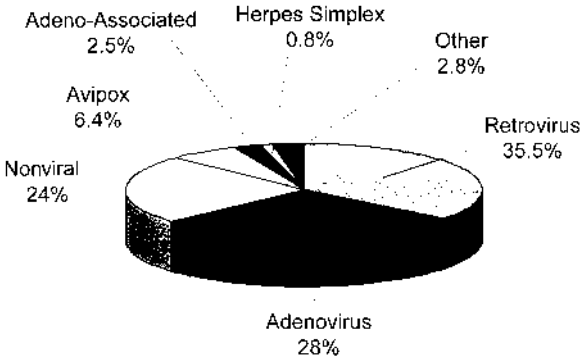

Figure 7 Distribution of vectors used in human clinical trials.

unfortunate death of a young man in 1999 who was enrolled in a gene therapy trial for congenital liver disease, there have been rare and limited side effects with the collection of vectors and genes under investigation (84,85). There have been no significant adverse events with nonviral or DNA-mediated gene transfer in human trials to date. The second important point is that gene transfer and expression in human cancer cells in vivo is possible with both viral and nonviral strategies. The last point is that tumor responses or reports of regression must be interpreted cautiously because the majority of trials remain in phase I or phase I/II and have limited controls for measuring outcomes. Fig. 8 depicts the breakdown of trials with respect to the phase.

At this early stage of human clinical trial investigation, the studies have focused on patients with advanced or incurable cancer. Although this patient population is a standard choice for establishing the safety of novel therapies, the greatest chance of eventual success with presently available suicide gene therapy strategies may be found in patients with less advanced disease. Another important potential for suicide gene therapy is in combination with immune therapies or standard therapy such as with surgery or radiation. As advancements in both preclinical development and clinical application continue, suicide gene therapy should achieve a role in the treatment of cancer.

I. INTRODUCTION

A. The Use and Choice of Selectable Markers

One of the major problems with current approaches to gene therapy is the instability of expression of genes transferred into recipient cells. Although in theory, homologous recombination or use of artificial chromosomes can stabilize sequences with wild-type regulatory regions, such approaches to gene therapy are not yet feasible and may not be efficient for some time to come. In most high efficiency DNA transfer in current use in intact organisms, selectable markers must be used to maintain transferred sequences; in the absence of selection the transferred DNAs or their expression is rapidly lost.

There are several different selectable markers that might be used for in vivo selection, including genes whose expression has been associated with resistance of cancers to anticancer drugs. Examples include: (a) methotrexate resistance due to mutant dihydrofolate reductase [DHFR] (1); (b) alkylating agent resistance due to expression of methylguanine methyltransferase [MGMT] (2); and (c) the expression of the multidrug transporting proteins P-glycoprotein (P-gp, the product of the *MDR*1 gene) (3) and MRP (multidrug resistance associated protein) (4). In this chapter, we will detail our experience with the *MDR*1 gene.

The resistance of many cancers to anticancer drugs is due, in many cases, to the overexpression of several different ATP-dependent transporters (ABC transporters), including the human multidrug resistance gene *MDR*1 (ABC B1) (3,5,6), MRP1 (ABC C1), the multidrug resistance-associated protein (7) and other MRP family members (8), and *MXR* (ABC G2) (9). *MDR*1 encodes the multidrug transporter, or P-glycoprotein (P-gp). P-gp is a 12 transmembrane domain glycoprotein composed of 2 homologous halves, each containing 6 transmembrane (TM) domains and one ATP binding/utilization site. P-gp recognizes a large number of structurally unrelated hydrophobic and amphipathic molecules, including many chemotherapeutic agents, and removes them from the cell via an ATP-dependent transport process (see Fig. 1).

MDR1 has many obvious advantages for use as a selectable marker in gene therapy. It is a cell surface protein that can be easily detected by FACS or immunohistochemistry. Cells expressing P-gp on their surfaces can be enriched using cell sorting or magnetic bead panning technologies. The very broad range of cytotoxic substrates recognized by P-gp makes it a pharmacologically flexible system, allowing the investigator to choose among many different selection regimens with differential toxicity for different tissues and different pharmacokinetic properties. Furthermore, as will be discussed in detail in this chapter, P-gp can be mutationally modified to increase resistance to specific substrates and alter inhibitor sensitivity. Hematopoietic cells initially appeared to tolerate relatively high levels of P-gp expression without major effects on differentiated function (10).

B. Lessons from Transgenic and Knockout Mice

Two lines of evidence support the concept of using *MDR*1 as a selectable marker in human gene therapy. Transgenic mice

expressing the *MDR*1 gene in their bone marrow are resistant to the cytotoxic effects of many different anticancer drugs (10–12). *MDR*1 transgenic bone marrow can be transplanted into drug sensitive mice, and the transplanted marrow is resistant to cytotoxic drugs (13). Mice transplanted with bone marrow transduced with the human *MDR*1 cDNA and exposed to taxol show specific enrichment of the *MDR*1-transduced cells (14–16), and this transduced marrow can be serially transplanted and remains drug resistant (16). Recently, this ability to select transduced bone marrow with taxol has been demonstrated in a canine bone marrow transplantation model (17).

The mouse *mdr*1a and *mdr*1b genes have been insertionally inactivated in mice (18–21). These animals, although otherwise normal, are hypersensitive to cytotoxic substrates of P-gp. This hypersensitivity is due in part to the abrogation of the *mdr*1a-based blood brain barrier (22), and to enhanced absorption and decreased excretion of *mdr*1 substrates (23). These studies demonstrate the critical role that P-gp plays in drug distribution and pharmacokinetics, and argue that specific targeting of P-gp to tissues that do not ordinarily express it (as in gene therapy), will protect such tissues from cytotoxic *mdr*1 substrates.

II. SELECTABLE MARKERS IN HEMATOPOIETIC SYSTEMS AND IN THE SKIN

As noted above, studies on mice transgenic for human *MDR*1 established that constitutive overexpression of this gene protects animals from antineoplastic agents. Drugs could be administered safely at dose-levels several-fold higher than to mice of the respective background strains (10,11). To demonstrate the specificity of this protection, verapamil, an inhibitor of P-glycoprotein, was coadministered, resulting in reversal of drug resistance (12). Similarly, mice transgenic for a mutated dihydrofolate reductase (DHFR) or an O^6-methylguanine DNA methyltransferase cDNA were protected from methotrexate or 1,3-bis (2-chloroethyl) nitrosourea (BCNU) toxicity, respectively (26–24).

Upon overexpression in target cells, drug resistance genes may also protect them from environmental toxins such as carcinogens in addition to amelioration of anticancer chemotherapy (27). For instance, transfer of O^6-methylguanine methyltransferase increases repair of DNA damage in sensitive cells. In vitro and in vivo studies confirmed this aspect of the function of drug resistance genes (28–29). Liu et al. (30) showed that rapid repair of O^6-methylguanine-DNA adducts in transgenic mice protected them from N-methyl-nitrosourea-induced thymic lymphomas. This protection from carcinogens can be targeted to other organs like liver or skin by suitable promoter systems (31,32).

Chemoprotection exerted by overexpression of chemoresistance genes in hematopoietic organs of transgenic animals could be transferred by transplantation of bone marrow to normal recipients (13,33). These experiments provided a basis for gene therapy approaches with drug resistance genes. Hence, drug resistance genes that were initially studied because of their association with failure of anticancer chemotherapy are expected to serve as useful tools for gene therapy of cancer by protecting patients from the toxic side effects of chemotherapy. Protection of chemosensitive cells from toxic compounds may be particularly helpful in the case of the hematopoietic system because most cells in blood and bone marrow are highly susceptible to antineoplastic compounds. $CD34^+$ hematopoietic progenitor cells do not express glutathione-S-transferases (34), and only very low levels of the endogenous *MDR*1 gene are expressed in myeloid and erythroid progenitor cells (35,36). These low expression levels are not capable of providing protection from the cytotoxicity of anticancer drugs. Conversely, the high susceptibility of normal hematopoietic cells to cytotoxic agents allows selection strategies exploiting drug resistance genes if sufficient levels of resistance can be conferred.

A variety of different genes have been used to confer drug resistance on bone marrow cells (see Table 1). Retroviral transduction with a full-length *MDR*1 cDNA promoted by Long-Terminal Repeats (LTRs) of Harvey sarcoma virus protected normal, clonogenic hematopoietic precursors or erythroleukemia cells from anticancer drugs (37,38). Transduced cells were found to be resistant to multiple drugs including taxol, colchicine, and daunomycin. Murine hematopoietic stem cells originating from fetal liver (39), peripheral blood following mobilization with the use of growth factors (40), or from bone marrow (41), were efficiently transduced with retroviral *MDR*1 vectors. In the latter study, it was shown that transplantation of transduced hematopoietic stem cells results in efficient expression of functional human P-glycoprotein in recipient mice. In spite of generally lower transduction frequencies, $CD34^+$ human progenitor cells could also be transduced with retroviruses conveying the multidrug resistance gene (42,43). Similarly, vectors containing MRP1 (44) or mutated DHFR cDNAs are highly efficient in rendering bone marrow cells resistant to methotrexate or trimetrexate, respectively (45,46).

Pluripotent human hematopoietic stem cells or early progenitors, respectively, are difficult to transduce with amphotropic retroviruses (47). Fruehauf et al. (48) targeted immature, cobblestone area-forming progenitor cells. However, in this study significant vincristine resistance was achieved only in a small minority of the immature cell population. This might be due to endogenously high *MDR*1 expression in hematopoietic stem cells (49), which can make it difficult to analyze the function of the transgene. DHFR might be a better marker for selection at the level of long-term culture-initiating cells (50).

Transplantation of *MDR*1-transduced murine bone marrow cells into W/W^v mice (14) or lethally irradiated normal syngeneic mice (15) resulted in significant gene expression in the bone marrow of recipient animals. Both investigators detected elevated levels of *MDR*1 expression after treatment of recipient mice with taxol, favoring the idea of a selective advantage in vivo of hematopoietic cells overexpressing the *MDR*1 transgene. This observation was in marked contrast to previous studies with selectable markers such as genes conferring resistance to neomycin, puromycin, or hygromycin. Because of their pharmacology or pharmacokinetics such compounds cannot be used for selection in vivo.

Further support for the potential usefulness of drug resistance genes for selection in vivo was provided by experiments in which *MDR*1-transduced bone marrow was first transplanted into recipient mice (16). After taxol treatment of recipient mice, their bone marrow was then retransplanted into a second generation of recipient mice. In several cycles of retransplantation and taxol treatment of recipient animals, increasingly high levels of drug resistance were generated in vivo. Mice of the fifth and sixth generation survived doses of taxol that were lethal for mice that had not undergone bone marrow transplantation.

Bunting et al. (51) reported that transduction of murine bone marrow cells with a pHaMDR1 retroviral vector enables *ex vivo* stem cell expansion, which might help account for the ability of transduced cells to survive multiple cycles of transplantation. However, the biological safety of expansion of transduced stem cells is currently under scrutiny. When *MDR*1-transduced progenitor cells are expanded with growth factors for extended periods (up to 12 days), uncontrolled proliferation occurs, as has been observed in one study (51). The authors concluded that the finding was related to the *MDR*1 transgene because the development of a myeloproliferative syndrome was not observed following transfer of DHFR. Other groups have not observed this adverse effect after *MDR*1 transfer to murine hematopoietic cells. More importantly, comparable studies in nonhuman primates did not reveal perturbations of myelopoiesis (52). It appears possible that these differences are related to the recent finding that the integration sites of retroviral vectors reveal predilections for certain chromosomes and are not randomly distributed in the genome of bone marrow repopulating cells (53).

These concerns have prompted recent investigations with vector systems other than retroviruses. For instance, SV40 pseudovirions allow for highly efficient *MDR*1 gene transfer to hematopoietic cells (54,55). Alternatively, Epstein-Barr virus-based vectors can be designed that contain the *MDR*1 cDNA episomally in target cells (56). With such vector sys-

O^6-methylguanine methyltransferase (O^6-MGMT)	Nitrosourea (BCNU)	Allay et al., 1995 (78)

tems life-long expression cannot be achieved because they fail to integrate into the genome. Conversely, for protection of hematopoietic cells during a series of chemotherapy cycles, sustained expression may not be required. Loss of *MDR*1 expression after the period of chemotherapy might in fact increase the safety of *MDR*1 gene therapy.

With the use of retroviral vectors, functional drug resistance of hematopoietic progenitor cells transduced by *MDR*1 vectors was first demonstrated in tissue culture (37) and recently in mice transplanted with transduced human progenitor cells (57). As a result, recipient animals can be treated safely with intensified chemotherapy following reinfusion of *MDR*1-transduced cells (58).

The efficiency of chemoprotection during antineoplastic chemotherapy is questionable if the cancers themselves express high amounts of P-glycoprotein. To further enhance the efficiency of this approach a vector has been designed that contains a mutant *MDR*1 cDNA (59). A point mutation in amino acid position 938 by which phenylalanine is replaced by alanine has little effect on the substrate specificity of P-glycoprotein but abolishes the reversing effect of a chemosensitizing agent, trans(E)-flupenthixol (60). Such vectors can be useful to overcome multidrug resistance in cancer cells, which are protected by wild-type P-glycoprotein, whereas hematopoietic cells are protected by the mutant gene even in the presence of anticancer drug and chemosensitizer.

Treatment of *MDR*1-transduced hematopoietic cells with anticancer drugs in tissue culture increases expression of *MDR*1 mRNA and P-glycoprotein in the surviving cell population as a result of clonal selection (61). Moreover, *MDR*1 transduced hematopoietic cells exposed to high concentrations of anthracyclines or colchicine prior to transplantation maintain their ability to engraft and rescue recipient mice from otherwise lethal irradiation (62). These animal studies provide useful models for the optimization of conditions for clinical applications.

Several of the drug resistance genes have been used to protect hematopoietic cells from drugs used in anticancer treatment. As has been seen with *MDR*1, chemoprotection of hematopoietic progenitor cells and a selective advantage in vitro were demonstrated following transduction by mutated DHFR cDNAs that confer resistance to methotrexate and trimetrexate (1,63–66). Williams et al. (67), Cline et al. (68), and Vinh et al. (69) demonstrated protection of recipient animals from lethal doses of methotrexate. Human $CD34^+$ cells can be transduced efficiently with a DHFR vector (1).

Mice transplanted with DHFR-transduced hematopoietic cells display resistance against high levels of trimetrexate, which can be transferred to a second generation of transplant recipients (70). Interestingly, mice can be transplanted with low amounts of DHFR-transduced cells following mild total body irradiation at a reduced dose of 1 Gy and acquire methotrexate resistance by treatment with this drug for 60 days following transplantation (71). Retransplantation experiments performed with dihydrofolate reductase (72) gave results comparable to those obtained with *MDR*1 (16); both genes facilitate increased levels of resistance after several cycles of transplantation and drug treatment of recipient animals.

In vivo selection of retrovirally transduced hematopoietic cells has convincingly been demonstrated with the DHFR as a selectable marker (73). In this study mice were transplanted with DHFR-transduced bone marrow cells. Drug treatment resulted in significantly increased expression in granulocytes, erythrocytes, platelets, and T- and B-lymphocytes. Secondary recipients revealed that selection had occurred at the stem cell level.

Resistance to another antimetabolite drug, cytosine arabinoside, which is a major component of treatment for acute leukemias, is conferred by cytidine deaminase. Hematopoietic cells were rendered resistant to cytosine arabinoside by transfer of this gene (74).

Different patterns of chemoresistance can be attributed to various drug resistance genes. For instance, the *MRP*1 gene is genetically and functionally related to *MDR*1. Retroviral transfer of *MRP*1 resulted in resistance to doxorubicin, etoposide, and vincristine (4). However, since binding and transport of inhibitors to *MDR*1 may be different from *MRP*, transfer of this gene may be useful if naturally occurring resistance due to *MDR*1 overexpression in cancer cells has to be overcome to allow for effective chemotherapy of an *MDR*1-expressing cancer.

Resistance to alkylating agents is multicausative, and several genes may be useful as selectable markers. Retroviral transfer of a rat glutathione S-transferase Yc cDNA to hematopoietic cells conveyed moderate resistance to melphalan, mechlorethamine, and chlorambucil (75). Resistance to cyclophosphamide or 4-hydroperoxycyclophosphamide, respectively, could be conferred on hematopoietic cells by transfer of aldehyde dehydrogenase with the use of retroviral vectors (76,77). Leukemic or primary hematopoietic cells were rendered resistant to BCNU by retroviral transfer of a human O^6-alkylguanine-DNA alkyltransferase cDNA (2,78,79). Transplantation of transduced bone marrow cells rescued recipient animals from the toxicity of nitrosoureas (80). In particular, nitrosourea-induced severe immunodeficiency can be overcome by transduction of immature progenitor cells (80,81). Furthermore, resistance to nitrosoureas in combination with an inhibitor of O^6-alkylguanine-DNA alkyltransferase, a key enzyme involved in naturally occurring resistance to nitrosoureas, could be conferred by retroviral transfer of a mutated O^6-methylguanine DNA methyltransferase cDNA (26). This approach protected mice from lethal drug doses and allowed selection of transduced hematopoietic progenitor cells.

To widen the range of anticancer drugs to be inactivated by gene therapy, vectors have been constructed for coexpression of two different drug resistance genes. For instance, a vector containing *MDR*1 and O^6-alkylguanine-DNA-alkyltransferase rendered human erythroleukemia cells resistant to the MDR1 substrates, colchicine and doxorubicin, as well as to alkylating agents, N-methyl-N-nitrosourea and temozolomide (82).

A different approach to utilize vectors that allow for coexpression of two genes is to include a second gene that may

enhance the efficacy of a selectable marker gene. This has been shown by construction of a vector that contained an MRP1cDNA and a cDNA encoding γ-glutamyl-cysteine synthetase, the rate-limiting enzyme of glutathione biosynthesis (83). Resistance to substrates of MRP1 was thereby increased due to elevated glutathione levels in transduced cells. The MRP1 transporter extrudes glutathione-conjugated compounds from the cell; hence, elevated concentrations of glutathione increase the transport of potential substrates.

Based on experiments in tissue culture and animal models, early clinical trials on transfer of the *MDR*1 gene to hematopoietic progenitor cells have been conducted (84–86). Bone marrow or peripheral blood progenitor cells from patients suffering from advanced neoplastic diseases were retrovirally transduced and reinfused after high-dose chemotherapy (87–89). These studies revealed that transduction efficiencies using *MDR*1 vectors as detected in bone marrow or peripheral blood of patients tended to be low, and varied from one patient to another. Notably, in two recent studies enrichment of *MDR*1-transduced cells was observed following treatment with etoposide or paclitaxel, respectively (90,91). The studies confirm the concept that the human multidrug resistance gene can serve as a drug-selectable marker gene in vivo in the hematopoietic system. However, gene transfer procedures and selection strategies need to be improved to efficiently protect human hematopoietic cells from the cytotoxicity of drug treatment. In particular, clinical studies should be conducted with novel vector constructs and improved culture conditions that allow for increased transduction rates.

Improvements in vector design have been suggested by several groups. Using the multidrug resistance gene, Metz et al. (92) showed that retroviral vectors derived from Harvey viruses can be substantially shortened without reduction of gene transfer efficiency, thereby increasing the maximum size of the packaged gene of interest. By systematic analysis of the U3-region of various 5′-long-terminal repeats, Baum et al. (93) optimized *MDR*1 transfer to hematopoietic cells. Notably, transfer to immature hematopoietic progenitor cells, which are generally difficult to transduce, was improved (94). More recent improvements of posttranscriptional processing led to a vector that reliably ensured *MDR*1 expression and drug efflux in human hematopoietic cells following an in vivo passage in immunodeficient mice (95). Other vector systems used for chemoresistance gene transfer to hematopoietic cells include adeno-associated virus vectors (96) or liposomes (97) (see Sections IV and V.).

New vector constructs increase the efficiency of gene transfer to hematopoietic cells but do not necessarily ensure gene expression for sustained periods. A major obstacle to long-term gene expression is the limited lifespan of some transduced cell clones. Since only hematopoietic stem cells have the capability of self-renewal, the lifespan of progeny generated by more differentiated progenitor cells is limited. Berger et al. (98) have shown that expansion of cells with cytokines, particularly with interleukin-3 (IL-3), reduces the frequency of long-term culture-initiating cells (LTC-IC), which correlated with reduction of Rhodamine-123 efflux from immature progenitor cells. In accord with these findings, Schiedlmeier et al. (99) reported that IL-3-stimulated hematopoietic cells engrafted more poorly than cells grown in the presence of other growth factor combinations. Both studies resulted in efficient retroviral *MDR*1 transfer to primitive human progenitor/stem cells.

A different approach to improve the utility of selectable markers is to coexpress two drug resistance genes, thereby conferring resistance to a broad range of cytotoxic agents. To this end, mutated dihydrofolate reductase has been coexpressed with *MDR*1 or with thymidylate synthase (100,101), and *MDR*1 has also been expressed with O^6-methylguanine-DNA-methyltransferase (102,103). Coexpression of glutathione S-transferase and cytidine deaminase rendered cells resistant to cytosine arabinoside and alkylating agents such as melphalan and chlorambucil (104). These compounds are used in chemotherapy of malignant lymphomas.

Alternatively, a dominant-positive selectable marker gene can be coexpressed with a negative selectable marker such as thymidine kinase from Herpes simplex virus (HSV-TK) (105,106). The latter approach allows selective elimination of transduced cells. Such an approach may increase the safety of gene transfer if cancer cells contaminating hematopoietic cell preparations are inadvertently rendered drug-resistant, or if transduced cells become malignant (51,107). Selective killing of *MDR*1-HSV-TK transduced cells in vivo has been demonstrated (106). Thymidine kinase may not only facilitate selective killing of cancer cells but instead increase the efficacy of certain selectable marker genes. A bicistronic vector in which thymidine kinase was combined with dihydrofolate reductase displayed enhanced resistance as compared to a construct that contained a neomycin phosphotransferase instead of thymidine kinase (108). The authors concluded that thymidine kinase may be useful to salvage thymidine.

To increase the safety of gene therapy of cancer, drug resistance genes may be combined with cDNAs that specifically eliminate cancer cells. This has been demonstrated for chronic myeloid leukemia (CML), which is characterized by a specific molecular marker, the BCR/ABL gene fusion. A vector has been constructed that combined a methotrexate-resistant dihydrofolate reductase with an antiBCR/ABL antisense sequence (109). Transfer of this vector to CML cells led to the restoration of normal cellular function of BCR/ABL cDNA+ cells due to reduced levels of transcripts while conferring drug resistance.

In addition to improvement of gene therapy of cancer, drug resistance genes may be helpful for gene therapy of nonmalignant diseases if increased gene expression is desired. In fact, there is considerable interest in using drug selectable marker genes to introduce and enrich otherwise nonselectable genes in target organs. Gene therapy, although thought to bear the potential of curing genetically determined diseases, is frequently hampered by low gene expression in target organs. This is particularly true for hematopoietic disorders because the efficiency of gene transfer is often limited, and stable expression of transgenes in bone marrow has been found difficult to accomplish.

For instance, Gaucher disease is characterized by accumulation of a glucosylceramide in glucocerebrosidase-deficient hematopoietic cells. These patients suffer from skeletal lesions, severe hepatosplenomegaly, anemia, and disorders of the central nervous system. While it is possible to efficiently transduce a glucocerebrosidase cDNA to hematopoietic progenitor cells (110,111), expression levels tend to decrease after several weeks or months in vivo because of silencing or limited lifespan of the transduced cells' progeny. To increase expression of glucocerebrosidase in vivo, Aran et al. (112) constructed a transcriptional fusion between *MDR*1 and the glucocerebrosidase gene. Increased expression of the latter gene was achieved by selection with cytotoxic substrates of P-glycoprotein. Appropriate selection strategies allowed complete restoration of the underlying genetic defect in cells from Gaucher patients (113). Transduction of such bicistronic vectors into hematopoietic stem cells might allow treatment of patients by chemotherapeutical elimination of non-transduced cells that continue to synthesize or store glucosylceramide. Moreover, following chemotherapy, the numbers of genetically corrected hematopoietic progenitor cells should increase in bone marrow to maintain physiological numbers of mature granulocytes, monocytes, and lymphocytes in peripheral blood. Recently, in vivo selection for cells expressing glucocerebrosidase was demonstrated with a vector containing the selectable marker gene, DHFR (114).

Similarly, bicistronic vectors that facilitate coexpression of *MDR*1 and α–galactosidase A have been engineered (115). Defects of α–galactosidase A are the cause of Fabry disease, a globotriaosylceramide storage disorder that affects the skin, kidneys, heart, and nervous system. Other applications for bicistronic fusions include immunological disorders such as chronic granulomatous disease and X-linked or adenosine deaminase (ADA) deficiency-related severe combined immunodeficiency (SCID) syndromes. For treatment of these diseases, vectors have been constructed that contain a gp91phox or an ADA cDNA (116–119). DHFR was used as a selectable marker gene in a bicistronic vector for correction of α_1-antitrypsin deficiency (120). Further discussion of the use of bicistronic vectors is found in Section III.

A different strategy to exploit the *MDR*1 gene as a drug-selectable marker for correction of ADA deficiency was described by Germann et al. (121). In this study, both genes were fused to a single cDNA encoding a bifunctional chimeric protein. This approach, however, cannot be used if the two proteins are physiologically located in different cellular compartments.

Another system in which selectable markers may be useful is in the skin. It is possible to grow keratinocytes in culture and introduce the *MDR*1 gene via retroviral vectors. Such keratinocytes are resistant to MDR drugs in vitro, and when transplanted on keratinocyte ''rafts'' to recipient animals, they remain resistant to colchicine, which can be applied as an ointment. If colchicine is withdrawn, transplanted keratinocytes are gradually replaced by nontransduced host skin; in the presence of selection, the transplanted keratinocyte graft is maintained. It should be possible in such a system to introduce other nonselectable genes via bicistronic vectors to serve as a source of protein to treat a genetic defect in the skin or elsewhere in the host (122).

While MDR vectors are well characterized in vitro, their usefulness in vivo has still to be established. We have recently demonstrated in a large-animal model that expression of a nonselectable gene that had been undetectable for more than one year can be recovered by coexpression with a drug-selectable marker, *MDR*1 (17). In this study, high levels of the nonselectable, therapeutic gene were achieved in peripheral blood and bone marrow following treatment of the animal with paclitaxel. The toxicity of this treatment, however, was considerable. Thus, further investigations in animal models are needed to optimize selection strategies in live animals.

Detection of the function of transferred genes may be difficult if normal animals are utilized because of the activity of the respective endogenous gene product. To circumvent this difficulty, ''knock-out'' animals whose gene has been inactivated by targeted disruption can serve as useful models. For instance, mice whose α–galactosidase gene has been disrupted may be helpful to characterize a bicistronic vector in which *MDR*1 is combined with the respective human gene for correction of Fabry disease (123). Another alternative is to use marking genes that are not physiologically expressed at high levels in normal tissues. To characterize bicistronic vectors containing *MDR*1, this gene has been coexpressed with a green fluorescent protein or β–galactosidase (124).

These model systems should help to improve protocols for efficient drug selection and to identify strategies for selection at limited systemic toxicity. For instance, addition of P-glycoprotein inhibitors at low concentration to cytotoxic drugs may increase the stringency of drug selection, thereby allowing use of anticancer drugs at low concentrations for selection (113).

III. BICISTRONIC VECTORS CONTAINING SELECTABLE MARKERS

Although coexpression of two proteins can be achieved through the use of separate promoters, the coexpression is frequently uncoupled due to promoter interference or shutoff of gene expression from one of the promoters, which causes the selected cells not to express the desired protein. To overcome this problem, the selectable marker may be expressed with the therapeutic gene as a translational or transcriptional fusion. A therapeutic protein can be directly linked to the carboxylterminus of the multidrug transporter P-glycoprotein (P-gp). The resulting fusion protein possesses functions of both P-gp and the target protein (125). Since P-gp is an integral membrane protein that functions on the cell plasma membrane, unless two proteins can be separated by a posttranslational proteolytic modification, the expressed target protein will be associated with the plasma membrane regardless of its normal cellular location. Thus, even though translational fusions guarantee protein coexpression, their potential is limited. On the other hand, transcriptional fusions, e.g., using

bicistronic or polycistronic mRNA to encode more than one cDNA, may prove to be more generally applicable.

A. *MDR*1 Bicistronic Vectors Containing Internal Ribosome Entry Sites (IRES)

A DNA segment corresponding to one polypeptide chain plus the translational start and stop signals for protein synthesis can be loosely defined as a cistron. An mRNA encoding only a single polypeptide is called monocistronic mRNA; if it encodes two or more polypeptide chains, it may be called bicistronic or polycistronic mRNA. Almost all eukaryotic mRNA molecules are monocistronic. Initiation of translation of eukaryotic mRNA is mediated by cap-binding protein that recognizes a methylated guanosine cap at the 5′ terminus of mRNA. However, some viral mRNA molecules transcribed in eukaryotic cells are polycistronic. They can use a cap-independent mechanism to initiate translation in the middle of mRNA molecules. For picornavirus, this cap-independent internal initiation of translation is mediated through a unique internal ribosome entry site (IRES) within the mRNA molecule (126,127).

Identification of IRES sequences has led to the development of bicistronic vectors that allow coexpression of two different polypeptides from a single mRNA molecule in eukaryotic cells (128,129). Using a bicistronic vector containing an IRES to coexpress a target gene and a selectable marker has several advantages. First, since two polypeptides are translated from the same mRNA molecule, the bicistronic vector guarantees coexpression of a selectable marker and a second protein. Secondly, bicistronic mRNA allows two polypeptides to be translated separately. Thus, this system does not compromise the correct intracellular trafficking of proteins directed to different subcellular compartments. In addition, using a bicistronic vector, expression of a target gene is proportionate to the expression of a selectable marker. Hence, expression of a target protein can be achieved quantitatively by applying selections of different stringencies.

To demonstrate coexpression of a dominant selectable marker with a therapeutic gene using a bicistronic vector, our laboratory has coexpressed P-gp with glucocerebrosidase (112,113), β-galactosidase (115), adenosine deaminase (118), a subunit of the NAPH oxidase complex (116,117), the shared gamma chain of the interleukin receptors (119), and a hammerhead ribozyme targeted to the U5 region of HIV-1 LTR (130). In those experiments, *MDR*1 served as a selectable marker linked to the target gene by an IRES from encephalomyocarditis virus (EMCV) and constructed in a retroviral vector containing Harvey sarcoma virus LTR (131). Two configurations, in which *MDR*1 is placed either before or after the IRES, have been examined in some cases. As demonstrated in those experiments, P-gp and the target gene are coexpressed in the cells selected using cytotoxic P-gp substrates, such as colchicine or vincristine; the expressed target proteins are functional as detected using in vitro, or ex vivo analysis. In one case, using subcellular fractionation, we have demonstrated that P-gp and glucocerebrosidase are translocated separately to the cell plasma membrane and lysosomes, indicating correct intracellular protein trafficking (112). The demonstration that a noncoding RNA, such as a hammerhead ribozyme, can function even though tethered to an mRNA encoding a functional *MDR*1 provides an additional powerful way to use bicistronic vectors (130).

Another approach to the use of *MDR*1-based bicistronic vectors is to develop ''suicide'' vectors for cancer gene therapy. Using *MDR*1 to protect bone marrow cells from cytotoxic drugs represents a promising approach to improve cancer chemotherapy. However, contaminating cancer cells may be inadvertently transduced with *MDR*1, or transduced bone marrow cells may accidentally develop new tumors. In those cases, overexpression of P-gp could cause multidrug resistance in inadvertently transduced tumor cells that contaminate bone marrow, or in any transduced cells that later become malignant. A bicistronic ''suicide'' vector developed in this laboratory links P-gp expression with herpes simplex virus thymidine kinase (TK) expression (105,106). Thus the cells containing this vector can be eliminated through ganciclovir treatment.

A third approach is to link two drug resistance genes together using a bicistronic vector system to extend the ability of the vector to confer drug resistance. Examples include the use of *MDR*1 with dihydrofolate reductase that confers methotrexate resistance (132), *MDR*1 plus methylguanine methyltransferase (MGMT) that confers resistance to certain alkylating agents (102,103,133), and *MRP*1 plus gamma-glutamylcysteine synthetase that confers resistance to alkylating agents as well (83).

Finally, bicistronic vectors can be used to introduce marker genes into selected cells. For example, *MDR*1 vectors containing green fluorescent protein or β-galactosidase have been constructed to determine the efficiency of expression of the target gene in transduced and *MDR*1 selected cells (124).

B. Efficiency of IRES-dependent Translation

Using an IRES to generate a bicistronic mRNA ensures coexpression of two different proteins. However, IRES-dependent mRNA translation (or cap-independent translation) is less efficient than cap-dependent translation, so that the two proteins are not expressed in equal amounts. It has been shown that in a monocistronic vector, insertion of an IRES upstream from an open reading frame of either P-gp or dihydrofolate reductase (DHFR) reduces the translation efficiency by 2- to 10-fold (129,134). Using a bicistronic vector, expression of *neo* in the position downstream from the IRES is 25% to 50% of that observed when *neo* is in the upstream position (128). The asymmetric expression pattern of the bicistronic vector results in a significant difference in *MDR*1 transducing titer between a configuration with P-gp placed before the IRES and a configuration in which P-gp is placed after the IRES. We have found that the apparent titer of a bicistronic vector containing *ADA-IRES-MDR*1 was only 7% of the titer of a bicistronic vector containing *MDR*1*-IRES-ADA* (118). Similar reductions in *MDR*1 transducing titer and in expression of

the nonselected downstream gene was seen with *MDR*1-β-galactosidase bicistronic vectors too (115). The apparent *MDR*1 transducing titer of the retrovirus is based on the drug resistance conferred by expression of P-gp as the result of retroviral infection; thus the viral titer is proportional to the P-gp expression level. Insufficient expression of P-gp is unable to protect the cells from cytotoxic drug selection. To achieve P-gp expression at the same level, the lower efficiency of translation would have to be compensated for by a higher level of transcription, which can occur only in a minority of the cells in the transduced population. This may account for the apparent lower *MDR*1-transducing titer of bicistronic vectors with a configuration of P-gp placed after the IRES. On the other hand, when cells express P-gp at the same level (i.e., the cells survived vincristine or colchicine selection at the same concentration), ADA expressed from *ADA-IRES-MDR*1 is 15-fold higher than the ADA expressed from *MDR*1-*IRES-ADA*. This difference is probably due to a combination of the lower translation efficiency of ADA located downstream from the IRES and the high transcription level of *ADA-IRES-MDR*1 as the result of vincristine selection. A similar asymmetric expression of P-gp and human β−galactosidase A is also observed in NIH3T3 cells, where the difference is about 8-fold.

IRES-dependent translation is a complex process, in which mRNA containing IRES interacts with various cellular proteins, including IRES transacting factors [reviewed in Hellen and Sarnow (135)]. The efficiency of IRES-dependent translation can be affected by the cell type (136), IRES origin (137,138), and the size and structure of a particular mRNA molecule. We have found that the titer of retrovirus containing pHa-*MDR*1 was higher than pHa-*MDR*1-*IRES-ADA*, even though P-gp translation was cap-dependent in both cases. P-gp expressed from pHa-*MDR*1 was also at a higher level in a vincristine resistant cell population than the P-gp expressed from pHa-*MDR*1-*IRES-ADA*. A possible explanation for the relatively low retroviral titers observed is RNA instability or alternative splicing, since no DNA rearrangement was detected by Southern blot analysis of the transduced cells using an *MDR*1 probe.

In addition to IRESes derived from viruses, several IRES elements have been identified in human genes. Those IRESes play important roles in cell cycle-dependent or stress-response translation regulation [reviewed in Sachs (139)]. In contrast to viral IRESes, human IRESes are shorter and are complementary to 18s rRNA [reviewed in Mauro and Edelman (140)]. It has been found that a 9-nt sequence from the 5′-UTR of the mRNA encoding the Gtx homeodomain protein can function as an IRES. Ten linked copies of the 9-nt sequence are 3- to 63-fold more active than the classical EMCV IRES in all 11 cell lines tested (141). Similarly, an IRES isolated from the human EIF 4G gene also exhibits 100-fold more IRES activity than EMCV IRES in 4 different cell lines (142). In addition to higher efficiency and smaller size, translation from a human IRES can be regulated by cellular events (142), which may be advantageous for certain cancer gene therapies.

C. Flexibility Using Bicistronic Vectors in Coordinating Expression of Selectable Markers and a Therapeutic Gene

Selectable bicistronic vectors provide great flexibility in coordinating expression of a selectable marker, such as P-gp, and a therapeutic gene. The low translation efficiency of the IRES results in asymmetric expression of genes positioned before and after the IRES. This asymmetric expression pattern makes it possible to alter the relative expression level of a therapeutic gene and P-gp to achieve maximum therapeutic effects while applying minimal selective pressure using a cytotoxic drug. By choosing different configurations, i.e., placing *MDR*1 before or after the IRES, we can select cells expressing a therapeutic gene at either a low level (*MDR*1 before the IRES) or a high level (*MDR*1 after IRES).

In addition, expression of a therapeutic gene can also be achieved at a desired level by altering the selection conditions. The degree of multidrug resistance conferred by P-gp corresponds to the amount of P-gp expressed on the plasma membrane. Using a bicistronic vector, the expression of a target gene is proportional to the expression of P-gp, which is directly linked to the selection conditions. In a highly stringent selection, instead of increasing the concentration of cytotoxic drug, P-gp reversing agents can also be applied in combination with low concentrations of cytotoxic drugs (143). P-gp reversing agents, also known as chemosensitizers, are noncytotoxic hydrophobic compounds that interact with P-gp and cause a direct inhibition of P-gp function. In the presence of a P-gp reversing agent, most P-gp-expressing cells are killed by the cytotoxic drug unless they express a large amount of P-gp to overcome the inhibitory effects. Using a combination of cytotoxic drug and chemosensitizer allows selection of cells expressing the therapeutic gene at a high level without need for a high concentration of cytotoxic drug. This strategy is especially desirable for an in vivo selection in which avoiding systemic toxicity is essential.

High expression of the target gene can be selected using cytotoxic drugs, cytotoxic drugs combined with chemosensitizers, or the vector configured to place the target gene placed before the IRES. However, those approaches also reduce the overall number of cells that can survive the selection. Nevertheless, using a minimum concentration of drug, the selectable bicistronic vector provides options for selecting a large population of cells with low expression of the target gene, or a small population of cells with high expression of the target gene. Both options may be useful for gene therapy. For instance, ADA levels in normal individuals occur over a very broad range. Heterozygous carriers can be immunologically normal even with as little as 10% of the normal amount of ADA [reviewed by Blaese (144)]. Expression of ADA at a low level in a large number of cells may prove sufficient to treat SCID. On the other hand, high ADA-expressing lymphoid cells, even through present as a small percentage of total cells, are also able to correct the SCID syndrome due to a beneficial by-stander effect (145). In gene therapy applications, the choice of the approach depends on the thera-

peutic strategy for a specific disease. Experiments on animal models are essential to prove the concepts that underlie gene therapy using selectable markers such as *MDR*1.

IV. NONRETROVIRAL AND EPISOMAL VECTORS EXPRESSING SELECTABLE MARKERS: AAV, SV40, AND EBV

Efficient delivery of a therapeutic gene to the appropriate target cells and its subsequent maintenance and expression are important steps for successful gene therapy. Genes introduced into cells are rapidly lost unless there is a mechanism to retain these genes within the nucleus and to ensure that the genes are also replicated and partitioned into daughter cells during cell division. Long-term expression of the transgene within cells can be achieved either via the integration of the transferred DNA into the host genome or maintenance of the introduced DNA as an autonomously replicating extrachromosomal element or episome. In either case, inclusion of a drug-selectable marker, like the *MDR*1 gene, in the construct would ensure that rapidly dividing cells containing the transgene are given a selective growth advantage.

Delivery modalities can be viral or nonviral. Retroviral gene transfer, one of the most exploited systems for gene transfer into actively dividing cells, has been discussed earlier in this chapter while liposomal gene delivery will be discussed later in the chapter. In this section, nonretroviral and/or episomal vectors expressing selectable markers will be described.

A. AAV

In addition to retroviruses, adeno-associated virus (AAV) can also facilitate integration of the transgene into the host genome. Unlike retroviruses, AAV was found to integrate preferentially into a specific site on chromosome 19 (146). AAV is a naturally defective, nonpathogenic, single-strand human DNA parvovirus. For productive infection and viral replication, coinfection with helper viruses, e.g., adenovirus, herpesvirus, or vaccinia virus are required. In the absence of a helper virus, AAV establishes latency in the host by integrating itself into the host genome. AAV has a broad host range and is also able to infect both dividing and nondividing cells (147). Hence recombinant AAV (rAAV) vectors have been exploited as alternative vehicles for gene therapy.

AAV-based vectors (148) are simple to construct, requiring only that the viral inverted terminal repeat (ITR) (which are 145 nucleotides each) is upstream from the gene of interest. Other important viral genes like rep (involved in replication and integration) and cap (encoding structrual genes) can then be supplied in trans. One disadvantage with such rAAV vectors is that site-specific integration of the gene of interest into the host genome is not observed (96). This is probably because the rep gene, which is important for mediating site specific integration in the absence of helper viruses, is not included in the construct with the gene of interest. Nonetheless, rAAV has been successfully applied to the delivery of various genes into a variety of tissues and persistence of transgene expression in these nondividing tissues, was reported (149–154). Baudard et al. (96) demonstrated that in rapidly dividing cells, continuous selective pressure is necessary to sustain gene expression in cells. *MDR*1 was used as the selectable marker in this study. Being among the smallest DNA animal viruses (~20 nm in diameter), another disadvantage of the AAV system is its limited packaging capacity since it can accomodate only aproximately 4.7 kb of the gene of interest. As such, a small and efficient promoter would be required to drive the expression of large genes. One such promoter is the AAV p5 promoter, which, together with the ITR, forms a 263-base pair cassette capable of mediating efficient expression in a CF bronchial epithelial cell line (149,150). Baudard et al. further demonstrated that the reduction of the p5 promoter-ITR cassette to 234 bp was also able to promote efficient gene expression (96).

B. SV40

Vectors that facilitate extrachomosomal replication have some advantages. High gene expression is often observed in such vectors. This could be a result of vector amplification, promotion of nuclear localization and retention, as well as transcriptional activation by viral genes involved in episomal replication. Selective pressure using selectable markers like the *MDR*1 gene, however, is necessary to maintain these episomes in actively dividing cells. Thus, another potential advantage of using episomally replicating vectors is that since they are not integrated into the cells, one could potentially extinguish expression at will by withdrawing selective pressure to replicating cells. Episomally replicating vectors can be easily created by the inclusion into the vector design of replicons that can be derived from DNA viruses like the Simian Virus 40 (SV40) (155), Epstein-Barr virus (EBV) (156) and the BK virus (157–159). Such replicons usually comprise a viral origin of replication as well as a viral gene product that is important for maintaining extrachromosomal replication.

SV40 is a 5.2 kb DNA papovavirus that was discovered as a harmless contaminant in early preparations of the Salk polio vaccine (160,161). SV40 is a double-stranded circular 5.2 kb DNA simian virus. It is a nonenveloped virus that belongs to the papovavirus family. The SV40 capsid is composed of 72 pentamers of the major capsid protein VP1, which are tied together through their carboxy-termini. VP2 and VP3, which share 234 amino acids at their carboxy-termini, connect the minichromosome core to the axial cavities of VP1. It has been suggested that correct interpentamer bonding is facilitated by host chaperones (162,163). SV40 infection begins with the virus binding to its primary receptor, the major histocompatibility complex class I (MHC class I), without internalization of the receptors. The entry is mediated by caveolae and the virus is transported to the Golgi membranes. Its pathway extends to the endoplasmic reticulum (ER), where it is disassembled. The mechanism by which the virus reaches the nucleus is not yet known (164–167). The wild-type virus is unable to replicate its DNA in rodent cells; therefore no progeny

virions can be produced in these cells (168). Infection of SV40 wild-type virus in cells can result in the integration of viral DNA into the host chromosome, permitting transmission of expression to daughter cells (169). Some reports associate SV40 DNA (specifically the T-antigen) with human tumors, mainly based on the presence of sequences from SV40 wild-type in some brain tumors and melanomas (170,171).

The two major SV40 delivery systems are vectors that use SV40 sequences or the wild-type virus as a helper, and vectors that are packaged in vitro, with no SV40 sequences and in which the wild-type virus is not present. SV40 has numerous advantages as a gene-delivery vehicle (54,172,173): it is able to infect a wide variety of mammalian cells, including human cells, and to express its genes in these cells; the vector system has an ability to deliver untranslated RNA products; the gene expression may be transient or stable in cell lines, depending on the specific SV40 system that is used; and episomal replication in SV40 virus requires the SV40 replication origin as well as the large T antigen (T-Ag), which activates the replication origin . Such episomal replication can generate more than 105 copies per cell of recombinant plasmids (174). Using the SV40 delivery systems, no immune response is expected, as well as no inflammatory reaction.

Replacing the late or early region with a foreign gene can generate SV40 recombinant viral particles (169,172,175–181). These are then propagated using either wild-type, or a temperature-sensitive mutant of SV40 as helper, or via a viral producer cell line, COS7, that stably expresses an origin-defective SV40 mutant and is capable of supporting the lytic cycle of SV40. Multiple infections result in higher titers of the virus — up to 10^{10} infectious units/ml. It has been demonstrated that when the large T-antigen (T-Ag) gene is replaced with a reporter gene, replication-deficient recombinant SV40 viruses can be produced and can mediate gene transfer *in vivo*. Reporter gene expression was detectable for about 3 months without selection. Present SV40 vectors of the first type have most of the viral coding sequences removed, retaining only the packaging sequences, the polyadenylation signal, and the early promoter of the virus, thus increasing the capacity for DNA to ~5.3 kb. The DNA from these vectors integrates into the genome of the target cells.

Rund et al. (54) demonstrated very efficient delivery (> 95%) of the drug-selectable marker, *MDR*1, into various murine and human cell types including primary human bone marrow cells (54). SV40 vectors efficiently deliver HIV-1-inhibitory RNAs using pol II or III promoters. Other vectors, which encode a variable fragment antibody recognizing HIV-1 integrase, inhibited HIV-1 infection in SCID mice. This system may prove to be useful in antiHIV-1 therapeutics. Fang et al. (182) reported a different packaging system for SV40 vectors where the vector carrying the gene of interest contains only the SV40 origin of replication (182). Instead of using wild-type SV40 viruses as helpers to package the recombinant vector, recombinant adenoviruses expressing SV40 capsids were used in COS7 cells. The helper adenovirus can be effectively heat-inactivated without adverse effect on the infectivity of the recombinant SV40 viruses due to the differential heat sensitivity of these two viruses. Strayer et al. (169) found evidence for integration of the recombinant gene or parts of it, a few days after transduction in random sites, which might explain the long-term expression of this system.

Pseudovirions can transfer the gene of interest to a variety of cells (including hematopoietic cells) with high efficiency, but their clinical applicability is currently limited by the presence of wild-type SV40 sequences. The in vitro, method of preparing helper-free SV40 vectors utilizes the SV40 viral late proteins, VP1, VP2, VP3 and agno or VP1 only (183–186). Nuclear extracts of baculovirus-transduced *Spodopterafrugiperda* (Sf9) insect cells that include these proteins are incubated with supercoiled plasmid DNA in the presence of 8 mM $MgCl_2$, 1 mM $CaCl_2$, and 5 mM ATP to form the SV40 in vitro, packaged vectors (55). Such in vitro, assembly allows larger DNA plasmids (up to 17.6 kb) to be packaged very efficiently, with no need for SV40 sequences. We have demonstrated very efficient delivery of the *MDR*1 (*ABC B1*), *MXR* (*ABC G2*), and *MRP*1 (*ABC C1*) genes, which can confer multidrug resistance on virtually all cell types (human, murine, and monkey cell lines), in addition to delivery of the *GFP* gene as a reporter (187). The expression of both *MDR*1 and *GFP* genes is dose dependent. The alteration in the level of expression suggests that MHC class I receptors play an important role in determining the efficiency of transduction. *MDR*1 constructs that carried a promoter with an intron demonstrated higher expression than those without the intron. In low-expressing MHC class I cell lines, the CMV promoter produced more P-gp expression compared with the SV40 promoter. In vitro packaged-*GFP* vectors that carried the CMV promoter consistently confirmed higher expression than those that carried the SV40 promoter. Expression was transient up to 21 days, but did last for 3 months under colchicine selection for MDR1 and was lost soon after selection was withdrawn (55).

The short-term expression of the SV40/*MDR*1 in vitro, vectors may be an advantage for use in chemoprotection. Long-term expression beyond the chemotherapy period is undesirable, and may put patients at risk for treatment-induced myelodysplasia or secondary leukemia. The SV40/*MDR*1 vectors that are prepared in vitro, may provide not only a safe vehicle for gene delivery but will also potentially avoid the problem of persistent bone marrow drug resistance in cancer patients.

C. EBV and Other Episomal Vectors

Episomal vectors based on EBV are also being developed for gene therapy purposes. EBV is a human B-lymphotropic herpesvirus that resides asymptomatically in more than 90% of the adult human population by establishing latency and maintaining its genome episomally (188). The life cycle of EBV comprises two phases, a lytic and a latent phase. During the lytic phase, EBV DNA replicates via a rolling circle intermediate to achieve a 1000-fold increase in copy number. The origin of replication, Ori Lyt, and the transacting element ZEBRA are required for the lytic replication. Rolling circle replication results in the formation of linear head-to-tail con-

catamers. The presence of the EBV terminal repeat (TR) sequence causes cleavage of the concatemerized DNA to molecules of about 150–200 kbp, which are then packaged into virions. Upon infection into a permissive cell, the viral DNA circularizes by ligation of TR. Latency is established in the cells by episomal replication of the circular DNA.

Episomal replication in EBV is maintained by two elements interacting to ensure that the viral genome is retained within the nucleus, efficiently replicated and partitioned into daughter cells. Although the copy numbers of episomal viral DNA varies from 1–800, only between 4–10 episomal copies per cell are usually observed using vectors containing EBV OriP and EBNA-1 (189). Unlike other episomal vector systems, very low rates of spontaneous mutation have been observed with EBV-based episomal vectors (190). The *cis*-acting element responsible for episomal replication is a 1.8 kb OriP while the transacting element is EBNA-1. OriP comprises two distinct sequence motifs, the dyad symmetry motif (DS) from which replication is initiated and the family of repeats (FR) that serves as a replication fork barrier. Interaction of EBNA-1 with DS initiates bidirectional replication, while binding of EBNA-1 to FR enhances transcription from the episome and terminates DNA replication. EBNA is reported not to be oncogenic nor immunogenic. It evades the host immune system via the presence of the repeat motif, Gly-Ala, which was found to interfere with antigen processing and MHC class I-restricted presentation (191). These EBV episomal vectors replicate once per cell cycle (192) and are capable of stably maintaining human genomic inserts of sizes between 60–330 kb for at least 60 generations (193).

Banerjee and colleagues (194) developed a helper-dependent infectious recombinant EBV to evaluate the feasibility of using such a vector system to correct hereditary syndromes in B-lymphocytes already harboring the EBV virus latently. The EBV-containing target B-lymphocytes will supply EBNA-1 *in trans* for the episomal maintenance of the transgene. Hence only minimal cis-EBV elements for episomal replication (OriP), viral amplification (Ori Lyt), and packaging (TR) are included in their construct. The hygromycin resistance gene was included as a selectable marker in their vector. Infectious virions are generated by the producer cell line HH514. They demonstrated successful transfer of such infectious virions carrying the therapeutic gene, Fanconi anemia group C (FA-C) cDNA, into HSC536, a FA-C patient cell line. Upon selection with hygromycin, long-term (at least 6 months) correction of the Fanconi phenotype in vitro, was observed, as determined by cellular resistance to the cross-linking agent, diepoxybutane. They also observed that in the absence of selective pressure, their episomal vector is retained in rapidly dividing cells at a rate of 98% per cell division translating to a half-life of 30 days in cells doubling every 20 hours.

Our laboratory has been exploring the use of EBV episomal vectors containing only the OriP and EBNA-1 and carrying the selectable marker *MDR*1 as potential gene therapy vectors. Using the liposome formulation, DOGS/DOPE (1:1) (195), we successfully delivered the vector to various cultured cells as well as human $CD34^+$ stem cells. *MDR*1 was found to be expressed at a higher level in the episomal vector compared to its nonepisomal counterpart and more drug colonies were obtained upon selection. Episomal plasmids could be recovered in drug selected cells for many weeks (56).

Other episomally replicating vectors can be derived from BPV viruses (196) or the BK virus (158). Unfortunately, BPV vectors cannot be reliably maintained as episomes as they exhibit high spontaneous mutation rate (~1%), frequently undergoing integration, deletion, recombination, and rearrangements (197). Furthermore, BPV has a limited host range and BPV vectors cannot be efficiently maintained in human cells. Not too much is known about BK-virus-derived episomal vectors. Nonetheless, successful stable maintenance of episomal gene expression was reported in human transitional carcinoma cells using BK-based vectors but not EBV-based vectors, probably due to the differential tropism of BK and EBV viruses for human uroepithelial cells (157).

Various chimeric viruses have been developed to improve the efficiency of gene transfer as well as the maintenance of gene expression within target cells. These chimeric virus systems attempt to combine the favorable attributes of each vector system and overcome the limitations associated with each system. The episomal replication ability of EBV was exploited to produce both rapid and long-term high-titer recombinant retroviruses (up to 10^7 TU/ml) for efficient gene transfer into human hematopoietic progenitor cells (198,199). A novel adenoviral/retroviral chimeric vector was also reported in which an adenoviral delivery system was utilized to efficiently deliver both the retroviral vector and its packaging components, thereby inducing the target cells to function as transient retroviral producers capable of infecting neighboring cells. This system capitalizes on the superior efficiency of adenoviruses to deliver genes in vivo and the integrative ability of retroviruses to achieve stable gene expression (200). An EBV/HSV-1 amplicon vector system was also described that combines the efficiency of HSV-1 virus to transfer DNA into various mammalian cells, including the postmitotic neuronal cells and the ability of EBV to maintain genes episomally. This vector system contains the HSV-1 origin of DNA replication (oriS) and a packaging signal, which allow replication and packaging of the amplicon into HSV-1 virions in the presence of HSV-1 helper functions as well as EBV oriP and EBNA-1 (201). Another report describes the use of a similar HSV-1 amplicon system for efficient gene transfer, but AAV was included in their vector to achieve stable expression. This HSV/AAV hybrid vector contains OriS and packaging sequences from HSV-1, a transgene cassette that is flanked by AAV ITRs as well as an AAV rep gene residing outside the transgene cassette to mediate amplification and genomic integration of ITR-flanked sequences (202). An HVJ-liposome vector system reported by Dzau et al. (203) was utilized to improve the efficiency of liposome-mediated transfer of an EBV-episomally maintained transgene (204,205). This system exploits the fusigenic properties of the hemagglutinating virus of Japan (HVJ or Sendai virus) since envelope proteins of inactivated HVJ were found to mediate liposome-cell mem-

brane fusion and facilitate cellular uptake of packaged plasmid DNA, bypassing endocytosis and lysosomal degradation.

One of the limitations with using viral episomal systems is the limited host range of such vectors. Although EBV episomal vectors replicate well in various human and primate cells, they are unable to replicate in rodent cells, limiting their utility in gene therapy since testing of these vectors in rodent models is not easy. Nonetheless, it was found that large fragments of human genomic DNA (between 10–15 kb) can mediate autonomous replication if there is also a mechanism to retain them in the nucleus (206). Such vectors based on a human origin of replication were also found to be capable of replicating in rodent cells (207), probably due to the common host factors that drive their replication. A hybrid class of vectors was thus developed, which employs a human origin of replication to mediate vector replication as well as the EBV FR and EBNA-1 gene product to provide nuclear retention functions. [see Calos (208)]. EBNA-1 binding to the FR of the vector DNA causes the adherence of this complex to the chromosomal scaffold in a noncovalent fashion, thus retaining the vector DNA in the nucleus (209). These vectors were reported to replicate somewhat in synchrony with chromosomal DNA once per cell cycle. Maintenance of these vectors within cells is related to the frequency of cell division (208). Such vectors have been reported to persist in cells for at least 2 months under no selective pressure (206,210).

Ultimately, the development of a true mammalian artificial chromosome (MAC) without dependence on viral elements will be the key to obtaining stable episomal replication without dependence on selective pressure. Functional elements in mammalian cells important for maintaining DNA episomally as a minichromosome include a replication origin to promote autonomous replication, telomeres to protect ends of linear DNA and replicate DNA termini, and a centromere to facilitate correct segregation of the construct during mitotic division. Various mammalian chromosomal DNA replication initiation sites have been identified [reviewed in DePamphilis (211)] and found to comprise a 0.5–11 kb primary origin of bidirectional replication (OBR) flanked by an initiation zone of about 6–55 kb. These sequences show characteristics of DNA unwinding, a densely methylated island, attachment sites to the nuclear matrix, and some palindromic sequences.

Vectors utilizing human genomic sequences that promote extrachromosomal vector replication have already been successfully applied as mentioned above. Telomeres that are required for the stability and integrity of the eukaryotic chromosome have been well characterized. In mammalian cells, the telomeric tracts comprise 2–50 kb of tandem TTAGGG repeats. Human centromeres, necessary for proper chromosome segregation at mitosis and meiosis, have been localized cytogenetically as primary constrictions of the chromosomes. They are thought to consist of up to several megabases of highly repetitive DNA belonging to the alpha satellite DNA family (212) and are attached to microtubules (213). Until recently, the functional isolation of the centromere has been a great hurdle in the progress towards the construction of an MAC. The group of Harrington et al. developed the first generation of human artificial microchromosomes (HAC) by creating synthetic alpha satellite arrays ~1 Mb in size (214). They found that such an HAC which is about 6–10 Mb is size is mitotically and cytogenetically stable for up to 6 months in culture in the absence of selective pressure. Nonetheless, the technical challenge of assembling a mammalian artificial chromosome is still formidable as cloning and manipulating such large constructs are not trivial using conventional bacterial cloning systems, and transfer to mammalian cells is difficult.

V. USE OF LIPOSOMES TO DELIVER VECTORS WITH SELECTABLE MARKERS

Liposome-mediated gene transfer appears to be a safe and noninvasive method of DNA delivery into cells. Since high efficiency and stable expression have not yet been achieved using liposomal methods, the use of the human *MDR*1 gene as a selectable marker may allow for the selection and enrichment of the recipient cells and may be useful in the future for the long-term maintenance of the cationic liposome:DNA complex.

Previous studies in our laboratory have shown that a liposomal delivery system can mediate successful *MDR*1 transfection of mouse bone marrow cells and in vivo expression of functional P-gp in hematopoietic cells (97). The introduction via liposomes into hematopoietic cells of an *MDR*1 gene driven by Harvey murine sarcoma virus long-terminal repeat sequences (Ha-MSV-LTR) was achieved either ''directly'' by intravenous administration into mice, or ''indirectly'' by adoptive transplantation of previously in vitro-transfected bone marrow cells. In these studies, using a cationic liposome complex consisting of dioctadecylamidoglycyl spermidine (DOGS) and dioleoylphosphosphatidyl ethanolamine (DOPE), *MDR*1 transfection was detected in up to 30% of unselected and 66% of vincristine preselected murine bone marrow cells as demonstrated by drug resistance in an in vitro, colony-forming unit assay. Although transfection into human bone marrow cells is likely to be much less efficient, the potential of obtaining drug-selectable mouse bone marrow progenitor cells after gene transfer using such a liposome delivery system may eventually make it possible to protect cancer patients undergoing chemotherapy from bone marrow toxicity of anticancer drugs.

Liposome-mediated gene transfer can also be used for in vivo delivery of Adeno-Associated-Virus (AAV)-*MDR*1-based vectors. Recently, drug-selected coexpression of both P-gp and glucocerebrosidase (GC) was achieved with an AAV vector containing the *MDR*1-IRES-GC fusion delivered to NIH 3T3 cells by lipofection (96). Moreover, a single intravenous injection of this bicistronic vector complexed with cationic liposomes into recipient mice allowed detection of GC and *MDR*1 sequences by PCR in all organs tested 7 weeks later.

For nonintegrating DNA vectors such as EBV-based systems (see Section IV) and the AAV system (96), liposome-based gene delivery usually results in transient transgene expression due to the episomal nature of the transfected plasmid and loss of the plasmid when the cells proliferate (215,216). Use of a selectable marker such as *MDR*1 may make it possible to maintain nonintegrated episomal forms in proliferating cells (see Section IV). Since only cells carrying such episomal *MDR*1-based vectors would survive the selection, this advantage should be useful for gene therapy with episomal *MDR*1 vectors in vivo. Combining liposomes with AAV- or EBV-based vectors and *MDR*1 as a selectable marker may make it possible to expand the population of expressing cells by *MDR*1-drug selection.

We are developing a gene therapy model to treat Fabry disease (123) using intravenous injections of a pHa-aGal-IRES-MDR bicistronic vector complexed to cationic liposomes into α-galactosidase A deficient mice (T. Shoshani and M. M. Gottesman, unpublished results). Both human α-Gal and *MDR*1 were detectable in the lungs of the recipient Fabry mice by Southern blot analysis 7 days after injection. Reverse transcriptase polymerase chain reaction (RT-PCR) analysis of total RNA extracted from the kidneys of recipient Fabry mice showed the presence of both human α-Gal and *MDR*1 mRNA. The expression in the kidneys was specific to the α−galactosidase-A-deficient mice, where renal tubule cells may be damaged by an accumulation of glycosphingolipids. In situ hybridization analysis localized the mRNA expression to the renal distal tubule epithelial cells. Higher RNA expression was obtained in Fabry mice that were injected 3 times every third day. The repeated administration is tolerated by the recipient mice and no toxic effects were obtained. It remains to be determined whether selection in vivo will allow expansion of cell populations expressing human α-Gal by repeated administration of cytotoxic *MDR*1 substrates.

VI. ENGINEERING MDR VECTORS TO IMPROVE EFFICIENCY OF DRUG SELECTION

One of the goals of gene therapy is to modify cells genetically such that they can supply a useful or necessary function to the cell (3). One of the most promising applications of the *MDR*1 gene in therapeutic vectors as a selectable marker in vivo is the protection of bone marrow cells during intensive chemotherapy. During chemotherapy, the *MDR*1 gene is transduced or transfected into drug-sensitive bone marrow cells and selected for by exposure to MDR agents. The untransfected/untransduced cells will necessarily be killed and those containing the *MDR*1 gene will expand. The efficacy of this therapy depends on the interaction between P-gp and the selecting agent employed. Thus, it is important to be able to distinguish between the endogenous P-gp and the exogenously introduced molecule. Furthermore, it obviously would be beneficial to create a P-gp molecule that would confer very high levels of resistance to certain drugs, giving an advantage to transduced cells/tissues compared to wild-type P-gp. Studies of a number of mutations made in P-glycoprotein have suggested that it should be possible to construct mutant ''designer'' transporters useful for *MDR*1-based gene therapy.

One of the hallmark characteristics of the multidrug transporter is its extremely broad substrate specificity. Over the past several years, the identification of specific domains and amino acid residues involved in substrate recognition has contributed to our present understanding of the mechanism of action of P-gp. The major sites of interaction have been shown to reside in transmembrane domains (TM) 5 and 6 in the N-terminal half of the protein and in TMs 11 and 12 in the C-terminal half and the loops that conjoin them (217–221). For the purposes of chemoprotection, the design of a P-gp that has increased resistance to chemotherapeutic agents compared to the endogenous P-gp would be most useful because increased doses of the agent could be administered without harming the bone marrow cells expressing the exogenous P-gp molecule. To date, a number of these types of mutations have been described.

Mutations in TM domains of P-gps from both rodent and human have demonstrated significant alterations in substrate specificity (3,222). An F338A mutation in hamster P-gp enhances resistance to vincristine, colchicine, and daunorubicin but has little impact on resistance to actinomycin D (223,224). An F339P mutation in the same molecule only increases actinomycin D resistance. However, the double F338A/F339P mutant demonstrates an increased level of resistance to actinomycin D and vincristine but a lowered level of resistance to colchicine and daunorubicin (223,224). Of these mutants, the F338A may prove most useful because it confers increased resistance to a wider range of chemotherapeutic agents. In human P-gp, however, a homologous mutation at F335 confers greater resistance to colchicine and doxorubicin but causes a severe reduction in resistance to vinblastine and actinomycin D (225,226) . Additionally, cells expressing a Val->Ala mutation at position 338 also exhibit preferential resistance to colchicine and doxorubicin but are severely impaired for vinblastine (226). Resistance to actinomycin D, however, is unaffected. Alanine scanning of TM 11 in mouse P-gp encoded by *mdr*1a revealed that two mutants, M944A and F940A, show an increase in resistance to doxorubicin and colchicine while maintaining wild-type levels of resistance to vinblastine and actinomycin D (227). For certain treatment protocols, it is conceivable that increased resistance to certain agents would be desirable, and the reduction in levels of resistance to other compounds would not be problematic, especially if a well-defined chemotherapy regimen was being employed.

Although the majority of residues that increase resistance to various chemotherapeutic agents reside in the TM domains, a number of residues in the putative cytoplasmic loops also have been implicated in defining drug resistance profiles for cytotoxic drugs. The best characterized of these mutations is the G185V mutant that confers an increased resistance to colchicine and etoposide but decreased resistance to actinomycin D, vinblastine, doxorubicin, vincristine, and taxol

(228–231). Interestingly, and perhaps relevant clinically, when this mutation is made in conjunction with an Asn->Ser mutation at residue 183, increased resistance to actinomycin D, vinblastine, and doxorubicin is achieved without loss of the increase in colchicine resistance (229). Mutations of Gly-141, 187, 288, 812, or 830 to Val in human P-gp increase the relative resistance of NIH3T3 cells to colchicine and doxorubicin but do not alter resistance to vinblastine (232). Only the mutations at positions 187, 288, and 830 confer decreased resistance to actinomycin D to cells in culture.

Due to its broad substrate specificity, P-gp not only interacts with chemotherapeutic compounds but also with reversing agents and inhibitors. In combination chemotherapies, reversing agents increase the efficacy of cytotoxic agents in *MDR*1-expressing cancers. Two of the most potent reversing agents currently in use or in clinical trials are cyclosporin A and its nonimmunosuppressive analog PSC833. Recently, a number of mutants have been described that affect sensitivity to these agents. Cells expressing a human P-gp containing a deletion at Phe335 or Phe334 are substantially resistant to cyclosporin A and PSC-833 [(233), Hrycyna, C.A., Pastan, I., and Gottesman, M.M., unpublished data]. A similar phenotype has been observed for a transporter containing 5 mutations in the region including TM 5 and TM6, namely Ile299Met, Thr319Ser, Leu322Ile, Gly324Lys, and Ser351Asn (234). Additionally, in hamster P-gp, the substitution of an alanine at position 339 with proline results in a transporter that confers lowered sensitivity to cyclosporin A (224). From these studies, it appears that TM6 plays an important role in the recognition of cyclosporin A and its analogs. The decreased sensitivity to these reversing agents observed in cells expressing the TM6 mutations could help protect bone marrow stem cells transduced with the mutant *MDR*1 gene from the toxic effects of chemotherapy given with reversing agents to sensitize *MDR*1-expressing tumors.

The *cis* and *trans* isomers of flupentixol, a dopamine receptor antagonist, have also been shown to inhibit drug transport and reverse drug resistance mediated by P-gp (235,236). The substitution of a single phenylalanine residue at position 983 with alanine (F983A) in TM 12 affects inhibition of P-gp-mediated drug transport by both isomers of flupentixol (59,60,237). Both isomers were found to be less effective at reversing P-gp mediated drug transport of daunorubicin and bisantrene. However, the inhibitory effects of other reversing agents such as cyclosporin A were not affected. The reduced sensitivity of the F983A mutant to this compound coupled to the apparent lack of clinical toxicity of (*trans*)-flupentixol (235), suggests that this mutant may be useful in combining *MDR*1 gene therapy with chemotherapy including *trans*-flupentixol as a chemosensitizer. This approach, in theory, should allow for effective treatment at lower doses of chemotherapeutic agents while maintaining bone marrow protection.

The use of *MDR*1 gene therapy in bone marrow chemoprotection protocols has undergone preliminary analysis in clinical trials (89,90,238). Results indicate a low efficiency of marking bone marrow cells using retroviral vectors, but some selective advantage manifested as an increased percentage of positive cells after chemotherapy (89). In the future, with the generation of higher resolution structures of human P-gp, it should be feasible to model and synthesize new, more effective cytotoxic drugs or modulators capable of blocking P-gp function clinically. However, until that time, the analysis of spontaneously occurring or engineered mutants, coupled to our knowledge of the current battery of anticancer and reversing agents, offers an opportunity to begin designing second-generation vectors for use in these trials.

VII. CONCLUSIONS AND FUTURE PROSPECTS

We have argued in this review that drug-selectable marker genes may be helpful for gene therapy in two ways: first, to protect bone marrow progenitor cells (and other sensitive cells) from the cytotoxicity of anticancer drugs, thereby allowing safe chemotherapeutic treatment at reduced risk of severe side effects, and second, to enrich the expression of otherwise nonselectable genes in drug-sensitive cells to overcome low or unstable gene expression in vivo. Given the current instability of expression of genes from existing vectors, especially episomal vectors, such selectable markers may be an essential component of gene therapy protocols.

We are still in the early stages of vector development, and until transduction efficiencies into human tissues such as bone marrow are improved and shown to be safe, long-term human gene therapy will not be feasible. The combination of more efficient gene transfer targeted vector systems, and effective, relatively nontoxic selection systems to maintain gene expression may make long-term correction of human genetic defects feasible and safe.

Ligand-dependent Transcription Switches and Their Potential for Gene Therapy

Carlo Toniatti, Fabio Palombo, Riccardo Cortese, and Gennaro Ciliberto
I.R.B.M. P. Angeletti
Pomezia, Italy

I. TRANSCRIPTIONAL REGULATION IN GENE THERAPY

The potential advantage offered by gene therapy over conventional medicine for the treatment of several diseases is unquestionable. It is nonetheless also clear that efficacy, and more importantly safety, remain the main issues to be solved before this technology can be adopted routinely as a standard therapeutic practice (1,2). At the time of writing this article, beginning in 2003, clinical efficacy of gene transfer has been convincingly demonstrated only for Severe Combined Immune Deficiency (SCID). In contrast, safety concerns have been raised as a consequence of adverse side effects in several clinical trials (3–8). Therefore, the major challenge still remains the development of vectors characterized by maximum transduction efficiency combined with minimal toxicity (9,10). In current years the continuous application of ''good basic science'' to the gene therapy field has been directed at fulfilling these two main goals. With the decline of the initial concept of a ''universal vector'' for all diseases, the emerging scenario is to generate a large repertoire of safe vectors, each suited to target a given tissue or cell type, or tailored to treat a specific clinical condition. (11–13). Based on these premises, any work directed at developing systems, which allow to control and finely tune the expression of therapeutic gene(s), must be taken into serious consideration.

Until now, clinical trials of somatic gene therapy have made exclusive use of constructs where transgenes are delivered under the control of potent and constitutively active promoters. In these applications the risk of toxic effects caused by overproduction of the therapeutic proteins was negligible for a variety of reasons, related partly to the features of the vector used and in part to the nature of the target disease. In some cases short-term transgene expression was expected because the vector, for example 1st generation adenovirus, was not capable per se of long-term gene expression (2). In others, such as naked DNA delivered to muscle, it was known that gene transfer was not efficient enough to elicit too high levels of the transgene product (14). When cancer or other acute diseases were targeted, prolonged treatment was not required, and the main goal was to maximize gene transcription and protein production for a short period of time (15). Finally, in clinical trials of chronic diseases, where long-term gene expression was required, gene therapy was directed at curing clinical conditions in which the expressed proteins had large therapeutic indexes (TIs). Examples of this are coagulation factor IX for Hemophilia B, IL-2 receptor gamma-chain or adenosine deaminase for SCID, and CFTR for Cystic Fibrosis (16–18).

Constitutive promoters, however, have limited applications in gene therapy. The main reason is that they cannot be used for the delivery of proteins with small TI. In practical terms, several diseases could benefit from the delivery of genes whose activity must be kept within a narrow therapeutic window. Good examples are disease caused by protein hormone deficiencies, such as anemia or pituitary dwarfism, or those that require treatment with soluble receptors, cytokines and antibodies (19). These clinical conditions are currently treated by repeated administration of recombinant proteins, but less frequent or one-time delivery of the gene coding for the therapeutic protein would indeed represent a more cost-effective and successful approach (14). For these cases, regulating transgene expression would be crucial to maintaining the circulating levels of the protein within a well-defined therapeutic window, thereby preventing toxicity. Regulated gene tran-

scription would also allow therapy to be modulated in response to disease evolution, which varies greatly from patient to patient, and in the individual response to the therapy itself. Finally, the possibility to terminate and resume therapy (i.e., stop and restart transgene production) at will, would not only allow therapy to be halted in the presence of adverse side-effects, but would also enhance the flexibility of a gene-based approach by enabling combinations with conventional therapeutic modalities.

In addition, it has to be taken into account that vector improvements will probably increase efficiency and longevity of gene transfer over the next year. As a consequence, the expression levels of proteins with large therapeutic indexes will also need to be controlled. In the long term, therefore, it is not premature to think that regulating therapeutic gene expression will become an indispensable mechanism in broadening the application range of gene therapy and increasing both clinical efficacy and safety of the majority applications.

A. Endogenous Regulatory Systems

To be used in the context of human gene therapy, a transcription regulation system must precisely modulate target gene expression in response to administration or withdrawal of a specific external stimulus. Initial attempts to generate regulated gene expression systems were mainly based on using endogenous promoters and enhancer elements specifically responsive to environmental stimuli such as metal ions, heat, and oxygen tension (20). A detailed description of these systems is beyond the scope of this chapter, but it is worth remarking that these types of regulatory systems have severe drawbacks. The most important is that the inducer stimuli heavily interfere with the regulatory networks of the host and therefore display pleiotropic effects. Moreover, these systems display a relatively high basal activity in the uninduced state, promote only modest levels of induction, and frequently lose responsiveness to the inducer over time (20). These limitations obviously preclude the use of endogenous control systems in human gene therapy, and have been gradually superseded by more efficient approaches based on exogenous regulators.

B. Ligand-dependent Regulatory Systems

Over the past decade, several artificial systems have been developed that enable regulable expression of the desired transgene in response to a small molecule ligand (21). In general, these systems are based on two components. The first is a chimeric transcription factor obtained by fusing a DNA-binding domain (DBD), (which usually does not bind endogenous cellular sequences), a transcription activation domain (AD), and a domain that interacts with a small molecular weight compound that acts as inducer drug. The second component is an artificial promoter consisting of multimeric binding sites for the DBD followed by a minimal promoter sequence containing a TATA box. The chimeric transcription factor is recruited to (or in some cases released from) the specific target promoter upon interaction with the exogenously added drug: transcription of a transgene cloned downstream of this promoter can thus be modulated in vivo by systemic delivery or withdrawal of the inducer drug (Fig. 1).

To be suitable for human gene therapy, the ideal pharmacologically regulated system should fulfill several criteria listed below:

1. ON switches vs. OFF switches: the ligand should activate (ON switches) rather than inhibit (OFF switches) activity of the chimeric transcription factor. In practice, off switches are unlikely candidates for human gene therapy because of two major drawbacks: in order to fully repress an off-switch system, all intracellular molecules of the chimeric activators must theoretically be bound to the drug. This implies that prolonged exposure of patients to high doses of the drug would be required to silence the system in vivo, thus increasing the probability of drug-related side effects. Secondly, induction kinetics would be poor in the case of off switches and mainly determined by the rate of drug clearance (inactivation of the drug or its removal from body tissues).
2. Specificity: the system should not interfere with endogenous regulatory pathways. This means that the transcription factor should only activate the target promoter and the drug should be devoid of pleiotropic effects.
3. Bioavailability of the drug: the inducer drug should be orally bioavailable and capable of readily penetrating all tissues, as well as crossing the blood-brain barrier in cases of gene therapy to the CNS.
4. Drug safety: the inducer compound must have a safety profile compatible with prolonged therapeutic use in humans.
5. Reversibility: the system should be fully and rapidly reversible to enable prompt modification of the dosing regimen when required. In relation to this, it is important that the inducer drug is cleared from body tissues within a reasonable amount of time, thus enabling rapid switching from the on- to the off-state upon drug delivery and withdrawal, respectively.
6. Low basal activity: the system should be inactive in the absence of the drug when delivered with any type of vector of both viral and non viral origin. It is important that this tight control should be maintained at all vector doses and in every target tissue.
7. High degree of inducibility: the system should be induced over a wide dose range. In particular, strong induction should be obtained at relatively low (i.e., compatible with therapy in humans) drug concentrations.

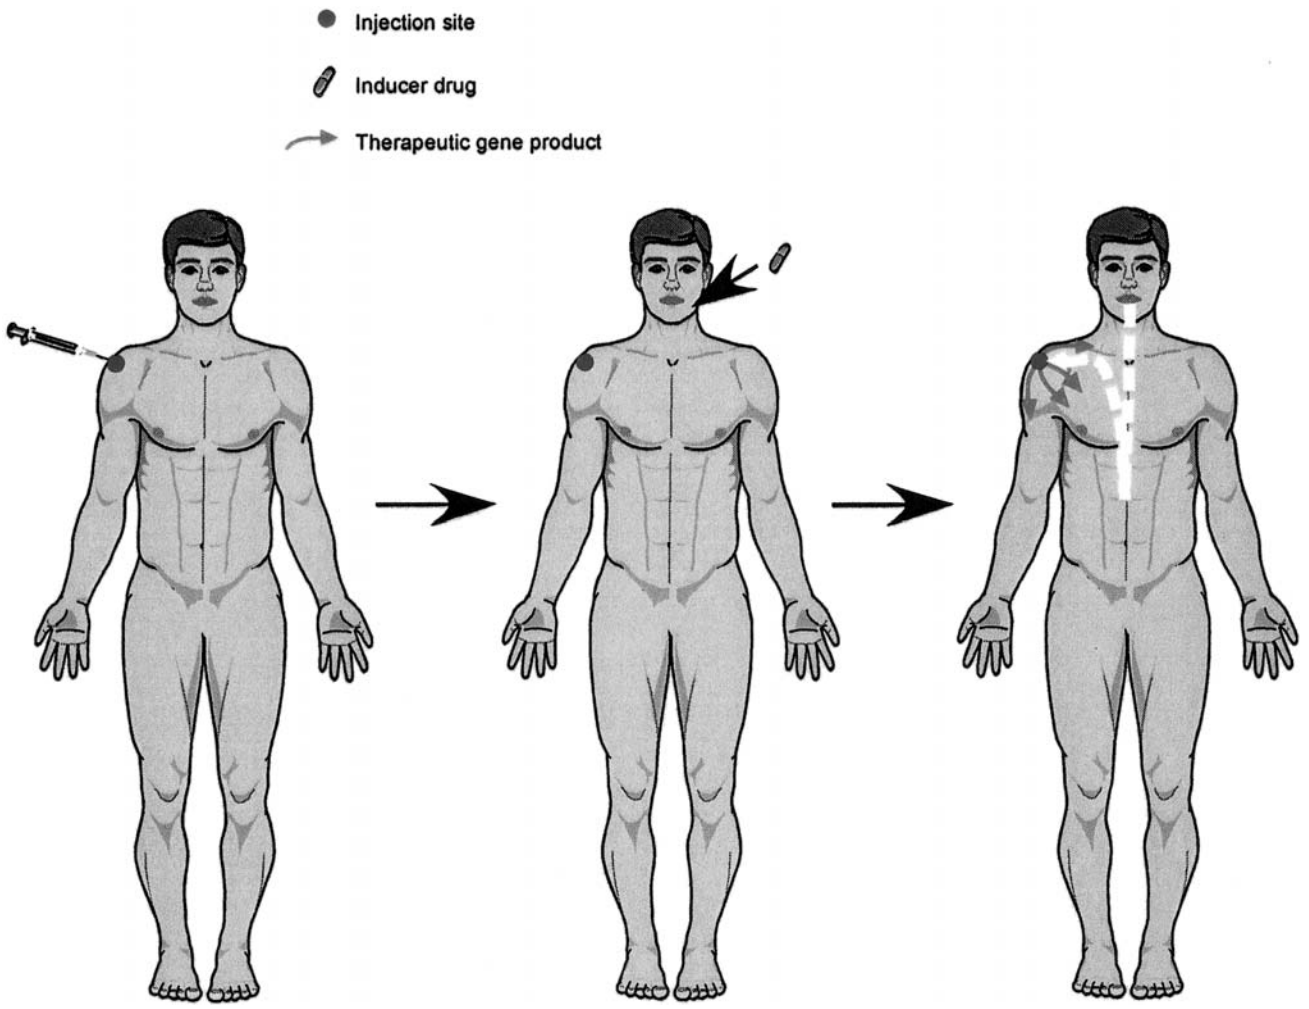

Figure 1 Drug-dependent expression of a therapeutic gene. Local delivery of a ligand-regulated gene results in systemic production of the corresponding therapeutic protein upon drug administration. See the color insert for a color version of this figure.

8. Dose-dependence: a pre requisite for a fine modulation of protein production in vivo is that a precise correlation must exist between drug dosage and target gene expression level.
9. Low immunogenicity: to enable long-term applications, the chimeric transcriptional activator(s) should exhibit a low potential of eliciting an immune response in man.

Several ligand-dependent systems have been described in the past years, but only four of them have been extensively tested in animal models and are currently being refined for use in human applications. These four systems are regulated by a) the tetracycline (Tet) antibiotics or its analog doxycycline (Dox); b) chemical dimerizers such as the immunosuppressants rapamycin and its analogs; c) the synthetic steroid antagonists mifepristone (RU486) and tamoxifen (TAM); and d) insect steroid ecdysone or its analogs. In this chapter we will review in depth ligand-dependent gene regulation with particular emphasis on these four systems, and will discuss to what extent they come close the ideal features outlined above.

II. TETRACYCLINE-DEPENDENT REGULATORY SYSTEM

A. General Principles

The tetracycline-dependent regulatory system is based on the *E. coli* Tn*10*-encoded tetracycline resistant operon, which was adapted to work in eukaryotic cells. Tetracycline (Tc) resistance operon consists of two genes, the resistance gene *TetA*, which codes for a membrane protein that exports invaded Tc

out of the bacterial cell, and the regulator gene *TetR*, which codes for a dimeric DNA-binding protein (22). In the absence of Tc, TetR protein inhibits its own expression as well as expression of TetA by binding to operator sequences (tetO) of the tet operon. Tc or other antibiotics belonging to the same class, such as doxycycline (Dox) prevent this binding (Fig. 2). These antibiotics bind to the TetR and induce allosteric change, which results in releasing the repressor from its target DNA sequence, thus enabling transcription of *TetA* and *TetR* genes (22).

The Tc operon evolved to strongly repress TetA expression in the absence of the antibiotic, but at the same time, to sense very low (i.e., subinhibitory) concentrations of Tc. Therefore, TetR binds to tetO with extremely high affinity (2×10^{11} M^{-1}) and the association constant of Tc to tetR is very high ($K_{Ass} = 3 \times 10^9$ M^{-1}) (22) and references therein]. Based on these properties, the use of elements of the Tc operon to regulate gene expression in eukaryotes was considered an attractive possibility.

Initial studies in plants demonstrated that TetR was able to repress activity of a plant promoter containing three tetO sequences in close proximity to the TATA box (23). In this configuration, binding of TetR interfered with initiation of transcription. As in bacteria, repression was reversible by Tc: upon adding the antibiotic, the TetR was released from DNA and transgene expression was induced (23). However, several lines of evidence indicate that the repressing mechanisms active in bacteria are not appropriate for regulating promoter activity in eukaryotes. In fact, a repressor-binding site, such as tetO, should be efficiently (i.e., almost fully) occupied by the repressor to adequately inhibit transcription: this implies that when tight repression is required, the repressor itself should be expressed at high and possibly toxic levels within the target cells. Moreover, constitutively high intracellular concentrations of the repressor may severely limit the inducibility of the system (24). Finally, studies in cells have demonstrated that efficient silencing of eukaryotic promoters requires proper positioning of tetO according to rules that may vary in accordance to the target promoter (25).

Regulatory systems based on ligand-regulated activators have less severe requirements: in the simplest case, the target promoter is constitutively silent and becomes active only when bound by the cognate activator. Notably, overexpression of the activator is not necessary, provided it is present above a certain threshold level. These considerations prompted H. Bujard and colleagues to convert the TetR into a positively acting factor and use it to regulate gene expression in eukaryotic cells (26).

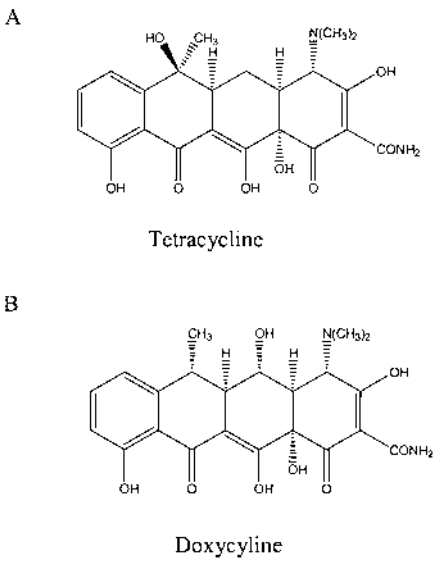

Figure 2 Chemical structure of tetracycline and doxycycline, inducers of the Tet-system. (A) Tetracycline effectively stimulates tTA (Tet-OFF system) but not rtTA (Tet-ON system). (B) Doxycycline activates both Tet-ON and Tet-OFF systems.

B. Transcription Factors

TetR was converted to a transcriptional transactivator, called tTA, by fusing the VP16 transactivation domain of *H. simplex* virus to the C-terminus of TetR (26). tTA retained the DNA-binding and ligand-binding properties of TetR: it was prevented from binding to tetO by Tc or its derivatives, such as doxycycline (Dox), a most potent effector for both TetR and tTA. tTA proved capable of activating expression from tetO-containing promoters in a tetracycline-dependent manner in eukaryotic cells (26). In this ''Tet-OFF'' configuration, therefore, transcription is stimulated by drug withdrawal (Fig. 3). tTA retained an exquisite responsiveness to the effector molecule, in that it was completely inactivated by Dox concentrations as low as 20 ng/ml (26,27). Since its development, the Tet-OFF system has become one of the most widely used systems for modulating gene expression in cells and transgenic animals (28).

As outlined in the introduction, however, a system in which gene expression is induced by drug administration rather than by its withdrawal is highly preferable in the vast majority of gene therapy applications. To generate a Tc-inducible switch, the allosteric behavior of TetR was reversed. By combining chemical mutagenesis and genetic selection in *E. coli*, a mutant form of TetR was identified that carries four amino acid substitutions and is able to bind tetO only in the presence of tetracycline. Fusion of this mutated TetR to VP16 produced a reverse tTA (rtTA), capable of stimulating transcription only upon adding ligand (Tet-ON system, Fig. 4) (27). However, the same mutations that reversed the phenotype of tTR also affected its affinity for the inducer drug. In fact, rtTA was not induced by Tc and was about 100-fold less responsive to Dox than tTA (27). As a consequence, maximum activation of rtTA is achieved at Dox concentrations as high as 1–3 μg/ml, which is only about 5-fold lower than the toxic dosage for mammalian cells (29). Moreover, rtTA displayed a significant basal activity that was mainly due to a residual binding of rtTA to

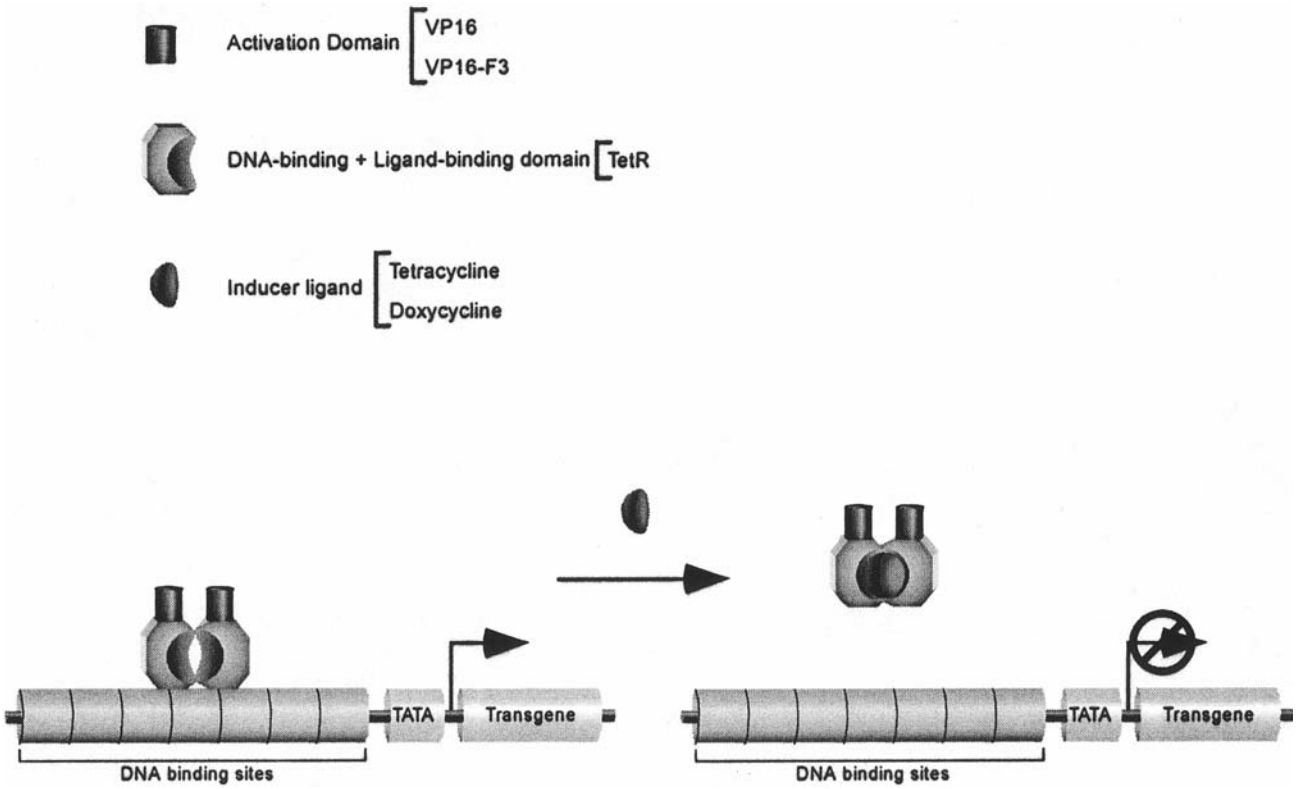

Figure 3 tTA-based, Tet-OFF system. tTA consists of the tetR fused to VP16 or VP16-derived activation domain. In the absence of the inducer drug, tTA binds and activates a promoter consisting of a minimal TATA box containing promoter located downstream of seven tet operator (tetO) sites. Upon addition of Tc or Dox, tTA is released from DNA and the promoter becomes inactive. For the sake of simplicity, only one molecule of tTA is represented.

tetO in the absence of the inducer Drug (28–30). Both factors limit the potential of tTA for gene therapy applications (see below).

More recently, improved versions of rtTA have been isolated by functional selection in yeast (30). These novel transactivators, called rtTA2^S-S2 and rtTA2^S-M2, carry different mutations compared to rtTA but retain Dox-dependency and display considerably lower activity in the off state (30–33). These latest versions of the rtTA also carry an optimized activation domain (VP16-F3) consisting of three tandem repeats of a 12 amino acid peptide derived from the VP16 activation domain (34). Finally, the cDNAs for these novel transactivators have been optimized for expression in human cells. Because of their lower leakiness, both rtTA2^S-S2 and rtTA2^S-M2 were better inducers than rtTA and enabled hundreds-fold stimulation of gene expression in transiently and stably transfected cells (30–32). rtTA2^S-S2 displays the lower uninduced activity between these two novel versions, thus enabling more stringent control. rtTA2^S-M2 is more responsive to Dox, as it is about 10-fold more sensitive to Dox than rtTA and is fully induced by Dox concentrations as low as 100–200 ng/ml (30,33).

A modified version of the tet system has been used to repress transcription in a ligand-dependent manner. Dox-dependent silencing was achieved by fusing the transrepressor KRAB (Kruppel-associated box) domain of the human Kid protein to the tetR (35,36). In the absence of Dox, this transrepressor, called tTS, was able to silence a CMV promoter engineered to contain seven tetO sequences in its 5′ region (36). In the presence of the effector molecule, tTS is released from DNA and gene expression is induced. For the reasons outlined above, systems based on repression are probably not appropriate for gene therapy.

More interestingly, tTS has now become a standard technology in combination with rtTA to repress basal activity in uninduced conditions, thus widening the regulatory window of the Tet-ON system. A tTS unable to heterodimerize with rtTA was designed, which contains a dimerization domain of different class specificity compared to rtTA (37,38). As indicated in Fig. 5, in the absence of Dox, tTS binds to *tetO* and inhibits basal transcription: as Dox is added, tTS dissociates from the target DNA while rtTA becomes active and triggers transcription (37,38). Coexpressing tTS and rtTA (rtTA/tTS system) reduces the basal expression to almost un-

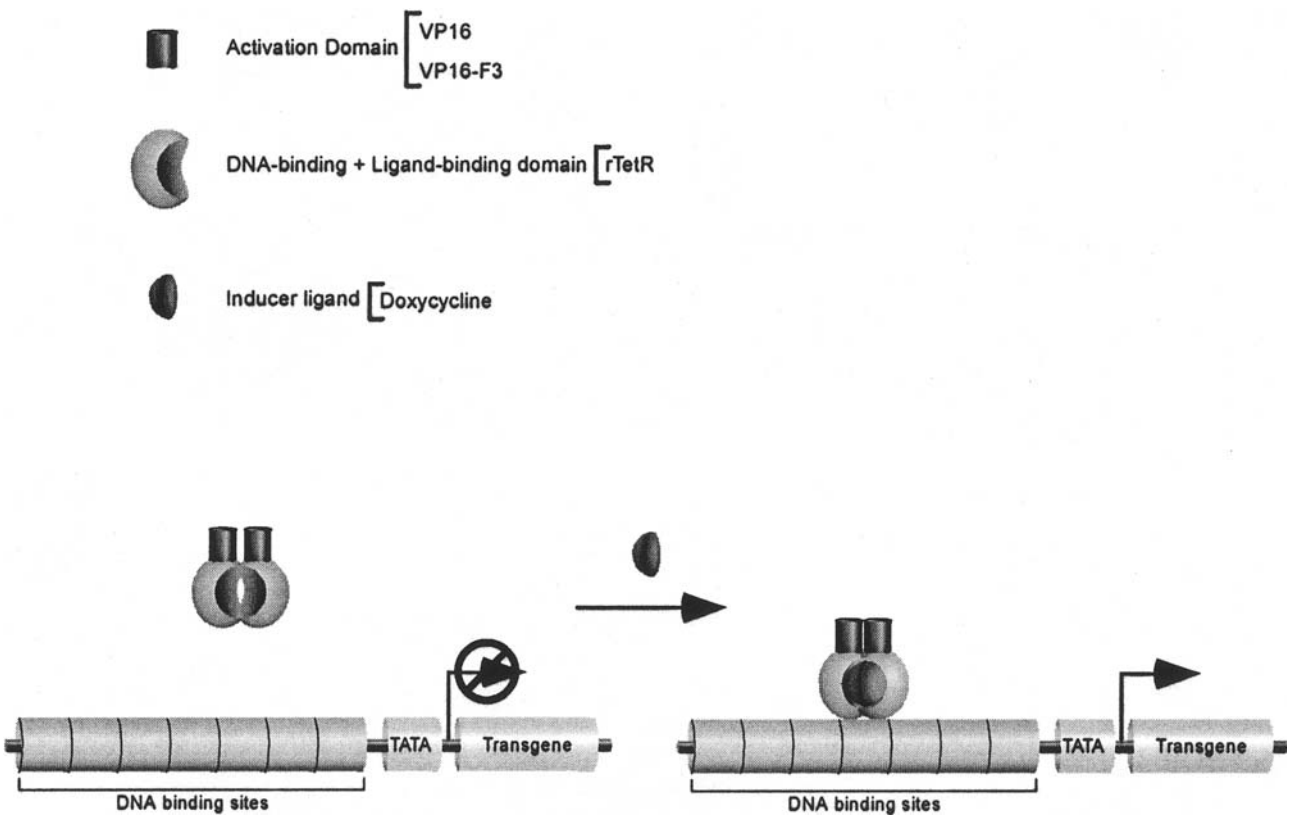

Figure 4 rtTA-based, Tet-ON system. rtTA consists of rTetR fused to an activation domain, usually derived from VP16. rtTA is inactive in the absence of the drug: following Dox administration, it binds and activates the target promoter. See text for additional details.

detectable levels in vivo (39–43). Despite these attractive features, one drawback of the rtTA/tTS system is that it is fully active only at high (μg/ml) Dox concentrations, because of the low responsiveness of rtTA to Dox (33,37,44). From this viewpoint, the use of the most advanced version of rtTA in combination with tTS proved useful. The properties of rtTA/tTS, rtTA2^S-S2/tTS, and rtTA2^S-M2/tTS combined systems have been compared in a recent study (33). Both rtTA2^S-S2/tTS and rtTA2^S-M2/tTS displayed a lower baseline activity and a 10-fold expanded dynamic range of induction than rtTA/tTS, with thousands-fold induction measured in Dox-treated cells in the absence of detectable leakiness. Moreover, the rtTA2^S-M2/tTS system displayed the highest Dox sensitivity, as it became fully active at concentrations as low as 100–200 ng/ml of Dox (33). Of course, the greater Dox-responsiveness of rtTA2^S-M2/tTS makes this system more suitable for gene therapy applications in humans.

C. Tet-responsive Promoter

The Tet-responsive promoter in its more classical configuration ($P_{hCMV*-1}$, also called P_{tet-1}) consists of a minimal version of the human cytomegalovirus immediate-early promoter fused 5′ to a heptameric tetO repeat (tetO7) (29). In this configuration, the promoter may display a relatively high leakiness because of the intrinsic basal activity of the CMV minimal promoter (29). The use of different minimal promoter sequences, such as a modified mouse mammary tumor virus (MMTV) promoter or a core promoter derived from the plant viral 35S promoter, decreases the basal activity of the Tet-responsive promoter by one order of magnitude (45,46). However, such promoters are also considerably less potent than $P_{hCMV*-1}$ upon induction with Dox: therefore, it may be particularly appropriate to use them in those cases where stringency of control is the most critical factor. It is worth mentioning that the leakiness of $P_{hCMV*-1}$ is effectively suppressed by tTS also when coexpressed with the various activators (see above).

The heptameric version of the tetO was initially evaluated as the most potent operator, and therefore little or no effort was dedicated to modifying this architecture (26). In point of fact, the heptameric sequence is the standard target sequence for tTA, tTS, and the various versions of rtTA. It has been recently reported that IFNα-stimulated response elements (ISREs) are located in the linker regions between the heptam-

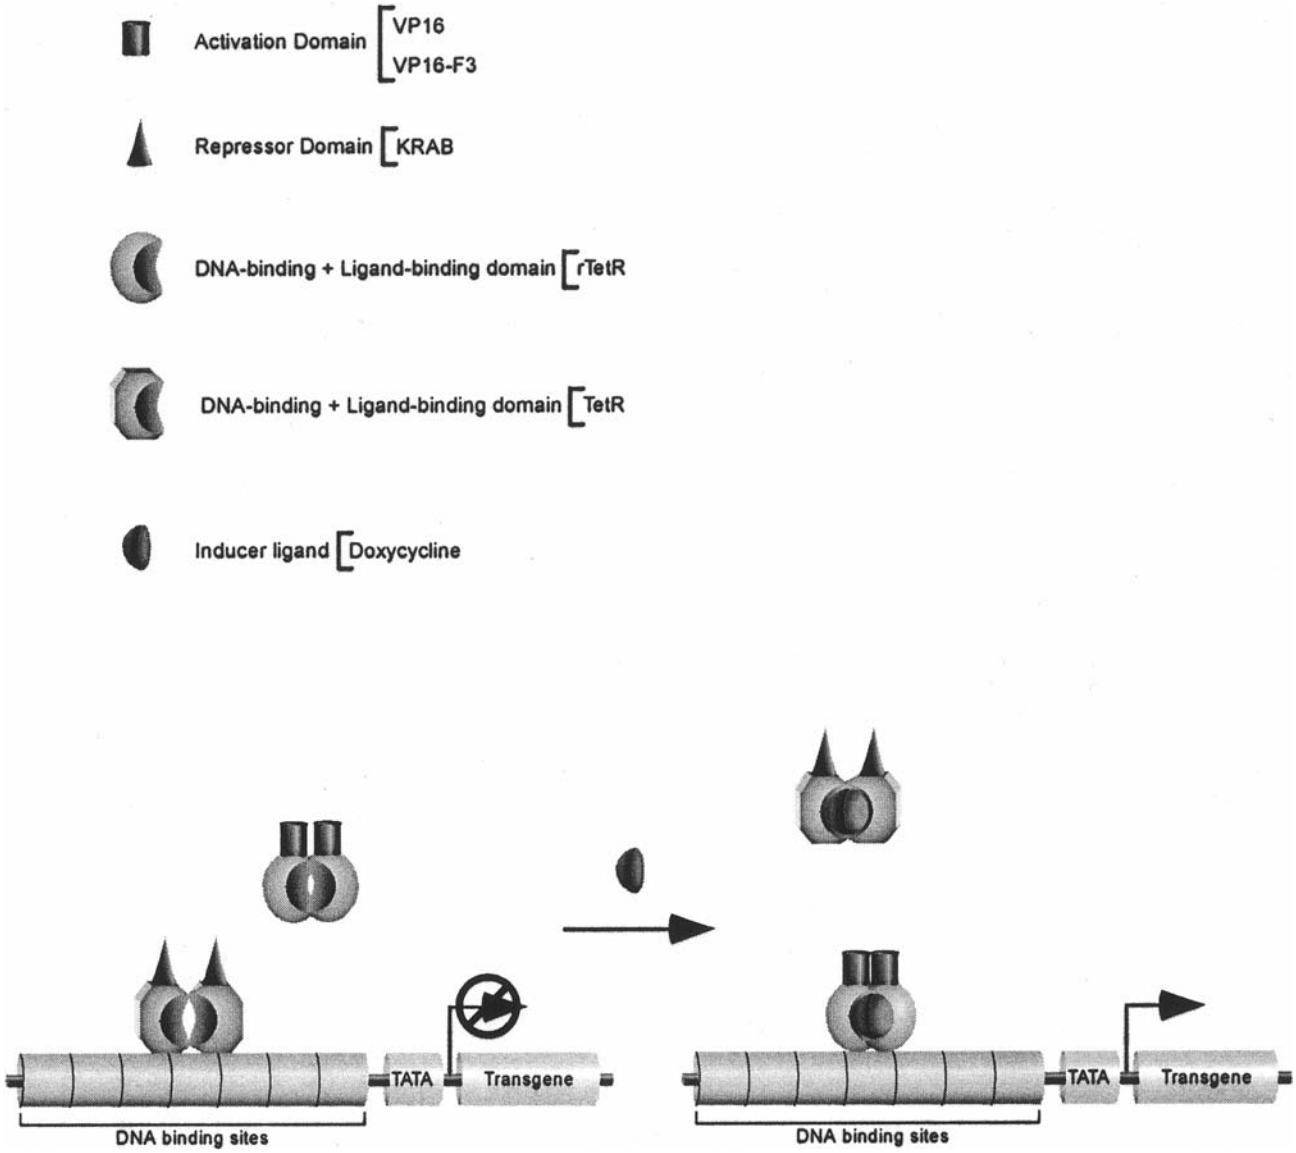

Figure 5 rtTA/tTS-based system, Tet-ON system. rtTA consists of rTetR fused to the VP16 activation domain and tTS consists of TetR fused to the KRAB repressor domain. rtTA and tTR recognize the same DNA sequence but cannot dimerize because they carry dimerization domains of different class specificity. In the absence of Dox, tTS binds and represses the target promoter. Following drug administration, tTS is released from DNA while rtTA interacts with the target promoter, thus triggering gene expression.

eric tetO sequences (47). Consequently, IFNα can stimulate tet promoter activity, thus interfering with the stringency of gene control (47). To avoid undesired induction, these ISREs would probably have to be deleted before this system can be used in humans.

D. Tet System for Gene Therapy Applications

The various versions of the Tet systems have been delivered in animal models by a variety of vectors and in several different tissues to regulate expression of reporter as well as therapeutic genes (29).

The tTA system has been and continues to be used to regulate transgene transcription in vivo in a variety of animal models (48–54). However, because of the unfavorable properties of an OFF-system in vivo, these reports can be considered as interesting proof-of-concept studies, which are nonetheless unlikely to move from the preclinical to the clinical setting.

In contrast, results obtained with the various configurations of the Tet-ON system are of greater interest and forecast future

outcomes in humans. A few reports, listed in Table 1, have indeed demonstrated that the original rtTA-based system, delivered in mice and nonhuman primates using both viral and nonviral vectors, can be used for long-term regulation of gene expression in a Dox-dependent manner (55–58). However, a certain leakiness was observed, especially in those cases where rtTA was used for modulating expression of high-potency protein hormones, such as erythropoietin (Epo), the major regulator of erythropoiesis in mammals (59). In this case, even the low amount of protein produced in the uninduced state stimulated a hematocrit (Hct) increase in untreated mice (31,55,57).

In vitro and in vivo leakiness was more pronounced in those cases where the rtTA cDNA was cloned downstream of strong enhancer/promoter elements and inserted with the tet-responsive gene into the same vector (55,60). This type of configuration probably results in very high intracellular concentrations of rtTA, which may thus unspecifically activate transcription. Moreover, the basal activity may be increased by the interference between the regulatory elements driving rtTA expression and the intrinsically ''leaky'' $P_{hCMV*-1}$ promoter. As a matter of fact, more efficient control could be achieved by splitting the system into two vectors, thus allowing to cells to be transduced with substoichiometric amount of transactivator with respect to the regulated gene (56,57,61).

As expected on the basis of in vitro results, the novel versions of rtTA enabled tighter control when used in vivo (Table 1). Better results were obtained with the less leaky $rtTA2^S$-S2. In a mouse model of hepatitis, intrahepatic delivery of a gutless-Ad vector carrying an $rtTA2^S$-S2-regulated IFNα protected mice from the disease: protection was only observed in mice treated with Dox, which stimulated IFNα production in a Dox-dose dependent manner (62). $rtTA2^S$-S2 also enabled tight control of Epo gene when delivered intramuscularly by electroinjection as plasmid DNA (31). Epo production and Hct levels could be modulated up to 300 days postinjection in response to Dox delivery and withdrawal, in the absence of any background expression in untreated mice. Notably, this result was achieved by using a single plasmid containing a CMV-$rtTA2^S$-S2 expression cassette and the tet-responsive Epo gene (31). In the same experimental setting, $rtTA2^S$-M2 displayed a certain degree of leakiness, which was, however, much lower than that of rtTA (31). The leakiness of $rtTA2^S$-M2 was also evident in another study, in which a gutless-Ad vector containing $rtTA2^S$-M2-regulated secreted alkaline phosphatase (SEAP) gene was delivered into mouse muscles (63). In vivo experiments thus confirmed that $rtTA2^S$-S2 represented a major improvement over rtTA in terms of basal activity. Moreover, Dox-dose response experiments demonstrated that the system is activated in mice by oral dosages of Dox comparable to those normally used in clinical practice in humans (31). Nonetheless, vector-dose response experiments demonstrated that the tightness of control is partially lost at higher vector doses, thus imposing an upper limit to the amount of vector that can be delivered (31,33,62). Use of this activator may be appropriate in those cases in which a certain degree of basal expression level is acceptable.

Coexpression of tTS has been adopted as an alternative strategy to reduce the basal activity of rtTA following in vivo delivery. For historical reasons, initial studies involved the use of tTA with rtTA (Table 1). In a first study, the system

Table 1 Tet-on System: In Vivo Studies in Animal Models of Gene Therapy

[a] GFP = Green Fluorescent Protein; Epo = erythropoietin; GH = Growth Hormone; IFNα = Interferon α; SEAP = Secreted Alkaline Phosphatase; IL10 = Interleukin 10.

was split into two AAV vectors: a regulatory vector expressing in a constitutive manner rtTA and tTS, and a reporter vector containing a tet-responsive Green Fluorescent Protein (GFP) cDNA. The two vectors were coinjected subretinally in mice at a 1:1 ratio: GFP expression was only detected in Dox-treated animals, with no evidence of basal expression in untreated mice (39). Similarly, a binary AAV vector system injected into rat hypothalamus was used to regulate leptin expression in a Dox-dependent manner (43).

However, more sophisticated vector architecture was required to tightly control Epo expression using a binary AAV system. Because of its highly specific activity, Epo expression in the uninduced state was further decreased. This was achieved by modifying the architecture of the reporter AAV vector, which in this case contained both Epo and tTS under the control of the $P_{hCMV^{*}\text{-}1}$ tet-responsive promoter (40). Intramuscular coinjection of this vector with the rAAV expressing rtTA and tTS allowed a stringent control over an 8-month period, with the untreated mice showing normal Hct levels for the whole duration of the experiment. Repeated cycles of induction were successfully performed, indicating that the silencer did not interfere with reinducibility of the system (40). The fact that leakiness is strongly dependent on vector structure is also suggested by a recent study reporting an efficient but not absolutely tight control of IL-10 expression upon intramuscular electroinjection of plasmid DNA (42). Also in this case a combination of two-vector system was used, but the vector containing the inducible IL-10 also expressed rtTA, with tTS being expressed from the other plasmid vector (42). Results with the rtTA/tTS system thus demonstrated that tTS significantly reduced the basal activity of the system in vivo, provided that vector architecture is optimized.

In a further advanced and more recent version of the system, the repressing activity of tTS has been combined with the reduced leakiness and enhanced Dox-responsiveness of the $rtTA2^{S}$-M2 (Table 1). Bicistronic cassettes have been constructed that coexpress tTS with the novel $rtTA2^{S}$-M2 activator via an internal ribosome entry site. When tested in transient transfection, this cassette mediated 10^{4}-fold induction of reporter gene expression in a strictly Dox-dependent manner and with no detectable leakiness (33). When used in the context of gutless-Ad vectors or of plasmid DNA delivered into mouse muscles, the $rtTA2^{S}$-M2/tTS system mediated thousands-fold induction of SEAP expression, with no basal activity in uninduced mice (33,60). Maximum induced levels were comparable to those achieved with vectors expressing SEAP under the control of the CMV enhancer/promoter element mice, confirming the efficiency of the system (33,60). The same $rtTA2^{S}$-M2/tTS switch delivered as plasmid DNA in mouse muscles mediated stringent modulation of Epo gene expression over a 1-year period (33). With both adenoviral and plasmid vector, transgene expression was strictly dependent on Dox administration and completely extinguished upon Dox withdrawal: moreover, the tightness of control was maintained also at high vector doses (33,60). Dox-dosing experiments demonstrated that the extent of Epo gene expression, and of the consequent Hct increase, could be finely modulated over a 1-year period by varying oral Dox dosage (33). The reliability of the $rtTA2^{S}$-M2/tTS system was confirmed by the tight control of SEAP expression observed in Rhesus monkeys upon intramuscular electroinjection of plasmid DNA (33). Of interest for potential application in humans, the system was fully induced in mice and nonhuman primates by Dox-dosing regimens comparable to those used in the clinical practice (33).

E. Inducer Drugs

A major advantage of tetracyclines is the broad knowledge we have about their pharmacological and chemical properties, as several members of this class of compounds have been used in human and animal medicine for decades. As indicated above, doxycycline efficiently stimulates both the Tet-OFF and the Tet-ON system, and was therefore used as the effector of choice in animal models.

With its efficient oral absorption (93%), prolonged half-life (14–22 h), and excellent tissue penetration, Dox would be the ideal agent also for controlling the Tet-system in a human gene therapy setting (64). Experiments in animals (see above) and theoretical considerations strongly indicate that the latest versions of the ON systems, which are fully activated at Dox concentrations of about 200 ng/ml, will be efficiently stimulated in vivo by the Dox therapeutic regimen commonly used for antibiotic therapy. In fact, administration of 200 mg of Dox in humans produces peak serum concentration of 3 μg/ml after 2 h, with a plateau-shaped concentration curve that remains over 1 μg/ml at 24 h. Also, lower dosages should be effective: for instance, following administration of 20 mg Dox, twice a day, the mean peak concentration in plasma is about 800 ng/ml and the average steady-state concentration is about 400 ng/ml (64) and references therein]. Because of its capacity to penetrate the blood-brain barrier, Dox has the potential to modulate gene expression in the central nervous system (CNS), as extensively demonstrated in animals. Finally, the principal excretory organ for Dox is intestine, thus rendering this drug useful also in cases of preexisting renal disfunction (64).

Dox is usually well tolerated: the most serious side effect is photosensitivity (characterized by overreaction to sunburn). It is dose-dependent and may occur in 1–3% of the patients after prolonged (several months) therapy. Since Dox accumulates in the bones, it may cause yellow-brown coloration of the teeth. In conclusion, Dox has an excellent safety profile for short-term (i.e., a month or less) applications: less is known on the potential adverse effects following more prolonged administration.

Finally, the major concern on the use of an antibiotic-driven regulatory switch is the possibility of raising resistance to the antibiotic itself (64). Actually, tetracyclines are less used than in the past, but may represent the treatment of choice for serious diseases, like anthrax, Lyme disease and Rickettsial disease. Therefore, nonantibiotic Dox analogs capable of activating the Tetsystem would be desirable in a clinical context.

F. Perspectives

During the past years the tet system has been significantly improved in terms of basal activity, inducibility, and sensitivity to the inducer drug. The latest versions of the Tet-ON activators and the tightness guaranteed by the tTS suppressor have significantly enhanced the potential of this system for gene therapy applications.

An attractive feature of the system is its flexibility, which allows generation of a set of TetR protein derivatives with different phenotypes, but which still maintains the main characteristic of the wt protein: ligand-regulable binding to a specific DNA sequence. An example was the construction of tTA and rtTA homodimers that recognize different promoters and respond differentially to the various tetracyclines (65,66). We can thus expect novel versions of the Tet-Off and Tet-On system to be available in the future.

The Tet system uses prokaryotic elements and might therefore prove immunogenic in humans. It has been demonstrated that activators could be partially humanized by substituting the VP16 AD with ADs derived from human proteins (such as the p65 activation domain from human NF-kB and the activation domain from E2F4) without loss of efficacy (67,68). Nonetheless, the core of the activators is of bacterial origin and its immunogenic potential may limit its application to the short-term range in humans.

Until now, no immune response in mice against the tet system delivered with viral and nonviral vectors in a great variety of tissues has been reported. On the contrary, recent studies suggest that intramuscular injections of plasmids or viral vectors expressing Dox-dependent activators may elicit a cellular and humoral response against Tet-ON activators in nonhuman primates (58,69). Of course, this is an issue of primary importance and must be carefully and extensively studied in further works. Among the possible strategies that could be applied to reduce the potential immunogenicity of the activators are: immunosuppression of the host at the time of vector delivery, use of vectors with low intrinsic immunogenicity, such as AAV, and using tissue-specific promoters to restrict expression of the exogenous genes to nonprofessional antigen-presenting cells. Testing these and other strategies in nonhuman primates will probably be the major challenge in the near future.

III. NOVEL INDUCIBLE EUKARYOTIC GENE EXPRESSION SYSTEMS BASED ON PROKARYOTIC ELEMENTS

In recent years significant efforts have been directed to developing additional transcription systems which, along the same basic principle exploited by Bujard and colleagues (26), utilize well-known, ligand-induced, transcriptional activators taken from the bacterial world and convert them into eukaryotic transcription factors via simple manipulations such as the addition of ADs. The advantage of these systems is that they rely on DNA binding proteins that: a) do not interfere with eukaryotic transcriptional networks, b) recognize DNA binding sites that are not bound by mammalian transcription factors, and c) are capable of binding with high affinity distinct classes of small molecular weight ligands, some of them already used in the clinic. Although these new systems have not yet reached the same level of preclinical characterization of the Tet system, they show highly interesting properties for future translation to clinical applications.

A. A Switch Based on the Quorum-sensing Transcription Factor TraR

Bacteria are capable of ''sensing'' fluctuations in their population density, and respond by changing the pattern of gene expression. This response, called Quorum Sensing, is based on a simple mechanism consisting of a signal molecule, an acylated homoserine lactone (AHL) that accumulates in the immediate external environment, and a cognate transcription factor that it activates (70). Over 50 species of gram-negative bacteria produce AHLs that differ in the acyl side chain: an attractive feature of this two-component regulatory system is the existence of several variants in nature. The bacterial quorum sensing system represents a natural combinatorial library that could be exploited to generate reagents for the development of artificial eukaryotic gene regulation systems. To this end, it is necessary to reengineer the prokaryotic basic module, i.e., the signal and its cognate ''receptor,'' so it may function in eukaryotic cells.

TraR belongs to the LuxR family of transcriptional activators (70,71,72). Binding the small, diffusible *Agrobacterium* quorum-sensing signal 3-oxo-C8-HSL (Fig. 6) results in TraR activation and subsequent interaction with promoters containing one or more copies of an 18-bp inverted repeat called *tra* box (73–75). The 3-dimensional structure of TraR has recently been solved. The protein consists of two separate domains; an N-terminal domain with ligand-binding and dimerizing properties, and a C-terminal domain that binds DNA (76,77). This modular structure makes the LuxR family of transcriptional activators a promising candidate for genetic manipulation.

A hybrid transcription factor was generated by fusing the activation domains VP16-F3 or p65 N-terminally to the cDNA fragment corresponding to the TraR wt protein (34,78). Both activation domains were separated from TraR by a short amino acid linker (79). In addition, a nuclear localization signal was added to the linker region of p65 in order to ensure nuclear localization of the chimeric protein. As in the case of authentic TraR, the chimeric transcription factors bind to DNA containing a *tra* box only in the presence of a cognate ligand, such as 3-oxo-C8-HSL (79). Importantly, 3-oxo-C8-HSL must be present during the protein synthesis reaction, in accordance with previous findings that the ligand is necessary for proper folding of TraR (80,81). In fact, the 3-dimensional structure shows that the ligand-binding site is deeply embedded in the protein core. This requirement brings the advantage that the system is totally silent in the absence of the ligand, but is

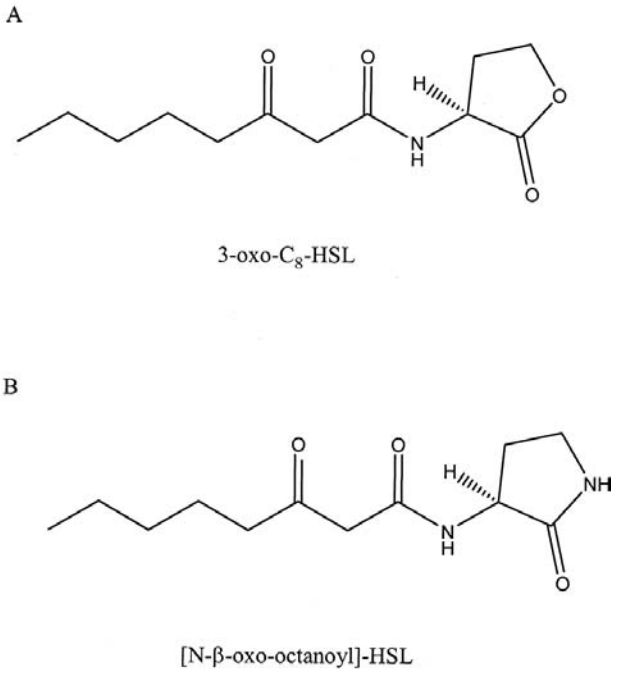

Figure 6 Chemical structure of acylated homoserine lactone molecules, inducers of the TraR-based system. (A) *Agrobacterium* quorum sensing *N*-(3-oxo-octanoyl)-homoserine lactone (3-oxo-C_8-HSL); (B) Synthetic [N-β-oxo-octanoyl]-homoserine lactam.

limited by there always being a substantial time lag between cell exposure to AHL and gene activation.

It was observed that the affinity of 3-oxo-C8-HSL for the ligand-binding domain of TraR does not significantly change in the context of the chimeric protein. However, the apparent affinity of 3-oxo-C8-HSL for TraR in eukaryotic systems is lower than in bacterial strains (μM vs. nM, respectively) (79). The reason for this is not presently understood, and future work will be needed to address this issue. P65NtraR and F3-TraR induced transcription of gene clones downstream of TraR-responsive promoters in eukaryotic cells (Fig. 7). The highest inducibility was obtained with p65NtraR acting on a target promoter consisting of seven *tra* boxes. The leakiness was low, and adding 3-oxo-C8-HSL to the cell culture medium led to strong induction of gene expression, comparable to the activity of the constitutive CMV enhancer/promoter. Robust induction of SEAP expression in the presence of p65NtraR and 3-oxo-C8-HSL was shown in different human cell lines, and TraR induction was dose-dependent for 3-oxo-C8-HSL, reaching up to 1000-fold induction (79).

A lactone moiety, which undergoes spontaneous lactonolysis upon prolonged exposure to aqueous conditions (82), is invariably present in all the quorum sensing signal molecules of the LuxR family of transcriptional regulators (70). The limited chemical or enzymatic stability of lactones thus poses an obstacle to future development of this system. In the attempt to design a ligand more suitable for experiments in eukaryotes, Nedderman et al. (79) synthesized [N-β-oxo-octanoyl]-homoserine lactam (Fig. 6). Notably, the [N-β-oxo-octanoyl]-homoserine lactam was stable under experimental conditions and nontoxic up to a concentration of 500 μM. The affinity of p65NtraR for the lactam was about 10-fold lower than that for 3-oxo-C8-HSL (EC_{50} 70 μM vs. 6 μM); nonetheless, because of the nontoxic nature of the compound, strong induction was achieved by using higher concentration (hundreds μM) of the compounds (79). Thus, in spite of the striking conservation of the lactone ring in natural quorum sensing signal molecules, it is possible to develop compounds that combine increased stability with biological activity.

In conclusion, although the characterization of this new system is still preliminary, its low basal transcriptional activity and the robust dose-dependent induction offer significant advantages. Its general properties suggest that it is perhaps possible to engineer other LuxR proteins that respond to different AHLs and thus increase the repertoire of genes whose expression could be simultaneously regulated, provided that the cognate AHL for one LuxR protein does not activate the others.

B. Streptogramin- and Macrolide-responsive Systems

In recent years, M. Fussenegger and colleagues have developed two regulatory systems which, similar to the Tet system, are based on naturally evolved mechanisms of antibiotic resistance.

1. Streptogramin-responsive System

A gene regulatory system was developed based on a Streptomyces antibiotic resistance operon (83). To tolerate their own antibiotic products, Streptomyces have developed various resistance mechanisms. A pristinamycin resistance operon was identified and cloned from *S. pristinaespiralis*. *S. pristinaespiralis* produces pristinamycin, a composite streptogramin antibiotic consisting of a pair of structurally unrelated molecules: pristinamycin I (PI, also called Streptogramin B), a cyclic hexadepsipeptide, and pristinamycin II (PII; also called Streptogramin A), a polyunsaturated macrolactone (84). *S. pristinaespiralis* genome codes for an efflux-type pristinamycin-resistance determinant (*ptr*), whose expression is induced by pristinamycin itself. A repressor protein, called Pip (pristinamycin induced protein), binds to the *ptr* promoter (Ptr) and represses transcription of the resistance gene. In the presence of pristinamycin, the antibiotic binds to Pip, and this results in the release of Pip from Ptr and induction of gene expression (85). Similar to the Tet system, the pristinamycin repressible Pip-Ptr interaction was adapted for use in mammalian cells. Two configurations were developed: PipOFF and PipON (Fig. 8).

In the PipOFF system, a pristinamycin inducible transactivator (PIT) was obtained by fusing Pip to the VP16 activation domain, and a PIT responsive promoter, called Ppir (pristinamycin repressible promoter) was constructed by combining

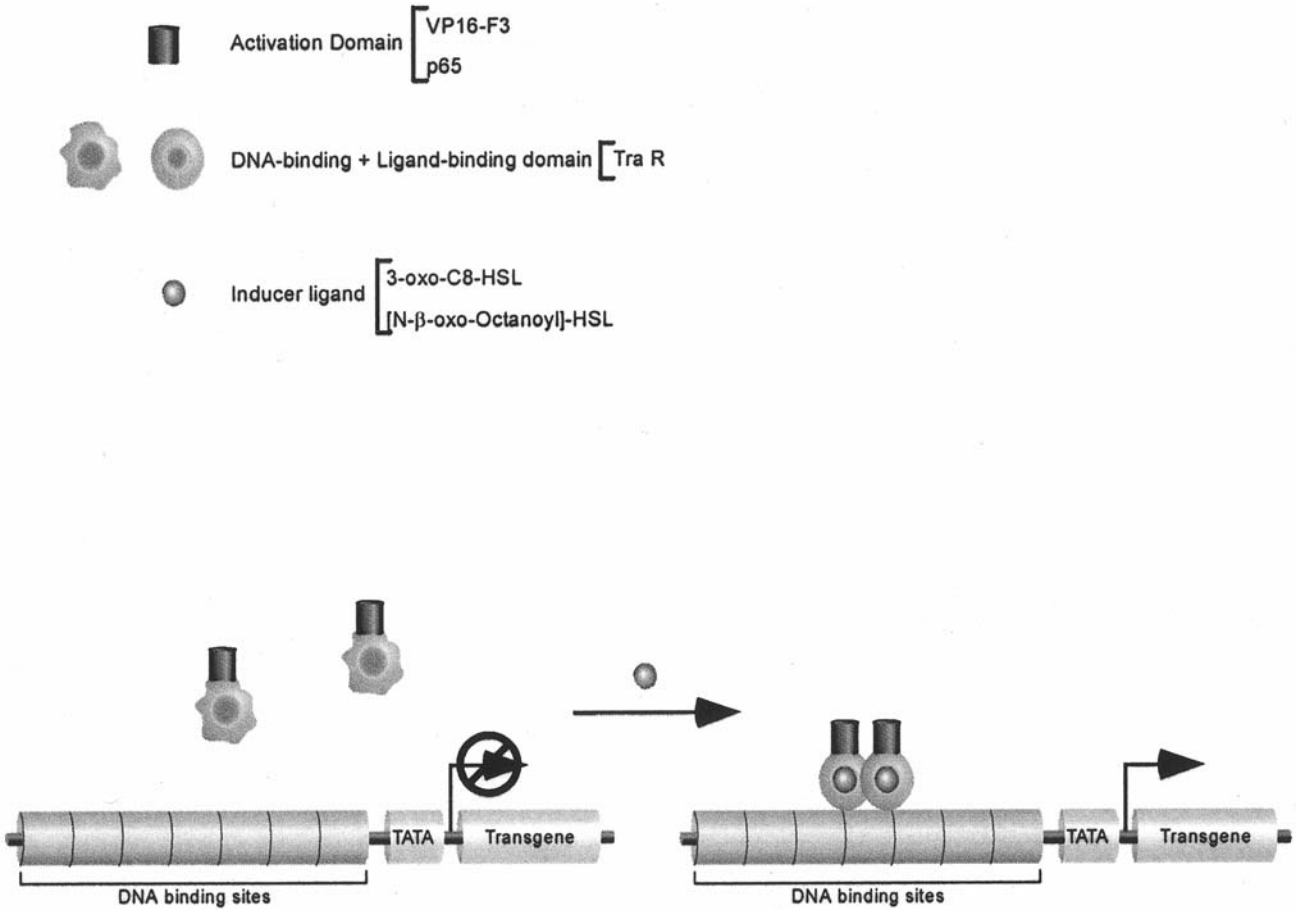

Figure 7 TraR-based regulatory system. The activator consists of TraR fused to an activation domain. In the absence of the ligand, the protein is unfolded: drug administration promotes appropriate folding of the chimera, which acquires the capability of binding and activating a target promoter containing multimeric TraR binding sites. See text for additional details.

three Pip operator sequences with a minimal promoter from Drosophila heat-shock protein 70 gene ($P_{hsp70min}$). In the absence of the ligand, PIT binds and activates Ppir, whereas the system is silenced in the presence of the antibiotic, which disrupts PIT-Pir interaction (83).

The PipON system is based on the use of Pip coupled with a pristinamycin-inducible promoter (PpirON, also called PSV40-PIR3), which consists of multiple Pip operator sequences cloned downstream of the SV40 strong constitutive promoter. In the absence of the antibiotic, Pip binds to PpirON and blocks the SV40 driven expression: in the presence of the antibiotic, Pip is released and gene expression induced. In the PipON configuration, fusing Pip with the KRAB repressing domain further enhanced its repressing capability: in this configuration, the system displays a 10-fold lower basal activity but also a reduced maximal activity (83).

Both systems have so far been tested only *ex vivo* in mammalian cells, by transient transfection or retroviral infection. They enabled hundreds-fold induction of reporter gene expression and displayed a relatively low basal activity. Interestingly, the PipON and PipOFF systems are only responsive to PI (Fig. 9), while PII had no effect. This finding is of interest when translated into a human therapeutic context: in fact, the use of PI alone as a stimulatory molecule is unlikely to elicit broad antibiotic resistance against composite streptogramin (PI + PII) (85).

2. Macrolide-responsive System

More recently, Fussenegger and colleagues developed a system regulated by macrolide antibiotics, such as erythromycin (EM), whose structure is shown in Fig. 10. Also in this case, the key elements derive from an antibiotic resistance operon. The *Mph(A)* gene codes for a 2′-phosphotransferase that inactivates 14-membered macrolides (85). Its expression in basal conditions is repressed by a prokaryotic repressor, MphR(A), which binds to a 35-bp operator sequence (ETR) overlapping

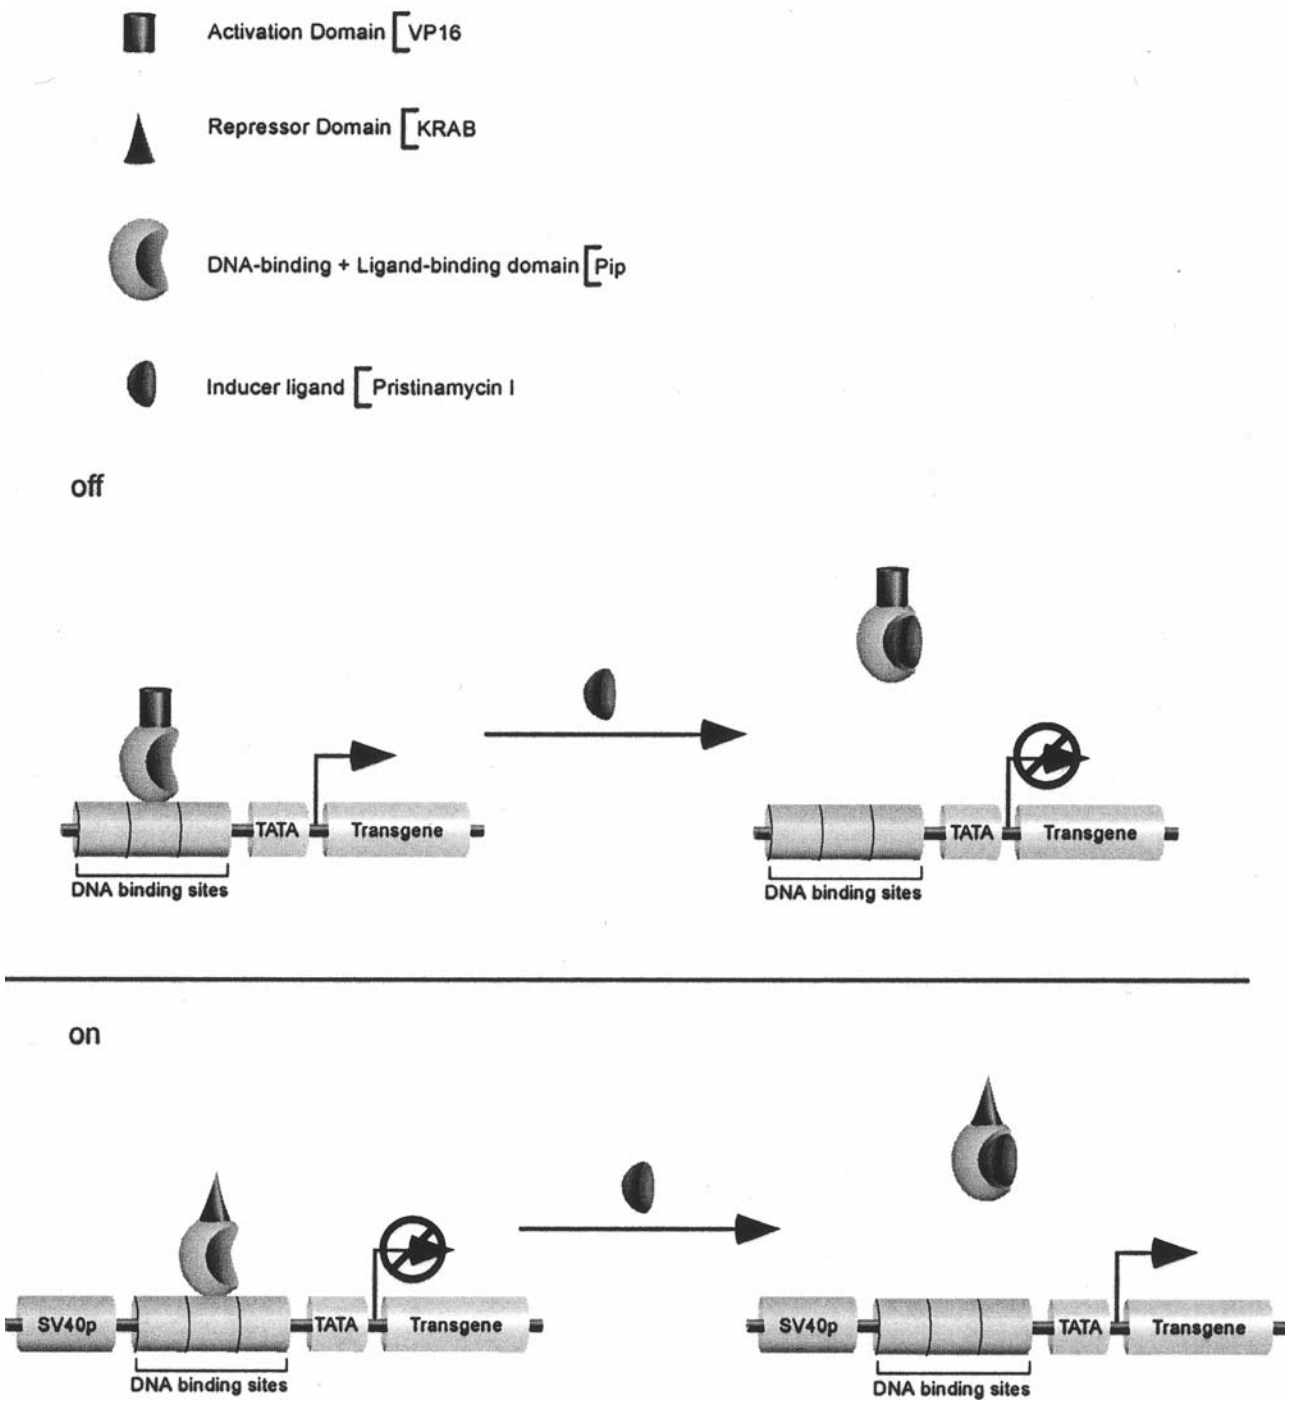

Figure 8 Streptogramin-responsive system. PipOFF: the chimeric activator (called PIT) consists of Pip fused to an activation domain. In the absence of pristinamycin, it binds and activates the target promoter consisting of three Pip binding sites (operator sequences) upstream of a minimal promoter. In the presence of the ligand, PIT is released from DNA and transcription is terminated. PipON: the chimeric repressor consists of Pip fused to the KRAB repressor domain and the target promoter consists of Pip operator sequences cloned downstream of the SV40 promoter. In the absence of the drug, the Pip-KRAB fusion binds to its target sequences, thus silencing the SV40 promoter. Drug administration results in release of the Pip-KRAB fusion from DNA and consequent derepression of the SV40 promoter. The macrolide-responsive system operates according to the same principles. See text for additional details.

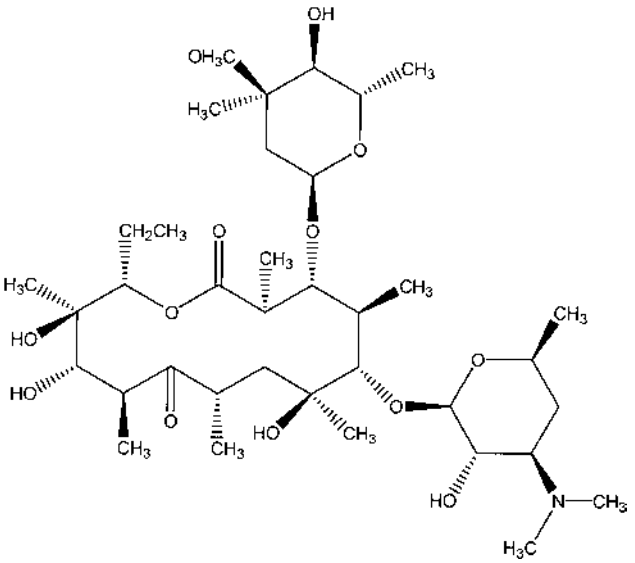

Figure 10 Chemical structure of erythromycin, inducer of the macrolide-responsive system. See text for additional details.

the *Mph*(*A*) promoter. Upon binding to EM, MphR(A) dissociates from its target DNA sequence, thus allowing transcription of *Mph*(*A*) gene (85).

Very similarly to the streptogramin system, Erythromycin ON (E_{ON}) and OFF (E_{OFF}) systems were generated (86). The E_{OFF} system is based on an erythromycin dependent transactivator ET1, a fusion between MphR(A) and VP16, which binds to an erythromycin responsive promoter (P_{ETR}) consisting of the *Mph*(*A*) operator fused to $P_{hsp70min}$ minimal promoter. The E_{ON} switch relies on MphR(A)-KRAB fusion binding to an artificial ETR octamer cloned downstream of the SV40 promoter. As expected from the ligand-binding and DNA-binding properties of MphR(A), and similar to the streptogramin systems, the E_{OFF} and E_{ON} systems are activated by drug withdrawal and administration, respectively. Also in this case, MphR(A)-KRAB fusion proteins increased the stringency of the E_{OFF} system. Hundreds-fold induction and low basal activity were reported in transient and stable transformants. In addition, both the on and off systems proved capable of regulating Epo expression in an EM dose-dependent manner from intraperitoneally injected stable transformants carrying the regulatory system and the regulated Epo gene (86).

Both the streptogramin- and the macrolide-responsive systems are still in their infancy and we can predict that, as happened with other systems, they will be progressively improved in terms of inducibility, potency, and drug-responsiveness. In line with this prediction is the recent report that the performance of both systems can be dramatically improved by introducing minor modifications to the molecular architecture of their target promoters (87).

An attractive feature of both systems is that they are activated by clinically licensed compound, which may facilitate their use, especially for short-term applications. As for the Tet system, the ON configurations have greater potential for gene therapy applications, but additional work in preclinical models will be required to more precisely evaluate the positive and, possibly, negative features of both systems.

IV. DIMERIZER-REGULATED SYSTEM

A. General Principles

The initial concept of using chemical dimerizers of protein-protein interaction in order to activate biological processes is due to the pioneering work of S. Schreiber and G. Crabtree (88,89). However, its further evolution and adaptations to a variety of applications, including transcriptional activation, is due mainly to the activity of the ARIAD Gene Therapeutics Inc. group. Several recent reviews have nicely summarized the work in this area (90–92).

The foundation of this system is the use of chemical dimerizers, small chemical entities with two distinct binding surfaces for identical or different polypeptides (89,92). The prototype molecule utilized for this purpose, FK1012, is a homodimer of the immunosuppressant drug FK506. It bears two identical, high-affinity, protein-binding surfaces for FKBP12, a 12-kDa cytoplasmic protein (88,89). FK1012 as

a protein homodimerizer is utilized mainly for ligand-induced receptor dimerization and activation of intracellular signaling, thanks to the use of chimeric receptors that contain the ligand-binding domain of FKBP12. These synthetic receptors have been engineered to undergo dimerization in the presence of FKBP binders but not of endogenous ligands (88,89,93).

The modular nature of eukaryotic transcription factors enabled the construction of a dimerizer-induced regulatory system (94). DNA Binding Domains (DBDs) and Activation Domains (ADs) can be expressed independently of each other. Each domain maintains its proper folding: a DBD bound to its target promoter is unable to activate transcription unless the AD is placed in close proximity. This simple concept has been extensively exploited in the setting of two-hybrid assays in yeast (95). By fusing a DBD and an AD with a drug-binding domain, assembling an active transcription factor thus depends on adding of a dimerizer-ligand capable of bridging the DBD and AD by simultaneously interacting with the drug-binding domains of the fusion proteins. In this context, however, fusion of the DBD and the AD with the same ligand-binding domain and the use of homodimerizing drugs are not appropriate, as it would also lead to the generation of inactive DBD-DBD and AD-AD homodimers. To prevent homodimerization, this system has been evolved to incorporate chemical heterodimerizers. Since no chemical entity is known with sufficient affinity and selectivity to bring together a DBD and an AD, attention has been directed to utilizing the natural targets of known chemical heterodimerizers. One such molecule is another immunosuppressant drug, rapamycin, a natural product macrolide (Fig. 11).

Rapamycin binds the immunophilin FKBP12 with a nanomolar affinity (96), and this complex interacts with FRAP (FKBP rapamycin-associated protein) (97) also called mTOR (mammalian target of rapamycin), a PI3-kinase homolog involved in control of cell growth and division (98). FKBP and an 89-aa fragment of FRAP, called FRB, sufficient to bind the FKBP-rapamycin complex (99), can be linked to a DBD and to an AD, respectively. These two components, namely DBD-FKBP and FRB-AD, associate noncovalently in the presence of rapamycin. A gene cloned downstream of a promoter containing sites recognized by the DBD-FKBP fusion is thus only transcribed in the presence of the dimerizer drug, according to the scheme shown in Fig. 12.

B. Transcription Factors

The dimerizer-regulated system was constructed by using protein domains of human origin in order to minimize its potential immunogenicity. DBD-FKBP and FRB-AD were thus generated by using human protein domains. The two heterodimerizing components FKBP and FRB are human proteins. The selected DBD, ZFHD1, is a composite DNA-binding domain with novel DNA recognition specificity (100). It is a 122 polypeptide constituted by a 58 aa zinc-finger domain from the natural human Zif268 zinc-finger protein linked via two glycine residues to the 62 aa POU domain of the human transcription factor Oct-1. The AD is derived from the carboxy-terminal region of the human transcription factor NF-kB p65 (78). The two transcription components have been called ZFD1-FKBP (the version that carries three tandem copies of FKBP, named ZF3, was initially selected because of its excellent drug-dependent activity in transfected cells) and FRB-p65, respectively (also called S1) (101). They can be expressed either from separate transcription units or from a single bicistronic transcript by means of the ECMV (encephalomyocarditis virus) internal ribosome entry site (IRES).

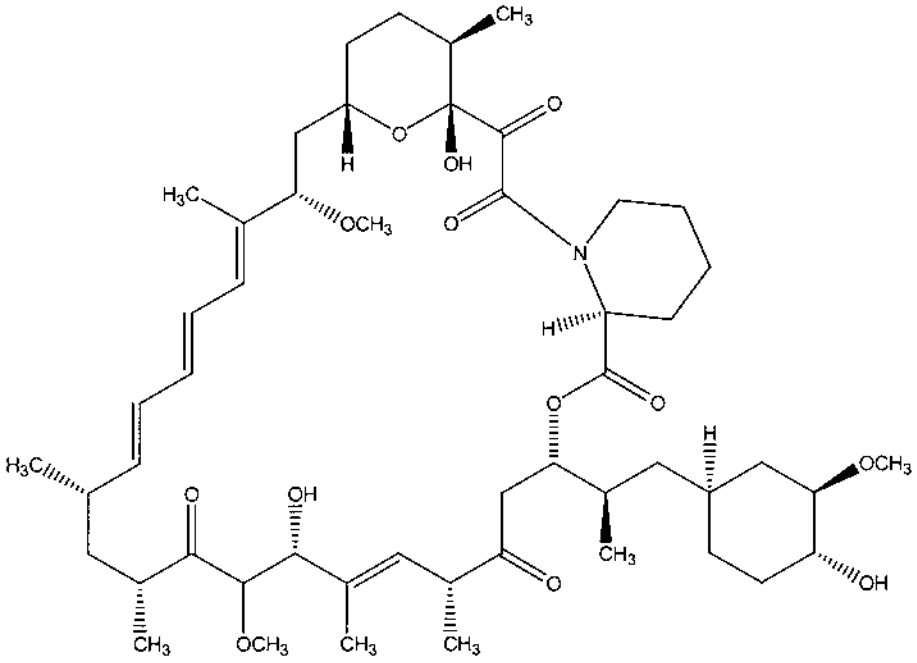
Further modifications/improvements of these transcription factors have been obtained, through the generation of more potent FRB-carrying components. A widely accepted concept is that enhancing the efficiency with which activators are delivered to a promoter strongly potentiates transcription efficiency (102). Linking two ADs, namely those of human p65 and of human heat shock factor 1, to FRB, generated a more potent factor (103). Use of this more potent factor may be appropriate when higher sensitivity is required, for example when low gene copies/cell are transduced by retroviral vectors (103). A second elegant example was the generation of FRB-p65 fusions that carry a portion of the *E. coli* lactose repressor between the two domains that form tetrameric bundles and therefore multimers of the AD (104). These improved activators induce higher maximum expression levels of the regulated reporter genes and are more responsive to rapamycin. However, while the first solution is entirely based on human proteins, the second suffers from the potential immunogenicity of its *E. coli*-derived component.

More recently, a system similar to that induced by rapamycin has been described that responds to nonimmunosuppressive analogs of FK506. FK506 heterodimerizes FKBP and calcineurin, a protein phosphatase that mediates the mitogenic stimuli from the T cell receptor (105). The FK506-FKBP binding interface of calcineurin is composed of aminoacid residues that belong to its component polypeptides, called can and CnB. Based on the X-ray structure of the FKBP-FK506-can-CnB complex, protein design was used to generate a synthetic calcineurin A-B fusion, called mCAB, which binds FKBP-FK506. A yeast three-hybrid system was then used to identify mCAB mutants that interact with FK506 analogs unable to bind calcineurin and therefore not immunosuppressive. A regulatory switch based on DBD-FKBP and mCAB-AD components was significantly activated by these FK506 analogs in transiently transfected cells (106). The potential of this system for gene therapy applications remains to be verified (see below).

C. Dimerizer-responsive Promoters

As with other ligand-dependent regulatory systems, dimerizer-responsive promoters are essentially composed of a downstream element, the minimal promoter, and an upstream element with a variable number of binding site(s) for the inducible transcription factor. The downstream elements used are

A



B

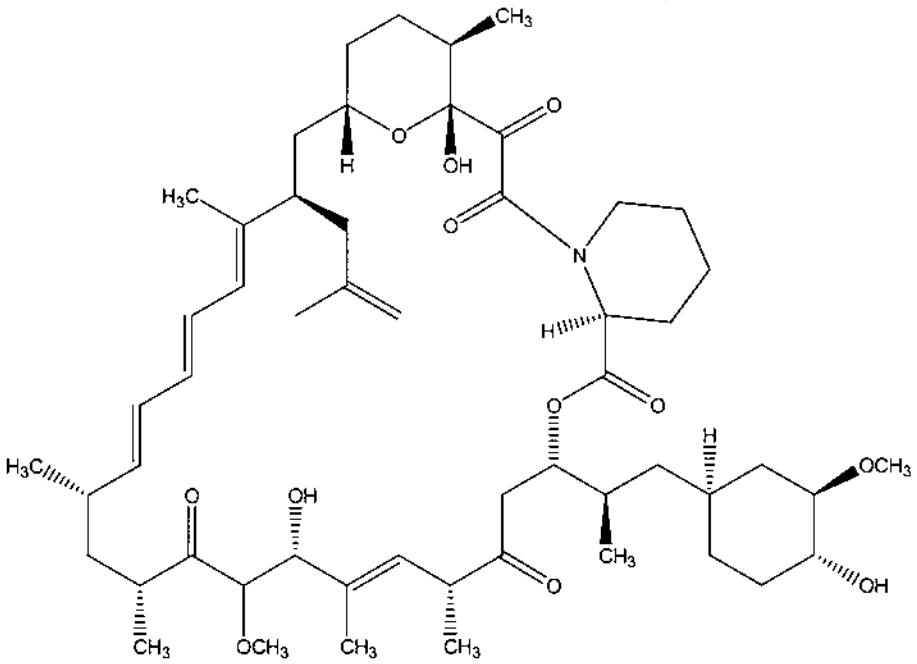


Figure 11 Chemical structure of dimerizer-dependent system inducers. (A) Rapamycin, the more commonly used inducer of the system; (B) Rap*, nonimmunosuppressive rapamycin-derivative.

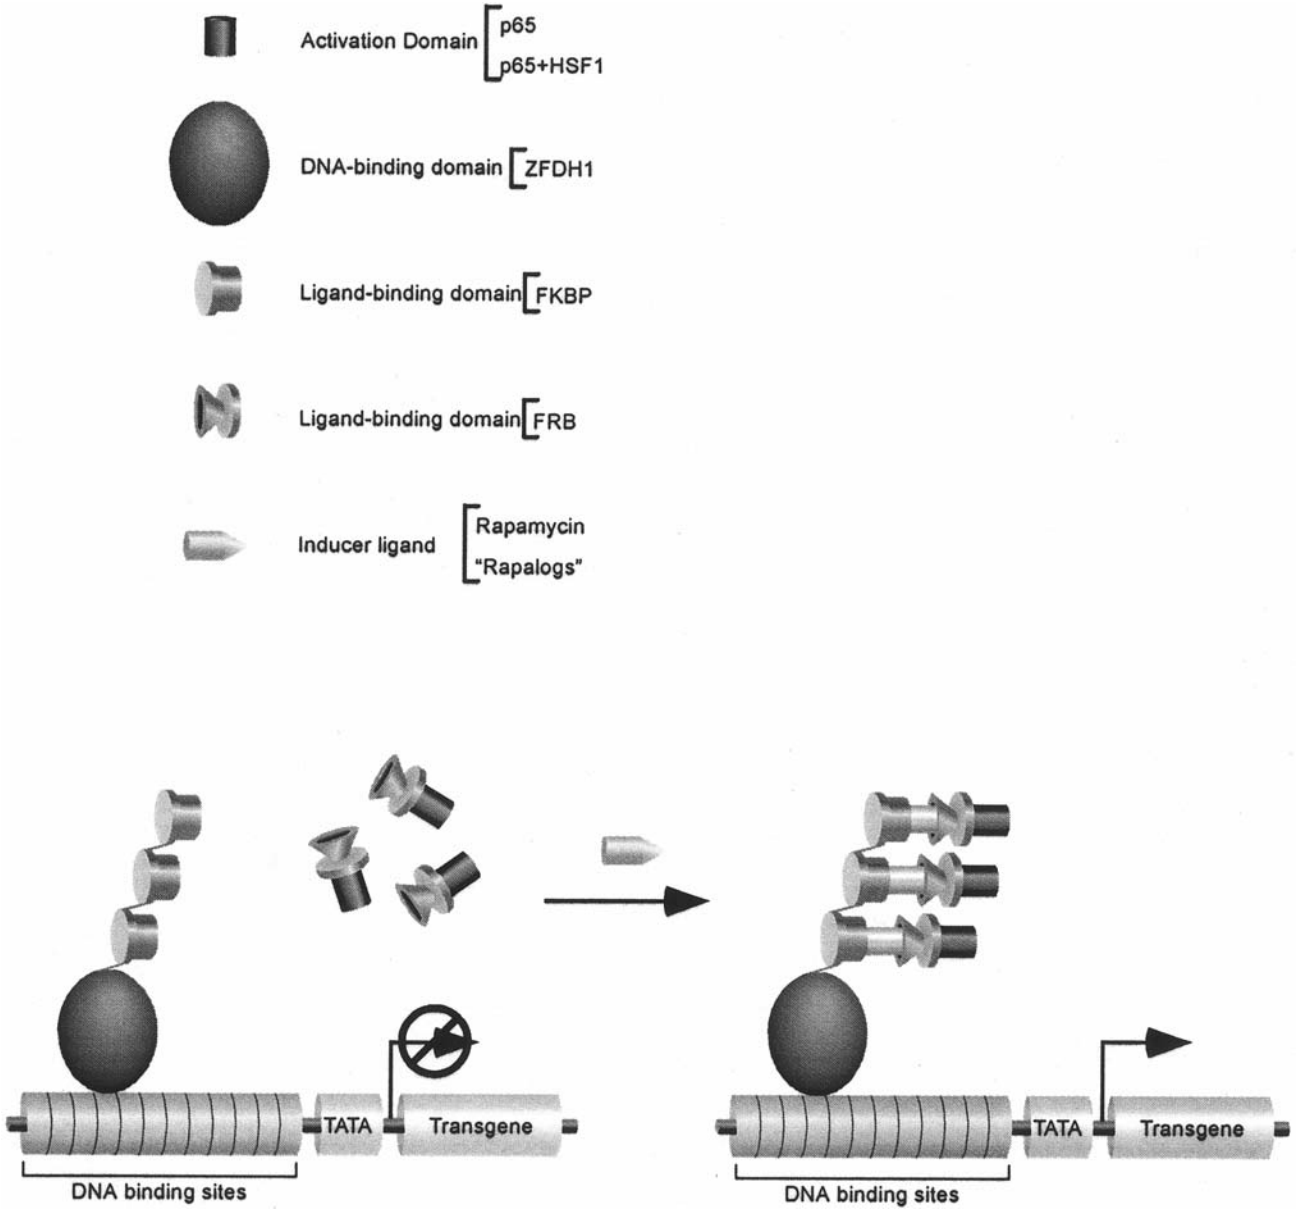

Figure 12 Dimerizer-dependent system. One component is a DNA binding domain consisting of a composite zinc-finger homeodomain (ZFHD1) fused to three FKBP repeats. The second component is an activation domain fused C-terminally to the FRB domain. The two fusion proteins can be joined by heterodimerizer drugs, thus generating a composite transactivator that activates a target promoter consisting of 12 ZFHD1-binding sites.

commonly the minimal cytomegalovirus immediate early promoter (101), or the minimal IL-2 promoter (107).

The upstream element is the binding site for ZFDH1. As described above, ZFDH1 is a synthetic DBD generated by protein design. Its consensus DNA-binding site (DBS), 5′-TAATTANGGGNG-3′, has been derived by selection from a random pool of oligonucleotides (100). The particular juxtaposition of its two components, the two zinc fingers from Zif268 and the POU domain of Oct-1, allows ZFDH1 to selectively bind the sequence 5′-TAATGATGGGCG-3′ with a dissociation constant of 8.4×10^{-10} M, an affinity at least 30-fold higher than that of either Zif268 or Oct-1 for the same sequence. Hence, the ZFDH1 DBS is not recognized by endogenous transcription factors: multimers of this DBS linked

to a minimal promoter and to a reporter gene, when transfected in cells, do not give rise to detectable reporter gene expression (101). The most commonly used promoter configuration contains 12 tandem copies of the ZFDH1 DBS (Z12).

D. Dimerizer-regulated System for Gene Therapy Application

In general, dimerizer-based systems display a very low basal activity in the absence of the inducer drug. The main reason for this is the physical separation of the DBD from the AD in two distinct fusion proteins that cannot interact in the absence of ligand. This tight regulation was constantly observed in cells after transient or stable transfection, and also when stably transfected cells were implanted in vivo at various dosages (101,108). The tightness of the system was demonstrated by efficient generation of stable cell lines carrying an inducible highly toxic gene (103).

Since basal transcription ranges from low to undetectable, induction ratios in the presence of rapamycin are very high (up to 1000-fold) in cultured cells. The dose-response curve with the standard system, i.e., ZF3/S1, reaches maximal induction in stably transfected cells at approx. 50 nM rapamycin with an EC_{50} of 6–8 nM. Maximal gene expression levels are comparable to those obtained with constitutive strong promoters like the CMV promoter/enhancer (107). However, in a comparative study with the rtTA2-M2-based tet-on system, the rapamycin system displayed lower leakiness but also lower maximum induced activity after transient transfection (109).

The dimerizer-regulated switch enabled tight control of gene expression also when delivered in various animal models of gene therapy using viral vectors (mainly AAV), moving from small animals to nonhuman primates (Table 2). When delivered by AAV vectors in mouse muscle, the system enabled long-term and strictly rapamycin-dependent control of GH and Epo (107,110). Importantly, varying dosage of the inducer drug modulated gene expression (107,110). Inducible expression was also demonstrated in mouse eye and liver following AAV and adenoviral gene transfer (111,112).

Similar studies were also performed in nonhuman primates: of particular relevance was the demonstration that a regulated macaque Epo gene delivered with AAV vectors in the muscle of rhesus macaques could be repeatedly induced upon systemic drug delivery (110). Inducibility of transgene expression was not maintained over a prolonged period of time in all animals: out of six primates tested in total, three underwent expression shut-off. However, it has been recently reported in an extended trial involving eight animals injected with an improved system that all of them show persistent expression (92). This is a preliminary indication that the shut-off observed in the first study may not be due to immunological response against the activator but, possibly, to decreased expression of the two transactivators below a therapeutic threshold.

Further confirmation of this system reliability comes from the inducibility of Epo expression in the anterior chamber of macaque eye after subretinal injection of AAV vectors (112).

A recent report described use of the rapamycin-dependent system to control replication of adenoviral vectors in cancer cells. Conditionally replicating adenoviral vectors have been recently introduced in clinical trials with promising results (113). These vectors are designed to undergo replication and spread only to cancer cells. For this purpose, intratumoral, loco-regional, or also systemic delivery are being investigated. However, safety concerns have raised the interest in pharmacological regulation of replicating adenoviral vectors. A recent study has shown that it is possible to engineer a conditionally replicating adeno in which the E1a gene is put under the control of a minimal promoter with 12 ZFDH1 sites (114). Direct coinjection in tumor cells of this virus with a first generation adeno expressing the two hybrid transcriptional activators ZH3 and S1 leads to rapamycin-inducible adenovirus replication (114). Although therapeutic efficacy in a xenograft model has not yet been convincingly shown, and the current system requires two complementary adenoviruses, a refined version in which all these elements are contained in a single vectors can be envisaged as a new weapon in the fight against cancer.

E. Inducer Drugs

Rapamycin is the principal ligand used to stimulate the dimerizer-based regulatory system, which indeed is commonly known as the ''rapamycin system.'' Its pharmacological and pharmacodynamic properties are well known (115). It is orally bioavailable (see below) and has a half-life of 4.5 h. A fairly extensive characterization of the kinetics of transgene induction-deinduction in vivo was performed in mice after IM implantation of stable clones expressing the hGH under the con-

Table 2 Dimerizer-dependent System: In Vivo Studies in Animal Models of Gene Therapy

Transactivator	Transgene[a]	Vector	Tissue	Species	Refs.
ZF3 + FRAP-S1	GH	Ad, AAV	muscle	mouse	107
ZF3 + FRAP-S1	Epo	AAV	muscle	mouse, monkey	110
ZF3 + FRAP-S1	Epo	AAV	retina	rat, monkey	111
ZF3 + FRAP-S1	Ins	Ad	liver	mouse	112
ZF3 + FRAP-S1	E1a, E1b	Ad	tumor xenograft	mouse	114

[a] GH = Growth Hormone; Epo = erythropoietin; E1a, E1b = adenovirus early genes; Ins = insulin.

trol of the dimerizer system. After a single IV or oral administration, peak transgene levels were reached after 24 h, maintained for the following 48 h, and then started to decline with a half-life of one day (108). Considering that the half-life of GH is only minutes and that of rapamycin is 4.5 h, this extended kinetic of expression is probably due to the rapamycin-mediated complex between the chimeric DBD and AD being highly stable for several hours in the cell nuclei. As a consequence, transcription shut-off in response to drug withdrawal is a slow process, which depends on degradation rate of the two transcription factors via the proteasome pathway. The intrinsic inertia of the dimerizer system may thus render daily drug administration superfluous to keeping the system in the on state. On the other hand, this also precludes prompt silencing of the system by drug withdrawal if and when required.

Rapamycin is only partially orally bioavailable (115). Maximal activation is observed at 10-fold higher doses after oral delivery than by parenteral administration and, while the ED_{50} derived from intravenous administration is slightly above 1 mg/kg, that derived from oral dosing is 9–10 mg/kg. This explains why in the majority of published studies the ligand was administered by intraperitoneal injection (107,108,110–113). Indeed, at the common doses of 1–2 mg/kg used in small and large animal models, transgene expression is already half-maximally activated after parenteral injection of rapamycin, while only marginally induced when the drug is given orally (108). Highly immunosuppressive oral doses would thus be required to reach therapeutic levels of the target transgene in humans, thus making this version of the system impractical for clinical applications. These high concentrations of the ligand might also interfere with the physiological functions of FKBP, such as calcium channel modulation and cardiac development (116,117). The potential solution to these issues is to use rapamycin analogs that maintain the capacity to heterodimerize DBD-FKBP and FRB-AD but have lost their immunosuppressive properties.

Immunosuppression by rapamycin is due to the inhibition of FRAP enzymatic activity (118). The 3-dimensional structure of the ternary complex of FKBP, rapamycin, and FRAP is known, and has helped redesign the binding interface of rapamycin with FRAP (119). Bulky substituents were introduced in the C16 position of rapamycin, which abolished binding to wt FRAP and, as a consequence, its immunosuppressant properties. Likewise, compensatory mutations were obtained by genetic selection in yeast of a FRAP mutant library. These restored binding of a C16 substituted nonimmunosuppressant rapalog called Rap*, carrying a methallyl substituent (Fig. 11) (120). A triple substitution mutant, T2098L/W2101F/K2095P, called FRB*, was shown to efficiently and specifically bind the FKBP-Rap* complex. When the FRB*-p65 fusion was used in transfected cells as a replacement of the original FRB-p65 component, it induced target gene expression in the presence of Rap* at an EC_{50} below 10 nM.

Other rapalogs substituted in the C7 position have been obtained (121). Although their structure has not yet been disclosed, they are assumed to act in combination with a single aminoacid-substituted FRB T2098L. This preferred FRB variant (called $FRAP_L$) and some of its corresponding rapalogs AP22565 and AP21967 have been shown to efficiently induce gene expression in cell lines transduced with a retroviral vector or in vivo in tumors injected with conditionally replicating adenoviral vectors (103,114). Based on these results, it would seem the solution to immunosuppression at hand. However, it has to be kept in mind that changes to the structure of rapamycin may modify its pharmacology and drug metabolism. Until now, no transcription-specific rapalog has been reported with a defined oral bioavailability and acceptable pharmacokinetics.

F. Perspectives

This class of transcriptional activators and their related ligands are of relatively new conception but have quickly acquired importance as highly promising for in vivo gene therapy applications and future clinical development. The system embodies most of the properties required, i.e., low basal activity in the absence of the ligand, high dynamic range, and full reversibility of the transcription switch upon ligand withdrawal. Its level of characterization in in vivo preclinical models is fairly advanced, and the intrinsic flexibility and modularity of its components offer opportunities for future evolution.

In particular, zinc-finger technology has made such significant progress over the past years that it is now possible to engineer zinc-finger domains targeted to any desired DNA sequence (122). These novel polypeptides can be used to activate or block gene expression when targeted to open chromatin domains of resident genes. By using appropriately designed zinc fingers, it may thus be possible to generate dimerizer-regulatory systems capable of specifically targeting and activating promoters of endogenous genes. This approach worked for VEGF gene regulation in a stably transfected cell line (123). Rapamycin- or rapalog-inducible endogenous VEGF gene expression has been shown to be tight and rapid, of magnitude similar or superior to that achieved by the natural stimulus hypoxia, and accompanied by the simultaneous expression of the whole repertoire of VEGF splice variants. Although in its initial phase, this strategy has great potential for gene therapy (see also steroid-regulated systems).

The exclusive use of human components to assemble these two hybrid proteins should significantly decrease the possibility of immune response, but might not completely eliminate it. In fact, each polypeptide contains one or two novel junction epitopes that can be presented in the context of MHC class-I molecules and recognized as nonself, depending on the haplotype in which they are expressed. In theory, our greater knowledge of the immune system may permit these epitopes to be redesigned in order to reduce their possibility for presentation (124).

Of importance are the efforts of synthetic chemistry to expand the set of available heterodimerizers. Examples in this direction are the creation of fusions between methotrexate and a synthetic FKBP ligand or between methotrexate and dexamethasone, which are capable of triggering the formation

of heterodimerizers between DHFR and FKBP12 or between DHFR and the glucocorticoid receptor respectively (125,126). The extensive use of combinatorial chemistry, coupled with molecular modeling and protein design, will expand the number of reagents in the following years. We can expect to see a proliferation of dimerizer-regulated systems, which will significantly differ according to the type of inducer used. Demonstration of their feasibility in cell cultures will be merely the first and easiest step. This will have to be followed by the demonstration of suitable pharmacological properties and lack of toxic effects in vivo. As with every drug discovery project, these new chemical entities will have to pass the severe examination of in vivo pharmacology, safety assessment, and drug metabolism before becoming suitable for transferring to a clinical setting.

V. STEROID-REGULATED SYSTEMS

A. General Principles

Steroid receptors are natural examples of ligand-dependent transcription factors but cannot be used for gene therapy in their native form because they lack the required specificity, i.e., would also activate endogenous genes. Hence, by taking advantage of the modular nature of steroid receptors, in which DNA-binding, transactivation and ligand-binding functions reside in distinct domains, regulatory switches have been developed (127). Domain-swapping experiments have demonstrated the independent character of these domains. Heterologous proteins can be rendered hormone responsive by fusing them with the hormone-binding domain (HBD) of steroid receptors (128). In the absence of the ligand, the fusion protein is bound to the heat shock protein 90 complex (HSP90) through the HBD: in this state the fusion protein is inactive, probably due to steric hindrance and/or maintenance in an inactive conformation. Upon binding of the specific ligand to the HBD, the fusion protein is released from the HSP90 complex and becomes active.

The number of proteins adaptable to this approach is continuously expanding and includes kinases, recombinase, integrases, and oncogenes (129). This strategy has also been applied to generate hormone-dependent transcription factors. In pioneering works, the HBD of the estrogen receptor (ER) was fused to the DNA-binding domain of the yeast transcription factor GAL4 and to the Herpes simplex virus transactivation domain VP16 (GAL4-ER/HBD-VP16). This chimeric protein was able to stimulate transcription from artificial promoters containing GAL4-responsive elements in an Estradiol (E2)-dependent manner in cultured cells (130). This activator is predicted to be highly specific in terms of transgene transcription, because it only recognizes promoters containing the 17-mer GAL4 DNA-binding sequence that is not present in the mammalian genome. However, chimeric transactivators that carry natural HBDs of steroid receptors cannot be used in gene therapy applications because their activity would be severely influenced by endogenous steroids.

Thus, more recent studies have focused on the development of inducible chimeric activators equipped with mutant HBDs that do not interact with natural steroids but only bind to synthetic analogs. HBD-based chimeric transactivators that are specifically induced either by the antiprogestin RU486 or by the antiestrogen 4-hydroxytamoxifen (4-OHT) have been constructed and used to regulate transcription of target genes in animal models of gene therapy (Fig. 13). Here we describe the molecular architecture of these systems, summarize the results obtained in vivo, and discuss the potential of this type of switches for human gene therapy.

B. GeneSwitch: An RU486 Dependent Regulatory System

1. Transcription Factors

In 1992, BW. O'Malley and colleagues demonstrated that the C-terminus of the progesterone receptor (PR) is essential for its transcriptional activity upon interaction with progesterone (131). They also isolated a 42-amino acid C-terminal deletion mutant of the PR (called hPRB891) that no longer interacted with progesterone or other endogenous steroids, but retained its ability to bind progesterone antagonists, such as RU486, also known as mifepristone (Fig. 14) (131).

Based on this finding, the same group constructed a first version of an RU486-dependent transcription factor by fusing the HBD of hPRB891 (PR-HBD$_{640–891}$) C-terminally to the GAL4 DNA binding domain (DBD). This activator, called pGL, only minimally activated transcription from reporter genes cloned downstream of 4 tandem repeats of GAL4 binding sites (132). A more potent activator was obtained when the VP16 transactivation domain (residues 411–487) was fused N-terminally to the GAL4 DBD. This activator, called GLVP (or GS 1.0), enabled from 10- to 50-fold induction of reporter genes in cultured cells (132). As expected, GLVP transcriptional activity was stimulated only by adding RU486 but not in the presence of natural progesterone or synthetic progesterone agonists.

A more potent activator, called GL$_{914}$VPc' (or GS 2.0), was then generated by using a 19-amino-acid C-terminal deletion of the PR-HBD (aa 640–814) and by placing the VP16 activation domain at the C-terminus of the chimera (133). GS 2.0 induced gene expression in transiently transfected cells at 10-fold lower concentrations of RU486 than GS 1.0 (0.01 nM vs. 0.1 nM). However, GS 2.0 displayed a basal activity higher than that of GS 1.0, so that the net increase in induction was only 2–3 fold. By substituting the VP16 activation domain with that of the p65 subunit of human NF-κB protein, GLp65 activator (also called GS 3.0) was obtained, which was 2-fold less potent than GS 2.0, but displayed a lower basal activity in the uninduced state (78). Additional modifications were made by Valentis Inc., which now commercializes the system with the registered trademark ''GeneSwitch.'' The version called GLp 65.1 (or GS 3.1) is identical to GS 3.0 in terms of functionality and overall structure and only differs for the

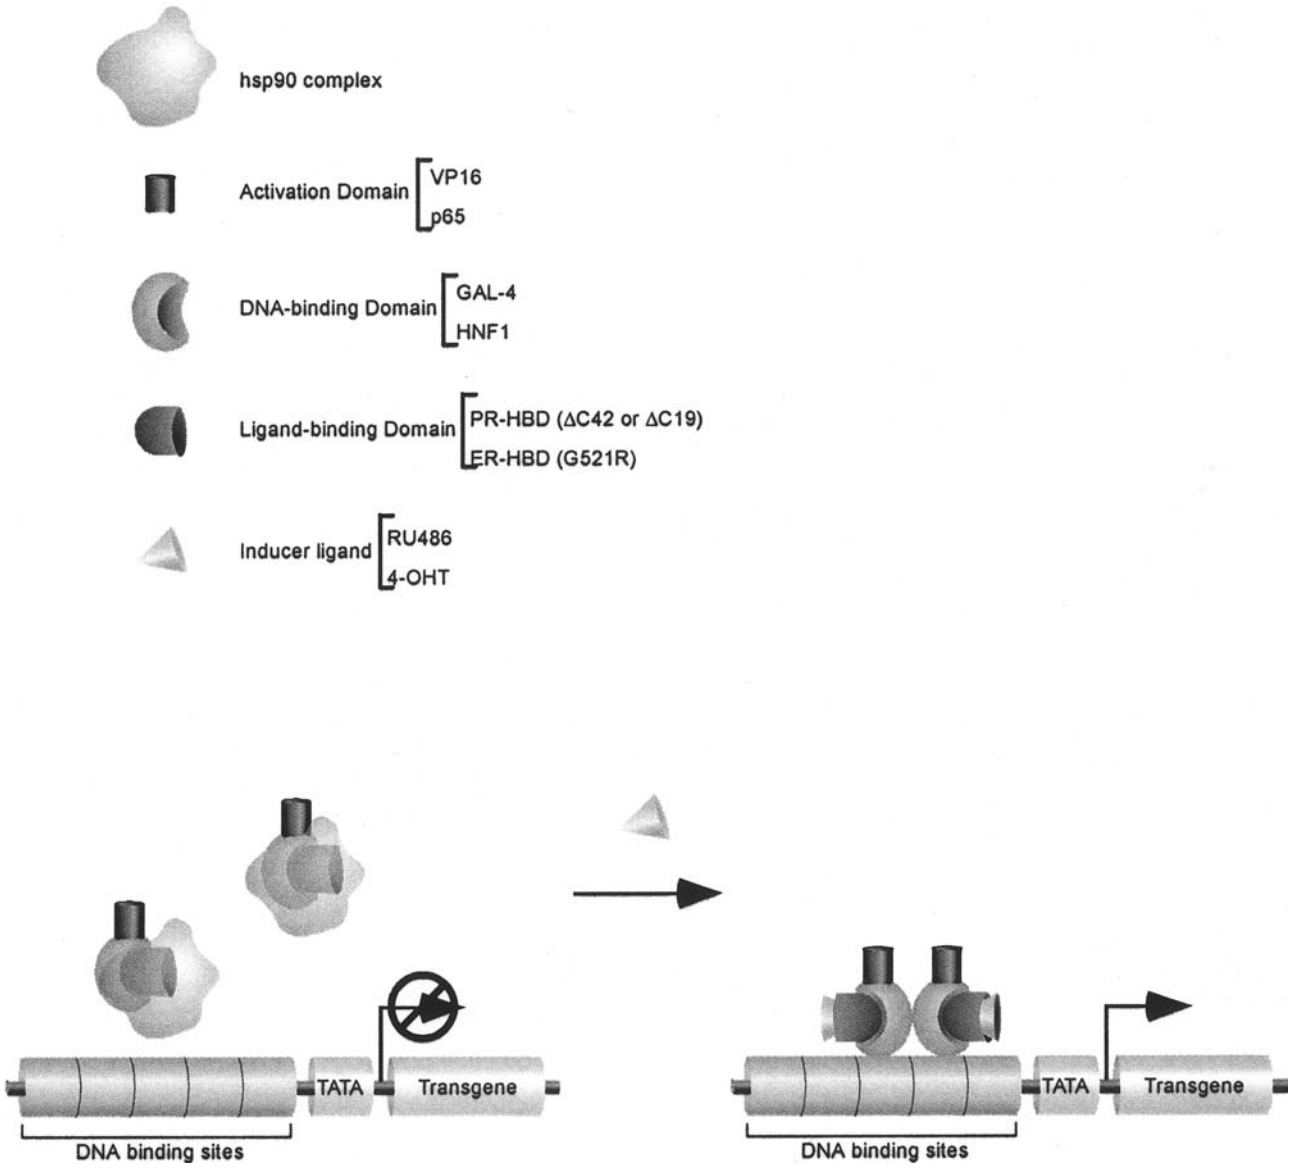

Figure 13 Hormone Binding Domain (HBD)-based regulatory switches. The activator consists of a DNA binding domain (GAL4 or HNF1, but also zinc fingers) fused to a mutant HBD, unable to bind endogenous steroids, and to an activation domain, such as VP16 and p65. In the absence of the ligand, the protein is bound to the hsp90 (heat-shock protein 90) complex and therefore inactive. In the presence of the inducer drug (RU486 or 4-OHT), the activator is first released from hsp90, and then binds and activates the target promoter, which consists of multimeric DNA binding sites upstream of a minimal promoter sequence.

shorter (3 aa long) linker between the PR-HBD and the p65 activation domain. GS 3.1 is responsive to RU486 concentrations ranging from 10–11 M to 10–8 M, with half-maximal activation occurring at 10–10 M (134). It is worth mentioning that a further version of this transactivator, called GS 4.0, has been described. It carries a shorter version of the GAL4 DBD and is claimed to have a lower basal activity as a consequence of the reduced capability to homodimerize in the absence of the ligand (135). However, no data have been published in support of this.

2. GeneSwitch Responsive Promoters

The structure of the GeneSwitch responsive promoters has not been significantly modified over the years (135). Initial experiments in cultured cells demonstrated that the composition of the minimal promoter cloned downstream of the mul-

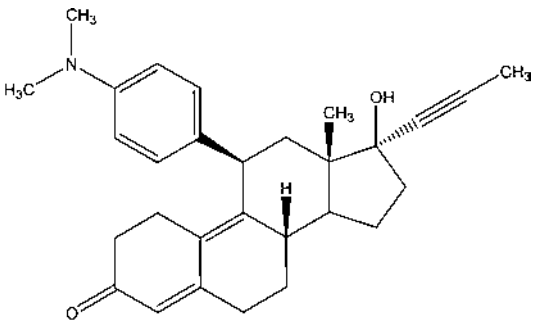

Figure 14 Chemical structure of RU486, inducer of the GeneSwitch system. RU486 (mifepristone) is a synthetic progesterone antagonist.

timeric GAL-binding sites significantly influences both the basal and maximal activity of the system. The minimal promoter that displayed the best compromise between basal activity and inducibility contained only the TATA box from the adenoviral major late promoter E1b. No further improvement in this direction has been reported following these early findings. In its most frequently used configuration, a GeneSwitch promoter consists of 6 tandem copies of GAL4 binding sites cloned upstream of the E1 TATA box (6 × GAL4-TATA)

3. GeneSwitch for Gene Therapy Applications

The efficiency of GeneSwitch in regulating transcription of target genes in vivo depends heavily on the delivery vectors used (Table 3). In a first study, a replication incompetent HSV vector carrying a CMV-driven GS 1.0 expression cassette and the β-gal gene under the control of a GAL responsive promoter was inoculated into rat hippocampus (136). Forty-eight hours postinjection, a 150-fold increased expression of β-gal was measured in brain extracts from rats treated with RU486. Minimal background β-gal expression was measured in untreated rats.

In another study using viral vectors, GS 3.0 under the control of the liver-specific transthyretin (TTR) promoter and a GAL4-responsive human growth hormone (hGH) cDNA were incorporated into the same helper-dependent adenoviral vector (78). Infection of cultured hepatoma cells and of mouse livers resulted in thousands-fold induction of hGH expression in rats treated with RU486. Following RU486 withdrawal, hGH expression returned to basal levels. hGH expression was repeatedly reinduced over a 9-month period, but the extent of induction progressively decreased (78,137). It was not established whether this decrease was caused by an immune response against hGH and/or GS 3.0, loss of vector DNA or transcriptional inactivation of TTR, and/or the GAL4-responsive promoter.

When delivered intramuscularly as plasmid DNA, GeneSwitch performed more poorly (Table 3). A 15-fold induction of SEAP gene expression was measured upon codelivery into mouse muscles of a CMV-driven GS 3.0 expression vector and a GAL4-responsive SEAP plasmid (134). Moreover, time-course experiments revealed that the leakiness increased over time, resulting in lower magnitude of induction at later time points. Interestingly, this poor induction level upon intramuscular delivery of plasmid DNA correlates with the finding that GeneSwitch displays a significant basal activity in transient transfection of several cell types, resulting in low induction ratios in the range of 10–40-fold (134). The relatively low potency of this system upon intramuscular plasmid injection was confirmed in experiments performed in rats (138).

Intramuscular delivery of GeneSwitch as a plasmid DNA may thus represent a valid therapeutic approach only in those cases where a low-fold induction is sufficient. This was demonstrated by a recent experiment in which intramuscular electroinjection of the GeneSwitch systems as plasmid DNA in SCID mice was used to regulate expression of the growth hormone-releasing hormone (GHRH) (Table 3). Prolonged treatment with RU486 led to a 1.1–1.7 rise in IGF-1 levels, presumably as a consequence of enhanced GHRH expression. This low-fold induction nonetheless provoked a significant increase in body weight, lean body mass, and bone mineral density with a concomitant decrease of fat mass (139).

In an attempt to increase the dynamic range of induction, an autoinducible GeneSwitch system was generated (140). In this system, the GS 3.1 transactivator was placed under the

Table 3 GeneSwitch System: In Vivo Studies in Animal Models of Gene Therapy

Transactivator	Transgene[a]	Vector	Tissue	Species	Refs.

control of an autoinducible promoter that consists of four GAL4 sites upstream of the tk minimal promoter. Because of the residual basal activity of the tk minimal promoter (see above), GS 3.1 was expressed in the absence of the ligand, but only at low levels. Treatment with RU486 activates GS 3.1, which in turn promotes its own transcription, as well as that of the codelivered reporter gene cloned downstream of the classical 6 × GAL4-TATA promoter. In this autoinducible configuration, GeneSwitch displays lower basal activity, and the fold induction thus increases by one order of magnitude following intramuscular delivery in mice. However, expression levels of the target gene are lower than those obtained from more conventional constructs (140).

4. Inducer Drug

RU486 is a small, orally bioavailable, hydrophobic molecule that diffuses passively through cell membranes and freely distributes to several tissues, including the brain. RU486 is approved in several countries in combination with prostaglandins as a treatment to terminate pregnancy (141). In this context it is important to observe that RU486 dosages required to activate GeneSwitch are significantly lower than those required to induce abortion (132,134).

RU486 readily activates the GeneSwitch: in general, transgene product is already detectable 3 h after administration of a single dose. A dose-response experiment in mice demonstrated that GeneSwitch is maximally and half-maximally stimulated by intraperitoneal doses of about 300 μg/kg and 30 μg/kg, respectively (134). Since the bioavailability of RU486 after oral dosing is 40% in rodents, we can assume that GeneSwitch would be maximally stimulated by an oral dose of 600 μg/kg (142). A comparison between the pharmacokinetic properties of RU486 in rodents and humans allows the conclusion that maximal and half-maximal stimulation of the system in humans would be achieved by oral doses of approximately 30 mg and 3 mg, respectively (143). These dosages are significantly lower than those required to induce abortion (200–600 mg) and are well tolerated in humans (143). Nonetheless, even at these low dosages, RU486 affects the ovarian cycle and has a contraceptive activity related to the dosing schedule. For instance, a 2-mg daily dose inhibits ovulation, and 5 mg once weekly prevents implantation (144,145).

Finally, RU486 has been recently demonstrated to inactivate the human cytochrome P-405-3A4 (CYP3A4) and is thus expected to increase the bioavailability of several clinically used drugs that are metabolized by CYP-3A4 (146). The potential for drug-drug interaction must be taken into account in planning long-term treatment with RU486.

In conclusion, therefore, the contraceptive effect of RU486 at low doses but also the potential for drug-drug interactions may curtail the acceptance of GeneSwitch in clinical practice.

5. Perspectives

GeneSwitch has been constantly upgraded over the years in order to meet the stringent criteria required for gene therapy applications. Experiments in animals indicated that the system enables transgene regulation, but also suggested that additional improvements are required. A major drawback appears to be the ratio of potency vs. leakiness: GeneSwitch system is probably leakier and less potent than the most advanced versions of the tet system upon electroinjection of plasmids into mouse muscles. A direct comparison with the rapamycin-dependent system is not possible because the experimental settings in which the two systems have been so far tested are too different. The recently described autoregulatory circuit has reduced its leakiness but is also less potent and is not amenable for the construction of tissue-specific regulatory systems. In relation to this point, GS 4.0 may represent a major improvement.

The ligand-dependent activator has been partially humanized by using the p65 activation domain as a substitute for VP16: 82% of its amino acid sequence is now of human origin. Nonetheless, the GAL4 DBD may still be immunogenic in primates. In relation to this point, however, it is worth remembering that the system is highly flexible and can accept DBD of human origin (see below, 4-OHT-dependent regulatory system). Indeed, substituting the GAL4 DBD with artificial zinc fingers of predetermined specificity has generated novel RU486-inducible activators. In transient transfection experiments, these activators specifically induced transcription of reporter genes cloned downstream of multiple zinc-finger binding sites in an RU486-dependent manner (147,148).

C. HEA-3: A Humanized TAM-dependent Transcription Activator

1. General Principles

As outlined above, HBD-based chimeric activators have been generated, which carry synthetic polydactyl zinc fingers or the DBD of the yeast GAL4 transactivator. These DBDs enable specific transgene regulation because they recognize DNA sequences that are not the target of mammalian endogenous transcription factors. Nevertheless, these heterologous DBDs may be immunogenic in humans and therefore of limited efficacy for long-term gene therapy applications.

An HBD-based activator containing a DBD derived from a human protein is expected to have a lower potential for immunogenicity. DBDs derived from ubiquitous transcription factors are not appropriate for this purpose, because the responsive promoter would be constitutively activated in every tissue. In theory, however, customized molecular switches, which make use of human DBDs and effectively regulate gene expression in selected tissues, can be constructed. To this aim, two requirements must be fulfilled: first, the DBD must be derived from a transcription activator that is not expressed in the target cell/tissue; second, the inducible gene must be placed under the control of a synthetic promoter that carries only binding sites for that specific DBD. A fully humanized HBD-based activator (called HEA-3) specifically designed to work in muscle cells has been recently described and used to regulate gene expression in vivo (149).

2. Transcription Factor

HEA-3 is composed of three elements. At the N-terminus, it carries the DBD of the transcription factor Hepatocyte Nuclear Factor 1 (HNF-1). HNF-1α and its closely related variant HNF-1β, are dimeric homeoproteins expressed mainly in hepatocytes, where they are required for the expression of liver specific genes, and in a few other epithelial cells (150,151). The two proteins are not expressed in muscle (152). The DBD of human HNF-1 was fused in frame with the HBD of the human ERα. To prevent activation by endogenous steroids, an HBD containing the mutation glycine to arginine at residue 521 (G521R) was used. This mutant HBD binds the antiestrogen 4-OHT, whose structure is shown in Fig. 15, but not endogenous estradiol (E_2) (153,154). The activation domain from human p65 protein was added at the C-terminus (78).

3. Target Promoter

As for other regulatory switches, HEA-3 responsive promoters consist of multimeric binding sites cloned upstream of a minimal promoter. Seven tandem repeats of HNF1 binding sites were linked either to a minimal promoter sequence derived from the human C-Reactive Protein (CRP) gene (7 × H1/CRP promoter) or to the TATA box sequence from the adenovirus E1b gene (7 × H1/E1b promoter) (149).

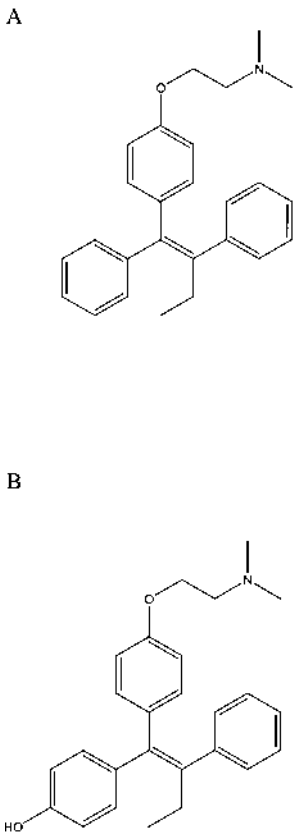

Figure 15 Chemical structure of Tamoxifen (TAM) and 4-hydroxytamoxifen (4-OHT), inducers of HEA-3. TAM (A) and 4-OHT (B) activates the HEA-3-based system in vivo and in vitro, respectively. See text for additional details.

4. HEA-3 for Gene Therapy Applications

Artificial promoters containing multimeric HNF1 binding sites were silent in muscles and in cell lines that lacked endogenous HNF1α but were strongly activated by HEA-3 in the presence of 4-OHT. The system was half-maximally stimulated at a 4-OHT concentration of about 40 nM. In transiently transfected cells, HEA-3 induced thousands-fold induction of reporter genes in a 4-OHT-dependent manner. Importantly, E2, progesterone, and RU486 did not stimulate the system activators (149).

The system was delivered in mice as plasmid DNA by using muscle electroinjection and induced by oral doses of Tamoxifen (TAM, Fig. 15), which is converted to the active metabolite 4-OHT in vivo. In this experimental setting, HEA-3 upregulated by about 100-fold SEAP gene expression in a strictly TAM-dependent manner. Dose response experiments demonstrated that the system was significantly induced by as low as 1 mg/kg of TAM. HEA-3 also enabled long-term and fully reversible regulation of mouse erythropoietin gene over a 10-month period (149).

5. Inducer Drug: Tamoxifen

Tamoxifen is a clinically validated drug that is currently used to prevent recurrence of breast cancer (155). However, several lines of evidence suggest that the system should be significantly improved in order to meet the safety requirements required for applications in humans.

An oral dose of 1 mg/kg/day of TAM significantly (but not maximally) stimulates HEA-3 in mice (149). This dosage regimen ensures a steady–state 4-OHT plasma concentration in mice of about 30 nM, a value close to the EC_{50} of the drug for HEA-3 (see above). The plasma concentration of 4-OHT in patients undergoing long-term TAM therapy (20 mg/kg, daily) is about 10 nM: this indicates that TAM dosages higher than those normally used in clinical practice would be required in humans to exploit the full dynamic range of the HEA-3-based system (155–158). Therefore, the sensitivity of this system should be increased by at least one order of magnitude for gene therapy applications in humans. This is of particular relevance when considering that TAM is extremely well tolerated at the usual dosage, but that prolonged treatment (i.e., years) is associated with a low, but well-defined, increased risk of endometrial cancer (157,159).

6. Perspectives

HEA-3 was specifically designed to work in muscle, as the use of this tissue as a bioreactor for producing therapeutic proteins is an attractive possibility for gene therapy (160). However, HEA-3 can be considered a prototype of a series of humanized regulatory switches. DBDs of transcription factors other than that of HNF1 can thus be selected to construct

additional humanized chimeras specifically designed to work in tissues other than muscle. It is tempting to speculate that the combined use of tissue-specific DBDs and of mutant HBDs recognizing only synthetic steroids would generate a whole series of ''customized,'' ligand-dependent, humanized chimeras, specifically designed to work in a restricted range of tissues and cells.

Such customized molecular switches would recognize DNA sites within the chromosomes and might therefore affect endogenous gene expression. This may or may not be a concern, depending of the affected genes. However, it is worth considering that gene transcription in higher eukaryotes is governed by a complex network of interacting activating and repressing factors, whose equilibrium in a specific cell cannot be easily modified by overexpressing a single transcription factor not normally present (161). Therefore, we can hypothesize that molecular switches such as HEA-3 are unlikely to profoundly modify the expression profile of a target cell. This is partially confirmed by the observation that both albumin and α1-AT genes, whose expression in hepatocytes is regulated by HNF1, are not turned on in HEA-3-transduced muscles (149). Nonetheless, it will be necessary to study this safety issue in greater detail with the help of new sensitive technologies such as DNA microarray or whole-cell proteomics.

HEA-3 uses tamoxifen, a clinically accepted drug that acts as a steroid receptor antagonist. For gene therapy applications, inducer drugs that do not have any effect on endogenous proteins would be more appropriate. Future work should focus on redesigning the HBD-hormone interface in order to differentiate it from endogenous receptors, and to identify novel ligands that only bind to those mutated HBDs, an approach that has been successfully used to generate nonimmunosuppressive analogs of rapamycin or FK506.

VI. ECDYSONE-RESPONSIVE REGULATORY SYSTEM

A. General Principles

The steroid hormone ecdysone, which is normally found in mammals, plays a fundamental role during *Drosophila* molting and metamorphosis. Pulses of 20-hydroxyecdysone mediate that cascade of morphological modification, which results in degeneration of larval tissues and development of adult structures (162). Ecdysone acts by stimulating a transcription factor, the ecdysone receptor (EcR). The EcR is a member of the nuclear receptor superfamily, and its modular organization resembles that of steroid receptors (163). The functional EcR is a noncovalent heterodimer with the insect protein ultraspiracle (USP): the two proteins share the multidomain organization of the nuclear receptor family. USP is an obligatory heterodimeric partner of RcR, required for both ligand and DNA binding (164). EcR carries a transcriptional silencer in its ligand-binding domain, which acts by recruiting corepressors such as N-CoR and SMRT (165,166). Binding of the cognate ligand induces a conformational change that makes the corepressor dissociate from the receptor and recruits activators, which ultimately leads to transcriptional activation of genes under EcR control. Also, USP contains a ligand-binding domain, but the natural ligand is unknown: interestingly, recent evidence suggests the USP ligand-binding pocket may be locked in an inactive conformation (167,168).

The mammalian counterpart of USP is the retinoid-X-receptor (RxR), a member of the nuclear receptor family, whose natural ligand is the 9-*cis*-retinoic acid (9cRA), a vitamin A metabolite, which binds to and activates RxR (169). RxR forms homodimers as well as heterodimers with several hormone and orphan receptors. The vitamin D receptor (VDR), the peroxisome proliferator activated receptor gamma (PPAR-γ), the hepatocyte nuclear factor 4 (HNF4), the retinoic acid receptor (RAR) and the thyroid hormone receptor (TR) are among the normal heterodimeric partners of RxR (169). RxR heterodimerize also with the EcR, albeit much less efficiently than USP (170,171).

B. Transcription Factors

In pioneering experiments, insect responsiveness to ecdysone or its analog muristerone A (Fig. 16), was recreated in cells by cotransfecting Drosophila EcR and USP with an EcR-responsive gene. However, in this configuration, muristerone A stimulated transgene expression only to a very limited extent (164,172).

Several modifications were introduced to enhance the dynamic range of the system generating a system schematically represented on Fig. 17. The N-terminal activation domain of EcR was substituted with the VP16 activation domain, thus obtaining a chimeric activator called VpEcR, and the natural heterodimeric partner USP was substituted with RxR. This heterodimer stimulated gene expression up to 1000-fold in cultured CV1 cells (173). Since the mammalian farnesoid-X-receptor (FxR) can weakly activate transcription from EcR-responsive elements, using a mutant ECR DBD capable of binding a synthetic responsive element further increased the specificity of gene regulation. The mutant activator and the synthetic sequence were called VgEcR and E/GRE element, respectively (173). Although FxR can activate a promoter containing the wild-type EcR element, it cannot bind the E/GRE site. The salient attribute of this system was its low basal activity, which is probably due to the natural repressing capability of the EcR (see above) in the absence of the ligand. The VgEcR/rRxR system is now sold commercially and is widely for conditional gene expression in transfected cells.

A modified system, called RheoSwitch, has been recently described. It relies on the coexpression in target cells of GAL4-EcR, which consists of the fusion of the GAL DBD with the EcR of the lepidopteran Choristoneura occidentalis, and VP16-RxR, a fusion between RxR and the VP16 activation domain (174). In stable transfectants, RheoSwitch enabled up to 500- and 100-fold induction of integrated SEAP and luciferase genes, respectively. In this case, GS-E was used as an inducer (Fig. 16). GS-E is a member of a family of diacylhydrazines

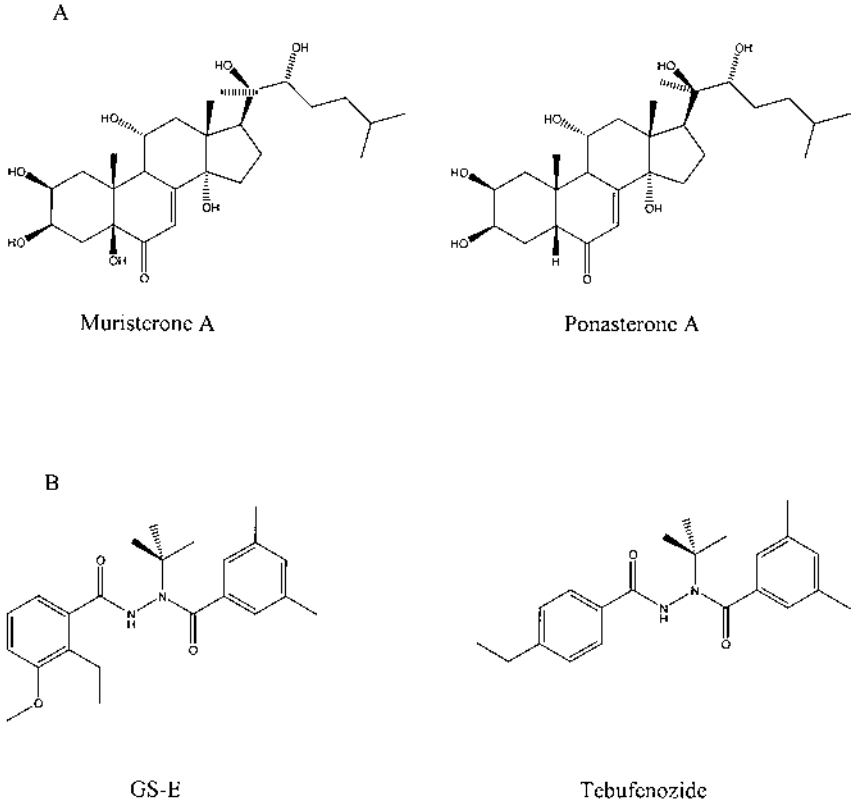

Figure 16 Chemical structure of ecdysone-dependent regulatory system inducers. (A) Plant-derived inducers (Muristerone A and Ponasterone A); (B) synthetic dibenzoylhydrazine compounds (GS-E, Tebufenozide).

that have been found to act as nonsteroidal ecdysone mimics that can function as gene inducers (see below).

VgEcR/rRxR and RheoSwitch systems are based on the Drosophila EcR, which is a reluctant dimer partner for RxR. Since RxR is generally expressed at low levels, efficient EcR mediated stimulation can only be achieved by overexpressing RxR in the target cells (164,172). Overexpression of RxR in target cells is undesirable for human gene therapy (see next paragraph). Therefore, the recent finding that EcR from Bombyx mori (BeCR) dimerize much more efficiently with RxR is of particular interest (175). The determinants of this higher affinity map within the HBD and the hinge D domain of BEcR. As a consequence of this higher affinity dimerization, VBEcR (a fusion between BEcR and the VP16 activation domain) strongly stimulates transcription in the absence of cotransfected RxR. BecR is also more responsive than EcR to nonsteroidal agonists (175).

In a more advanced version, the properties of VgEcR and of BEcR were combined. The activation and DNA-binding domain of VgEcR were fused to the hinge region and the HBD of BEcR. This hybrid-receptor (called DB-EcR) thus recognizes the unnatural E/GRE responsive elements but does not require RxR to induce gene expression in mammalian cells and responds more efficiently to nonsteroidal agonists (176).

C. Responsive Promoters

Various EcR responsive promoters have been described that shares the same basic architecture. They usually consist of four EcR-responsive elements (or E/GRE sites, in the case of VgEcR and DB-EcR) cloned upstream of a variety of minimal promoters such as those derived from the Drosophila heat shock or timidine kinase genes (173,175). RheoSwitch recognizes multimeric GAL4 binding sites (174).

D. Ecdysone-regulated Systems for Gene Therapy Applications

The ecdysone system enables tight regulation of gene expression in cell culture and transgenic animals, but its potential for gene therapy applications has not been systematically explored yet.

As to the VgEcR/rRxR and RheoSwitch, several shortcomings may prevent their application in human gene therapy. Both systems are based on overexpression of wild-type RxR, which would thus be overrepresented in all endogenous RxR-containing receptors (see above). This poses a safety concern, considering the large number of metabolic pathways in which heterodimers containing RxR are involved. The recent finding

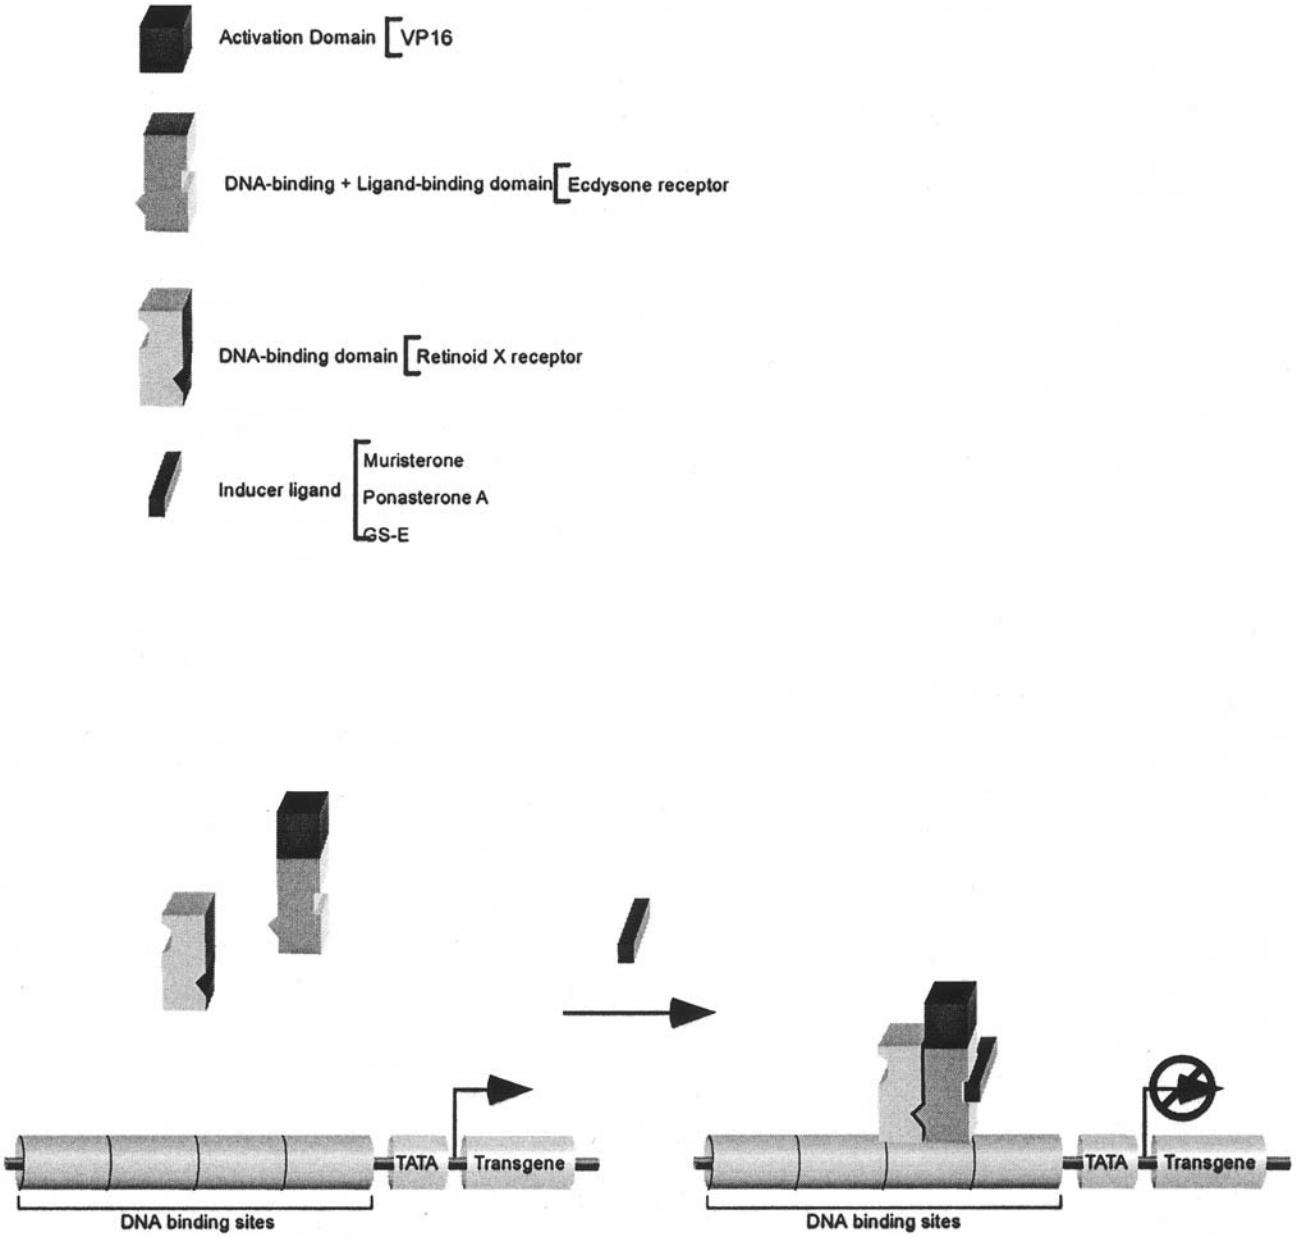

Figure 17 Ecdysone-responsive regulatory system. One component consists of the human retinoid X receptor (RxR) that carries a DNA-binding domain. The second component consists of a modified ecdysone receptor (EcR) that carries a DNA binding domain and is fused to a VP16 activation domain. Following administration of the drug, the modified EcR binds the ligand and forms a functional heterodimer with RxR. This heterodimer recognizes a specific DNA sequence and therefore activates promoters containing multimers of this sequence.

that RxR overexpression in cardiomyocyte caused dilated cardiomyopathy in mice further emphasizes this aspect (177). Similar concerns would also apply to USP, with the additional problem that this heterologous protein might prove strongly immunogenic in humans. Another issue is the fact that ligands for RxR can modulate the effect of EcR agonists on the RxR/EcR heterodimers (171). This implies that activity of the RxR/EcR receptor would not be controlled solely by the inducer drug but also by endogenous natural ligands for RxR, such as the natural agonist 9cRA. Notably, mutant RxR unable to

bind the endogenous ligands cannot be used because they would probably also affect activity of all the heterodimeric receptor for RxR.

As outlined in the preceding paragraph, DB-EcR does not require a codelivered dimerizing partner: its use is thus much more suitable for gene therapy applications. So far, this system has been delivered in vivo only by intramyocardial injection of recombinant adenovirus vectors in adult rats. In a first study, the VgEcR/rRxR and DB-EcR regulatory systems were inserted into two distinct Ad vectors (176). Each vector was then coinjected intramyocardially with a reporter Ad vector containing a luciferase gene under the control of an E/GRE-based promoter: rats were then injected intraperitoneally with 45 mg of GS-E (Fig. 16). Three days after, relative luciferase activity was measured: GS-E treatment caused a 40-fold induction of luciferase activity in rats injected with the DB-EcR regulatory system, while it was essentially ineffective in those injected with VgEcR/rRxR. This confirms that VgEcR/rRxR is inefficiently activated by GS-E-like molecules. Basal activities of the two systems were comparably low (176). In a related study, the DB-EcR regulatory system was delivered by adenoviral vectors to express a dominant negative form of a myocardial ion channel in a GS-E-dependent manner (178).

These studies indicate that DB-EcR may be useful for gene therapy applications, but they also highlight that the potency of the system is at this stage inadequate for most gene therapy applications and should therefore be increased. Moreover, the sequestration of endogenous RxR by DB-EcR could have deleterious effects, which may only become evident in long-term experiments. Additional work with different vectors and target tissues is required.

Finally, the presence of the nonhuman protein domains poses the usual concerns about the potential immunogenicity.

E. Inducer Drugs

Ecdysterone is not able to efficiently stimulate the ecdysone-responsive system in mammalian cells (171). More efficient analogs were isolated from plants, which protect themselves from insect feeding by producing substances that are toxic to insects. Ecdysteroids are among these chemicals: when insect larvae eat the leaves of the plant, they also ingest ecdysteroids, which stimulate the EcR to start an abnormal molting that leads to premature death (179). Ecdysteroids may represent up to 1% of the total dry weight of a plant (180).

The most efficient phytoecdysteroids isolated so far are Muristerone A (murA) and Ponasterone A (PonA) (Fig. 16). MurA was isolated in the early 1970s from the seeds of *kaladana*, a rare plant native to the southern slopes of the Himalayas. It proved capable of stimulating the VgEcR/rRxR and related systems with an EC_{50} comprised between 0.5 and 1 uM (173). Difficulties in obtaining seeds from *kaladana* prompted investigators to identify inducers derived from other plants. Ponasterone A (ponA) was thus identified: it can be purified from the leaves of widespread diffused plants and is as potent as MurA (181). It is conceivable that other inducers will be isolated in the future.

Ecdysteroids are usually presented as safe compounds based on the consideration that humans eat large amounts of phytoecdysteroids (contained in vegetables) without apparent detrimental effect (180). Nonetheless, it is clear that in the light of their potential use in human gene therapy, more detailed toxicology data would be required. Oral bioavailability of ecdysteroids is also a matter of concern: PonA and MurA have always been administered to rodents by intraperitoneal or subcutaneous injections (173,176,178,181). The possibility also exists that patients harboring the ecdysone-receptor switch will have to reduce their oral intake of dietary phytoecdysteroids to avoid nonspecific activation of the system.

A family of bisacylhydrazines has been identified that function as insecticides by mimicking the activity of ecdysone on the EcR (179). Not surprisingly, they have also been found to function as inducers of the ecdysoneswitch. These molecules, such as tebufenozide and GS-E, are less active than PonA on the VgEcR/rRxR system (Fig. 16) (181), but more potent on the DB-EcR switch (176). These compounds can be easily manufactured but show a very poor solubility: this limits their potential for in vivo applications (179,181). A recent study demonstrates that molecular modeling and site directed mutagenesis of the EcR generated a mutant EcR, which induces transcription of target genes in response to bisacylhydrazines but not to ecdysteroids (182). As outlined above, because of the dietary intake, the development of ecdysteroid-insensitive regulatory switches might be necessary in humans. Therefore, albeit the clinical potential of bisacylhydrazines remains to be established, more soluble molecules would represent an important starting point and prove a useful tool.

VII. CONCLUSIONS

The generation and refinement of new ligand-induced transcription switches is an area of active investigation, but probably none of the available systems is ready for use in humans. Much progress has been made during the last few years to improve performances of tetracycline, rapamycin, RU486, and ecdysone technologies in terms of tightness of regulation and inducibility. It can be predicted that also the most recently described systems will undergo a similar process of optimization. However, while constructing systems that work in cell cultures and animal models is becoming a relatively easy task, the generation of a transcription switch compatible with long-term application in humans is still a very difficult challenge. In a very schematic view, the development of a ligand-induced transcription switch for use in humans is mainly an immunological and a medicinal chemistry/pharmacology task. The activators must not be recognized as nonself, and the ligand must have good oral bioavailability and pharmacokinetic profiles in the absence of toxicity. The need to satisfy both requirements tremendously complicates this particular process and reduces the probability of success.

This is clearly evident if we compare the tetracycline and dimerizer technologies that emerge over the others for their

better characterization in living organisms, including nonhuman primates. On one side, there is the tetracycline system that relies on proteins of bacterial origin that may be immunogenic in humans but is induced by a relatively safe drug. On the other side stands the dimerizer-based switch, which has a reduced potential for immunogenicity but is induced by non-immunosuppressive rapamycin analogs that have not yet been characterized for their pharmacological and safety profile.

Despite these difficulties, the future is still bright with promise: the enormous progress in the last years makes us confident that systems fully compatible with use in humans will emerge in a not-too-distant future.

ACKNOWLEDGMENTS

We are thankful to J. Clench, E. Emili, U. Koch, and F. Marchioni for their invaluable help in the preparation and editing of this manuscript.

Monitoring Gene Therapy in Living Subjects with Molecular Imaging Technologies

S. Biswal and S. S. Gambhir
Stanford University School of Medicine
Stanford, California, U.S.A.

I. INTRODUCTION

Human gene therapy trials can be significantly aided by the ability to determine the location(s), magnitude, and time variation of transgene expression. Gene therapy vectors have to be held accountable for their actions, and recent developments in noninvasively imaging gene expression in living subjects is certain to help in this regard. Following delivery of a therapeutic vector into a patient, a gene therapist wants to know the answers to some fundamental questions: Did the vector get delivered to the desired target organ, tumor, or cell population, or have inappropriate tissues been transfected? Did gene transfer and/or transcription take place? How much gene product is being generated from the transgene? How much control do I have in the expression of this vector? What happens to expression levels as the patient responds (or fails) to therapy? Current clinical methods have difficulty in answering these questions: they rely upon serum markers, tissue-sampling followed by histochemical analysis or autoradiography, anatomical-based imaging, and physical exam, most of which are either inefficient, invasive, or inadequate in this era of targeted gene therapy and molecular medicine. Answering these questions rapidly, easily, and effectively during a patient's clinical course is clearly desirable, not only to tailor an individual patient's needs and improve clinical outcomes, but also to promote gene therapy for routine clinical use.

Recognizing this need, molecular imaging researchers have advanced the principles of reporter gene technology for use in intact, viable subjects. To the molecular biologists, reporter gene technology is well-trodden territory, and they have been familiar with the process of coupling a reporter gene to a therapeutic gene as a means of measuring the efficacy of gene delivery and tracking gene expression. Commonly used reporter genes for in vitro or ex vivo analyses include: a) chloramphenicol acetyltransferase, which transfers (radioactive) acetyl groups to chloramphenicol. Detection is rendered through thin-layer chromatography and autoradiography (1–3); b) β-galactosidase (GAL), which hydrolyzes colorless galactosides to yield colored precipitate, is detected via tissue extracts or histochemical techniques (4–6); c) β-lactamase, which catalyzes hydrolysis of cephalosporin, is monitored by a change in fluorescence emission of a substrate (7,8); d) green fluorescent protein (GFP), which fluoresces upon radiation, is examined with epifluorescence microscopy or utilized in cell sorting techniques (9–11); e) firefly luciferase, which oxidizes D-Luciferin to generate bioluminescence, can be visualized using luminometry or microscopes outfitted to specialized cameras (12,13); and f) *Renilla* luciferase, which catalyzes oxidation of coelenterazine, leading to bioluminescence (14). While some of these technologies cannot make the jump into studies of living subjects (e.g., chloramphenicol acetyltransferase, β-galactosidase) because of technical limitations, the optically-based technologies, such as those based on GFP and the luciferases, have been applied to intact, living subjects using sensitive optical detection systems (15–18).

Furthermore, there has been an exciting surge in the development of reporter gene technologies that are compatible with current clinical imaging modalities such as the radionuclide-based techniques [positron emission tomography (PET) and single photon emissions tomography (SPECT)], magnetic resonance imaging (MRI), and magnetic resonance spectroscopy (MRS). To understand these clinical technologies does not

require a large leap of faith. In fact, they are conceptually similar to the optical systems described above. All in vivo reporter techniques, including the aforementioned optical techniques, depend on the detection of electromagnetic homing signals that arise either from the probe itself or the specific interaction of a reporter protein and its corresponding reporter probe. Just as GFP emits photons in the visible range of electromagnetic spectrum that can be seen with the naked eye or cameras, radionuclide-based reporter techniques emit photons in the gamma ray-wave range that are detected by specialized scintillation crystals. Table 1 lists the various reporter systems available for in vivo imaging. In the following review, we will discuss the basic principles of the various tools now available, display several examples of the images generated from such tools, and, at the end, provide a strategy to help those scientists or gene therapists interested in using in vivo reporter techniques to choose optimal strategies.

II. IMAGING INSTRUMENTATION FOR LIVING SUBJECTS

A. Basic Principles of Optical Charged Couple Device (CCD) Imaging (Fluorescence and Bioluminescence)

Although photons emitted in the visible light range of the electromagnetic spectrum face considerable obstacles traveling through layers of tissues, notable advances in light sensor technology have permitted the use of optical reporter genes in intact organisms. There are fundamentally 2 different types of optically based imaging systems: a) fluorescence imaging, which uses emitters such as green fluorescent protein (GFP), wavelength-shifted GFP mutants, red fluorescent protein (RFP), ''smart'' near-infrared fluorescent (NIRF) probes, and b) bioluminescence imaging, which utilizes systems such as Firefly luciferase-D-Luciferin or Renilla luciferase-coelenterazine (15,19,20). Each of these systems will be discussed in further detail in a later section. Emission of light from fluorescent markers requires external light excitation while bioluminescence systems generate light de novo after an injectable substrate is introduced and the appropriate conditions are met (Fig. 1). In both cases, light emitted from either system can be detected with a thermoelectrically cooled charge-couple device camera (CCD) since they emit light in the visible light range (400 nm to 750 nm) to near-infrared range (~800 nm). Cooled to −120 to −150°C, these cameras can detect weakly luminescent sources within a light-tight chamber. Being exquisitely sensitive to light, these desktop camera systems allow for quantitative analysis of the data. The method of imaging bioluminescence sources in living subjects with a CCD camera is relatively straightforward: the animal is anesthetized, subsequently injected intravenously or intraperitoneally with the substrate and placed in the light-tight chamber for a few seconds to minutes. A standard light photographic image of the animal is obtained, followed by a bioluminescence image captured by the cooled CCD camera positioned above the subject within the confines of the dark chamber. A computer subsequently superimposes the 2 images on one another, and relative location of luciferase activity is inferred from the composite image. An adjacent color scale quantitates relative or absolute number of photons detected. This scale does not reflect the color (wavelength) of the emitted photons, but only the number of such photons, measured in relative light units per minute (RLU/min). Differences between fluorescence and bioluminescence systems are discussed in a later section of this chapter.

Comparison of optical-based imaging systems with the other imaging modalities, such as the radionuclide-based or MRI-based systems, reveals important differences. Advantages of optically-based reporter systems is that they are at least an order of magnitude more sensitive than the radionuclide-based techniques at limited depths (21). Furthermore, the direct and indirect costs are generally less than radionuclide-based techniques or MRI. However, there is significantly less spatial information obtained from optical imaging, and signal obtained from light-emitting reporter systems is limited by the tissue depth from which it arises. Furthermore, while significant progress has been made to localize fluorescent signals tomographically to obtain distribution of fluorochromes in deep tissues (22), there is currently no commercially available technique to obtain 3-dimensional localization of the targeted optical probes.

B. Basic Principles of PET

With recent breakthroughs in molecular/cell biology and target discovery, it is now possible to design specific markers to image events noninvasively in small animals and humans with positron emission tomography (PET) (23,24). Natural biological molecules such as glucose, peptides, proteins, and a variety of other structures can either be labeled with a radioisotope or slightly modified to accommodate a radioisotope. In the jargon of molecular imagers, these radiolabeled molecules are referred to as molecular probes, reporter probes, markers, or tracers. In PET imaging, molecules are labeled with isotopes that emit positrons from their nucleus. This is in contrast to gamma camera or SPECT imaging (discussed below), where molecules are ''tagged'' with radioisotopes that emit gamma rays. When a molecular probe is injected into a living subject and then placed into a PET scanner, the image we acquire is a snapshot of the physiological distribution and concentration of that tracer.

Let's take the example of 2-deoxy-2-[^{18}F] fluoro-D-deoxyglucose (FDG), a glucose analog labeled with the positron-emitting isotope, ^{18}F. In the synthesis of this tracer, PET radiochemists have devised a method to replace one of the hydrogens with the ^{18}F radioisotope. Following intravenous injection, this particular probe distributes readily from the intravascular compartments to the extravascular and intracellular compartments. FDG becomes sequestered in cellular populations and tissues that have a predilection for glucose, i.e., cells that possess larger number of glucose transporters and/or hexokinase II activity. When FDG encounters hexokinase II, it becomes phosphorylated and subsequently trapped

Table 1 Summary of Reporter Gene Systems Used in Living Subjects

Method	Imaging	Reporter gene	Action	Imaging agent/substrate	Ref.
In vitro (selected few)	Chromatography and autoradiography	Chloramphenicol acetyltransferase	Acetylation	Radioactive acetyl group	(2)
	Light Microscopy	β-galactosidase	Hydrolysis	Metabolized galactosides	(6)
		β-glucuronidase	Hydrolysis	Metabolized glucuronides	(109)
	Epifluorescence Microscopy	β-lactamase	Hydrolysis	Metabolized cephalosporin	(8)
		Green fluorescent protein	Light excitation	None (irradiation)	(9)
		Red fluorescent protein	Light excitation	None (irradiation)	(42)
		Enhanced Green Fluorescent protein	Light excitation	None (irradiation)	(37)
	MRI	Tyrosinase	Hydroxylation	Melanin production	(110)
Living subjects	Optical: Fluorescence	Green fluorescent protein	Light excitation	None (irradiation)	(18)
		Red fluorescent protein (dsRed)	Light excitation	None (irradiation)	(111)
	Optical: Fluorescence activation	Cathepsin D	Enzymatic cleavage	Quenched NIRF fluorochromes	(19)
		Matrix metalloproteinase (MMP2)	Enzymatic cleavage	Quenched NIRF fluorochromes	(44)

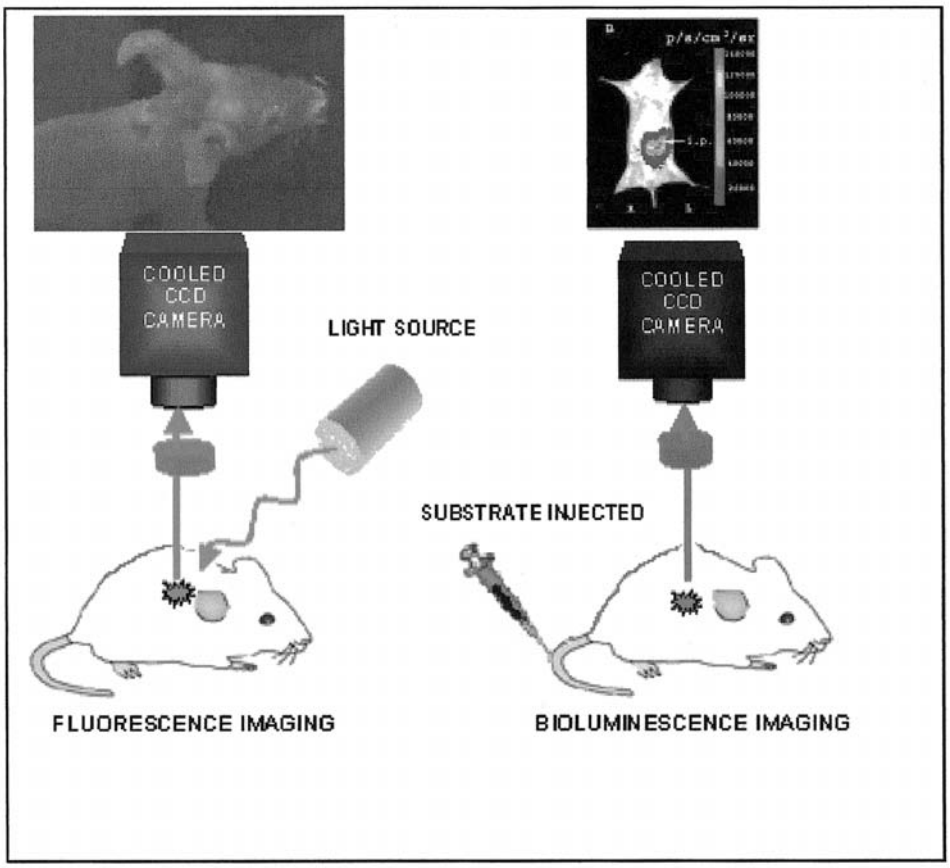

Figure 1 Basic Principles of Optical CCD Imaging (Fluorescence/Bioluminescence) There are fundamentally 2 different types of optically-based imaging systems: fluorescence imaging, which uses emitters such as green fluorescent protein (GFP), wavelength-shifted GFP mutants, red fluorescent protein (RFP), ''smart'' probes, and near-infrared fluorescent (NIRF) probes, and bioluminescence imaging, which utilizes systems such as Firefly luciferase/D-Luciferin or Renilla luciferase/coelenterazine. Emission of light from fluorescent markers requires external light excitation, while bioluminescent systems generate light de novo when the appropriate substrates/cofactors are made available. In both cases, light emitted from either system can be detected with a thermoelectrically cooled charge-couple device camera (CCD) since they emit light in the visible light range (400 nm to 700 nm) to near-infrared range (~800 nm). Cooled to −120 to −150°C, these cameras can detect weakly luminescent sources within a light-tight chamber. Being exquisitely sensitive to light, these desktop camera systems allow for quantitative analysis of the data. The image shown above the Fluorescence Imaging schematic is representative of the one obtained from a glioma model which expresses RFP (image used with permission from Anticancer, Inc.). The method of imaging bioluminescent sources of living subjects with a CCD camera is relatively straightforward: the animal is anesthetized, subsequently injected with the substrate, and immediately placed in the light-tight chamber. A light photographic image of the animal is obtained, which is followed by a bioluminescence image captured by the cooled CCD camera positioned above the subject within the confines of the dark chamber. The 2 images are subsequently superimposed on one another by a computer, and relative location of luciferase activity is inferred from the composite image. An adjacent color scale confers relative concentration of luciferase activity. Sample image above the Bioluminescence Imaging schematic is a typical image obtained with this technology (image courtesy of Bhaumik and Gambhir, Ref. 15. In this specific example, the image was obtained after intravenous injection of coelenterazine into a mouse containing intraperitoneal *Renilla* luciferase-expressing tumor cells. Significant bioluminescence is detected from the region of the xenograft. See the color insert for the color version of this figure.

within the cell. In contrast, FDG clears from cells or tissues that lack the ability to transport or phosphorylate FDG. The positron emitting moiety of FDG, in this example, ^{18}F, decays by emitting a positron from its nucleus. This positron eventually collides with a nearby electron, resulting in an annihilation event where two 511,000 eV photons in the form of gamma rays are emitted ~180° apart. The 2 emitted photons travel extracorporeally and are detected nearly simultaneously as they interact with the PET ''camera''—a ring array of detectors (composed of scintillation crystals and photomultiplier tubes) surrounding the subject (Fig. 2). Detection of a single annihilation event results in the ''activation'' of detectors opposing one another, which is recorded as a ''coincident event'', thus defining a set of coincident lines (25). The recording of multiple detector pair combinations yields a large number of these coincident lines. Sophisticated mathematical analyses of the coincident lines, which include filtered back projection and attenuation correction, yield the location of cell populations or tissues that have accumulated FDG. Tomographic images of relative probe concentration can be reconstructed in the sagittal, coronal, and transverse imaging planes. Quantitative information obtained from the images is, in turn, related to the underlying biochemical process.

Radiolabeling molecules is not just limited to ^{18}F. A collection of positron-emitting isotopes is available for use, which includes the more commonly utilized isotopes ^{15}O, ^{13}N, ^{11}C, and ^{18}F, and the less commonly used ^{14}O, ^{64}Cu, ^{62}Cu, ^{124}I, ^{76}Br, ^{82}Rb, and ^{68}Ga. Most of these isotopes are created in a cyclotron, a device used to accelerate charged particles to create the relatively short-lived positron-emitting isotopes (for example, ^{18}F, the half-life of which is 110 minutes) (26). Automated synthesizers can then couple the isotope to a molecule of interest to produce the molecular probe (tracer). Given the relatively short half-life of positron emitters, the process of producing isotopically labeled molecules has to be performed with great efficiency and in relatively close proximity to the hospital, clinic, or animal research facility. In this regard, a modest number of PET radiopharmacies are available worldwide, producing PET tracers on a daily basis.

Clinical PET scanners have been around for several decades and, in recent years, PET cameras for small animals have been developed for the purpose of developing molecular imaging assays in small rodents prior to their application in humans. The spatial resolution of most *clinical* PET scanners is ~$(6–8)^3$ mm^3 with the more recent scanners achieving ~$(3)^3$ mm^3 capabilites. By comparison small animal PET scanners (microPET) have a resolution of ~$(2)^3$ mm^3 with newer generation scanners attaining ~$(1)^3$ mm^3 (27,28). When compared to other modalities, the sensitivity of PET is relatively high—on the order of 10^{-11} to 10^{-12} moles/liter (MRI's intrinsic sensitivity is ~10^{-4} to 10^{-5} M) (29). Furthermore, the location depth of the tracer of interest does not affect sensitivity. In contrast, the imaging of many optical imaging probes is significantly affected by tissue depth. Under appropriate conditions, the smallest cluster of cells that can be visualized by a clinical PET scanner is 10^6 to 10^9 in number. Thus, radiotracer imaging techniques afford the detailed location(s), magnitude, and persistence of probes or tracers for in vivo use in animals and humans.

C. Basic Principles of the Gamma Camera and SPECT imaging

Imaging with a gamma camera is similar to PET, but the radiolabel emits gamma rays instead of positrons. A variety of radiolabels, each emitting at characteristic photon energies, can be attached to molecules including ^{111}In (171, 245 keV), ^{125}I (27–35 keV), ^{131}I (364 keV), and ^{99m}Tc (140 keV). Once introduced into the body, detection of these radiolabeled probes is performed with a gamma camera, a scintillation detector consisting of collimator, a sodium iodide crystal, and a set of photomutliplier tubes (Fig. 3). Upon decay, these radionuclides emit a gamma ray at their characteristic energies in different directions. Some of the gamma rays will scatter or lose energy and others may never interact with the camera. Since the gamma camera is situated only on 1 side of the subject, only rays directed toward the camera will be ''captured''. Furthermore, only those gamma rays that arise parallel to the collimator will be detected since the collimator will absorb scattered gamma rays. Those rays that successfully reach the crystal will be converted into photons of light. In turn, the photomultiplier tubes convert the light into an electrical signal that is proportional to the incidental gamma ray. Gamma rays, which arrive at the detector lower than the expected characteristic energy, are thought to be the result of scattering and summarily rejected from the analysis. Since gamma cameras acquire data in a single plane, the resultant images are a 2-dimensional representation of a 3-dimensional subject (referred to as ''planar imaging'').

While more affordable and accessible than PET, the limitations of gamma camera imaging are obvious: 1) diminished sensitivity, since many decay events are either rejected or never captured, 2) decreased signal-to-noise since overlapping foci of activity are not delineated, and 3) lower spatial resolution. Alleviating some of these problems is single photon emissions computed tomography (SPECT), which acquires volumetric data by rotating the gamma camera around the subject and/or using multidetector systems (30) (Fig. 3). As with microPET, small animal SPECT devices (microSPECT) have been created to study the use of gamma-emitting radiolabeled reporter probes in animal models of cancer and gene therapy. These instruments have resolutions on the order of 1 mm^3. Thus, advantages of the SPECT systems are that they generally allow for better spatial resolution. Another advantage of SPECT is that 2 radioisotopes of different energies can be imaged simultaneously, allowing for the concurrent study of 2 distinctly radiolabeled molecules (1 radiolabeled with ^{99m}Tc and another radiolabeled with ^{125}I). With PET imaging, such simultaneous imaging is not possible since all positron emitting events are 511keV.

A disadvantage for SPECT, however, is that it is an order of magnitude lower in sensitivity than PET. To accommodate for the loss of sensitivity, more radiolabeled probe and, thus,

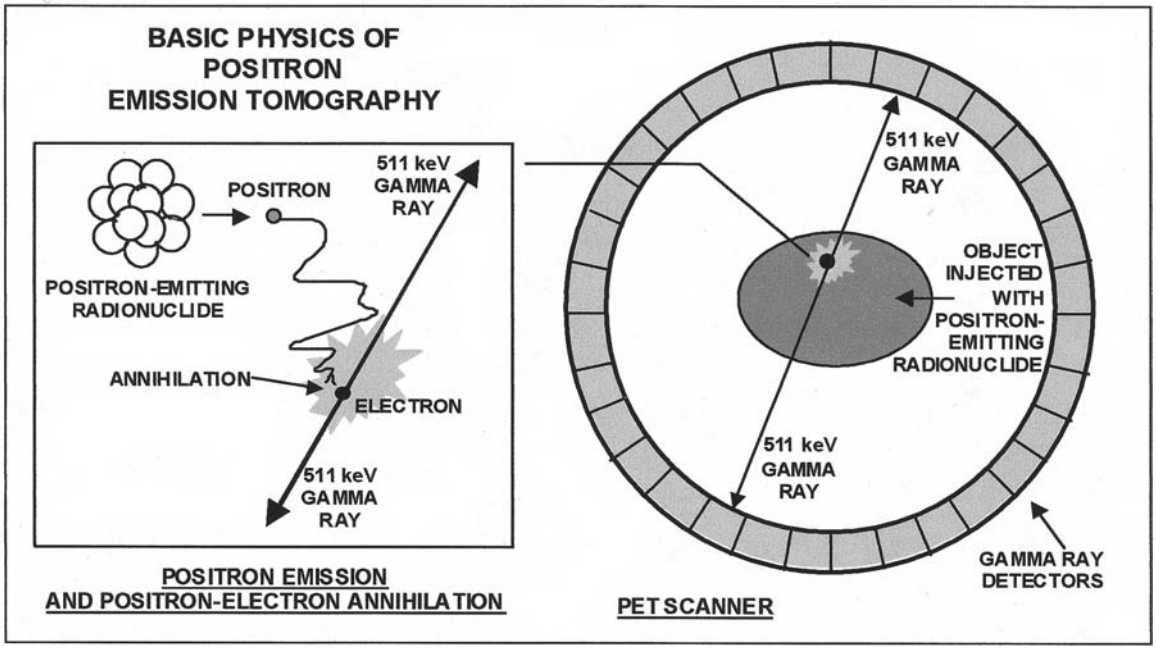

Figure 2 Basic Principles of Positron Emissions Tomography (PET) Imaging Biologically active molecules such as glucose, peptides, and proteins can be radiolabeled with positron-emitting radioisotopes. This radiolabeled molecule is referred to as a probe or tracer. The positron-emitting isotope decays by emitting a positron from its nucleus. This positron eventually collides with a nearby electron, resulting in an annihilation event where 2 511,000 eV photons in the form of gamma rays are emitted ~180° apart. The 2 emitted photons travel extracorporeally and are detected nearly simultaneously as they interact with a ring of detectors (composed of scintillation crystals and photomultiplier tubes) surrounding the subject. Detection of a single annihilation event results in the ''activation'' of detectors opposing one another, which is recorded as a ''coincident event.'' The recording of multiple detector pair combinations yields a large number of these coincident lines. Sophisticated mathematical analyses of the coincident lines, which include filtered back projection and attenuation correction, yield the location of cell populations or tissues that contain the molecule labeled with the positron emitter. Tomographic images of relative probe concentration can be reconstructed in the conventional sagittal, coronal, and transverse imaging planes or, actually, in any arbitrary plane. The resultant image depicts the distribution and concentration of the radiolabeled tracer. Sensitivity of PET is in the range of 10^{-11} to 10^{-12} moles/liter and is independent of the location depth of the tracer of interest. It is also important to note that all positron-emitting radioisotopes produce 2 gamma rays of the same energy, so if 2 molecular probes—each with a different positron-emitting isotope—are injected simultaneously, there is no way for the PET camera to distinguish between the 2 molecular probes. Therefore, to perform studies that look at 2 or more distinct molecular events (e.g., suicide gene therapy and imaging apoptosis, cardiac gene therapy, and perfusion ^{13}N ammonia imaging, etc.), one has to inject molecular probes separately, which allows decay of the isotope.

higher levels of radioactivity have to be injected into the subject to maximize signal to noise.

D. Basic Principles of Magnetic Resonance Imaging

With regards to the electromagnetic spectrum, MRI works with longer wavelengths (lower energies) than those used by radionuclide or optical techniques. A comprehensive review of MRI is beyond the scope of this chapter; there are several excellent reviews and books available (31,32). A very brief, simplistic description follows here: Spinning charged nuclei generate a magnetic field, and MR imaging depends on these charged atomic nuclei, which contain an odd number of protons. Those nuclei that contain an odd number of protons always have an unpaired proton, which gives the atom a net magnetic field or ''magnetic dipole moment'' (MDM). In contrast, atoms, which have an even number of protons, have a net magnetic field of zero. Thus, the nucleus of hydrogen (^{1}H), which possesses a single unpaired proton as its nucleus and is present in abundance (in the form of H_2O and $-CH_2-$) in cells and tissues, is primarily used for MR imaging.

The majority of available MR scanners are outfitted with a superconducting magnet in the shape of a long hollow tube. The magnet creates an ''external magnetic field'' (B_0) and, within the hollow center of the tube-shaped magnet, the mag-

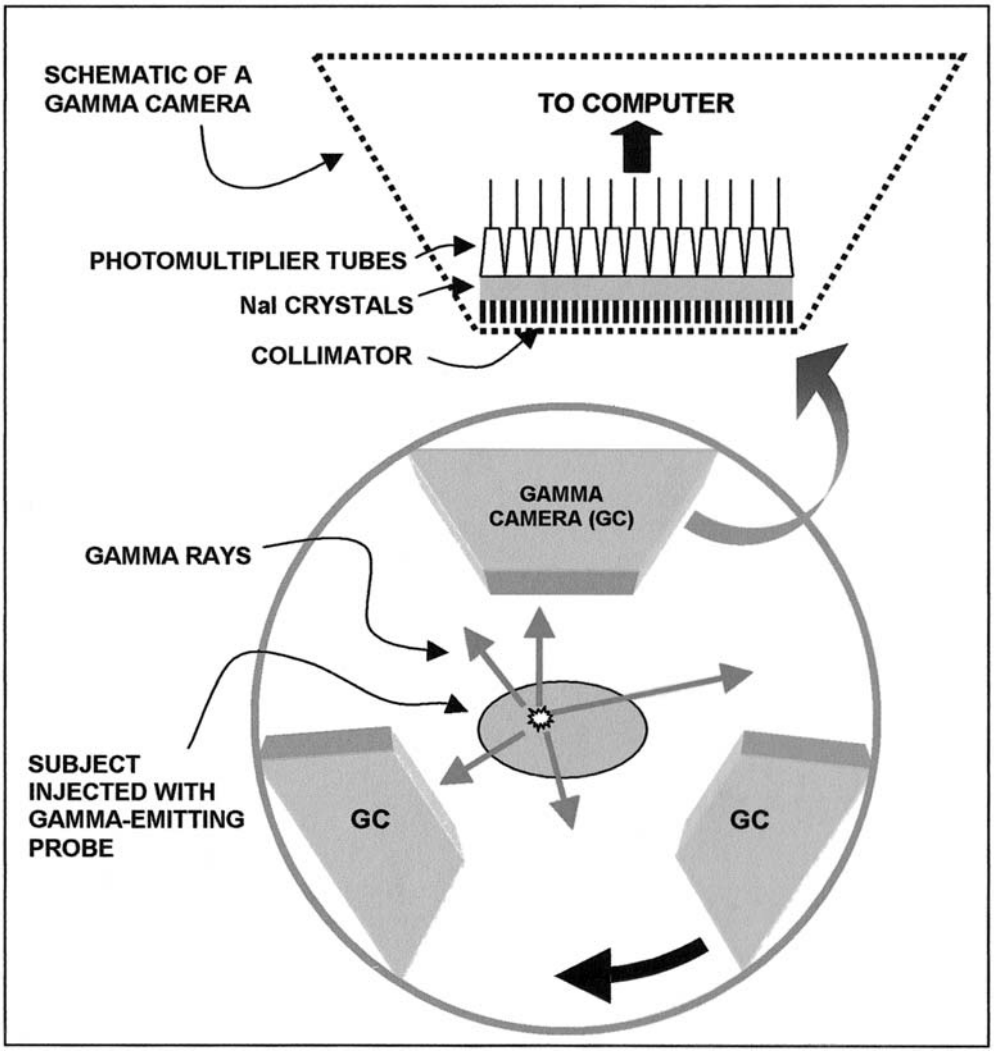

Figure 3 Basic Principles of Gamma Camera/SPECT Imaging Imaging with a gamma camera is similar to PET, but the radiolabel emits gamma rays instead of positrons. A variety of radioisotopes, each emitting at characteristic photon energies, can be attached to a variety of molecules. Examples of isotopes include ^{111}In (171, 245 keV), ^{125}I (27–35 keV), ^{131}I (364 keV), and ^{99m}Tc (140 keV). Once introduced into the body, detection of these radiolabled probes is performed with a gamma camera, a scintillation detector consisting of collimator, a sodium iodide crystal and a set of photomultiplier tubes. Upon decay, these radionuclides emit a gamma ray at their characteristic energies in different directions. Some of the gamma rays will scatter or lose energy and others may never interact with the camera. Since the gamma camera is situated only on 1 side of the subject, only rays directed toward the camera will potentially be ''captured''. Furthermore, only those gamma rays that arise parallel to collimator will be detected since scattered gamma rays will be absorbed by the collimator. Those rays that successfully reach the crystal and are stopped by it will be converted into photons of light. In turn, the photomultiplier tubes convert the light into an electrical signal that is proportional to the incidental gamma ray. Gamma rays that arrive at the detector lower than the expected characteristic energy are thought to be the result of scattering and summarily rejected from the analysis. Since gamma cameras acquire data in a single plane, the resultant images are a 2-dimensional representation of a 3-dimensional subject (referred to as ''planar imaging''). Single photon emission computed tomography (SPECT) acquires volumetric data by rotating a gamma camera around the subject and/or using multidetector systems (shown above). (From Ref. 30.) See color insert for color version of this figure.

netic field is nearly homogeneous and parallel to the long axis of the tube. When a subject is placed within the hollow confines of the magnet, the MDMs of the hydrogen atoms align themselves with the main magnetic field B_0- much like the way iron filings behave when placed in the vicinity of a magnet.

Once equilibrium has been established in the external magnetic field, B_0, a magnetic pulse (an electromagnetic wave), otherwise known as radiofrequency (RF) pulse, is introduced perpendicular to B_0. It is called an RF pulse because the frequency (and energy) of the pulse is in the radiofrequency range of the electromagnetic spectrum (3–100 MHz). This causes the hydrogen nuclei to transiently orient their MDM parallel to the new magnetic field (perpendicular to B_0). After the RF pulse, they realign (relax) their MDMs to the main magnetic field B_0, and, in the process give off energy in the form of radiofrequency waves that can be detected by receiver coil, which typically surrounds the subject. To reiterate, both a RF pulse and magnetic field are used to perturb the underlying subject, with an RF wave being generated in the process that is used to produce an image. Also, the time it takes hydrogen nuclei to relax to equilibrium (or a fraction thereof) can be measured. The rate at which a hydrogen nucleus relaxes is dependent upon the nature of its parent molecule such as a freely mobile water proton vs. the rigidly attached proton of hydrocarbon backbone of a fatty acid. Water protons, which randomly tumble in aqueous solution, take longer to regain equilibrium with the main magnetic field, B_0, than those protons associated with much larger, more fixed molecules. The measurements of relaxation rates can be converted into a value, which translates into image pixel value, with each pixel representing a small, representative, unit volume of the subject (voxel). On a certain MR imaging protocol called a ''T1-weighted'' sequence, a voxel composed mostly of fatty (hydrocarbons) protons will have a high (bright) signal since the rate of relaxation is rapid. Compare this to the voxel that contains a large number of water protons: this voxel will have a low (dark) signal on T1-weighted MR imaging since the rate of relaxation is much longer. Each MR image is 256 × 256 or 512 × 512 pixels, each a representative slice through the subject (Fig. 4).

Certain exogenous or endogenous atoms/molecules, like Gadolinium (paramagnetic) and iron/hemosiderin (superparamagnetic), respectively, can influence the local magnetic field by their powerful magnetic properties, significantly alter the rate of relaxation of the protons and therefore generate contrast in the image. Paramagnetic substances have unpaired electrons. They become magnetized in the presence of an external magnetic field and contribute to an increase in the effective magnetic field. Examples include the rare-earth element, gadolinium (Gd) (7 unpaired electrons), deoxyhemoglobin (4 unpaired electrons), and methemoglobin (5 unpaired electrons). Hemosiderin, an end-stage by-product of hemorrhage, has more than 10,000 unpaired electrons and, thus, belongs to *superparamagnetic* group of substances. The magnetic susceptibility of superparamagnetic substances is 100 to 1000 times stronger than paramagnetic substances. Both super- and paramagnetic substances help localize reporter gene expression during MRI (see also Fig. 10). As we will see in a later section, the properties of paramagnetic and superparamagnetic compounds are exploited for MR-based reporter systems.

MRI techniques offer phenomenal spatial resolution (voxel resolutions of ~10 μm^3 in vitro and ~50 μm^3 in small animals) but are several orders of magnitude less sensitive than optical and radionuclide-based techniques. Sensitivity of MRI is on the order of 10^{-3} M while PET imaging is 10^{-12} M, and thus, substantially more MRI probe has to be injected into the living subject in order to provide sufficient contrast (33).

E. Computed Tomography

Computed tomography (CT) deals in the X-ray range of the electromagnetic spectrum. In CT, the subject is placed in the center of a ring of detectors. A rotating, focused X-ray source emits radiation that penetrates the subject and reaches a set of detectors on the other side of the patient. The amount of X-ray reaching the detector depends upon the amount absorbed by the patient and is inversely proportional to the density of tissues encountered as it passes through the patient. The amount of radiation reaching a detector is given a value, and, through a complex set of back calculations, tomographic images in the transverse plane can be constructed.

While this modality is not currently utilized to monitor gene expression, efforts are under way. Rather, CT's main role in human gene therapy will grow significantly as it currently serves as an anatomical adjunct to PET imaging. Both CT and PET data sets can be coregistered, and because of its superior spatial resolution, CT gives PET information more specificity. Clinical CT scanners have recently achieved spatial resolutions under 1 mm. Small animal CT scanners (microCT) have attained resolutions of 50 μm (34). Already showing its prowess in oncology, PET/CT clinical machines as well as small animal machines should help to show gene expression coupled to anatomy. More details about PET/CT can be found elsewhere (23).

III. REPORTER GENES AND REPORTER PROBES

A. Optical Reporter Systems

There are essentially 4 different types of optical reporter genes currently in use for studies in living animals. These genes either encode a) a protein that contains a chromophore (a short, internal peptide segment that contributes to the protein's fluorescent capabilities following obligatory posttranslational modifications), which fluoresces when externally irradiated (fluorescence imaging), b) an enzyme that can convert an exogenously added, optically quiescent substrate into a fluorescent complex, or an enzyme that changes the conformation of a substrate such that it fluoresces a different color (fluorescence imaging), c) luciferases that generate light when presented with the appropriate substrate (bioluminescence imaging), or d) fusion proteins that couple transgene products with

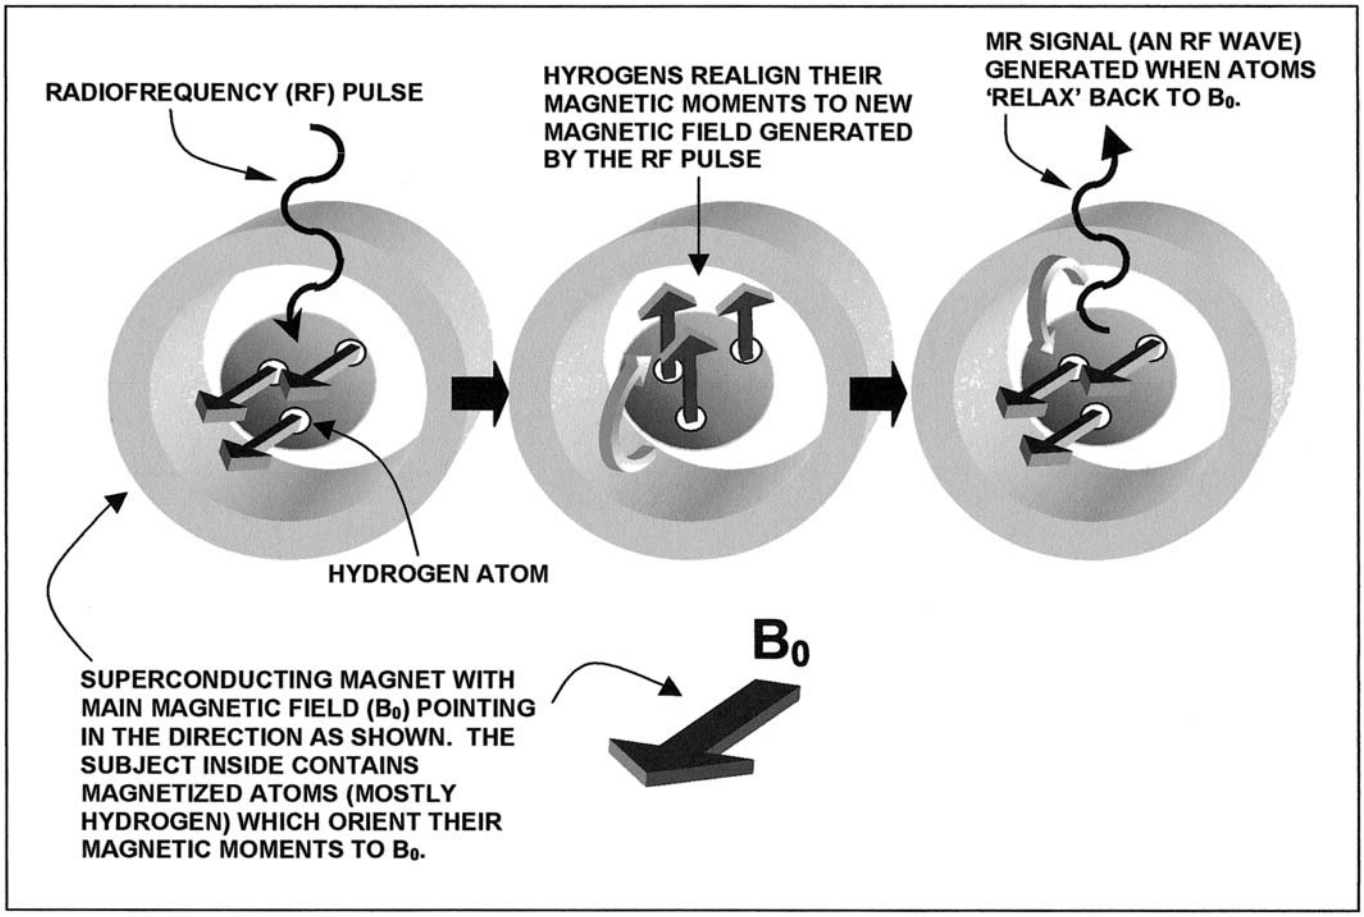

Figure 4 Basic Principles of Magnetic Resonance Imaging (**MRI**) In MRI, subjects are placed in a strong, external, magnetic field, B_0, produced by a hollow, cylindrical magnet. The B_0 field is nearly uniform and points parallel to the long axis of the magnet. Imaging with MRI is dependent upon atomic nuclei with an odd number of protons, such as hydrogen (^1H). Such atoms have their own net magnetic field [a.k.a., magnetic dipole moment (MDM)] and their moments align accordingly when placed in this external magnetic field. Once equilibrium has been achieved between the subject and the magnet, energy can be added to the system in the form of a radiofrequency (RF) pulse. In most cases, this pulse, which generates its own magnetic field, can change the alignment of the hydrogen atoms such that their moments are now perpendicular to B_0. Once the RF pulse is ''turned off'', the hydrogen atoms realign or ''relax'' to B_0 and give up energy in the form of RF waves during the relaxation period. Receivers located in the magnet capture this RF wave. One of the calculations made from the captured information is the rate at which the hydrogen atoms relax to equilibrium. Image construction and image contrast are possible with MRI because hydrogen atoms associated with macromolecules like fat and proteins have a significantly different relaxation rate than the hydrogen atoms of bulk water. The measurements of relaxation rates can be converted into a value, which translates into image pixel value, with each pixel representing a small, representative, unit volume of the subject (voxel). On a certain MR imaging protocol called a ''T1-weighted'' sequence, a voxel composed mostly of fatty (hydrocarbons) protons will have a high (bright) signal since the rate of relaxation is rapid. In contrast to voxels that contain a large number of water protons, this voxel will have a low (dark) signal on T1-weighted MR imaging since the rate of relaxation is much longer. See color insert for color version of this figure.

fluorescence or bioluminescence optical reporters with a peptide linker (discussed in greater detail in a later section). When compared with other imaging modalities, fluorescence and bioluminescence imaging techniques hold tremendous potential for study of small living animals because of their relative affordability, relative ease of use, high assay sensitivity, and low requirement for specialized support personnel. In contrast to the radionuclide-based techniques described earlier, all optical reporter gene/probe systems are forms of indirect imaging. The measured light emissions generated from these re-

porter systems may or may not correlate to the amount of therapeutic gene product present. Briefly reviewed below, extensive work in the past several years has been dedicated to mutating existing or cloning new fluorescent or bioluminescence genes that are more compatible for use in living subjects.

Mammalian tissues pose a number of obstacles for the propagation of light and, thus, are a challenge for the evaluation of fluorescence or bioluminescence-based reporter genes in living subjects. Fluorescent-based techniques, in particular, face additional challenges since both the light used to excite the reporter probe and the light emitted from the probe are subject to absorption, scatter, and other optical tribulations. More specifically, the excitation light is not only limited by its ability to penetrate nontransparent tissue, but also contributes to background autofluorescence (from hemoglobin and cytochromes) especially when excitation wavelengths are in the blue and green portions of the spectrum, which is generally the case when green fluorescent proteins (GFP) [and its close relatives such as blue fluorescent proteins (BFP)] are used as reporter genes (21). As a result, fluorescence imaging has relatively poor signal-to-noise when compared to bioluminescent techniques.

Light emitted from either fluorescence-or bioluminescence-based techniques is subject to tissue absorption and scattering. In mammalian tissues, the blameworthy structures responsible for light absorption are predominantly molecules of hemoglobin, which absorb wavelength emissions of 400–600 nm. To a lesser extent, melanin and other pigmented macromolecules also contribute to light absorption, and, thus, experiments using white-furred or hairless subjects are preferred when using optical reporter systems. Light absorption by water molecules is also another important factor, but not until wavelengths approach >900 nm range. Light scatter is another important confounding factor in the detection of low-level photon emissions; the interfaces at the surface membranes of cells and organelles are largely the cause for this occurrence (21).

Yet, despite these impediments, recent advances in the fields of optics and sensor technology make it possible to detect relatively low emission events with great sensitivity and generate remarkable images (35,36). Furthermore, optical reporters are being developed to operate with longer wavelengths; that is, away from the blue-green part of the spectrum and towards the red (a.k.a. ''red-shifted,'' between 600–900 nm) so as to maximize transmission, minimize absorption, and minimize background autofluoresence. Additionally, the fluorescence efficiency of each of the fluorescent proteins is being optimized through site-directed mutagenesis. The intrinsic physical and chemical properties of the mutants are altered. Characteristics such as protein stability, extinction coefficients, fluorescence quantum yield, tendency to dimerize or form multimers, requirement for oxygen, efficiency of fluorochrome formation, and susceptibility to photoisomerization and photobleaching can be modulated through mutagenesis, and, thus, the amount and rate of light photons emitted from such structures can be optimized (37).

For example, wild-type *Aequorea* GFP, a 238 amino acid polypeptide (27–30 kD) specifically isolated from the Pacific jellyfish (*Aequoea victoria*), is a highly fluorescent molecule with excitation peaks at 395 nm (largest peak) and 475 nm (38). GFP's emission peak is 509 nm, which is in the lower green portion of the visible spectrum. On the skin surface, GFP expression can be easily visualized. However, for optimal visualization of GFP expression in deeper structures, such as the brain and pancreas, skin or skull windows need to be created by surgical incision (39). Additionally, GFP fluorescence is not immediate and only detectable at about 7 h after injection of recombinant adenovirus carrying GFP (vAd-CMV-GFP). The rate-limiting step in GFP ''maturation'' appears to be a necessary oxidation step in chromophore formation (40).

Extensive work has been dedicated to creating GFP mutants, since wild-type GFP possesses a few factors compromising its use in living subjects. The list of available GFP mutants, each having their own idiosyncrasies, is quite lengthy. An excellent review is available (37). One of the more thoroughly studied mutants S65T, also known as enhanced GFP (EGFP), has some impressive advantages. Ser65, one of the amino acids of the chromophore, is replaced by Thr in this mutant. The wild-type 395 nm excitation peak is suppressed, and the 475 nm peak is enhanced 5- to 6-fold in amplitude (6-fold increase in brightness), the peak is shifted to 489–490 nm (40). It is 4-fold faster during the rate-limiting oxidation step, not subject to photoisomerization, and exhibits very slow photobleaching (41). Examples of the use of EGFP in living subjects is shown in Fig. 5.

GFP mutants come in all kinds of colors: blue, cyan, yellow, and green. However, the maximum emission peak attained by the GFPs is 529 nm. Recently cloned red fluorescent protein (dRFP), a 28-kDa protein responsible for red coloration seen in the coral *Discosoma*, has broken the 529 nm barrier, and excitation and emission maxima are at 558 nm and 583 nm, respectively (42). The relatively high extinction coefficient and fluorescence quantum yield indicate that the brightness of the mature, well-folded protein is comparable to any other fluorescent protein. Furthermore, a commercially available mutant, DsRed, is resistant to photobleaching and has been further red-shifted to 602 nm, which reduces the tissue absorption of the emitted light photon. Unfortunately, there are some significant limitations to the use of dRFP. It is an obligate tetramer and is quite slow in its maturation—it takes days for it to mature from green to red. Mutations attempted thus far have not been able to alleviate these problems (42). Figure 1 contains a fluorescent image example of an RFP-expressing glioma in a mouse model.

Two recently developed ''smart'' fluorescent probes have been developed that are significantly red-shifted—so much that they work in the near-infrared portion of the electromagnetic spectrum (excitation wavelength 673 nm; emissions wavelength of 689 nm), making them ideal fluorescent agents for use in intact organisms. Although they are being exploited to measure endogenous protein levels, they are worth mentioning here since they have the potential to be activated by exoge-

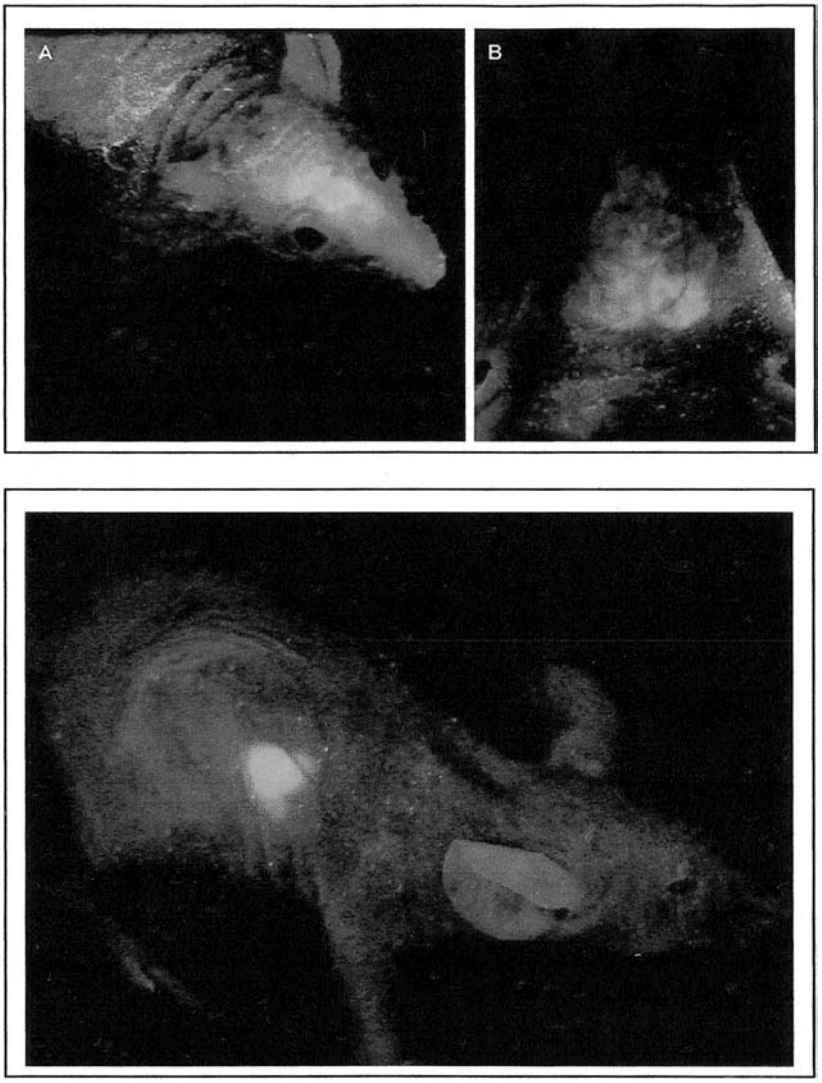

Figure 5 Optical (Fluorescence) Imaging of Transgene Expression The adenoviral (vAd) vector AdCMV5GFPAE1/AE3 [vAd-green fluorescent protein (GFP)] (Courtesy of Quantum, Montreal, Canada) constitutively expresses an enhanced GFP (eGFP), which is driven by a CMV promoter. The vector was delivered to the brain after an upper midline scalp incision and creation of a parietal skull window. Twenty mL containing 8×10^{10} plaque-forming units (pfu)/mL vAd-GFP per mouse was injected into the brain. Twenty-four hours later, fluorescence imaging of the entire animal (lower magnification) was carried out in a light box illuminated by blue light fiber optics, which provided the external excitation wavelength, and was imaged using a cooled color charge-coupled device camera. Emitted fluorescence was collected through a long-pass filter GG475 on a 3-chip thermoelectrically cooled, color CCD camera. Images of 1024×724 pixels are captured directly on a personal computer or continuously through video output on a high-resolution video recorder. Images are subsequently processed for contrast and brightness and analyzed with imaging software. Higher magnification images (not shown here) can be accomplished by using a fluorescence stereomicroscope equipped with a 50 W mercury lamp. In this scenario, selective excitation of GFP is produced through a D425/60 band-pass filter and 470 DCXR dichroic mirror. Emitted fluorescence are captured and processed as described above. Images A and B demonstrate GFP transgene expression following adenoviral delivery to the brain. Image C demonstrates Ad-CMV-GFP delivery to the liver via portal vein cannulation. See color insert for color version of this figure. (Images courtesy of Anticancer, Inc., Ref. 18.)

nously delivered genes and to be used to monitor gene therapy (19). This new breed of fluorescent probe is dependent upon the close proximity of multiple near-infrared fluorochromes (NIRF), Cy5.5, when bound to a synthetic graft copolymer consisting of a cleavable backbone [partially methoxy poly(-ethylene glycol)-modified poly-L-lysine] (43). When placed in close proximity, a pair of these fluorochromes will ''quench'' each other and, therefore, not be detectable. Upon enzymatic cleavage of the backbone with a protease that has lysine-lysine specificity, the fluorochromes are spatially dissociated and will begin to fluoresce.

Because tumor progression and angiogenesis necessarily elaborate certain proteases, these clever or ''smart'' biocompatible autoquenched near-infrared fluorescent probes can be used to detect tumors that are known to upregulate certain proteases. Cathepsins B and H are tumor proteases that have lysine-lysine specificity and have been shown to activate this fluorescent probe in tumor xenografts. Other known tumor-enhanced proteases, Cathepsin D and matrix metalloproteinase-2 (MMP-2), which are dependent on other specific peptide sequences for their action, can also activate this probe if the NIR fluorochromes are attached to the backbone via Cathepsin D-sensitive or MMP-2-sensitive sequences; these enzyme-specific probes have been demonstrated in living subjects (19,44).

Bioluminescent optical systems are increasingly being used in the study of living subjects because of their inherently low background (no excitation irradiation needed that would otherwise cause background autofluorescence). The most commonly used bioluminescence reporter gene is the Firefly luciferase gene, *Fluc*, which encodes a 550 amino acid, 61-kDa monomeric protein (FL) derived from *Photinus pyralis*, the North American firefly (36). Photon emission is achieved through oxidation of its native substrate, D-Luciferin [D-(−)-2-(6′-hydroxy-2′-benzothiazolyl) thiazone-4-carboxylic acid] into oxyluciferin in a reaction that requires ATP, Mg^{2+}, and O_2. The reaction produces a broad spectral emission that peaks at 560 nm. A number of modifications to the gene since its discovery has facilitated its use in mammalian tissues, which include amino acid substitutions that red-shift the emissions peak above 600 nm, optimized mammalian codon language, removal of a peroxisome targeting site for increased expression levels, and cytoplasmic localization (21,45). Once produced, luciferase does not require post translational processing for enzymatic activity, and it can immediately function as a genetic reporter. Examples of the use adenoviral-mediated firefly luciferase gene delivery are given in Figs. 6 and 7. Figure 6 is an example of cardiac gene therapy and Fig. 7 is an example of how tissue-specific transgene expression can be achieved using tissue-specific promoters in living subjects.

A second bioluminescence system utilizing the *Renilla* luciferase gene (*Rluc*) that encodes a 36-kDa monomeric protein (RL), has recently been tested in small rodents (15). Its peak emission displays a blue-green bioluminescence at 480 nm when *Renilla* luciferase interacts with its substrate, coelenterazine. In comparison to FL, RL does not need cofactors or ATP to oxidize its substrate, and therefore it will be less taxing to the cell in which it is expressed. It also has much more rapid kinetics in terms of light production so that it can potentially be used simultaneously with FL through the injection of both substrates and multiple time-point imaging (15).

Comparing the technical and practical aspects of fluorescent and bioluminescence systems reveals substantial differences, which are briefly mentioned here. Fluorescence imaging benefits greatly from relatively high photon yield from its proteins and dyes so that, in some cases, living subjects can be imaged with conventional photographic equipment rather than the more expensive, cooled CCD cameras. In comparison, the photon yield of bioluminescence systems is significantly lower, and imaging of living subjects always requires a cooled CCD camera. Fluorescence imaging can potentially be used to image simultaneous signals of different colors, whereas multiplexing different and simultaneous signals in bioluminescence imaging is difficult, owing to the differential enzyme kinetics and time-to-peak photon flux among varying luciferases.

On the other hand, bioluminescence imaging has certain advantages over the fluorescence systems. For example, autofluorescence, a source of noise in the image, is significantly less in bioluminescence for reasons discussed earlier. Also, bioluminescence reporters can be utilized as soon as they are synthesized. In contrast, the fluorescent proteins usually have a requisite period, some substantially longer than others, of posttranslational processing and maturation prior to their function as a fluorescent reporter (37). In some cases, where temporal resolution is an important issue in the monitoring of gene therapy, the use of fluorescence techniques may be limiting in this regard. Bioluminescence proteins also take some finite time to mature, but anecdotal evidence suggests that it is not as long as the fluorescent proteins; future studies are certain to address this issue.

Imaging with bioluminescence techniques permits rapid, repetitive, or prolonged imaging periods so long as the required substrates and cofactors are available. The physical phenomena of photobleaching, a property seen in many fluorescent proteins where the fluorochrome is permanently extinguished after light excitation or ultraviolet light exposure, makes imaging difficult if prolonged excitation periods or rapid repetitive imaging is needed; repeat imaging can only take place once fresh fluorescent protein has been generated. Photobleaching is not an issue in bioluminescence imaging. Having stated the above, no formal comparison has yet been made between fluorescence and bioluminescence using the same animal model, fusion reporter/individual reporters, and the same CCD camera. These studies should help to better define which is the more ideal reporter.

B. Radionuclide-Imaging Reporter Systems

Currently, PET or Gamma/SPECT reporter genes encode either a receptor, enzyme, or ion pump, which bind a radiolabeled ligand, interact with a radiolabeled substrate, or facilitate intracellular translocation of ionic radioisotopes, respectively. The reporter gene product is designed to sequester the

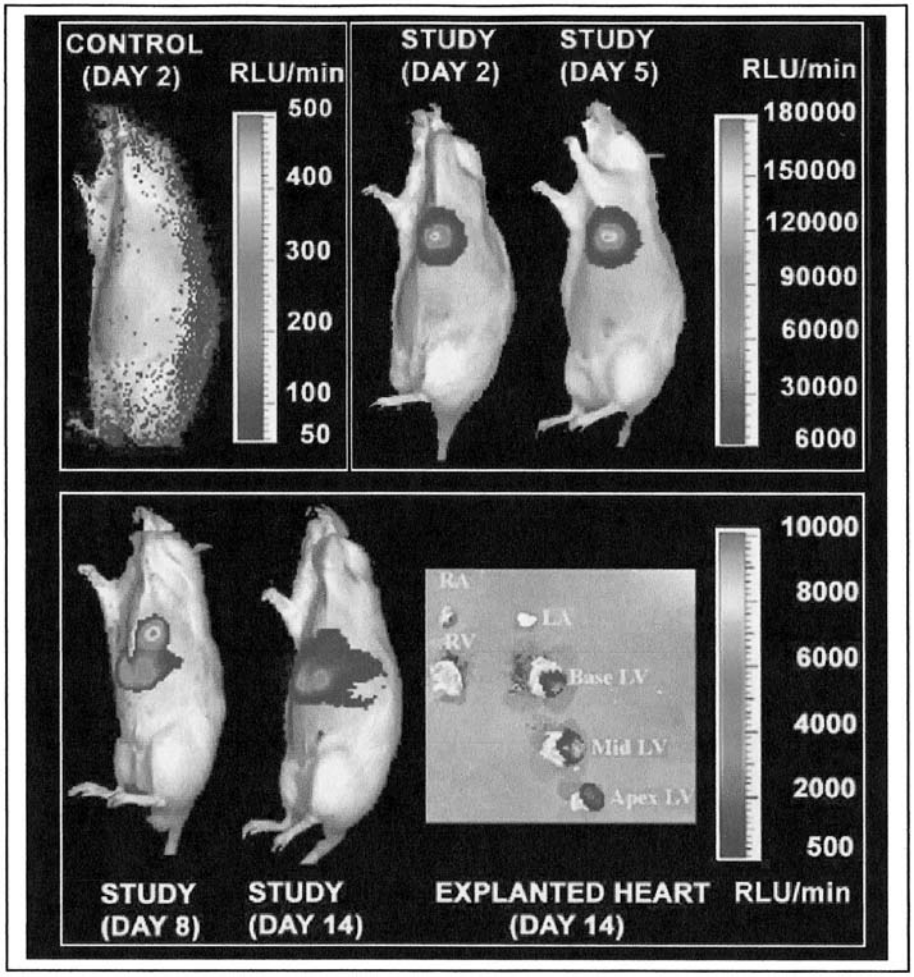

Figure 6 Optical (Bioluminescence) Imaging of Cardiac Reporter Gene Expression Replication-defective adenovirus carrying firefly luciferase (*Fluc*) driven by a constitutive cytomegalovirus (CMV) promoter (Ad-CMV-*Fluc*, 1×10^9 pfu) was injected directly into the myocardium (anterolateral wall) of a rat. Images obtained 2, 5, 8, and 14 days later from a cooled CCD camera demonstrate significant cardiac emissions from firefly luciferase activity ($P<0.05$ vs. control). By day 8, luciferase activity is seen in the liver, which is probably from spillover of adenoviral vector into the systemic circulation and subsequent hepatic transfection of the virus via coxsackie-adenovirus receptors on hepatocytes. On day 14, the heart of the same rat was explanted after whole-body imaging was performed and sliced into 3 sections (bottom right). Firefly luciferase activity is localized at the anterolateral wall of the left ventricle along the site of virus injection. Control rats, which received an intracardiac injection of Ad-CMV-HSV1-sr39*tk* (1×10^9 pfu), demonstrate no significant firefly luciferase activity 2 days after the injection (upper left). Please note the bioluminescent scales are different for control rat, study rat days 2 to 5, and study rat days 8 to 14 to account for the wide range of cardiac firefly luciferase activity observed. Scales are a quantitative indicator of light photons detected [relative light units (RLU)/minute (min)]. RA indicates right atrium; RV, right ventricle; and LV, left ventricle. See color insert for color version of this figure. (Images reproduced with permission, Ref. 116.)

probe intracellularly and/or on the surface of cells expressing these genes. Ideally, those cells lacking the transgene will be unable to trap the reporter probe. The amount of probe or tracer used is typically in the nanogram range and does not lead to any pharmacological effect (46). In contrast, bioluminescence strategies, NIRF and MRI, require mass amounts of probe (usually μg–mg) and, as a result, may produce a pharmacological effect.

Radionuclide imaging has significant advantages in that it permits quantitative and repetitive imaging in the same subject over time (47–50). Perhaps the main drawback of radionuclide-based techniques is that unsequestered probe circulates

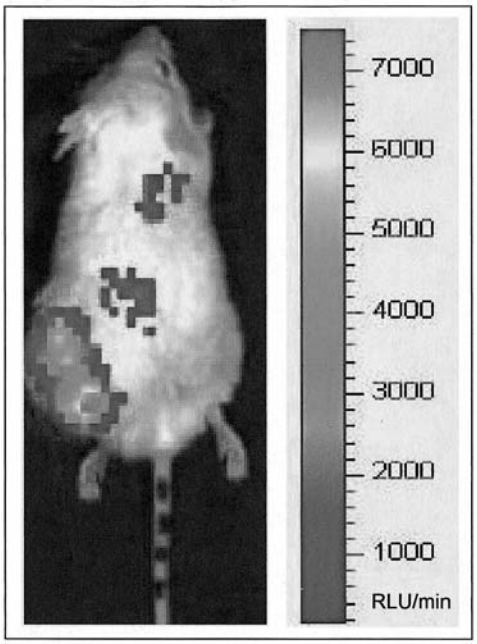

Figure 7 Optical (Bioluminescence) Imaging of Targeted Transgene Expression Using a Tissue-Specific Promoter One way to target gene therapy is through the use of tissue-specific promoters. However, most tissue-specific promoters yield low levels of transcription. In this example, certain key regulatory elements of the promoter and enhancer of prostate-specific antigen (PSA) have been multimerized to yield a construct, PSE-BC, which is 20-fold more active than the native PSA promoter/enhancer. Following incorporation into an adenovirus vector (AdPSE-BC-luc) and subsequent intratumoral injection into a human prostate cancer xenograft model (LAPC series), firefly luciferase expression can be seen in the main tumor xenograft (left flank) as well as other extratumoral sites, such as the back and chest, in this male SCID mice 21 days after vector delivery. Detailed histological analysis of the xenograft and extratumoral sites demonstrates that firefly luciferase expression is restricted to the prostate tumor and prostate metastases, respectively. The metastases, in this case, are located in the spine and lung. By comparison, CCD imaging and histological analysis of xenografts injected with AdCMV-luc show markedly diminished expression of firefly luciferase in the xenograft and increased nonspecific expression in the liver at 21 days postinjection (figure not shown). Results from this study indicate that tissue-specific transgene expression is possible and that CCD imaging can be used to track firefly luciferase-marked tumor cells. Scale indicates the number of photons detected (RLU/min). See color insert for color version of this figure. (Images reproduced with permission, Ref. 117.)

in the enterohepatic system or is excreted in the kidneys. As a result, probe can collect in the gut, kidneys, urinary bladder, or gall bladder, making it difficult to specifically evaluate these organs. Discussed below are 2 fundamentally different approaches to radionuclide-based reporter imaging: direct and indirect imaging.

1. Direct Radionuclide Imaging: HSV1-TK, Mutant HSV1-TK, Sodium Iodide Symporter, and Cytosine Deaminase

One of the major advantages of using a radionuclide technique is that it allows the opportunity to directly image delivered therapeutic genes (i.e., ''direct imaging''). In direct imaging, there is no need to couple the therapeutic gene with an additional reporter gene since reporter probes already exist for the therapeutic gene. The herpes simplex virus type 1 thymidine kinase gene (HSV1-*tk*) is an exemplary model of direct imaging.

Mammalian thymidine kinases phosphorylate thymidine for its normal incorporation into DNA during replication. The HSV1 thymidine kinase gene (HSV1-*tk*), on the other hand, is normally employed as a suicide gene product for the therapy of cancer. The gene product, with its broad substrate specificity, is able to phosphorylate acycloguanosine, guanosine, and thymidine derivatives and subsequently trap these substrates intracellularly much more efficiently than endogenous thymidine kinase. Thus, HSV1-*tk* acts as a suicide gene when delivered with a prodrug (such as acyclovir, ganciclovir, and penciclovir) since high concentrations of phosphorylated nucleoside analogs cause premature chain termination by their inhibition DNA polymerase, which leads to cell death. Transfected cell populations particularly affected by this type of therapy are those that have a high mitotic index. When radiolabeled acycloguanosines (e.g., 9-[(3-[^{18}F] fluoro-1-hydroxy-2-propoxy)methyl]guanine ([^{18}F]FHPG); 9-(4-[^{18}F] fluoro-3-hydroxymethylbutyl)guanine ([^{18}F]FHBG)), guanosines (e.g., fluorogangciclovir ([^{18}F]FPGV); fluoropenciclovir ([^{18}F]FPCV)), and thymidine derivatives (2′-[^{124}I] fluoro-2′deoxy-1-β-D-arabinofuranosyl-5-iodouracil ([^{124}I]FIAU)) are used in nonpharmacological (trace) doses, they can serve as PET reporter probes. Similarly, [^{131}I]FIAU and [$^{123/125}$I]FIAU can be used as gamma camera or SPECT reporter probes. The details of the synthesis and kinetics of these and other similar agents have been reviewed (51–56).

Endogenous thymidine kinase, HSV1-*tk*, and a mutated form of HSV1-*tk*, HSV1-sr39*tk*, each demonstrate different substrate specificity that can be exploited for therapeutic and imaging purposes. For example, endogenous thymidine kinase demonstrates narrow substrate specificity and cannot efficiently phosphorylate radiolabeled prodrugs. While endogenous thymidine kinase can phosphorylate the prodrugs/probes to a minor degree, nontransfected cells cannot accumulate significant amounts of the radiolabeled prodrugs. Instead, these radiolabeled prodrugs preferentially localize to cells, tissues, or tumors that express the HSV1-*tk* gene.

Comparison of the HSV1-*tk* probes demonstrates that [^{124}I]FIAU displays favorable pharmacokinetics (greater sen-

sitivity, better contrast, less background noise) and, thus, the best imaging potential (57). [^{124}I]FIAU, in particular, may be advantageous over the other tracers in some cases because the half-life of ^{124}I is 4.2 days, allowing for longer systemic clearance. On the other hand, this longer half-life may also prove problematic in cases when frequent repeat imaging is needed since a minimum 10 to 12 days between imaging sessions is needed to allow clearance of prior probe administration. Further testing has shown that [^{18}F]FHPG and [^{18}F]FHBG are inferior agents for HSV1-TK. This variability seen amongst HSV1-TK reporter probes is in part due to differences in biological half-life, stability, substrate competition, degree of nonspecific binding, specific retention, rates of cellular transport, method of transfer (viral-mediated vs. stable transfection), and routes of clearance (58).

Mutated versions of the suicide gene, HSV1-*tk*, have been created to enhance its killing potential by increasing its ability to phosphorylate prodrugs (59). From a library of site-directed mutants, it has been determined that the product of mutant HSV1-sr39*tk* suicide gene is more adept at phosphorylating ganciclovir and less efficient in phosphorylating endogenous thymidine when compared to wild-type HSV1-TK. In light of this, mutant kinase has been exploited as a reporter gene since radiolabeled reporter probes already exist and are identical to those used for the wild-type HSV1-TK. As expected, HSV1-sr39TK efficiently phosphorylates [^{18}F]FGCV, [^{18}F]FPCV, [^{18}F]FHPG, and [^{18}F]FHBG, with [^{18}F]FHBG as the most effective substrate for the mutant thymidine kinase. The ability to trap the reporter probe is improved by at least a factor of 2.0–3.0 in mutant TK-expressing tumor xenografts when compared with wild-type TK. Significantly improved uptake of the reporter probe is seen in the liver following systemic delivery of a recombinant adenoviral vector carrying the mutated transgene, resulting in enhanced sensitivity for imaging this transgene in vivo when compared to wild-type HSV1-*tk* (60). An example of the use of HSV1-sr39*tk* as a potential reporter gene for cardiac gene therapy is provided (Fig. 8). As an aside, an example of an optical reporter for use in cardiac gene therapy (using a nearly identical adenoviral vector and the firefly luciferase reporter gene) is provided for side-by-side comparison to better demonstrate the spatial advantages of microPET imaging (Fig. 8).

Another therapeutic transgene that lends itself to direct imaging in living subjects is the sodium/iodide symporter (NIS) gene (Fig. 9). NIS is an intrinsic membrane protein that is responsible for translocating and concentrating iodide within thyroid follicular cells. In this normal, physiological situation, iodide is eventually used to make the thyroid hormones (61). Recent cloning of the symporter has permitted the investigation of its role as a suicide gene. Because the symporter can concentrate high intracellular levels of iodide (including radioiodide, ^{131}I), targeted cells expressing the symporter can be killed in this form of targeted radiotherapy; by the accumulation of radioiodide, it is estimated that a dose of up to 50,000 cGy of ionizing radiation can be achieved in targeted cancer cells (62)! The lethal effects of the NIS have been cleverly demonstrated in vitro, in a variety of cell lines including melanoma, colon cancer, and ovarian carcinoma, and in a murine model of a transfected melanoma xenograft following intraperitoneal injection of ^{131}I (63). Also, tissue-specific expression of NIS transgene is possible by fusing a prostate-specific antigen (PSA) promoter fragment with the NIS gene—the result being tissue-specific expression of NIS transgene and subsequent accelerated death of an androgen-dependent prostatic carcinoma xenograft after injection with a therapeutic dose of radioiodine (64).

Imaging of the NIS transgene is relatively straightforward since the therapeutic agent, ^{131}I, can also be used as an imaging agent with a gamma camera or SPECT. Similarly, ^{123}I or ^{125}I, both of which are commercially available, can also be used as reporter probes. A significant advantage of this reporter system is that the reporter probe is relatively simple to produce and commercially available. Specialized radiochemistry, such as that required for HSV1-*tk* reporter probes, is not needed here. Another significant advantage of this system is that this reporter system can readily be imaged with PET using ^{124}I as the positron-emitting reporter probe, which already is available (65); the very same living subject carrying the NIS transgene can be imaged with either SPECT or PET depending upon the choice of reporter probe. The main confounding issue with using this reporter system, on the other hand, is that radioiodine will not only localize to target cells, but will also accumulate in normal tissues such as the thyroid, salivary glands, breast, and stomach, all of which express physiological levels of endogenous NIS. As it currently stands, it is also not clear if the NIS approach is as sensitive as the HSV1-*tk*/sr39*tk* approaches.

The cytosine deaminase (CD) transgene, another suicide gene, encodes an enzyme that converts 5-fluorocytosine to the toxic 5-fluorouracil (5-FU). Efforts to image this transgene, which have been performed with radiolabeled fluorocytosine as a probe, have largely been hampered by suboptimal pharmacokinetics: poor tracer uptake and poor retention of the toxic metabolite (66). Extended periods of up to 48 h are required to see differential accumulation of tracer between transfected and control cells. While targeted delivery of CD remains a viable method of suicide gene therapy (67), alternative substrates for CD, which are rapidly transported, deaminated, and trapped intracellularly, will have to be developed in order to use this transgene as a reporter gene.

2. Indirect Radionuclide Imaging: D2R, Mutant D2R, and Somatostatin-2 Receptor

In cases where a reporter probe does not already exist for a delivered transgene, a number of strategies exist for indirect transgene imaging. Indirect imaging involves the simultaneous coexpression of the therapeutic gene and reporter gene with both driven by the same or identical promoter. Because reporter gene expression can directly correlate with transgene expression, such approaches have the potential to give us valuable information on the quantity and localization of transgene expression (68). It should be noted, however, that it is not a given that they directly correlate; one can hope that they do but each approach/application has to be tested. Further details

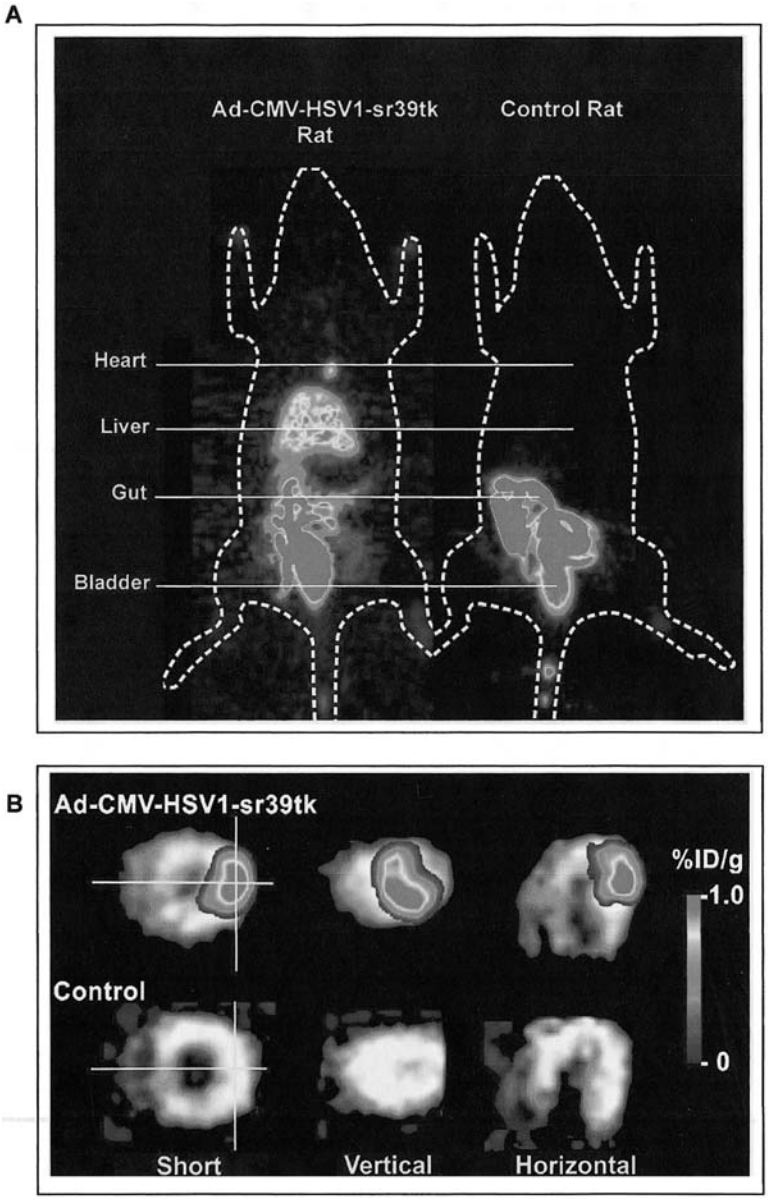

Figure 8 Micropet and Optical (Bioluminescence) Imaging of Cardiac Reporter Gene Delivery (A) Imaging cardiac gene expression using adenoviral-mediated mutant thymidine kinase (HSV1-sr39*tk*) as PET reporter gene and [^{18}F]FHBG as PET reporter probe. Trapping of tracer occurs only in cells expressing the reporter gene. At day 4, whole-body microPET image of a rat shows focal cardiac [^{18}F]FHBG activity at the site of intramyocardial Ad-CMV-HSV1-sr39*tk* injection. Liver [^{18}F]FHBG activity is also seen because of systemic adenoviral leakage with transduction of hepatocytes. Control rat injected with Ad-CMV-*Fluc* shows no [^{18}F]FHBG activity in either cardiac of hepatic regions. Radiolabeled probe is always ''visible'' with radionuclide imaging regardless of whether it has localized to its target or not. As a result, radionuclide-based images will exhibit a certain degree of nonspecific tracer localization since the ''unbound'' reporter probe is metabolized through either the enterohepatic or urinary system or both. In this example, nonspecific reporter probe activity and gut and bladder activities are seen for both study and control rats because of route of [^{18}F]FHBG clearance. (B) Tomographic views of cardiac microPET images. The [^{13}N]NH_3 (gray scale) images of perfusion are superimposed on [^{18}F]FHBG images (color scale), demonstrating HSV1-sr39*tk* reporter gene expression. [^{18}F]FHBG activity is seen in the anterolateral wall for experimental rat compared with background signal in control rat. Perpendicular lines represent the axis for vertical and horizontal cuts. Color scale is expressed as % ID/g. (C) Comparison of typical images obtained with PET (left) and optical imaging (right). The optical method is more sensitive (at limited depths), easier to perform, and demonstrates minimal background noise. With PET, we can see that the transgene was delivered to the anterolateral aspect of the left ventricle. Such spatial resolution is not afforded by in vivo optical imaging at this time. See color insert for color version of this figure. (Images reproduced with permission from Refs. 116,118.)

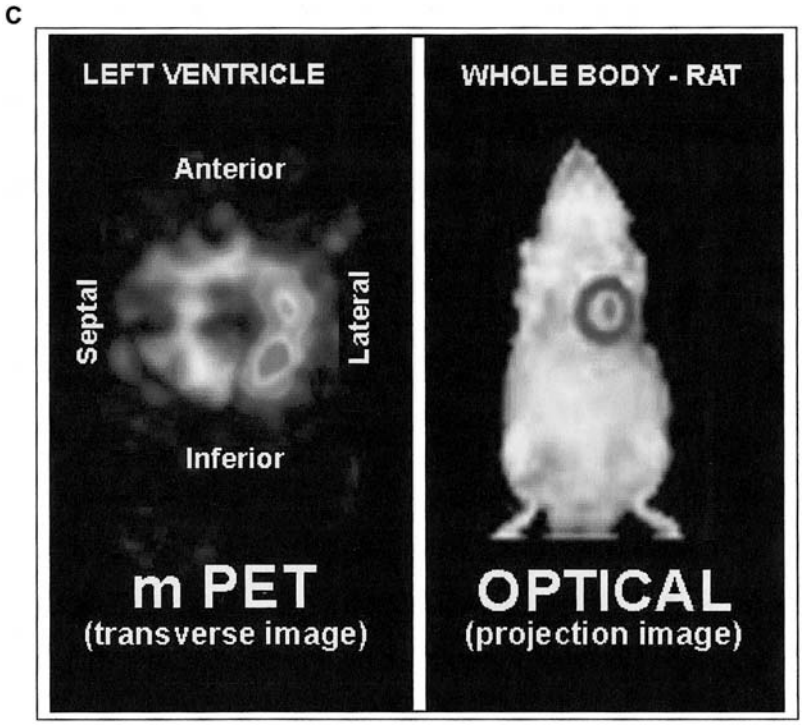

Figure 8 Continued.

regarding such indirect approaches are provided in a later section.

In radionuclide imaging, one way to perform indirect imaging is to couple the therapeutic gene to a reporter gene that encodes a receptor that can bind, and, therefore, trap radiolabeled ligands. Following transfection, targeted cells may express the therapeutic gene product and receptor in proportional amounts. Subsequently, the ectopically expressed receptor will either localize to the cell membrane and/or remain intracellular. Following exposure to radiolabeled ligand probe, cells expressing the receptor will specifically bind the probe, resulting in a complex that can be detected by PET/SPECT/gamma camera imaging. The intensity of activity on the PET image is directly proportional to the number of these receptor-ligand complexes, and, therefore, correlated to the amount of therapeutic gene expressed. Ideally, those cells not producing the receptor will be devoid of tracer signal.

An example of a receptor-based reporter gene is the dopamine type 2 receptor reporter gene (D2R) (49). D2R is normally an endogenous, cell-surface receptor predominantly expressed in the striatum. When activated, it causes a G-protein-coupled reduction of cyclic adenosine monophosphate (cAMP) via its inhibition of adenylate cyclase. When D2R is used as a reporter gene, a radiolabeled D2R antagonist, spiperone [3-(2′ [^{18}F]fluoroethyl)spiperone ([^{18}F]FESP)], serves as the receptor's ligand and accumulates intracellularly and on the cell surface of D2R-expressing tissue. Radiolabeled spiperone, originally used to monitor levels of endogenous levels of striatal D2 receptors in vivo, binds to D2R with high affinity and is able to cross the blood-brain barrier. To overcome potential deleterious effects of *ectopic* D2R activation by circulating *endogenous* ligands, mutant D2R reporter genes, D2R80A and D2R194A, have been created that are disengaged from downstream transduction events while maintaining a high binding affinity for ligand probe (48).

A few advantages of the D2R-based reporter system are worth commenting. [^{18}F]FESP's ability to cross the BBB and cell membranes favors its use in the central nervous system relative to other reporter systems such as the HSV1-*tk* (mutant or not) reporter systems since [^{18}F]FHBG is not as efficient in crossing this important barrier. Furthermore, [^{18}F]FESP has a relatively easier time of localizing to target, which is a cell-surface and intracellular receptor. In contrast, [^{18}F]FHBG has to cross the cell membrane in order to interact with the target enzyme and is, therefore, subject to transport kinetics. Also, D2R, an endogenous protein, is not immunogenic compared to HSV1-TK and therefore probably more appropriate for repeated imaging during longitudinal studies. Interestingly, despite these relative advantages of the D2R/[^{18}F]FESP system, equivalent sensitivities are reported between the D2R/[^{18}F]FESP and mutant HSV1-*tk*/[^{18}F]FHBG PET reporter gene imaging systems in the liver (~20% ID/g in the liver when used with adenoviral delivery systems carrying constitutive CMV-based expression of the reporter gene). One must

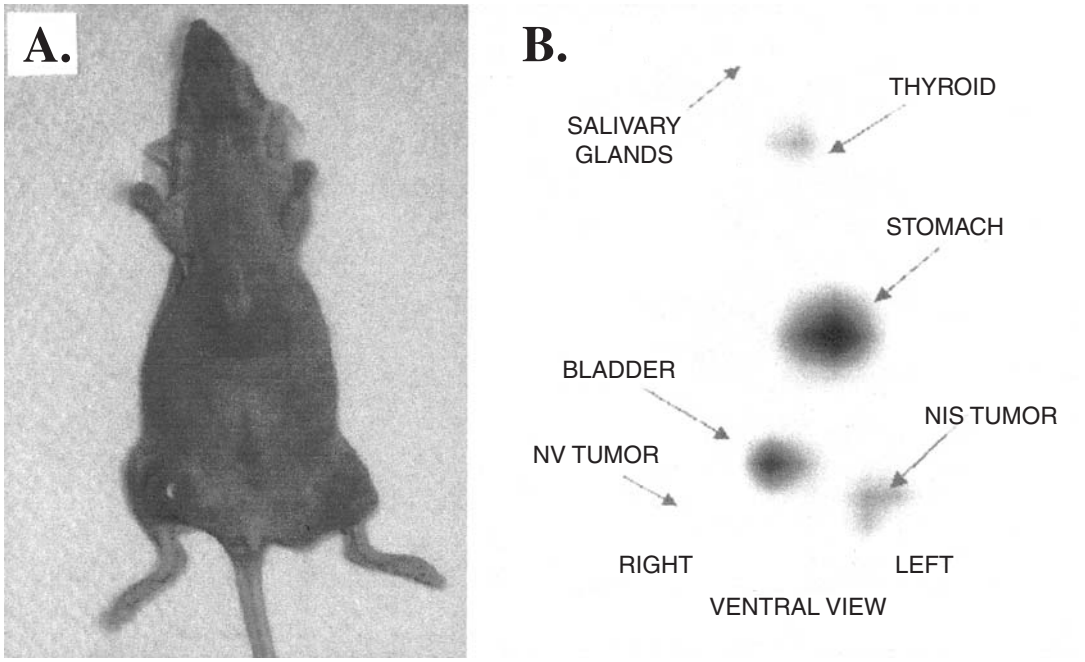

Figure 9 Gamma Camera Imaging of the Sodium Iodide Symporter Transgene Recently cloned rat and human sodium iodide symporter genes (rNIS and hNIS, respectively) are increasingly showing their potential as a novel suicide gene therapy for a variety of cancer models. Once transduced to a cancer cell line, tumor, or target organ via recombinant viral transfection or liposomal-mediated techniques, the expressed membrane proteins facilitate the active intracellular transport of iodide (I^-) into targeted cells. Exogenously administered radiotracers ^{123}I, ^{125}I, or ^{99m}Tc-pertechnetate results in intracellular accumulation of these tracers in cells that are transduced with this symporter. The distribution of these tracers can be imaged with a gamma camera or SPECT and, therefore, be used as a means of localizing cells that have been transduced with NIS. Similarly, targeted brachytherapy can be performed by the administration of ^{131}I. (A) A retroviral vector carrying the rNIS gene was used to transduce A375 human melanoma cell line. Transduced (NIS) and nontransduced (NV) tumor xenografts were subcutaneously implanted into the left and right flank of the photographed mouse, respectively. (B) By 30 days, the tumor had reached approximately 10 mm in diameter. An intraperitoneal dose of ^{131}I was administered, and a gamma camera image was obtained after a 1-h incubation period. rNIS-transduced xenograft (left flank) demonstrates radioiodide uptake while nontransduced tumor (right flank) does not. The thyroid, stomach, and, to a lesser extent, the salivary glands endogenously express sodium iodide symporters and, thus, normal, physiological radioiodide uptake is seen in these organs. (Images reproduced with permission from Ref. 63.)

also note that endogenous D2R expression in the striatum will produce background noise and, therefore, [^{18}F]FESP imaging will only be useful outside the striatum.

Another receptor-based reporter system takes advantage of the somatostatin membrane receptors (SSTR), which also belong to the family of G-protein-coupled receptors. Under normal conditions, the interaction between SSTR and its ligand, somatostatin (SS), is known to have a variety of biological effects including a role in vasoconstriction, immunomodulation, and an inhibitory effect on endocrine and exocrine secretory functions; more recently, SSTR-activated signal transduction pathways have been implicated in the induction of apoptosis and inhibition of cell growth (69) (70). SSTRs have also been found in normal and hyperplastic human endothelium where it is felt that the SSTR exerts negative effects on angiogenesis. Five different somatostatin receptor subtypes have been described thus far (SSTR1 through SSTR5), and their respective genes have been cloned (71).

Historically, the development of this reporter gene centered around probes that were already in existence and were being used clinically to identify diseased states characterized by upregulated SSTR receptors. Radiolabeled somatostatin analogs, for example, have been clinically used to identify a number of primary human cancers and their metastases where elevated levels of somatostatin receptors are seen. Neuroendocrine tumors (including carcinoid, islet cell tumors, small-cell lung cancers, pheocromocytomas, gastrinoma, paragangliomas, and medullary thyroid cancers), pituitary gland tumors as well as sarcomas, meningiomas, low-grade astroctomas, lymphomas, some breast cancers, and metastatic prostate cancers are known to express high levels of SSTR, particularly SSTR2. In fact, the combination of high SSTR receptor den-

sity seen in some tumors and the antiproliferative, antiangiogenic, and antisecretory effects of SS analogs form the premise for somatostatin analog therapy for cancer patients (72,73).

The favorable binding kinetics of SS-SSTR are the basis for use of the *sstr2* gene as reporter gene. Currently, [^{111}In]-DTPA-D-Phe^{1}-octreotide (Octreoscan) and [^{99m}Tc]-depreotide (Neotect) are radiolabeled somatostatin analogs that have been in routine clinical use for the past several years for the imaging of SSTR-positive tumors using gamma cameras or SPECT, i.e., SSTR scintigraphy (74,75). These agents have also been useful in the imaging of non-neoplastic conditions that are associated with SSTR upregulation, such as a variety of autoimmune and granulomatous diseases.

The potential of using *sstr2* as a reporter gene has been realized. Fig. 10 demonstrates adenoviral delivery via intratumoral injection of human *sstr2* gene into a tumor xenograft of a mouse. The transfected tumor is subsequently detected with a gamma camera following an intravenous injection of [^{99m}Tc]P2045, a somatostatin analog (76). For *sstr2* to serve as a true reporter gene, however, it will have to be uncoupled from signal transduction since it may have undesireable effects in targeted and surrounding cells in its current state.

On a side note, *sstr2* is being tried as a ''double-edged'' suicide transgene for cancer therapy. Not only does SSTR primarily mediate antimetabolic effects as described earlier, but it can also be utilized for its ability to internalize and retain SS analogs. Efforts are being made to deliver cytotoxic agents to targeted cells by using the receptor as a courier of toxic SS analogs, such as [^{90}Y]-DOTA-D-Phe^{1}-Tyr^{3}-octreotide ([^{90}Y]-SMT 487). ^{90}Y exerts its lethal effects by local irradiation via emitted β particle. When SSTR-null tumor xenografts are injected with recombinant adenovirus encoding the SSTR2 receptor, they become susceptible to systemically administered [^{90}Y]-SMT 487 (77). This version of targeted radiotherapy is able to significantly reduce quadrupling times of the xenograft. When the *sstr2* transgene is used in this manner it can be directly imaged using Octreoscan.

Indirect imaging can also be accomplished by coupling the therapeutic gene to a reporter gene that encodes an enzyme which converts freely dispersible radiolabeled substrate probes into sequestered products (78). For example, previously described HSV1-*tk* or HSV1-sr39*tk* can be used as a reporter gene by using [^{124}I]FIAU or [^{18}F]FHBG at tracer levels (subpharmacological, nontherapeutic dose). In this manner, the HSV1-*tk* or mutant counterpart can be utilized strictly as a reporter gene.

C. MRI Reporter Genes

Imaging transgene expression using MRI depends on reporter genes that encode receptors or enzymes which specifically interact with probes which are attached or chemically modified to accommodate paramagnetic or supraparamagnetic substances. Once localized to their targets, these probes alter the local magnetic field, which changes the relaxivity of nearby protons, and, concomitantly, effects a change in the radiofrequency signal detected by the receiver. At least two MRI reporter systems have been proven in animal studies: engineered transferrin receptor (ETR)-dependent reporter systems and the *lacZ*-EgadMe system.

Iron (Fe) is a superparamagnetic ion that can cause significant changes of the local magnetic field, which can be detected by MRI if supraphysiological concentrations can be achieved. Transferrin (Tf), an iron-binding protein, and its cell-surface receptor (Tf-R), a receptor ubiquitously present on most cell types, mediate normal cellular iron metabolism and regulation. Normal intracellular stores of iron are dependent upon internalization kinetics of this receptor-ligand complex. By removing the 3′ untranslated region (UTR) regulatory sequence from the Tf-R gene and mRNA destabilization motifs in the 3′ untranslated region, engineered transferrin receptor (ETR) has been created to be constitutively overexpressed and liberated from feedback regulatory control (79,80). As expected, ETR-transfected cells accumulate approximately 500% more probe (holo-Tf) than control cells. To further augment the difference between transfected and control cells, the reporter probe itself has been modified to possess even greater magnetic susceptibility characteristics. It involves the synthesis of a 3 nm monocrystalline iron oxide nanoparticle (MION) that is surrounded by a layer of low molecular-weight dextran to which holotransferrin is covalently bound (Tf-MION). On the average, each MION particle contains approximately 2000 superparamagnetic Fe atoms (compared with the 2 Fe atoms present in a single molecule of the paramagnetic chelate, holotransferrin). As expected, T2-weighted gradient echo MR imaging (1.5T; imaging time 3–7 min per sequence; voxel resolution 300 × 300 × 700 μm) reveals significantly lower signal intensity in ETR^{+} tumor xenografts than control following intravenous administration of Tf-MION (79). Recently, a second superparamagnetic reporter probe, a dextran cross-linked iron-oxide (CLIO) superparamagnetic particle conjugated to trasnferrin (Tf-CLIO) has also been effective in identifying ETR+ tissues with MR imaging (81).

The other MR imaging method shown to be compatible with living subjects relies on an enzymatic amplification strategy to monitor gene expression. As mentioned before, gadolinium (Gd) is a rare-earth element with the largest number of unpaired electrons. With 7 unpaired electrons, Gd is a strong paramagnetic substance, collectively affecting the spins of water protons immediately surrounding it. The increased signal (for T1-weighted sequences) seen in Gd-enhanced MR imaging is afforded by the increased relaxation rate of intimately associated water protons surrounding a Gd atom. Gadolinium's ability to affect the relaxation rate of protons varies inversely to the distance between the paramagnetic ion and water protons.

Based on these principles, a reporter probe, (1-(2-(β-galactopyranosyloxy)propyl)-4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane)gadolinium(III) (EgadMe), has been cleverly formed by ''encasing'' Gd in a water-proof package—an artificial barrier or cage designed to keep water molecules at bay so as not to be affected by the Gd's magnetic personality (Fig. 11A) (82). In this configuration, water has

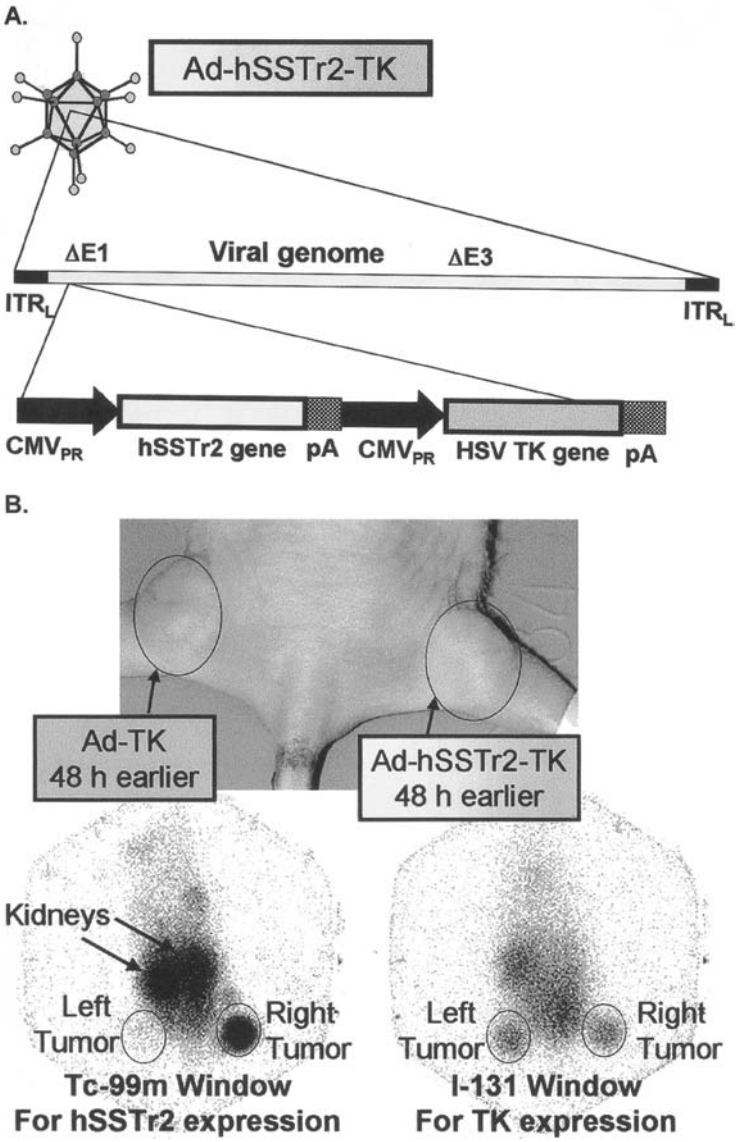

Figure 10 Gamma Camera Imaging of a Dual Promoter Construct (A) To measure target (therapeutic) gene expression, several strategies are employed to ''link'' the therapeutic gene with a reporter gene on a single vector. In one strategy, indirect measurements of a target gene expression can be made by a downstream reporter gene with both genes driven by separate and identical promoters (i.e., the 'dual-promoter' construct). Replication-incompetent adenovirus encoding human type 2 somatostatin receptor (*hsstr2*) and the herpes simplex thymidine kinase (TK) enzyme (Ad-CMV-*hsstr2*-CMV-*tk*) is an example of this construct. Both transgenes are driven by the cytomegalovirus promoter element. (B) Human nonsmall cell lung cancer tumor xenografts were subcutaneously implanted in the right and left flank of a mouse. The left tumor was injected with Ad-CMV-tk and the right tumor was injected with Ad-CMV-*hsstr2*-CMV-*tk*. Forty-eight h later, the mouse was simultaneously injected (IV) with both ^{99m}Tc-P2045, which is a somatostatin receptor peptide ligand, to detect expression of *hsstr2* and radioiodinated ^{131}I-2′-deoxy-2′-fluoro-β-D-arabinofuranosyl-5-iodouracil (FIAU) to detect TK expression. Imaging was performed with an Anger gamma camera 5 h after injection of the radiotracers. The gamma camera can be 'tuned' to select for gamma rays that fall within a defined range. It is this property of the gamma camera that can discriminate among the activity of different radioisotopes such as ^{99m}Tc (140 keV) and ^{131}I (364 keV). Thus, 2 images can be obtained from the same animal by changing the window settings in the gamma camera—one for ^{99m}Tc (for *hsstr2* expression, lower left image) and the other for ^{131}I (for TK expression, lower right image). The right flank xenograft, which was injected with the dual promoter construct (Ad-CMV-*hsstr2*-CMV-*tk*), demonstrates uptake of both radiotracers, while the left flank xenograft (injected with Ad-CMV-*tk*) demonstrates [^{131}I]FIAU uptake only. These finding support the feasibility of the dual promoter approach for tracking transgene delivery. (Images reproduced with permission from Ref. 76.)

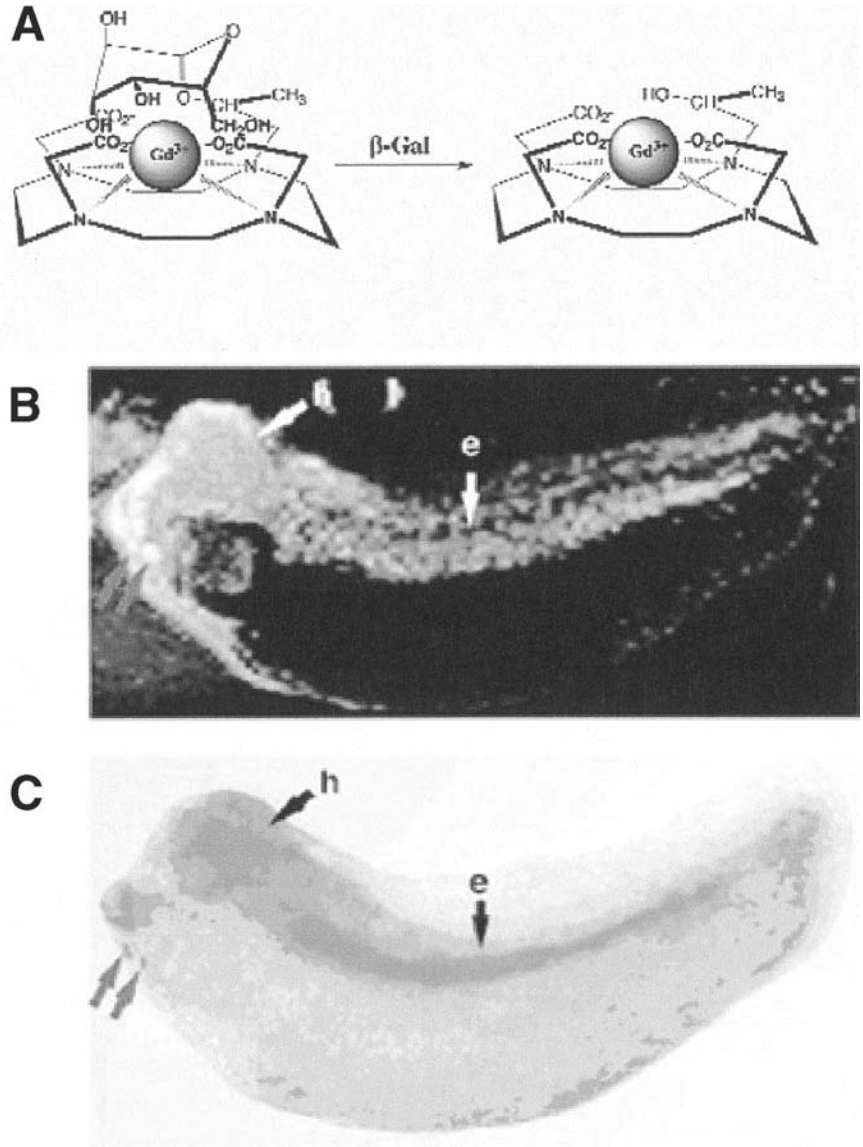

Figure 11 Magnetic Resonance Imaging (MRI) of β-galactosidase-activated MRI Reporter Probe (EgadME) One can obtain image contrast in MRI by using paramagnetic substances that change the local magnetic field and, thereby, increase the relaxation rate of nearby water protons. Gadolinium (Gd) is an example of a paramagnetic substance, and a relatively high local concentration of this agent translates into enhanced brightness as seen on T1-weighted images. (A) A reporter probe, EgadMe, has been formed by 'encasing' Gd in a molecular casing—an artificial barrier designed to keep water molecules at bay so as not to be affected by the Gd's magnetic effects. In this configuration, water has no access to the paramagnetic ion, and therefore, this probe is 'silent' on MR imaging. Part of the physical barrier is composed of a sugar, a galactopyranose cap, which has been attached to the cage by a β-galactosidase-cleavable linker. If *lacZ* is used as a reporter gene, subsequent enzyme cleavage releases the cap and allows water access to the gadolinium ion, thus, 'activating' this novel MR contrast agent. (B) EgadMe permits MRI detection of *lacZ* gene expression. Linearized plasmid cDNA encoding *lacZ* is injected into 1 of the cells of the 2-cell stage *Xenopus laevis* embryo. EgadMe is injected into both cells of the 2-cell stage. Subsequent enzyme expression is on 1 side of the animal since the 2 cells represent the future right and left sides of the animal. MR imaging of the embryos has been obtained at approximately the 100,000-cell stage using a 11.7 T magnet. As expected, β-galactosidase activity is seen in one half of the animal depicted as areas of high signal intensity within the endoderm (e) and head (h). (C) Light microscopic images of the same embryo fixed and stained with X-gal. Areas of X-gal staining follow regions of high signal intensity on MR image. (Images reproduced with permission from Ref. 82.)

no access to the paramagnetic ion and is therefore this probe is ''silent'' on MR imaging. As cleverly designed, part of the physical barrier is composed of a sugar—a galactopyranose cap, which has been attached to the cage by a β-galactosidase-cleavable linker. If *lacZ* is used as a reporter gene, subsequent enzyme cleavage releases the cap and allows water access to the gadolinium ion, thus, ''activating'' this novel MR contrast agent. β-galactosidase activity, following introduction of linearized plasmid cDNA encoding *lacZ* into a specific subset of cells in a *Xenopus laevis* embryo, has been imaged after an intracellular injection of EgadMe (Fig. 11B,C).

In its current state, EgadMe has difficulty crossing cell membranes and, as a result has to be directly injected intracellularly to maximize detection in vivo. Furthermore, relatively slow kinetics of cleavage for this agent is perhaps suboptimal for imaging gene expression (82). Regardless, these relatively recent developments will be refined, and they indicate great potential for MR imaging of transgene expression.

D. Magnetic Resonance Spectroscopy (MRS) Reporter Genes

Certain metabolites produced physiologically from endogenous enzymes or uniquely from exogenous enzymes have unique chemical signatures that can be detected using MRS (a.k.a., nuclear magnetic resonance (NMR) spectroscopy). These enzymes can be overexpressed in target tissues and can be used as MRS reporter genes to successfully track gene expression in transgenic models, transfected tumor xenografts, or viral-mediated gene transfer experiments. At this time, MRS does not produce true, spatial ''pictures'', and, instead, shows spectral tracings of the various metabolites it is able to identify. It is a sensitive, quantitative, and relatively fast technique when compared to MRI (29).

One particular MRS-sensitive metabolic reaction produces ATP, a process catalyzed by creatine kinase (CK):

$$H^+ + PCr + ADP \leftrightarrow ATP + Cr \quad (1)$$

where PCr is phosphocreatine and Cr is creatine. More specifically, ^{31}P-MRS identifies amounts of phosphocreatine (PCr), ATP, ADP, and free phosphorus in the reaction. This molecule can be detected readily in the heart, muscle, and brain since they are produced in great quantities in these organs. The liver, on the other hand, has very low levels and thus can serve as a background for situations where CK is overexpressed. A transgenic mouse model that overexpresses this enzyme in the liver has shown that it can generate MRS-detectable levels of PCr (83). This technique is however invasive in nature, for a tissue window has to be created to minimize background noise from the overlying muscle and other surrounding structures rich in CK. Future developments in ^{31}P 3D spectroscopy may eventually prove helpful.

A related study employs an invertebrate analog of CK as its reporter gene. *Drosophila melanogaster* arginine kinase (AK) has been cloned and, when introduced into mammalian muscle, produces phosphoarginine (PArg) in the following reaction (84):

$$H^+ + PArg + ADP \leftrightarrow ATP + Arg \quad (2)$$

PArg provides a unique phosphorus signal that is amplified when the transgene for AK is delivered to mammalian tissues (Fig. 12). One important consideration in the use of *Drosophila* AK is it can act as an ATP buffer in mammalian tissues and, thus, the consequences of this need to be explored prior to its widespread use as an in vivo gene reporter gene.

Another MRS-friendly system is the cytosine deaminase (CD) reporter system (85). Using ^{19}F MRS, the conversion of the relatively benign 5-fluorocytosine (5-FC) to the cytotoxic agent (5-FU) driven by this enzyme can be detected. Tumor xenografts transfected to express yeast CD have been shown to produce 5-FU with MRS.

IV. STRATEGIES FOR TRACKING VEHICLES AND TRANSDUCED CELLS

The list is quite long for the array of vehicles being developed, both viral and nonviral, for the delivery of gene vectors. The details of such carriers are, of course, provided elsewhere throughout this book. There are 2 fundamentally different ways to track the biodistribution of delivered agents. One method is to track the sites of successful gene transfer/expression (various methods described in this chapter) and the other method relies on directly labeling vehicles, DNA or cells with radionuclides, fluorescent dyes, or MR-compatible contrast agents. The latter method may give better spatiotemporal information with respect to distribution of the vehicles or DNA material used for therapy, but does not give any information with regards to the success of gene transfer. The latter method has been reviewed recently and includes the direct labeling of herpes virus with ^{111}In, adenoviral knob with ^{99m}Tc, liposomes with ^{111}In, double-stranded DNA by peptide-based chelates ([^{99m}Tc]PBC), genetically modified mesothelioma cells with technitium ([^{99m}Tc]PA1-STK), myoblasts with technetium, and DNA-delivery systems with MRI-detectable, DNA-binding chelates (86–93).

For those involved in the development of novel viral or nonviral delivery vehicles, targeting and efficiency of gene transfer are primary concerns, and, thus, examples of the former method are given here. The success of exogenous gene expression is dependent on its ability to at least survive the following series of stringent events: the DNA-vehicle complex has to bind specific cell-surface receptors, undergo receptor-mediated endocytosis, survive endosomal lysis, be released from endosomal captivity, endure the cytoplasmic environment, be destined for targeted entry of the nucleus, and ultimately released from carrier molecules to facilitate gene expression (94). Whether it is pseudo-typed lentiviruses, modified PEI complexes, liposomes, etc., one major role reporter genes are expected to provide is the monitoring of localization, biodistribution, and gene transfer efficiency of these delivery vehicles in living subjects. Noninvasive localization

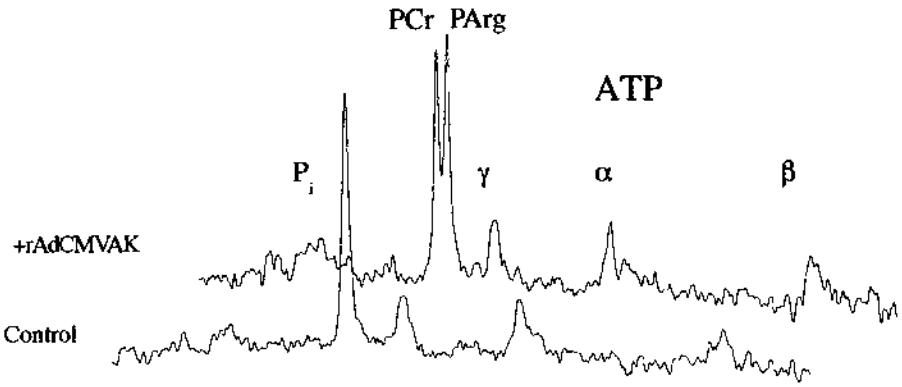

Figure 12 Magnetic Resonance Spectroscopy (MRS) of Transgene Expression ^{31}P-MRS has the ability to detect phosphorus NMR signals. A recombinant adenovirus (rAdCMVak) can be constructed to deliver arginine kinase, an enzyme unique to invertebrates, into muscle. Once introduced into mammalian muscle, the enzyme catalyzes the production of phosphoarginine (PArg), which has a unique spectral signature (both in magnitude and location on the spectrum) that can be detected by MRS. Figure represents in vivo basal ^{31}P spectra from the hind limbs of a 6-month-old mouse. ^{31}P-MRS spectra from the rAdCMVAK-injected limb (upper spectrum) reveal a ^{31}P resonance at the chemical shift for PArg that is not present in the contralateral control limb (lower spectrum). (Images reproduced with permission from Ref. 84.)

of retroviral- (95), adenoviral- (96), and herpes viral vector- (97) mediated HSV1-*tk* gene transfer has been performed. Fig. 13 is an example of replication-conditional, oncolytic herpes simplex virus-mediated gene delivery. Constitutively expressed optical and/or PET reporter genes have been helpful in studying the distribution of nonviral vehicles such as PEI polyplexes, which have been covalently modified with transferrin to facilitate targeting (Fig. 14), and cationic lipid-DNA complexes (Fig. 15).

V. MONITORING GENE THERAPY LEVELS

Precise localization and quantitative assessment of the magnitude and temporal variation of transgene expression is a necessary component of any gene therapy trial. Direct imaging with a transgene-specific imaging probe is ideal but neither feasible nor practical in most cases. To develop a specific probe for each individual transgene is not always technically possible; furthermore, it is necessarily labor and cost-intensive. Using

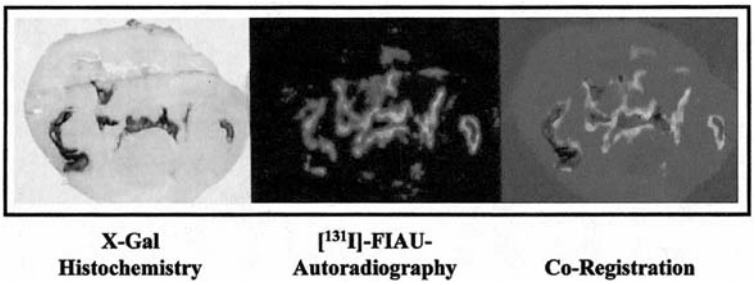

Figure 13 Tracking HSV Infection with [^{131}I]FIAU Using Autoradiography Tracking wild-type HSV-1 infection with radionuclide-based techniques can be accomplished using the virus's native thymidine kinase gene and a reporter probe such as radiolabeled [^{131}I]FIAU. To help corroborate imaging findings with histochemistry findings, a replication conditional, oncolytic recombinant HSV-1 virus vector, hrR3, containing a *lacZ* insertional mutation within the *RR* gene locus, has been prepared. Following injection of the vector into rat gliosarcoma xenografts, tumors were processed for tissue-sectioning, autoradiography, and β-galactosidase-stained histology. Image coregistration of tumor histology, HSV-1-*tk*-related radioactivity (assessed by [^{131}I]FIAU autoradiography), and *lacZ* gene expression (assessed by β-galactosidase staining) demonstrated a characteristic pattern of gene expression around the injection sites. A narrow band of *lacZ* gene expression immediately adjacent to necrotic tumor areas is observed, and this zone is surrounded by a rim of HSV-1-*tk*-related radioactivity, primarily in viable-appearing tumor tissue. PET images (not shown) of injected tumors in the intact animal have also been performed using [^{124}I]FIAU as a reporter probe; the areas of PET-labeled probe uptake correlate well with the β-galactosidase-stained photomicrographs. See color insert for color version of this figure. (Image reproduced with permission from Ref. 97.)

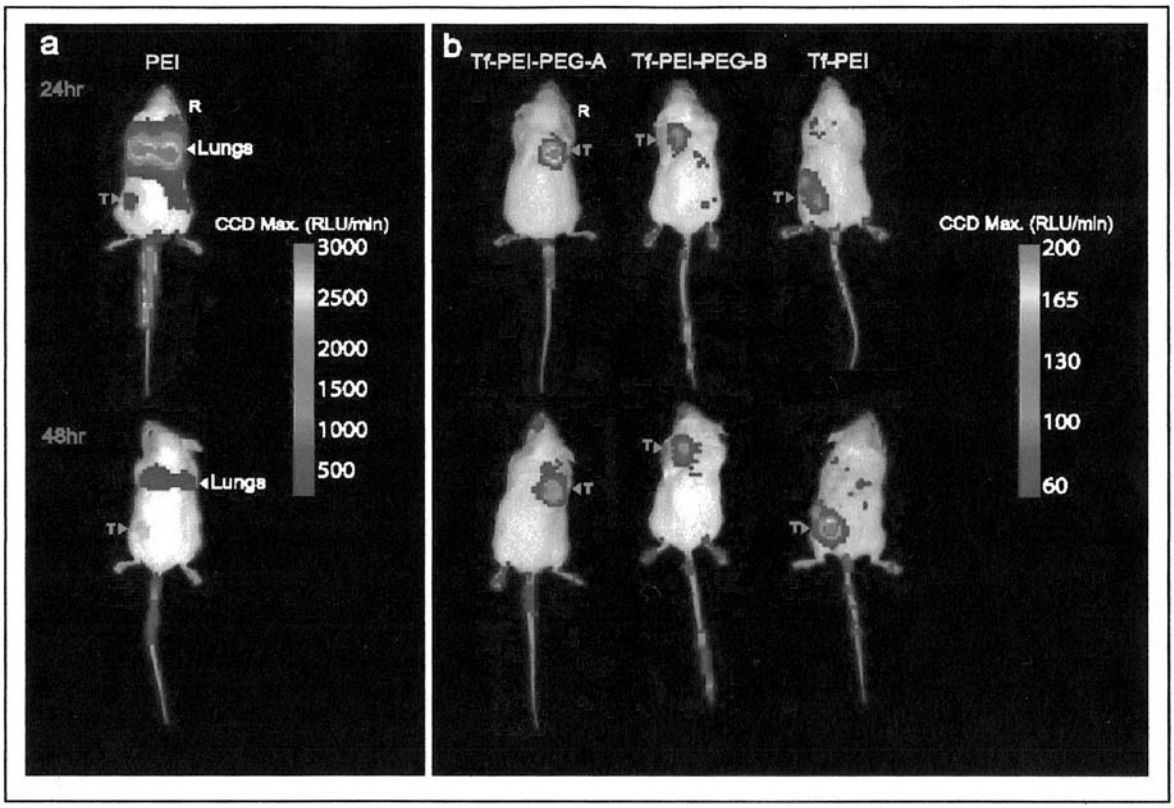

Figure 14 Tracking Transferrin Targeted Polyethylenimine (PEI)-Mediated Gene Delivery Using Optical Bioluminescence Imaging Delivery of the bioluminescence reporter gene, firefly luciferase (*Fluc*), by CMV-*Fluc* DNA/PEI polyplexes and subsequent *Fluc* expression can be imaged in living mice using a cooled CCD camera. Additionally, the biodistribution of modified PEI polycation complexes, altered with molecules such as transferrin and/or polyethylene glycol (PEG), can be studied in this manner. Transferrin targeting has been shown to improve the transfection efficiency in certain tumor cell lines, and PEG modification has been shown to improve circulation times of DNA/PEI complexes and prevent their nonspecific uptake by the reticuloendothelial system. All CCD images are of living mice carrying N2A xenograft 24 or 48 h after intravenous injection of various DNA/PEI polyplexes. Site of tumor is indicated (T). (a) PEI (positive control) treated animals show relatively high *Fluc* expression (using 1× D-Luciferin) in the lungs as compared with the tumor. The activity on the left hind limb is from the N2A cell tumor (T). Nonspecific tail activity occurs at the DNA/PEI polyplex injection site. All *Fluc* expression decreases at 48 h. (b) Tf-PEI-PEG-A-, Tf-PEI-PEG-B-, and Tf-PEI-treated mice show *Fluc* expression (using 2× D-Luciferin) in the tumor (T) and tail regions, but no detectable signal in the lungs. For each formulation, expression in the tumor varied over 24 to 48 h. All images are quantitated as indicated by the 2 scales (RLU/min). See color insert for color version of this figure. (Image reproduced with permission from Ref. 119.)

indirect imaging methods by linking a portable reporter gene to a therapeutic gene allows for more flexibility, as a variety of transgenes can be individually monitored by cloning a reporter gene into appropriate sites of the vector. Coexpression of the therapeutic gene product and reporter gene product in a coordinated and regulated manner enables a correlative and quantitative relationship between the 2 genes. Thus, levels of therapeutic gene expression can be inferred by the amount measured from reporter genes, provided that the expression of both genes remains coupled. Several such approaches, ranging from the more straightforward, like the dual vector approach, to the more sophisticated, such as the bidirectional transcriptional approach, are currently being developed and are briefly discussed below (78).

A. Covector Administration

One relatively simple method to monitor gene therapy in vivo is to coadminister 2 different vectors that are identical in every regard with the exception of the transgene they are carrying: one vector would encode the therapeutic gene, the other would encode the reporter gene, and both genes would be driven by the same promoter. This approach has been validated using the 2 PET reporter genes, HSV-sr39*tk* and D2R, each cloned

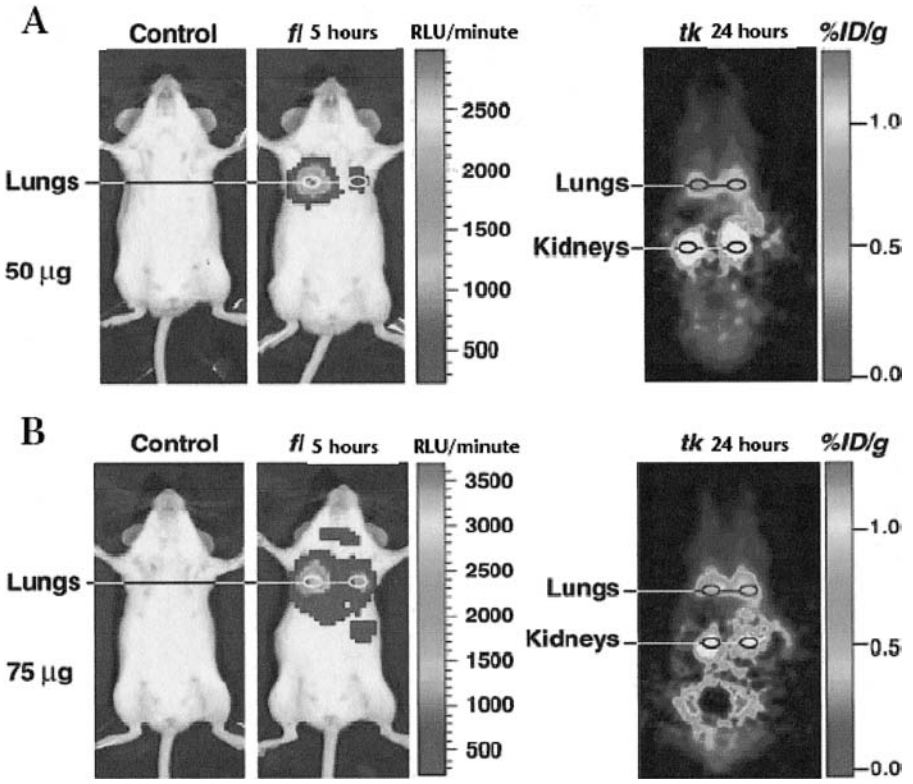

Figure 15 Tracking Cationic Lipid-Mediated Reporter Gene Delivery Using Optical (Bioluminescence) and PET Imaging Cationic lipids associate with negatively charged DNA to form complexes that bind to cell surfaces by way of electrostatic interaction, thereby allowing a nonviral means of gene transfer. Distribution of systemic administration of DNA-lipid complexes in mice is demonstrated by delivering prepared DNA-lipid complexes that carry optical and PET reporter genes. CMV-*fl* plasmid DNA (cytomegalovirus (CMV) promoter driving expression of firefly luciferase (*fl*) gene) was mixed with cationic lipid, 1,2-dioleoyl-3-trimethylammonium-propoane (DOTAP) and cholesterol, to form *fl* DNA-lipid complexes. A similar procedure was used to prepare HSV1-sr39*tk* DNA-lipid complex (*tk* DNA-lipid complex). (A, B) Figures A and B show images following administration of 50 μg and 75 μg each of *fl* and *tk* DNA-lipid complexes via tail vein injection into CD-1 mice, respectively. Bioluminescent images (left images) were obtained 5 h after injection of the vector and 5 min after intraperitoneal injection of D-Luciferin. MicroPET images (right images) were obtained 24 h after vector delivery and 1 h after [^{18}F]FHBG injection. Control mice (left) optical images were obtained prior to administration of D-Luciferin. Optical and PET images demonstrate that lungs are primary organs for transgene expression. Increased dose of DNA-lipid complex results in greater pulmonary transgene expression. Activity seen in the kidneys in the microPET images is the result of excreted, unsequestered, reporter probe, [^{18}F]FHBG. See color insert for color version of this figure. (Image reproduced with permission from Ref. 120.)

into distinct adenoviral vectors and both driven by the same CMV promoter (68). While individual cell differences in expression levels may be seen, macroscopic measurements made at the tissue culture or organ level (adnenoviral-mediated hepatic transfer) correlate quite well ($r^2 \geq 0.93$). The technique may prove useful in specific experimental situations.

B. Single Vector Approaches

The use of an internal ribosomal entry site (IRES) is a hallmark of the bicistronic approach to coupling genes (98–100). In a bicistronic expression cassette, an IRES sequence is interpositioned between the therapeutic and reporter gene, usually the first and second cistron, respectively. Both genes are under the control of the same promoter, and transcription of this construct results in a single mRNA molecule. Initiation of translation of the first cistron is by way of the usual cap-dependent manner, but translation of the second cistron is facilitated by the IRES sequence in a cap-independent mechanism, which allows binding a translation by a second ribosome. This approach has been verified in a few studies. For example, an IRES derived from an encephalomyocarditis virus has been used to construct a bicistronic vector from

which both D2R and HSV1-sr39*tk* reporter genes are coexpressed from a common CMV promoter (pCMV-D2R-IRES-HSV1-sr39*tk*) (47). The levels of D2R and HSV1-sr39tk activity demonstrate a high degree of correlation ($r^2 = 0.97$) using [^{18}F]FESP and [^{18}F]FHBG as imaging probes, respectively. Another vector that encodes Renilla luciferase (*Rluc*) in a bicistronic configuration, pCMV-*Rluc*-IRES-sr39*tk* or pCMV-sr39*tk*-IRES-*Rluc*, also shows excellent correlation (47). Similar relationships have also been seen with the use of an HSV1-*tk* gene that has been ''IRES-linked'' to the *lacZ* gene (101); imaging with iodinated FIAU (SPECT reporter probe for HSV1-*tk*) correlates well with β-galactosidase activity seen by light microscopy. These studies corroborate the use of radionuclide and optical reporter genes as a means of quantitatively determining relative levels of target gene expression.

One interesting finding in this approach, however, is that expression levels from the gene upstream to IRES sequence is consistently more robust then the levels seen from the gene downstream to the IRES (47). This may have to do with cell-specific differential translation from the IRES sequence, but, regardless, emphasizes the need for a highly sensitive reporter system, as levels of the reporter gene product will be significantly diminished compared to the upstream gene. Further understanding and exploitation of regulatory ''modules'' recently found within the IRES may help circumvent this problem in the future (102). Alternatively, 2 different genes from 2 distinct, but identical, promoters within a single vector can be expressed to avoid the attenuation problem and tissue variation issues experienced with the IRES-based approach. This is a variation of the bicistronic approach and is otherwise known as the ''dual-promoter'' approach (76). Strong correlation between 2 reporter genes, *hsstr2* and HSV1-*tk*, each driven by an independent but identical CMV promoter, has been exhibited (Fig. 10).

In some situations, gene therapists will want to externally control the levels of transgene expression and, additionally, will need to verify the extent of control with imaging techniques. One particularly novel indirect imaging method makes this entire scenario possible by the use of a single inducible bidirectional tetracycline-responsive element and 2 flanking minimal CMV promoters (Fig. 16A). The fusion transactivator protein rtetR-VP16, which is constitutively expressed and can potentially be incorporated into the same bidirectional vector, binds to TRE only in the presence of tetracycline or 1 of its analogs. By varying levels of an exogenously added inducer such as doxycycline, a gene therapist can control transcription and magnitude of expression, which can be verified by the accompanying reporter gene. Proof of principle has been shown in rat xenograft models using the reporter genes D2R and HSV1-sr39*tk* (Fig. 16B) (103).

The fusion gene/protein approach is yet another powerful means of indirect monitoring of gene therapy. Constructs in this protocol contain 2 or more genes linked together within the same reading frame so that a single protein is translated. The resultant hybrid or fusion protein will have therapeutic and reporter properties, and the expression of the fused gene can be closely monitored since the expression of the therapeutic component is stoichiometrically coupled to the reporter component of the protein. HSV1-*tk*-*gfp*, HSV1-*tk*-*Fluc*, *gfp*-*Fluc*, and HSV1-sr39*tk*-*Rluc* are a few successful examples (21,104–106). The fusion gene is engineered such that the proteins are linked via a short peptide spacer. However, while appealing in concept, it is quite challenging in practice to produce generalizable proteins, since fusion proteins are often inactive or less active than their individual counterparts; furthermore, fusion proteins also may not localize to appropriate compartments since appropriate signaling mechanisms are either masked or unavailable (78). Using this technique for every therapeutic gene developed would prove to be a daunting task, since each newly generated fusion protein has its own peculiarities. Future technological improvements in the physical linkage of 2 proteins may help minimize discrepant behavior and allow more flexibility for this technique.

VI. CLINICAL APPLICATIONS

While human gene therapy trials have been in effect for several years, the imaging of transgene expression in humans has only started. Transgenes, which can serve as both therapeutic genes and reporter genes (i.e., ''direct imaging''), will most likely have an easier transition towards clinical application when compared to indirect imaging methods. More specifically, the kinetics, biodistribution, stability, dosimetry (needed for radionuclide approaches), and safety of the transgene and reporter probe have to be determined in direct-imaging reporter protocols. In comparison, an additional verification and characterization of the reporter gene product has to be performed in indirect imaging systems.

Utilizing a direct-imaging method, such is the case with the HSV1-*tk* suicide/reporter gene and one of its reporter probes, [^{18}F]FHBG, where the requisite pharmacokinetics, biosafety, and other related testing have been established in human volunteers (55). The study indicated that while [^{18}F]FHBG demonstrates acceptable characteristics and should prove to be an acceptable probe for HSV1-*tk* imaging, [^{18}F]FHBG does not readily cross the BBB. Methods used to disrupt the BBB during [^{18}F]FHBG administration may aid in this regard if needed. Furthermore, imaging HSV1-*tk* reporter gene expression near the gall bladder, kidneys, and bladder with [^{18}F]FHBG may prove to be difficult since nonsequestered [^{18}F]FHBG passes through these organs, contributing to the background signal seen in these structures. Clinical trials with [^{18}F]FHBG in patients undergoing HSV1-*tk* gene therapy have recently begun.

In another study, which also employs a suicide/reporter gene system, a small group of patients suffering from recurrent glioblastomas have been treated with suicide gene therapy (HSV1-*tk*) (Fig. 17) (107). The construct has been delivered with a cationic liposomal vector and among the 5 patients treated with this therapy, 1 shows accumulation of the reporter probe [^{124}I]FIAU in a portion of the tumor. Following a 2-week course of ganciclovir, FDG PET, and methionine (MET), PET scans at the end of treatment indicate that necro-

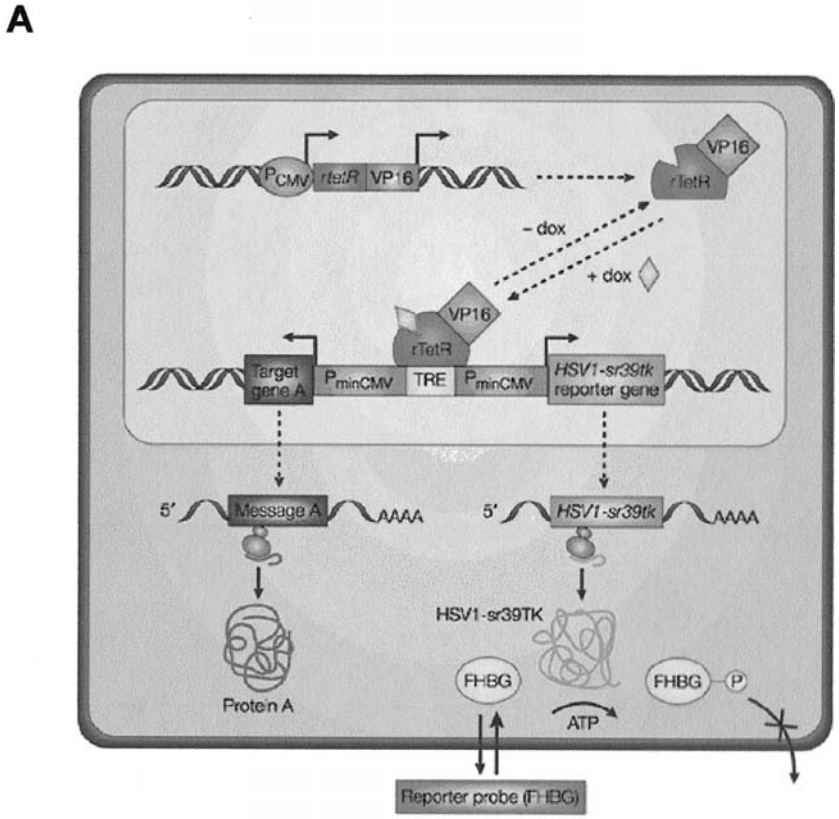

Figure 16 Indirect PET Imaging Using a Bidirectional Transcriptional Approach (A) Target (therapeutic) gene expression can be measured indirectly by imaging reporter-gene expression if expression of the 2 genes is 'linked.' Both genes can be simultaneously expressed from 2 minimal cytomegalovirus (CMV) promoters that are regulated by a single bi directional tetracycline-responsive element (TRE). The rTetR–VP16 fusion protein is produced constitutively from a CMV promoter. When the rTetR–VP16 fusion protein binds to doxycycline, this complex binds to the TRE regulatory sequence and substantially enhances expression from the 2 minimal CMV promoters. The target gene *A* in 1 coding region and a reporter gene (for example, a reporter kinase such as HSV1-sr39*tk*) in the alternative coding region are transcribed simultaneously into 2 mRNA molecules. Translation of the 2 mRNA molecules yields two distinct proteins in amounts that are directly correlated with each other. (B, see pg. 474) Quantitative imaging of the location(s) and magnitude of PET reporter-gene expression by trapping of a PET tracer inside the cell (for example, by phosphorylation of [^{18}F]FHBG by the HSV1-sr39TK reporter protein) provides an indirect measure of target-gene expression. Sequential microPET (positron-emission tomography) imaging studies of a nude mouse carrying 4 tumors. Four tumor cell lines—2 positive controls (constitutive reporter-gene expression), 1 negative control, and 1 inducible line (reporter-gene expression induced by doxycycline)—were injected subcutaneously into 4 separate sites in a single mouse. When tumors reached a size of at least 5 mm, the mouse was imaged with 9-(4-[^{18}F] fluoro-3-hydroxymethylbutyl)guanine ([^{18}F]FHBG). Doxycycline was then added to the water supply for 7 days. The mouse was then scanned again with [^{18}F]FHBG. Doxycycline was removed from the water supply for the next 7 days, and the mouse was again scanned with [^{18}F]FHBG. The locations of the 4 tumors and the mouse outline are shown by the dotted regions of interest. All images are 1–2 mm coronal sections through the 4 tumors. The % ID/g (% injected dose per gram tissue) scale for [^{18}F]FHBG is shown on the right. The negative control tumors show no gene expression, and the positive control tumors show increased expression over the time course. The tumor on the top right, with inducible gene expression, initially does not accumulate [^{18}F]FHBG, then at 7 days after addition of doxycycline, induction of reporter-gene expression traps [^{18}F]FHBG. Seven days after withdrawal of doxycycline, there is decreased induction and minimal trapping of [^{18}F]FHBG. The [^{18}F]FHBG image signal correlates well with target-gene expression (not shown). See color insert for color version of this figure. (Images reproduced with permission from Ref. 23.)

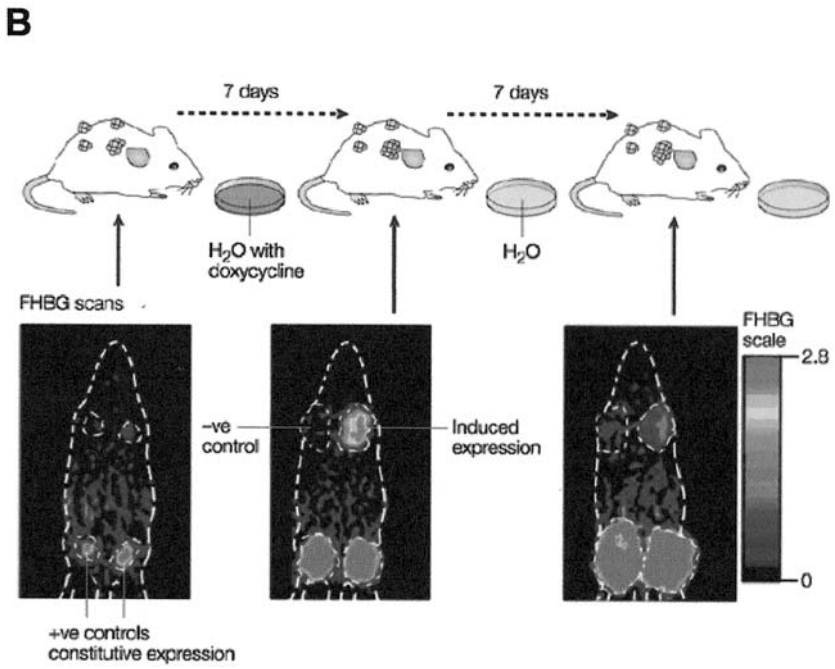

Figure 16 Continued.

sis occurs in the region where [^{124}I]FIAU uptake was previously shown, suggesting successful suicide gene transfer to a portion of the tumor. Those patients who could not accumulate detectable levels of [^{124}I]FIAU in their infused tumors were found to have a low mitotic index in their tumors.

With this small yet extremely exciting study, we are able gain a significant amount of knowledge about human gene therapy using in vivo imaging methods. For example, the investigators were able to identify and localize successful gene transfer in 1 patient 68 h after tumor infusion. Also, in the patient where [^{124}I]FIAU uptake was seen, only a fraction of the tumor was sequestering [^{124}I]FIAU. This suggests that the rest of the tumor was either not transduced or that the transduction was too weak to detect. Additional follow-up scans of the patient would help to determine the outcome of the heterogeneously treated tumor as well as the importance of reporter-probe uptake. In the patients that did not demonstrate [^{124}I]FIAU uptake, the failure to see [^{124}I]FIAU reporter-probe accumulation may be due to sheer lack of transducible cells or failure of gene transfer. Future studies of these and other issues are certain to be extremely helpful in understanding the effectiveness of gene therapy.

VII. DECISION ALGORITHM FOR REPORTER GENE TECHNOLOGY

The road to clinical gene therapy trials is an arduous one but can be helped with the variety of reporter-gene technologies described in this chapter. As with any drug testing, there is a prerequisite period of preclinical testing, much of which takes place in animal models. As expected, there will be a strong inclination towards optical and radionuclide approaches, since these approaches are the most accessible and more rigorously tested among the imaging options. Furthermore, it is likely that a single investigator or a single group of investigators working on a specific gene therapy will most likely have to utilize a combination of modalities (e.g., optical *and* radionuclide-based technologies) to efficiently test gene-therapy vectors and to facilitate their use in higher organisms. As testing progresses in higher species, efforts need to be made toward the radionuclide approaches, and substantial investment of time and money may be needed to develop PET-reporter probes. Eventually, human trials will employ PET, Gamma/SPECT, and, in the future, MR-based methods. The decision and timing to use certain reporter systems over others is a relatively complex one, and we will attempt to simplify the decision-making process by providing the set of guidelines we use to make such decisions.

The first decision depends upon whether an investigator is attempting to study the biodistribution/pharmacokinetics of a gene-delivery vehicle or whether one is interested in monitoring gene expression. From an earlier discussion (see Section IV), the distribution of a vehicle can be directly imaged by directly labeling the vehicle with radioisotope, fluorescent, or MR-compatible markers. Distribution of injected vehicle can also be inferred from a reporter gene coupled to a constitu-

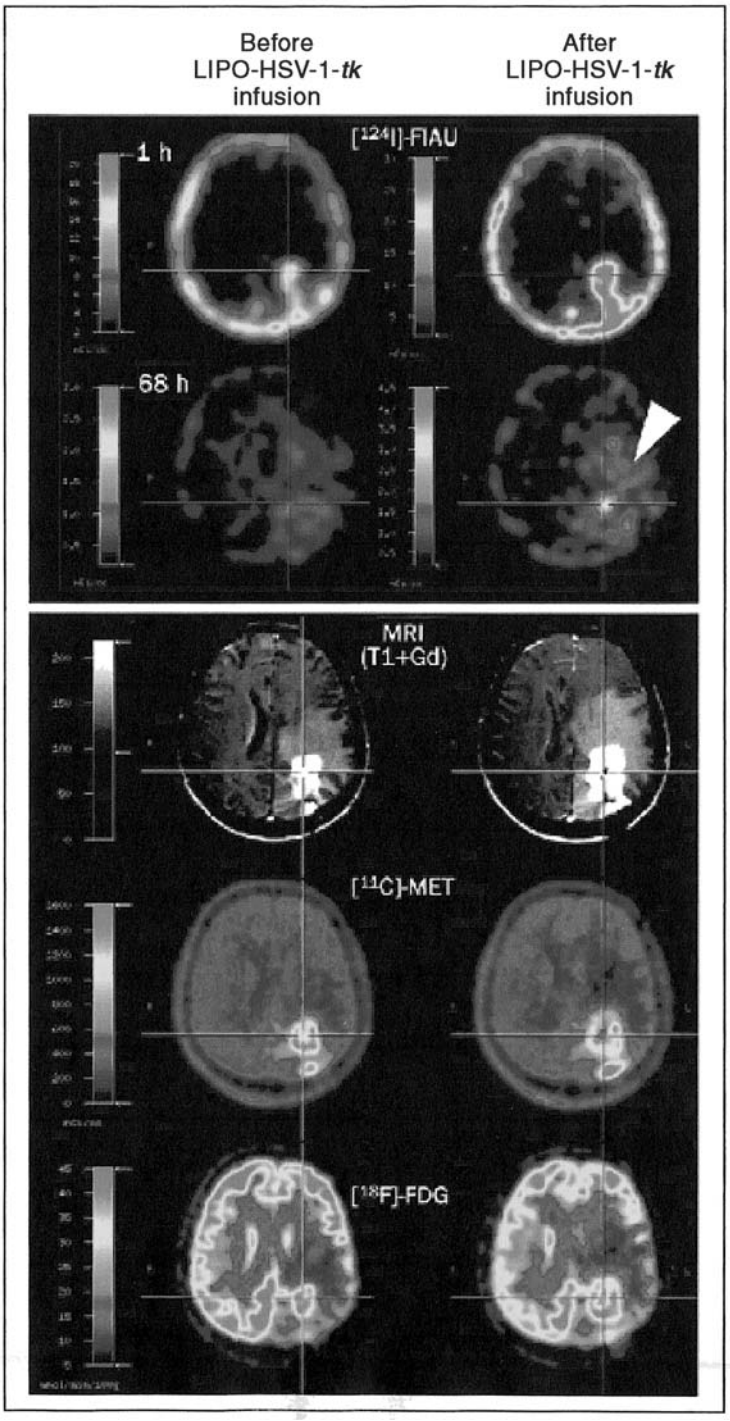

Figure 17 Human Brain Tumor HSV1-tk Suicide Gene Therapy Using Direct PET Imaging PET brain imaging of HSV1-*tk* suicide gene therapy in a patient with [^{124}I]FIAU as a reporter probe. A single, representative transverse image of a brain from a patient suffering from recurrent glioblastoma pre- and post-gene therapy treatment. Coregistration of [^{124}I]FIAU-PET, MRI, [^{11}C]methionine (MET)-PET, and FDG-PET before and after intratumorally infused liposome-gene complex containing HSV1-*tk* (LIPO-HSV-1-*tk*). The white arrow marks the region within the tumor where specific [^{124}I]FIAU retention was imaged after LIPO-HSV-1-*tk* transduction (2nd row, 2nd column). The cross hairs in the right column indicate signs of necrosis after ganciclovir treatment (5 mg/kg twice a day over 14 days) that was started 4 days after vector application. The area of necrosis in the tumor as depicted by reduced methionine ([^{11}C-MET]) uptake and decreased glucose [FDG] metabolism. See color insert for color version of this figure. (Images reproduced with permission from Ref. 107.)

tive promoter. However, this method is less sensitive since the rate of gene transfer is always less than 100%, and often significantly lower.

For investigators interested in monitoring transgene expression, a search for reporter probe(s) that may already exist for the transgene is mandatory. For example, for those who use the suicide gene, HSV1-*tk*, a number of reporter probes already exist, and direct-imaging protocols can be performed using radionuclide techniques. In the example of HSV1-tk, the decision to use [^{124}I]FIAU over other probes such as [^{18}F]FHBG is based on preliminary favorable evidence towards [^{124}I]FIAU described earlier. However, the selection of the appropriate reporter probe is not trivial, and, as further tests are being performed, it is likely that the other reporter probes may prove to be just as or more efficient than FIAU, depending on specific cell-type, local pharmacokinetics, mode of delivery of the transgene (viral vs. nonviral), etc. As we learn more about each reporter system, selection of specific transgene-reporter probe combinations will be disease-specific; it is likely that each reporter combination will have certain strengths and weaknesses depending on the disease model and target tissues. The investigator(s) will have to adjust accordingly. Future studies are bound to address these and other related issues.

If no reporter probe for the transgene exists, then indirect-imaging methods are needed. This requires the coupling of the therapeutic gene(s) with an optical, radionuclide-based or MR-based, reporter gene(s). As described earlier, a number of indirect methods are available, including the dual promoter approach, bidirectional approach, bicistronic approach, etc. The selection of 1 of these promoter configurations will largely depend upon the nature of the promoter of the therapeutic gene. If a robust, constitutive promoter drives the therapeutic gene, then the dual promoter, the bicistronic (IRES-mediated), or bidirectional approach may suffice. However, if a weak or tissue-specific promoter drives the therapeutic gene, then amplification strategies for either the reporter gene (and possibly the therapeutic gene) will need to be employed. Amplification strategies for tissue-specific promoters using the VP16 transactivating domain fused to the yeast GAL4 DNA-binding domain has been verified for use with reporter genes (108).

A variety of other factors also dictate the selection of reporter gene systems. For example, if a research group is intent on bringing a specific gene therapy to human application, it behooves them to use multimodality reporter-gene systems, i.e., use fused reporter genes such as HSV1-*tk*-*Fluc* (keeping in mind, HSV1-*tk* is *not* being used as a therapeutic gene in this case when the reporter probe is administered in nonpharmacological amounts). By coupling a therapeutic gene to a fused reporter gene, it will be possible to move quickly between the preclinical verification phase (optical imaging of Firefly luciferase) to the clinical phase (radionuclide-based imaging of HSV1-*tk*). Alternatively, if a research group strictly deals with small animals, then the use of optical reporter genes only may suffice. Along this line of reasoning, the use of large animals precludes the use of optical methods, and as a result, radionuclide-based or MR-based technologies become more important.

Imaging disease processes in the central nervous system (CNS) also limits the selection of reporter genes. Some of the radionuclide-based technologies, such as HSV1-*tk* and its mutants, are limited since their reporter probes do not readily cross the blood-brain barrier (BBB). On the other hand, [^{18}F]FESP, the reporter probe for D2R, easily crosses the blood-brain barrier and can be used to a certain extent in the CNS. Use of the D2R-[^{18}F]FESP system in the CNS is limited in the striatum where endogenous dopamine receptors are present. Optical methods, both fluorescence and bioluminescence, can be utilized if specific spatial localization is not needed. The substrates of the bioluminescence methods, D-Luciferin and coelenterazine, easily cross the BBB, which facilitates the use of these reporter genes in the CNS.

By the same token, imaging in the lung, connective tissue, or cortical bone may limit the use of superparamagnetic-labeled agents in MR imaging since it will be difficult to differentiate between the signal from the contrast agent and the signal of these anatomical structures, since they are identical in certain MR sequences.

Other important factors in the selection of reporter genes include the need for good spatial resolution (preference given to radionuclide and MRI-based imaging), repetitive imaging (preference given to bioluminescence and most radionuclide approaches), and image quantitation (preference given to radionuclide, optical, and MRS-based methods). Cost, institutional infrastructure, requirement for support personnel, and the physical space required can also be significant factors that favor the optical and gamma camera methods and less so towards the PET and MR-based methods. Thus, a large number of factors have to be considered prior to the selection and implementation of reporter genes in living subjects. With careful planning, an optimal imaging strategy can be followed and be enormously helpful in the study of gene therapy and disease entities.

VIII. SUMMARY AND FUTURE DIRECTIONS

A wide array of tools is becoming available for the evaluation of gene therapy in living subjects. These tools will be extremely helpful towards the advancement of human gene therapy by providing a means of continuous monitoring of location(s), magnitude, and temporal variation of gene delivery and expression. Viral and nonviral transfer of genetic material is bound to improve, and these developments will be supported by direct and indirect reporter-gene technologies. The ability to monitor gene expression through a variety of bicistronic vectors and to control gene expression, either through inducible promoters and/or through tissue-specific amplification techniques, is likely to play an increasing role in gene therapy as we begin to move away from constitutive expression in some cases.

In the next decade, PET/CT and SPECT/CT will probably be the major workhorses for human gene therapy trials. PET-

based technologies particularly have an advantage given their greater sensitivity as well as the ability to use biological molecules that nearly mimic its the parent molecule after being radiolabeled. Future technical improvements are certain to aid optical and MR-based protocols for human application. Continued alliances between gene therapists, molecular biologists, engineers, chemists, physicists, and pharmacologists will help build the next generation of molecular imaging technologies to expand its capabilities in gene therapy.

Gene Transfer into Hematopoietic Stem Cells

David M. Bodine
National Human Genome Research Institute, National Institutes of Health
Bethesda, Maryland, U.S.A.

The goal of this chapter is to describe the properties of hematopoietic stem cells (HSC) and the introduction of novel genetic material into HSC. The purification, phenotype, and analysis of mouse and human HSC will be reviewed as will animal models that demonstrate the potential and the risks of gene therapy. Finally, some of the problems confronting gene therapy for diseases of the hematopoietic system will be discussed. The work described in this chapter comes from many different fields of study to which many authors and laboratories have contributed. The references cited should be considered to be representative, not complete.

I. PROPERTIES OF HEMATOPOIETIC STEM CELLS

The hematopoietic stem cell (HSC) is the ultimate progenitor of all of the cells found in the peripheral blood. In mammalian systems, small numbers of HSC have been shown to be capable of extensive proliferation, generating millions of mature blood cells in regulated numbers each day. HSCs are multipotent and differentiate into cells of the erythroid (red cell), megakaryocytic (platelets), myeloid (granulocytes and monocytes), and lymphoid (B- and T-cell) lineages (Fig. 1). HSC can self-renew without differentiating, generating pluripotent progeny, which themselves can proliferate and differentiate into mature blood cells, [for reviews see (1–4)]. The ability of HSCs to self-renew allows the transplantation of a small number of HSCs to reconstitute the entire hematopoietic system of patients whose bone marrow had been ablated by chemotherapy or radiation (5–7).

The hematopoietic stem cell is especially attractive as a target for gene therapy of hematopoietic diseases (8–10). In theory, a small number of HSCs could be exposed to gene transfer vectors ex vivo and returned to a myeloablated recipient. Repopulation of the recipient with gene corrected HSC would ensure a lifetime supply of modified peripheral blood cells of all lineages. If the transferred gene (transgene) were expressed at the appropriate levels in mature hematopoietic cells carrying the transgene, gene therapy could be the treatment of choice for many inherited and acquired hematopoietic diseases (8–10). In addition, recent evidence has suggested that the most primitive mouse bone marrow cells can give rise to cells of the vascular endothelium, and perhaps to many solid tissues as well (11–14). Thus the therapeutic potential of HSC may extend beyond the treatment of hematopoietic diseases. At this point, the experiments suggesting that primitive hematopoietic cells can directly transdifferentiate into functional cells other than the vasculature should be considered exciting but preliminary, as alternate explanations are possible (15).

As with any novel therapy, a careful examination of possible negative outcomes should also be considered. Many hematopoietic malignancies arise as a result of mutations in primitive hematopoietic cells with great proliferative potential. In fact, many of the gene transfer vectors used to deliver new genetic material to HSC are derived from viruses first identified as pathological agents (16,17). The many modifications made to these viruses to negate possible pathological consequences is the subject of other chapters, but it should be remembered that even the most highly engineered vector still contains viral elements that can cause disease.

II. MOUSE HEMATOPOIETIC STEM CELLS

A. Transplantation Assays

The definitive assay for mouse hematopoietic stem cells is the repopulation of stem cell deficient mice with transplanted hematopoietic cells (1,3,4). Repopulation by donor cells, as opposed to repopulation by residual host cells, is demonstrated

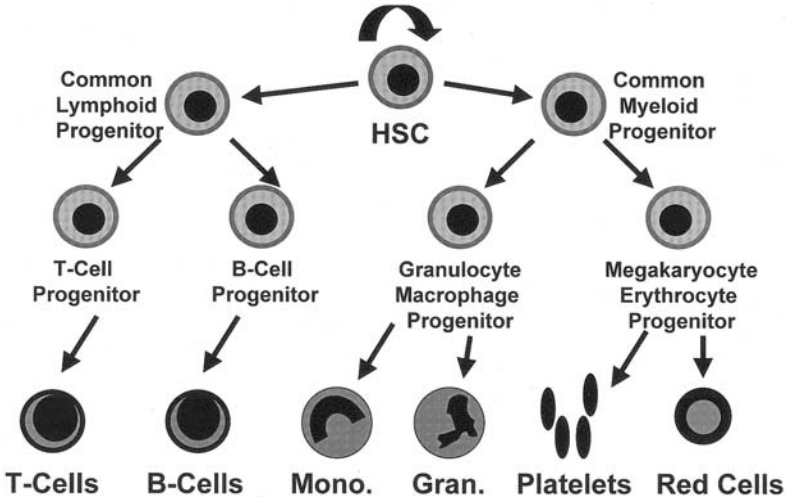

Figure 1 A model of hematopoiesis. Hematopoietic stem cells (HSC) can either self-renew or give rise to progenitor cells committed to either myeloid (CMP) or lymphoid (CLP) differentiation. As differentiation progresses, hematopoietic cells proliferate (not shown) and become progressively restricted to specific lineages of cells.

by analysis of genetic markers that differ between the donor and recipient mouse. The genetic markers used include chromosomal translocations (18), isozyme polymorphisms (19,20), Y-chromosome-specific DNA sequences (21), cell surface markers (22), and combinations of these. Multilineage repopulation of lethally irradiated hosts is demonstrated by the detection of the host genetic marker in cells of the different hematopoietic lineages (3,4).

The repopulation of recipient mice with limiting numbers of bone marrow cells has shown that HSC are a rare population of cells. For example, 1 study transplanted bone marrow cells from female mice heterozygous for the X-linked isozyme marker Phosphoglycerate Kinase (Pgk) into stem-cell-deficient W/W^v mice (19,23). Due to random inactivation of 1 X chromosome, individual HSC from heterozygous Pgk-a/b mice express either Pgk-a or Pgk-b. The peripheral blood cells of mice repopulated with large numbers of bone marrow cells contained an equal amount of Pgk-a and Pgk-b. In animals repopulated with successively fewer HSC, the relative contribution of individual HSC becomes greater. As predicted, the peripheral blood cells of individual mice repopulated with limiting numbers of bone marrow cells contained high levels of either Pgk-a or Pgk-b. This work and related studies demonstrated that a single HSC could repopulate a mouse, but that repopulation required an average of 1×10^5 bone marrow cells (19,20,24). By contrast, limiting dilution assays have shown that the concentration of the repopulating stem cell in the bone marrow is more than 10-fold less than the concentration of the Colony Forming Unit-Spleen (CFU-S) (25), a multipotent cell that forms a mixed colony in the spleen of irradiated mice. The concentration of repopulating stem cells is also 10-fold less than the cell that is required for the 30-day survival of irradiated mice (3).

Competitive repopulation assays, in which mixtures of genetically distinguishable hematopoietic cells injected into stem-cell-deficient mice allow the relative ability of each population of cells to repopulate recipient animals can be quantified (26,27). These assays are a powerful tool for identifying, characterizing, and quantifying HSC.

B. Phenotype of Mouse Hematopoietic Stem Cells

The advent of Fluorescence Activated Cell Sorting (FACS) and the development of monoclonal antibodies that recognize specific markers expressed on the surface of hematopoioetic cells have made it possible to separate the rare HSC from the large number of more mature hematopoietic cells. Spangrude et al. (22) demonstrated that mouse HSC do not express antigens present on surface of mature cells of the different hematopoietic lineages. Lineage marker negative (Lin $-$) cells represent less than 10% of bone marrow cells. Further enrichment of HSC was achieved by selecting Lin $-$ cells expressing low levels of Thy-1.1 and the Sca-1 (Stem Cell Antigen) marker. Lin $-$ Thy-1.1^{lo} Sca-1 $+$ cells comprise less than 1% of Lin $-$ cells and are highly enriched for HSC and other primitive progenitor cells, including CFU-S and radioprotective cells (22).

The Sca-1 marker is expressed in about 50% of all inbred mouse strains, and the Thy-1.1 allele is present in only a few inbred strains (28). The Sca-1 and Thy-1.1 markers are found together in only 1 strain of mice (29). Several groups have shown that c-kit, the receptor for the hematopoietic growth factor SCF (Stem Cell Factor), can be used to discriminate between HSC and more mature hematopoietic cells (30–34). In most strains of mice, Lin $-$ cells expressing high levels of

c-kit, (c-kit^{HI}) are highly enriched for HSC (30). In strains expressing Sca-1, the Lin− c-kit^{HI} cells are also Sca-1 positive (33). HSC can also be distinguished from primitive progenitors that give rise to myeloid or lymphoid cells, the common myeloid progenitor (CMP) (35) and common lymphoid progenitor (CLP) (36) respectively. CMP are Lin− and c-kit+, but do not express Sca-1 or the Interleukin 7 receptor (IL-7R−). CLP are Lin−, c-kit+ and IL-7R+. The most accurate and widely accepted phenotype for mouse HSC is Lin−, IL-7R−, c-kit+, Sca-1+ (Fig. 1). An average of 30–50 cells enriched using these markers will repopulate 100% of recipient mice (3,4).

The fluorescent dyes Rhodamine 123 and Hoechst 33342 are pumped out of cells by ABC transporter proteins, primarily ABCG2, which is expressed at high levels in HSC (37–40). Many groups have used the Rhodamine 123 dye in combination with other markers to identify primitive hematopoietic cells, and Lin− cells that retain low levels of Hoechst 33342 (Ho^{LO}) and Rho 123 (Rho^{LO}) are enriched for HSC (41–43). A novel method to enrich HSC analyzes the blue and green fluorescence of bone marrow cells stained with Hoechst 33342 only. A rare ''side population'' of cells with low levels of blue and green fluorescence has been shown to be highly enriched for HSC (44). Side population cells express c-kit and Sca-1, and are Lin− (44). Finally, using a fluorescent substrate for aldehyde dehydrogenase (ALD), Jones et al. demonstrated that a population of small, Lin−, hematopoietic cells that express high levels of ALD were highly enriched for HSC (45). Injection of an average of 10 small Lin− ALD positive cells led to the repopulation of 100% of recipient mice.

C. Sources of Mouse Hematopoietic Stem Cells

During mouse development, hematopoiesis begins in the yolk sac at day 8.5 of the 21-day gestation period (23,46,47). Yolk sac hematopoiesis generates only nucleated erythrocytes containing embryonic hemoglobin. Yolk sac hematopoietic cells are capable of repopulating chemically ablated newborn mice (48,49), but do not repopulate adult animals (50). The first HSC capable of repopulating lethally irradiated adult mice are found in the aorta-gonad-mesonephros (AGM) region of mouse embryos at day 11.5 of gestation (50). AGM region HSC are negative for lineage specific markers and express c-kit (50). From day 12.5 to day 17.5 of gestation, the fetal liver becomes the site of hematopoiesis, producing mature erythroid, myeloid, and lymphoid cells. Fetal liver HSC are lineage marker negative, express c-kit, and the marker AA4.1 (51). After day 17.5, the fetal spleen becomes the primary site of hematopoiesis (23), and by the time of birth, the bone marrow has become the primary site of hematopoiesis. In adult mice, HSC are found in the bone marrow, spleen, and peripheral blood (23,52–54). Competitive repopulation assays have been used to estimate that approximately 80% of the HSC are found in the bone marrow, 19% of the HSC reside in the spleen, and less than 0.5% of HSC are found in the peripheral blood (53,54).

The relative and absolute number of HSC in the peripheral blood of mice can be manipulated by treatment of animals with either hematopoietic growth factors or anti tumor agents such as cyclophosphamide (CP). The redistribution of HSC and progenitor cells into the peripheral blood is termed mobilization (55). For example, in mice treated with Granulocyte-Colony Stimulating Factor (G-CSF) for 7 days, approximately 10% of the HSC are found in the bone marrow, 88% of the HSC reside in the spleen, and 2% of HSC are found in the peripheral blood (53,56,57). Mice treated with FLT3 ligand (FL) and G-CSF for up to 10 days showed greater than 200-fold increases in the repopulating ability of the peripheral blood compared to normal mice (58–60). Eight days after treatment with CP, the relative number of HSC in the peripheral blood is increased nearly 30-fold to a level similar to the HSC content of untreated bone marrow (61). Combinations of cytokines have even more pronounced effects on the level of peripheral blood stem cells, particularly in splenectomized mice. Treatment of splenectomized mice with G-CSF and SCF for 5 days causes a 3-fold increase in the total number of HSC, with 81% of the repopulating ability in the peripheral blood and 19% in the bone marrow (56,57). Similar results have been described with numerous other cytokines and cytotoxic drugs (58–61). An unexpected finding in mice treated with G-CSF and SCF was a greater than 10-fold increase in the repopulating ability of the bone marrow 14 days after cytokine treatment was discontinued (62).

III. HUMAN HEMATOPOIETIC STEM CELLS

A. Clinical Transplantation Models

The ability of human HSC to repopulate all hematopoietic lineages has been demonstrated by the success of bone marrow transplantation for the treatment of hematological diseases. Since the initial descriptions of successful bone marrow transplants (6,7), there have been many improvements in the way the recipient's bone marrow is ablated and the management of histocompatibility differences between the donor and the recipient. These developments have made bone marrow transplantation a common treatment for many inherited and acquired hematological diseases (63). Similar to studies in mice, the properties of human HSC can be analyzed in selected patients transplanted with genetically distinguishable donor hematopoietic cells (64). Through the use of isozyme polymorphisms, DNA polymorphisms, and sex chromosome differences, it has been shown that the donor bone marrow can repopulate the lymphoid, myeloid, and erythroid lineages of human recipients. In a classic example, analysis of transplant recipients infused with bone marrow from female donors heterozygous for the X-linked isozymes glucose-6-phosphate dehydrogenase (G-6-PD), phosphopglycerate kinase (PGK), or hypoxanthine phosphoribosyltransferase (HGPRT) has shown that human hematopoiesis can be reconstituted from a limited number of HSC (64).

Several sources of human HSC have been used successfully for transplantation. While bone marrow and mobilized

peripheral blood are the most common sources of HSC, fetal liver and cord blood HSC are also used [for reviews see (65–67)]. Human HSC are mobilized into the peripheral blood by treating the donor with cytokines such as G-CSF alone or in combination with other growth factors. Apheresis of the donor after 5–7 days of treatment gives a very high yield of cells, which generally exceeds the average number of stem and progenitor cells that can be harvested from bone marrow (67). Cord blood collected after delivery has also been shown to be a rich source of transplantable HSC. Recent work has shown that the HSC content of approximately 100 mL of cord blood is sufficient to repopulate 80-kg recipients (66).

B. In Vitro Assays for Human HSC

The development of in vitro assays for the most primitive human hematopoietic cells has greatly facilitated the study of human hematopoiesis. The long-term bone marrow culture (LTBMC) (68,69) and the ''extended'' LTBMC (70) are initiated by growing an adherent layer of stromal cells consisting of fibroblasts, endothelial cells, and macrophages. The stromal layers are then seeded with bone marrow cells to start the bone marrow culture. At biweekly intervals, a portion of the culture medium is replaced, and the nonadherent cells in the aspirated medium can be analyzed for myeloid progenitor colony formation. Human long-term bone marrow cultures initiated by single cells generate myeloid-colony-forming cells for periods of 40–60 days (71). After several weeks of culture, the standard LTBMC medium can be replaced with medium that supports the growth of lymphoid progenitor colonies. Following the medium change, the same culture will begin to produce lymphoid progenitor cells (72). In the extended LTBM, the remaining hematopoietic cells are reseeded onto a fresh layer of stromal cells where hematopoiesis continues for another 50–60 days. The continuous generation of hematopoietic progenitor cells over a long period of time from the extended LTBMC suggests strongly that these in vitro assays are good surrogates for the transplant experiments used to study mouse HSC (70,71).

Clonal hematopoiesis in vitro has been demonstrated using long-term culture initiating cell (LTCIC) assay (69). In this assay, hematopoietic cells are enriched for HSC, and single cells are cultured on preexisting stromal layers and analyzed for proliferation and colony formation for 40–60 days. In mouse models, the behavior of purified murine HSC has been compared in both in vivo transplant models and in LTCIC. The number of LTCICs and the number of repopulating HSC were directly proportional (73). These studies suggest that human LTCIC assays are also recognizing the most primitive hematopoietic cells. In the extended LTCIC assay, hematopoietic cells are replated onto a ''fresh'' layer of stromal cells, which are cultured for an additional 40–60 days. The cells that have the capacity to generate colony-forming cells in the extended LTCIC assay have the most primitive phenotype, and the rate at which LTCICs are marked by transduction with retrovirus vectors closely resembles the rate at which human HSC are marked with retrovirus vectors (70).

C. Immune Deficient Animal Models

Attempts to develop an in vivo transplantation assay for human hematopoietic stem cells have focused on immune-deficient sheep [reviewed in (74,75)] or mice [reviewed in (76,77)] as recipients for human hematopoietic cells. During development, the sheep hematopoietic system undergoes a rapid expansion between days 50 and 60 of gestation, while the sheep immune system does not become functional until days 67 to 77 of gestation. The window between days 55 and 63 of gestation provides an opportunity to introduce human hematopoietic cells into fetal sheep. The transplantation of human cells during the ''expansion'' period facilitates engraftment, and the presence of human cells in the fetal sheep before the immune system becomes active induces tolerance to human antigens [Fig. 2; (74,75)].

In a large series of sheep generated over the last 10 years, approximately 70% of the animals transplanted with human fetal liver cells had human hematopoietic cells in their peripheral blood and bone marrow. The human cells accounted for approximately 5% of the total number of peripheral blood and bone marrow cells, and all lineages were represented. Human cells were identified at all time points for periods of up to 4 years (78–82). To evaluate HSC self-renewal, bone marrow cells from primary animals are transplanted into preimmune fetuses. In approximately 1/3 of the recipients, human cells were detected demonstrating self-renewal of the original engrafted cells (82,83).

Human bone marrow or cord blood HSC can also engraft into fetal sheep. Approximately 50% of recipient sheep transplanted with human marrow or cord blood cells show long-term persistence of human cells. The levels of human cells in sheep transplanted with either bone marrow or cord blood HSC were as good (bone marrow) or better (cord blood) than that seen in the recipients of human fetal liver cells (84–86). Approximately 80% of these recipients showed signs of Graft vs. Host Disease (GVHD), as might be expected from transplants including mature human T-lymphocytes (84–86). The transplantation of T-cell-depleted bone marrow or cord blood prevented GVHD, but was associated with lower levels of engraftment and a lower percentage of animals engrafted (87). These observations are nearly identical to what are observed in human bone marrow transplant recipients and validate the fetal sheep model as an assay for the most primitive human hematopoietic cells.

The low percentage of human cells in the chimeric sheep can be increased by the injection of recombinant human cytokines. Injection of human Interleukin-3 (IL-3) and Granulocyte-Macrophage Colony Stimulating Factor (GM-CSF), or injection of Stem Cell Factor (SCF) increased the number of human cells in the blood or marrow, 5- and 2-fold respectively (82,83).

Although the fetal sheep model satisfies all of the criteria for a xenograft model for human hematopoiesis, the sheep model is not practical for most research laboratories. As a result, many groups have sought to develop small animal models for human hematopoiesis that combine the advantages

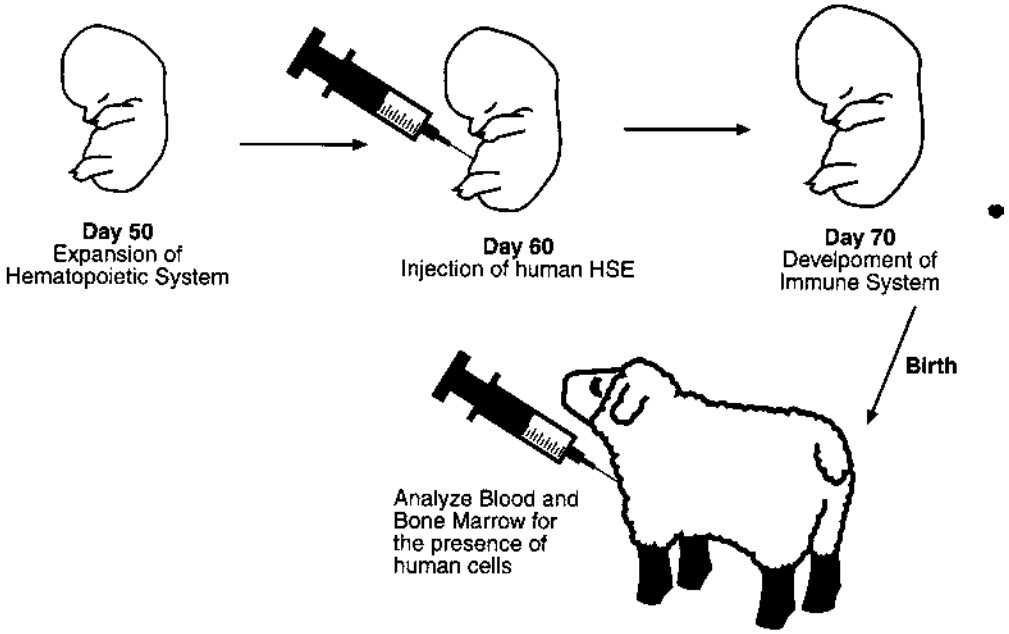

Figure 2 The fetal sheep model for the engraftment of human hematopoietic stem cells. The hematopoietic system of the developing sheep begins a rapid expansion around day 50 of gestation, but the immune system does not begin to develop until around day 70 of gestation. Injection of human hematopoietic cells around day 60 of gestation leads to engraftment and expansion of human cells that can be recovered from newborn and older sheep.

demonstrated in the fetal sheep model with the cost effectiveness of a small animal model. These efforts have focused on either beige, nude, xid (BNX) mice or mice homozygous for the severe combined immunodeficiency (scid) mutation (reviewed in (88–90).

BNX mice are homozygous for 3 mutations causing immune deficiency in the mouse. The combination of the natural killer cell deficiency caused by the *beige* mutation, the lack of a thymus caused by the *nude* mutation, and the loss of some B-cell functions caused by the *xid* mutation renders BNX mice almost completely immune-deficient. In the original report, human bone marrow cells were injected into sublethally irradiated BNX mice (91). The recipient mice contained low levels of human cells in the bone marrow and spleen (<1%), which could be detected by the presence of human repetitive DNA in these organs. In addition, human colony-forming cells from the same tissues could be identified by their selective growth in medium supplemented with human IL-3 and GM-CSF. Since hIL-3 and hGM-CSF do not support the growth of mouse colony-forming cells, it was possible to rescue a low number of human progenitor cells for up to 8 weeks posttransplantation (91). The BNX model has been refined by the injection of human stromal cells engineered to produce human IL-3 along with human bone marrow cells (92). Human hematopoietic progenitors were recovered from the spleens and bone marrow of recipient mice for up to 9 months after transplantation. The coinjection of engineered human stromal cells improved the level of human cells in the bone marrow to approximately 6% (92).

The ability of a single cell to give rise to both lymphoid and myeloid progeny is a unique property associated with HSC. This property has been demonstrated in the BNX mouse model by transplanting human CD34+ umbilical cord blood cells transduced with a retrovirus containing a neomycin resistance (neo^r) gene (93). Following transplantation, a small number of human hematopoietic progenitor cells containing the neo^r provirus in the recipient animals were detected. If a myeloid progenitor cell and a T-lymphocyte containing the neo^r provirus are derived from the same progenitor cell, the provirus should be integrated into exactly the same genomic site in each type of cell. DNA was extracted from human myeloid colonies grown in semisolid medium and from individual human T cells. The insertion site of the provirus was demonstrated using inverse PCR. Inverse PCR amplifies circular fragments generated by digestion of DNA with an enzyme that cuts once inside the provirus and at other random sites throughout the genome. Using primers specific to a single region of the provirus for PCR, the circular fragments can be amplified, generating a specific fragment for each proviral insertion that can be identified by its DNA sequence (94). Many insertion sites were detected in the myeloid colonies, 4 of which were shared by T-lymphocyte clones isolated from the same mouse. DNA sequence analysis demonstrated that the proviruses were integrated into the same spot in the ge-

nome. These studies provided the first and most definitive evidence that among the human cells that engraft into the BNX mouse are cells that have the properties associated with HSC (93).

Mice homozygous for the *scid* mutation lack functional B and T lymphocytes due to defects in V(D)J recombination and double-stranded, break repair due to mutations in the gene encoding the catalytic subunits of DNA-PK and DNA-PK_{CS} (95). Improved levels of engraftment and proliferation of human bone marrow cells transplanted into CB.17 scid/scid (SCID) mice. Human cells were detected in the bone marrow of transplanted CB.17 SCID mice at levels of 3% or higher for 8–10 weeks (96). Higher levels of human cells were detected in CB.17 SCID mice treated with human stem cell factor (SCF) and PIXY 321, a fusion molecule between human IL-3 and GM-CSF (96). Human myeloid and lymphoid cells were detected in the peripheral blood of transgenic SCID mice transplanted with human bone marrow cells for up to 24 weeks in a line of transgenic mice that expressed the human GM-CSF, IL-3, and SCF genes (97).

The meticulous work of Shultz and colleagues showed that the NOD strain of mice, which is susceptible to Non-Obese Diabetes, was NK-cell-deficient (98). When the *scid* mutation was crossed onto this strain, the resulting NOD-SCID mouse was more immune-deficient than any other strain carrying the scid mutation (98). A number of groups have demonstrated that NOD-SCID mice make superior hosts for engraftment of human hematopoietic cells (76). NOD-SCID carrying the knockout allele of β-2 microglobulin are even more immune-deficient and are further improved recipients of transplanted human cells (99).

NOD-SCID mice have been further engineered to provide the optimal microenvironment for human hematopoiesis. SCID mouse models in which pieces of human fetal thymus and fetal liver are implanted under the kidney capsule demonstrated the presence of human T-lymphocytes and myeloid cells are detected in the peripheral blood of transplanted SCID-hu animals for 6–12 months (100). Examination of the engrafted organs revealed the presence of multipotential myeloid and erythroid progenitor cells, and a full complement of differentiating human T-lymphocytes (100,101). Further refinement of the SCID-hu model implanted human fetal bone, thymus, and spleen fragments (abbreviated BTS) into SCID mice. The SCID-hu BTS mouse that can support human hematopoietic cells of all lineages for 36 weeks or more (102). The fetal bone fragments can be directly injected with purified hematopoietic cells that can then be analyzed for their capacity to repopulate and proliferate (102).

The demonstration of clonal hematopoiesis on the SCID models has not been as clear as in the BNX mouse model. For example, Josephson et al. examined multiple clones of CD19+ B-lymphocytes, and expanded populations of single myeloid cells obtained from NOD-SCID mice transplanted with foamy virus-transduced cells 6 weeks earlier. Less than 20% of the proviral insertions present in the B-lymphocyte clones were also represented in myeloid cells (103). It is clear that NOD-SCID mice allow the engraftment and proliferation of both HSC and more committed progenitor cells. Recent data analyzing NOD-SCID mice at 12 weeks posttransplantation suggest that the hematopoietic cells present at the later stages of transplantation are derived from the most primitive cells (104).

D. Phenotype of Human HSC

The enrichment of human HSC has used strategies that are similar to those used to enrich mouse HSC. Human hematopoietic cells expressing lineage markers have no ability to form colonies in vitro and are inactive in the LTCIC assay (105). All human hematopoietic colony-forming cells express the glycoprotein CD34. Human CD34+ cells isolated from bone marrow, mobilized peripheral blood, umbilical cord blood, or fetal liver are used for clinical transplantation, indicating that the CD34+ population contains HSC. Human HSC can be separated from colony-forming cells based on the presence of the CD38 antigen (106). Colony-forming cells express CD38 (Lin− CD34+ CD38+), while the more rare Lin− CD34+ CD38− cells are the only cell type capable of generating extended LTCIC in vitro (70).

As described above, human CD34+ cells engraft and proliferate in the BNX, SCID, and fetal sheep models (92,107–110). Recently, several lines of evidence have demonstrated the existence of human CD34− HSC. Differential Hoechst staining of human bone marrow cells reveals a substantial number of CD34− cells in the side population (111). (Lin− CD34− CD38−) bone marrow cells have been shown to engraft and proliferate in the fetal sheep (112) and NOD-SCID mouse models (113). These results indicate that at least some human HSC are CD34−, while others are CD34+. The difficulty in separating the repopulating CD34− CD38− cell from the large number of other CD34− cells may have prevented the injection of sufficient numbers of CD34− cells in previous studies.

IV. HEMATOPOIETIC STEM CELLS AS TARGETS FOR GENE THERAPY

A. Requirements for Effective Gene Therapy

The ability of the HSC to completely repopulate the entire hematopoietic system following transplantation makes the hematopoietic system a particularly attractive target for a permanent correction of inherited or acquired defects (8–10,(114). Integration of new genetic material into the genome of HSC would ensure a continuous supply of modified hematopoietic cells in the transplant recipient. In addition, the repopulation of the thymus with the progeny of transduced HSC has been shown to induce immune tolerence to the transgene product, which would allow the production of a new protein in the recipient without triggering an immune response, a frequent problem encountered in gene therapy (115). In contrast, gene transfer into progenitor cells, which do not have the ability

to repopulate or self-renew, would be transient and would require periodic gene transfer procedures to maintain a supply of corrected cells. Adeno-associated viruses have been shown to integrate into the genome of cells cultured in vitro, and transduction of HSC with recombinant AAV vectors has been attempted (116–118). At the present time, the frequency of recombinant AAV integration into the HSC genome has been too low to predict that AAV-mediated gene transfer to HSC would be an efficient gene transfer strategy. Similarly, adenovirus vectors, which do not integrate into the host cell genome, would not be effective for HSC gene therapy (119). Oncoretrovirus and lentivirus vectors integrate into the host cell genome, and have been developed specifically for gene transfer into HSC (120–122). The development of oncoretroviral and lentiviral vectors is discussed in other chapters; this chapter will focus on the use of oncoretrovirus and lentivirus vectors to transduce HSC.

Successful oncoretrovirus-or lentivirus-mediated gene transfer into hematopoietic stem cells requires several critical events (123–125). First, the virus particle must enter the target cell. The interactions between the target cell and the virus are mediated by the envelope protein of the virus and specific receptor molecules on the surface of the target cells (126,127), and the choice of virus envelope can have dramatic effects on the efficiency of gene transfer. After the viral genome has entered the target cell, the reverse transcriptase (*pol*) protein packaged with the virus converts the RNA genome into a double-stranded DNA molecule (124,125). This step is regulated by the availability of deoxynucleotide triphosphate molecules (dNTP) in the cytoplasm. Cells in the G_0 phase of the cell cycle (like HSC) typically have low levels of dNTPs, while cells in the G_1 phase of the cell cycle have increased levels of cytoplasmic dNTPs in preparation for DNA synthesis (128,129). The double-stranded DNA enters the nucleus where the *pol* protein-mediated integration into the host cell DNA (Fig. 3) (124,125). After integration, the transferred gene must be expressed at the appropriate levels in the appropriate cell type to correct the genetic defect (121). For some hematopoietic diseases, such as ADA deficiency, the expression of the ADA enzyme in hematopoietic cells of all lineages might have a beneficial effect (10). However T-lymphocytes must express the ADA gene at relatively high levels for gene therapy to be effective (130,131). For other diseases such as IL-2 receptor common chain (γc) deficiency (X-SCID), expression in lymphoid cells in essential (132), while expression of γc in myeloid cells would have no beneficial effect on the disease (133).

B. Oncoretrovirus-mediated Gene Transfer

The Moloney Murine Leukemia Viruses (MMuLVs) were originally studied as the causative agents of leukemia in mice (16,17). The MMuLV life cycle is very well understood (124,125), and despite the fact that replication competent MMuLVs can cause leukemia in mice and monkeys, MMuLVs were the first retroviruses to be adapted for gene therapy (122). Murine retroviruses are classified based on differences in their envelope proteins. The envelope protein of ecotropic retroviruses binds to a murine basic cationic amino acid transport protein, mCAT (134,135). The 3 amino acid sequence of this protein that serves as the virus binding site is not conserved in CAT from other mammals (136–138), restricting ecotropic retrovirus transduction to mouse cells. The envelope protein from amphotropic retroviruses binds to a phosphate transporter protein, Pit-2 (139–141). The binding site for the amphotropic envelope is conserved among the different mammalian Pit-2 molecules, giving amphotropic viruses a broad host range that includes human cells. Currently, most human gene therapy trials have involved amphotropic retroviruses (123).

Other retrovirus envelopes have been adapted for packaging recombinant retrovirus vectors. The envelope protein of the Gibbon Ape Leukemia Virus (GALV) binds to a distinct phosphate channel protein known as Pit-1 (142,143), which is approximately 60% identical to Pit-2 at the amino acid level (139,140). The Pit-1 amino acid sequence that binds the GALV envelope protein is conserved in most mammalian Pit-1 proteins with the exception of mouse Pit-1. Recombinant virus particles with a GALV envelope (144) have been used to improve gene transfer into mature lymphocytes (145,146). The 10A1 virus is a laboratory recombinant whose envelope protein binds to mouse and human Pit-1 and Pit-2 (147).

The Vesicular Stomatitis Virus type G (VSV-G) envelope recognizes a cell membrane phospholipid as a receptor, allowing VSV-G retrovirus particles to transduce almost all cell types regardless of species (148–150). In contrast to most other retroviruses, virus particles containing the VSV-G envelope can be agglutinated and concentrated to titers 2 orders of magnitude greater than can be obtained with other retroviruses (151–153). The envelope of the endogenous feline retrovirus RD114 recognizes a neutral amino acid transporter protein, and the binding site is conserved among larger mammals, but not mice (154). Recombinant retrovirus vectors with the RD114 envelope have been used to transduce high levels of CD34+ cells that engraft into NOD-SCID mice and fetal sheep (155,156).

A variety of recombinant MMuLV gene transfer vectors has been described in previous chapters, each of which has advantages that may be exploited for gene transfer applications [for review see (122)]. The LTRs from different murine retroviruses express downstream transgenes differently in different cell types. Each LTR has its own advantages in terms of the level of expression and the cells in which the highest levels have been achieved. In general, MMuLV LTRs are most active in lymphoid cells, while the Harvey Murine Sarcoma Virus (157), Myeloproliferative Sarcoma Virus (MPSV), and Mouse Stem Cell Virus (MSCV) LTRs promote relatively high levels of transgene mRNA in both myeloid and lymphoid cells (158–160).

It is well documented that transgene expression in hematopoietic cells can be silenced over time (161). A detailed analysis of active and silent proviruses derived from the same hematopoietic stem cell identified site-specific methylation within

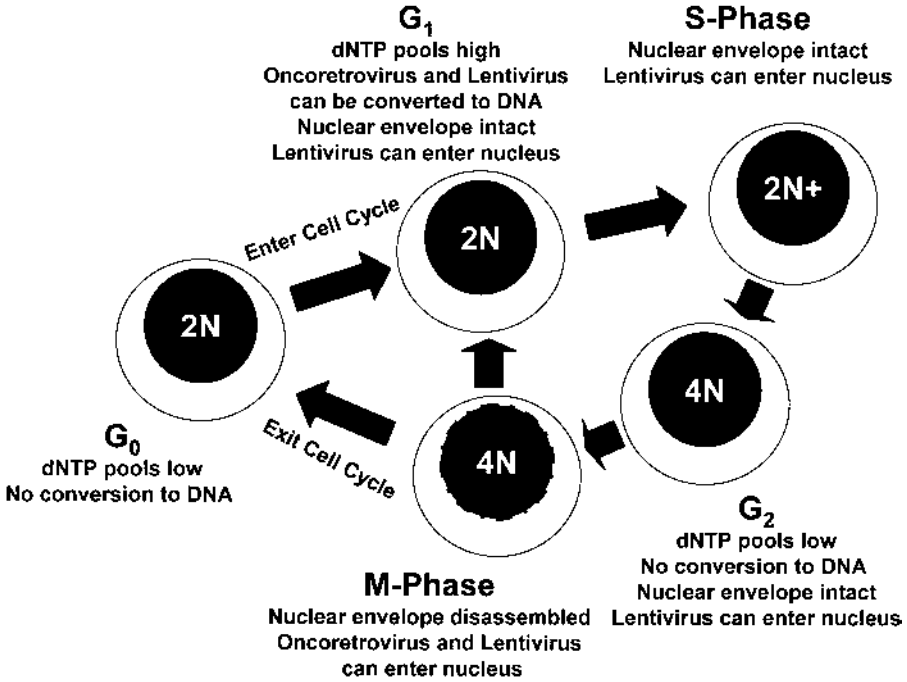

Figure 3 The relationship between the cell cycle and oncoretrovirus-and lentivirus-mediated gene transfer. RNA virus-mediated gene transfer is critically dependent on the abundance of virus receptors and the availability of deoxyribonucleotides for reverse transcription. The lentivirus life cycle differs from the oncoretrovirus life cycle in that lentivirus DNA genomes can be transported into the nucleus while oncoretrovirus integration requires the breakdown of the nuclear envelope during M phase.

the MMuLV LTR is associated with the silencing of gene expression (161). Mutation of the methylation sites combined with deletion of a negative regulatory region in the virus has dramatically improved the duration of gene expression in mouse hematopoietic cells (162,163). Gene expression from the MSCV LTR promoter has also been shown to be resistant to silencing (164).

C. Lentivirus-mediated Gene Transfer

After the RNA virus genome is converted to DNA, it must enter the nucleus for integration into the host cell DNA (123,124). This requirement limits oncoretrovirus-mediated gene transfer into HSC because oncoretrovirus DNA can only gain access to the genome when the nuclear envelope breaks down during mitosis. Since HSCs are usually quiescent or have a prolonged cell cycle (22,165–167), oncoretrovirus DNA must remain intact in the cytoplasm for a prolonged period of time. Lentiviruses, of which the Human Immunodeficiency Viruses HIV-1 and HIV-2 are the most familiar examples, have been shown to be able to integrate into the genome of nondividing cells (168). Similar results have been described with feline-derived lentivirus vectors (169,170). As described in previous chapters, the nuclear transport is mediated by two virion proteins, matrix and *Vpr*, which promote the transport of the HIV preintegration complex to the nucleus using the host cell nuclear transport machinery (171,172). The majority of lentivirus vectors are packaged with the VSV-G envelope (173), but recent studies have shown that lentivirus can also be packaged with amphotropic and RD114 envelopes (154,174). Compared to oncoretrovirus vectors, the lentivirus vectors integrated into irradiated or cell cycle arrested fibroblast cell lines at 5-to 20-fold greater efficiency (173,175). These studies have confirmed high rates of transgene integration into nondividing cells, including primitive human hematopoietic progenitor cells. However, direct comparisons in mouse models has shown that the efficiency of gene transfer into HSC is similar to that of oncoretrovirus vectors (176).

To date HIV vectors have been used only for gene transfer in animal models. The best application of the lentivirus technology has been the development of stable vectors containing the human β-globin gene and regulatory elements (177,178). For many years the inability of oncoretrovirus vectors to transfer an intact β-globin expression cassette had frustrated attempts to develop gene-based therapies for Sickle Cell Disease and the thalassemias (179). Several lines of evidence suggested that splicing of the β-globin retrovirus genomic RNA was responsible for the failure of an intact vector to integrate into the host cell genome. Lentivirus vectors are packaged in the presence of the *rev* protein, which suppresses splicing of

the lentiviral RNA, and containing the β-globin cassette were introduced intact into mouse HSC, with expression of therapeutic levels of β-globin (177,178). It is clear that there will be many safety concerns to address in the future in the design of HIV packaging and gene-transfer vectors. It appears that many of the modifications made to improve the safety of oncoretrovirus vectors could be used to improve the safety of lentivirus vectors.

V. MOUSE MODELS FOR RETROVIRUS-MEDIATED GENE TRANSFER INTO HSC

A. Proof of Principle

The initial attempts to introduce new genetic material into mouse HSC were made using recombinant ecotropic oncoretrovirus particles. The proof-of-principle experiments targeted a primitive hematopoietic progenitor cell, the Colony Forming Unit-Spleen (CFU-S). The CFU-Ss are derived from a single cell similar to the common Myeloid progenitor (CMP) (25,35), and gives rise to macroscopic colonies in the spleen of irradiated mice that contain mature cells of all myeloid lineages (25). The vectors used for these studies contained dominant selectable marker genes, either DHFR (180) or neomycin phosphotransferase (neor) (181,182). Mouse bone marrow cells were cultured on a monolayer of virus-producing cells, often in medium conditioned with the hematopoietic growth factor Interleukin-3 (IL-3) before recovery and injection into lethally irradiated mice. Proviral DNA was identified in high-molecular-weight DNA extracted from individual spleen colonies. These studies established that primitive progenitor cells had been transduced without destroying the ability of those cells to differentiate (180,181).

Extensions of these experiments examined lethally irradiated mice repopulated with cells that had been exposed to recombinant ecotropic oncoretroviruses. Southern blot analysis of proviral insertion sites in the bone marrow spleen and thymus revealed that a single HSC could repopulate all 3 organs (Fig. 4) (181,183). Cells containing the unique proviral insertion site persisted in the peripheral blood, marrow, spleen, and thymus of these mice for periods of 12 months or more, with no changes observed after 90 days (21,184–186). These studies established that a single HSC could be transduced without destroying the ability to repopulate the lymphoid and myeloid lineages.

In these early studies, less than 10% of recipient mice had long-term persistence of retrovirus-marked cells. In the rare positive mice, 10% or less of the hematopoietic cells contained a provirus (20,185). A variety of protocols were developed which improve the transduction of mouse HSC, all of which share common elements. The best results are obtained when the donor animals are treated with 5-fluorouracil, a cell-cycle-specific drug that is toxic to cycling cells like hematopoietic progenitor cells (16,187). The depletion of progenitor cells in the host may induce cycling of their more primitive precursors, which promotes retroviral integration (183). Combining IL-3 with IL-6 and SCF in the culture medium extended the viability of PHSC in culture without significant loss of repopulating ability, and improved gene transfer (185–189). Other cytokines, notably FLT3 ligand in combination with SCF, IL-6, and/or IL-3 (190,191), have had similar effects.

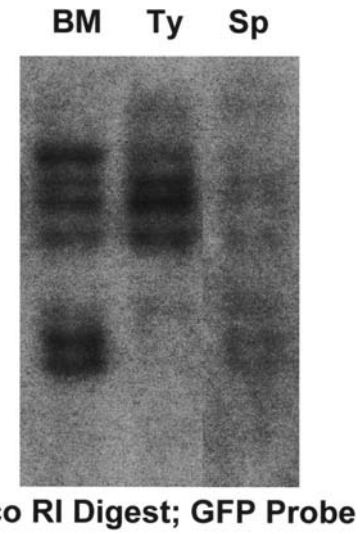

Figure 4 Transduction of mouse HSC. Mouse peripheral blood HSC were exposed to ecotropic retrovirus particles containing a GFP gene. Sixteen weeks after transplantation DNA was extracted from the bone marrow (BM), thymus (Ty), and spleen (Sp) and digested with Eco RI for Southern Blot analysis. Eco RI cuts once in the provirus, giving a unique insertion site for each proviral integration. Most of the bands are shared in DNA from the 3 hematopoietic organs, demonstrating the transduction of HSC.

Many protocols include 48-hour ''prestimulation'' of bone marrow cells in medium containing cytokines, prior to exposure to retrovirus particles (185,192). Recent experiments have shown that this prestimulation period appears to prevent the ''loading'' of retrovirus receptors with virus prior to the entry of HSC into cell cycle (166). Delaying the addition of virus until many HSC are competent for transduction optimizes the ability of the HSC to take up and integrate the provirus. Using the optimum combination of hematopoietic growth factors and transduction protocols, most laboratories achieve gene transfer in 100% of transplanted mice, and the proviruses are easily detected by Southern Blot analysis (Fig. 4).

B. Mouse Gene Therapy Models

Mouse models exist for many inherited diseases of the hematopoietic system. Gene therapy using retrovirus-mediated gene transfer into HSC followed by transplantation has been evaluated in several of these models. These include severe combined immune deficiencies (193,194), inborn errors of metabolism (195), and hemoglobinopathies (21,185,196)

genes. The first successful correction of a mouse model for human disease was reported by Wolfe et al. (197), who introduced the β-glucuronidase gene into the HSC of the mouse model for Sly Syndrome (β-glucuronidase deficiency). The authors reported prolonged life spans comparable to littermate controls and a reversal of the disease phenotype seen in untreated control animals. Subsequently, oncoretrovirus-mediated gene transfer has been used to correct both the X-linked (gp91phox deficiency) and autosomal (p47phox deficiency) forms of Chronic Granulomatous Disease (CGD) (198,199). Severe Combined Immune Deficiencies (SCID) caused by deficiencies of the Jak3 kinase and the common gamma chain (XSCID) have been cured by the transplantation of oncoretrovirus-transduced HSC (200–205). As noted above, lentivirus-mediated gene transfer of a human β-globin gene has significantly improved the phenotype of mouse models of β-thalassemia and Sickle Cell Disease (177,178).

The insertion of oncoretrovirus and lentivirus LTRs into the regulatory regions of specific genes is a well-described mechanism for leukemogenesis in animal models (16,17). Thousands of mice transplanted with oncoretrovirus-or lentivirus-transduced HSC have been evaluated in the disease models described above and related studies with other transgenes. Adverse events resulting in uncontrolled growth of hematopoietic cells have been described on two separate occasions. Bunting et al. described a myeloproliferative syndrome in mice transplanted with bone marrow cells transduced with an oncoretrovirus containing the p170 glycoprotein [or multiple drug resistance (mdr)] gene and expanded in vitro for 3 weeks. Follow-up studies demonstrated that the myeloproliferative syndrome was the result of the prolonged in vitro culture and the overexpression of the mdr gene (206). Li et al. described the insertion of a myeloproliferative syndrome in a single mouse caused by the insertion of a recombinant provirus near the Evi-1 locus (207). In strains of mice with high levels of endogenous wild-type oncoretrovirus, the development of hematopoietic malignancies is common, and oncoretrovirus insertions near the Evi-1 locus are found in a high percentage of myeloid leukemias in the AKXD-23 strain of mice (208). It was calculated that leukemia causing insertions represented less than 1/10,000 of all of the oncoretrovirus insertions in AKXD-23 mice (208). The AKXD-23 leukemias are similar to the one described by Li et al., demonstrating that recombinant oncoretrovirus insertions can cause leukemia, albeit at a low frequency (207). These findings stress the importance of extensive follow-up of animal models and the data and need to consider every possible means to ensure the safety of any gene therapy strategy.

VI. RETROVIRUS-MEDIATED GENE TRANSFER INTO HEMATOPOIETIC STEM CELLS FROM LARGER ANIMALS

A. Demonstration of Stem Cell Transduction

Most experiments using mouse models demonstrated that oncoretroviruses pseudotyped with the ecotropic envelope could introduce genes into HSC. Because ecotropic retroviruses can only transduce mouse cells, vectors with different pseudotypes were developed for gene transfer into HSC of large animals (123). The original large animal gene transfer protocols involved cocultivation of Rhesus monkey bone marrow cells on a layer of amphotropic oncovirus producer cells, similar to the successful strategies developed for mouse retrovirus-mediated gene transfer. Despite the use of similar protocols, the transduction of monkey HSC was more than 10-fold less frequent, with an average of less than 1% positive cells present in the best examples (209,210).

Safety concerns about the transduction of patient bone marrow cells with oncoretroviral vectors were increased after the discovery that replication-competent virus emerging from producer cells could cause leukemia in severely immunosuppressed Rhesus monkeys (211). These observations made it clear that only virus containing media shown to be negative for replication competent virus (and any other agents) could be used for patient studies. For most workers in the field, this meant transduction of hematopoietic cells in the absence of producer cells. One procedure seeded populations of Rhesus monkey CD34+ progenitor cells and HSC onto a previously established layer of bone marrow stromal cells that express SCF. The CD34+ cells were cultured for 96 hours in medium containing an amphotropic retrovirus containing the mouse ADA gene. The virus containing medium was replaced every 24 hours. After exposure to virus, the cells were collected and infused into the donor animal that had been irradiated while the CD34+ cells were in culture. The ADA provirus has been detected in 2% of mature blood cells of all lineages and bone marrow for a period of 9 years at the time of this writing (212,213). Mouse ADA was expressed at approximately 1–2% of the endogenous monkey ADA levels (212).

Another gene transfer protocol was evaluated in a dog bone marrow transplant model. Bone marrow cells from the donor animal were used to establish a long-term bone marrow culture (LTBMC). LTBMC require regular replacement of media, which offers the opportunity for repeated exposure to virus conditioned medium. At the end of 4 weeks in culture, the LTBMC was harvested and the cells used to transplant irradiated donor dogs. Gene transfer efficiency using this protocol was similar to that observed in monkey models with less than 1% of peripheral blood and bone marrow cells of the repopulated recipient containing the provirus (214–217). Transgene-marked hematopoietic cells were detected in the peripheral blood and bone marrow of these animals for periods of 5 years or more posttransplantation (217).

The discovery that the HSC in cytokine-mobilized peripheral blood cells or bone marrow cells from cytokine-treated animals were transduced at higher frequencies than untreated bone marrow HSC has led to significant improvements in gene transfer into Rhesus monkey and canine models. Using a combination of amphotropic or GALV pseudotyped oncoretrovirus particles, support on fibronectin, and cytokine primed peripheral blood or bone marrow cells, several groups have reported the transduction of 5–20% of HSC (218–220). Similar approaches have been attempted with lentivirus vectors,

but the efficiency of gene transfer has been similar to that of oncoretrovirus vectors (221).

VII. PROBLEMS AND DIRECTIONS FOR THE FUTURE

A. Low Titer

The low level of gene transfer into human and large animal HSC can be attributed to a combination of factors. One consistent problem with retrovirus-mediated gene transfer appears to be the relatively low titer of retrovirus preparations. The titer of even the best preparations of retrovirus rarely exceeds 1 million particles per milliliter of conditioned medium, and the movement of retrovirus particles in solution is limited by Brownian motion (222). Thus, most HSC do not come in contact with retrovirus particles under standard culture conditions. To increase interaction between retrovirus particles and HSC, investigators have used centrifugation to move HSC through a large volume of virus containing supernatant (223). Alternatively, the cells may be immobilized on a filter through which large volumes of retrovirus containing supernatant can be drawn (224,225). Both of these procedures have been shown to improve gene transfer into hematopoietic progenitor cells and may ultimately prove useful for the transduction of human HSC.

Another approach to increasing the contact between virus particles and HSC involves the use of fibronectin-coated gene transfer vesicles. It has been demonstrated that retrovirus particles and HSC bind specifically to a 35 kd fragment of fibronectin (226,227). The colocalization of the target cell and the retrovirus particle increases the probability that a cell will become transduced. The use of fibronectin has become standard in human gene transfer protocols. Titer can also be increased by concentration of virus particles in supernatant. A variety of protocols has been used to concentrate amphotropic, RD114, and VSV-G pseudotyped virus particles (228,229, 151–153).

B. Selection of Transduced HSC In Vivo

Recognizing the inefficient transduction of human HSC by oncoretroviral or lentiviral vectors, several groups have attempted to transfer drug resistance genes into HSC. These studies have a short-term goal of rendering bone marrow cells resistant to chemotherapeutic agents active against solid tumors, and a long-term goal of providing a means to select and amplify the rare transduced HSC. If the virus vector contained a therapeutic transgene along with the drug resistance gene, the result would be a high level of cells containing the therapeutic gene. This concept has been shown to be feasible in mouse models using the DHFR gene. When methotrexate selection is applied in the presence of nucleoside transport inhibitor nitrobenzylmercapt-purine riboside 5′ monophosphate (NBMPR-P), DHFR-expressing HSC demonstrate preferential survival (230). Similar results were observed when the human ENT-2 gene was introduced into mouse HSC followed by a similar selection protocol (231). Other strategies have involved the introduction of the MGMT gene followed by treatment of the animals with temozolomide, O6-benzylguanine, or similar drugs. As in the case of DHFR, transduced cells expressing MGMT were resistant to the effects of the drug treatment (232–234).

Alternatively, other groups have attempted to induce HSC self-renewal by expressing either chimeric receptor molecules that can be dimerized by small molecules, thus transducing a signal, or by expressing growth-factor receptors that ordinarily are not expressed by HSC. Treatment with either the small molecule or the cytokine triggers a ''growth switch'' that selectively amplified transduced HSC. This approach has been demonstrated in both mouse and nonhuman primate models (235–238).

C. Low Levels of Retrovirus Receptors

Many groups have observed that while the transduction of progenitor cells with amphotropic oncoretroviral vectors is relatively efficient, the transduction of HSC in the same population of cells is inefficient. These observations conflict with data in the mouse models with ecotropic oncoretrovirus particles, which can transduce both progenitors and HSC efficiently. One hypothesis proposed that ecotropic receptor levels were relatively high on mouse HSC, but that amphotropic retrovirus receptor levels were low or absent on mouse, primate, and human HSC.

Using a semiquantitative RT-PCR assay, Orlic et al. showed that the mRNA encoding the mouse ecotropic retrovirus receptor (mCAT) was easily detectable in mouse HSC, progenitor, and bone marrow cells. The mRNA encoding the amphotropic receptor (amphoR) was easily detectable in human or mouse hematopoietic cell lines and primary hematopoietic progenitor cells. However, amphoR mRNA was nearly undetectable in mRNA isolated from mouse and human HSC (239). Further investigation identified and isolated a rare subpopulation of mouse HSC that had higher levels of amphoR mRNA. To correlate receptor mRNA levels with transduction, amphoR positive and negative HSC were simultaneously transduced with genetically distinguishable oncoretroviruses, one packaged by ecotropic packaging cells, the other by amphotropic packaging cells. Greater than 90% of the animals in these experiments contained ecotropic proviral sequences in their hematopoietic cells, indicating that there was sufficient cell division to allow the integration of oncoretroviral vectors into HSC. More than 50% of mice repopulated with amphoR-positive HSC also contained amphotropic proviral sequences, while less than 10% of mice repopulated with amphoR-negative HSC contained amphotropic proviral sequences. In animals repopulated with amphoR-negative HSC, the relative number of ecotropic proviral sequences was 25-fold higher than the level of amphotropic proviral sequences, similar to the relative difference in the levels of ecoR and amphoR mRNA in HSC (239). Related work has demonstrated a low level of GALV receptor mRNA in human HSC as well (240). It would appear that a major obstacle to gene therapy for

human hematopoietic diseases is the low level of retrovirus receptor on the surface of HSC (Fig. 5).

The use of VSV-G pseudotyped retroviruses may eventually circumvent problems with low titer and low numbers of receptors. As noted previously, VSV-G particles can be efficiently concentrated to high titers without loss of activity (151,152). Since the VSV-G receptor is a membrane phosholipid (150), it would appear that there should be fewer problems with low receptor numbers. Problems associated with the toxicity of VSV-G *env* have slowed the development of VSV-G mediated gene therapy (149), but recent work with concentrated and purified VSV-G vectors has shown great promise in model systems (152,177,178). Other oncoretroviruses have been isolated from cats and sheep with novel envelopes that may recognize more abundant receptors on human HSC. For example, oncoretroviruses pseudotyped with the feline RD114 virus envelope have been shown to give high levels of gene transfer in canine models (241).

D. Quiescent HSC

Because Moloney Murine Leukemia Virus (MMuLV)-based retroviral vectors require cell division to integrate into the host cell genome, another obstacle to retrovirus-mediated gene transfer is the fact that most HSC are quiescent. Although relatively efficient transduction of mouse HSC can be achieved with ecotropic MMuLV vectors, it is not clear that human HSC are as prone to enter the cell cycle during the time they are exposed to the virus. One approach to this problem has been to expose human HSC to retroviral vectors under culture conditions that would lower the levels of cell cycle inhibitors. A recent study showed that the level of the cell cycle inhibitor p15(INK)4B could be decreased in human CD34+ progenitor cells by culture in serum-free medium containing antibodies against TGF-β. In addition, antisense oligonucleotides inhibited the expression of a second cell cycle inhibitor P27(KIP-1) in CD34+ cells and promoted cell cycling (242). Human CD34+ CD38− HSC were cultured in serum-free medium containing SCF, Il-6, IL-3, FL, anti TGF-β antibodies and antisense p27(KIP-1) oligonucleotides for 12 h and exposed to retrovirus vectors containing a neo gene for 12 h. Parallel cultures of cells were cultured in the same cytokines minus the anti TGF-β antibodies and antisense p27(KIP-1) oligonucleotides for 12 h and then exposed to the same virus. Cells from both conditions were equally capable of engrafting and proliferating in the BNX mouse model. One year after transplantation, no neo transgenes were observed in the human hematopoietic cells derived from cells not exposed to the anti TGF-β antibodies and antisense p27(KIP-1) oligonucleotides. In contrast the neo transgene was detected in about 10% of cells derived from CD34+ CD38− HSC exposed to anti TGF-β antibodies and antisense p27(KIP-1) oligonucleotides (242). These results clearly show that cell-cycle induction can promote retrovirus-mediated gene transfer into HSC without damaging the ability of the HSC to repopulate BNX mice.

The gene transfer problems relating to cell cycle may ultimately be overcome by the use of lentivirus-based vectors,

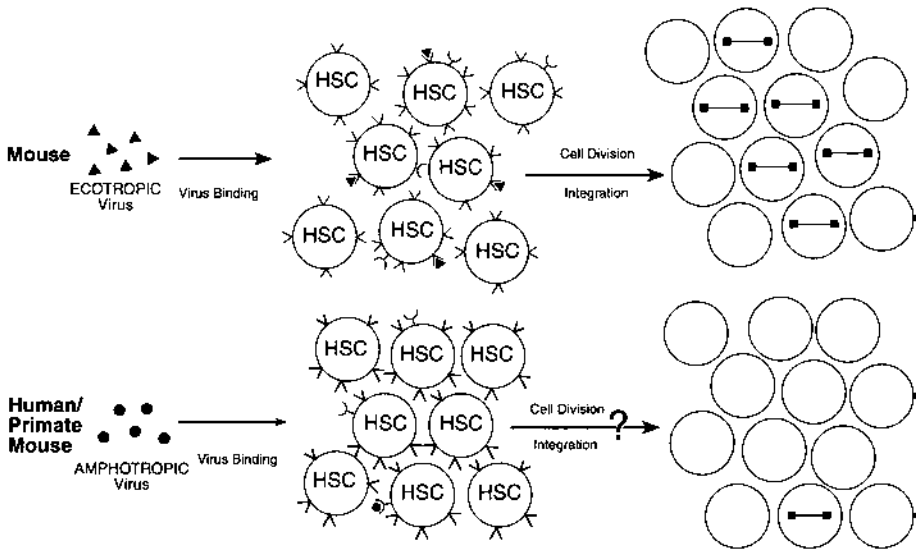

Figure 5 Comparison of transduction by ecotropic and amphotropic retrovirus particles. In the mouse (top), the high level of ecotropic retrovirus receptor allows many cells to bind a virus. Subsequent cell division allows these viruses to integrate into the genome. Amphotropic transduction of mouse primate or human HSC (bottom) is limited by low levels of amphotropic receptor expression on HSC. There are fewer opportunities for virus to bind to cells and therefore any cell division that occurs is unlikely to result in a viral integration.

which do not require cell division for integration. VSV-G pseudotyped lentivirus vectors have been shown to be greater than 20-fold more efficient at transducing freshly isolated human Lin− CD34+ CD38− HSC than MMuLV vectors (243). In addition, the expression level of the GFP reporter gene in lentivirus-transduced cells persisted for 5 weeks in culture, while expression of GFP from the MMuLV vector was lower and rapidly was silenced (243). Although the initial transductions of nonhuman primate and mouse HSC with lentivirus vectors have been similar to results with oncoretrovirus vectors, lentivirus mediated gene transfer still has theoretical advantages over oncoretrovirus-mediated gene transfer.

E. Summary

Improving the efficiency of gene transfer and the expression of the transferred genes are the critical basic research goals that will extend gene therapy from possibility to reality. Basic research into the biology of the PHSC has demonstrated low levels of retrovirus receptors and cell cycling as well as solutions to these problems. Basic research into retrovirus envelope proteins and backbones have lead to new recombinant retrovirus vectors that are capable of transferring and expressing genes at higher rates. As clinical experience is acquired in the use of retrovirus vectors for marking human HSC, it is clear that therapeutic gene transfer to human HSC could soon be a practical method for the treatment of ADA deficiency and other immune disorders. I predict that success in treating these diseases by gene transfer to HSC would be rapidly expanded to the treatment of a wide variety of other inherited and acquired hematological diseases.

I. INTRODUCTION

Clinical gene transfer to hematopoietic cells began on May 22, 1989 when autologous T-lymphocytes from a cancer patient were gene marked and transplanted back into the patient (1). Gene marking studies such as this have played an important role in the evolution of the field of gene therapy. Since 1989, over 250 patients have been enrolled in hematopoietic cell gene marking or gene therapy protocols. This chapter will review the practical issues involved in the conduct of a clinical gene therapy trial, as well as the published trials to date.

There are two general strategies to clinical gene transfer protocols for hematopoietic cells. The first strategy is to target the pleuripotential hematopoietic stem cell (HSC) with the goal of permanent gene transfer to all 3 hematopoietic cell lineages. Clinical HSC trials to date have involved transfer of both marker genes as well as therapeutic genes. The second strategy involves gene transfer into a single, terminally differentiated hematopoietic cell lineage. With this strategy, persistence of gene corrected cells is dependent on the lifespan of the target cell. At present, this approach has been applied clinically to allogeneic and autologous lymphocytes.

There are 3 broad categories of genes that have been used in clinical trials targeting hematopoietic cells: 1) marker genes, 2) suicide genes, 3) therapeutic genes. Marker genes provide a mechanism for detection of the transduced cells by introducing a gene product that is easily detectable by flow cytometry, enzymatic activity, or by conferring a drug resistance phenotype. Antibiotic resistance genes such as the bacterial neomycin phosphotransferase gene are most commonly used as markers. Suicide genes allow for in vivo elimination of transduced cells. The herpes thymidine kinase, for example, confers sensitivity of the transduced cell to the drug ganciclovir. There are a number of different types of therapeutic transgenes that have been utilized in clinical trials. Some are designed to interfere with the life cycle of the human immunodeficiency virus, some are designed to protect normal hematopoietic stem cells from chemotherapy, and others are designed to correct inherited monogenic disorders. Table 1 summarizes the published clinical gene transfer trials involving hematopoietic cells.

II. MURINE-BASED RETROVIRAL VECTORS

All clinical gene therapy trials to date targeting hematopoietic cells have utilized murine-based retroviral vectors from the oncovirinae subfamily. The simplicity of the murine retroviral genome has facilitated the development of a class of replication-incompetent vectors that can be produced by specially engineered producer cell lines. (Discussed in Chapter 1.) However, murine retroviral vectors can efficiently transfer genes only to actively replicating target cells (2). Relatively quiescent target cells such as HSCs, which reside predominantly in the G_0/G_1 phase of the cell cycle, are inefficiently transduced by murine retroviruses.

Most retroviral vectors that have been used clinically for hematopoietic cell gene transfer are based on the oncovirus called Moloney Murine Leukemia Virus (MoMLV) (3). Some clinical vectors are derived from the Harvey Murine Sarcoma Virus (HaMSV), and more recently vectors derived from the Murine Stem Cell Virus (MSCV) have been employed in clinical trials. HaMSV and MSCV are similar to MoMLV in overall structure and function, as are the modifications incorporated to make them replication-incompetent and safe to use in humans. The HaMSV and MSCV long terminal repeats (LTRs) may function

[b] Suicide Gene Studies

better in hematopoietic stem cells and may be less subject to silencing, but this has not been proven in humans or nonhuman primates. Modifications to the MoMLV LTR have been made by some investigators to achieve a similar goal of preventing silencing related to methylation by altering methylation sensitive sites (4). The general description below of MoMLV also applies to the other related oncovirinae.

The MoMLV is composed of 2 copies of RNA ranging in size from 2–9 kb. In order to render these vectors replication-incompetent, the *gag* (core proteins), *pol* (reverse transcriptase and integrase), and *env* (envelope protein determining the host cell range or tropism of the retrovirus) genes are deleted. What remains are the 5′ and 3′ LTR sequences on each end of the construct along with the packaging (Ψ) site. The 5′ LTR functions as the promoter and enhancer region and the 3′ LTR contains the poly-A signal. The Ψ region serves as a binding site for the *gag* polyprotein, which packages the RNA into a viral core. The transgene is cloned into a site downstream of the Ψ region. In some vectors, splice donor and acceptor sites are retained or deliberately engineered into the Ψ region to generate, from a portion of the full-length mRNA, a subgenomic mRNA that more efficiently translates the downstream inserted cDNA open reading frame.

Replication-incompetent viral particles are produced in specifically engineered ''packaging cells.'' Packaging cell lines such as PA317 (5) (NIH3T3 derived murine fibroblasts), AM12 (6), Ψ crip (7), or 293SPA (8) (293 derived human embryonal kidney cells) constitutively express the *gag*, *pol*, and *env* proteins and therefore secrete empty virions into the culture media. When plasmid DNA of the retroviral vector is transfected into the packaging cells, clones of producer cells can be selected that secrete into the culture media replication-incompetent but infectious virions containing the transgene. The culture media, known as ''viral supernatant'' can then be collected and used ex vivo to infect the desired target cells.

An important issue regarding retrovirus vector transduction of hematopoietic cells is that stem cells and lymphocytes express relatively low levels of the surface receptor required for binding of the most widely used amphotropic envelope packaging element (9). Some studies have suggested that packaging lines using the envelope proteins of the Gibbon Ape Leukemia Virus (GALV) or the feline endogenous virus (RD114) may be advantageous for targeting both stem cells and T lymphocytes because these cells have higher levels of receptor for this envelope (10,11).

III. PRACTICAL CONSIDERATIONS OF HEMATOPOIETIC CELL GENE THERAPY

The following section outlines the 3 phases of a retroviral-based hematopoietic stem cell (HSC) and lymphocyte gene transfer protocol: 1) hematopoietic cell procurement, 2) ex-vivo gene transfer, and 3) reinfusion of the corrected cells. (Fig. 1)

A. Gene Transfer to Hematopoietic Stem Cells

1. Hematopoietic Stem Cell Procurement

Collection of large numbers of autologous hematopoietic stem cells is the first step in an HSC gene therapy protocol. The 3 sites from which HSC can be harvested are: 1) bone marrow, 2) cytokine or chemotherapy/cytokine-mobilized peripheral blood, and 3) umbilical cord blood. Although the precise phenotype of a true HSC is unknown, large numbers of HSCs are contained in a population of cells expressing the CD34 antigen (12). $CD34^+$ cells make up 0.5–5% of nucleated cells in the bone marrow and only a fraction of these are HSCs. HSCs can be safely aspirated from bone marrow of the poste-

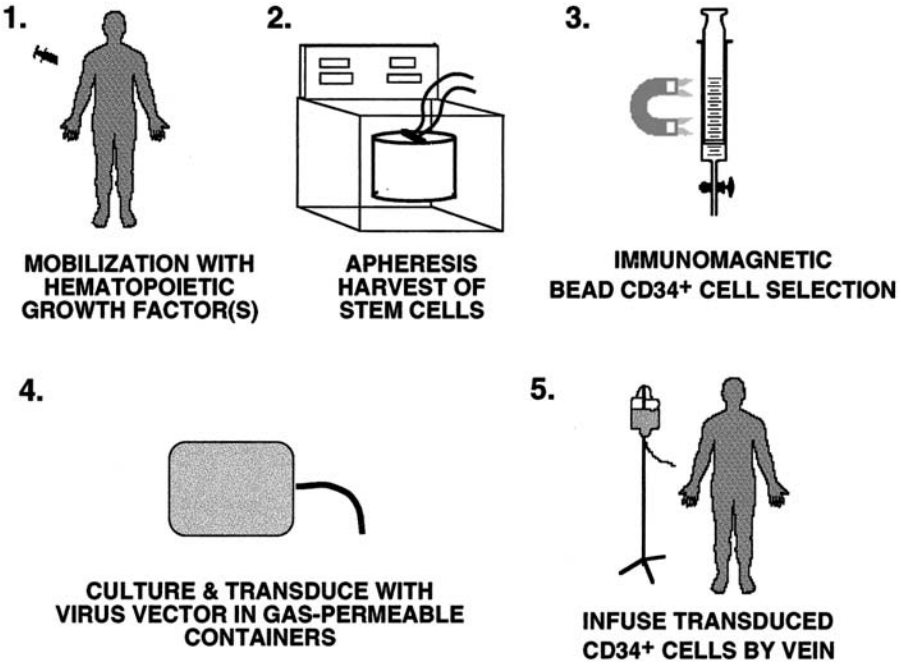

Figure 1 Clinical scale hematopoietic stem cell gene therapy scheme. See the color insert for a color version of this figure.

rior superior iliac crest in a minor operative procedure. The major side effects of this procedure include mild discomfort at the aspiration site and an occasional hematoma. For smaller individuals, symptomatic anemia may require a blood transfusion, which, if anticipated in advance, can be an autologous unit. The major disadvantage of large volume bone marrow aspiration is that it must be done under general anesthesia, which adds risk to the procedure. Because of these issues, repeated large-scale marrow harvests are not desirable.

In most individuals, administration of Granulocyte-Colony Stimulating Factor (G-CSF) at 10–16 μg/kg per day subcutaneously for 5 or 6 days results in a transient 20- to 100-fold increase in the frequency of $CD34^+$ hematopoietic progenitor and stem cells in the circulation (a phenomenon termed stem cell mobilization). Other growth such as Flt-3-ligand (Flt3-L) (13–15), Granulocyte-Macrophage Colony Stimulating Factor (GM-CSF) (16–19), and Stem Cell Factor (SCF) (20,21), which are used alone or in combination, are also effective for stem cell mobilization. Large numbers of $CD34^+$ cells ($2–10 \times 10^6$ cells/kg patient weight) may be obtained from a single or repeated apheresis procedure following mobilization with growth factors. Furthermore, the mobilization process may be safely repeated at 4- to 8-week intervals. Unlike the procurement of bone marrow, no operative procedure is needed and the entire process can be done without a hospital admission.

Dunbar and coworkers (22) have demonstrated improved gene marking in nonhuman primates when peripheral blood HSC mobilized with G-CSF and SCF are compared to bone marrow HSC. The same group later showed superior in vivo gene marking of nonhuman primate HSC mobilized with G-CSF and SCF compared to HSC mobilized with G-CSF and Flt-3 ligand or G-CSF alone (23). High resolution cell cycle analysis of cytokine mobilized peripheral blood HSC has revealed that these cells are more likely to have entered cell cycle and express higher levels of the amphotropic receptor mRNA (24–26). While certainly easier to collect, human gene marking studies have yet to demonstrate unequivocally that cytokine-mobilized peripheral blood HSCs are better targets for retroviral transduction than bone marrow HSCs. However, the logistical advantages to obtaining peripheral blood HSCs dictate these as the preferred source for gene therapy and other transplant purposes except when the donor has a poor $CD34^+$ mobilization response to cytokine adminstration.

Umbilical cord blood contains a higher concentration of primitive hematopoietic progenitors than bone marrow (27). Recent data suggests that the HSCs from umbilical cord blood may also express higher levels of the amphotropic retrovirus receptor (28), which may result in more efficient transduction with amphotropic retroviral vectors. On average 20×106 $CD34^+$ cells can be collected from the placenta at the time of delivery, which is approximately 10-fold less than what can be collected from mobilized peripheral blood of an adult. Because of the low efficiency of HSC transduction with current techniques, clinical application for gene-corrected umbilical cord blood stem cells may only be practical in neonates.

2. Ex Vivo Gene Transfer

Optimization of ex-vivo retroviral transduction conditions for HSCs has proven to be a formidable task. It appears that 48

to 72 h of culture in growth factors is required for quiescent lineage negative $CD34^+$ cells to enter the cell cycle and thus become receptive targets for retroviral tranduction (29). However, studies have shown that prolonged ex vivo culture of HSCs results in loss of long-term repopulating ability as a consequence of lineage commitment and of an acquired defect in the ability of cycling cells to engraft (30,31). This loss of repopulating potential with ex vivo culture may be gradual and to some degree reversible. Takatoku and coworkers manipulated the ex vivo culture conditions and growth factor combinations such that HSCs from nonhuman primates were first induced into cell cycle by using a combination of active cytokines, thereby facilitating retroviral transduction. Then, before the cells were transplanted back into the animal, they were returned to a quiescent state by incubating the cells in media containing only stem cell factor. This method of ''resting'' stem cells prior to reinfusion resulted in improved engraftment of gene-marked cells (32).

Measurable gene transfer into HSCs in the clinical setting has been reported with ex vivo transduction periods ranging from 6 to 72 hours (33,34). While the report using a 6-hour regimen appeared to succeed in achieving measurable gene transfer without use of growth factors (33), most investigators have found that growth factors and an ex vivo culture period of 48–96 hours are required for optimum transduction. Growth factors are also essential to prevent apoptosis of HSCs during prolonged ex vivo culture.

Some investigators have used autologous bone marrow stromal cell layers in an attempt to enhance transduction with retrovirus vectors while preserving reconstitutive potential (35–38). Despite encouraging results in small animal models, there is no evidence that use of bone marrow stromal layers has resulted in better outcome in human clinical studies. Not only does the establishment of autologous stromal culture require a bone marrow aspiration, but this approach greatly increases the complexity and handling involved during clinical scale-up. Moreover, to achieve the highest level of transduction efficiency of HCSs grown on stromal layers, it is still essential to add growth factors to the culture.

Much current investigation is focused on determination of growth factor combinations used without stromal layers that can achieve highest transduction while maintaining reconstitutive potential of the transduced HSC. Flt3-L (39) and thrombopoietin (TPO) (39,40) have emerged as important agents to add to the ex vivo culture in relatively high concentrations (100–300 ng/ml) to achieve these dual goals. These growth factors work optimally in synergy with other growth factors. SCFs at more modest concentrations of 50–100 ng/ml appear to be important as well. Interleukin 3 (IL-3) and interleukin (IL-6) have also been widely used ex vivo in clinical trials to enhance cycling and may help to prevent apoptosis of HSC. However, use of concentrations of IL-3 higher than 30–50 ng/ml may be detrimental to preservation of cells with long-term engraftment potential. Other factors essential for maintenance and development of lymphoid progenitors from stem cells, such as IL-7, have not been used clinically, but may in the future prove to be a growth factor for the transduction of lymphocytes (41,42).

A number of techniques have been devised to encourage the interaction of hematopoietic progenitors with viral particles during the ex vivo transduction period. Most investigators have opted to transduce a cell population enriched for CD34 expression. $CD34^+$ cell enrichment enables an improved stem cell/viral particle ratio, thereby optimizing the multiplicity of infection while using less of the valuable clinical grade retroviral supernatant. A variety of stem cell selection devices that use monoclonal antibodies specific for the CD34 antigen have been employed in experimental clinical protocols [Reviewed in (43,44)]. These devices are able to select large numbers of $CD34^+$ cells from a bone marrow or mobilized peripheral blood apheresis graft at 50–80% efficiency yielding a product which consists of 60–90% $CD34^+$ cells.

For reasons that are not well defined, centrifugation of target cells during incubation in a retrovirus vector supernatant increases transduction efficiency, a technique that has been termed ''spinocculation'' (45). The g-forces employed to achieve the effect are as low as $1200 \times g$ for 20 min, making it unlikely that the effect is due to sedimentation of individual virus particles. Cocultivation of the target cells on a confluent layer of retrovirus producer cells has also been shown to enhance transduction. However, regulatory issues related to the safety of cocultivation of HSC with producer lines make this approach impractical for clinical application.

One of the more exciting techniques to be described is the finding that a specific proteolytic fragment of fibronectin facilitates stem cell–retroviral particle interaction when this peptide is used to coat the surface of the culture vessel (46). Fibronectin, a prominent component of the extracellular matrix of bone marrow stromal cells, has numerous hematopoietic cell-binding domains. Moritz and coworkers have demonstrated binding of both viral particles and hematopoietic target cells to a proteolytic fragment of fibronectin that contains the CS1 binding site (47). The CS1 binding site of fibronectin interacts with the VLA4 adhesion molecule found on hematopoietic stem cells (48). Thus, when HSCs are incubated with retroviral particles in the presence of this specific fibronectin fragment, transduction efficiency is improved.

The availability of a clinical grade recombinant human C-terminal fibronectin fragment (CH-296) has facilitated its use in several clinical gene therapy trials targeting HSC. Even with retrovirus vectors of modest titer, acceptable transduction of $CD34^+$ cells can be achieved. Of note is that with retrovirus vectors at titers $>5 \times 10^6$ infective particles per mL, the use of CH-296 fibronectin fragment coated culture vessels can achieve transduction of 50–70% of $CD34^+$ cells routinely at clinical scale. It is also possible that use of fibronectin fragment coating may help to preserve the long-term engraftment potential of cultured HSC (49).

3. Transplantation of Transduced HSC

Following transduction, the HSCs are infused into a peripheral vein of the patient. Within 24 h, the majority of the HSCs have homed to the bone marrow. Experience with stem cell

transplantation for treatment of hematological malignancies has shown that the bone marrow can be completely reconstituted by transplanted HSCs (autologous or allogeneic) following myeloablative doses of chemotherapy and/or radiation. Because loss of long-term repopulating ability may occur during ex vivo transduction of HSC, it is unethical to rescue hematopoiesis in a myeloablated patient with ex vivo manipulated HSCs only. However, preclinical and clinical studies suggest that some degree of cytoreductive therapy administered prior to infusion is required to establish clinically relevant levels of gene marking. Using clinically applicable tools, long-term marking at levels of 5–10% can be achieved in nonhuman primates following the administration of high-dose total body irradiation (30,50,51). Long-term multilineage gene marking has not been demonstrated in large animals or humans without bone marrow conditioning. Aiuti and colleages were the first to employ nonmyeloablative bone marrow conditioning in a human gene therapy study for children with adenosine deaminase-deficient severe combined immunodeficiency (discussed in more detail below) (52).

B. Gene Transfer to Lymphocytes

1. Lymphocyte Procurement

With few exceptions, large numbers of lymphocytes circulate in the peripheral blood and are therefore easily harvested from gene therapy candidates using apheresis. Lymphocytes may also be harvested from special sites such as tumors. These cells are of particular interest since they may possess unique antitumor properties.

2. Ex Vivo Gene Transfer and Reinfusion

Compared to HSC, fewer hurdles exist in the quest to optimize retroviral gene transfer of lymphocytes. Since these cells are terminally differentiated, loss of phenotype during ex vivo manipulation is not a concern. T-lymphocytes, which are the most common target for lymphocyte-based gene therapy, are expanded in culture with agents such as IL-2 and/or monoclonal antibodies to CD3. While being cultured, many of the cells are stimulated into active phase of the cell cycle and become susceptible to permanent retroviral integration. It has been observed that with long-term culture of T lymphocytes, enrichment of CD8 T lymphocytes relative to CD4 T lymphocytes develops. This issue may be addressed by altering the ratio of cells added to the initial culture mixture (53).

Techniques that have been shown to improve lymphocyte transduction efficiency include: 1) the use of retroviral vectors pseudotyped with the Gibbon Ape Leukemia Virus (GALV) envelope protein, 2) upregulation of amphotropic or GALV retroviral receptor expression by growth in phosphate depleted media, and 3) transduction in a culture vessel coated with the CS1 fibronectin fragment (54,55). Incorporation of these techniques together in the same protocol can yield transduction efficiency of 50–60%.

Reinfusion of the gene-corrected lymphocytes takes place as would any routine infusion of cell products. Cytoreductive conditioning of the recipient appears not to be necessary to achieve persistence of the transplanted lymphocytes, particularly where the therapeutic gene may provide a survival advantage (i.e., correction of ADA SCID).

C. Clinical Scale-up

The transition from a laboratory-based gene transfer assay to one that is ready for inclusion in a clinical protocol can be quite challenging. The most obvious differences relate to the number of hematopoietic progenitors that must be transduced at one time. Large volumes of retroviral supernatant must be produced in a facility licensed to provide clinical grade material. It is common to find a decrement in the viral titer of the clinical material compared to what is obtained in the laboratory. Besides the requisite sterility and endotoxin testing, the product must always be tested for the presence of replication-competent retrovirus. Regulatory and proprietary issues regarding use of reagents or devices often hinder the ability to replicate in the clinical setting what is done with ease in the laboratory. Performing retroviral transduction in a clinically approved facility may require modifications of a laboratory optimized assay (56). Use of closed-system, gas-permeable, culture containers compatible with the standard sterile transfer techniques used by blood banks is one method that has been adapted for this purpose (57).

IV. HUMAN GENE TRANSFER TRIALS

A. Hematopoietic Stem Cell Gene Transfer Studies

1. Marker Gene Studies

The insertion of marker genes into hematopoietic stem cells has been useful in the evolution of gene transfer technology and has led to a better understanding of autologous stem cell transplantation. The first, and arguably the most successful of these studies was reported by Brenner et al. in 1993 (33). This study enrolled 20 patients under the age of 20 who were candidates for autologous bone marrow transplantation for acute myelogenous leukemia or neuroblastoma. Bone marrow was harvested as the patient recovered from a cycle of cytotoxic chemotherapy. Two-thirds of the harvest was immediately frozen and the remaining one-third was transduced with a retroviral vector containing the neomycin resistance gene. In vitro transduction efficiency, measured as percentage of hematopoietic colonies resistant to G418 (neomycin analogue), ranged from 2–14%. The transduced and unmanipulated bone marrow cells were infused after the administration of high-dose chemotherapy. Using PCR analysis, the marker gene was detected in approximately 5% of bone marrow mononuclear cells 1 month following transplantation. G418 resistance was observed in 5–20% of bone marrow colony forming units (CFU) in 5 of 5 evaluable patients at 1 year, and in 2 patients at 18 months. Three important principals emerged from this study. First, the study proved that long-term repopulating cells could be successfully gene marked ex

vivo. Second, the study demonstrated that autologous marrow infusion following high-dose chemotherapy participates in the marrow recovery. Finally, the authors also reported that tumor cells obtained from patients who relapsed after the gene-marked, autologous BMT contained the neomycin resistance gene, suggesting tumor cell contamination of the autologous stem cell graft (58). Deisseroth et al. performed a similar gene-marked, autologous, BMT study in patients with chronic myelogenous leukemia where gene-marking of normal bone marrow CFU was demonstrated 6 months postinfusion. The investigators also demonstrated gene-marked tumor cells at relapse, suggesting tumor contamination of the autograft (59). Two other studies were unsuccessful at demonstrating tumor contamination of autografts, which may be a consequence of much lower rates of ex vivo gene transfer (60,61).

Dunbar et al. employed HSC transduction conditions optimized by others with animal models (36,62,63) in an attempt to improve the low ex vivo transduction efficiency reported by Brenner et al (33,58). This gene-marking study also set out to compare the engraftment capabilities of bone marrow and peripheral blood stem cells (PBSC) and their suitability as targets for retroviral transduction (64). Bone marrow and chemotherapy/cytokine-mobilized peripheral blood mononuclear cells were procured from breast cancer and multiple myeloma patients who were candidates for autologous stem cell transplantation. Two-thirds of each product was cryopreserved without manipulation. $CD34^+$ cells were purified from the remaining one-third of the mobilized peripheral blood, and bone marrow product and retroviral transduction of each product was performed using 1 of 2 molecularly distinct retroviral vectors containing the neomycin resistance gene. Since the bone marrow and peripheral blood $CD34^+$ cells were not transduced with the same vector, the contribution of each to engraftment following autologous stem cell transplantation could be tracked using PCR. Ex vivo transduction conditions consisted of a 72-hour culture of the target cells with retroviral supernatant supplemented with the hematopoietic cytokines IL-3, SCF, and IL-6 (IL-6 omitted from the culture of $CD34^+$ cells from multiple myeloma patients). All transduced and unmanipulated cells were pooled and reinfused following high-dose chemotherapy administration. The ex vivo transduction efficiency as measured by a clonogenic assay was 18–24%. Following transplantation, gene-marked bone marrow and peripheral blood cells were detected in 10 of 10 evaluable patients at a frequency of 0.1–1% using a semiquantitative PCR technique. At 600 days post infusion, only 1 patient had detectable levels of gene-marked cells. The authors did not identify any significant difference between bone marrow or peripheral blood stem cells as targets for retroviral gene transduction.

2. Chronic Granulomatous Disease (CGD)

CGD is an inherited immune deficiency caused by genetic mutations in any of the 4 subunits of the phagocyte NADPH oxidase ($p47^{phox}$, $p67^{phox}$, $gp91^{phox}$, $p22^{phox}$) resulting in the inability of phagocytes to produce microbicidal superoxide and hydrogen peroxide. CGD patients are prone to recurrent bacterial and fungal infections as well as granuloma formation (65). Stem cell transplantation can cure CGD, indicating that stem cells are the appropriate target for gene therapy (66–70). Preclinical work demonstrated that normal oxidase-positive neutrophils differentiate from CGD stem cells transduced with retroviral vectors encoding the corrective normal oxidase subunit cDNA (71–73). Based on this work, investigators at the National Institutes of Health have undertaken two clinical gene transfer studies to treat CGD.

The first study targeted CGD patients with deficiency of the $p47^{phox}$ subunit (57). The $p47^{phox}$ cDNA was cloned into the MoMLV-based MFGS retrovirus vector, and this vector was packaged by the murine Ψ-crip amphotropic packaging cell line. Mobilized PBSC were apheresed from patients after treatment with G-CSF followed by $CD34^+$ enrichment using an immuno-paramagnetic bead-selection device (Nexell Isolex®). Retroviral transduction of the PBSC was performed in serum-free media for 6 h in the presence of hematopoietic cytokines (PIXY321, G-CSF) for 3 consecutive days. The transduced PBSC were then transfused into the patient without marrow conditioning. Ex vivo transduction efficiency was determined by several methods, including quantitative assessment of oxidase-positive (Nitroblue tetrazolium dye test) myeloid colonies as well as determination of vector copy number using Southern blot hybridization. The percent of oxidase positive colonies ranged from 9 to 29%. This was closely correlated with the vector copy number of 5 to 18% found in transduced and cultured PBSC. Following intravenous infusion of transduced autologous $CD34^+$ cells into patients, the appearance of oxidase-normal neutrophils in the peripheral blood was assessed using a highly sensitive flow cytometry assay based on the increased fluorescence of oxidized dihydrorhodamine 123 (DHR) (74). Oxidase-normal neutrophils first appeared 2 weeks after transplantation and peak correction occurred after 3–6 weeks. The frequency of corrected neutrophils ranged from 0.004 to 0.05%.

The NIH investigators then performed a follow-up study that targeted CGD patients with the X-linked form of CGD caused by mutations in the transmembrane $gp91^{phox}$ subunit (personal communication). All 5 patients enrolled in this trial had the $gp91^{phox}$ null form of X-linked CGD and had previously received allogeneic normal granulocytes as treatment for severe infection. A high titer MFGS-$gp91^{phox}$ retroviral vector was prepared using the human-derived 293 (8) amphotropic envelope packaging cell line. In this study, GM-CSF combined with Flt-3 ligand (Immunex Corp.) was used to mobilize $CD34^+$ cells for apheresis. This novel cytokine combination was used to improve mobilization because previous studies had shown that CGD patients have a moderate defect in the mobilization response to G-CSF (75). Immune-selected cells (Isolex 300I®) were exposed to retroviral supernatant in experimental gas-permeable containers, which were coated with a clinical grade preparation of the CS-1 fibronectin fragment, Retronectin™ (Takara Shuzo). Transduction occurred on 4 consecutive days in serum-free media supplemented with Flt-3 ligand, Pixykine 321(Immunex Corp.), and stem cell factor. As in the first trial, cells were then reinfused into the

patient without marrow conditioning. Two or 3 cycles of gene therapy were administered at approximately 50-day intervals. Ex vivo transduction efficiency was assessed by flow cytometry using an anti-gp91 monoclonal antibody as well as by nitroblue tetrazolium dye testing for oxidase-positive colonies. 75–85% of $CD34^+$ $CD38^-$, Lin^-, HLA DR^- cells were positive for the gp91 protein as detected by flow cytometry after 7 days of in vitro culture. 50% of the myeloid CFU were found to be oxidase positive. Gene-corrected neutrophils were detected in 3 of the 5 patients beginning 2–3 weeks following the infusion of cells. One patient peaked at almost 0.15% oxidase-positive neutrophils. Similar peaks of corrected neutrophils were seen after each cycle, but the size of the peak correlated with the dose of gene-corrected cells that was infused. Gene-corrected cells gradually disappeared from the peripheral circulation approximately 3 months after the last cycle. In 1 patient, corrected neutrophils were recovered from the pus of a liver abscess that predated the time of enrollment in the study. The inability to detect corrected neutrophils in 2 of 5 patients may be a result of immune-mediated elimination of gene-corrected cells in this protein-null, inherited disorder.

3. Multidrug Resistance (MDR1) Gene Transfer

The MDR1 gene encodes a drug efflux pump called P-glycoprotein [Reviewed in Refs. (76–78)]. This pump confers resistance to a variety of anticancer agents including doxorubicin, mitoxantrone, vincristine, etoposide, and taxol. MDR1 can be used as both a therapeutic gene and as a selectable marker for other therapeutic genes (79).

In most cases, myelosuppression is the dose-limiting toxicity of chemotherapeutic agents used to treat cancer. Therefore, if the transfer of MDR1 into HSC is able to attenuate myelosuppression, higher and potentially more effective doses of chemotherapy could be delivered safely to the patient. Proof of this principal was provided in transgenic mice engineered to constitutively express MDR1 (80). These mice could tolerate several-fold higher doses of taxol and daunomycin than their wild-type counterpart (81,82). A similar effect has been demonstrated using retroviral gene transfer of MDR1 into HSC (83–85).

Results from the early studies were severely compromised by low levels of ex vivo transduction of HSCs, a low transplanted dose of transduced HSCs, and by the advanced stage of the cancer patients that were treated (86,87). Subsequent studies were notable for the fact that they provided evidence that in a few select patients, engrafted MDR1 transduced HSCs could reduce the intensity of the neutrophil nadir following high-dose chemotherapy and that repeated cycles of chemotherapy provided them with a selective advantage (88–90). The most notable MDR1 clinical trial came from Abonour and coworkers (89). The transgene vector consisted of a Harvey murine sarcoma virus backbone packaged in the AM12 amphotropic packaging cell line. Autologous peripheral blood $CD34^+$ cells were transduced on dishes coated with the fibronectin derivative CH-296 in media containing fetal calf serum and cytokines (SCF and IL6 or G-CSF/megakaryocyte growth and development factor[MGDF]/SCF) and reinfused into the patient following conditioning with VP16 and carboplatin. Peripheral blood cells containing the transgenes were detected by quantitative real-time PCR in 7 of 12 patients, with 1 patient as high as 5.6% 2 weeks following the transplant. No definitive evidence of hematopoietic chemoprotection was demonstrated when the gene therapy patients were treated with further chemotherapy. However, there was an increase in the percentage of transgene-containing cells in 6 patients following additional chemotherapy, suggesting a selective advantage for these cells. Importantly, no unexpected adverse events occurred in the study participants.

Safety issues regarding the use of MDR1 as a selectable marker have been brought into question by a recent study that demonstrates development of a myeloproliferative syndrome in mice transplanted with MDR1-transduced cells. Of note is that the transplanted cells had been subjected to prolonged ex vivo culture (91). Further studies in large animal models are needed to confirm this possible toxicity. Use of MDR1 and other promising selectable markers such as mutant dihydrofolate reductase is discussed in further detail in Chapter 21.

4. Adenosine Deaminase Deficiency (ADA)

The inherited deficiency of adenosine deaminase (ADA) is responsible for approximately one-quarter of the cases of severe combined immunodeficiency (SCID). In the absence of ADA, lymphocytes accumulate high levels of 2′-deoxyadenosine, which is converted to the toxic compound deoxyadenosine triphosphate. The result is a patient with profound T and B lymphocyte dysfunction that is susceptible to infections with opportunistic pathogens. ADA deficiency is an attractive target for gene therapy because corrected lymphocytes have a survival advantage over noncorrected, ADA-negative lymphocytes. Multiple gene therapy trials for ADA SCID targeting HSC as well as lymphocytes have been performed (34,52,53,92–95). Discussion in this section will focus on HSCs as the target for gene therapy.

Van Beusechem and coworkers laid the groundwork for HSC-based, ADA gene transfer by demonstrating in nonhuman primates that prolonged low-level expression of human ADA from peripheral blood cells was possible after bone marrow cells were transduced with retrovirus containing the ADA cDNA (96).

In 1995, Bordignon and coworkers in Milan, Italy published results of a clinical trial in which both peripheral blood lymphocytes and HSCs were transduced with 2 molecularly distinct retroviral vectors carrying the ADA and neomycin resistance genes and then reinfused into the patient without cytoreductive preconditioning (92). One patient received 9 injections of gene-corrected cells over a 2-year period. The other patient received 5 injections over 10 months. Prolonged detection of both transgenes were observed in both bone marrow and peripheral blood myeloid and lymphoid cells for the entire 35-month period of follow-up. Until the 35-month time point, the vector used for HSC correction was detected only in circulating granulocytes and bone marrow cells but not in

the lymphocytes. Gene-marked lymphocytes contained only the vector used to transduce lymphocytes. At 35 months however, lymphocytes derived from the gene-corrected HSCs were first detected and subsequently became more prevalent than those that carried the lymphocyte-specific vector. For ethical reasons, all patients treated in this study were treated concomitantly with PEG-ADA, thereby blunting the inherent selective advantage that exists for the gene-corrected cells. In 1 patient however, immune function became progressively dysfunctional despite PEG-ADA therapy and sustained long-term expression of the ADA gene in genetically modified lymphocytes. This provided the investigators with the rational for discontinuation of PEG-ADA therapy, with hope of restoring a selective advantage to the corrected cells and improving immune function (97). Prior to discontinuation of the PEG-ADA, the patient received additional gene-corrected autologous lymphocytes. The results of this intervention were positive. There was an increase in total peripheral blood T-cell numbers, an increase in intracellular adenosine deaminase levels, and normalization of in vitro T-cell responsiveness to anti-CD3 and alloantigens. Finally, the patient showed evidence of improved humoral immune function as measured by generation of anti-ψX174 antibodies following vaccination. However, the investigators also measured a concomitant increase in the toxic metabolites of adenosine in red blood cells, suggesting that despite the encouraging clinical effects of PEG-ADA withdrawal, repair of the underlying metabolic defect was incomplete.

Using improved transduction methodology and, for the first time in the setting of gene therapy for a nonmalignant disorder, low-intensity bone marrow conditioning (Busulfan 4mg/kg), the Italian group in collaboration with investigators from Israel transplanted 2 additional PEG-ADA SCID patients with gene-corrected HSC (52). Using this approach, the patients demonstrated an impressive increase in the number of peripheral blood T-cells within 2 months following gene therapy, obviating the need for PEG-ADA therapy and thus preserving the selective advantage of the corrected cells. Concurrent with increased T-cell numbers was normalization of T-cell proliferative responses, increased levels of IgM and IgA, and in 1 patient, a robust humoral response to vaccination with tetanus toxoid. The most notable finding from this trial is that 1 patient had sustained, high-level (5–15%) gene-marking in multilineage bone marrow and peripheral blood cells as measured by real time PCR. This finding will undoubtedly impact the development of future gene transfer trials in which the gene-corrected cells are not afforded a selective advantage, as they are in SCID.

Kohn et al. transduced $CD34^+$ cells isolated from umbilical cord blood of 3 ADA-deficient neonates with an MoMLV-based retroviral vector containing human ADA cDNA as well as the cDNA encoding the bacterial neomycin resistance gene (34). Cells were returned to the unconditioned recipient on the 4th day of life. Ex vivo transduction efficiency as measured by percent G418 resistant CFU ranged from 12–19%. Clonogenic myeloid precursors from the bone marrow were assayed at 1 year and found to be G418-resistant at a frequency of 4–6%. Concurrent with the infusion of gene-corrected HSC, the patients began ADA replacement therapy with PEG-ADA. As a result, the selective advantage of ADA positive clones was partially blunted. After 4 years of follow-up, the levels of gene-corrected cells in the peripheral blood mononuclear cell fraction has increased 50–100-fold in all 3 patients (93). The frequency of gene-corrected T-lymphocytes increased to 1–10%. This rate of increase was far greater than that observed in the granulocyte series (0.01–0.03%). In an attempt to assess clinical efficacy of gene transfer, PEG-ADA administration was discontinued in the patient with the highest level of gene-corrected T-lymphocytes. This resulted in reduction of S-adenosylhomocysteine hydrolase activity and loss of antigen specific T-lymphocyte reactivity, suggesting inadequate ADA production by the transduced cells. After 2 months, PEG-ADA replacement was restarted when oral monilia, sinusitis, and an upper respiratory tract infection developed. Despite the inability to demonstrate clinical benefit, the persistence of the transgene for over 4 years in both the lymphoid and the myeloid cell lines suggests that gene transfer into true long-term repopulating HSCs is possible from cells collected from umbilical cord blood.

5. X-linked Severe Combined Immunodeficiency

The majority of patients with SCID carry a mutation in the common γ chain of the receptors for interleukin 2, 4, 7, 9, and 15. Without a functional γ chain, there is complete absence of T-cell and NK cell development resulting in a profound immunodeficiency that is usually fatal in the first year of life. HLA-identical or more commonly, haploidentical parental bone marrow stem cell transplantation with or without antecedent cytotoxic bone marrow conditioning (due to selective advantage of normal T-cells) restores T-cell function and a relatively normal quality of life in 70–90% of patients. B-cell function is often deficient in patients who are transplanted without marrow conditioning. Such patients are dependent on life-long immunoglobulin supplementation to remain healthy.

The residual humoral immune defect, along with risks of graft vs. host disease and conditioning-related toxicity for patients treated with a traditional stem cell transplant led investigators from the Necker hospital in Paris to conduct the first stem cell gene transfer trial for X-linked SCID. $CD34^+$ bone marrow stem cells from 5 affected boys were tranduced with a Moloney murine leukemia virus (MFG) packaged in the Ψcrip producer line and reinfused without bone marrow conditioning. In 4 of 5 patients, normal functioning gene-corrected T-cells and NK cells were detected in peripheral circulation approximately 3 months after the transplant. As a result of the selective advantage for gene-corrected T-cells, total T-cell numbers reached normal levels within 6 months. Serum immunoglobulin levels normalized in 3 of 5 patients and was low but detectable in the 4th patient. All patients with successful engraftment of gene-corrected stem cell showed resolution of all stigmata of profound immunodeficiency, making this the first gene therapy trial to provide clear-cut clinical benefit. Gene-corrected cells were never detected in 1 of the patients

and he was subsequently successfully treated with allogeneic stem cell transplantation (98).

Unfortunately, excitement surrounding the success of this trial was tempered by the development of T-cell leukemia in 2 patients. Molecular analysis of the tumor cells revealed that malignant transformation most likely occurred as a consequence of insertional mutagenesis of LMO-2, a gene linked to T-cell leukemia (99,100). How this event will affect future gene therapy trials for X-linked SCID or other inherited stem cell disorders is not clear.

6. Fanconi Anemia

Fanconi anemia (FA) is an autosomal recessive disorder manifested by aplastic anemia, physical malformations, and cancer susceptibility (101). Eight separate genotypic groups of FA have been described (FA-A though FA-H) (102). Cells carrying the FA mutation are hypersensitive to DNA-damaging agents such as mitomycin C (103). Since stem cell transplantation successfully treats the hematological manifestations of FA (104,105), it is a logical candidate for stem cell gene therapy. In addition, there is evidence to suggest that normal stem cells may have a selective growth advantage over HSCs with the mutated FA gene (106).

After demonstrating in vitro that HSCs from patients with the FA group C (FAC) gene mutation could be functionally corrected by retroviral gene transfer of the normal FAC gene, Liu et al. initiated a clinical trial (107). Three children and 1 adult with the FAC mutation were treated with sequential cycles of autologous, G-CSF-mobilized CD34 selected progenitor cells that were transduced with a MoML V-based retroviral vector containing the cDNA for FAC and neomycin resistance. The cells were transduced in the presence of hematopoietic cytokines IL-3, IL-6, and SCF for 72 h and returned to the patient without cytotoxic bone marrow conditioning. The cell dose for patients 1 and 2 were extremely low due to poor CD34+ cell mobilization in response to G-CSF. FAC vector sequence was detected by PCR in the peripheral blood and bone marrow of all 3 patients at levels that ranged from 0.01–3%. Multilineage, peripheral blood-marking was detected in 1 patient for a 16-month period during which the patient received 4 cycles of gene transfer. The other patients had only transient bone marrow and peripheral blood positivity despite repeated cycles of gene therapy. Bone marrow sampling of each patient following the infusion of gene-corrected cells revealed an increase in the number of colonies resistant to the DNA-damaging effects of mitomycin C.

Radiation therapy delivered to patient 4 approximately 50 days following gene therapy for treatment of squamous cell carcinoma of the vulva resulted in detection, for the first time, of gene-marked cells in the peripheral blood. These gene-corrected cells were undetectable prior to radiation therapy, suggesting that they were afforded a selective advantage by the radiation treatments (108).

7. Gaucher's Disease

Gaucher's disease is an autosomal recessive disorder that results in a deficiency of the lysosomal enzyme glucocerebrosidase (109). This leads to the accumulation of glucosylcerebroside in macrophages throughout the reticular endothelial system. Although the clinical course is quite variable, most patients develop hepatosplenomegaly and painful, lytic, bone lesions. Conventional treatment includes stem cell transplantation or glucocerebrosidase supplementation.

Dunbar et al. has published the first clinical gene therapy trial for Gaucher's disease (38). Three patients received CD34-selected (Cellpro Ceprate) bone marrow or mobilized PB transduced on autologous stroma +/− cytokines with a retroviral vector containing the human glucocerebrosidase cDNA. Transduction efficiencies were low, ranging from 1–10% using a semiquantitative PCR assay. Transgene was detected in peripheral blood mononuclear cells (<0.02%) for 3 months in the patient whose cells were transduced with the highest efficiency.

8. Human Immunodeficiency Virus

HSC and mature T-lymphocytes are targets for anti-HIV gene therapy. Strategies include transfer of genes encoding ribozyme, which target the viral RNA genome, RNA decoys, and mutant transactivator genes that interfere with viral gene expression (110–112). These approaches, along with a review of the clinical trials are discussed in Chapter 31.

9. Summary

Techniques for gene transfer to HSC have advanced to the point where definitive clinical benefit has been achieved in a small number of patients with SCID. Sustained engraftment of transduced HSC whose progeny do not have a selective advantage is best demonstrated in the gene transfer studies where cytotoxic bone marrow conditioning was administered prior to the transplant (33,58,64,124). Besides reducing the number of resident naive stem cells, marrow conditioning results in a bone marrow microenvironment that is more conducive for engraftment of transduced HSC. Improvement in retroviral transduction conditions that utilize cytokines such as FLT-3 ligand and thrombopoietin have resulted in impressive rates of HSC gene transfer in myeloablated nonhuman primates (30,51). Alternative vectors such as those derived from lentivirus hold considerable promise for future HSC-gene-transfer strategies, assuming that their safety can be maximized. Given the newly described cases of insertional mutageneis that has complicated the X-SCID trial, risk vs. benefit of gene therapy will need to be reevaluated for each candidate stem cell disorder.

B. Lymphocyte Gene-transfer Studies

1. Gene-marking Studies

The first clinical gene-therapy trial involved gene transfer into lymphocytes and was undertaken in the late 1980s as a means of characterizing tumor-infiltrating lymphocytes (TIL) (1). TIL were isolated from tumors of patients with metastatic melanoma. These cells were expanded and then transduced with a retroviral vector containing the neomycin resistance gene. Following reinfusion, the marker gene was used to track

the migration of the marked lymphocytes. TIL were consistently found in the peripheral blood as well as tumor deposits for up to 2 months. A similar approach was employed to study the persistence of Epstein-Barr virus (EBV)-specific cytotoxic T-lymphocytes (CTL) generated ex vivo and infused as treatment of post bone marrow transplant EBV-related lymphoproliferation (113,114) EBV-specific CTLs marked with a neomycin-resistance vector were detectable in the peripheral circulation for 10 weeks post infusion.

2. Adenosine Deaminase (ADA) Deficiency

Blaese et al. were the first to use a therapeutic gene in a retroviral gene transfer trial for ADA-deficient SCID patients (53). Two patients with an incomplete response to PEG-ADA therapy were infused with T-lymphocytes transduced with an MoMLV-based retroviral vector containing the cDNA coding for ADA. The transduction efficiency of lymphocytes prior to infusion ranged from 0.1–10%. Patients were treated with multiple cycles of transduced T-cells over a period of 1–2 years. Gene-corrected cells were detected in circulation for 2 years following the final cycle of gene therapy, demonstrating a T-lymphocyte lifespan much longer than what was predicted. There was clear-cut evidence of improved cellular and humoral immune response following gene therapy in 1 of the 2 patients treated. This discrepancy in patient response was attributed to superior ex vivo transduction efficiency obtained in the responding patient. No toxicity was attributed to the conduct of the protocol.

Using the identical experimental design and retroviral vector, Onodera et al. accomplished similar results in 1 patient treated in Japan (95). These studies, in conjunction with the previously described Bordignon study (92) demonstrate the potential of lymphocyte-based gene therapy to provide prolonged clinical benefit.

3. Suicide Gene Transfer

The use of herpes simplex virus thymidine kinase (HSV-TK) gene and other ''suicide'' genes for gene therapy is discussed in Chapter 20. Introduction of the HSV-TK gene into a cell allows for the phosphorylation of nucleoside analogs such as ganciclovir. Once phosphorylated, ganciclovir becomes toxic to the cell as it is incorporated into DNA. There are 3 published hematopoietic cell gene therapy trials utilizing the HSV-TK. Lymphocytes were the target cells in both studies (115,116,117). In an attempt to make HIV therapy with autologous cytotoxic T-cells safer, Riddell et al. transduced HIV-specific cytotoxic T-cells with the HSV-TK gene (115). The transduced cells could then be eliminated with ganciclovir treatment if toxicity were to arise from their presence. The vector used to transduce the lymphocytes also carried the hygromycin phosphotransferase gene. Unexpectedly, the transduced lymphocytes were rejected by a brisk host cytotoxic T-lymphocyte response against the transduced cells and thus, efficacy could not be assessed.

In allogeneic bone marrow transplantation, lymphocytes taken from the bone marrow donor are often infused into the recipient to treat tumor relapse via the graft vs. tumor effect, or to aid in immune reconstitution. Significant toxicity may arise if transplanted lymphocytes mount an immunological attack against the recipient (graft vs. host disease). As in the Riddell study, Bonini et al. studied HSV-TK-transduced donor lymphocyte infusions as a method of protecting against graft vs. host disease (GVHD) (116). The vector used for transduction also carried the marker gene that coded for a truncated form of the human low-affinity receptor for nerve growth factor (NGFR) as well as the neomycin resistance gene. Gene-marked lymphocytes were detected in 7 of 8 patients available for analysis with a range of 0.01% to 13.4% of the total circulating lymphocytes. Three of the patients developed GVHD and were treated with ganciclovir. The percent of genetically modified lymphocytes decreased dramatically with complete resolution of GVHD in 2 of 3 patients. Partial resolution of GVHD occurred in the other. While there was no evidence of an immune-mediated elimination of the transduced cells, these bone marrow transplant patients were likely immunocompromised even more profoundly than the HIV+ patients studied by Riddell et al.

Using a similar strategy, Tiberghien and coworkers infused donor lymphocytes transduced with a MoMuL V-derived retroviral vector carrying the genes for HSV-TK and neomycin resistance into recipients of a T-cell-depleted allogeneic stem cell transplantation (117). Of the 12 patients treated, 4 developed clinically significant GVHD, prompting ganciclovir administration. Ganciclovir adminstration resulted in resolution of GVHD in 3 of 4 patients and, as in the earlier study, correlated with a drop in the number of gene-marked lymphocytes.

V. CONCLUSION

To date, all clinical trials involving transduction of hematopoietic cells have utilized murine-based retroviral vectors. When lymphocytes are the target cell, modest clinical benefit was observed in both the ADA and HSV-TK trials. This is attributable to the relatively high level of transduction efficiency using the latest techniques. Though clinical applicability of HSC gene transfer is much broader than for lymphocytes, long-term repopulating HSCs are less receptive to retroviral-based gene transfer. While alternate vectors such as lentivirus, and adeno-associated viral vectors are promising, a number of studies have proven that the retroviral vector can successfully target the long term repopulating cell, albeit with an extremely low efficiency. To improve the ability to transduce HSC, further knowledge of stem cell biology such as their cell cycle characteristics, their trigger for self-replication vs. lineage commitment, and the optimal ex vivo growth conditions will aid in the ability to transduce these cells. The production of high titer, replication-defective, retroviral supernatant is another technique that must be perfected. It is unclear to what extent host immune rejection of cells expressing the transgene will hinder progress of gene therapy for protein-null disorders or disorders where a heterologous gene product is produced.

And finally, it is becoming clear that some degree of cytoreductive bone marrow conditioning will be necessary to achieve clinically significant levels of HSC gene transfer.

The earliest, and perhaps most obvious, clinical embodiments of gene transfer technology have involved the treatment of rare genetic disorders. The development of effective methods of manipulating gene expression in vivo, however, coupled with an explosive growth in the understanding of changes in gene expression associated with the onset and progression of acquired diseases, has created a prospect for revolutionizing the clinician's approach to common disorders. As researchers learn more about the genetic blueprints of disease, they gain the potential to alter, or even reverse, pathobiology at its roots. Nowhere are these possibilities more avidly sought, nor more likely to impact a significant population of patients, than in the arena of cardiovascular disease.

Gene therapy has come to embrace both the introduction of functional genetic material into living cells as well as the sequence-specific blockade of certain active genes. These systems have included recombinant viral vectors that allow relatively efficient insertion of genetic information and oligonucleotides that can be used to alter native gene expression (1,2). This increased breadth of gene manipulation technology has accompanied the identification of genes that are either activated or repressed during disease. Recent discoveries have uncovered therapeutic targets (2,3) both for the improvement of conventional cardiovascular therapies, such as balloon angioplasty or bypass grafting, and for the development of entirely novel approaches, such as the induction of angiogenesis in ischemic tissues. As enthusiasm grows for these new experimental strategies, it is important for clinicians to be aware of their limitations as well as their strengths, and for careful processes of evaluation to pave the possible integration of these therapies into routine practice. This chapter will explore general principles of gene manipulation in the cardiovascular system, review a number of prominent examples of experimental reduction to practice, and is intended as a source to assist in the consideration of future developments in this exciting field.

I. GENETIC MANIPULATION OF CARDIOVASCULAR TISSUE

A. Gene Therapy Strategies

Gene therapy can be defined as any manipulation of gene activity, or gene ''expression,'' that influences disease. This manipulation is generally achieved via the introduction of foreign DNA into cells in a process known as transduction or transfection. Gene therapy can involve either the delivery of whole, active genes (gene transfer), or the blockade of native gene expression by the transfection of cells with short chains of nucleic acids known as oligonucleotides.

The gene transfer approach allows for replacement of a missing gene product, or for the ''overexpression'' of a native or foreign protein that can prevent or reverse a disease process. The transfer of a gene into a target cell leading to subsequent gene expression is known as *transduction*, and the new gene can be referred to as the *transgene*. Gene *replacement* or *aug-*

mentation involves the transfer of a gene that is either missing from a cell, present in a defective form, or simply underexpressed relative to the level of protein expression desired by the clinician. The protein expressed may be active only intracellularly, in which case a very high gene transfer efficiency may be necessary to alter the overall function of an organ or tissue. Alternatively, proteins secreted by target cells may act on other cells in a paracrine or endocrine manner, in which case delivery to a small subpopulation may yield a sufficient therapeutic result.

Gene blockade can be accomplished by transfection of cells with short chains of DNA known as antisense oligodeoxynucleotides (ODN) (4). This approach attempts to alter cellular function by the inhibition of specific gene expression. Genes are defined by a specific sequence of bases that make up the DNA chain. Antisense ODN are designed to have a base sequence that is complementary in terms of Watson-Crick binding to a segment of the target gene. They are generally 15–20 bases in length, which confers specificity to a single site within the genome. This complementary sequence allows the ODN to bind specifically to the corresponding segment of messenger RNA (mRNA) that is transcribed from the gene during expression. This binding of ODN to mRNA prevents the translation of RNA into the protein product of the gene (4).

Another form of gene blockade is the use of ''ribozymes,'' segments of RNA that can act like enzymes to destroy only specific sequences of target mRNA (5). Ribozymes contain both a catalytic region that can cleave other RNA molecules in a sequence-specific manner, and an adjacent sequence that confers the specificity of the target. Because the sequence recognition portion of the ribozymes is generally limited to approximately 6 bases, these gene-inhibitory agents are generally more susceptible to nonspecific interactions than their antisense counterparts.

A third type of gene inhibition involves the blockade of gene-regulatory proteins known as transcription factors. Transcription factors regulate gene expression by binding to chromosomal DNA at specific promoter regions, and this binding turns on, or ''activates,'' an adjacent gene. Double-stranded ODN can therefore be designed to mimic the chromosomal binding sites of these transcription factors and act as ''decoys,'' binding up the available transcription factor and preventing the subsequent activation of target genes (6).

The transfer of genetic sequences exogenous to the human genome has been envisioned, such as the gene encoding thymidine kinase (TK) from the herpes simplex virus. This has been used to enhance metabolic activation of the cytotoxic prodrug ganciclovir, which may be useful in treating vascular proliferative disorders such as restenosis (7). Scientists studying gene transfer technology have often relied on a class of genes known as *reporter* or *marker genes*. These genes encode proteins, such as a form of β-galactosidase found in *E. coli* (known as *lacZ* or *β-gal*) or a small fluorescent molecule known as green fluorescent protein (GFP), that can be detected easily via histochemistry, fluorescent microscopy, or other techniques that allow rapid identification and quantification of successful gene transfer.

B. Vectors for In Vivo Cardiovascular DNA Delivery

For the purpose of cardiovascular gene therapy, the ''ideal'' DNA delivery vector would be capable of safe and highly efficient delivery to all cell types, both proliferating and quiescent, with the opportunity to select either short-term or indefinite gene expression. This ideal vector would also have the flexibility to accommodate genes of all sizes, incorporate control of the temporal pattern and degree of gene expression, and to recognize specific cell types for tailored delivery or expression. While progress is being made on each of these fronts individually, researchers remain far from possessing a single vector with all of these characteristics. Instead, a spectrum of vectors has evolved, each of which may find a niche in different early clinical gene therapy strategies.

Viral vectors may represent nature's solution to the problem of efficient gene transfer; however, the attempt by humans to harness these resources has also been confounded by the biological barriers that have evolved to protect cells and organisms from viral infection. Immunological responses not only limit the efficacy of viral gene transfer, particularly when repeat administrations are considered, but the inflammatory response to viral antigens, even those associated with replication-deficient vectors, may impede or negate the benefits of expression of the transferred gene (8). Furthermore, engineering of viral genomes does not always preclude residual cytotoxicity in infected cells, and the possibility for regression to replication proficiency.

Scientists have therefore continued to explore nonviral avenues for achieving efficient DNA delivery. One advantage of nonviral delivery systems is that they can be used not only for gene transfer but also for the delivery of oligonucleotides and protein-nucleic acid complexes that can be used for alternative forms of genetic manipulation. Whereas *transduction* refers generally to the delivery of an intact gene to a target cell, and *infection* is used to describe the process of viral gene delivery, *transfection* is a term used to describe nonviral (i.e., physical/chemical) delivery of genes or oligonucleotides. Below is a brief description of DNA-delivery vectors that have been exploited in the cardiovascular system (Table 1).

1. Retroviral Vectors

Recombinant, replication-deficient retroviral vectors have been used extensively for gene transfer in cultured cardiovascular cells in vitro, where cell proliferation can be manipulated easily. Their use in vivo has been more limited due to low transduction efficiencies, particularly in the cardiovascular system where most cells remain quiescent. Nabel et al. (9) first demonstrated the feasibility of transducing blood vessels with foreign DNA in vivo by infecting porcine iliofemoral arteries with a recombinant retroviral vector containing the β-galactosidase gene. Several cell types in the vessel wall were transduced, including endothelial and vascular smooth muscle cells (VSMCs). Using a β-galactosidase retroviral vector to genetically modify endothelial cells in vitro, Wilson et al. (10) demonstrated expression up to 5 weeks after implanta-

Table 1 Comparison of Vectors Used for Cardiovascular Gene Transfer

	Efficiency (in vivo)	DNA integration	Duration of gene expression	Level of expression (max.)	Ease of preparation	Host response	Risks
Viral							
Retrovirus	+	Yes	Life-long	++	+++	+	Oncogenesis Viral mutation
Adenovirus	++++	No	1–2 weeks	++++	++	++++	Cytotoxicity Viral mutation
AAV	+	Sometimes	Life-long	+	+	+	Oncogenesis Viral mutation Viral contamination
Nonviral							
Liposomes	+	No	Limited	+	++++	+	Cytotoxic at high concentrations
Fusigenic Liposomes	++	No	Limited	+	+	+	Cytotoxic at high concentrations
Naked Plasmid	+	No	Limited	+	+++	+	Cytotoxic at high concentrations

+ = lowest, ++++ = highest, AAV = adeno-associated virus.

tion of a prosthetic vascular graft seeded with genetically transformed cells. The random integration of traditional retroviral vectors such as MMLV into chromosomal DNA involved a potential hazard of oncogene activation and neoplastic cell growth. While the risk may be exceedingly low, safety monitoring will be an important aspect of clinical trials using viral vectors. Recent improvements in packaging systems (particularly the development of ''pseudotyped'' retroviral vectors that incorporate vesicular stomatitis virus G-protein) have enhanced the stability of retroviral particles and facilitated their use in a wider spectrum of target cells.

2. Adenoviral Vectors

Recombinant adenoviruses have become the most widely used viral vectors for experimental in vivo gene transfer, and have been used extensively in animal models of cardiovascular disease (11). Adenoviruses can infect nondividing cells and generally do not integrate into the host genome. These vectors can therefore achieve relatively efficient gene transfer in quiescent vascular tissue, but transgenes are generally lost when cells are stimulated into rounds of cell division. Expression of DNA in a nonchromosomal, or episomal state, also appears to be less stable, and adenoviral transduction has proven to be transient in cells even in the absence of replication.

Many scientists have concluded that the immune response to adenoviral antigens represents the greatest limitation to their use in gene therapy. Conventional vectors have generally achieved gene expression for only 1–2 weeks after infection. It is not certain to what extent the destruction of infected cells contributes to the termination of transgene expression given that the suppression of episomal transgene promoters appears to occur as well. However, longer expression has been documented after injection of tissues in immune deficient mice. Even in the context of such reactions, the adenoviral vector has been postulated to provide an adjuvant effect that amplifies the immune response. In the vasculature, physical barriers such as the internal elastic lamina apparently limits infection to the endothelium, with gene transfer to the media and adventitia only occurring after injury has disrupted the vessel architecture. Although gene delivery to 30–60% of cells after balloon injury has been reported with adenoviral vectors carrying reporter genes, the fact that atherosclerotic disease has also been found to limit the efficiency of adenoviral transduction may pose a significant problem for the treatment of human disease.

3. Adeno-associated Viral Vectors

Adeno-associated virus (AAV) is a dependent human parvovirus that has not been linked to human disease (12). It can infect a wide range of target cells and can establish a latent infection by integration into the genome of the cell, thereby yielding stable gene transfer as in the case of retroviral vectors. Although AAV vectors transduce replicating cells at a more rapid rate, they possess the ability to infect nonreplicating cells both in vitro and in vivo. AAV is limited by its small size (transgenes cannot be longer than about 4 kb) and the need to eliminate helper viruses from viral preparations. The efficiency of AAV-mediated gene transfer to vascular cells, and the potential use of AAV vectors for in vivo vascular gene therapy, remains to be determined. However, a number of groups have reported successful transduction of myocardial cells after direct injection of AAV suspensions into the heart tissue, and these infections have yielded relatively stable

expression for greater than 60 days (13). It has not yet been clearly established whether long-term recombinant AAV transgenic expression is associated with genomic integration as is the wild-type AAV infection. In general, AAV transgene expression does not occur at significant levels during the first 2–4 weeks after infection, although the reason for this delay remains speculative.

4. Lipid-mediated Gene Transfer

Numerous nonviral methods are available for the delivery of DNA into cells in vitro, including calcium phosphate, electroporation, and particle bombardment. The development of similarly effective methods of in vivo transfection, however, has posed a significant challenge to cardiovascular and other clinical researchers who hope to avoid cumbersome and invasive steps of harvesting and culturing tissues or cells from the patient. The encapsulation of DNA in artificial lipid membranes (liposomes) can facilitate its uptake and cellular transport. The primary advantages of lipid-based gene transfer methods are ease of preparation and flexibility in substituting different transgene constructs in comparison with the relatively complex process of producing recombinant viral vectors. Cationic liposomes have been used extensively during the last 5 years for cellular delivery of plasmid DNA and antisense oligonucleotides (14). A wide variety of cationic lipid preparations are currently available for DNA transfer both in vitro and in vivo. In addition to cationic lipids, other substances, such as lipopolyamines and cationic polypeptides are now being investigated as potential vehicles for enhanced DNA delivery both for gene transfer and gene blockade strategies (15).

5. Fusigenic-liposome Mediated Gene Transfer (HVJ Liposomes)

This method utilizes a combination of fusigenic proteins of the Sendai virus [Hemagglutinating Virus of Japan (HVJ)] in conjunction with neutral liposomes. HVJ is an RNA virus and belongs to the paramyxovirus family, which has HN and F glycoproteins on its envelope (16). HN binds with glycol-type sialic acid groups that act as receptors on the cell surface, and F protein can interact directly with a cellular lipid bilayer and induce fusion. HVJ liposomes consist of neutral liposomes complexed with UV-light-inactivated HVJ virus. Fusion of HVJ liposome complexes with the cell membrane may result in the release of DNA directly into the cytosol and facilitating nuclear uptake. HVJ-liposome methods have been successfully employed for gene transfer in vivo to many tissues including liver, kidney, and the vascular wall. A major limitation to current HVJ-liposome techniques is the need to undertake a multistep liposome preparation procedure immediately prior to use and the poor long-term stability of the complexes.

6. Other In Vivo Gene Transfer Methods

Plasmids are circular chains of DNA that were originally discovered as a natural means of gene transfer between bacteria. Naked plasmids can also be used to transfer DNA into mammalian cells. The direct injection of plasmid DNA into tissues in vivo can result in transgene expression. Plasmid uptake and expression, however, has generally been achieved at reasonable levels only in skeletal and myocardial muscle (17). The uptake of naked oligonucleotides is also inefficient after either intravascular administration or direct injection. Various catheters that have been designed to enhance local drug delivery to isolated segments of target vessels have been proposed as vehicles for local vascular gene therapy. The controlled application of a pressurized environment to vascular tissue in a nondistended manner has recently been found to enhance oligonucleotide uptake and nuclear localization. This method may be particularly useful for ex vivo applications such as vein grafting or transplantation, and may represent a means of enhancing plasmid gene delivery, as well (18).

7. Regulating Transgene Expression

In addition to effective gene delivery, many therapeutic settings will demand some degree of control over the duration, location, and degree of transgene expression. To this end, researchers have developed early gene promoter systems that allow the clinician to regulate the spatial or temporal pattern of gene expression. These systems include tissue-specific promoters that have been isolated from genetic sequences encoding proteins with natural restriction to the target tissue, such as the von Willebrand factor promoter in endothelial cells and the a-myosin heavy chain promoter in myocardium (19). Promoters have also been isolated from nonmammalian systems that can either promote or inhibit downstream gene expression in the presence of a pharmacological agent such as tetracycline, zinc, or steroids (20). In addition, regulation of transgene expression may even be relegated to the physiological conditions, with the incorporation of promoters or enhancers that respond to specific conditions such as hypoxia or increased oxidative stress (21).

II. GENE THERAPY FOR HYPERLIPIDEMIA AND SYSTEMIC DISEASES

Hyperlipidemia, in both its acquired and inherited forms, has been clearly shown to be an independent risk factor for the development of atherosclerotic vascular disease, myocardial infarction, and stroke. The use of drug therapies in the treatment of acquired forms of this disease, through either 3-hydroxy-3-methylglutaryl-coenzyme A (HMG CoA) reductase inhibitors or bile acid binding resins, has proven effective in decreasing the morbidity and mortality associated with hyperlipidemia. However, these same regimens have had their limitations in the treatment of inherited disorders such as familial hypercholesterolemia (FH) and apo E deficiency. The shortcomings of conventional pharmacological therapy have therefore stimulated an interest in the genetic replacement of these missing proteins in hepatocytes as a potential means of reducing cholesterol levels in patients with these rare disorders.

A. Ex Vivo Approach

Familial hypercholesterolemia, caused by mutations in the low density lipoprotein (LDL) receptor, is the most common ge-

netically linked source of hypercholesterolemia, and the heterozygous form is the most common inherited cardiovascular disease (22). The receptor functions to facilitate the uptake of LDL in the liver and is essential for maintaining normal cholesterol levels. In a rabbit model of LDL receptor deficiency, Chowdhury et al. surgically harvested autologous hepatocytes, and stably transferred the gene for the LDL receptor into those cells in culture using a replication-deficient retrovirus. The cells were then infused back into the animals' liver via the portal circulation, and ingraftment of the genetically engineered cells into the liver succeeded in lowering plasma cholesterol levels (23). These encouraging results spawned several clinical trials, the results of which were not as dramatic (24,25). Despite a 30% reduction in serum LDL levels for up to 6 months in the rabbit model, therapeutic reductions in LDL in the clinical trials ranged from 0–15%, with a significantly shorter duration. These differences likely reflect the need for a much higher number of genetically modified autologous cells in the human subject to produce significant therapeutic changes. The immunological response to these infected cells cultured in media containing nonhuman proteins may have also played a role in reducing the duration of clinical efficacy.

B. In Vivo Approach

Researchers have shown that after intravenous injection of adenovirus, more than 90% of transgene expression occurs in the liver. This finding led to the investigation of an in vivo approach to the genetic treatment of this FH. Several groups have reported complete correction of elevated LDL levels in mouse and rabbit models of FH after injection of a replication-deficient adenovirus containing the LDL receptor gene (26–29). However, these effects were found to be transient, once again likely due to the immune responses directed both to adenoviral proteins as well as to the transgene product. Additionally, Kozarsky et al. has reported effective adenoviral-mediated gene transfer of the VLDL receptor in a mouse model for FH with transient correction of hypercholesterolemia (30). Apo E-deficiency has been shown to lead to marked hypercholesterolemia, hypertriglyceridemia, and increased levels of cholesterol-rich VLDL and chylomicron remnants. Apo E-deficient mice treated by adenovirus-mediated gene transfer of the human apo E3 gene resulted in a shift in the plasma lipoprotein distribution from primarily VLDL and LDL in the control mice to predominantly HDL in transfected mice (31). Furthermore, in normal mice, adenovirus-mediated transfer of a gene encoding apo A-I produced transient, physiologically relevant elevations of HDL cholesterol that were comparable to elevations observed in transgenic animals that overexpressed the apo A-I gene (32).

The progress achieved in the treatment of experimental FH through the in vivo genetic manipulation of hepatocytes has brought researchers a step closer toward the permanent correction of this devastating disease. With the development and/or improvement of gene delivery vector systems that can produce long-term, stable integration and that do not lead to a significant inflammatory or immune response, one can also foresee a time where other systemic diseases like diabetes and coagulopathies such as hemophilia can be cured.

III. GENE THERAPY FOR VASCULAR DISEASES

A. Gene and Oligonucleotide Therapy of Restenosis

Recurrent narrowing of arteries following percutaneous angioplasty, atherectomy, or other disobliterative techniques is a common clinical problem that severely limits the durability of these procedures for patients with atherosclerotic occlusive diseases. In the case of balloon angioplasty, restenosis occurs in approximately 30–40% of treated coronary lesions and 30–50% of superficial femoral artery lesions within the first year. Intravascular stents reduce the restenosis rates in some settings; however, the incidence remains significant and long-term data are limited. Despite impressive technological advances in the development of minimally invasive and endovascular approaches to treat arterial occlusions, the full benefit of these gains awaits the resolution of this fundamental biological problem.

Restenosis is an attractive target for gene therapy not only because of its frequency (and its associated costs incurred on the health care system) but more so because it is a local tissue reaction that develops precisely at a site of intervention to which access has already been accomplished. A potential advantage of the genetic approach over more conventional pharmacotherapies is that a single dose of a gene therapy agent may have a protracted biological effect. It has been reasoned that the appropriate genetic modification, performed locally at the time of angioplasty, could induce a long-term benefit in patency by altering the healing response. The potential role for gene therapy in the prevention of restenosis will depend on the identification of an appropriate molecular target, a suitable vector system for efficiently targeting vessel wall cells, and methods of achieving local delivery without producing undue damage or distal tissue ischemia. Presently, considerable hurdles remain despite significant progress in each of these areas.

The pathophysiology of restenosis reflects a paradigm of the healing response of arteries that are injured by reconstructive techniques. It is comprised of a contraction and fibrosis of the vessel wall known as remodeling, and an active growth of a fibrocellular lesion composed primarily of VSMC and extracellular matrix. The latter process, known as neointimal hyperplasia, involves the stimulation of the normally ''quiescent'' VSMCs in the arterial media into the ''activated'' state characterized by rapid proliferation and migration. A number of growth factors are believed to play a role in the stimulation of VSMCs during neointimal hyperplasia, including platelet derived growth factor (PDGF), basic fibroblast growth factor (bFGF), transforming growth factor beta (TGF-β), and angiotensin II (33). Activated VSMCs have also been found to produce a variety of enzymes, cytokines, adhesion molecules, and other proteins that not only enhance the

inflammatory response within the vessel wall but also stimulate further vascular cell abnormality (34–37).

Although it is now thought that remodeling may account for the majority of late lumen loss after balloon dilation of atherosclerotic vessels, proliferation has been the predominant target of experimental genetic interventions. There have been 2 general approaches: cytostatic, in which cells are prevented from progressing through the cell cycle to mitosis, and cytotoxic, in which cell death is induced. A group of molecules known as cell cycle regulatory proteins act at different points along the cell cycle, mediating progression toward division. It has been hypothesized that by blocking expression of the genes for 1 or more of these proteins, one could prevent the progression of VSMCs through the cell cycle and inhibit neointimal hyperplasia. Morishita et al. demonstrated near-complete inhibition of neointimal hyperplasia after carotid balloon injury via HVJ-liposome-mediated transfection of the vessel wall with a combination of antisense ODN against cell cycle regulatory genes (38,39). Arrest of the cell cycle via antisense blockade of either of 2 proto-oncogenes, c-myb or c-myc, has been found to inhibit neointimal hyperplasia in models of arterial balloon injury (40,41), although the specific antisense mechanism of the ODN used in these studies has subsequently been questioned (42,43).

In addition to transfection of cells with antisense ODN, cell cycle arrest can also be achieved through manipulation of transcription factor activity. The activity of a number of cell cycle regulatory genes is influenced by a single transcription factor known as E2F (44). In quiescent cells, E2F is bound to a complex of other proteins, including a protein known as the retinoblastoma gene product (Rb), that prevents its interaction with chromosomal DNA and its stimulation of gene activity. In proliferating cells, E2F is released, resulting in cell-cycle, gene activation. A transcription factor decoy bearing the consensus-binding sequence recognized by E2F can be employed as a means to inhibit cellular proliferation (Fig. 1). Morishita et al. demonstrated the use of this strategy to prevent VSMC proliferation and neointimal hyperplasia after rat carotid balloon injury (45). Alternatively, Chang et al. showed that localized arterial infection with a replication-defective adenovirus encoding a nonphosphorylatable, constitutively active form of Rb at the time of balloon angioplasty significantly reduced smooth muscle cell proliferation and neointima formation in both the rat carotid and porcine femoral artery models of restenosis (46). Similar results were also obtained by adenovirus-mediated overexpression of a ''natural'' inhibitor of cell cycle progression, the cyclin-dependent kinase inhibitor, p21, that likely prevents hyperphosphorylation of Rb in vivo (47). In addition to the blockade of cell-cycle, gene expression, interruption of mitogenic signal transduction has been achieved in experimental models as well. For example, *Ras* proteins are key transducers of mitogenic signals from membrane to nucleus in many cell types. The local delivery of DNA vectors expressing *Ras* dominant negative mutants, which interfere with *Ras* function, reduced neointimal lesion formation in a rat carotid artery balloon injury model (48).

Nitric oxide mediates a number of biological processes that are thought to mitigate neointima formation in the vessel wall, such as inhibition of VSMC proliferation, reduction of platelet adherence, vasorelaxation, promotion of endothelial cell survival, and possible reduction of oxidative stress. In vivo transfer of plasmid DNA coding for endothelial cell nitric oxide synthase (ecNOS) has been investigated as a potential paracrine strategy to block neointimal disease. EcNOS cDNA driven by a β-actin promoter and CMV enhancer was transfected into the VSMCs of rat carotid arteries after balloon injury. This model is known to have no significant regrowth of endothelial cells within 2–3 weeks after injury and therefore capable of loss of endogenous ecNOS expression. Results revealed expression of the transgene in the vessel wall, along with improved vasomotor reactivity and a 70% inhibition of neointima formation (Fig. 2) (49).

An example of a direct cytotoxic approach to the prevention of neointima formation is the transfer of a suicide gene such as the herpes simplex virus-TK (HSV-TK) gene into VSMCs. Using an adenoviral vector, HSV-TK was introduced into the VSMCs of porcine arteries rendering the smooth muscle cells sensitive to the nucleoside analog ganciclovir given immediately after balloon injury. After 1 course of ganciclovir treatment neointimal hyperplasia decreased by about 50% (7). More recently, Pollman and associates (50) induced endogenous machinery for VSMC ''suicide'' in a strategy designed to inhibit the growth or achieve regression of neointimal lesions. This strategy involved antisense ODN blockade of a ''survival'' gene known as Bcl-x, which helps protect cells from activation of programmed cell death, or apoptosis.

Another potentially relevant biological target for treatment of restenosis is reendothelialization, which might be accelerated by local delivery of a proangiogenic factor [e.g., vascular endothelial cell growth factor (VEGF)] at the angioplasty site. This is the basis for the only current U.S. clinical trial of gene therapy for the prevention of restenosis in the peripheral circulation, in which the human VEGF gene is administered as a ''naked'' circular DNA plasmid directly to the injured arterial wall on the surface of the angioplasty balloon (51). The investigators hypothesize that the low efficiency of this delivery method is balanced by the high biological potency of this secreted, angiogenic cytokine, enabling a significant local biological effect despite poor gene transfer.

Successful and efficient gene transfer to the injured, atherosclerotic, arterial wall presents unique mechanical and kinetic challenges. For strategies designed to attenuate or prevent VSMC proliferation, the target cell mass lies within the media of the vessel wall. Following balloon angioplasty, mechanical disruption and dissection of plaque may facilitate particle delivery to deeper layers of the vessel wall; however, uniform gene delivery to the bulk of target VSMCs has been difficult to achieve despite the development of a number of specialized local delivery catheters. Experimental models of neointima formation in animals may not be clinically relevant given their high, uniform, cellular content and absence of the more pre-

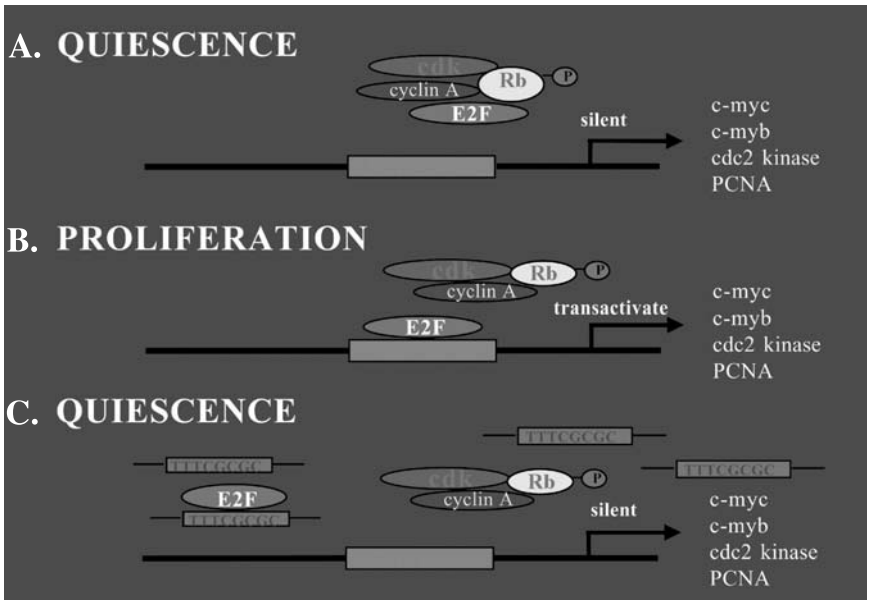

Figure 1 Principle of E2F ''decoy'' strategy. TTTCGCGC, consensus sequence for the E2F binding site. (A) In quiescent cell state, the transcription factor E2F is complexed Rb (retinoblastoma gene product), cyclin A, and cyclin-dependent kinase cdK2. (B) Phosphorylation of releases free E2F, which binds to cis elements of the cell-cycle regulatory genes, resulting in the transactivation of these genes. (C) The E2F decoy cis-element double-stranded oligonucleotide binds to free E2F, preventing E2F-mediated transactivation of cell-cycle regulatory genes. See the color insert for a color version of this figure.

dominant noncellular components of complex atherosclerotic plaque in humans.

An ex vivo gene transfer approach, involving implantation of genetically modified endothelial cells or VSMCs at sites of arterial injury, is also being investigated. Conte et al. successfully demonstrated efficient repopulation of denuded rabbit arteries with genetically modified autologous endothelial cells (52). The need to harvest autologous donor tissue for target cells, coupled with the increased costs and complexity of tissue culture, have greatly dampened the enthusiasm for this strategy in favor of more direct methods. Nonetheless, it remains clinically feasible and, in the case of endothelial cells, the implanted cells alone may confer beneficial properties to the healing arterial wall. Application of these cell transplantation approaches would be greatly facilitated by the development of ''universal donor'' cell lines in which major histocompatibility antigens have been ''knocked out.'' Such a development, while clearly years or decades away, may no longer be merely science fiction fantasy.

In summary, it would appear that the application of gene therapy for post angioplasty restenosis may be somewhat premature (53). In addition to major obstacles in delivering gene transfer agents to the atherosclerotic vessel wall, the fundamental biological process remains incompletely understood. Nonetheless, continued progress on each of these fronts warrants an optimistic view for genetic approaches to control the arterial injury response. These developments will undoubtedly yield important corollaries for the surgical treatment of arterial occlusive diseases as well.

B. Gene Therapy vs. Molecular Therapy for Angiogenesis

The vascularization observed in neoplastic tissue led researchers such as Judah Folkman in the 1970s to investigate the role of molecular factors in the induction of new blood vessel growth (54). The subsequent identification and characterization of ''angiogenic'' growth factors created an opportunity not only to target the growth of solid tumors, but also to attempt the therapeutic ''neovascularization'' of tissue rendered ischemic by occlusive disease in the native arterial bed. Angiogenesis has come to refer more strictly to the sprouting of new capillary networks from preexisting vascular structures, whereas vasculogenesis is the de novo development of both simple and complex vessels during embryonic development. Although it has been clearly established in a number of animal models that angiogenic factors can, in fact, stimulate the growth of capillary networks in vivo, it is less certain that these molecules can induce the development of larger, more complex vessels in adult tissues that would be capable of carrying significantly increased bulk blood flow. Nevertheless, the possibility of an improvement even of just the microvascular collateralization as a ''biological'' approach to the treatment of tissue ischemia has sparked the beginning of human clinical trials in neovascularization therapy.

After the first description of the angiogenic effect of fibroblast growth factors (FGFs), an abundance of ''proangiogenic'' factors were discovered to stimulate either endothelial cell proliferation, enhanced endothelial cell migration, or both. Many of these factors possess heparin-binding domains, which not only increase their retention in heparin-rich extracellular matrix, but also play critical roles in mediating the interaction of the factors with cell surface receptors. Although the list of angiogenic factors includes such diverse molecules as insulin-like growth factor, hepatocyte growth factor, angiopoeitin and platelet-derived endothelial growth factor, the molecules that have received the most attention as potential therapeutic agents for neovascularization are vascular endothelial growth factor (VEGF) and two members of the FGF family, acidic FGF (FGF-1) and basic FGF (FGF-2).

Whereas all angiogenic factors share some ability to stimulate capillary growth in classical models such as the chick allantoic membrane, much debate persists regarding the optimum agent and the optimum route of delivery for angiogenic therapy in the ischemic human myocardium or lower extremity. VEGF may be the most selective agent for stimulating endothelial cell proliferation, although VEGF receptors are also expressed on a number of inflammatory cells, including members of the monocyte-macrophage lineage (55). This selectivity has been viewed as an advantage, since the unwanted stimulation of fibroblasts and VSMCs in native arteries might exacerbate the growth of neointimal or atherosclerotic lesions. Despite this theoretical selectivity, however, the experimental use of VEGF in animal models has been associated not only with capillary growth, but also the development of more complex vessels involving these other cell types (56). The FGFs are believed to be even more potent stimulators of endothelial cell proliferation, but, as their name implies, are much less selective in their proproliferative action (57).

Optimizing the route of drug delivery depends heavily on the pharmacokinetic properties of the agent. Angiogenesis, however, is a very complex biological process involving multiple cell types engaged in multiple activities, including extracellular tissue dissolution and remodeling, cell proliferation, cell migration, cell recruitment, and programmed cell death. The role of any single agent must be understood within the complicated orchestration of multiple signaling agents and effectors. Despite the large amount of data that has become available in the past two decades, details of the cellular and molecular mechanisms of angiogenesis remain poorly understood. Still, it is believed that many of the known angiogenic factors, including VEGF and the FGFs, are exquisitely potent and would not, therefore, require large or prolonged dosing regimens. These conclusions are partly based on the results of in vivo experiments in which a broad range of dosing strategies, ranging from implantation of sustained release formulations to single intra-arterial boluses, have been reported to induce similarly successful increases in tissue perfusion (55).

The contribution of gene therapy to the potential development of therapeutic neovascularization is primarily one of drug delivery. The availability of the genetic sequences encoding these paracrine peptide agents provides an opportunity for the establishment of local tissue factories for drug production. Both intravascular as well as extravascular modes of gene product delivery are feasible, as gene transfer can be attempted either in the walls of vessels feeding the ischemic tissue or in the target myocardial or skeletal tissue itself. In fact, muscle tissue of both myocardial and skeletal origin are among the most receptive for gene transfer with the simplest of agents, pure plasmid DNA (58). Adenoviral vectors are also effective at achieving transgene expression in these muscle cells. A number of reports have suggested that plasmid injections can result in long-term gene expression in these muscle tissues, whereas the higher levels of expression associated with adenoviral vectors is likely limited to 1 or 2 weeks (18,59).

Preclinical studies of angiogenic gene therapy have utilized a number of models of chronic ischemia. An increase in capillary density was reported in an ischemic rabbit hind limb model after VEGF administration, and these results did not differ significantly regardless of whether VEGF was delivered as a single intra-arterial bolus of protein, plasmid DNA applied to surface of an upstream arterial wall, or direct injection of the plasmid into the ischemic limb (55). Direct injection of an adenoviral vector encoding VEGF also succeeded in improving regional myocardial perfusion and ventricular fractional wall thickening at stress in a model of chronic myocardial ischemia induced via placement of a slowly occluding Ameroid constrictor around the the circumflex coronary artery in pigs (60).

Unlike VEGF, FGF-1 and -2 do not possess signal sequences that facilitate secretion of the protein, so that transfer of these genetic sequences is less likely to yield an adequate supply of growth factor to target endothelial cells. To overcome this limitation, Tabata and associates constructed a

plasmid encoding a modified FGF-1 molecule onto which a hydrophobic leader sequence had been added to enhance secretion (61). Delivery of this plasmid to the femoral artery wall, even at very low transfection efficiencies, was found to improve capillary density and reduce vascular resistance in the ischemic rabbit hind limb. Applying a similar strategy, Giordano et al. employed intracoronary infusion of 10^{11} viral particles of an adenoviral vector encoding human FGF-5, which does contain a secretory signal sequence at its amino terminus, to achieve enhanced wall thickening with stress and a higher number of capillary structures per myocardial muscle fiber 2 weeks after gene transfer (62).

Another novel approach to molecular neovascularization has been the combination of growth factor gene transfer with a potentially synergistic method of angiogenic stimulation: transmyocardial laser therapy. The formation of transmural laser channels, though not yet fully established as an effective means of generating increased collateral flow, has had documented, clinical success in reducing angina scores and improving myocardial perfusion in otherwise untreatable patients. In a porcine Ameroid model, Sayeed-Shah et al. found that direct injection of plasmid DNA encoding VEGF in the region surrounding laser channel formation yielded better normalization of myocardial function than either therapy alone (63), and this therapeutic strategy can now be delivered either through minimally invasive thoracotomy or a percutaneous catheter-based approach (Fig. 3).

A number of Phase I safety studies have already been reported in which angiogenic factors or the genes encoding these factors have been administered to patients in small numbers (64,65). These studies have involved either the use of angiogenic factors in patients with peripheral vascular or coronary artery disease who were not candidates for conventional revascularization therapies, or the application of proangiogenic factors as an adjunct to conventional revascularization. The modest doses of either protein factors or genetic material delivered in these studies were not associated with any acute toxicities. Concerns remain, however, regarding the safety of potential systemic exposure to molecules known to enhance the growth of possible occult neoplasms, or that can enhance diabetic retinopathy and potentially even occlusive arterial disease itself. Despite early enthusiasm, there is also little experience with the administration of live viral vectors in extremely large numbers to a large number of patients, and it is uncertain whether potential biological hazards of reversion to replication-competent states or mutation and recombination will eventually become manifest.

In addition to issues of safety, it is also unclear whether the clinical success of conventional revascularization, which has involved the resumption of lost bulk blood flow through larger conduits, will be reproduced via biological strategies that primarily involve increased microscopic collateral networks. It must also be remembered that neovascularization is itself a naturally occurring process, and that the addition of a single factor may not overcome conditions that have resulted in an inadequate endogenous neovascularization response in patients suffering from myocardial and lower limb ischemia. Despite these limitations, angiogenic gene therapy may provide an alternative not currently available to a significant number of patients suffering from untreatable disease, and may offer an adjunct to traditional therapies that improves their long-term outcomes.

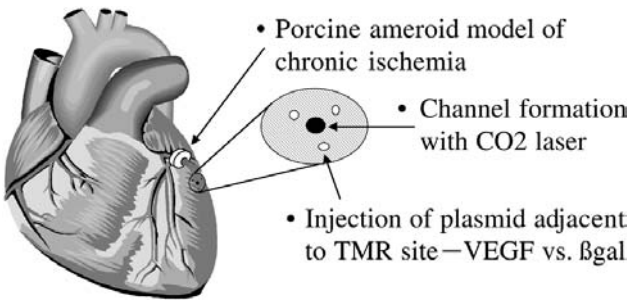

Figure 3 Combined gene transfer and transmyocardial laser revascularization (TMR). Schematic representation of chronic ischemia induced by placement of Ameroid constrictor around the circumflex coronary artery in pigs. Ischemic hearts that underwent TMR, followed by injection of plasmid encoding VEGF, demonstrated better normalization of myocardial function than either therapy alone. See the color insert for a color version of this figure.

IV. GENE THERAPY FOR VASCULAR GRAFTS

A. Vein Graft Engineering with E2F Decoy ODN

The long-term success of surgical revascularization in the lower extremity and coronary circulations has been limited by significant rates of autologous vein graft failure. No pharmacological approach has been successful at preventing long-term graft diseases such as neointimal hyperplasia or graft atherosclerosis. Gene therapy offers a new avenue for the modification of vein graft biology that might lead to a reduction in clinical morbidity from graft failures. Intra-operative transfection of the vein graft also offers an opportunity to combine intact tissue DNA transfer techniques with the increased safety of ex vivo transfection, and a number of studies have documented the feasibility of ex vivo gene transfer into vein grafts using viral vectors.

The vast majority of vein graft failures have been linked to the neointimal disease is part of graft remodeling after surgery (66). Although neointimal hyperplasia contributes to the reduction of wall stress in vein grafts after bypass, this process can also lead to luminal narrowing of the graft conduit during the first years after operation (67). Furthermore, the abnormal neointimal layer, with its production of proinflammatory proteins, is believed to form the basis for an accelerated form of atherosclerosis that causes late graft failure (68).

Similar to observations made in the arterial balloon injury model, it was found that a combination of antisense ODN that inhibit expression of at least two cell cycle regulatory genes could significantly block neointimal hyperplasia in vein grafts (69). Additionally, E2F decoy ODN yielded similar efficacy in the vein graft when compared to the arterial injury model (70). In contrast to arterial balloon injury, however, vein grafts are not only subjected to a single injury at the time of operation, but are also exposed to chronic hemodynamic stimuli for remodeling. Despite these chronic stimuli, a single, intraoperative ODN treatment of vein grafts resulted in a resistance to neointimal hyperplasia that lasted for at least 6 months in the rabbit model (69). During that time period, the grafts treated with antisense ODN were able to adapt to arterial conditions via hypertrophy of the medial layer. Furthermore, these genetically engineered conduits proved resistant to diet-induced graft atherosclerosis (Fig. 4) and were associated with preserved endothelial function (71).

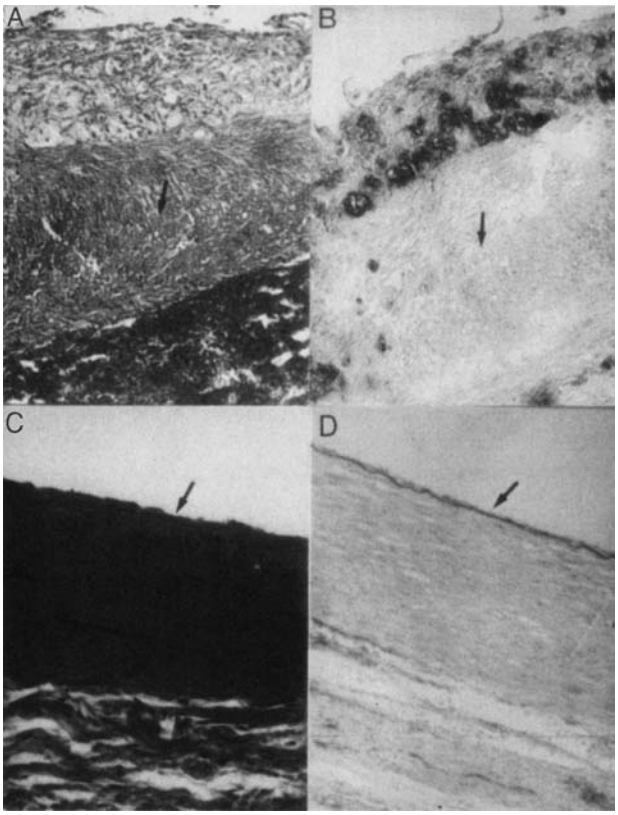

Figure 4 Control oligonucleotide-treated (A and B) and antisense oligonucleotide (against cdc2 kinase/PCNA)-treated vein grafts (C and D) in hypercholesterolemic rabbits, 6 weeks after surgery ($\times$ 70). Sections were stained with hematoxylin/van Gieson (A and C) and a monoclonal antibody against rabbit macrophages (B and D). Arrows indicate the location of the internal elastic lamina.

A large-scale, prospective, randomized, double-blind trial of human vein graft treatment with E2F decoy ODN has been initiated (18). Efficient delivery of the ODN is accomplished within 15 min during the operation by placement of the graft after harvest in a device that exposes the vessel to ODN in physiological solution and creates a nondistending, pressurized environment of 300 mm Hg. Preclinical findings indicated ODN delivery to greater than 80% of graft cells, and effective blockade of target gene expression. This study will measure the effect of cell-cycle gene blockade on primary graft failure rates, and represents 1 of the first attempts to definitively determine the feasibility of clinical genetic manipulation in the treatment of a common cardiovascular disorder.

B. Vein Graft Gene Transfer

With the development of viral-mediated gene delivery methods, some investigators have begun to explore the possibility of using these systems ex vivo in autologous vein grafts. Chen et al. (72) demonstrated the expression of the marker gene b-galactosidase along the luminal surface and in the adventitia of 3-day porcine vein grafts infected with a replication-deficient adenoviral vector at the time of surgery. The vein segments were incubated in a high viral titer suspension for approximately 2 h prior to implantation. Although these researchers documented expression of a soluble vascular cell adhesion molecule-1 (sVCAM-1) isomer on the luminal and abluminal surfaces of 3-day grafts infected with an adenoviral vector encoding this protein, no long-term expression or functional effect of this gene was reported. In a study previously alluded to, Kupfer et al. (73) explored the use of a novel adenovirus-based transduction system, in which adenoviral particles were linked to plasmid DNA via biotin/streptavidin-transferrin/polylysine complexes. β-galactosidase expression was documented 3 and 7 days after surgery in rabbit vein grafts that had been incubated for 1 h with complexes prior to grafting. Expression was again greatest on the luminal surfaces of the grafts, although then presence of transfected cells in the medial and adventitial layers was also reported.

The feasibility of gene transfer in vein grafts has subsequently led to the investigation of potential therapeutic endpoints such as neointima formation. George et al. (74), using a replication-deficient adenovirus expressing tissue inhibitor of mettaloproteinasee-2 (TIMP-2), was able to demonstrate a dramatic decrease in neointimal formation in a saphenous vein organ culture model. In vivo gene transfer has also been shown to effectively reduce neointima formation in experimental vein grafts. Bai et al. (75) performed intra-operative transfection of the senescent cell-derived inhibitor (sdi-1) gene, a downstream mediator of the tumor suppresser gene p53, using the HVJ-liposome system, and was once again able to demonstrate a significant reduction in neointima formation. The use of gene transfer in vein grafts may reach beyond the treatment of the graft itself. The expression of therapeutic proteins by transduced grafts can lead to the treatment of diseases in tissues downstream to the location of graft implantation, further expanding the versatility of this bypass conduit.

C. Bioprosthetic Grafts

Prosthetic materials, such as PTFE or Dacron, often used as small-caliber arterial substitutes or in the construction of arteriovenous grafts, have been limited in their long-term use due to their thrombogenic surfaces. A bioengineering, cell-based strategy for decreasing or eliminating this thrombogenicity may therefore yield a prosthetic graft capable of maintaining normal flow. Successful isolation of autologous endothelial cells and their seeding onto prosthetic grafts in animal models has been well characterized (76). Furthermore, it has been hypothesized that one can enhance the function of these endothelial cells via the transfer of genes prior to seeding of the cells on the graft surface. Such a bioprosthesis could be useful for delivering genetically engineered factors that would enhance graft function and survival or even provide an avenue for intravascular drug delivery. First indication for the possible use of this strategy was presented by Wilson at al. (10), who demonstrated successful endothelialization of a prosthetic vascular graft with autologous endothelial cells transduced with a recombinant retrovirus encoding the *lacZ* gene. Additionally, seeding of transduced vascular smooth muscle cells into the interstices of a PTFE graft then luminally seeded with untreated endothelial cells revealed stable expression of the reporter gene after 3–5 weeks (77).

Successful clinical applications of these concepts, however, have not been reported. In an attempt to decrease graft thrombogenicity, Dunn et al. (78) seeded 4-mm Dacron grafts with retrovirally transduced endothelial cells encoding the gene for human tissue plasminogen activator (TPA) and implanted them into the femoral and carotid circulation of sheep. The proteolytic action of TPA resulted in a decrease in seeded endothelial cell adherence, with no improvement in surface thrombogenicity. The use of VEGF in this context also has potentially significant clinical applications. VEGF, a potent endothelial cell mitogen, when transduced into a limited number of endothelial cells and placed on the graft surface, may promote endothelial survival and replication, and yield improved and more rapid graft coverage with a nonthrombogenic endothelial layer. Additionally, secretion of VEGF could lead to angiogenesis distal to the grafted area in what is likely to be an ischemic tissue bed. Yamamoto et al. (79) has demonstrated successful seeding of PTFE grafts with VEGF-transduced, adipose-derived, endothelial cells and expression of the transgene after several weeks. Further studies are needed to determine the local effect of VEGF secretion on endothelial cell proliferation along with distant angiogenic stimuli.

V. GENE THERAPY FOR THE HEART

Failure of the myocardium due to insults such as ischemia, infection, metabolic disorders, or substance abuse afflicts millions of Americans annually. Traditional pharmacotherapy and surgical intervention has succeeded in ameliorating these problems, but the advent of gene transfer technology has brought a heightened interest in either correcting, preventing, or limiting the functional deficits sustained by the myocardium. The myocardium has been shown to be receptive to the introduction of foreign genes. As seen in noncardiac muscle (80), measurable levels of gene activity have been found after direct injection of plasmids into myocardial tissue in vivo (81). Although limited to a few millimeters surrounding the injection site, these observations have laid the basis for consideration of gene transfer as a therapeutic approach to cardiac disease. The distribution of myocardial expression of genes after direct injection in rats has been enhanced via incorporation of the gene into an adenoviral vector (59). Additionally, both adenoviral and adeno-associated viral vectors can be delivered to the myocardial and coronary vascular cells via intracoronary infusion of highly concentrated preparations in rabbits and porcine models, respectively (82,83). Gene transfer into the myocardium has also been achieved via either the direct injection or intracoronary infusion of myoblast cells that have been genetically engineered in cell culture (84).

A. Gene Therapy to Enhance Contractility

The β-adrenergic receptor (β-AR) is known to be a critical player in mediating the ionotropic state of the heart and has received significant attention as a target for genetic therapeutic intervention in congestive heart failure. Milano et al. (85), using transgenic mice expressing the β_2-AR under the control of the cardiac α-MHC promoter, demonstrated an approximately 200-fold increase in the level of β_2-AR along with highly enhanced contractility and increased heart rates in the absence of exogenous β-agonists. This genetic manipulation of the myocardium has generated considerable interest toward the use of gene transfer of the β-AR gene into the ailing myocardium as a means of therapeutic intervention. To date, attempts at exploring this exciting possibility have been primarily limited to cell culture systems. Akhter et al. (86) successfully demonstrated improved contractility in rabbit ventricular myocytes that have been chronically paced to produce hemodynamic failure after adenoviral-mediated gene transfer of the human β_2-AR. An enhanced chronotropic effect resulting from the injection of a β_2-AR plasmid construct into the right atrium of mice has been demonstrated by Edelberg et al. (87), but no evaluation of enhanced contractility by transfer of this gene into the ventricle has been reported. These results demonstrate the feasibility of using the β-adrenergic pathway and its regulators as a means by which to treat the endpoint effect of the variety of cardiac insults that exist.

There has also been recent interest in the enhancement of contractility through the manipulation of intracellular calcium levels. Sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA2a) transporting enzyme, which regulates Ca^{2+} sequestration into the sarcoplasmic reticulum (SR), has been shown to be decreased in a variety of human and experimental cardiomyopathies. Using adenoviral-mediated gene transfer, Hajjar et al. (88) was able to overexpress the SERCA2a protein in neonatal rat cardiomyocytes. This led to an increase in the peak $[Ca^{2+}]_i$ release, a decrease in resting $[Ca^{2+}]_i$ levels, and more importantly to enhanced contraction of the myocardial cells as detected by shortening measurements. The success of this ap-

proach to improving myocardial contractility has yet to be documented in vivo, but once again, provides a novel and potentially exciting means by which to treat the failed heart.

B. Gene Therapy for Myocardial Infarction

Coronary artery atherosclerosis and resulting myocardial ischemia is a leading cause of death in developed countries. Reperfusion injury has been linked to significant cellular damage and progression of the ischemic insult. In addition to stimulating therapeutic neovascularization, genetic manipulation may be used as a means to limit the degree of injury sustained by the myocardium after ischemia and reperfusion.

The process of tissue damage resulting from ischemia and reperfusion has been well characterized. Briefly, the period of ischemia leads to an accumulation of adenosine monophosphate, which then leads to increased levels of hypoxanthine within and around cells in the affected area. Additionally, increased conversion of xanthine dehydrogenase into xanthine oxidase takes place, which upon exposure to oxygen during the period of reperfusion, converts hypoxanthine to xanthine, leaving behind the cytotoxic oxygen radical, superoxide anion (O_2^-). O_2^- can then go on to form hydrogen peroxide (H_2O_2), another oxygen radical species. Ferrous iron (Fe^{2+}), which accumulates during ischemia, reacts with H_2O_2, which leads to the formation of the most potent oxygen radical, hydroxyl anion (OH^-) (89). These oxygen radicals result in cellular injury via lipid peroxidation of the plasma membrane, oxidation of sulfhydryl groups of intracellular and membrane proteins, nucleic acid injury, and breakdown of components of the extracellular matrix such as collagen and hyaluronic acid (90). Natural oxygen radical scavengers, such as superoxide dismutase (SOD), catalase, glutathione peroxidase, and hemoxygenase (HO), function through various mechanisms to remove oxygen radicals produced in normal and injured tissues.

The degree of oxygen radical formation produced after ischemia-reperfusion in the heart can overwhelm the natural scavenger systems. Overexpression of either extracellular SOD (ecSOD) or manganese SOD (MnSOD) in transgenic mice has revealed improved postischemic cardiac function and decreased cardiomyocyte mitochondrial injury in adriamycin-treated mice, respectively (91,92). These findings suggest a role for gene transfer of these natural scavengers as a means by which to protect the myocardium in the event of an ischemia-reperfusion event. Li et al. (93) demonstrated substantial protection against myocardial stunning using intra-arterial injection of an adenovirus containing the gene for Cu/ZnSOD (the cytoplasmic isoform) into rabbits, although no studies have investigated the direct antioxidant effect and ensuing improvement in myocardial function of this treatment after ischemia and reperfusion. This application of gene therapy technology may offer a novel and exciting approach for prophylaxis against myocardial ischemic injury if incorporated into a system of long-term, regulatable transgene expression. In addition to the overexpression of antioxidant genes, some researchers have proposed intervening in the program of gene expression within the myocardium that leads to the downstream deleterious effects of ischemia reperfusion. For example, the transfection of rat myocardium with decoy oligonucleotides that block activity of the oxidation-sensitive transcription factor NFκ-B, linked to expression of a number of proinflammatory genes, succeeded in reducing infarct size after coronary artery ligation (94).

At the cellular level, myocardial infarction results in the formation of a scar that is composed of cardiac fibroblasts. Given the terminal differentiation of cardiomyocytes, loss of cell mass due to infarction does not result in the regeneration of myocytes to repopulate the wound. Researchers have therefore pursued the possibility of genetically converting cardiac fibroblasts into functional cardiomyocytes. The feasibility of this notion gained support from the work of Tam et al. (95), who demonstrated the in vitro conversion of cardiac fibroblasts into cells resembling skeletal myocytes via the forced expression of a skeletal muscle lineage-determining gene, MyoD, using retroviral-mediated gene transfer. Fibroblasts expressing the MyoD gene were observed to develop multinucleated myotubes similar to those seen in striated muscle, which expressed MHC and myocyte-specific enhancer factor-2. Additionally, Murry et al. (96) also showed expression of myogenin and embryonic skeletal MHC after transfection of rat hearts injured by freeze-thaw with an adenovirus containing the *MyoD* gene. At this time, however, functional cardiomyocytes have not yet been identified in regions of myocardial scarring treated with in vivo gene transfer.

C. Gene Therapy for Immunomodulation

Genetic manipulation of donor tissues offers the opportunity to design organ-specific immunosuppression during cardiac transplantation. Although transgenic animals are being explored as potential sources for immunologically protected xenografts (97), the delivery of genes for immunosuppressive proteins, or the blockade of certain genes in human donor grafts, may allow site-specific, localized immunosuppression and a reduction or elimination of the need for toxic systemic immunosuppressive regimens. Gene activity has been documented in transplanted mouse hearts for at least 2 weeks after intra-operative injection of the tissue with either plasmid DNA, or retroviral or adenoviral vectors (98). The transfer of a gene for either TGF-b or interleukin 10 in a small area of the heart via direct injection in this model succeeded in inhibiting cell-mediated immunity and delaying acute rejection (99,100). In another study, the systemic administration of antisense ODN directed against intercellular adhesion molecule-1 (ICAM-1) also prolonged graft survival and induced long-term graft tolerance when combined with a monoclonal antibody against the ligand for ICAM-1, leukocyte function antigen (101,102).

VI. SUMMARY

Gene therapy has begun a gradual ascent from the realm of pure theory, and has entered a period of intense research into

practical clinical applications. Although the first documentation of clinical success remains eagerly sought, gene manipulation strategies appear now to provide a meaningful addition to the tools available in the design of novel approaches to cardiovascular disease. Further refinement of both current gene therapy methodologies as well as the cardiovascular biologist's understanding of the molecular basis of complex disease processes will enhance the likelihood of such success, and may prove essential to its realization. Nevertheless, ''proof of principle'' has been clearly established; a thoughtful and thorough scientific approach has therefore become warranted as these exciting new possibilities continue to expand.

Gene Therapy for Cancer

Karsten Brand
CUSTOS Biotechnologie GmbH
Berlin, Germany

I. INTRODUCTION

Gene therapy for cancer has generated great interest for more than a decade and intensive experimental and clinical investigations are underway. In general, it comprises different technologies to deliver a cDNA of choice to cancer cells or to normal tissue for a variety of diagnostic and therapeutic applications. Based on the complex nature of cancer, these technologies are very heterogeneous, as demonstrated by a variety of concepts such as immunomodulation, and the ''suicide strategy'' (i.e., transfer of the cDNA of a prodrug-converting enzyme); gene replacement strategies such as transfer of a tumor suppressor and/or an antioncogene; viral oncolysis; antiangiogenic and antiproteolytic gene therapy; or the delivery of drug-resistant genes into hematopoietic precursor cells. Many experimental approaches are now in clinical evaluation and more than 630 trials have been published or initiated or are pending. More than 60% of these trials are directed against cancer. In the first part of this contribution, I have tried to summarize the current state of the art of the gene therapeutic vectors now available and to review gene therapy principles strictly from the point of view of cancer therapy. In the second part, I have described experimental and clinical approaches for several types of cancer. The peculiarities of the respective cancer types allow or require customized gene therapeutic approaches, particularly in a clinical setting.

This contribution cannot give a complete picture of all current gene therapy approaches and I apologize for any omissions. Cross-references to the most recent literature reviews and to the corresponding chapters in this book are given. Helpful tools for getting an overview of gene therapy trials are found under www.wiley.co.uk/genetherapy/DATABASE at the Genetic Medicine Clinical Trials Database and under www4.od.nih.gov/oba/, a website provided by the NIH, Office of Biotechnology.

II. THERAPEUTIC PRINCIPLES

A. Immunomodulation

It has long been recognized that tumors exhibit to a certain extent immunogenicity (1). As demonstrated by several studies, (for further details on these studies, see Tables 2 and 3 beginning on pg. 551) the human immune system seems to respond to this immunogenicity by recognizing specific tumor antigens and, consequently, by mounting humoral and cellular responses. However, during cancer development, this response is only of limited intensity and duration (2,3). As the mechanisms that cancer cells use to escape detection by the immune system have been elucidated, more and more strategies have been developed to reconstitute an effective antitumor immune response. The tremendous increase in the knowledge of the immunobiology of cancer has made immunological approaches, e.g., immunomodulation, the most dominant strategy in cancer gene therapy during recent years (4). In general, immuno-modulation studies can be categorized according to (a) the target cells (tumor cells, host cells, T-cells, or antigen-presenting cells such as dendritic cells or other cells); (b) the mode of gene delivery (which vector, in vitro, ex vivo, in vivo); or (c) the transferred transgenes (cytokines, costimulatory molecules, tumor-associated antigens). Four examples from the multiplicity of these approaches will be described in more detail.

One of the most attractive target cell types for genetic modification are T-lymphocytes. The application of cytokine-transduced, tumor-infiltrating T-lymphocytes (TILs) (5–8) was among the earliest clinical protocols for gene therapy. More recently, T-lymphocytes have been the target for ex vivo genetic modification by cytokine gene transfer and for redirection by tumor antigen-specific T-cell receptors or chimeric receptor genes (extracellular domain: antigen-binding,

intracellular domain: cell-signaling). They have also been isolated from genetically modified tumors or their draining lymph nodes (9–11). Other approaches enhance T-cell reactivity with antibodies that are targeted directly at the respective receptors on T-cells (12,13). These approaches are complemented by different methods to enhance antigen recognition on the surface of tumor cells.

Another immunological approach to generate a local inflammatory response is the use of short-range communications between immune and nonimmune cells. Cytokine-transfected tumor cells or fibroblasts are transferred, which are then supposed to directly activate specific as well as nonspecific immune cells. In this context, the continuous local release of cytokines has been shown to increase the therapeutic index. Additionally or alternatively, costimulatory molecules can be transferred. In tumor cells where MHC class I or class II molecules or costimulatory molecules such as HLA-B7 are downregulated, the transfer of the corresponding wild-type cDNA can reactivate antigen recognition on the surface of the transduced tumor cells.

During the last decade, more and more tumor-derived antigens have been defined. These became a very interesting target for gene transfer approaches (14). In addition to applications of the corresponding peptides, some of these antigens have been transferred by viral vectors or as naked DNA either directly to the tumors or via dendritic cells, evoking an immune response against the tumor. Detection of new tumor antigens with new powerful methods, such as SEREX (serological analysis of tumor antigens by recombinant expression cloning) (2,15), or methods for detection of differential gene expression such as microarray technologies, holds great promise for the future.

Finally, antibody-based immunotherapy should be mentioned in this context (16), particularly since recombinant antibodies have finally shown marked clinical benefit. The underlying concept of this strategy is to raise monoclonal antibodies against soluble tumor antigens or against antigens that are expressed on the surface of the malignant cells or on the tumor stroma. A cancer gene therapeutic use of antibody genes is probably only a matter of time.

B. Prodrug-Converting Enzymes (''Suicide Strategy'')

The ''suicide strategy'' in oncology combines classical cytotoxic chemotherapy with gene transfer technology. The underlying concept is to limit the action of a known cytotoxic drug to the local area of the tumor lesion. To this end, the cDNA of a prodrug-converting enzyme is delivered into the tumor by a vector system of choice. This is followed by regional or systemic application of the corresponding nontoxic prodrug. Once the prodrug reaches the tumor and is taken up by the tumor cells that express the prodrug-converting enzyme, it is converted into the cytotoxic drug. In conventional chemotherapy, toxic and myeloablative side effects can be dose-limiting. In contrast, when using the suicide gene concept, the cytotoxic effects of the converted drug are mainly restricted to the area of tumor infiltration, and the time of action is limited to the presence of the cancer cells expressing the prodrug-converting enzyme. In addition, the efficacy of the suicide strategy is enhanced by the ''bystander effect.'' This molecular mechanism allows the killing of even uninfected tumor cells in the neighborhood of infected cells due to intercellular communication mediated by gap junctions (for example). However, this mechanism is still not fully understood. There are many different prodrug-converting enzymes under experimental or clinical investigation, and the number of systems developed is increasing rapidly (17). For a more detailed overview of the application of the suicide strategy in cancer gene therapy, please see Chapter 20 by B. O'Malley Jr.

The prodrug-converting enzyme most often used for clinical purposes is the herpes simplex virus thymidine kinase gene (HSV tk). The enzyme thymidine kinase (tk) phosphorylates the prodrug ganciclovir (GCV) to GCV-monophosphate, which is then further phosphorylated to toxic GCV-triphosphate. Inhibition of the DNA polymerase by GCV-triphosphate finally leads to cell death. As demonstrated in various studies, tumor eradication has been achieved even if only 10% of the tumor mass is transduced (18). This effect is probably due to a very potent bystander effect. In preclinical animal experiments, a vector carrying the HSV tk gene is usually applied intratumorally. In several reports using immunocompromised animals, a reduction of tumor volume of more than 50% of the controls was achieved in various experimental settings and even complete remissions were frequently observed. In addition to these experimental studies on immunocompromised animals, reports on immunocompetent animals suggest that the immune system may play a supportive role in the efficacy of this approach (19). Promising results of tumor growth inhibition are not without side effects induced by the HSV tk system. Using an in vivo model of adenovirus-mediated gene transfer to the liver of mice and rats, liver toxicity was observed due to unwanted transduction of normal tissue. This can be eliminated either by targeted vectors or tissue-specific gene expression (20,21).

As in other gene therapy strategies, the capability of the suicide strategy to kill cancer cells in experimental and clinical studies is limited by overall low efficacy of gene transfer in vivo. This is probably the main reason for the overall limited clinical efficacy of the suicide strategy in several Phase I, II, and III clinical trials for several types of cancer. Even with the most efficient vector systems, direct intratumoral vector application only leads to a partial transduction of tumors with a nonhomogenous intratumoral vector distribution. Consequently, low antitumor efficacy is seen, particularly in humans, which present much larger tumor burdens than rodents in a typical laboratory situation. Vector distribution could, however, be improved by changing the anatomical route of vector application (intravesical, intraperitoneal, intrathecal, intraventricular, repeated, and bulk-flow); through the use of conditionally replication-competent vectors; by enhancing the bystander effect through the transfer of connections that

increase the number of gap junctions; and by receptor targeting (see Chapter 3 by D. Curiel).

C. Tumor Suppressor Genes and Anti-Oncogenes

During the last decade, an increasing number of genes has been identified which become dysregulated during carcinogenesis. During a complex and multifactorial process leading ultimately to the macroscopic presence of cancer, genes become dysregulated by different molecular mechanisms including gene deletion, mutation, or promotor silencing. At the end of these processes of genetic alteration, which result in activation or inactivation of multiple genes, the cancer cell proliferates in an uncontrolled fashion. It is not able to go into apoptosis and achieves invasive potential. Genes promoting these processes, like oncogenes, become activated. Genes suppressing the processes, like tumor-suppressor genes, become inactivated.

Current approaches in this area include the inactivation of overexpressed oncogenes by antisense molecules or dominant negative mutants or, alternatively, the reconstitution of cells with tumor-suppressor genes that have been lost or have mutated. The rationale is not so much the reversion of tumor cells back into normal cells. This task would be difficult to accomplish because more than one mutation is usually acquired by the tumor cell during the transformation process. The aim is rather to define the weak point in the cell's regulatory balance and consequently to identify the gene or combination of genes that would have the highest impact on the exertion of cell-cycle arrest or better apoptosis. To this end, it is of crucial importance to acquire a sufficient understanding of the cell's balance with respect to signal transduction, cell cycle regulation, and finally, susceptibility to apoptosis. The targeting of the genes known to be dysfunctional in the respective tumor is usually the most efficient procedure. In some cases, a combination of several genes could increase specificity and efficacy. The main obstacle to this therapeutic approach is the need for a particularly high gene-transfer efficacy. Although a mild bystander effect has been reported in the context of p53 gene transfer (22), a high transfer efficacy is usually necessary for eradication of tumors—at least in those cases where the immune system as an adjuvant is not dramatically activated. Such high transfer efficacies are the exception with current vectors. Therefore, a breakthrough for this highly tumor-specific approach particularly depends on future vector development. Among several tumor suppressor genes that have shown in vivo efficacy, p53 has made it into the clinic and is discussed in more detail (e.g., in the chapter dealing with lung cancer). Besides proapoptotic bax (23) and bcl-x_s (24), caspases (25), PTEN, and BRCA1, those genes involved in the regulation of the G1-phase of the cell cycle, have been evaluated particularly closely in animal experiments. Tumor growth could be inhibited by transfer of wild-type and truncated pRb (26,27), which in its active form binds E2F-1 and prevents entry into S-phase, as well as by the cdk/cyclin inhibitors p16 (28,29) and p21 (30), which mainly keep pRb in its hypophosphorylated, active state. It remains to be shown whether cell-cycle arrest is sufficient for therapy of established tumors or whether a strong induction of apoptosis as sometimes seen by transfer of p16 and p27 (29) is required. Undoubtedly, restoration of tumor cells with p53 or p21 can increase the cells' sensitivity to radiation (31–33) and chemotherapy (34–37). Also, combinations of tumor suppressor genes could prove to have overadditive tumoricidal effects as has been shown for the combination of p53 and p16 (28).

Gene therapy directed against oncogenes or apoptosis suppressors like bcl-2 or bcl-x_l has targeted several types of cancer, and several clinical trials are underway. These are discussed in more detail in Part 4 of this contribution and in Chapter 42 by J.A. Roth. The antioncogene approach is in principle supported by the recent success of small molecular inhibitors of oncogenes: inhibitors of the EGF receptor, the RAS pathway, and the ABL gene (Gleevec). Gene therapy has the potential to compete with small molecules because small molecules still efficiently target only enzymes and receptors, whereas transdominant antioncogenes, antisense oligonucleotides, and (recently) the very promising RNA-interfering nucleotides (38,39) can inhibit virtually any oncogene of relevance.

D. Tumor Lysis by Recombinant Viruses

Since its early beginnings, cancer therapy by viral oncolysis has been one of the most challenging strategies to treat human malignancies (40). The idea that viruses may be used as selective anticancer agents dates back almost a century (41). In 1957, 4 years after their discovery, replicating adenoviruses were used in cancer therapy. Of patients with advanced cervical carcinoma receiving intratumoral or intra-arterial injections of wild-type human adenoviruses, 65% had a marked to moderate local tumor response and only 3 out of 30 patients on steroids had a viral syndrome of short duration (42). The underlying concept of this strategy is to inject the virus directly into the tumor, leading to the transduction of a certain number of cells in which viral replication takes place. Consequently, the infected cells are finally disrupted and viral progeny are released, allowing the spread of the infection and an increase in transfer efficacy. Interest and research in this area of molecular biology has exploded, and the available virus-production techniques and purification techniques have been markedly improved. Thus, much larger amounts of adenovirus can now be applied. However, one of the major concerns has been how to limit the viral replication to the site of the tumor. One strategy to confer tumor-specific replication has been developed that utilizes the dependence of the replicating adenovirus on the genetic status of p53 in the infected host cell. Like many DNA viruses, adenoviruses have also developed specific gene products that seem to counteract apoptosis-inducing molecules such as p53. Among the adenoviral genes, the E1B 55kD gene blocks p53, the best-known inducer of apoptosis and indirect inducer of cell cycle arrest. In an intriguing approach (43), the E1B gene was deleted from the adenoviral genome, allowing viral replication only in p53-negative tumor cells but

creating apoptosis upon viral infection in p53-positive normal cells (43,44). Since more than 50% of common solid tumors lack functional p53, this approach was thought to be widely applicable. In the meantime, both the lack of replication in all p53-positive cells and the potent replication in all p53-negative cells (45,46) have been questioned. It seems that defects further down the p53 pathway, as well as functions of E1B55K independent from inactivation of p53, need to be taken into account. They may perhaps moderately limit the applicability of the approach. Independent of the outcome of this debate, this concept has already stimulated virologists and cancer biologists to develop further generations of conditionally replication-competent adenoviruses. Adenoviral E1A inactivates pRB, the well-known tumor suppressor and inducer of cell cycle arrest, and facilitates adenoviral replication by allowing cellular replication. In an approach similar to the one described above, E1A was mutated so as to no longer bind and inactivate pRb; this should lead to viral replication only in tumor cells that typically have defects in the pRb pathway. This concept has been successfully applied in vitro and in vivo (47–49).

Another way to achieve cancer-specific replication is through the use of tissue-specific or tumor-specific gene expression. The adenoviral E1A region, which controls viral replication through several mechanisms, was placed under the control of a tissue- or cancer-specific promoter instead of the E1A promoter. This approach allowed specific replication in the respective cancer cells and tumors when prostate-specific antigen (PSA) or probasin promoters (50,51); TCF-responsive elements that are preferentially activated in colon cancer; or the MUC1 promoter (which is active in breast carcinoma) (52) were used to drive the E1A gene (53). Besides adenoviruses, other oncolytic viruses have been tested in animal models. Like adenoviruses, Herpes simplex virus (HSV), a neurotrophic DNA virus, directly lyses cells during viral shedding. First-generation HSV contains a 360-bp deletion in the thymidine kinase gene; this seems to prevent replication in quiescent cells but allows replication in rapidly proliferating cells (54,55). Second-generation viruses with additional mutations have been generated to increase tumor-specific replication and reduce neurovirulence (56). Newcastle Disease virus (NDV) is a chicken paramyxovirus associated with minimal disease in humans. Cytotoxicity for numerous human tumor cell lines and resistance of several human fibroblast lines have been reported (57). The mechanism that causes tumor selectivity is not fully resolved, but a failure to mount a protective interferon response may be causally involved. Tumor-cell killing may involve virus replication and direct cell lysis and/or induction of tumor necrosis factor (TNF) secretion as well as increased sensitivity of tumor cells to TNF-mediated killing (58,59). Recently, a clinical trial of intravenous injection of NDV into 67 patients with solid tumors was published. Objective responses occurred at higher doses (60).

Autonomous parvoviruses are DNA viruses with small genomes that depend on helper viruses or specific cellular functions for replication. Their cytopathic effect seems to be dependent on DNA replication as well as on the expression of nonstructural gene products and enhanced sensitivity to their effects (56).

In the future, the tremendous increase in knowledge in the field of tumor and virus biology can be used to create appropriate vectors. Several factors that potentially influence clinical efficacy have already been defined. Among these are (a) characteristics of the viruses, such as the size, the time between infection and lysis, as well as the number of virions produced or the induction of a humoral or cellular immune response; and (b) characteristics of the tumor such as distribution of the vasculature or physical barriers to virus spread such as fibrosis. An example of how to surmount such a natural barrier is the demonstration that inactivation of particular adenoviral serotypes by preformed antibodies can be circumvented if other serotypes are used (61).

E. Antiangiogenic and Antiproteolytic Gene Therapy

These types of gene therapy differ markedly from the majority of the other nonimmunological gene cancer therapeutic approaches because the products of the delivered genes act extracellularly. This fact obviates the need to transduce the majority of tumor cells and even allows one to target normal tissue, which may be easier to transduce than the tumor. In addition, these approaches are usually appropriate for long-term treatments. Therefore, the conventional demands of cancer gene therapy—high efficacy of gene transfer, acceptance of immunogenicity, and sufficiency of short duration of gene expression—are replaced by requirements more typical for the treatment of monogenetic disease. These include low immunogenicity of vector and transgene, long-duration gene expression, and achievement of at least threshold levels of gene product in the target tissue or in the blood.

Inhibition of angiogenesis has become a very promising target for cancer therapy. Advantages of targeting the growth of new blood vessels as opposed to other types of therapy include: the avoidance of tumor cell-resistance mechanisms, the broad and generally applicable mechanism, and easy access to targets within the vasculature. More than 20 endogenous inhibitors of angiogenesis and nearly as many stimulators that can serve as targets for small inhibitory molecules have been characterized (62). Interestingly, several standard chemotherapeutic drugs have been found to exert their antitumor effect in part through inhibition of angiogenesis.

There are over 75 antiangiogenic agents (proteins as well as small molecules) in clinical trials. In general, antitumor efficacy has been observed, although overall success rates have not lived up to expectations. One important reason is perhaps the choice of disease stage. Although antiangiogenic therapy will most likely be of highest efficacy at the early stages of tumor growth or metastasis, patients with excessive tumor burdens have been mostly treated so far.

Antiangiogenic gene therapy has not yet been tested in patients, but several preclinical experiments have shown promise (62). Among the first genes examined were the genes for the soluble form of endothelial cell receptor proteins, Tie2

and FLT-1. These proteins interact with the angiogenetic factors angiopoietin-1 and VEGF (vascular endothelial growth factor), respectively. These genes were transferred in vivo or ex vivo and resulted in significant inhibition of tumor growth (63–65). Other strategies include the transfer of antiangiogenic proteolytic fragments such as angiostatin or endostatin, of immunomodulatory genes with antiangiogenic properties such as interferons and IL-12, or of other molecules better known for other functions in the body such as tissue inhibitors of metalloproteinases (TIMPs), p53, or p16.

There are several advantages of molecular therapy over direct application of the effector substance. Firstly, the use of targeted vectors allows increased intratumoral concentrations of antiangiogenic factors without the risk of potential side effects on wound healing, endometrial maturation, or embryo growth (66). Secondly, the cost of gene delivery may be lower than prolonged protein therapy. Thirdly, experimental data suggest that effective antiangiogenic therapy requires the continuous presence of the inhibitor in the blood, which may perhaps be more efficiently achieved by gene therapy than by bolus protein therapy.

Antiangiogenic therapy itself is only in its infancy, and the future development of this treatment modality will obviously have a large impact on the corresponding gene therapy approach. Because of its mainly tumoristatic nature, it seems likely that this form of therapy will have its main impact before or after surgery, with a view to facilitating surgery and preventing recurrence of distant metastases, as well as in combination with conventional chemotherapy, radiotherapy, or immunotherapy.

Excessive degradation and remodeling of the extracellular matrix (ECM) is one of the hallmarks of cancer progression at nearly every step from the first breakdown of the basal membrane of a primary tumor up to the extended growth of established metastases. There are 4 known classes of proteases implicated in ECM turnover: matrix metalloproteinases (MMPs), serine proteinases, ADAMs, and the BMP1 family. The naturally occurring inhibitors of the MMPs, the 4 known TIMPs, and the inhibitors of serine proteases, the plasmin activator inhibitors (PAI), have been preclinically evaluated for antitumor efficacy and are the most prominent examples of antiproteolytic gene therapy. Intratumoral injection of first generation TIMP-2 adenovirus into subcutaneously growing tumors of mammary, colorectal, and bronchial origin reduced tumor size by 60–80% as compared to the controls, and the incidence of lung metastases was reduced by 90% (67). A similar efficacy was achieved by adenovirus-mediated transfer of TIMP-3 into subcutaneously growing melanomas (68). Systemic delivery of TIMP-2 by adenovirus application into the tail vein of immunocompetent mice bearing orthotopically implanted breast tumors resulted in 50% growth inhibition (69), and the intraperitoneal injection of TIMP-2 carrying liposomes for the treatment of spontaneously arising breast tumors allowed for a 40% size reduction and a dramatic reduction of the incidence of lung metastases (70). An intraperitoneal approach was taken to treat peritoneally disseminated pancreatic cancer, and adenoviral delivery of either TIMP-1 or TIMP-2 resulted in a 75% to 85% reduction of tumor loads and a significant prolongation of survival (71).

A prevention of colorectal liver metastasis of up to 95% was achieved if Ad-TIMP-2 was injected into the tail vein of mice, leading to a preferential transduction of the liver with the antitumor gene (72). Administration of TIMP-2 vector to mice bearing established liver metastases resulted in a 77% growth inhibition. When this same concept of gene transfer into the host tissue was applied for the treatment of lymphatic liver metastases, adenoviral transfer of TIMP-1 reduced metastatic deposits by 93% (73). The peculiarity of this approach is the transfer of anticancer defense genes into the normal noncancerous tissue, which was termed the ''impregnation'' approach.

In contrast to these findings of a marked antitumor efficacy of TIMP-1, -2, and -3 with 3 different types of animal models and modes of vector administration, systemic transfer of TIMP-4 by intramuscular electro-adjuvated injection of naked plasmid for the prevention of orthotopically growing breast tumors resulted in a 3-fold increase in size and up to a 7-fold increase in the incidence of primary tumors (74). None of the cited papers has reported any TIMP-related toxicity. Mild and probably vector-related toxicity to the liver was occasionally seen when first-generation adenovirus was delivered systemically.

Transfection of tumor cells with PAI-1, an inhibitor of serine proteases, reduced metastasis. Treatment with adenovirus-mediated PAI-1 gene transfer reduced the growth of uveal primary tumors as well as the incidence of metastases (75). Similarly, gene transfer of PAI-2 had unequivocal antitumoral effects (75). In contrast and unexpectedly, transgenic mice overexpressing PAI-1 developed pulmonary metastases at the same rate as wild-type mice in a melanoma model (76). Even more paradoxically, PAI-1 knock-out mice displayed a dramatically reduced local invasion and tumor vascularization of transplanted malignant keratinocytes and administration of PAI-1 by adenoviral gene transfer restored invasion and associated angiogenesis (77). These data indicate that antiproteolytic therapy with PAIs, and to a lesser extent with TIMPs, can have dramatic antitumor efficacy but that paradoxical tumor-promoting effects can occur. Similar to the MMPs and TIMPs, the PAs and PAIs have been shown to display effects independent from the degradation of the ECM (78), which may be partly responsible for the unexpected findings. Therefore, increased knowledge of either protease/inhibitor system may help us to better understand the underlying mechanisms, resolve some unexpected findings, and to draw conclusions with therapeutic relevance.

F. Drug-Resistance Genes

Instead of killing tumor cells, this strategy is aimed at preventing toxic side effects of modern chemotherapy, e.g., by making normal cells resistant to chemotherapeutic toxicity. This approach tries to solve the problem that the cytotoxicity of chemotherapy cannot usually discriminate between proliferat-

ing normal and cancer cells. Proliferating normal cells like hematopoietic precursor cells are especially affected, as evidenced by the fact that bone marrow suppression is still dose-limiting in most high-dose courses of chemotherapy. To overcome this limitation, different experimental approaches have been developed. One strategy to make hematopoietic precursor cells resistant to chemotherapy is the direct gene transfer of drug-resistance genes such as transporters that extrude drugs across the plasma membrane. These include the multiple drug-resistance gene 1 (MDR1), the multiple drug-resistance proteins (MRPs), or enzymes that render drugs resistant to alkylating agents such as gluthathion-S-transferase and O6-alkylguanine DNA alkyltransferase or antimetabolites such as dihydrofolate reductase (DHFR) (79). The MDR1 gene encodes for P-glycoprotein, a cell membrane multidrug transporter that effluxes a broad spectrum of hydrophobic and amphipathic compounds, including several chemotherapeutic drugs currently used in clinical studies (80). Ex vivo transfer and expression of the MDR1 gene in hematopoietic progenitor cells have been shown to increase the resistance of hematopoietic precursor cells to chemotherapy in rodent models (81–85). In the first of several clinical trials, low level expression of the transferred gene was reported only occasionally. More recently, however, prompt hematopoietic recovery and long-term in vivo vector expression was seen (86,87). We may see further clinical improvements if efficient transduction is achieved (especially of very immature cells) and drug selection strategies are further optimized. The encouraging report of in vivo correction of X-linked severe combined immunodeficiency (SCID) (88,89) with at least 5 of 5 patients now benefiting from this life-saving gene therapy also indicates that transduction of human hematopoietic stem cells is now feasible. Clinical benefit may result in situations where corrected cells have an in vivo selective advantage.

G. Marker Genes

Six percent of all clinical gene therapy protocols use marker genes for several purposes (90). Marker trials have confirmed the assumption that contamination of reinfused bone marrow with tumor cells causes tumor recurrence after autologous bone marrow transplantation (91). In other studies, hematopoietic stem cells or T-cells were marked and traced over a longer duration, providing important insights into their long-term survival.

III. VECTORS FOR CANCER GENE THERAPY

A. Virus-Based Gene Transfer Vectors

In this chapter, the various gene transfer vectors (e.g., adenovirus and retrovirus-based vectors) will be discussed with respect to their specific relevance for efficacy and toxicity in cancer gene therapy. For the general biology, development, and design of the vectors, the reader is referred to the corresponding chapters in this book that focus on particular vectors.

One of the most widely used vectors for in vivo application in cancer gene therapy is the replication-deficient recombinant adenovirus. First-generation adenoviral vectors (Ad vector) can be generated to the highest titers [up to 10^{12}/plaque forming (i.e., infectious) units/mL)] among viral vectors (92). Moreover, they easily infect cells of epithelial origin including cancer cells, most likely because these cells express the appropriate receptors, the coxsackie adenovirus receptor (93) and integrins (94) for binding and internalization, respectively. Since Ad vectors infect dividing and nondividing cells, dormant tumor cells, which can make up a considerable fraction of the tumor mass, can also be killed. These properties have made first-generation adenoviruses one of the vectors of choice for clinical studies targeting cancer. Of the 634 clinical gene therapy protocols initiated to date, 171 (26.9%) use Ad vectors, the majority of those for cancer treatment. Ad vector-mediated gene transfer can be accompanied by toxic side effects on normal tissue mainly due to residual adenoviral gene expression in occasionally transduced normal cells (95–100). This toxicity can be reduced using Ad vectors of the second generation where adenoviral genes such as the E4 region or the E2a gene are deleted (92,101–105), or helper-dependent (i.e., minimal or gutless) adenoviral vectors (HD-Ads), which are completely devoid of all viral genes (106–108). The side effects of first-generation Ad vectors such as toxicity and immunity can be turned into a desired adjuvant situation for cancer therapy as demonstrated by the group of Chen et al. (109). However, in cancer gene therapy where vector toxicity to the tumor cells at the first glance may be desirable, this toxicity may be of disadvantage in some situations. For instance, leakage of intratumorally injected vectors carrying a prodrug-converting enzyme (''suicide gene strategy'') into the host organ has been shown to produce severe side effects (20). Regional and systemic application of vectors with the aim of targeting metastases will inevitably transduce normal tissue. Other anticancer strategies are even explicitly based on transduction of normal tissue for its use as a bioreactor as in the antiproteolytic impregnation concept, antiangiogenic, and some immunological approaches. Therefore, cancer gene therapy (like gene therapy of other diseases) will depend enormously on safer vectors. In addition to increased safety (110), HD-Ads have some other advantages over first-generation vectors, including an extremely high packaging capacity that allows for a better adaptation to the tumor cell's particularities, as well as the potential for long-term gene expression [e.g., (111)], apparently higher gene expression (112), and better retained tumor-specific gene expression (113). The 2 main disadvantages of HD-Ads have been contamination with helper virus and difficulties in obtaining high titer preparations. Helper contamination has been significantly improved and titers of up to 2×10^{11} bfu (blue-forming units) are possible with modern techniques. HD-Ads have been tested in several preclinical models including cancer models (114), but no clinical trials have been conducted so far.

Another very popular vehicle for gene transfer, accounting for more than one-third of all trials and half of all patients treated, are retrovirus-based vectors. Most of these are derived

from murine leukemia virus (MLV). Retroviral vectors were the first vectors for which all the viral genes were provided by vector producer cells (VPCs). The retroviruses themselves contain only the LTRs, the packaging signal, and the transgene. In the field of cancer therapy, these vectors have dominated trials utilizing ex vivo transfer of markers, drug resistance, and immunomodulatory genes. For in vivo gene transfer, the VPCs themselves were often directly applied into the tumors due to the initially low achievable titers of 10^6/mL in the retroviral supernatant with the rationale that these VPCs will deliver retroviruses until they are eliminated by the immune system (115). As for adenoviral vectors, many animal studies were carried out, including in vivo gene transfer of retro VPCs or retroviral vectors into established tumors, and complete remissions of microscopic tumors have been reported [e.g., (115)]. Current packaging cell lines give titers of greater than 10^7 infectious particles per mL (116). Moreover, the use of different envelope proteins, such as the G protein from vesicular-stomatitis virus, has improved titers following concentration to greater than 10^9/mL (116), although these titers are still far below what is achievable with adenoviruses. Especially from a safety standpoint, their property of only infecting dividing cells may prevent toxicity to nondividing normal tissue. On the other hand, these vectors leave out dormant cancer cells, which may decrease their antitumor efficacy.

In contrast to MLV-based vectors, lentiviral retroviruses based on pseudotyped HIV-1 are able to infect nondividing cells (117–120), although there is some debate about whether hematopoetic stem cells should preferentially not be in the G_0 phase of the cell cycle (121) and whether hepatocytes are much more efficiently transduced in vivo if proliferating (122–124). Lentiviral vectors may therefore be of interest for cancer gene therapeutic approaches, which rely on long-term transduction of noncancerous tissue for cancer therapy. Mainly due to (perhaps overestimated) safety concerns with respect to the generation of wild-type virus, no clinical trials have been initiated yet. However, the use of apathogenic animal lentiviruses (125,126) may soon circumvent this concern.

Based on their tropism for neuronal tissues, herpes simplex viruses (HSVs) are in principle highly suitable for neurological cancer therapy. In general, they can infect dividing and nondividing cells. Similar to adenoviruses, cytotoxic genes must be deleted from the viral genome, and genes must be provided from helper viruses or cell lines in order to prevent unwanted toxicity if normal tissue is transduced. Successful attempts in this direction have been made (127–132). HSV has already been used in 5 clinical trials, and the intratumoral injection mode at least did not cause severe toxicity (see Section IV.D on Glioblastoma).

A fourth type of vector that has become very interesting for gene therapy in general during the last few years is adeno-associated virus (AAV)-based vectors. These helper virus (e.g., adenovirus)-dependent vectors induce only a minor cellular immune response and have the potential to integrate into the host genome. Therefore, they are very promising candidate vectors when long-term expression is required (for instance, for the protection of hematopoietic precursor cells during high-dose chemotherapy). With respect to clinical trials, AAVs are fairly advanced. Fifteen trials have already been initiated and at least 1 of them is planned for cancer (MediGene, Munich, German press release). For the general biology of AAV-based gene-transfer vectors, please refer to the respective chapter by Carter in this book (Chapter 5).

The poxviruses, fowlpox virus, and vaccinia virus infect a wide variety of cell types. In addition, they are safe and have a high packaging capacity (133). Due to their highly intrinsic immunogenicity, they have mainly been used as an adjuvant and transfer vehicle for immuno-gene therapy of cancer. This feature, as well as the nearly 100% preexisting antibodies, has prevented their more widespread use in gene therapy so far. Despite these limitations, an impressive number of 39 clinical studies using pox virus have been initiated.

In addition, several other viruses have been used for the transfer of genes into cancer cells. They usually have some interesting features but also bring certain disadvantages, which have so far prevented widespread use. EBV viruses have a natural tropism for B-cells, but the potential development of wild-type, transforming viruses by homologous recombination raises a safety concern. Baculoviruses are insect viruses and cannot replicate in human cells, but they have been shown to efficiently infect a variety of human cell lines (134,135). However, the human complement system rapidly inactivates these vectors such that extensive modification of the cell surface is required (135–137) to improve gene transfer in vivo. Alpha viruses such as Sindbis Virus (138) and Semliki Forest Virus (139) can efficiently multiply their RNA genome in target cells, allowing for very high transgene expression. Further improvements in their packaging systems could make these vectors very interesting agents for the future, especially for gene delivery to the brain, antitumor therapy by induction of apoptosis, or intratumoral replication and immuno-gene transfer (140).

Autonomous parvoviral vectors (141) such as H1, MVM, and LIII can only replicate during the S-Phase of the host cell and have been used as replication-competent viruses for cancer gene therapy in vitro or in preclinical settings (i.e., Newcastle disease virus, reovirus, poliovirus, and vesicular stomatitis virus) (142).

Chimeric vectors that are constructed by the use of 2 or more viruses may have the advantages and disadvantages of both vectors. To date, several types of hybrid vectors have been published, including first-generation adenovirus/AAV (143–145), HD-Ad/AAV (146,147), HD-Ad/transposon (148), HD-Ad/retrotransposon (149), first-generation adenovirus/retrovirus (150–152), or HD-Ad/lentivirus (153). These chimeras were evaluated mainly to combine the high efficacy of gene transfer with the long duration of gene expression; to facilitate AAV production; and to overcome the limited cloning capacity of AAV. HSV/AAV (154,155) chimeras or baculovirus/AAV chimeras (156) were constructed to combine cell specificity with stable gene expression.

With respect to long-term safety of viral vectors, occasional reports of possible oncogenicity have been described in animals for AAV (157) as well as for MLV-derived retroviruses (158), most likely due to insertional oncogenesis. This is not the case for HD-Ads, which can integrate at a low rate as well (159,160). Recently, a case of leukemia occurred in a trial for severe combined immunodeficiency that was very successful to that point.

Gene silencing as a reason for limited duration of gene expression despite vector integration has been described extensively for retrovirus and also for AAV (161), but, with the inclusion of MARs or SARs, matrix or scaffold attachment regions can improve the problem (162).

In summary, it seems that with respect to viral vectors it is possible to exploit nature's evolutionary achievements to our benefit and even to deviate markedly from nature's path without deleterious consequences. It is sometimes quite mysterious that even dramatic modifications of viral genomes still give viable and effective vectors. Since it seems that there is a way around nearly every problem, as long as time and money are provided, one can be confident that the vector problem—still the main issue in gene therapy—can be solved as long as the target diseases justify the effort and alternative ways of treatment are not provided.

B. Nonvirus-Based Gene Transfer Vectors

In general, nonviral vector systems have some advantages over viral systems. They are less toxic, less immunogenic, and easier to prepare. On the other hand, they have a much lower efficacy of gene transfer, particularly in vivo, and a more limited duration of gene expression than several viral vectors. Roughly 20% of clinical trials have utilized nonviral vectors. Half of these used naked DNA plasmids and the other half cationic liposomes, which are probably the most important nonviral vectors to date. Attempts to increase efficacy of gene transfer with cationic lipids and polymers will have to target 3 major barriers: stability during and after the manufacturing process, extracellular barriers, and intracellular barriers. An important step in improving extracorporeal stability of positively charged liposomes and polymers (which have a tendency to aggregate and precipitate) was the inclusion of hydrophilic polymers such as polyethylene glycol (PEG). This provides steric stabilization. PEGylation seems also to reduce interactions of cationic particles with blood components such as albumine, which present major extracellular barriers to nonviral gene transfer. Modifications to decrease unwanted preferential uptake of liposomes by the reticulo-endothelial system include the addition of sialic acid to make ''stealth'' liposomes (163). The most challenging and perhaps most rewarding task will be the elucidation of intracellular barriers to nonviral gene delivery. Cationic DNA complexes bind to the negatively charged cell membrane and are taken up by endocytosis. As for viral vectors, targeting by addition of ligands for cellular receptors has been used to circumvent extracellular barriers. For example, transferrin is a common ligand used to target tumor cells (164,165). Endocytosed DNA is largely retained in the endosomal compartment, and it is important that endosomal release is completed before lysosomal degradation initiates. Fusogenic lipids such as DOPE, fusogenic peptides from viral vectors (166), or substances with high buffering capacity (which in addition can swell like PEI) have been used to release DNA from endosomes. After vesicle escape, the nucleic acid must traffic to the nucleus. DNA is not very stable in the cytoplasm, which may be due to the presence of cytoplasmic nucleases. It is therefore particularly important to define the optimal time-point to release DNA from protection by the endosome or from coverage from vector after endosomal release. Once the vector arrives at the nucleus, another hurdle has to be overcome since nuclear entry of DNAs larger than 250 bp is hardly possible. A promising attempt to circumvent this problem is the inclusion of nuclear localization signals [NLS (167,168)].

Naked DNA is most interesting for immunological approaches in which efficacy of gene transfer is not the most crucial criterion. Interestingly, skeletal muscle cells are fairly susceptible to transfection with directly injected plasmid DNA. However, in mice, systemic application of naked DNA has led to astonishingly high rates of gene transfer in mice if administered systemically in extremely high volumes and with generation of high pressure in target organs (169,170).

In addition to liposomes and naked DNA, cationic polymers have gained attention during recent years, although no clinical trials yet exist. Other modalities include electroporation and particle bombardment (171–173). In this latter technique, 1–3 μm gold or tungsten particles are covered with plasmid DNA accelerated in an electrical field and fired onto the target tissue. Due to a penetration depth of up to 50 cell layers, this approach is applicable for vaccination into superficial skin cancers.

C. The Transgene

A gene therapeutic expression cassette consists of the regulatory elements, the transgene, and the poly A signal.

The transgene is usually a wild-type cDNA but other structures are possible. Among these are mutated transgenes, such as dominant negative oncogenes to inhibit oncogenes, or mutated cDNAs that lead to other defects favorable for cancer gene therapy. The availability of high-capacity vectors such as HD-Ad or HSV has allowed the inclusion of full-length genes, including introns and other features that may eventually be as interesting for cancer gene therapy as they already are for the treatment of monogenetic disease. Finally, recent developments of small, double-stranded DNA oligonucleotides that apparently can interfere with RNA may dramatically influence cancer gene therapy. These oligonucleotides have already been included in viral vectors, and antitumor efficacy has been reported after ex vivo gene transfer (39).

D. Cancer-specific Gene Expression (Transcriptional Targeting)

If one wants to exploit differences between tumor and normal tissue for tumor therapy, tumor-specific gene expression is a

particularly rewarding area. Transcriptional targeting restricts gene expression to the target tissue even if undesired tissues have been transduced as well, thereby providing a significant improvement in safety. Tumor-specific promoters are only active in those target tissues naturally expressing their respective tumor-specific endogenous genes. If one engineers an expression cassette in which any therapeutic gene is placed behind that tumor-specific promoter, it will, due to its promiscuous nature, express this transgene in a tumor-specific fashion as well. A huge variety of tumor-specific promoters have been examined during the last years for their use in gene therapy. This is basically because every tumor type has its own more or less tumor-specific genes. Tumor-specific gene expression can obviously only be as specific as the degree of differential gene expression of the respective endogenous gene. Therefore, it has certain limitations. In other words, residual gene expression in undesired tissues is frequently observed. Among the promoters used are tissue-specific promoters, which will also be active in the corresponding normal tissue, and proliferation-specific promoters, which will be active in proliferating nonmalignant tissue. In addition, the expression levels are often only gradually higher in the tumor than in the normal tissue. One must carefully examine how these gradual differences translate into the therapeutic situation.

Tumor-specific promoters are particularly interesting in the situation of metastatic cancer where the tissue-specific promoter allows transgene expression in the metastatic tumor cell but not in the surrounding normal tissue, even if it is transduced by the vector. For instance, the carcinoembryonic antigen (CEA), which is physiologically expressed predominantly in colon tissue but not in liver tissue, allows transgene expression predominantly in colon cancer cells metastatic to the liver. Toxicity to the liver seen with the ubiquitous CMV promoter that expresses a suicide gene (20,174) can be prevented if the CEA promoter is used instead (21). Other examples of such a promoter strategy include the AFP (alpha-fetoprotein) promoter for hepatocellular carcinoma (HCC); the promoters of erbB2, an oncogene often found in breast tumors; the prostate-specific antigen (PSA); or the promoter of the tyrosinase gene, which has specificity for melanoma.

However, the maintenance of tissue specificity can be a problem after inclusion into a vector. For adenoviral vectors, loss as well as maintenance of tissue specificity has been reported (21,175–180). In this context, the orientation of the expression cassette can play an important role. For instance, the transcriptional activity of the E1A enhancer, which is not deleted in E1-deficient first-generation adenoviruses, can induce loss of tissue specificity. This type of promoter interference can even stem from regions located downstream from the expression cassette (181). This can even occur if the expression cassette is inserted in the reverse orientation to the main adenoviral reading frame (author's observations). To circumvent this problem, an insulator element derived from the chicken gamma-globin locus (HS-4) was employed to shield an inducible promoter from viral enhancers. Induction ratios could be improved up to 40-fold as compared to vectors with an uninsulated promoter (181). In a similar approach, transcriptional terminators have been implemented to restrict read-through of the E1A enhancer (182). Finally, insertion of a specific promoter at a site distant from the E1A enhancer (e.g., close to the right ITR) has retained higher specificity and lower background (183).

In contrast to first-generation adenovirus, HD-Ads seem to allow full maintenance of promoter specificity. This has recently been demonstrated for the PSA and the tyrosinase promoters (113).

Also, in contrast to first-generation adenovirus, insertion of expression cassettes in reverse orientation into retroviral vectors normally maintains tissue specificity. Orientation in frame, however, puts the transgene under the influence of the strong retroviral LTR with subsequent loss of specificity (184). Alternatively, SIN (self-inactivating) vectors, which do not possess any promoter on the 3′ or 5′ end of their genome after integration into the host cell genome (185), can be used. The LTR can also be replaced by the tissue-specific promoter. The problems of tissue-specific expression seen in adenovirus or retrovirus vectors do not seem to occur in AAV vectors (186,187). This is probably because the flanking ITRs possess no regulative activity. Recently, maintenance of tissue-specific expression was reported for the PSA promoter in a lentiviral vector (188).

A major problem with tumor-specific promoters, whose specificity may be satisfying, can be insufficient promoter strength. An ingenious strategy to compensate for the weakness of tumor-specific promoters has been made possible through the introduction of the CRE lox system into the concept of transcriptional targeting. On 1 of the constructs, the tumor-specific promoter regulates the expression of the CRE recombinase. This enzyme then recognizes loxP sites (on a second construct), which flank a spacer region separating a strong viral promoter and a therapeutic transgene. Cleavage of the loxP sites excises the spacer, thereby inducing transcription of the transgene. Expression of the transgene with this system is supposed to be higher than with simple tumor-specific expression because the stability of the CRE enzyme will amplify the tumor-specific effect. The utility of this system has been proven using the AFP promoter in vitro (189) and the CEA promoter in vivo (190). Other strategies to compensate for promoter weakness have used transcriptional transactivators under tissue-specific control, which then have activated a minimal promoter for transgene expression (191–193). So far, all these systems have used 2 types of adenoviruses for either promoter/transgene construct. However, incorporation of both expression cassettes on 1 vector should be possible.

As in other fields of gene therapy, the packaging size of the vector to be used for gene transfer is one of the most important limitations for the construction of cancer-specific expression cassettes. So far, vectorologists have mainly worked with the intron-free cDNA coding for the transgene. Recently, the availability of vectors with substantially increased packaging capacity, such as HD adenoviruses, has allowed the inclusion of whole mini-genes into a viral vector

(107,144,194,195). This provides the necessary space for longer and potentially even more specific regulatory elements.

In contrast to constitutive promoters, tumor specificity in patients who are resistant to chemotherapy could be mediated by therapy-inducible promoters. In this respect, the examination of gene-regulation mechanisms in cancer cells such as the multidrug resistance gene (MDR1), the X-irradiation-induced, tissue-type, plasminogen activator (t-PA), the early growth response gene (Egr-1), the human, heat-shock protein HSP 70, or the glucose-regulated protein (GRP78) led to the discovery of a class of promoter sequences that are involved in such stress responses. These promoters carry responsive elements that are inducible by either radiotherapy, cytostatic drugs, or hyperthermia (all conventional treatment modalities). It has already been shown that the expression of therapeutic genes could be enhanced and the efficacy increased if placed under the control of therapy-inducible promoters (196). The combination of therapeutic genes under the control of therapy-inducible promoters used with conventional cancer treatment methods could enhance overall treatment efficacy and also retain specificity.

E. Targeted Vectors

Currently, the predominantly used viral vectors for gene transfer can infect a broad variety of target cells and tissues. Although this is of interest for cell-type, independent, gene expression, it is a disadvantage when tissue-specific, gene expression is required as in cancer gene therapy. Therefore, the surface of the vector needs to be modified to infect the cancer cell in a more specific manner (retargeting).

Several approaches have been developed to redirect the tropism of adenoviral vectors in favor of cancer cells. The efficacy of binding to the surface of a given target cell by an adenovirus depends on the presence of specific receptors such as the coxsackie-adenovirus receptor (CAR) and to a lesser extent the alpha2 domain of MHC class I on the cell surface, which interact with the adenoviral fiber knob protein (93,94,197,198). After binding, the adenovirus is internalized through clathrin-coated pits. This process is mediated through an interaction between RGD motifs on adenoviral penton base protein loops and integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$. Two major strategies have been used to redirect adenoviral infection: conjugate-based strategies and genetic targeting strategies. Conjugate-based strategies include bispecific recombinant proteins, peptides, or chemical conjugates to redirect adenoviral infection. Examples include bispecific conjugates consisting of the Fab fragment of a neutralizing antiknob monoclonal antibody covalently linked to folate (199–201); polymer-mediated ligand coupled to adenoviral capsid, or avidin bridging between biotinylated adenovirus; and biotinylated potential ligands for cellular receptors. Increases of 100-fold and more in infectability have been described in several in vitro studies as compared to wild-type adenovirus. The best results reported so far for in vivo systemic vascular delivery of 2-component, targeted vectors were obtained using adenovirus with bispecific antibodies. These blocked the CAR binding domain and redirected the vector either to: FGF receptors on tumor cells, which led to substantially increased survival using the HSVtk/GCV approach (202), or to angiotensin-converting enzyme on pulmonary capillary epithelium, which enhanced gene transfer to the lung at least 20-fold. The same group has recently initiated the first clinical study using retargeted adenoviruses for the treatment of cancer with a suicide gene approach (203).

Conjugate-based approaches have 2 main advantages: the wide range of cellular receptors that can be targeted and the fact that there is no need to make structural changes to the adenovirus itself. The disadvantages of the system include the larger size and irregular shape of the particles, as well as regulatory issues such as the need to obtain approval of all components of a 2- or 3-component system.

These problems can be circumvented by genetic targeting approaches that genetically modify fiber, penton base, and hexon capsid proteins. By far the most extensively studied alterations have been done on fiber knob, including fiber knob pseudotyping, genetic incorporation of targeting ligands into the fiber protein, and genetic fiber replacement strategies. Fortunately, 2 sites in the fiber protein have been identified where ligands can be inserted safely without disrupting fiber-knob trimerization. These are the C-terminal end of the fiber tail, which projects from the surface of the virion, and the so-called HI loop within the fiber knob. Incorporation of targeting ligands led to increased infectabilitiy of target cells in vitro of up to 3 orders of magnitude (204,205). The advantage of entire replacement of fiber over just incorporating ligands is the possibility of achieving real retargeting, because only then can initial affinity of adenovirus to CAR be abrogated. To date, attempts have been successfully made to abrogate infection of CAR positive cells, but infectability of retargeted adenoviruses in general was lowered 20-fold (206,207). A pseudotyped adenoviral vector has recently been utilized for targeting replication-competent adenovirus to liver metastases, and an increase of the transduction rate from 0% to 8% was observed (208).

A combination of conjugate-based strategies and genetic targeting has recently been described. Efficient and selective gene transfer into human brain tumor spheroids has been achieved using antibody-targeted vectors; native tropism to both CAR and integrin were abolished (209).

A variety of retargeting attempts have recently been undertaken for AAV. The primary attachment receptor for AAV is heparan sulphate proteoglycan (210), and coreceptors are fibroblast growth factor receptor-1 (211) and $\alpha_v\beta_5$ integrins (212). These receptors are widely expressed in the human body. Retargeting is therefore feasible, especially as AAV is an integrating vector. In addition, it seems that despite efficient internalization, nuclear trafficking of AAV may be inefficient. Retargeting to new receptors could allow for new and more efficient ways of trafficking. As for adenoviruses, genetic and nongenetic approaches have been used to retarget AAV. The former strategy has been more popular by far, however. In vivo gene transfer has been performed with AAV-2 pseudotyped with AAV-5 capsid or AAV-8 capsid; this pro-

duced higher levels of transduction than wild-type AAV-2 in injected skeletal mouse muscle or liver, respectively (213).

Much effort has recently been made in genetically incorporating targeting ligands into the AAV capsid. In contrast to adenovirus, the structure of the AAV capsid has not yet been elucidated. This will eventually enable pinpointing of the capsid epitopes, which mediate cell-surface, receptor binding and enable specific site-directed mutagenesis for ablation of wild-type AAV-2 tropism. Despite this drawback, by modeling the AAV capsid on the known structure of canine parvovirus, several studies have already demonstrated that genetic incorporation of peptide epitopes into the AAV capsid can modify tropism.

The first genetically targeted HD-Ad has recently been published (214).

The wild types of commonly used retroviruses such as ecotropic murine leukemia virus (MLV) strains do not recognize a receptor on human cells. They have therefore been pseudotyped with natural viral fusion proteins such as the amphotrophic MLV env protein or the vesicular stomatitis virus (VSV)-G glycoproteins (215). These pseudotyped retroviruses now infect a variety of human cells. This is not always desirable, as in the case of adenovirus and AAV. Therefore, retargeting of these vectors to specific cell types has been attempted. In addition, studies have shown that several cell types, including hematopoietic stem cells, are still insufficiently infected by pseudotyped vectors. Some specificity is achieved just by using other viruses for pseudotyping (such as gibbon ape leukemia virus (GALV) (216), human foamy virus (HFV) (217), simian immunodeficiency virus (218), and HIV-1 (219)).

More was expected from direct targeting approaches such as inclusion of a wide variety of ligands into the MLV glycoproteins. Efficient retargeting was achieved in several cases. Unfortunately, upon binding most of the chimeras were unable to trigger the highly complicated fusion events of viral envelope and target cell membrane necessary for efficient viral transduction. The most straightforward approach to circumvent this problem was the creation of tethering or escorting ligands. These were again cloned into the MLV env glycoproteins, but at a site that does not abrogate wild-type receptor interaction and disturb fusion. This type of retargeting has already proven successful for preclinical cancer therapy. Systemic application of an extracellular, matrix-targeted retrovirus allowed enhanced transduction of tumor tissue and significantly prolonged survival of mice as compared to a nontargeted vector (220). During these studies, an observation was made that was paradoxical at first glance: some receptor ligands conferred excellent binding to target cells, but due to lysosomal sequestration no gene transfer was achieved (221–223). This phenomenon, which has been called inverse targeting, can cause the selective transduction of EGF-receptor negative tissue if the vector has been engineered to contain EGF and if the EGF-receptor negative tissue is principally infectable by the wild-type vector (as has been demonstrated by inverse targeting of lentiviral vectors to the spleen) (224). This type of inverse targeting can be reversed into true targeting by inclusion of a protease cleavage site inserted between the EGF domain and the amphotrophic receptor. In this case, EGF serves as a tethering molecule, but extracellular proteases present on the target cells cleave it off and efficient infection occurs. This approach has proven to discriminate between (matrix metallo) protease rich and poor in EGF receptor-positive tumors in nude mice (225).

Another innovative way to achieve retargeting without losing fusion uses proteins of nonretroviral, enveloped viruses instead of the natural receptors. These proteins are able to trigger membrane fusion. MLV vectors coated with the influenza virus hemagglutinin (HA) glycoprotein, including a cell surface-specific ligand, could be selectively targeted to and incorporated into cells expressing the expected target cell surface molecules (226). Finally, similarly to adenovirus and AAV, bifunctional bridge proteins have been examined for targeting with success in vitro (227).

The benefit of combining transcriptional targeting and tropism-modified targeting was recently demonstrated using the endothelial, cell-specific FLT-1 promoter and an antiACE antibody. This combination achieved an impressive 300,000-fold improvement in adenoviral transduction of the lung (228).

IV. CLINICAL TARGETS FOR CANCER GENE THERAPY

A. Bladder Cancer

Superficial transitional cell cancer of the bladder (TCC) is the fifth most common solid malignancy in the U.S. (229). Seventy percent to 80% of patients with bladder cancer present with these low-grade, noninvasive tumors confined to mucosa. Although most superficial cancers can be managed with periodic transurethral resection, this is not an ideal situation because recurrence is the rule (230). Even with close surveillance and follow-up, at least 50% will eventually require a cystectomy. Intravesical chemotherapy or installation of Bacille Calmette-Guérin can prolong the disease, but still 30% of patients will die of recurrent metastatic bladder cancer within 15 years (230).

Intravesical gene therapy is a promising new approach for the treatment of refractory superficial bladder cancer. Several approaches have proven preclinical efficacy, including transfer of immunomodulatory genes such as IL-2 (231) and IFN-γ (232); installation of tumor cells transfected with GM-CSF, IL-2, or HLA B7-1; HSVtk-based suicide approaches (28,29); oncolytic Herpes virus, which was interestingly efficient against metastases if injected systemically (32); and transfer of p16 (35), pRb (33), or p53 (13).

A clinical trial of installation of empty vaccinia virus did not lead to any systemic toxicity, but recruitment of lymphocytes and induction of a brisk local inflammatory response were seen (233). Intravesical installation (but not intratumoral injection) of Adeno-p53 led to transgene expression and induction of the p53 target gene p21 in patients with bladder cancer awaiting total bladder resection. No dose-limiting toxicity was observed at a dose of up to 7.5×10^{13} particles (234).

The superficial nature of TCC and the unique opportunity of intravesical vector installation make this disease particularly suited for cancer gene therapy at the current state of development.

B. Breast Cancer

One of the most important target malignancies for cancer gene therapy is breast cancer. Breast cancer will affect 1 in every 9 women in the United States, and a similar incidence is seen in Europe (235). Conventional treatments such as surgery, radiotherapy, and adjuvant systemic therapy allow disease-free survival for many years. However, the loco regional recurrence rate and the rate of disseminated disease is high, and even 10–40% of patients without obvious axillary lymph node involvement at the time of surgery relapse (236). In these cases a curability by conventional methods is very unlikely.

Based on the unsatisfying outcome of classical strategies to improve cancer treatment, several gene-transfer approaches are under experimental and clinical investigation. These include immunological approaches or the transfer of tumor-suppressor genes or prodrug-activating enzymes.

Several immunological strategies are based on the use of tumor-specific antigens to improve recognition of breast cancer cells by the effector cells of the immune system. In this respect, several tumor-specific antigens are under experimental investigation to set up a specific vaccination strategy for patients with breast cancer. Candidate antigens are mucin 1 (MUC-1), MAGE-1, carcinoembryonal antigen (CEA), and members of the erbB gene family of cell surface receptors (237). A recombinant vaccinia virus expressing MUC1 and IL-2 has been used in a phase I/II study in 9 patients with advanced breast cancer (238); 1 patient had a concomitant decrease in carcinoembryonic antigen serum levels and remained clinically stable for 10 weeks.

Among the first immunological approaches for breast cancer patients was a phase-I study of immunotherapy of cutaneous metastasis using allogenic (A2, HLA-B13) and xenogenic [HLA-H-2K(k)] MHC-DNA liposome complexes (239). Several partial and complete responses of the injected tumorous nodules were observed.

Intra-tumoral adenovirus-mediated gene transfer of the 4-1BB costimulatory molecule-ligand (ADV/4-1BBL) to liver metastases in a syngeneic animal model of breast cancer induced a dramatic regression of preestablished tumor (240). Excellent tumor regressions were also observed with a combination of IL-2 and IL-12-expressing adenovirus in a mouse model of mammary adenocarcinoma; 63% of animals underwent complete regression of both treated and untreated tumors (241). Direct in vivo IFN-β gene delivery into established tumors generated high local concentrations of IFN-β, inhibited tumor growth, and in many cases caused complete tumor regression. Because the mice were immune-deficient, it is likely that the antitumor effect was exerted primarily through direct interferon-mediated inhibition of tumor cell proliferation and survival (242).

Gene transfer strategies for breast cancer patients can also be used to improve classical strategies in breast cancer therapy such as chemotherapy. In this field, purging techniques in high-dose chemotherapy are under intensive experimental investigation. Before initiation of high-dose chemotherapy for women with breast cancer, autologous stem-cell transplants are collected from the patient and are given back after the therapeutic protocol is completed. Because these preparations can still be contaminated by tumor cells, different strategies aim at purging these stem-cell transplants from contamination. However, magnetic purging techniques are expensive and not very efficient, while pharmacological purging is very effective but toxic not only to the tumor (243). Therefore, to limit the toxicity of pharmacological purging of contaminating cancer cells, either hematopoietic precursor cells of the autologous stem-cell transplants need to be made resistant to chemotherapy, or contaminating tumor cells need to be made more sensitive to chemotherapy. Thus, one genetic approach tries to infect only hematopoietic cells and make them resistant to chemotherapy through transfer of a multidrug-resistance gene (244). An example of the other strategy of making contaminating tumor cells more sensitive to chemotherapy is adenovirus-mediated gene transfer of a prodrug-activating enzyme like HSV-tk or CD (175,245,246). This approach exploits the fact that breast cancer cells that contaminate autologous stem-cell transplants express more adenovirus-internalizing integrins than hematopoietic precursor cells (247–249). Preclinical studies have already demonstrated that the concept of adenovirus-mediated gene transfer into contaminating breast cancer cells of autologous stem cells is a real alternative strategy for direct clinical application (250,251). Purging of hematopoietic stem cells from breast cancer cells has also been successfully performed with conditionally replication-competent HSV (252), and a complete lack of toxicity has been shown for a p53 adenovirus (253).

Another strategy that has been adapted for gene therapy of breast cancer is the use of antioncogene and tumor suppressor genes. In vivo administration of BRCA1 led to tumor growth retardation comparable to that obtained with p53 or p21 (254).

Hydrodynamic-based gene delivery of a secreted form of the tumor necrosis factor (TNF)-related apoptosis-inducing ligand, TRAIL, led to the regression of a human breast tumor established in SCID mice (255).

Adenovirus-mediated transfer of the cDNA of the proapoptotic bcl-x_s into breast cancer cells led to a significant reduction of tumor growth after the transduced cells were transplanted into immunodeficient mice (24,256). As described in the literature on colorectal cancer, breast cancer also develops by a succession of genetic alterations (257–261). Although the degree of genetic heterogeneity is particularly high in breast cancer, these multiple genetic changes may interfere with just a few critical cell-cycle regulatory pathways and therefore represent suitable targets for corrective gene therapy (262). Successful in vitro approaches include oligonucleotide-mediated transfer of antisense myc (263,264), ErbB-2 (265,266), cyclin D1 (267), and TGF alpha (268); the transfer of genes for intracellular antibodies, which prevent growth

factor receptors to reach the cell surface, as reported for ErbB-2 (269); and other transgenes such as PKA, EGFR, TGF-beta, IGFIR, P12, MDM2, BRCA, Bcl-2, ER, VEGF, MDR, ferritin, transferrin receptor, IRE, C-fos, HSP27, C-myc, C-raf, and metallothionin genes (270). Some of these have already been tested in vivo. For example, excellent inhibition of breast tumor growth in vivo was shown by retroviral transfer of antisense C-FOS (271).

The best existing in vivo data so far has been seen with adenoviral transfer of the tumor suppressor p53, which argues for the fruitfulness of combining a highly efficient gene transfer vehicle with a nearly universal apoptosis inducer (272). In addition, good efficacy of tumor-growth reduction was achieved using liposomes for the transfer of a p53 cDNA (273). The importance of the p53 status for the efficacy of chemotherapeutic drugs is a matter of intense debate. Whereas in the majority of studies the loss of p53 has been associated with decreased sensitivity to chemotherapy, the opposite was reported for the chemotherapeutic drug taxol (274). An interesting approach to counteract the MDM2 protein, which is often elevated in wtp53 positive tumors, was conducted by generating a recombinant adenovirus expressing a p53 variant (that is, deleted for the amino acid sequence necessary for MDM2 binding). Apoptotic activity of rAd-p53 expressing the mutated p53 with that of a recombinant adenovirus expressing wild-type p53 in cell lines that differed in endogenous p53 status caused higher levels of apoptosis in p53 wild-type tumor lines compared with wild-type p53 treatment, showed apoptotic activity similar to that seen with wild-type p53 treatment in p53-altered tumor lines, and showed greater antitumor activity in an established p53 wild-type (hepatocellular) tumor compared with treatment with wild-type p53 (275). With a similarly mutated adenovirus, tumor regressions were also observed in a sarcoma model (276). In combination with chemotherapy, coapplication of docorubicin did show an overadditive effect (277), whereas cyclophosphamide did not (278).

Stable preclinical tumor regressions were also achieved by intratumoral injection of an adenovirus harboring the adenoviral E1A gene under the control of the tumor-specific MUC1 promoter with and without an additional TNF-a transgene expression cassette (52). In a clinical trial, an E1A gene complexed with DCC-E1A cationic liposome was injected once a week into the thoracic or peritoneal cavity of 18 patients with advanced cancer of the breast ($n = 6$) or ovary ($n = 12$) and led to HER-2/neu downregulation, increased apoptosis, and reduced proliferation (279).

Injection of a plasmid harboring the CD gene under the control of the tumor-specific erbB-2 promoter in 12 patients with breast cancer showed the safety of the approach; expression of the transgene was seen in 90% of cases, although no antitumor efficacy was reported (280).

Injection of adenovirus-harboring dominant negative mutants of estrogen receptors into preestablished T47D tumors in nude mice induced tumor regressions (281).

Finally, in vivo studies of reovirus breast cancer therapy revealed that viral administration could cause tumor regression in an MDA-MB-435S mammary fat pad model in severe combined immunodeficient mice. Reovirus could also affect regression of tumors remote from the injection site in an MDA-MB-468 bilateral tumor model, raising the possibility of systemic therapy of breast cancer by the oncolytic agent (282).

In summary, although metastatic breast cancer poses high demands on current cancer gene therapists, nearly all therapeutic principles have been evaluated in animals and some are already in clinical evaluation.

C. Colorectal Cancer

Colorectal cancer is the third most frequent cancer in the United States (283). Surgical removal of the primary tumor is the established first-line therapy. This strategy can be a curative approach if all cancer cells are eliminated. However, already at a very early stage of tumor development, colorectal cancer metastasizes to the liver. In 60% of all cases, the only manifestation of distant metastasis (284) occurs in this organ. Consequently, liver metastasis of colorectal cancer is one of the very few indications where treatment of metastasis can lead to a significant improvement of the prognosis of the disease.

Single-liver metastasis of colorectal cancer represents a promising target for intratumoral and/or regional gene therapy. Studies in experimental animals demonstrated significant tumor reduction by gene transfer of the tumor suppressor gene p53 (285). However, neither a clinical trial applying p53 adenovirus into the hepatic artery (286,287) nor intratumoral injections (288) have revealed any clinical response. The suicide approach by gene transfer of prodrug-activating enzymes such as cytosine deaminase, HSV-tk, or nitroreductase followed by systemic application of the corresponding prodrugs 5-fluorocytosine, ganciclovir (GCV), or CB1954 has led to good results in animal experiments (289–291). A single dose of adenovirus transferring the HSV-tk gene, followed by a 10-day intraperitoneal GCV treatment, led to a reduced tumor growth of more than 90% and a significant reduction of the tumor volume (292,293). This experimental approach was extended by the combination of adenovirus vectors carrying the transgene of different cytokines with the adenovirus encoding for HSV-tk. The results so far have suggested that the HSV-tk/GCV effect can be increased by simultaneous cytokine gene expression (292). However, in an orthotopic model of colon carcinoma metastatic to the liver, the HSV-tk strategy was compromised by severe hepatic toxicity and the death of several animals (20). Similar toxicity was seen if the vector was applied intraportally for the treatment of HCC in mice or rats (174). In contrast, no toxicity was observed with retroviral vectors (294) (author's findings). The liver toxicity observed using adenovirus vectors could be abrogated if the CMV promoter was replaced by the colon-specific CEA promoter in these vectors (21). The generation of tumor-cell-specific transgene expression in colorectal liver metastases by adenovirus vectors can also be accomplished by modification of the adenoviral fiber protein by inclusion of the CEA receptor (295). Recently, the results of an adeno-HSVtk/GCV phase I

trial with intratumoral injection of an RSV.HSVtk-adenovirus were reported. Ultrasound-guided percutaneous injection of up to 10^{13} adenoviral vector particles only caused mild hepatic toxicity upon GCV treatment; this may indicate that extensive leakage into the liver tissue was prevented. No clinical benefit was observed (296).

A clinical phase I trial with conditionally oncolytic, replication-competent, E1B55K-deleted adenovirus was performed (297). It was possible to safely deliver virus by direct intratumoral, intra-arterial, and intravenous injection up to a dose of 3×10^{11} infectious particles. In a phase II trial for patients with colorectal liver metastases, virus was administered intra-arterially together with the chemotherapeutic 5-FU. After 3 months, stable disease was demonstrated in 6 of 7 patients (297).

Antiangiogenic and antiproteolytic strategies have been implemented but are still in the preclinical phase. A prevention of colorectal liver metastasis of up to 95% was achieved when Ad-TIMP-2 was injected into the tail vein of mice; this leads to a preferential transduction and quasi-impregnation of the liver with the antitumor gene (72).

Multiple liver metastases are also targets for immunological gene therapy strategies. In this respect, the CEA is one of the most promising candidates under investigation. In 2 clinical studies of recombinant vaccinia virus-CEA immunization, T-cell responses were demonstrated (298,299). In a recently published clinical trial of a dual-expression, plasmid-encoding, carcinoembryonic antigen (CEA) and hepatitis B surface antigen (HBsAg) in 17 patients with metastatic colorectal carcinoma, 4 patients developed lymphoproliferative responses to CEA after vaccination, although no objective clinical responses to the DNA vaccine were observed (300). In addition, significant tumor growth inhibition of xenografts from colon tumor cells in established animal models has also been accomplished using different approaches. These include: vaccinia virus-mediated transfer of B7-1 and IL-12 (301); adenovirus-mediated transfer of IL-12 (294); liposomal transfer of MHC class I molecules (302); or the transfer of fibroblasts that had been transduced in vitro with IL-2 (303) (this last result has led to the initiation of a clinical phase I study) (304). The results of these experimental studies indicate that the dormant or suppressed immunogenicity of colon tumor cells can be evoked by several immunomodulatory mechanisms. Moreover, the good antitumor efficacy achieved even with vector systems, which traditionally suffer from low gene-transfer efficacy, suggests that a certain level of gene transfer may be sufficient to induce an immune response.

In summary, colorectal liver metastases are unique. Their cure could mean a cure for the patient. Therefore, they have served as the model disease for gene therapy of metastatic disease. Initial, encouraging clinical results have been obtained.

D. Glioblastoma

Glioblastoma is the most common primary brain tumor. Despite advances in diagnosis and treatment, the median survival time is still only 1 year from the time of diagnosis (305). This tumor rarely metastasizes to distant organs, suggesting that improvements in local treatment could be of great benefit. Therefore, glioblastoma has been one of the model diseases for gene therapy with suicide genes. Recent reviews on this topic are provided by (306,307). The first preclinical studies for cancer gene therapy were performed using retrovirus-mediated transfer of the HSV-tk gene into established intracranial glioblastomas in Fisher rats (115). Based on these early promising results, other vector systems have been tested for the HSV-tk/GCV approach including adenoviruses, liposomes, AAV, or HSV. All these vectors have been successfully used in animal studies where it was frequently possible to observe complete remissions with long-term survival (Table 1). Consequently, several clinical phase I, II, and III trials were initiated making the gene therapy of glioblastoma by the HSV-tk/GSV approach the most advanced system for cancer gene therapy. The suicide gene approach has been combined with surgery. As much malignant tissue as possible is removed, leaving the local infiltrating parts for multiple vector injections. This strategy has to leave out the large isles of healthy tissue within the tumor network, which is a characteristic of this tumor. This is the reason why complete resections can be rarely performed. As demonstrated by results from a multicenter phase II trial in Germany, there is no ''clear-cut'' clinical outcome so far. In a 1-year follow-up report of 10 patients with recurrent glioblastoma multiforme, where retroviral vector packaging cells were administered into the tumor followed by application of GCV, 4 of the 10 patients died because of tumor progression. Of the other 6 patients, 1 presented a complete remission at 12 months, and 5 had progressive disease but with a significant increase in quality of life (308). Other reports demonstrated responses in the CT scan; a clear enhancement was visible in the areas were the retroviral VPCs carrying the transgene had been injected (309). However, clinical responses were rare and not marked. Unfortunately, the first phase III trial with HSV-tk retroVPCs did not have any treatment benefit (310). Some responders were observed in trials using adenoviral vectors, but therapy was accompanied by severe neurological symptoms (311,312). As discussed in the context of colorectal liver metastases, toxicity can in principle be abrogated by tissue-specific expression of the transgene e.g., by the nestin (313) or myelin basic protein (25) promoter or targeted vectors (310). Three phase I trials with conditionally replication-competent HSVs have been performed to date. Toxicities related to the vector were not reported, and occasionally antitumor efficacy was seen (314–316).

Besides the strategy of using prodrug-converting enzymes, gene transfer of the tumor suppressor gene p53 has also been commonly tested in experimental models with success either alone (317,318) or in combination with radiotherapy and chemotherapy (319–321). Among the cell-cycle inhibitory proteins, p16 is very often inactivated in glioblastoma. Adenovirus-mediated gene transfer of p16 generated significant tumor growth reduction in p16-negative glioblastomas (322). For the transcription factor E2F-1, it could be demonstrated that adenovirus-mediated overexpression resulted in a tumor

growth reduction in p53 wild-type-expressing glioblastoma cells (323). Other apoptosis-inducing genes [caspases (324) (325), TNF-α (326,327)], or antioncogenes [ras, (328), meningioma] have been successfully evaluated in animal models. In addition to the use of molecules regulating cell cycle and apoptosis, several immunomodulatory genes have been tested to treat experimental glioblastoma tumors either alone or in combination (329–332). Growth inhibition was seen in most cases, which indicates that although the brain is an ''immuno privileged'' site, this barrier could effectively be surmounted at least in some tumors. A clinical trial using interferon-β (333) has been initiated.

In summary, although the HSV-tk suicide gene trials probably represented one of the earliest sobering results in gene therapy, the disease is certainly a very good candidate for gene therapy. This is especially so if targeted vectors will distinguish between normal brain tissue and the deeply infiltrating and surgically inaccessible tumor branches of glioblastoma multiforme.

E. Head and Neck Cancer

Each year in the U.S., approximately 40,000 individuals will be diagnosed with carcinoma of the head and neck (HNSCC) and upper aerodigestive tract (334). More than two-thirds of the individuals with HNSCC present with stage II or IV of the disease (335) and 50–60% of these patients will ultimately develop local recurrence despite optimal local therapy. These patients may therefore obtain significant benefit from local or regional gene therapeutic approaches.

A high percentage of these tumors is negative for p53, and several clinical trials with percutanous or endobronchial p53 gene transfer are underway or already closed. Several clinical studies have used adenoviral vectors, while one trial used retroviruses. In summary, no major toxicity was observed. Indications of antitumor efficacy included increased survival times compared to historical controls in 4 of 15 patients with recurrent disease; dose-related improvements in time to disease progression in a large phase II trial; and partial response or at least stable disease in two-thirds of patients in a trial with 52 patients who had previously failed conventional treatment.

Despite these findings of clinical efficacy, improvements of the strategy are necessary, mainly because of the requirement of highly efficient gene transfer. Based on the bulky mass of head and neck cancer, it is unlikely that the large tumor burdens, which remain even after radical surgery, can be sufficiently transduced even by the highly efficacious, replication-deficient adenoviral vectors. Therefore, and because of the good accessibility, head and neck cancer has become the model disease for therapy with selectively replication-competent adenoviruses. The underlying concept of the use of replication-competent recombinant adenoviruses is based on the capability of adenovirus to induce cell lysis by its progeny inside an infected target cell (336,337). To limit the cytotoxicity only to tumor cells and not to normal cells, researchers exploited the fact that about 50% of tumors carry a mutation in the tumor suppressor gene p53. A recombinant, replication-competent adenovirus was constructed that should specifically replicate only in p53-negative tumor cells (43). For further explanation of this concept, please see Chapter II.D. Although the concept underlying the mode of action of the vector is not yet completely understood, several clinical trials have been performed. The published data, mainly with the vector ONYX-015, are among the most encouraging in clinical cancer gene therapy. With respect to toxicity, results suggest that the intratumoral injection of ONYX-15 limits proliferation of the vector to malignant tissue; it is well tolerated except for transient low-grade fever and injection site pain. Three clinical trials have been formally published so far (338–340): a phase I trial, a phase II trial for intratumoral injection of ONYX-15 alone, and 1 trial for the combination of virus and cisplatin. Five of 36 patients in the phase II trial showed partial or even complete ($n = 3$) responses (339). In the combinatorial approach, 63% as compared to 30–40% in the historical controls showed partial or complete responses (340).

Besides these dominant strategies for HNSCC, immune modulatory approaches have already been tested clinically. Partial responses have been observed in 4 out of 9 patients with advanced HNSCC upon intratumoral injection of HLA-B7 plasmid (Allovectin-7) (94). Among several approaches showing promising preclinical efficacy, including transfer of suicide genes, Bcl-2, superoxide, dismutase (SOD), and EGF receptor, transfer of adenovirus E1A in a liposomal formula-

tion has been tested clinically. It showed only minimal toxicity and modest clinical efficacy with 1 out of 24 patients with recurrent, unresectable HNSCC having a complete response; 2 patients having a minor response; and 7 patients having stable disease (341).

Head and neck cancer is probably the tumor type with the best clinical results in cancer gene therapy obtained so far. This may be due to the good accessibility for intratumoral approaches; the low tendency for metastazation, with the opportunity for long-time follow-ups; and (perhaps) a favorable immunological and intracellular molecular situation. These first successes have encouraged many researchers to believe that less favorable starting points in other cancer types can be overcome, leading to clinical efficacy.

F. Hematological and Lymphatic Malignancies

These malignancies are the domain of chemotherapy. Due to the development of advanced protocols, the initial rate of remission and the number of long-term survivors have dramatically increased. In all stages, the primary therapeutic intention is curative. The usual treatment regime consists of several cycles of intensive or high-dose chemotherapy up to a full eradication of the patient's bone marrow followed by autologous or allogeneic bone marrow transplantation. Due to the good susceptibility of leukemic and lymphatic cells for chemotherapy, conventional treatment usually leaves only minimal residual disease. This residual tumor load can, however, lead to relapses in up to 80% of patients with leukemia (342) and has usually a bad prognosis. Gene therapy could try to prevent this situation.

Several immunological approaches have been tried. Preclinical, in vivo gene transfer of TNF-alpha was used for T-cell lymphoma (343) and myeloma (344), B7 for several lymphomas (345,346), and GM-CSF for T-cell leukemia (347). Transfer of IL-2 into lymphomas is already in a clinical phase I study (348).

Human primary hematological malignant cells are unfortunately highly resistant to transduction by most available vectors. Only recently, modifications of vectors and ex vivo transduction protocols have allowed increased gene transfer—at least into cultured allogeneic vaccine lines with adenovirus, HSV, liposomes, and retroviral vectors. Another problem is the considerable phenotypic heterogeneity of the cancer, which can cause an incomplete representation of potential antigens of the whole malignant cell population in the population selected for gene transfer and vaccination.

Despite these problems, a considerable number of cancer gene therapy trials using ex vivo cytokine-transduced vaccines have been conducted. Among several cytokines, IL-4 and GM-CSF protected best against tumor challenge, and GM-CSF-transduced cells could also inhibit further progression of preestablished lymphatic tumors (349) in a mouse model. Most clinical trials used IL-2, but in others IL-4, 7, 12, IFN-γ, and GM-CSF vaccines were applied.

Vaccinations with the DNA of tumor antigens have also been carried out. Gene therapy provides an advantage here over the use of the respective protein when this is difficult to obtain in the required amount or in the correctly glycosylated form. Encouraging results were obtained in a clinical phase I study of the vaccination of patients with chronic lymphatic leukemia (CLL), with CLL cells adenovirally transduced to overexpress the CD 40 ligand (CD 154); a phase II trial has been initiated (350).

Ex vivo gene transfer into effector cells has also been examined clinically. In a phase I clinical trial, autologous, cytokine-induced killer (CIK) cells ex vivo transduced with IL-2 were infused in patients with metastatic disease. One out of 10 patients had a complete response to the lymphoma (351).

The generation of chimeric T-cell receptors (TCRs) has been another strategy to generate antitumor immunity for B cell lymphoma. T cells are directed against target cells by grafting an antibody V region of desired specificity onto the TCR and the constant regions. The specificity of this approach in vitro has been shown (352).

The transfer of donor leukocytes (353) or EBV-specific cytotoxic T lymphocytes (354) has been a successful approach for the treatment of B cell lymphoma. A potential problem of this strategy, however, could be graft vs. host disease (GvHD). An ingenious way to circumvent this problem is the transduction of the donor T cells with a suicide gene such as HSV-tk to be able to kill the donor T cells by GCV if signs of GvHD appear (355,356). In a clinical trial, GvHD resolved in 2 of 3 patients upon application of GCV. A recent review of the pros and cons of this strategy can be found at (357).

One sustained response in a clinical trial was observed upon the application of TILs engineered to secrete TNF (358).

For therapy of multiple myeloma, direct intratumoral gene transfer of the TNF gene was performed preclinically and a ''substantial gene transfer in nearly 50% of tumors was seen'' (359). Anecdotally, 1 woman received an injection of an IL-2 adenovirus into an occipital myeloma lesion, and gene transfer could be demonstrated although no tumor regression was observed (360). In fact, myeloma cells seem to be among the easiest transducable hematological cells, at least for adenoviruses (361) and AAV (362).

Lymphomas and leukemias have also been targeted with oligonucleotides against myc (263,363,364), bcl-2 (365), myb (366), bcr-abl (363,364), and bcr-abl ribozymes (367).Transfer efficacy of antisense oligonucleotides in vitro and in vivo is highly controversial, but the first clinical trial produced remarkable efficacy with nearly half of the patients showing stale disease and 1 patient being in remission for at least 3 years (Lattime 136, 137).

Therapy-associated side effects like infections and hemorrhages account for 70% of the deaths of adult patients with acute leukemia (368). The transfer of MDR genes into hematopoietic stem cells for chemoprotection holds promise, and clinical studies of the transduction of the MDR gene in patients with relapsed and resistant lymphomas are already under way. This approach, however, runs the risk that tumor cells are transduced, making them resistant to chemotherapy. Only the

future will show whether this problem can be neglected or circumvented (e.g., by targeted vectors).

In summary, it comes as no surprise that hematological malignancies as a systemic disease are the domain of immunological approaches, which have demonstrated clinical success in several cases.

G. Hepatocellular Carcinoma

Although hepatocellular carcinoma (HCC) is of moderate epidemiological relevance in the Western world, it is the most common cancer in large areas in Asia. HCC often remains localized to the liver, but only a minority of patients is amenable to local therapy such as surgery, liver transplantation, or cryo-ablation. Standard chemotherapy is largely ineffective. Therefore, HCC is a suitable target for intratumoral application of therapeutic genes. As demonstrated, adenovirus vectors can easily infect and express different types of genes in tumor cells of HCC (28,95). In addition, the alpha-fetoprotein (AFP) promoter is extremely HCO-specific (369) for achieving tumor-specific gene expression. Using adenovirus mediated gene transfer, different experimental approaches were studied demonstrating significant tumor volume reductions by IL-12 (370), HSV-tk/GCV (371,372), and oncolytic adenovirus (373); combinatorial expression of p53 and p16 (28); or p21 and GM-CSF using an EGF-receptor targeted adenovirus (374).

A pilot clinical study to assess the therapeutic potential of percutaneous intratumoral injection of wild-type p53 (wt-p53) in patients with primary hepatocellular carcinoma was initiated in 1996. Nine patients with primary hepatocellular carcinoma and 6 patients with colorectal liver metastases received percutaneous injections of a wild-type p53 DNA-liposome complex. In contrast to nonresponders with colorectal metastases, 4 of 9 patients with HCC showed a reduction of tumor volume and a significant decrease in serum AFP levels (375, 288). Phase I and II trials were conducted in which injection of B7-1 costimulatory molecules resulted in 12 of 33 patients having a significant drop in AFP levels. Three patients had a greater than 50% decrease in tumor size, allowing later surgery of initially inoperable tumor (376). A phase I trial was recently published that compared intratumoral injection of ethanol with that of conditionally oncolytic, replication-competent, E1B55K-deleted adenovirus. In the gene therapy group, 1 patient showed a partial response and 4 patients had progressive disease. In the ethanol-treated group, 2 patients had stable disease and 3 patients showed disease progression (377).

H. Lung and Pleural Cancer

In the Western world, lung cancer has become the most frequent tumor for males (368). The main reason for this is smoking; more than 90% of these patients are or were smokers. The prognosis of this cancer is bad. Due to regional or systemic metastases, tumors can be resected in only 25% of the patients. Only one-fourth of these patients will survive 5 years; only 6% of the patients are curable. Because of the tendency for early metastasis, gene therapy approaches aiming at a systemic response such as immuno-gene therapy are needed. A potent evocation of an immune response has only recently been reported in animal experiments (378). Mesothelioma is a rare type of cancer originating from the pleura.

Because lung cancer metastasizes early, this tumor is a very difficult target for gene therapy. However, the high epidemiological relevance of lung cancer creates an urgent need to develop alternatives to the standard therapeutic approaches. This is especially true for non small cell lung cancer (NSCLC). Because NSCLC is in most of the cases highly resistant to any kind of chemotherapy, and well-documented studies about genetic defects in NSCLC exist, this tumor was from the beginning an attractive target for the use of tumor suppressor genes, e.g., p53. Impressive results were obtained in preclinical studies: significant tumor growth inhibition in subcutaneous and orthotopic animal models (379,380). Therefore, one of the first cancer gene therapy trials was initiated to treat NSCLC by gene transfer of p53. A retroviral vector containing the wild-type p53 gene under control of a beta-actin promoter was used. Nine patients for whom conventional treatments had failed received direct injections into the tumor. Despite a low efficacy of gene transfer, and lacking evidence for an involvement of T-cell mediated immunity, partial tumor regression was noted in 3 patients, and tumor growth was stabilized in 3 other patients (381). To improve the in vivo gene transfer efficacy, adenoviral vectors were used for p53 gene transfer in 3 additional studies (382–384), and in 3 more studies p53 adenovirus was combined with chemotherapy (385–387). In several patients in these trials, transient local control was observed. This was clearly attributed to the gene therapy treatment.

Lung cancer has also been a model disease for antioncogene therapy. The K-ras oncogene is frequently overexpressed in lung cancer. Intratracheal transfer of retroviruses carrying an antisense K-ras construct markedly reduced tumor size and the number of lung tumors in nude mice (388). Another candidate for antisense therapy is the ErbB2 transmembrane protein kinase receptor whose aberrant expression has been shown to contribute to malignant transformation and progression. The promoter of the ErbB2 gene could be used for expression of toxic transgenes. Promoters that are activated by ionizing radiation (389) have also been used for this purpose. Researchers hope that sufficient specificity for tumor deposits will be achieved in the future, enabling even metastases to be efficiently transduced without toxicity for the surrounding normal tissue. Under these circumstances, the combination of gene therapy with conventional therapy could be a particularly attractive strategy as discussed above for p53 and cisplatin.

To date, there has been no published trial using suicide-gene therapy in patients with lung cancer. However, there are 2 reports of the treatment of patients with pleural melanoma (390,391). In both trials, HSV-tk adenovirus was injected intratumorally and only minimal side effects were observed. A marked difference between the trials was that in 1 study a high dose of glucocorticosteroids was applied to counteract vector-related immune responses (64). In this study, partial

tumor regressions were observed in some patients; 2 of them even remained tumor-free 3 years after treatment.

Several phase I and II immuno-gene therapeutic clinical trials for the treatment of lung cancer have been conducted using the adenovirally GM-CSF-transduced, allogenic, NSCLC cell line GVAX (392). An interim analysis of 30 patients from a multicenter phase I and II trial demonstrated a major response rate in 18% of the patients, 10 of whom showed complete tumor remissions (393).

Partial regression of a lung mass was observed in 1 of 10 patients treated with IL-2 transfected TILs (394). Another immuno-gene therapeutic approach with promising preclinical results is the application of adenovirally IL-7-transduced DCs for the treatment of lung cancer (395). A clinical trial of direct intratumoral injections of vaccinia virus harboring IL-2 for the treatment of pleural mesothelioma led to diverse immunological responses, although no significant tumor regressions were seen (396). In summary, some clinical efficacy with cancer gene therapy has been demonstrated. However, this is clearly neither satisfactory nor sufficient for this devastating disease.

I. Melanoma

Malignant melanoma is a tumor of average incidence worldwide but with extremely high incidence in certain areas such as Australia. Worldwide, an annual increase in incidence of 6–7% was reported (397). Melanoma is a tumor with a very high resistance to treatment. Treatment schedules, including radiation, chemotherapy, and combinations of both, have no significant impact on the overall survival of the patients (398,399). Although the primary tumor can usually easily be excised, distant metastases cause the death of nearly all patients. Early and fatal metastazation is 1 reason why this disease is an important target for approaches like immunotherapeutic therapies from which a systemic antitumor efficacy can be expected. Fortunately, melanoma displays a naturally high immunogenicity, which facilitates the recognition of the tumor by the immune system.

Basically, all principles of immuno-modulation described at the beginning of this chapter have been applied to melanoma. Trials in melanoma alone account for 54% of all open immuno-gene therapy trials in the U.S. At the time of writing, the number of clinical immuno-gene therapy studies for melanoma worldwide exceeds 50. The earliest trials were based on the transfer of TNF-transduced TILs (6). Phase I trials are now closed, but due to minor success no further trials entirely focusing on TILs have been initiated. However, in a later trial, TILs obtained from a patient's tumor nodules were injected with the HLA-B7 molecule, expanded and reinfused, and direct immunological effects were demonstrated (400). The use of chimeric T-cell receptors with cytokine or melanoma antigen domains is an interesting approach in the area of adoptive gene therapy with genetically modified, immune cells. In this approach, CD8 + T-cells are redirected to the tumor and create a favorable cytokine-rich environment (401).

Recently, much has been expected from adoptive transfer of dendritic cells (DCs), which are probably the most potent antigen-presenting cells in the body. They are also easy to transfect with several vectors. DCs have been transduced ex vivo with tumor antigens and costimulatory molecules. MART-1, antigen-transfected, dendritic cells in particular generated MART-1-specific immunity and arrested the growth of established tumors (402,403). Recently, it has been clearly shown that $CD8^+$ T-cells receive CD4 help directly through the receptor CD40 and that this interaction is fundamental for $CD8^+$ T-cell memory generation (404). Intratumoral injections of DCs that had been transduced in vitro with CD40-ligand led to regression of injected, as well as distant, B16 melanoma nodules (405).

The majority of preclinical and clinical data for melanoma immuno-gene therapy has been generated in vaccination trials. Vaccination is performed traditionally with autologous tumor cells, but allogeneic vaccines consisting of autologous fibroblast or standardized gene-transduced cell lines are used as well (reducing cost and time). Many human trials using either cytokines (e.g., IL-2,-4,-6,-7,-12, IFN-α, and IFN-γ) or costimulatory molecules have been completed or are still ongoing. The best results in clinical vaccination trials have probably been obtained with granulocyte-macrophage, colony-stimulating factor (GM-CSF); this had already shown the greatest degree of systemic immunity among 10 different cytokines in preclinical models (406). In a melanoma vaccination trial with GM-CSF-transduced, autologous, melanoma cells, extensive tumor destruction and pronounced immunological responses were observed in 11 of 16 patients (407). GM-CSF was also transferred intratumorally using vaccinia virus (485) or transfected into tumor cells to prime tumor-derived lymph node cells in a trial of adoptive gene transfer (486). Excellent responses, including complete remissions, have been obtained in both types of clinical studies.

More than 50 patients in 5 different studies have received intratumoral injections of HLA-B7 DNA using liposomes (348,408). DNA or protein was detected in the great majority of the patients. Toxicity not attributable to the mechanical irritations was the exception, and local or even general responses were seen in one-third of the cases.

Published results of a trial involving multiple intratumoral injections into melanoma metastases of a retroviral vector carrying the IFN gene showed either stable disease or partial or complete response of the injected lesions (409).

Besides the immunological approaches illustrated above, which clearly dominate gene therapy of melanoma, preclinical suicide-gene (Table 1) and tumor-suppressor gene (p53) (Table 1) therapies have also been performed. Combinatorial approaches (e.g., cotransfer of suicide genes and cytokines) have resulted in additive, tumor growth inhibition (344,410). A clinical phase I/II trial (411) for suicide therapy of metastatic melanoma with retroviral HSV-tk vectors resulted in significant tumor necrosis in 3 of 8 patients despite a low transfection efficacy of less than 1%.

Intratumoral injections of a p53 adenoviral vector for the treatment of patients with breast and melanoma metastases were associated with minimal toxicity and the detection of p53 mRNA in biopsies of injected tumors (412).

In the preclinical stage, treatment of melanoma cells with oncogene Ha-ras (413) or c-myc (414)-specific antisense oligonucleotides led to good antitumor efficacy in SCID mice. The application of dominant, negative Stat3 cancer-related gene led to tumor regressions due to massive apoptosis (414). In 1 clinical trial for the treatment of malignant melanoma with dacarbacin and antisense-bcl-2, one complete remission has been observed (487).

In summary, the preclinical and in particular the clinical results obtained with immuno-gene therapy of melanoma are among the most encouraging findings in the field of cancer gene therapy.

J. Osteosarcoma

Osteosarcoma primarily afflicts young people within the first decades of life and accounts for 5% of all childhood malignancies (415). The overall 2-year metastasis-free survival rate approaches 66% (416,417). Metastases, mainly to the lung, are the predominant cause for mortality. Therefore, immunological approaches such as the in vivo transfer of the B7 gene (418) may be particularly fruitful. However, the osteocalcin promoter constitutes an available tissue-specific promoter, which potentially allows systemic or regional treatment with cytotoxic genes. It has already been proven to be efficient in vivo in an adenoviral context (419). The osteocalcin promoter expressing the adenoviral E1A gene to allow for tumor-specific replication will also be used for intravenous application in a clinical trial for the treatment of metastasized osteosarcoma (420). Other successful preclinical approaches include aerosolic adenovirus-IL-12 (421), PEI-IL-12 (422), or PEI-p53 complexes for the treatment of lung metastases; adenovirus-IL-3-β gene transfer for isolated limb perfusion (423); and intratumoral injection of retrovirus VPCs-HSVtk (424).

K. Ovarian Cancer

Ovarian cancer is the leading cause of death from gynecological malignancies in women (419). Due to improvements in surgery, radiation, and chemotherapy techniques, the 5-year survival rate has improved over the last 20 years. However, over two-thirds of the patients have advanced stage disease at presentation; despite transient responses, the long-term survival of these patients rarely exceeds 15% to 30%. Although even patients with advanced stages often have their disease confined to their abdomen for extended periods of time, intraperitoneal chemotherapies have only moderate success. Basically, this is because they do not provide the reduced toxicity profiles initially hoped for. Therefore, ovarian cancer has become one of the model diseases for gene therapeutic approaches with intracavital vector applications.

Several clinical studies have been initiated with HSV-tk as transgene in which vectors or modified cells were applied intraperitoneally. Transfer of adeno-HSVtk at doses up to 1×10^{11} pfus led to stable disease in 5 of 14 patients and transient fever in 4 patients. Transient hematological grade 3 and 4 toxicities were observed if an adeno-HSV-tk was combined with topotecan chemotherapy, but since toxicity was not related to vector dose, these side effects are more likely related to the chemotherapy (425). In a vaccine/suicide trial with patients receiving irradiated PAI-1 ovarian cancer cells ex vivo transfected with HSVtk, a high incidence of fever and abdominal pain was seen in several patients, along with resolution of ascites or decreased CA-125 levels (426). Results of a trial using retroviral VPCs (427) have not yet been published.

Phase I trials have also been initiated for adenoviral delivery of an anti-erbB-2, single-chain antibody gene (428,429). This ''intrabody'' approach could become a potent alternative to antisense strategies. In a clinical trial, adeno-anti-erbB-2 was injected intraperitoneally. Despite the relatively low dose of up to 1×10^{11} pfus, 5 of 13 evaluable patients had stable disease (425).

The results of 2 trials using p53-adenovirus have been published. In 1 trial, 2 of 11 patients had a partial response, 4 patients had stable disease, and no major toxicity was reported despite multiple injections of up to 3×10^{12} viral particles (430). In the second phase I/II trial enrolling 36 patients, adeno-p53 was administered either alone or combined with chemotherapy at single or multiple doses. A comparison with historical controls led the authors to suggest 1 of 2 explanations: either the combination of chemotherapy and gene therapy had a synergistic effect; or gene therapy changes the nature of the cancer, contributing to a chronicity of the disease that favorably impacts survival (431,432).

A trial with replication-competent adenovirus showed significant toxicity but no efficacy (433).

Finally, intraperitoneal injection of a retrovirus harboring a BRCA-1 splice variant showed partial responses in 3 of 12 patients in a phase I study. However, the lack of any response led to an early termination of a subsequent phase II study (434,435). The authors discuss differences in tumor burden and immune system status of the patients as possible reasons for the differing response to BRCA1 gene therapy.

Further interesting approaches with significant growth retardations of ovarian carcinoma have been demonstrated in preclinical experiments. These include liposomal transfer of E1A (436) or mutant SV 40T antigen (437). Preliminary data from a clinical trial for intracavital application revealed (279) HER-2/neu downregulation, increased apoptosis, and reduced proliferation. The most common treatment-related toxicities were fever, nausea, vomiting, and/or discomfort at the injection sites.

In summary, intracavital gene therapy of ovarian cancer showed clinical antitumor effects with immunological and nonimmunological approaches.

L. Pancreatic Cancer

This disease has a low incidence but a very bad prognosis, mainly because the primary tumors are not resectable at the

time of discovery. It accounts for only 2% of all newly diagnosed cancers in the United States but for 5% of all cancer deaths (438). Moreover, the tumors are highly chemoresistant. Partial remissions of up to 15% of the cases have only recently been seen with the new drug gemcitabine (368).

More than 80% of pancreatic tumors contain a mutation of the ras oncogene in position 12 (439). Since this mutation (as well as others) is recognized by the immune system, ras-peptide-based immunotherapy has been successful in mice. Clinical studies have been performed and an association between prolonged survival and an immune response against the vaccine was seen (440–442). Recently, antigen-presenting cells, genetically modified to express tumor antigen, were shown to induce antigen-specific cytotoxic T cell responses in vitro and in vivo (443). H-ras antisense oligos have also been used in a phase II clinical trial, and clinical stabilization was seen in 2 out of 16 patients (444).

Because the local disease is often life-limiting in pancreatic cancer, the disease is attractive for cytotoxic gene therapy approaches (445–447). A combination of HSV-oncolysis and HSV-tk/GCV cytotoxicity increased the percentage of mice with peritoneal pancreatic tumors, obtaining significantly prolonged lifespan to 70% as compared to 40% with oncolysis alone (448). A very interesting trial used ex vivo suicide, gene-transduced, autologous tumor cells for localized activation of chemotherapy. Genetically modified allogeneic cells, which expressed a cytochrome P450 enzyme, were encapsulated in cellulose sulphate and delivered by supraselective angiography to the tumor vasculature. These cells locally activated systemically administered ifosfamide. The tumors of 4 of 14 patients regressed after treatment, and those of the other 10 individuals who completed the study remained stable. Median survival was doubled in the treatment group by comparison with historic controls, and 1-year survival rate was 3 times better (449).

Effective preclinical gene therapy for pancreatic cancer was also seen by combining oncolytic, conditional, replication-competent adenoviruses and IL-2 or IL-12 adenoviruses (450). Replication-deficient IL-2 adenoviruses were used in a phase I/II trial for digestive cancer, and a single intraoperative intratumoral injection did not cause any adverse effects (451).

In a phase I study, allogenic pancreas cells engineered to secrete GM-CSF were intradermally applied, and 3 patients who had received higher doses of cells seemed to have increased survival times (452).

M. Prostate Carcinoma

Prostate cancer (PCA) is the most frequently diagnosed cancer in men in the U.S. and the second leading cause of death from malignancy (453,454). Locally restricted tumors can be treated by surgical resection or radiotherapy. Androgen-ablative therapy often induces dramatic responses, but virtually all patients progress to an androgen-refractory state with a median survival of 12–18 months. The prostate is a unique accessory organ and expresses several hundred unique gene products as potential targets for gene therapy. Prostate cancer can therefore serve as a model disease for tumor-specific gene therapy. The efficacy and specificity of the PSA promoter has been proven in animal experiments (455). This promoter has also been used to confer prostate-specific replication of conditionally replication-competent adenoviruses (50). A clinical trial using this vector for injection into locally recurrent prostate carcionoma provided relative safety with no grade 4 toxicity and a more than 50% reduction in PSA levels in all patients treated with the highest dose (456).

More than 20 immuno-gene therapeutic trials for prostate cancer have been initiated, and some results have been published. A GM-CSF-secreting, autologous PCA vaccine increased antibody titers against prostate tumor antigens (457); direct intratumoral injection of liposomal IL-2 plasmid led to decreases in serum PSA levels in 80% of patients (458); and vaccinia virus MUC-1-IL-2 also decreased PSA levels (458).

As an example of gene-replacement therapy, a trial with direct injection of retrovirus-BRCA-1 should be mentioned: while it did not reveal any antitumor efficacy, it did at least demonstrate the safety of the approach (459). Clear objective responses were observed when adenovirus-HSV-tk was injected into the tumorous prostate. At the highest treatment dose, PSA levels declined by 50%. However, reversible grade 4 thrombocytopenia and grade 3 hepatotoxicity occurred (460).

Successful preclinical experiments have been reported for the transfer of the antiIGF-1 receptor (461), p21 (462), p53 (462,463), p16, and antisense myc (464). Three gene therapeutic clinical trials have already been initiated with antisense myc.

The future use of prostate-specific regulatory elements and target genes holds promise in the treatment of disseminated disease, the major cause of death in prostate cancer patients. Treatment will eventually be possible if systemic application of the vectors harboring cytotoxic genes can be done without major toxicity.

V. CONCLUSIONS

We have now seen nearly 15 years of preclinical gene transfer and more than a decade of clinical gene therapy. A wide variety of vectors and transgenes has been successfully tested in animals. Several types of vectors and many different therapeutic principles have been evaluated clinically, producing 403 studies of cancer gene therapy (Tables 2–4).

The general outcome of these clinical studies indicates that gene therapeutic vectors are usually tolerated with mild-to-medium acute toxicity. The toxicity has been reversible in all cases. No cases of long-term toxicity have been reported. In the majority of clinical trials, at least some efficacy was seen. In some trials, a clear benefit for the patient was observed in comparison with either historical controls or (in some exceptional cases) with internal controls. Apparently, in all cases where the best results in clinical trials have been achieved, the cancer target was naturally most well suited to current cancer gene therapeutics. Examples of this are the good accessibility of superficial bladder cancer for intravesically in-

(*text continues on p. 566*)

Table 2 Cancer gene therapy, in vivo gene transfer, preclinical studies, 1990–1998

Strategy	Transgene	Vector	Route	Dose	Efficacy	Animal model, organ, cell line, site, pretreatment size	Reference[a]
Anti-Oncogenes

Transgene	Vector	Route	Dose	Tumor type	Indication of gene transfer	Clinical efficacy	Lab findings efficacy	Toxicity	References[a]
HSV-tk	Ad	i.tu.	$2*10^9$–$2*10^{12}$ particles	advanced recurrent malignant brain tumors		death within 10 month (77%) or 25 month (14%), survival longer than 29 months (7%)	necrosis, infiltration	central nervous system toxicity	Trask TW, 2000 [13]
wt p53	Ad	i.tu.	tumor size dependent	metastatic melanoma or breast cancer	mRNA detectable	stable disease (67%), progressive disease (33%)		mild reactions	Dummer R, 2000 [14]
HLA-B7	Lip	i.tu.	max 250μg DNA	renal cancer	gene product detectable	stable disease or progressive disease	no autoimmune reponse	no complications	Rini BI, 1999 [15]
HSV-tk	Retro	intracerebral		recurrent glioblastoma multiforme	vector DNA in leukocytes	marginal effect		transient neurological disorders	Shand N, 1999 [16]
IL-2	Lip	i.tu.	6*10–300μg	metastatic melanoma, renal cell carcinoma	plasmid detectable	response (86%)	CD8+ infiltration	mild constitutional symptoms to grade III toxicity	Galanis E, 1999 [17]
IL-2	Ad	s.c.	10^7–10^{10} pfu	melanoma or breast cancer	mRNA and vector sequences detectable	24% patients showed incomplete local tumor regression	tumor necrosis and lymphatic infiltration	local inflammation	Stewart AK, 1999 [18]
wt p53	Ad	i.tu.	10^6–10^{11} pfu	head and neck cancer	expression detectable	27% of patients stayed free of disease		fever, injection site pain	Clayman GL, 1999 [19]
IFN-γ	Retro	i.tu.	$1,5*10^8$ cfu	advanced melanoma	DNA-transduction detectable	feasiblity confirmed		no complications, no replication of vector	Nemunaitis J, 1999 [20]
IFN-gamma	Retro	i.tu.	multiple times max 10^7 pfu	advanced melanoma		53% stable disease, 47% elevated anti-tumor antibodies	antitumor immune response	Grade I/II events, no replication of vector	Nemunaitis J, 1999 [21]
HSV-tk	Ad	i.tu.	10^8–10^{11} infectious units	adenocarcinoma of the prostate	Vector detectable by PCR	objective response (17%)		Grade I/II events, no replication of vector	Herman JR, 1999 [22]
wt p53	Ad	i.tu.	10^6–10^{11} pfu	lung cancer	Vector DNA and RNA detectable by PCR	partial response(8%), stable disease(64%), progression (28%)	apoptosis detectable	Grade I/II events, one patient grade III	Swisher SG, 1999 [23]
wt p53	Ad	i.tu.		lung cancer	gene transfer detectable by RT-PCR and PCR	Stable(66%) or progressive disease(33%)		flu-like symptoms	Kauczor HU, 1999 [24]
HSV-tk	Retro	cells injected into surgical cavity		glioblastoma		25% of patients survived longer than 1 year, 1 patient free of disease		no complications	Klatzman D, 1998 [25]
HSV-tk	Retro	i.tu.	$7,6*10^8$ to $1,2 \times 10^9$ cells	metastatic melanoma	Transgene detectable by PCR	Limited long-time tumor response		Inflammatory skin reactions, fever	Klatzman D, 1998 [26]

HLA-B7	Lip	i.tu.		squamous cell carcinoma	HLA-B7 detectable	44% partial response	Apoptosis-induction if transgene detectable	no complications	Gleich LL, 1998 [27]
none	Onyx-015	i.tu.	$5*10^{10}$ pfu	recurrent squamous cell cancer	tumor-selective viral replication	Objective responses	Necrosis of tumor	acceptable	Khuri FR, 2000 [28]
wt p53	Ad	i.tu.	10^{7}–10^{10} pfu	lung cancer	RNA detectable	transient local disease control (66%)		no complications	Schuler M, 1998 [29]
wt p53	Ad	i.tu.		lung cancer	expression evident	potentially useful clinical responses		no complications	Roth JA, 1998 [30]
IL-12	Cells	s.c.	10^{5}–10^{7} cells	melanoma	strong secretion of IL-12	increased antitumor immune response (66%)		no complications	Sun Y, 1998 [31]
HSV-tk	Ad	pleural cavity	10^{9}–10^{12} pfu	mesothelioma	gene transfer shown		Strong immune responses	minimal side effects	Sterman DH, 1998 [32]
HLA-A2	Lip	i.tu.	up to 80 μg DNA	several	expression detectable	Complete (25%) and partial response (50%)	strong local responses	no significant side effects	Hui KM, 1997 [33]
HLA-B7	Lip	i.tu.	up to 250 μg DNA	metastatic malignant melanoma	expression detectable	significant responses (60%)			Waddill W 3rd, 1997 [34]
HLA-B7	Lip	i.tu.	up to 250 μg DNA	colorectal carcinoma	plasmid, mRNA, Protein detectable			no serious toxicity	Rubin J, 1997 [35]
IL-2	Retro	chest cavity	$1–6*10^{10}$ cells	lung cancer		tumor size decreased in 1 of 6 patients		minimal fever	Tan Y, 1996 [36]
none	Newcastle Disease Virus	i.v. Intravascular	up to $12*10^{10}$ pfu	advanced solid cancers	replication of PV701	Objective responses	lymphoplasmacytic infiltrate	flu-like symptoms	Pecora AL, 2002 [37]
none	ONYX-015		$2*10^{8}$–$2*10^{12}$ particles	gastrointestinal carcinoma	viral replication detectable	objective response in combination with chemotherapy	increasing antibody titers	fever, rigors and fatigue	Reid T, 2001 [38]

stalled viruses; the easy access to manifestations of head and neck cancer for the intratumoral transfer of replication-competent vectors; and the good infectability of HCC by adenoviral vectors or of glioblastoma by HSV (which is a neurotrophic virus by nature). Particularly encouraging results have been obtained in many immuno-gene therapeutic trials that do not depend as heavily on efficacy of gene transfer as nonimmunological approaches. The sometimes astonishing modulatibility of vectors gives rise to the hope that cancers that are less suited for cancer gene therapy will also have particular vectors designed against them.

Although most clinical studies were designed as phase I or phase I/II trials with the aim of dose-finding and toxicity evaluation, the lack of a real breakthrough in clinical efficacy has been disappointing—at least for those who had envisioned a very rapid development of gene therapy into a routine treatment modality. The discrepancy between excellent preclinical data and the clinical outcome has been particularly difficult to understand, especially for the public. There are several reasons for this discrepancy. First of all, animal models are artificial models that have inherent simplifications as compared to the clinical situation. A well-known argument is that animal tumors are usually developed from 1 fairly homogenous cell line, whereas human tumors are often very heterogeneous, though they have also originated from a single clone. Consequently, a strategy that targets one specific molecular event in an animal tumor may only be effective against a fraction of tumor cells in a patient. But there are less sophisticated reasons such as the mere difference in size of tumors between a rodent and a human. This may also dramatically affect clinical outcome. Another explanation is that dose-limiting toxicity has not been reached in most of the trials performed so far. In addition, mice are probably more robust and will probably tolerate higher doses. It is evident that some kinds of treatments well tolerated in mice would hardly ever be considered for humans.

Other setbacks for cancer gene therapy have included the first severe adverse events in gene therapy: the death of a young man in a trial for the metabolic disorder OTC and the very recent occurrence of a case of leukemia in what was a very successful trial for severe combined immunodeficiency up to that point.

All these considerations lead to the conclusion that the therapeutic window of most cancer gene therapeutic strategies is apparently still too narrow to allow prominent antitumor efficacy. However, nearly all kinds of medical therapy have been confronted with this problem during their development into routine clinical applications. This therapeutic window can be broadened by either creating less toxic medicines, which allows one to increase the dose, or by creating more efficient medicines, which allows one to obtain efficacy without the necessity of increasing the dose. Both avenues have been followed in cancer gene therapy. An example of a less toxic vector is HD-Ad as compared to first generation Ad. An example of a more efficient therapeutic principle is the combination of conventional, suicide-gene strategies with replication-competent viral vectors to increase the efficacy of gene transfer. A third strategy, which allows a reduction in the dose without losing efficacy, is vector targeting—either in the form of transductional or transcriptional targeting. This extremely promising approach will eventually reveal the real potential of gene therapy: the design of intelligent drugs that are capable of overcoming intelligent cancer.

But won't the design of small molecular drugs be intelligent enough to solve the cancer problem? Do we need gene therapy if small molecules can do the job? Especially if one considers the recent genomics-related, dramatic increase in knowledge about potential drug targets? Maybe in some cases. Admittedly, the use of a vehicle to transfer a gene into the human body is less direct and usually more complicated than conventional methods of cancer therapy. However, the interposition of several steps between the application of an active substance and the generation of an observable effect allows an unusual high degree of freedom of regulation. In cancer gene therapy, one can comply with the biology and especially the weak spots of the cancer cells to a degree never before seen. Fortunately, nature seems to be predictable to a certain degree, which makes such complex therapeutic strategies possible. Since we are still far away from such a tight adaptation of our vectors and transgenes to the specificities of the cancer cells, it comes as no surprise that to date clinical efficacy of cancer gene therapy has not been convincing. However, the potential fruitfulness of a new method cannot be judged by its initial success but rather by the general limitations of the whole concept. Since in the area of cancer gene therapy such limitations have not yet been seen, a broad breakthrough in therapeutic efficacy will most likely be a matter of time.

ACKNOWLEDGMENTS

I would like to thank Anastassia Brodskaia and Dennis Kobelt for excellent technical assistance.

Overcoming Barriers to Efficient Airway Epithelial Gene Transfer

Larry G. Johnson

I. INTRODUCTION

The identification of human genes linked to clinical disease has raised hopes for the development of genetic therapies for many inherited and acquired diseases. Mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene lead to a common inherited disorder, cystic fibrosis (CF), with a high morbidity and mortality that makes it an attractive target for gene therapy. The autosomal inheritance pattern of this monogenic disorder in which heterozygotes are phenotypically normal, combined with the relatively large numbers of patients available for clinical studies, has lead to the establishment of CF as the prototypical disease for investigation of gene therapy in the lung.

Because CF heterozygotes exhibit a normal phenotype, introduction of a single wild-type (normal) copy of the gene into defective CF epithelial cells should restore the normal phenotype. Restoration of CFTR-mediated Cl^- transport function following introduction of wild-type *CFTR* into CF airway epithelial cells in vitro using retrovirus, vaccinia virus, liposomes, and adeno-associated virus (AAV) and adenovirus (Ad) vectors is consistent with this concept (1–5). These studies have also established the feasibility of gene therapy for CF.

The cellular targets for CF gene therapy in humans have not been clearly elucidated. The site where CF lung disease begins remains controversial with both the superficial columnar epithelial cells lining the lumen of the small airways and the serous cells of submucosal glands having been identified as potential sites. Clinical data tends to support the theory that the disease begins in the small airways (6,7), whereas the submucosal glands are the predominant site of CFTR expression (8). Where the disease begins is relevant because luminal (airway) delivery of gene transfer vectors primarily targets the superficial columnar airway epithelium, whereas intravenous (blood) delivery may be required to target the submucosal glands and basal cells in the airway.

Stem cell niches may also exist within the lung that may ultimately be the targets for airway gene transfer. These stem cell niches appear to consist of subpopulations of submucosal gland duct cells in the proximal airways and subpopulations of clara cell and/or clara cell secretory protein-expressing cells in the distal airway (9,10).

Following initial in vitro complementation studies, investigators rapidly moved to clinical safety and efficacy trials of gene transfer vectors delivered by luminal application to the airways of CF patients. Although some evidence for gene transfer was detected, the efficiency and efficacy of gene transfer failed to meet expectations and did not fully correct the known functional defects ascribed to this disorder (11–25). This failure forced exploration of potential barriers to gene transfer in airways and stimulated efforts to develop strategies to overcome these barriers. In this chapter, we discuss the barriers that have become apparent from preclinical and human studies, and explore current strategies to overcome these barriers to luminal airway gene transfer.

II. VECTORS FOR LUNG GENE TRANSFER

Naturally occurring viruses are attractive for gene transfer vectors because they have evolved the ability to introduce their own viral nucleic acid (DNA or RNA) into the host cell nucleus, leading to expression of viral genes that promote viral replication. This property has been exploited for the develop-

ment of viral vectors that introduce and express therapeutic genes (cDNAs) in lieu of their viral structural genes, which have been deleted. Nonviral vectors based on cationic lipids and poly-L-lysine-based polymers have also been developed. The characteristic features, advantages, and disadvantages of Ad, AAV, and nonviral vectors are summarized in Table 1.

Twenty-two phase I and II clinical gene transfer safety and efficacy trials in CF patients have been registered with the Office of Biotechnology Activities at the National Institutes of Health (http://www4.od.nih.gov/oba/rac/clinicaltrial.htm), and many others have been performed in the United Kingdom, France, and Italy. Most of these protocols involve direct delivery of CFTR vectors to nasal or lower airway epithelia, whereas the remaining trials deliver an alpha-1 antitrypsin lipoplex to the nasal airway and AdCFTR vectors intradermally. Initial phase I trials evaluated single administration of Ad-*CFTR* vectors to the nasal and/or lower airway epithelia of CF patients. Subsequent trials of Ad vectors have evaluated the feasibility of repetitive dosing and the safety and efficacy of aerosolized Ad vector administration. Trials of cationic liposomes complexed to CFTR plasmid DNA (lipoplexes) have increased in number, and in the past 2 to 3 years, trials of aerosolized AAV-mediated gene transfer to CF airways have been initiated. One trial of stabilized CFTR polyplexes (poly-L-lysine complexed to CFTR plasmid DNA) has also been registered, but clinical data have not been reported for this trial.

The preliminary results of the aerosolized AAV2 trial are perhaps noteworthy (see www.cff.org) (26). This study is a randomized, double-blinded, placebo-controlled trial of repetitive aerosol administration of an AAVCFTR vector (tgAAVCF) to 37 subjects (17 placebo, 20 aerosolized tgAAVCF) with mild lung disease. Subjects received 3 doses of 10^{13} DNase-resistant tgAAVCF particles at 30-day intervals. Preliminary results suggested a statistically significant improvement in FEV1 at 30 days with decreased IL-8 levels in subjected receiving aerosolized vector as compared with placebo controls. These data have not yet been published, but have stimulated initial planning for a larger trial to assess efficacy.

Despite these data, the general consensus from the literature would suggest that (1) in vivo gene transfer efficiency and efficacy has been inadequate to correct the functional properties ascribed to this disorder, (2) the inefficiency of all vectors tested would suggest that common barriers to gene transfer may exist in addition to vector-specific barriers, and (3) immune or inflammatory reactions may also limit gene transfer, particularly with regard to Ad vectors and some lipoplexes. In the next section, we focus on barriers in the airway lumen, at the cell surface, and intracellular barriers that limit binding, entry, and gene expression. Although safety is a major concern, immune barriers (e.g., neutralizing antibodies and immune/inflammatory responses to the administered vector that limit transgene expression) are not discussed in any detail because the major limitation to CF airway gene transfer is low efficiency.

III. BARRIERS TO AIRWAY GENE TRANSFER

Several barriers to luminal airway gene transfer have been described. These include contents within the airway lumen, such as mucus, inflammatory cells, or bacteria, and cell-associated components of the airway surface liquid (ASL) and glycocalyx. These components are referred to collectively as nonspecific barriers. Cellular barriers to airway gene transfer that are specific for a particular gene transfer vector (vector-

Table 1 Vectors for Airway Gene Transfer

Gene transfer vectors	cDNA insert size (kbp)	Duration of expression	Transduction of nondividing cells	Immune/inflammatory response	Risk of insertional mutagenesis
Adenovirus					
First Second generation	7–8	Transient	Yes	Humoral/cell	Minimal
Helper dependent	>30	Transient[a]	Yes	Humoral/cell	Minimal
Adeno-associated virus	4.5	Long term	Yes	Humoral	Low
Retrovirus					
MLV[b]	7	Long term	No	None	Yes[c]
Lentivirus[d]	>7	Long term	Yes	None	Yes
Cationic liposomes	>10	Transient	Yes	Inflammatory	Minimal
Polymers	>10	Transient	Yes	Unknown	Minimal

[a] Transient expression from helper-dependent Ad vectors can be prolonged.
[b] Derived from MLC.
[c] Two cases of leukemia have been reported in a human trial of X-linked severe combined immunodeficiency in which human stem cells were transduced with an MLV vector containing a gamma-C transgene under the control of the retroviral LTR.
[d] Derived from human immunodeficiency virus, equine infectious anemia virus, or feline leukemia virus. Experience with helper-dependent adenoviral vectors is limited.

specific barriers) include factors affecting cell binding and entry, nuclear translocation, and factors limiting transgene expression post nuclear entry. These barriers combine to make in vivo gene transfer to human airways inefficient.

A. Nonspecific Barriers to Gene Transfer

1. Luminal Contents

The current understanding of CF disease pathogenesis is based on mutant CFTR-mediating defective ion transport that reduces ASL height and volume with resultant abnormal secretions, ineffective mucociliary clearance, bacterial proliferation with multiresistant organisms and chronic inflammation, bronchiectasis, and premature death (27–30). An inflammatory response characterized by a massive influx of neutrophils, which releases oxidants and proteolytic enzymes promoting tissue injury and bronchiectasis, is a hallmark of this disorder. The influx of neutrophils also increases the load of DNA and actin in the airway secretions of the CF lung, leading to a markedly increased sputum viscosity with markedly elevated levels of the proinflammatory cytokines TNF-α, IL-1β, IL-6, and IL-8 that perpetuate the inflammatory response (31). This exaggerated inflammatory response with abnormal secretions, inflammation, and pseudomonas colonization is established early in life, often in the first year (32–35). Because current therapies fail to eradicate the chronic pulmonary infection and inflammation of the CF lung, luminal gene transfer approaches targeting the superficial airway epithelium must overcome the inflammatory response in order to gain vector access to the airway epithelium.

Stern et al. investigated the effect of fresh sputum obtained from CF patients on gene transfer to primary airway cells and to CF cell lines in vitro(36). A dose-dependent inhibition of gene transfer to COS-7, 16HBE14o$^-$, and 2-CFSMEO cells mediated by the cationic liposome DC-Chol/DOPE and an Ad-*lacZ* vector was detected in the presence of ultraviolet light-sterilized CF sputum. The effects of CF sputum on liposomal gene transfer were partially reversible with recombinant DNAse (rDNAse) pretreatment and completely reversible when rDNAse pretreatment preceded Ad gene transfer. Application of genomic DNA to cultures prior to transduction with DC-Chol/DOPE or an Ad-*lacZ* vector simulated the inhibitory effects of sputum on gene transfer suggesting that excessive DNA was a major contibutor to the inhibitory effects of noninfectious sputum components on gene transfer mediated by cationic liposomes and adenoviruses. Pretreatment with other mucolytic agents, including nacystelyn, lysine, n-acetylcysteine, and rAlginase, failed to increase liposomal or Ad gene transfer efficiency. However, in an ex vivo sheep tracheal model, pretreatment with n- acetylcysteine, nacystelyn, or mucus depletion overcame the effects of mucus on gene transfer mediated by L-polyethylenimine (L-PEI) polyplexes and p-ethyl-dimyristoylphosphatidyl choline (EDMPC) lipoplexes (37). Thus, both CF and normal mucus may have inhibitory effects on gene transfer.

Perricone et al. evaluated the effects of the CF sputum on Ad vector infectivity (38). Sputum was collected from CF patients with acute exacerbations receiving antibiotics and rDNAse, and separated into aqueous (sol) and gel components by ultracentrifugation. Pooled CF sol samples inhibited Ad gene transfer to fetal rat tracheal and normal human bronchial epithelial cells. Subsequent studies demonstrated that Ad-specific antibodies within the sol of CF sputum inhibited Ad gene transfer. Despite the presence of neutrophil elastase (NE) within the CF sol, pretreatment of CF sol with proteinase inhibitors did not prevent CF sol-induced inhibition of Ad gene transfer.

The technique of bronchoalveolar lavage (BAL) harvests luminal contents from the airways and the alveolar region of the lung. It may also harvest soluble components from the airway and alveolar surfaces. BAL fluid from CF patients has been shown to inhibit AAV gene transfer to IB3-1 cells and C12 cells in vitro (39). This inhibitory effect was reversible when CF BAL fluid was incubated with alpha 1-antitrypsin (α_1AT), and correlated with markedly elevated levels of NE and human neutrophil peptide (HNP) in BAL fluid from CF subjects. However, studies with purified HNP and NE demonstrated that HNP, rather than NE, mediated the major inhibitory effect on AAV gene transfer. Thus, HNP in BAL fluid from CF patients may have inhibitory effects on AAV gene transfer.

In contrast, Rooney et al. demonstrated that non-CF, rather than CF BAL fluid, inhibited Ad5 gene transfer to well-differentiated (WD) human airway epithelial (HAE) cells expressing glycosylphosphatidyl inositol (GPI)-coxsackie and adenoviral serotype 2/5 receptor (CAR) on the apical membrane (40). This effect was caused by the presence of IgG and I gA antibodies in BAL fluid, which could be removed by immunoprecipitation with staphylococcal A protein with restoration of Ad gene transfer efficiency. Unlike Ad5, neither CF nor non-CF BAL fluid had any effect on gene transfer mediated by an AAV5 vector.

Pseudomonas aeruginosa-induced bronchopulmonary inflammation may also inhibit Ad-mediated gene transfer (41). In an animal model of chronic bronchopulmonary infection, in which mice inoculated with pseudomonas aeruginosa-laden agarose beads develop bronchitis, bronchopneumonia, bronchiectasis, mucus plugging, and alveolar exudate with acute and chronic inflammatory cells, a greater than 2-fold reduction in gene transfer efficiency was detected following nasal instillation of an Ad-*lacZ* vector, as compared with mice that had sterile beads or Ad vector alone instilled. Similarly, the efficiency of Ad-*lacZ* gene transfer to nasal airways of pseudomonas (PAO1 strain)-infected mice was reduced by 10-fold as compared with noninfected nasal airways (42). Thus, the inflammatory milieu induced pseudomonas is a formidable barrier to transduction.

Airway and alveolar macrophages may also serve as barriers. Worgall et al. (43) used Ad-specific probes and Southern blot analysis to demonstrate a 70% loss of Ad-*lacZ* genomes within 24 h in both immunocompetent and immunodeficient mice 24 h following transtracheal administration of an Ad-*lacZ* vector. Pretreatment of murine lungs with liposomes containing dichloromethylene biphosphonate to eliminate macro-

phages, followed by administration of an Ad-*lacZ* vector, resulted in a significant increase in lung DNA and subsequent β-galactosidase expression. In vitro studies in cultured human alveolar macrophages demonstrated rapid loss of Ad vector genomes consistent with the in vivo data.

Retrovirus-mediated gene transfer to airway epithelia (44) may also be inhibited by alveolar macrophages. Transduction of human airway epithelial cells by an amphotropic enveloped retroviral vector was inhibited ~40% by alveolar macrophages and by more than 60% by lipopolysaccharide (LPS)-activated alveolar macrophages (35). Incubation of macrophages with dexamethasone (1 μM) partially reversed this inhibition of retroviral transduction. Rapid uptake of labeled vector into vesicles of macrophages was associated with loss of DNA within 24 h consistent with rapid degradation, rather than rapid transduction, of alveolar macrophages. These data suggest that macrophages can play a significant role in inhibiting in vivo gene transfer to lung epithelia.

2. Cell Surface Components

Components of the ASL and the glycocalyx may also have inhibitory effects on airway gene transfer. The effect of ASL on airway gene transfer has not been extensively evaluated. McCray and coworkers (44) demonstrated that airway surface liquid from WD HAE cell cultures harvested in a small volume of distilled water failed to inhibit retroviral transduction to naive airway cells in vitro. Airway surface fluid, obtained by washing the surfaces of WD airway cell cultures and bronchial xenografts, also had no effect on transduction mediated by AAV-2 vectors (45). Although the samples of the airway surface fluid used in these studies were dilute, these data would suggest that insignificant levels of vector inhibitory substances are present within the soluble components of airway surface fluid.

The glycocalyx is a complex structure on the apical surfaces of airways consisting of complex carbohydrate moieties (sugars), glycolipids, and glycoproteins. At least 5 mucin glycoproteins have been localized to airway surfaces: MUC1 and MUC4, which are tethered mucins and MUC2, MUC5AC, and MUC5B, which are secreted mucines that adhere to the cell surface (46–50). Arcasoy and colleagues (49,51) demonstrated that overexpression of the mucin MUC1 reduced Ad-mediated gene transfer to MDCK and bronchial epithelial cells that could be overcome by removal of sialic acid residues from the apical surface by neuraminidase pretreatment (49,51). Two groups have recently taken advantage of GPI-linked CAR to more carefully evaluate the role of the glycocalyx as a barrier to gene transfer. Overexpression of GPI-linked CAR in MDCK cells and HAE cells results in localization of CAR predominantly to the apical membrane of polarized cells (52,53). Pickles et al. demonstrated that an Ad5 vector failed to efficiently transduce MDCK cells overexpressing GPI-linked CAR following apical application, an effect that was reversible with removal of sialic residues by neuraminidase (52). In contrast, Walters et al. demonstrated that luminal application of an Ad2 vector efficiently transduced HAE cells overexpressing GPI-linked CAR on the apical membrane and that neuraminidase had no effect on gene transfer efficiency (53). Because Ad2 and Ad5 target the same region of CAR, it is unlikely that this incongruity results from differences in vector serotype. Rather, it may reflect differences in the levels of expression of glycocalyeal components between the different culture systems.

B. Vector-specific Barriers to Luminal Airway Gene Transfer

Cellular factors in airway cells may also affect the ability of gene transfer vectors to bind, enter, and translocate to the nucleus, and to express their transgenes after entry. These factors are discussed by vector below.

1. Ad Vectors

Adenoviruses are double-stranded DNA viruses, of which human serotypes 2 and 5 (90% homology) provide the backbone for current Ad vectors (54–57). Wild-type adenoviruses have a 36-kbp genome consisting of a series of early genes that are responsible for virus replication, antigen presentation and surveillance, and a series of late genes that encode viral structural proteins (54–57). Several generations of Ad vectors have been developed based on Ad serotypes 2 (Ad2) and 5 (Ad5). These generations are based on deletions of different regions of the Ad genome to improve safety.

In general, deletions of the early region one (E1) gene to make the vectors replication defective (58), with or without deletion of the E3 gene are characteristic of first-generation vectors. Additional deletions of the E2a region to form temperature-sensitive mutant viruses that may bring an additional safety feature to the vector (59–62), or alternatively, deletions in most [except for open reading frame six (ORF6)] or all the E4 region in an attempt to limit late viral gene expression (63–65), are characteristic features of second-generation vectors. Third-generation Ad vectors have had all their viral genes deleted, retaining only a small packaging signal and the inverted terminal repeats (66–72). These vectors can accept insert cDNAs or even genomic DNA in excess of 30 kb (56), but often require a stuffer sequence (70,72) for adequate packaging of vector constructs containing smaller cDNAs. Because these completely deleted vectors require coinfection of producer cells with an Ad helper virus for production of viral structural proteins, they are often referred to as gutless, high-capacity, or helper-dependent (HD) Ad vectors. Although the Ad helper virus may contaminate vector production stocks, the advent of Cre-lox recombination techniques has led to a reduction in the amount of Ad helper contamination to less than 0.5% to 1.0%.

Ad binds to a high-affinity CAR (73) on the cell surface and is internalized through an $\alpha_v\beta_{3/5}$ integrin-mediated vesicular (endocytic) process (74). As a result of endosomolytic properties mediated by the Ad penton base, Ad escapes the endosome and efficiently translocates to the nucleus, where it exists as an episome (extrachromosomal DNA)-mediating expression of therapeutic genes (cDNAs). Because Ad vectors do not

integrate at high frequencies, transient expression occurs so repetitive administration will be required for CF gene therapy.

Clinical trials and preclinical studies have established that luminal Ad gene transfer to airways is inefficient. Grubb et al. demonstrated that luminal application of an Ad-*lacZ* vector efficiently transduced basal cells, the predominant cell type at the site of mechanical injury in human and mouse tracheal explants, whereas uninjured lumen-facing columnar cells were resistant to gene transfer (75). This observation was confirmed in model systems of WD rat and human airway epithelia and extended to human intrapulmonary (bronchial) airways (76). Parallel experiments in excised human airway specimens demonstrated preferential transduction of undifferentiated regenerating or wound repairing cells by Ad vectors, as compared with WD pseudostratified columnar epithelia (77).

The causes of inefficient Ad gene transfer to WD airway epithelial cells following luminal application were delineated in subsequent studies. An early observation was that $\alpha_v\beta_{3/5}$ integrins were localized to the basolateral membrane, rather than the apical membrane, of columnar cells limiting vector entry (78). Subsequent experiments with radio- and fluorescent-labeled Ad vectors revealed evidence for decreased binding to the apical membrane of these polarized airway epithelial cells as compared with poorly differentiated airway cells, and a low rate of vector internalization out of proportion to the reduction in binding (76,79,80). Preferential transduction of polarized WD airway epithelia following basolateral application of vector as compared with the apical application was consistent with the binding and uptake studies (76,79,80). Immunofluorescent antibody studies ultimately localized CAR to the basolateral membrane (52).

Although the inefficiency of Ad-mediated gene transfer could be partially overcome by increasing the duration of Ad vector incubation with the epithelium (81,82), the markedly reduced rate of endocytic uptake in WD airway epithelia as compared with poorly differentiated airway epithelia (83) suggested that minimal enhancement of gene transfer would result from increasing nonspecific binding of Ad vectors to WD airway epithelia. Thus, vector-specific barriers to Ad-mediated gene transfer present on the apical membrane of WD airways lead to decreased uptake and decreased entry of vector.

2. AAV Vectors

Initially, AAV vectors were derived from the naturally defective and nonpathogenic wild-type human parvoviruses, AAV-2 and AAV-3 (84–88). The small genome (~4.7 kbp) of wild-type AAV-2 consists of the following: (1) inverted terminal repeats at the 5′ and 3′ ends of the molecule (84–87), which play a role in replication and are important for integration into the host cell genome; and (2) the viral genes *rep* and *cap*, which mediate viral replication and nucleocapsid formation. Deletion of *rep* and *cap* creates an AAV vector with an insert size of ~4.5 kb, which is at the upper size limit for insertion of full-length wild-type CFTR (coding region of ~4.5 kb) driven by an exogenous promoter. Thus, the small insert size of AAV vectors may serve as a barrier to gene transfer of human CFTR.

Poor binding and entry across the apical membrance of WD airway epithelia following luminal application of AAV vectors may also be limiting for CFTR gene transfer. A membrane-associated heparan sulfate proteoglycan has been identified as a receptor for AAV-2 (89) and fibroblast growth factor-1 (FGF-1) and $\alpha_v\beta_5$ integrins act as coreceptors for AAV-2 entry (90,91). Heparan sulfate proteoglycans and the coreceptors have been localized predominantly to the basolateral surface of WD HAE cells (45), which correlates with preferential transduction of these cells when vector is applied to the basolateral membrane relative to the apical membrane. However, binding of radiolabeled AAV-2 to the apical membrane of WD HAE cells was only reduced 4- to 7-fold reduction as compared with the basal membrane, which was incongruent with the 200-fold greater gene transfer efficiency detected following basal application. Thus, the existence of nonfunctional apical membrane receptors for AAV-2 in airway epithelia has been postulated (45,92).

Another barrier to transduction is inefficient conversion of single-stranded AAV genomes (ssDNA) into double-stranded DNA (dsDNA), a requirement for transgene expression (93,94). This limitation delays the onset of transgene expression, which can be overcome by waiting long enough for maximal transgene expression to occur (~4 weeks) or by the use of DNA damaging agents, topoisomerase inhibitors, and Ad early gene products (95–97). Thus, barriers to AAV-mediated transduction of CFTR into CF airways include small insert size, decreased binding, and uptake of vector due to absent or decreased functional receptor expression on the apical membrane, and inefficient single-strand to double-strand conversion of AAV genomes.

3. Retroviral Vectors

Retroviruses are members of a large group of viruses that infect vertebrates known as the Retroviridae (98,99). Several members of the mammalian C-type genus, which includes a variety of oncogenic retroviruses, and the lentivirus genus, which is associated with slowly progressive immunodeficiency states, have been developed into gene transfer vectors. Commonly used C-type retroviral vectors are based on murine leukemia virus (MLV). Lentivirus vectors derived from the human immunodeficiency viruses (HIV), feline immunodeficiency virus (FIV), and equine infectious anemia virus (EIAV) have each been developed as gene transfer vectors for cystic fibrosis.

Simple C-type retroviruses are RNA viruses whose genomes consist of 2 viral long terminal repeats (LTRs) that are important for cellular integration, but also contain promoter elements, a packaging signal, and a series of structural genes, *gag*, *pol*, and *env*. These structural genes encode the capsid protein, reverse transcriptase, protease, an integrase, and the envelope glycoprotein. Deletion of *gag*, *pol*, and *env* creates room for insertion of therapeutic cDNAs (genes) into the retroviral genome, forming a replication-defective retroviral vector (100). Production of the vector is performed by supplying

the deleted functions in *trans* with stable cell lines overexpressing helper proteins or by transient transfection.

Lentiviruses have a more complex genome than simple retroviruses that encode a variety of regulatory accessory proteins and pathogenesis factors that are not present in the genomes of simple retroviruses (101–104). Genes encoding proteins that use the cellular nuclear import machinery to target the preintegration complex to the nucleus are also encoded within this complex genome. Deletions in these accessory and pathogenesis factor genes have enabled the development of lentiviral vectors for gene transfer (101–104). Exogenous (internal) promoters have also been included within the sequences of the inserted gene cassette because transcription from the viral LTR may constitute a safety hazard. Deletions in the LTR to prevent transcription (self-inactivating or SIN vectors) have been introduced as a safety feature of retroviral vectors based on MLV and HIV (105,106).

The envelope glycoproteins of wild-type retroviruses and lentiviruses bind to cell surface receptors to facilitate entry of the virus into the cytoplasm where the viral RNA is reverse transcribed to form a cDNA, the provirus. This provirus is translocated to the nucleus where it integrates into the host cell chromosomes and through the normal process of DNA transcription, and encodes new viral proteins and new viral RNA, which are assembled at the cell surface into new viral particles. Replication-defective retroviral and lentiviral vectors infect cells by similar mechanisms, but unlike wild-type viruses, the integrated provirus from these vectors encodes the therapeutic gene and viral particles are not produced.

The lack of cell proliferation in WD airway epithelia in vivo (107) and low titers have traditionally served as major barriers to application of the C-type retroviral vectors derived from MLV to in vivo airway gene transfer efforts. The development of HIV, EIAV, and FIV vectors (101,102,104, 106,108,109), which can transduce nondividing airway cells, may overcome the requirement for cell proliferation by oncogenic retroviruses (110). Advances in retroviral production techniques and pseudotyping of vectors to create stable envelopes that permit concentration of vector stocks, may also soon overcome the limitations of titer (111). However, titers of retroviruses remain ~1 to 2 logs lower than that of Ad vectors or AAV vectors.

Apical membrane barriers to efficient transduction of WD airway cells are also limiting for retroviruses. Wang et al. demonstrated efficient transduction of polarized WD airway cells stimulated to proliferate with keratinocyte growth factor (KGF) when amphotropic-enveloped MLV vectors were applied to basolateral surface as compared with minimal to no gene transfer when vector was applied to the apical surface (112). The data are consistent with localization of the amphotropic receptor (RAM-1 or Pit-2) to the basolateral surface of polarized WD airway cells. Western blot data from this study suggested that receptor levels were extremely low in the absence of KGF. In vivo studies have confirmed low levels of expression of RAM-1 or Pit-2 in murine lung (113). However, Wang and colleagues have suggested that nonfunctional amphotropic receptors may be present on the apical membrane (114).

Similar findings have been observed with retroviral vectors bearing different envelopes. Wild-type vesicular stomatitis virus (VSV) preferentially infects polarized MDCK cells across the basolateral membrane (115). MLV and lentiviral vectors derived from HIV, EIAV, and FIV that have been pseudotyped with the envelope glycoprotein (G) of VSV also preferentially transduce polarized MDCK cells from the basolateral surface. In vitro and in vivo studies of transduction have confirmed this notion in MDCK cells, polarized WD HAE cells, and murine, rat, and rabbit tracheas in vivo (108,109,112,116–118). Thus, the lack of apical membrane receptors for retroviral or lentiviral vectors on the apical membrane of airway epithelia remains a significant barrier.

4. Nonviral Vectors

Cationic liposomes and naked plasmid DNA have been the principal nonviral vectors evaluated in CF clinical trials. Cationic liposomes are composed of cationic lipids mixed in varying molar ratios with cholesterol and dioleylphoshphatidylethanolamine (DOPE), a neutral phospholipid (119,120). A variety of cationic lipids have been used for gene transfer, including N[1-(2,3-dioleoxy)propyl] N,N,N trimethylammonium (DOTMA), 1,2-dimyristyloxypropyl-3-dimethylhydroxyethylammonium bromide (DMRIE), or 3β[N-N′,N′-dimethylamino ethane-carbamoyl] cholesterol (DC-Chol), N[1-(2,3-dioleoxy)propyl] N,N,N trimethylammonium methyl sulfate (DOTAP), EDMPC cholesterol, and N^4-sperminine cholesteryl carbamate (GL-67). Cationic liposomes bind to negatively charged plasmid DNA to form DNA–liposome complexes (lipoplexes). These lipoplexes enter cells primarily by endocytosis (121,122), although the mechanism and specificity of binding to the cell surface has not been clearly delineated. Cationic liposomes do not integrate into the host cell genome, so that expression may be lost with cell division. Thus, repetitive administration of lipoplexes will be required for CF gene therapy.

Naked or plasmid DNA has also been shown to mediate gene transfer to lung epithelia in vitro and in vivo. In a clinical trial of lipid GL-67 in the nasal epithelium of cystic fibrosis patients, plasmid DNA alone was as effective as GL-67/CFTR plasmid DNA lipoplexes, although the restoration of chloride secretion was small in both cases (24).

Plasmid DNA can be linked to a polymer (e.g., poly-L-lysine), and a receptor ligand to form a DNA–ligand–polymer complex (polyplex). This complex may then bind to a specific cell surface receptor and enter the cell by receptor-mediated endocytosis. Polyplexes based on poly-L-lysine that use a Fab fragment of IgG against human secretory component have been shown to deliver reporter genes to the airway epithelia in vitro and in vivo following intravenous administration (123,124). These polyplexes appeared to preferentially target the larger cartilaginous airways where expression of the polymeric IgA receptor predominates, but were immunogenic.

Poly-L-lysine has also been linked to specific peptides that bind the serpin enzyme complex receptor (SEC-R) in an at-

tempt to increase luminal airway epithelial gene transfer efficiency (125). The poly-L-lysine polymer has also been modified to enhance gene transfer efficiency. Kollen et al. (126,127) have demonstrated that lactosylated poly-L-lysine can significantly enhance gene DNA transfer to cultured CF cells in vitro.

Two major barriers to nonviral gene transfer have been identified. The data have been primarily developed from studies of cationic lipids, but may also apply to polymers and naked DNA. Nuclear entry has been identified as the rate-limiting factor for efficient liposome-mediated gene transfer into cell lines resistant to transfection (128), whereas gene transfer to WD airway epithelial cells may be limited by both inefficient nuclear entry and failure of DNA–liposome complexes to enter the cell (83). In rat and human airway cells grown as islands on permeable collagen substrates with poorly differentiated cells forming the edges of the islands and polarized (WD) cells forming the central portions, loss of phagocytic entry mechanisms, decreased cell surface binding, and decreased uptake of lipoplexes into differentiated airway epithelial cells (central cells) as compared with poorly differentiated cells (edge cells) were detected as the reasons for inefficient transduction. These observations were confirmed in a parallel study that demonstrated decreased amounts of cell-associated lipoplexes in differentiated airway epithelia as compared with poorly differentiated epithelia (129). Because liposome-mediated gene transfer into proliferating cells was enhanced relative to quiescent cells, the possibility of enhanced nuclear transport of DNA during mitosis due to breakdown of the nuclear envelope was suggested. Thus, barriers to efficient transduction of WD airway cells by nonviral vectors include decreased binding and uptake of lipoplexes, as well as poor nuclear translocation of DNA. Polymer-based vector systems that target specific receptors on cell surfaces may overcome poor binding and uptake of nonviral vectors, but poor nuclear translocation with trafficking of significant portions of vector to lysosomal compartments for degradation remains a concern.

IV. OVERCOMING BARRIERS TO AIRWAY GENE TRANSFER

In the preceding section of this chapter, the apical membrane of WD airway cells has been established as a formidable barrier to efficient transduction by all the current gene transfer vectors. Intravenous approaches might overcome many of the apical membrane barriers (123,124), but the multiple barriers that must be crossed (e.g. endothelium, endothelial basement membrane, interstitium, epithelial basement membrane), combined with the increased possibility of systemic toxicity inherent in blood delivery, have made luminal delivery of vectors more attractive. Current strategies have not fully addressed the problem with luminal contents (i.e., neutrophils, bacteria, excess DNA, inflammation), focusing instead on improving apical membrane binding and entry. The hope is that pretreatment with a_1AT, rDNase, or antibiotic therapy will limit the effects of luminal contents on gene transfer.

Two major approaches have been proposed for overcoming barriers to airway epithelial gene transfer following luminal application of vector. One approach focuses on modification of the host airway to enhance gene transfer and the other modifies vectors to target receptors expressed on the apical membrane of airways in vivo that have the capacity to internalize. These approaches are discussed in more detail below.

A. Host Modification

1. Modulating Paracellular Permeability

The application of methods modulating paracellular permeability to enhance gene transfer has been well established. Inhalation of the oxidant gas sulfur dioxide promotes denuding of the surface epithelium in a dose-dependent manner, while increasing paracellular permeability in less severely injured regions (116,117,130). This oxidant model was used to stimulate epithelial cell proliferation and enable relatively efficient gene transfer to the airways of mice by VSV-G pseudotyped retroviral and lentiviral vectors (116,117). The surface active detergent polidocanol has also been shown to increase permeability of polidocanol-treated murine airways, but not that of control animals without inducing frank morphologic injury (42). Pretreatment of nasal airways with polidocanol-enhanced gene transfer mediated by an Ad-*lacZ* vector and facilitated partial correction of the Cl^- transport defect in the nasal epithelium of CF mice following a single dose of vector. The single dose of Ad-CFTR vector used following pretreatment with the surface agent polidocanol generated the same degree of CFTR correction previously reported by Grubb (75) in which 4 doses of an Ad vector were required to generate a 40% to 50% correction of Cl^- transport.

Agents that more specifically alter paracellular permeability of airways to enhance gene transfer have also been tested. Retroviral gene transfer mediated by an amphotropic enveloped vector applied to the apical membrane of WD airway epithelia was enhanced following pretreatment with the calcium chelator ethylene glycol bis-(β-aminoethyl ether)-N,N,N′,N′-tetraacetic acid (EGTA) and hypotonic solutions (112). A 7- to 10-fold increase in transduction of WD primary HAE cell cultures by an AAV-GFP vector and transient permeabilization with EGTA/hypotonic solution has also been reported (45). EGTA/hypotonic solution treatment has enabled investigators to correct the Cl^- transport defect in WD CF HAE cells stimulated to proliferate with keratinocyte growth factor (KGF) when vector was applied to the luminal surface (112) and has enhanced FIV-based lentiviral gene transfer to rabbit airways in vivo (109), Ad gene transfer in vitro, and Ad gene transfer to murine airways in vivo (131). Chu et al. demonstrated that high concentrations of EGTA (0.1–0.4 M) were optimal for enhancement of Ad gene transfer to nasal and lower airway epithelia of mice in vivo (132). Medium chain fatty acids have also been shown to enhance airway gene transfer in vitro (133) and in vivo (133,134). Recently, lysophosphatidylcholine has been shown to enhance

HIV vector-mediated reporter gene transfer to murine nasal epithelia and to partially correct the the CF chloride permeability defect in the nasal epithelia of CF mice in vivo (135). These studies have established the feasibility of transient permeabilization of the paracellular path to enhance airway gene transfer in vivo mediated by vectors that bind to receptors that are localized on the basolateral membrane.

2. Enhancing Endosomal Processing

Duan et al. have suggested that receptors for AAV-2 may exist on the apical membrane of polarized WD HAE cells that can bind and mediate AAV-2 entry, but fail to mediate transgene expression (45,92). The rationale for this hypothesis was the observation that rAAV-2 transduction of WD HAE was 200-fold more efficient following basolateral application of 10^4 rAAV particles/cell as compared with apical application of an equal number of particles (45). This observation was incongruent with binding studies, which demonstrated only a 4- to 7-fold difference in binding between the apical or basolateral membranes. To further evaluate this observation, the investigators explored differences in the molecular state of rAAV 50 days after apical or basolateral transduction by Southern blot analysis of Hirt DNA (45). Following apical application of vector, rAAV genomes were detected consistent with cellular entry, but remained as ssDNA. In contrast, rAAV genomes that had been converted to dsDNA forms were detected after basolateral application of vector. DNA damaging agents did not increase gene transfer following apical infection, but the proteasome inhibitors z-LLL and LLnL, which prevent ubiquitination of molecules targeted for degradation, increased gene transfer efficiency to levels that were one-eighth of those observed following basolateral transduction. These data are consistent with a lumen-specific block to AAV endosomal processing and trafficking. Agents inhibiting proteasomal degradation also enhanced luminal rAAV-2-mediated airway gene transfer in vivo. These findings have not yet been verified by others in airways, although barriers to endosomal processing of AAV-2 have been identified in undifferentiated cell lines (136,137).

B. Vector Modification

Modifying the gene transfer vector is an alternative and perhaps, more popular approach to enhancing airway gene transfer efficiency. Retargeting the vector to receptors that are endogenously expressed on the apical membrane of WD HAE cells is the goal of this approach. The concept of targeting gene transfer vectors to alternative (non-wild-type) receptors is well established in the literature for adenoviral, retroviral, and nonviral vectors (138–149).

1. Ad Vectors

Methods for retargeting of Ad vectors have included the following: (1) genetic engineering of peptide ligand sequences or single-chain antibody fragments (scFv) into the fiber knob domain of Ad (139,148); (2) the adenobody approach, which is based on the use of scFv-fusion proteins with specificities for an Ad epitope while bearing a ligand-binding domain for a specific cell surface receptor (146); and (3) the use of bispecific antibodies composed of 2 antibodies—one directed against the Ad vector and the other against the specific cell surface receptor—that have been cross-linked (147,150).

A major concern for airway gene transfer has been which receptors are expressed on the apical membrane and whether the levels of expression are sufficient to promote successful gene transfer. $P2Y_2$-R, a 7 transmembrane purinoceptor that normally mediates acute airway epithelial cell responses to the luminal environment, the SEC-R, and the urokinase plasminogen activator receptor (uPA-R) have been proposed as potential targets on the apical membrane (125,151–154). In preliminary studies, bispecific monoclonal antibody-Ad vector complexes directed toward epitope-tagged external domains of $P2Y_2$-R can promote enhanced gene transfer efficiency to polarized cells (155). Targeted transduction of wild-type $P2Y_2$–R expressing cell lines mediated by vector conjugates composed of Ad complexed to the chemically modified ligand biotin-UTP has also been demonstrated (156). A uPA-polyethylene glycol (PEG)-coated Ad vector has also been shown to enhance Ad gene transfer to polarized airway epithelia (153,157).

Chimeric Ad vectors that target apical membrane of airway cells have also been developed. Zabner et al. screened 12 adenoviral serotypes from Ad subgroups A–F for their ability to bind and infect the apical surface of polarized WD HAE cells in culture (158). Wild-type Ad17 bound to WD HAE cells more efficiently than wild-type Ad2. Chimeric Ad2 vectors with Ad17 fiber were subsequently generated that transduced WD HAE cells ~100-fold more efficiently than the original Ad2 vector. These data suggested the feasibility of generating chimeric Ad vectors that more efficiently transduce HAE cells following luminal application.

2. AAV Vectors

Efforts to improve apical membrane targeting of AAV vectors have focused on identifying wild-type AAV vectors of other serotypes. These alternative serotypes have been developed into new gene transfer vectors or alternatively, their cap genes have served as pseudotypes for AAV-2 vectors. Six serotypes of AAV vectors have been cloned (159–161).

AAV-2 vectors pseudotyped with an AAV-6 capsid generated by transient transfection techniques have been developed (162). These AAV-6 pseudotypes bound heparin columns weakly as compared with AAV-2 and were not inhibited by soluble heparin sulfate, but luminally applied vector-transduced polarized primary CF HAE cells up to 100-fold more efficiently than AAV-2. AAV-6 pseudotypes also transduced a high percentage (up to 80%) of cells in some mouse airways in vivo that was 100- to 1000-fold higher than detected following AAV-2 gene transfer. Of note, AAV-6-pseudotyped AAV-2 vectors were produced in much higher titers than AAV-6 vectors, suggesting that pseudotyping may offer advantages for vector production. No studies of AAV-6 or AAV-6 pseudotyped (AAV capsid) vectors containing CFTR transgenes have been reported to date.

The molecular characteristics of AAV-4 and AAV-5 in comparison to AAV-2 have been reported (163). Significantly more AAV-4 and AAV-5 bound to the apical membrane of WD HAE cells than AAV-2, but only AAV-5 efficiently transduced airway cells following apical application. AAV-5 transduction was not inhibited by pretreatment with soluble heparin consistent with the use of a different receptor for binding and uptake of vector from AAV-2. AAV-5 vector-transduced lungs exhibited a 5-fold increase in the number of transduced cells/microscope field for airways and 20- to 30-fold increase for alveoli as compared with AAV-2-transduced lungs. Current data suggest that 2,3-linked sialic acid residues may serve as the receptor for AAV-5 (164). Thus, AAV-5 and AAV-6 may be candidates for enhancing AAV gene transfer following luminal delivery. However, confirmatory studies of gene transfer efficiency, CFTR transduction, and safety will be required.

The restriction on insert size that limits efficient packaging of wild-type CFTR with a suitable promoter has been an additional barrier to AAV-mediated CFTR gene transfer. Expression from AAV-CFTR vectors in clinical trials has been driven by endogenous promoter elements within the viral terminal repeats due to limits on insert size (19,20,165). Because AAV vectors undergo intermolecular circular concatermerization and recombination, a trans-splicing strategy has been proposed for full-length cDNAs in excess of the packaging size limits (166). In this strategy, rAAV vectors encoding either the 5′ or 3′ portions of a therapeutic transgene with splice donor sites intact would be delivered into the same cell where circular concatamers arising from intermolecular recombination permit functional trans-splicing of the component portions of the molecule into full-length therapeutic cDNAs (166). This strategy has been successfully applied to the human erythropoietin (Epo) gene in vitro and to animal models of renal failure-induced anemia (166). A similar strategy has been proposed to restore CFTR chloride channel function to CF epithelia, but the feasibility of this approach will depend on efficient delivery of the vector encoding each half of CFTR, or alternatively, a CFTR transgene in one vector and a promoter with a superenhancer in another to the same cell with a high frequency of trans-splicing (167).

An alternative methodology for introducing larger transgenes into WD airway cells in vitro and in vivo has recently been published (168). Halbert et al. have delivered 2 AAV vectors containing overlapping homologous fragments (AAV rec vectors) of the human placental alkaline phosphatase gene (AP) gene into airway cells in vitro and in vivo. Theoretically, homologous recombination between the fragments from the 2 different vectors would result in expression of the transgene. Delivery of the AAV rec vectors in vitro resulted in inefficient recombination and expression in vitro. However, AAV6 capsid AAV rec vectors transduced murine airways in vivo at nearly the same efficiency (~10%) as an intact AAV6 capsid-AP vector (168). These data suggested that application of alternative AAV pseudotypes combined with transplicing or AAV rec vector technology may overcome both the apical membrane and insert size limitations common to AAV-2 vectors.

3. Retroviral Vectors

Approaches that overcome in vivo barriers to retroviral transduction must address issues of titer, cell proliferation, and receptor localization. Retroviral vector titers have traditionally been in the range of 10^5 to 10^6 infectious units (IU)/mL, with further increases in titer limited in part by the stability of the envelope protein. Envelope proteins from a variety of viruses can be incorporated into the viral membrane of retroviral vectors, a process known as pseudotyping, which is common to most retroviruses including lentiviruses.

VSV-G pseudotyped MLV and lentiviral vectors have been developed that can be concentrated to high titer by ultracentrifugation without significant loss of infectivity (101–104, 108,109,111,116,169). Following concentration, retroviral titers approach titers within a log of AAV and Ad vectors and high titer VSV-G pseudotyped MLV and lentiviral vectors have been shown to correct the Cl^- permeability defect in poorly differentiated dividing (subconfluent), and WD primary CF HAE cells without selection (116,118). The toxicity of VSV-G envelope protein and some lentiviral accessory proteins initially limited the ability to develop stable packaging cells lines for vector production, but regulated expression of helper and envelope components with tetracycline-inducible promoters has permitted the development of stable VSV-G pseudotyped MLV and lentiviral vector producer lines (170–172).

Oncogenic retroviral vectors based on MLV require cell proliferation for nuclear entry, integration, and subsequent transgene expression. Two models have been developed to stimulate epithelial cell proliferation in vivo: (1) oxidant gas injury models, and (2) growth factors (109,112,113,116–118). Although oxidant gas injury and growth factors can lead to successful in vivo airway gene transfer with MLV-based vectors, the ability of lentiviral vectors to transduce a variety of nondividing cell types in vitro and in vivo has largely overcome the limitation of cell proliferation typical of oncogenic retroviruses (101–104,106,108,109,117,169). Johnson et al. evaluated whether HIV (VSV-G) vectors could transduce nondividing airway epithelial cells (117). An amphotropic enveloped vector [MLV (ampho)], HIV (VSV-G) vector, and MLV (VSV-G) vector each efficiently transduced growing or dividing CF tracheal epithelia cells (CFT1), whereas only the HIV (VSV-G) vector efficiently transduced aphidicolin-treated (growth-arrested) airway epithelial cells.

The envelope proteins of lentiviral vectors bind to cell surface receptors to facilitate entry with subsequent reverse transcription, nuclear import, and integration into the host chromosome culminating in gene expression. To evaluate the polarity of lentiviral transduction, VSV-G pseudotyped vectors have been applied to either the apical or the basolateral surfaces of polarized WD HAE cells. Thirty-fold greater transduction efficiency was detected in vitro when HIV (VSV-G) vectors were applied to the basolateral surface as compared with apical application of vector (173). Goldman and col-

leagues demonstrated that luminally applied HIV (VSV-G) vectors failed to transduce WD primary HAE cells in bronchial xenografts (173). Similar data have evolved for EIAV pseudotyped with VSV-G (J.C. Olsen, unpublished observations 1999), and for amphotropic and VSV-G enveloped FIV vectors (109,131). These data suggest that, although lentiviral vectors can transduce nondividing cells, the receptors for uptake and entry of amphotropic and VSV-G pseudotyped MLV and lentiviral vectors are predominantly localized to the basolateral membrane of polarized epithelial cells.

Two strategies have been proposed to overcome the lack of apical membrane receptor expression: (1) host modification with injury models and agents that increase paracellular permeability to increase vector access to basolateral membrane receptors and basal cells (173), and (2) targeting the apical membrane of polarized airway epithelia by pseudotyping lentiviruses with envelope proteins from other viruses that bind and enter across the apical membrane. Host modification has been discussed above. Targeting lentiviral vectors to receptors on the apical membrane to increase airway gene transfer are discussed here.

Retroviral targeting is typically approached by generating pseudotypes from envelope proteins of other viruses that target specific cell types. To identify potential pseudotypes tropic for the apical membrane of WD HAE cells, investigators have screened enveloped viruses for their ability to infect these cells following luminal application. Efforts have focused not only on common respiratory viruses, but have also included nonrespiratory viruses. Respiratory viruses considered as candidates for pseudotyping include respiratory syncytial virus (RSV), human corona virus, and influenza virus. Wild-type and replication-competent recombinant RSV infect or enter cells across the apical membrane of WD HAE cells (174,175). Human corona virus 229E (HcoV229E) has also been shown to bind and enter across the apical membrane of WD HAE cells (176). However, no successful lentiviral pseudotypes derived from the Env proteins of RSV and HcoV229E have been reported.

Preferential infection of the apical membrane of WD HAE cells by influenza A virus subtype H2N2/Japan/305/57 has been reported, whereas apical infection of HAE cells with subtypes H1N1 and H3N2 was inefficient (177). Apical membrane binding of the H2N2 subtype was specific for sialic acid α2,3-gal residues, suggesting that these sialic acid residues serve as apical membrane receptors for targeting of lentiviral pseudotypes. Morse et al. have shown in preliminary studies that coexpression of influenza M2 and neuraminic acid (NA) proteins in producer cells enhances titers of influenza hemagglutinin pseudotyped EIAV vectors (178). Moreover, these HA/M2/NA chimeric pseudotyped vectors transduced polarized WD HAE cells following luminal application.

The Env proteins of other viruses have also been considered. In a preliminary study, FIV-based vectors were pseudotyped with amphotropic, xenotropic, VSV-G, RD-114, 10A1, ecotropic, GALV, Marburg, and Ebola envelope glycoproteins by transient transfection techniques. Only FIV vectors pseudotyped with the Marburg virus envelope glycoprotein efficiently transduced WD HAE cells following luminal application (179).

The potential of the family of viruses known as the Filoviridae to target the apical membrane of airway epithelia (180) has been explored by Kobinger and colleagues. Filoviridae are enveloped nonsegmented negative sense RNA viruses, which include the Ebola and Marburg viruses among its members. To identify viral envelopes capable of mediating apical transduction of polarized air–liquid interface cultures, HIV vectors were pseudotyped with MLV, influenza-hemagglutinin, RSV F and G proteins, Mokola, Ebola Reston (Ebo-R), or Ebola Zaire (EboZ) envelopes. EboZ, but not EboR or other pseudotypes, efficiently transduced polarized HAE cells following apical application with gene transfer in up to 70% of cells as compared with up to 40% of cells following basolateral transduction. EboZ-pseudotyped HIV vectors also transduced WD HAE cells in xenografts and in freshly excised human tracheal explants. Thus, lentiviral vectors may overcome the limitations of low rates of cellular proliferation and pseudotyping lentiviral vectors with specific envelope proteins may overcome barriers to titer and the lack of apical membrane receptors on polarized WD HAE cells.

4. Nonviral Vectors

Poor apical membrane binding, and entry and inefficient nuclear transport, must be overcome to improve the efficiency of nonviral gene transfer in human airways. Until recently, cationic lipids and naked DNA had been the only nonviral vectors evaluated in CF clinical trials. Newer nonviral gene transfer vectors have been developed based on polymers that may have advantages over cationic lipids and 1 protocol polymer-based human clinical trial for cystic fibrosis has been registered with Office of Biotechnology Activities (OBA), National Institutes of Health. Polymers are inherently more flexible because they can readily be linked to ligands preferentially targeting the apical membrane. The localization of the SEC-R to the apical membrane of WD HAE cells has led to the development of polymer complexes (polyplexes) of SEC-R targeted peptide ligand-poly-L-lysine-DNA (125,154). These polyplexes efficiently targeted the apical membranes of murine nasal epithelia in vivo and partially corrected the functional chloride permeability defect in CF mouse nasal epithelia (181). Lactosylated poly-L-lysine has also been suggested as a nonviral polymer that may promote binding to the apical membrane of airways (126,127,182). Although this vector has shown promise in vitro, the ability to mediate efficient transduction of polarized WD HAE cells in vitro or in vivo has not been reported.

Fusogenic peptides, weak bases (chloroquine), and glycerol, which presumably has an osmotic effect on intracellular vesicles, have been proposed as agents promoting endolysosomal escape in an attempt to overcome inefficient nuclear transport of nonviral vectors, (183). The utility of these agents has not been verified in WD HAE cells in vitro or in vivo. Polyethylenimine polymers may also promote endosomal release (184), but appear to lack specific targeting moieties. Recent studies have suggested that polyplexes of lactosylated

poly-L-lysine and SEC-R targeted poly-L-lysine with condensed DNA may be more efficiently translocated to the nucleus (183,185). Lactosylated poly-L-lysine-DNA complexes appeared to enter undifferentiated CF primary and immortalized cells by a receptor-mediated process. Confocal micrographs of labeled complexes demonstrated rapid perinuclear accumulation of lactosylated poly-L-lysine polyplexes with a small amount of nuclear entry. However, agents that inhibit lysosomal trafficking markedly increased nuclear delivery, suggesting that the majority of the lactosylated polyplexes trafficked to the endolysosomal pathyway (183).

In preliminary studies of human hepatoma cells (HuH7), fluorescently labeled SEC-R-targeted complexes, which enter the cell by receptor-mediated endocytosis, were delivered to the perinuclear region within 5 min of binding with some free DNA, but no poly-L-lysine appeared in the nucleus (185). In contrast to studies with lactosylated poly-L-lysine, chloroquine did not increase gene transfer mediated by SEC-R-targeted polyplexes, consistent with nuclear translocation with efficient escape from the endolysosomal pathway (185). These data regarding the targeting of these polyplexes have not been verified in polarized airway cells.

5. Novel Systems

The paramyxoviruses have shown promise for gene transfer (186,187). Sendai virus (SeV) is an enveloped single-stranded nonsegmented negative strand RNA virus that mediates cell attachment and entry via the envelope glycoproteins hemagglutinin-neuraminidase (HN) and fusion protein (F). The ability of the ribonucleoprotein (RNP) of this virus—and paramyxoviridae family members in general—to mediate transcription and replication independent of nuclear functions or a DNA phase permits infection of nondividing cells. Reverse genetics has permitted the development of replication-competent SeV vectors and recently a nontransmissable SeV vector has been developed (187). Replication-competent SeV vectors have been shown to mediate efficient reporter gene transfer to murine lung throughout the conducting airways with expression present in ciliated columnar, nonciliated secretory cells, and submucosal gland cells, but not basal cells (186). Similar results were obtained following delivery to ferret lung in vivo and to freshly excised human airways ex vivo. Importantly, only a modest inhibition (50%) of SeV-mediated gene transfer has been reported in the presence of mucus. Dose-dependent inflammatory responses, which were detected in third-generation and smaller airways, and the loss of SeV-mediated expression with cell division are potential limitations of this vector.

Respiratory syncytial virus and parainfluenza virus-3 are other members of the paramyxoviridae family of viruses that have been considered for new vector development. RSV mediates cell entry through its glycoproteins G and F (188). Like SeV, transcription and replication are cystoplasmic events for both RSV and PIV-3. In preliminary studies, a replication-competent RSV-GFP virus efficiently transduced WD HAE cells following apical, but not basolateral, application of vector (174). Similar findings have been noted in WD HAE cells for PIV-3 (189). RSV and PIV-3 will likely have similar limitations as SeV for vector development. However, SeV, RSV, and PIV-3 offer exciting promise for future human airway gene transfer efforts.

V. SUMMARY

The airway epithelium is a formidable target for gene transfer approaches due to its complex anatomy, large surface area, innate immune functions, and the presence of specific barriers that limit entry of foreign particles. The inflammatory response in CF airways only serves to fortify the barrier to airway gene transfer. Nevertheless, progress has been made and several approaches have evolved to address the luminal barriers to gene transfer. Efforts to improve the ability of vectors to target the apical membrane of airway epithelia in vivo and methods that modify the host to increase vector access to cell targets offer hope, but more basic research will be required to achieve successful gene therapy of CF lung disease.

Gene Therapy for Neurological Diseases

William J. Bowers and Howard J. Federoff
School of Medicine and Dentistry, University of Rochester
Rochester, New York, U.S.A.

I. INTRODUCTION

Highly effective methodologies for therapeutic gene delivery to cells of the central nervous system (CNS) have borne from the exponential gains achieved in the area of molecular biology over recent decades. This capability has created promise for therapeutic intervention in neurodegenerative disorders. Presently, the most widely employed treatments for neurodegenerative diseases are based symptom alleviation through the use of pharmacological compounds, but these approaches offer little curative, or even neuroprotective properties. An ideal therapy for a neurodegenerative disorder would stabilize and/or repair afflicted cells and prevent other cells from succumbing to the pathophysiological process. Using gene transfer-based methodologies, it may be possible to create such therapies. The characteristics of presently available virus-based vectors are summarized in Table 1. Each vector platform exhibits a series of advantages and disadvantages that need to be assessed. However, prior to their implementation in the treatment of neurological disorders, a detailed understanding of the disease-specific mechanisms is crucial. These issues are addressed in greater detail below.

A. Therapeutic Transcriptional Unit

A thorough understanding of the molecular mechanisms underlying the neurodegenerative disease process is requisite for selection of a proposed therapeutic gene. In general, the therapeutic transcriptional unit should have 1 or more of the following properties: (1) neuroprotective, (2) neuroregenerative, (3) neurotrophic, or (4) antiapoptotic.

Equally important is choosing promoter(s) and regulatory element(s) to drive expression of the desired gene(s). The choice of these components will determine the specificity, duration, and regulation of transgene expression. Once the transcriptional unit has been designed, a suitable vector for delivering the DNA must be selected. The vector must be capable of delivering and expressing the desired genes in the appropriate cells to be targeted.

B. Vector Selection

Subsequent to selection of the gene therapeutic effector gene, whether it possesses a neuroaugmentative or neuroprotective mechanism of action, the appropriate gene delivery vector can be chosen. The following points must be considered for informed selection of an appropriate gene therapeutic vehicle for the treatment of neurodegenerative disorders: vector capacity, vector specificity, vector genome maintenance, vector-mediated transgene expression duration and levels, and vector safety profile. The length of the therapeutic transcription unit is sometimes used as a first criterion to limit vector choice. This category also includes a given vector's ability to harbor multiple transcription units, thereby potentially affording recapitulation of a complex biochemical pathway (i.e., dopamine biosynthesis in the case of Parkinson's disease). Potential applications for several presently available vectors are restricted by insertion size limitations and are sometimes excluded if multiple gene delivery is required for therapy. As demonstrated with adeno-associated virus (AAV) vectors, the coinjection of multiple vectors, where each expresses a different therapeutic gene, an approach to circumvent this issue (1).

Cell type specificity is also an important issue when developing a gene-based therapeutic intervention for neurodegenerative disorders. It would be most beneficial if the vector of choice could transduce and express in cell types that comprise the disease-affected neural pathway. Vector tropism can be

Table 1 Viral Vector Platforms Employed in CNS Gene Transfer

Viral vector	Payload capacity	Tropism	Duration expression	Other properties
Adenovirus	7–8 kb (Gen[a] 1/2); 30 kb (Gutless)	Glial/Neuronal	Months (Gen1/2); Year (Gutless)	Episomal; immunogenic (Gen 1/2); less immunogenic (gutless)
AAV	4.5 kb	Neuronal	Years	Episomal and integrative; minimal immune response
HSV recombinant	~10 kb	Neuronal> Glial	Months	Episomal; some cytotoxicity
HSV amplicon	~130 kb	Neuronal> Glial	Months to a year	Episomal; all viral genes deleted; little immune response
HSV/AAV hybrid amplicon	>20 kb	Neuronal	Months to a year	Episomal and integrative; all viral genes deleted
Lentivirus	8–10 kb	Neuronal	Years	Integrative

[a] Gen1/2, generation 1 and 2.

regulated through modulation of cellular receptor interactions by 1 or more of the following approaches: alteration of virus docking proteins, utilization of alternate serotypes, pseudotyping, and introduction of cellular receptors into the viral envelope. Once a vector is optimally targeted to the brain region of interest, therapeutic transgene expression can be restricted to selected cell populations via the utilization of cell type-specific promoters and/or transcriptional elements (2–6). Strict spatial control of transgene expression is important to ensure the correct cells will manufacture the gene product. This control, in turn, reduces the risk that ectopic transgene expression will occur and lead to untoward effects on adjacent neurological pathways.

Because many neurodegenerative disorders are protracted in duration, gene-base modalities will be required to impart therapeutic benefit for several decades of an individual's lifetime. To this end, a vector genome should be stably maintained within the transduced cell of the neural pathway for extended periods of time. Vector genome maintenance is, therefore, an important factor in selection of an appropriate gene therapy vehicle for such disorders. Vector genomes can exist episomally and/or as integrated forms within nuclei of transduced cells. The postmitotic property of CNS neuronal populations does not exclude the utilization of episomal vectors because genomes can be maintained without the fear of progressive loss due to mitosis. Integrating vectors circumvent this issue but their use augments safety concerns, including potential to transactivate nearby proto-oncogenes and to disrupt essential host genes via insertional mutagenesis. This fear has apparently become a reality as evidenced in the case of the children in Europe treated for X-linked severe combined immune deficiency disease (X-SCID) with a murine retroviral vector expressing the T cell growth factor, gammaC. Two of 10 enrolled infants developed similar leukemia-like illnesses, and the trial was halted to determine the genesis of the adverse event (7).

Another similar issue regarding vector selection relates to the desired levels and duration of gene product expression for treatment of neurodegenerative disorders. Depending the vector and transcriptional elements chosen, pharmacological or physiological levels of transgene expression can be achieved for short- or long-term periods of duration. As with other selection criteria, the decision of which level/duration of expression is preferred rests heavily on the underlying molecular mechanisms to be targeted and at which time during the disease course the intervention is to be implemented. Early interventions may require maintenance of long-term physiological levels of transgene expression (i.e., neuroprotective strategies) because the neuronal system is likely to be intact at this time. A vector/promoter combination that safely and stably maintains gene expression at nearly physiological levels in the CNS would serve as a potential candidate for such early treatment approaches. Treatment modalities that are implemented after presentation of clinical neurodegenerative disease symptoms may require long-term pharmacological levels of transgene product to restore neurological function to a brain region decimated by disease.

Safety is of utmost concern regarding the application of novel gene therapeutic strategies to the treatment of neurodegenerative disorders. Many presently available vectors trigger immunogenic and/or inflammatory responses when introduced into the CNS. These responses are known to arise from the humoral and/or cell-mediated arms of the immune system, and the magnitude differs depending which vector type is employed. For example, repeat administration of early generation viral vectors has been shown to lead to lower transgene expression and serious inflammation, likely the result of a primed immune system (8). Therefore, a vector that is stably maintained and that can express its encoded transgene for extended periods of time would likely prove to be a more favorable choice as a gene therapeutic vehicle for neurodegenerative disorders. Another aspect that is often overlooked regarding gene therapy safety is the role of transgene products in the elaboration of immune responses and toxicity. Transgene products that are of foreign origin, ectopically expressed, or

pharmacologically expressed possess the potential to induce cytotoxicity and/or immune responses. Research addressing these issues is imperative to elucidate the role of transgene products in the elaboration of these potentially harmful responses, and how such responses can be successfully circumvented. Utilization of regulation-competent transcriptional or posttranscriptional elements in delivery vectors to provide ''fine-tuning'' of therapeutic transgene expression levels is a way to minimize harmful clinical outcomes.

C. Vector Delivery

Once a suitable vector has been chosen for treating a particular neurological disease, a safe means for delivery must be established to provide optimal therapeutic benefit. With recent refinements of stereotactic surgical procedures, highly precise and reproducible delivery to specific regions of the brain are now performed [reviewed in (9)]. By placing the patient's head within a rigid frame and using 3-dimensional cartesian reference points, delivery of vectors or cells can be made to a defined space within the coordinate system. Gene therapeutic vectors can be introduced into the brain via direct or indirect means. Direct gene transfer involves either local or global delivery of a selected vector to the brain. Direct local delivery using stereotactic methods is highly suitable for treatment of certain neurological diseases due to the fairly circumscribed region that may be afflicted. Figure 1 illustrates the finely tuned and restricted delivery of an herpes simplex virus (HSV) amplicon vector expressing the β-galactosidase gene within the striatum of a mouse (10).

Other investigative groups have used more global approaches to CNS gene delivery that have broader applications for many neurological diseases where the volume of affected brain region is beyond the feasibility of conventional stereotactic methods. Convection-enhanced delivery (CED) has been developed to distribute homogeneous tissue concentrations of vectors over a large region of rodent or primate brain (11–14). This method has been used extensively in the development of gene therapeutic strategies for neurodegenerative disorders, but further research is required to determine if global distribution of vectors produces deleterious effects on neural pathway functioning. For example, global expression of vector-derived neurotrophic factors may induce uncontrolled neuritic sprouting, and subsequently, altered neuronal activity and physiology.

Indirect gene transfer, or ex vivo therapy, uses transplantation of genetically altered (vector-transduced) or unaltered cells capable of restoring functionality to a diseased region. Although ex vivo therapy includes the use of neural stem cells for repopulation of the denervated dopaminergic system and restoration of pathway function, this type of therapy is be discussed in this review. Vectors used to genetically modify transplanted cells typically express either secreted trophic factors for neuroprotection/neuroaugmentation of surrounding host tissues or cell-intrinsic survival factors for protection of

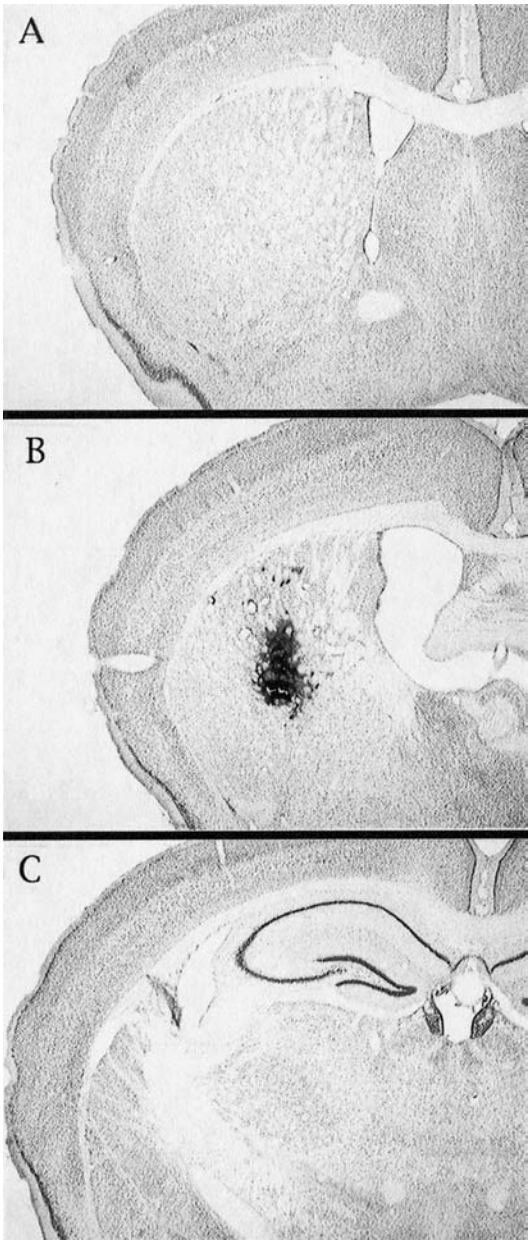

Figure 1 Stereotactic delivery of an HSV amplicon vector expressing β-galactosidase into the mouse striatum. Mice were injected with 1×10^5 transduction units of HSVlac using a microprocessor-controlled pump. Animals were sacrificed and perfused 4 days posttransduction and X-gal histochemistry was performed on 40-μm sections. Sections representative of the injection site (A), a site anterior of the injection (B), and a site posterior of the injection (C). All sections were counterstained with thionin and acquired at a magnification of 2.5×. The photomicrographs indicate that focal delivery of a viral vector can be achieved within the brain. (From Ref. 10, © 1998 Elsevier Science B.V.) See the color insert for a color version of this figure.

grafted cells from the stress of transplantation. Vectors delivered via ex vivo therapy must be able to integrate into the host cell genome because transplanted cell populations are expanded prior to grafting. Utilization of gene transfer technologies may allow for the expansion of the graft cell population or increased graft survival via expression of a growth or survival factor, thereby minimizing the amount of starting fetal tissue (15,16).

II. NEURODEGENERATIVE DISEASES AMENABLE TO GENE THERAPY

The following discussion illustrates the most common forms of neurodegenerative diseases (summarized in Table 2) and potential gene therapy approaches that have been employed based on current understandings of disease mechanisms.

A. Parkinson's Disease

Parkinson's disease (PD) is the second most common chronic neurodegenerative disease of humans. In 1995, the incidence of PD was estimated to be between 1:100 to 1:500 individuals (17,18). This incidence translates to approximately 1% of the population over the age of 65 (19–21). The disorder, initially described in 6 patients by Dr. James Parkinson, is typified clinically by symptoms including bradykinesia, resting tremor, rigidity, and gait abnormalities, followed by postural instability, dementia, and autonomic dysfunction. Pathologically, PD patients experience specific degeneration of dopaminergic neurons in the substantia nigra pars compacta as well as dopaminergic ventral tegmental area (VTA) neurons and noradrenergic neurons of the locus coeruleus. Furthermore, neuronal loss has been reported in other brain areas such as the cerebral cortex, anterior thalamus, hypothalamus, amygdala, and basal forebrain. In addition to neuronal loss, accumulation of proteinaceous cytoplasmic inclusions called Lewy bodies is a neuropathological hallmark of PD. The exact role of Lewy bodies in PD is unclear, but other neurodegenerative disorders also exhibit intracellular and extracellular protein aggregates. Understanding the molecular mechanisms underlying protein aggregates in neurodegenerative diseases may assist to illuminate a common target for gene therapy.

Although more than 180 years have passed since Parkinson's first description, the disease etiology is still largely unknown. Because the evolution of successful gene therapeutic strategies will rely heavily on a detailed understanding of the molecular and cellular processes governing the clinical presentations of PD, exploring the pathophysiology of PD is crucial. The following section summarizes possible mechanisms of PD and how methods in gene delivery and expression might be applied to interdict the pathogenic pathway(s) of this neurodegenerative disorder.

1. Mechanisms of Disease

PD exists as both a sporadic and familial disorder. Although the exact etiology of PD is unknown, the common pathway of both sporadic and familial PD is a loss of dopamine (DA) neurons. Importantly, this decline in DA neuron number below a critical threshold produces early symptomatic PD [reviewed in (22–24)]. Given that environmental factors such as pesticides, herbicides, and industrial chemicals have been

Table 2 Neurological Disorders Amenable to Gene Therapy

Disease	Age onset	Disease mechanism	Basis
Parkinson's	50–70s	Loss pigmented dopamine neurons in midbrain	*Genetic* (rare): α-synuclein, C-terminal ubiquitin hydrolase; parkin *Environmental*: pesticides, fungicides, neurotoxicants
Alzheimer's	50–80s	Aβ accumulation; tau hyperphosphorylation; synapse loss	*Genetic* (infrequent): APP, PS (susceptibility): ApoE4 *Environmental*: Viral infection/diet?
Lysosomal storage	Infancy	Enzyme deficiency leading to lysosomal protein accumulation and eventual peripheral and CNS degeneration	*Genetic*: lysosomal enzyme/transport gene deletion/mutation
Huntington's	20–50s	Loss of striatal medium spiny neurons	*Genetic*: Polyglutamine expansion in huntingtin gene locus
Stroke	Varies	Hypoxic insult leads to necrotic and apoptotic cell death	Potential genetic and environmental susceptibility interaction
Epilepsy	Childhood	Aberrant hypersynchronization of local or global neuronal networks	Unknown: potential early lifetime subclinical event
Motor neuron disorders	40–60s	Loss of spinal motor neurons	*Genetic*: missense mutations (ALS); gene deletions/aberrant splicing (SMA)

identified as potential risk factors for PD and genetic mutations have also been identified, it is likely that either alone or in combination, these triggers will produce a clinical syndrome similar to PD [reviewed in (24)]. Figure 2 outlines a common pathway for PD and suggests several targets for gene therapy without necessarily interdicting the initiating mechanism. In this ''common pathway'' model for PD, multiple triggering mechanisms such as genetic, toxicant, and environmental trigger, plus genetic vulnerability, converge on a shared common pathway to cell death. The first step along this pathway may encompass presynaptic injury and dysfunction followed by cellular compensation and metabolic stress. This preclinical injury and damage would result in DA deficiency and cell death. Gene therapy treatment opportunities would include (1) targeting specific triggering mechanisms, (2) targeting shared early pathways prior to presynaptic dopaminergic dysfunction, (3) targeting shared later pathways when dysfunction occurs, and (4) restoring DA biosynthesis in the denervated striatum. As stated above, PD is likely the result of a combination of environmental, toxin, and genetic triggering factors. Because of this, it is difficult to review the impact of each individually, but we attempt to briefly outline the potential impact of these factors on the etiology of PD and summarize their convergence on the pathophysiology of this disease.

2. Environmental Factors

Several findings support an etiologic role for exogenous factors in PD. The earliest observation was that a synthetic by-product of meperidine production produced a syndrome similar to PD. 1,2,3,6-Methyl-phenyl-tetrahydropyridine (MPTP) treatment of mice and monkeys has become a common method to achieve dopaminergic neuronal loss and an animal ''model'' of PD. The toxic compound MPTP is converted in glia to the pyridinium ion (MPP+) by monoaminoxidase type B (MAO-B) and subsequently taken up by dopamine neurons via the dopamine transporter. MPP+ is then actively transported to the mitochondria where it inhibits complex I, interfering with mitochondrial respiration and resulting in increased production of the superoxide anion. (25).

Recent reports lend biological plausibility to pesticide exposure as both an alternative model of nigrostriatal dopaminergic degeneration and a risk factor for PD (26–28). Greenamyre's group reported that chronic, systemic treatment of rats with the lipophilic pesticide, rotenone, resulted in highly selective nigrostriatal dopaminergic degeneration (27,29). This degeneration is associated with PD-like behavioral changes, including hypokinesia and rigidity. Neuropathologically, these animals accumulate fibrillar cytoplasmic inclusions that contain both ubiquitin and α-synuclein. This treatment represents an important alternate PD model because these inclusions resemble Lewy bodies, a hallmark of PD. Of equal importance is the suggestion from this model that mitochondrial dysfunction in dopaminergic neurons, in particular, complex I inhibition, plays an important role in the pathophysiology of Lewy body formation and some cases of idiopathic PD.

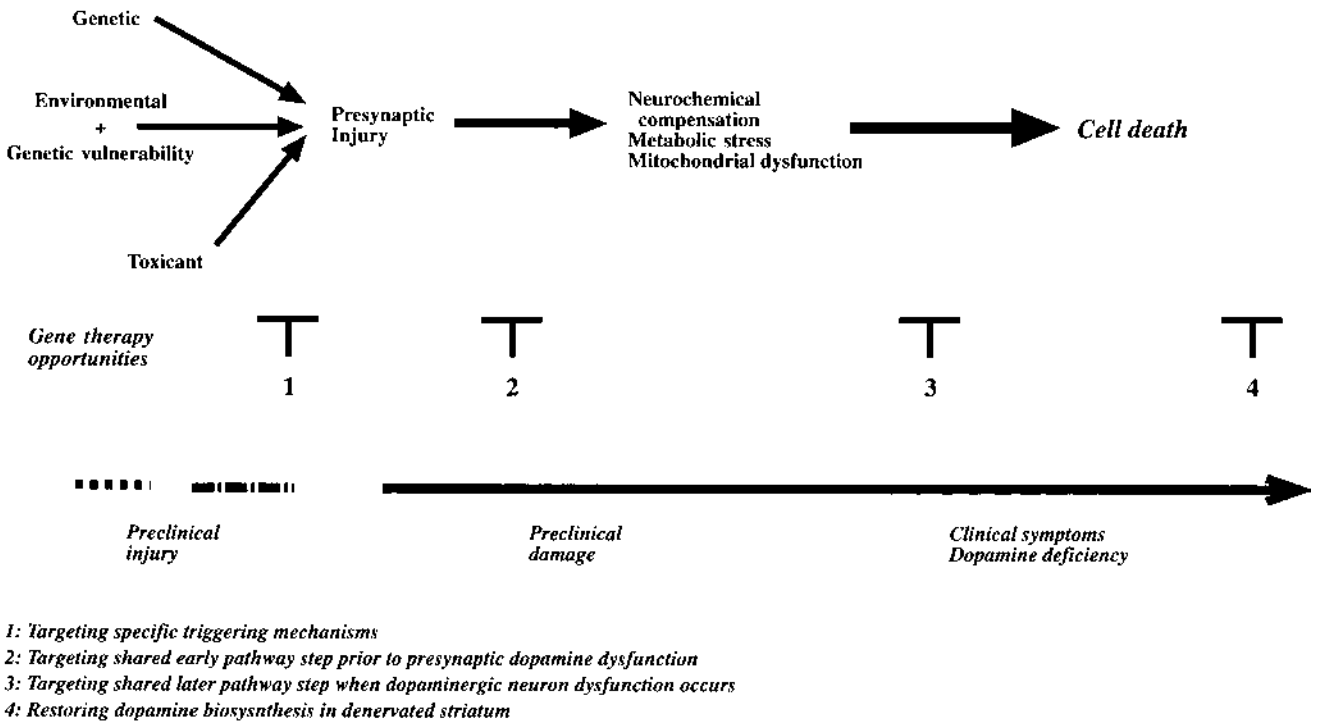

Figure 2 Schematic depicting the common pathway model for PD and points along this pathway where gene-based therapy may be applied. (From Ref. 252, © 2001 Elsevier Science B.V.)

Other groups have implicated a combination of herbicide and fungicide exposure as a potent risk factor for PD (26,28). Mice treated with a combination of paraquat and maneb demonstrated a sustained decrease in motor activity and reduced tyrosine hydroxylase immununoreactivity in the dorsal striatum. These effects were greater in combination than either paraquat or maneb alone, suggesting that multiple compound exposure alone, or in concert with genetic vulnerability, may trigger a cascade of events leading to PD.

3. Genetic Factors

Several genetic factors have recently been identified to play a central role in the etiology of familial PD. In 1996, genetic linkage strategies were applied to a large Italian family with early onset PD (17,30). The susceptibility gene was identified on the long arm of chromosome 4q21–q23 and positional cloning identified a missense mutation in the α-synuclein gene at position 53 (A53T) (31). Another mutation in α-synuclein, A30P, was identified in a German family (32). Although mutant α-synuclein is responsible for a small number of PD cases, it has vaulted to the forefront of PD research since wild-type α-synuclein has been identified as a key component of Lewy bodies. In fact, α-synuclein staining is now widely used as a neuropathological criterion for PD (33–38).

Two other genetic mutations related to proteasome function have been identified in familial PD. One mutation in the *parkin* gene was discovered in an early onset juvenile autosomal recessive form of parkinsonism (AR-JP) that presents with mild symptoms, slow progression, and the absence of Lewy bodies (39–41). Homozygous deletions and point mutations in *parkin* also account for the majority of autosomal recessive inherited PD (42–48). A second mutation in the ubiquitin carboxy-terminal-hydrolase-L1 (UCH-L1) gene has been identified in a German family with PD (49). Both Parkin and UCH-L1 are involved in the regulation of the ubiquitin-proteasome pathway that suggests dysregulation of protein processing in the pathophysiology of PD (21,50,51).

4. Potential Gene-based Therapies for Parkinson's Disease

As outlined in Fig. 1 and discussed above, toxicant and environmental triggers combined with genetic vulnerability are likely to converge on a common pathway toward cell death in PD. These common downstream events that culminate in neuronal cell death are all possible targets for gene therapy in the treatment of PD. Teaming the appropriate gene with the most powerful vector system will make these treatments a clinical reality for PD-afflicted individuals. The following sections summarize the present state of the art for the application of gene transfer technologies to treatment of PD.

a. Ad Vectors and PD. Adenovirus-based therapies for PD have been tested extensively in rodent models. A first-generation Ad vector encoding the TH gene, when introduced into the striatum of 6-hydroxydopamine (6-OHDA) lesioned rats, led to a reduction in amphetamine-induced rotational behavior (52). Vector-directed TH gene expression was observed for 1 to 2 weeks following gene transfer, but was accompanied by a vigorous inflammatory response, gliosis, and local tissue damage. Ad vectors expressing the TGF-β family member, glial cell line-derived neurotrophic factor (GDNF), have also been tested in 6-OHDA-lesioned rats where protection of the dopaminergic phenotype from chemical-induced damage is observed for up to 6 weeks postlesion (53). This protection was equivalent in scope if the vector was delivered to the striatum or the SN prior to the 6-OHDA lesion (54,55). GDNF delivery via an Ad vector was shown to exhibit differential effects in the lesioned aged rat as opposed to younger rats. Connor and colleagues demonstrated that Ad-mediated GDNF delivery was only protective in aged rats when the virus was delivered to the striatum, whereas the dopaminergic system of young 6-OHDA-lesioned rats could be protected by delivery to either the SN or striatum (56). This group hypothesized, based proposals by Zigmond et al., that compensatory changes occur in the CNS of the aged rat that likely increases its sensitivity to Parkinsonian lesioning (57).

b. AAV Vectors and PD. Recombinant AAV vectors exhibit great promise in the arena of PD gene therapy. For example, Kaplitt and others injected AAV vectors expressing either β-galactosidase or human tyrosine hydroxylase (hTH) into the brains of 6-OHDA-lesioned rats and demonstrated long-term transgene expression (3 months) and functional recovery (58). Mandel and colleagues demonstrated longer-term transgene expression (at least 1 year) in the rat striatum (59). In this series of experiments, AAV vectors were constructed to express either hTH or human GTP-cyclohydrolase I (GTPCHI) in the 6-OHDA-lesioned rat striatum. Elevated levels of L-dihydroxyphenlaline (L-DOPA) were observed in animals receiving both vectors, but disappointingly, no reduction in apomorphine-induced rotational behavior was apparent in these animals. CED-mediated delivery of AAV expressing the aromatic amino acid decarboxylase (AADC) gene to the striata of MPTP-lesioned monkeys resulted in L-DOPA-regulated dopamine production and release in these parkinsonian animals (11). An illustration of an experiment from this study is shown in Fig. 3. Another study using AAV vectors to deliver hTH and AADC genes to the brains of MPTP-treated monkeys showed that AAV vectors could direct long-term transgene expression devoid of significant toxicity (60). Recently, Shen and colleagues have used a triple AAV vector administration approach to combat PD (1). These vectors encode for TH, AADC, and GTPCHI, and were shown in combination in rats to enhance levels of tetrahydrobiopterin (BH4) and dopamine production, as well as to improve apomorphine-induced rotational behavior for up to 1 year. Other studies have also demonstrated extended expression in the CNS using AAV vectors (61–63).

A paper by During and colleagues (64) described the use of AAV vectors to express the glutamic acid decarboxylase (GAD) gene GAD65 in the setting of experimental PD to phenoconvert excitatory neurons (glutamate neurotransmitter releasing) to inhibitory neurons (GABA neurotransmitter-releasing). The rationale behind this novel approach relates to the altered neurotransmission that occurs within the basal gan-

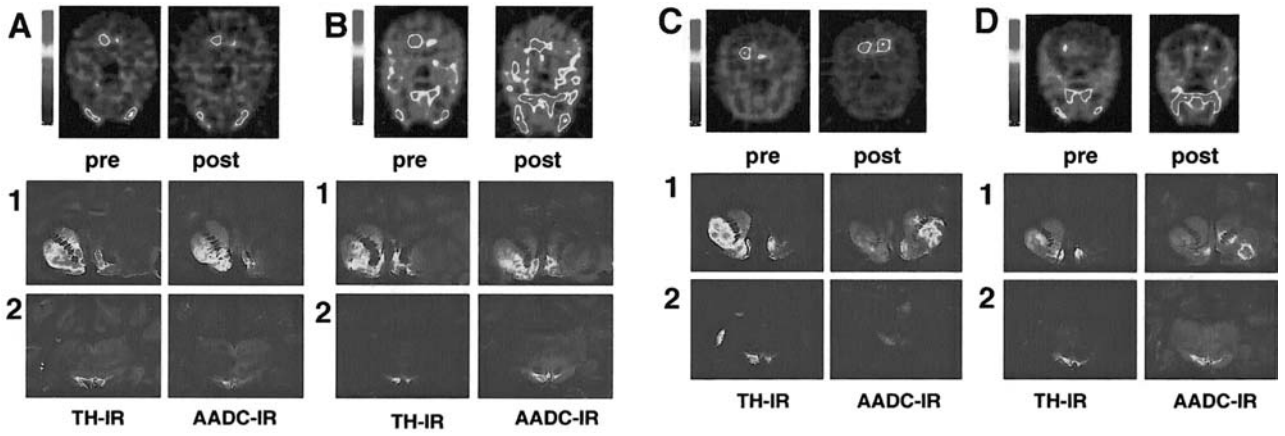

Figure 3 Convection-enhanced delivery of an AAV vector expressing the aromatic L-amino acid decarboxylase (AADC) gene in Parkinsonian nonhuman primates. Rhesus monkeys received the dopaminergic toxin MPTP to establish a stable parkinsonian state. A combined unilateral intracarotid artery and intravenous MPTP injection protocol was performed to produce a nearly complete dopaminergic lesion on the side of the carotid artery infusion (ipsilateral side) and a partial lesion on the other side (contralateral side). Once this was achieved, the animals received ipsilateral infusions of either AAV-AADC or the β-galactosidase control vector AAV-LacZ via convection-enhanced delivery into the striatum. Positron emission tomography studies of uptake of the AADC tracer 6-[18F]fluoro-L-*m*-tyrosine (FMT) in the striatum are shown for AAV-LacZ (upper segments of A and B) and AAV-AADC-injected monkeys (upper segments of C and D) pre- and postviral injection. FMT uptake was negligible in the ipsilateral striatum in all monkeys prior to AAV administration. After virus injection, AAV-LacZ-treated monkeys showed little change in ipsilateral FMT uptake, whereas AAV-AADC-treated animals demonstrated a dramatic increase in ipsilateral FMT uptake. After sacrifice, immunohistochemical analyses for tyrosine hydroxylase (TH-IR) and AADC (AADC-IR) expression were performed on the striatum (row 1 of each panel) and substantia nigra (row 2 of each panel). TH- and AADC-IR were markedly reduced in the ipsilateral striatum of AAV-LacZ-injected monkeys, whereas only AADC-IR was restored on the ipsilateral striatum of AAV-AADC-treated animals. In data not shown, AAV-AADC monkeys exhibited a marked enhancement in dopamine production when the animals were given L-DOPA, indicating that the AADC transgene product was bioactive. glia during PD. In this disease, dopaminergic neuron projections from the substantia nigra pars compacta to the striatum degenerate. The observed reduction in dopamine release in the striatum results in reduced GABA neurotransmission, also called ''disinhibition,'' in the subthalamic nucleus (STN). This state, coupled with direct disinhibition within the striatum itself, results in increased glutamate neurotransmission and thus excessive excitation of the substantia nigra pars reticulata (SNr) and the globus pallidum internal segment (GPi). Delivery of AAV expressing GAD65 to the STN led to increased GABA release in the SNr, shifted SNr single-unit recording responses from primarily excitatory to inhibitory, and if delivered prior to 6-OHDA lesioning protected rats from the neurotoxin. These results, although intriguing, require a comprehensive evaluation of long-term effects that neuronal phenoconversion may have on basal ganglia circuitry.

c. Lentivirus Vectors and PD. Lentivirus-based therapies for PD have been tested extensively in rodent and nonhuman primate models. Injection of a self-inactivating (SIN) lentivirus vector expressing GDNF has been shown to be protective in the 6-OHDA rat and MPTP nonhuman primate models of PD and in nonlesioned aged rhesus monkeys (65–67). An example of one of these studies is shown in Fig. 4. Long-term striatal overexpression of this potent factor by a lentiviral vector in nonlesioned rats has recently been shown to markedly down-regulate TH expression (68). The mechanism responsible for GDNF-mediated repression of TH expression is presently not understood, but the observation supplicates caution in implementation of gene transfer approaches clinically that involve long-term, uncontrolled GDNF expression.

Lentiviral vectors have been shown preclinically to be effective with other approaches to treat PD. The dopamine biosynthetic pathway, which is compromised in PD, may require the reintroduction of multiple components to restore physiological levels of dopamine. Due to the moderate size capacity of lentiviral vectors, multicistronic versions of the vector platform have been developed. Azzouz and colleagues recently created a lentiviral vector that coexpresses aromatic L-amino acid decarboxylase, tyrosine hydroxylase, and GTP cyclohydrolase I (69). Delivery of this vector to the striata of 6-OHDA-lesioned rats led to stable dopamine biosynthesis and functional improvement for up to 5 months posttreatment.

d. HSV Vectors and PD. Dependent the transgene size capacity of a given gene transfer vector, the use of cellular promoters to direct transgene expression appears to be another

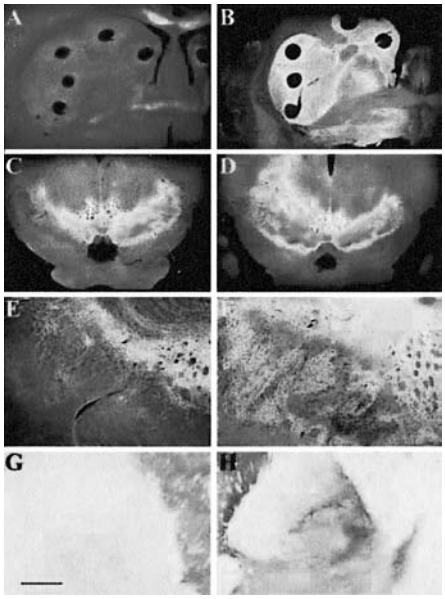

Figure 4 Delivery of a lentiviral vector expressing the glial cell line-derived neurotrophic factor (GDNF) gene in Parkinsonian nonhuman primates. Rhesus monkeys received the dopaminergic toxin MPTP unilaterally (right side) to establish a parkinsonian state. One week later, the animals received ipsilateral infusions of lentiviral vector expressing glial cell line-derived neurotrophic factor (lenti-GDNF) or one expressing the reporter protein β-galactosidase (lenti-βGal). Three months following treatment, the animals were sacrificed and immunohistochemistry was performed. A and B depict low-power, dark-field photomicrographs through the right striatum of TH-immunostained sections of MPTP-treated monkeys treated with lenti-βGal (A) or lenti-GDNF (B). There appeared to be a comprehensive diminution of TH immunoreactivity in the caudate and putamen of lenti-βGal-treated animals, whereas a nearly normal level of TH immunoreactivity was seen in the animals receiving lenti-GDNF. Low-power (C and D) and medium-power (E and F) photomicrographs are shown of a TH-immunostained section through the substantia nigra of animals treated with lenti-βGal (C and E) and lenti-GDNF (D and F). Note the loss of TH-immunoreactive neurons in the lenti-βGal-treated animals on the side of the MPTP infusion. TH-immunoreactive sprouting fibers, as well as an above normal number of TH-positive nigral perikarya, are observed in lenti-GDNF-treated animals on the side of the MPTP injection. G and H depict low-power, bright-field photomicrographs of a TH-immunostained section from a lenti-GDNF-treated monkey. Note the normal TH-immunoreactive fiber density through the globus pallidus on the intact side that was not treated with lenti-GDNF (G). In contrast, an enhanced network of TH-immunoreactive fibers is seen on the side treated with both MPTP and lenti-GDNF. Scale bar in (G) represents the following magnifications: A, B, C, and D at 3500 μm; E, F, G, and H at 1150 μm. (From Ref. 66, © 2000 AAAS.) See the color insert for a color version of this figure.

promising strategy for development of a gene-based therapy for PD because these promoters tend to yield longer-term, cell-specific expression. This has been demonstrated using HSV amplicons equipped with either the preproenkephalin or 9-kb tyrosine hydroxylase (TH) promoter in vivo. Kaplitt and colleagues showed extended expression duration and striatal cell specificity using a version of the preproenkephalin promoter inserted into an HSV amplicon (70). Using 9-kb rat TH promoter to drive expression of the β-galactosidase (*lacZ*) reporter gene in the mouse striatum, Jin et al. observed expression of *lacZ* in TH-positive dopaminergic neurons in the substantia nigra due to retrograde transport of amplicon virions (71). In one of the few published PD-related studies using amplicons as the chosen gene therapy vector, During and colleagues treated 6-OHDA-lesioned rats with an HSV amplicon expressing human TH (72). Behavioral and biochemical recovery was maintained for 1 year following vector introduction.

e. Nonviral Vectors and PD. The use of nonviral means of DNA delivery for treatment of PD is appealing due to the inherent lack of immunogenic and/or cytotoxic viral gene products in the system. Nonviral delivery of genes includes the following means of transfer: ''naked'' DNA, DNA encapsulated within cationic lipids or polycationic polymers, or DNA attached to positively charged metal particles and introduced via particle bombardment (3,73–75). Until recently, successful implementation of this gene transfer modality has largely been impeded by the low transfection efficiencies observed in neurons. In vivo nonviral means of DNA transfer were initially demonstrated to occur in muscle cells with surprising efficiency (76). DNA transfer using polycationic lipid formulations to glia and neurons has been also demonstrated, albeit at low efficiencies (10,73). Martinez-Fong and colleagues recently described their use of a neurotensin-SPDP-poly-L-lysine conjugate that was competent to bind and transfer plasmid DNA to neurotensin receptor-expressing cell lines (N1E-115 and HT-29) (77). Because the high-affinity neurotensin receptor is expressed by a subset of neurons of the nigrostriatal and mesolimbic dopaminergic systems, this nonviral gene delivery modality could prove useful in the treatment of PD. In Addition, the 25-kD cationic polymer polyethylenimine (PEI) was shown by Abdallah et al. to mediate transfer of a luciferase-expressing plasmid to neurons and glia of adult mice (78).

Pardridge and colleagues have developed an interesting nonviral gene delivery modality that has been recently tested in the 6-OHDA rat model of PD (79). A TH-expressing plasmid, encapsulated in PEGylated immunoliposomes (PIL) that were targeted to the brain with a rat transferrin receptor-specific monoclonal antibody, was administered intravenously. The plasmid was shown to effectively cross the blood–brain barrier and lead to transient normalization of TH levels within the striatum of 6-OHDA-lesioned rats. If issues regarding transgene expression silencing can be resolved and strict targeting to the striatum can be achieved, this approach may be one of the more promising applications of nonviral gene transfer-based therapies for PD.

B. Alzheimer's Disease

1. Introduction

As the most common cause of senile dementia, Alzheimer's disease (AD) affects millions of people worldwide. Clinically, patients experience progressive cognitive impairment leading to dementia and ultimately death. The neuropathological hallmarks of AD are senile neuritic plaques (NPs) and neurofibrillary tangles (NFTs). Neuritic plaques are extracellular aggregations of protein, including the fibrillar peptide, β-amyloid. NFTs are neuronal inclusions of filamentous structures containing hyperphosphorylated forms of the microtubule-associated protein tau. Although these tissue and cellular abnormalities are well described, the role of each in producing neuronal demise is still actively debated.

AD is divided into 2 types based on age of symptom onset, early (before 60 years) and late (after 60 years). Early-onset Alzheimer's disease (EOAD) is primarily an inheritable form of the disease. Genetic linkage studies of several families exhibiting EOAD identified a locus on the long arm of chromosome 21 near the amyloid precursor protein (APP) gene (80). Further studies revealed that mutations in APP gene increased the production of β-amyloid (a major constituent of senile plaques) (81). The APP linkage represents $<1\%$ of early onset cases suggesting other genetic loci exist. Two loci, one on chromosome 14q and the other on chromosome 1 containing the presenilin (PS)-1 and- 2 genes, have also been identified in linkage studies (82,83). Many mutations in PS-1 have been identified in EOAD cases, which account for $>50\%$ of all EOAD cases. The function of the PSs is currently emerging and appears to involve signal transduction (84–86).

A genetic locus on chromosome 19q is implicated in late-onset Alzheimer's disease (LOAD) (87,88). The apolipoprotein E gene is located in this region, but no mutations have been found in AD; however, 1 of 3 isoforms of ApoE, E4, is a significant risk factor for LOAD (81). Other potential LOAD-linked genes have been identified (89–95) and further study is needed to substantiate the importance of their linkage. The vast majority of LOAD cases are sporadic with no identified genetic component. Studies using microarray gene expression profile analysis are beginning to identify altered gene expression in LOAD compared with normally aged brains (P. Coleman, personal communication, 2003). Such analyses will lead to further studies characterizing the role of candidate genes in AD, possibly allowing for a genetic screen to identify the best therapeutic strategy.

2. Putative Mechanisms Underlying AD

Based on the neuropathological findings of AD, NPs, and NFTs, extensive research efforts have focused on their role in the pathogenesis of AD. Many hypotheses are under examination: the acetylcholine hypothesis (96,97), the amyloid cascade hypothesis (98–100), the neuroinflammatory hypothesis (101), energy metabolism hypothesis (102), and the oxidative stress hypothesis (103). A comprehensive review of the research behind each hypothesis is beyond the scope of this discussion; instead, each is discussed generally as a potential target area for gene therapy.

3. Potential Gene-based Therapies for AD

One of the affected brain regions is the basal forebrain cholinergic complex as cholinergic deficiency correlates with both the magnitude of pathological severity and degree of dementia (96,104–107). One therapeutic approach is to augment cholinergic function by increasing activity of the biosynthetic enzyme for acetylcholine, choline acetyltransferase (ChAT) to the affected area. Nerve growth factor (NGF) up-regulates expression of ChAT (108), and promotes survival and maintenance of the septohippocampal pathway that is a major pathway for memory and learning (109). Studies reporting that NGF increases β-amyloid production in vitro contrast with in vivo studies, suggesting that NGF delivery does not increase plaque formation in primates (110). Grafting of fibroblasts genetically modified to produce NGF via a Moloney murine leukemia virus vector promotes restoration and survival of the septohippocampal pathway (111–115). Figure 5 depicts an example of the bioactivity of these transduced grafts in vivo. NGF clearly has therapeutic potential but further studies will be needed to evaluate its efficacy in ameliorating symptoms of AD.

Amyloid-containing plaques may be a cause of AD or a byproduct of the disease process. Identified mutations in both the APP and the PS genes correlate with increased production of β-amyloid and potentially plaques. PSs are transmembrane proteins localized predominantly in endosomes and Golgi apparati and are believed to promote the aggregation of β-amyloid by increasing the activity of γ-secretase, the enzyme responsible for liberating the Aβ 1–42 fragment from APP (86,116). Gene products that may modify the activity of β- or γ-secretase or proteins capable of disrupting β-amyloid aggregation may potentially slow progression of the disease.

Other areas of therapeutic interest for AD are inflammation and oxidative stress. Many mediators of inflammation have been detected in the brain of AD brain [reviewed in (101)]. Whether inflammation is activated by the production of plaques and tangles or inflammation initiates production of plaques and tangles, which in turn propagates an inflammatory response is not clear. It is believed that the inflammatory response of glia that leads to neuronal demise (101). Epidemiological studies with antioxidants and nonsteroidal anti-inflammatory drugs suggest that decreasing free radicals and inhibiting inflammatory processes may confer protection against AD and/or slow the rate of cognitive decline seen in AD [discussed in (103)]. The delivery of gene products capable of scavenging free radicals and blocking inflammatory processes may also prove an effective therapeutic approach.

Recent publications have highlighted the potential of active and passive Aβ-based immunotherapies in the treatment of AD (117–119). Numerous investigative teams have reported diminution in AD-like pathology (i.e., Aβ deposition) and behavioral improvements in different animal models of the disease as a result of Aβ peptide immunization or via the administration of Aβ-specific antibodies. The biological

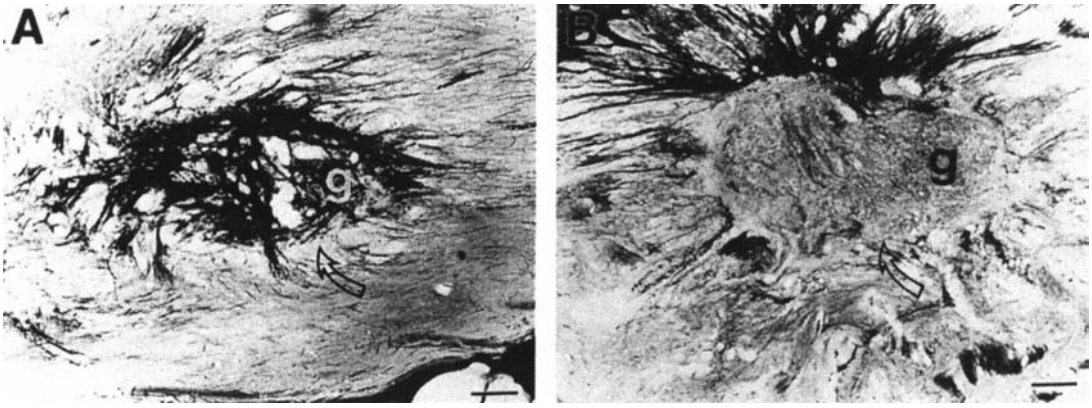

Figure 5 Neurite penetration into implanted primary fibroblast cells that have been transduced with a murine retrovirus vector expressing nerve growth factor. (A) depicts an NGF-secreting autologous fibroblast graft located in a region of intact Nucleus Basalis of Meynart (NBM) showing penetration by acetylcholinesterase (AChE)-positive neurites 1 month after grafting in cynomolgous monkey. Arrow and ''g'' indicate graft. In contrast, an implanted NBM graft initially transduced with a control β-galactosidase-expressing retrovirus vector (B) exhibits no penetration of AChE-positive neurites, although sprouting at the edge of the graft potentially due to astrocytic NGF secretion is apparent. These studies and many others suggested that NGF-expressing autologous fibroblast grafts might represent a viable approach to promote regeneration of cholinergic neuronal pathways targeted by Alzheimer's disease. Early-phase human clinical trials are in progress to determine the safety of this therapeutic methodology. (From Ref. 114, © 1994 Elsevier Science B.V.)

mechanism(s) by which these therapies act are still subject to interpretation. However, 2 nonmutually exclusive hypotheses have emerged: (1) Aβ-specific antibodies whether raised intrinsically or passively administered act at the blood–brain barrier (BBB) to alter the equilibrium of soluble $A\beta_{1-42}$ concentrations to favor its clearance from the brain. This is posited to prevent additional Aβ peptide deposition and perhaps promote aggregate dissolution. (2) Aβ-specific antibodies cross a compromised BBB and bind to Aβ within the brain parenchyma where antibody-Aβ complexes are postulated to be bound by complement, and recognized by microglia, which dissolve existing amyloid deposits. Both mechanisms of vaccine action can lead to possibly harmful side effects, with the most feared being systemic autoimmune disease and CNS inflammation as illuminated by recent findings from a Elan Pharmaceuticals peptide vaccine phase II clinical trial conducted in Europe [commentary in (120,121)]. Although presently untested, gene transfer technology due to its inherent versatility may allow for regulated antigen presentation and even codelivery of immunomodulatory gene products that could lead to safer and more efficacious vaccines for AD.

C. Lysosomal Storage Diseases

1. Introduction

Lysosomal storage diseases (LSDs) are a diverse group of greater than 40 disorders that originate from a deficiency of a lysosomal enzyme, resulting in accumulation of lysosomal proteins and cellular dysfunction. Many of the LSDs exhibit moderate to severe deleterious effects on somatic tissues as well as the CNS. These degenerative disorders differ from many of the neurodegenerative diseases described in that the pathogenic mechanism responsible for most LSDs is already known (i.e., lysosomal enzyme deficiency, defects in cofactors or transport proteins). There are examples of LSDs, however, for which the missing lysosomal function/protein activity has not been identified [e.g., a subset of the ceroid lipofuscinosis diseases; reviewed by (122)]. Depending the type of LSD, enzyme replacement by direct infusion of the missing enzyme into peripheral tissues has been an extremely successful strategy (123). This is no more evident than in the case of Gaucher disease, which results from a deficiency of glucocerebrosidase. Loss of glucocerebrosidase leads to accumulation of glucocerebroside, a byproduct of sphingolipid degradation, in macrophages resulting in spleen and liver enlargement, bone malformation, and pulmonary dysfunction (123). Infusion of recombinant glucocerebrosidase leads to significant correction of peripheral tissue disease (124). A similar approach has proven successful in the treatment of Fabry disease, another sphingolipid disorder that primarily affects kidney, heart, and skin [reviewed by (125)]. In clinical trials, intravenous delivery of α-galactosidase A was found to be safe and led to marked reductions in plasma glycosphingolipid levels and microvascular endothelial deposits in major organs (126,127).

Other LSDs exhibit both peripheral and CNS involvement. The CNS component of the mucopolysaccharidosis (MPS) storage disorders and other LSDs has proven a more difficult task to correct using standard enzyme replacement therapy. This difficulty lies in the inability of peripherally infused lysosomal enzymes to traverse the blood–brain barrier. Development of methodologies to effectively deliver and distribute

the deficient enzyme throughout the brain would represent a major advance in therapies for LSDs. To that end, the implementation of gene-based technology in this endeavor has been enthusiastically pursued and has demonstrated initial promise.

2. Potential Gene-based Therapies for Correcting CNS Dysfunction Caused by LSDs

Numerous mouse models for the various LSDs have been developed and have proven extremely useful in assessing novel therapies. Gus^{mps} mice exhibiting the β-glucuronidase enzyme deficiency associated with Sly disease undergo progressive lysosomal accumulation of non-egraded glycosaminoglycans in multiple organs including the brain. The Sands laboratory demonstrated that AAV vector-mediated delivery of β-glucuronidase into the anterior cortex and hippocampus of newborn MPS VII mice led to a reduction in glycosaminoglycan deposition and concomitant improvement in cognitive function as measured in the Morris Water Maze paradigm (128). Although transgene expression levels were generally greater than normal β-glucuronidase levels, particularly at the injection site, no overt toxicity was observed. In addition, these results suggested that a single point source of continuous enzyme expression produced lysosomal storage correction at distal sites. Several other groups have also demonstrated the utility of AAV vector-mediated β-glucuronidase delivery in gus^{mps} mice (129–131).

Davidson and colleagues have used recombinant viral vectors based on feline immunodeficiency virus (FIV) to deliver the β-glucuronidase gene to the brains of MPS VII mice to determine if restoration of this enzyme diminished preestablished lysosomal accumulations and corrected associated CNS deficits (132). FIV vector-mediated bilateral delivery of β-glucuronidase via the striatum led to bilateral correction of protein deposits and a reversal of spatial learning and memory impairments. The effect FIV vector-mediated expression of β-glucuronidase on lysosomal storage is illustrated in Fig. 6. Perhaps shedding light on potential mechanisms of action, gene expression profiling indicated significant increases in genes associated with neuronal plasticity mediation. An interesting extension of these studies was performed recently by Elliger and colleagues (133). The coding sequences for the Igκ secretion and HIV-1 TAT uptake signals were engineered into the β-glucuronidase open reading frame in order to effect therapeutic benefit in more distal organs. This modified transgene was delivered intrathecally via an AAV recombinant vector to newborn gus^{mps} mice. Treated mice were found to be more active, exhibited less stunted growth, and did not show evidence for abnormal storage deposits in the brain or liver, or in tissues not harboring AAV vector genomes.

The Twitcher mouse, which harbors a genetic disruption in the galactocerebrosidase locus, serves as an informative murine model for human globoid cell leukodystrophy (Krabbe disease). Intraventricular infusion of a recombinant adenovirus vector expressing galactocerebrosidase to newborn Twitcher mice led to marked reduction in lysosomal storage pathology (134). However, unlike in the case of gene delivery to MPS VII mice, treatment of Twitcher mice with preestablished disease had no significant effect on disease pathology. These results indicate that timing of interventions for Krabbe disease is crucial, and/or adenovirus vectors, due to their inherent immunogenicity and reduced duration of expression, are not as useful for treating this LSD. It is interesting to note that there exist autosomal recessive forms of Krabbe disease that have been identified in dogs and rhesus monkeys (135). As other gene transfer vector approaches are applied to this disease, these higher order mammalian models will become invaluable in the stepwise progression toward clinical application to the human form of Krabbe disease.

D. Huntington's Disease

1. Introduction

Huntington's disease (HD) is a fully penetrant genetic neurodegenerative disorder that is inherited as an autosomal dominant mutation of the *HD* gene (136). Affected individuals begin to exhibit symptoms in the third to fifth decade of life with some cases of juvenile (under 20 years old) and late onset (over 65 years old) (137,138). Clinical manifestations of the disease include progressive chorea, emotional disturbances, and dementia. Neuropathological features of HD include an extensive loss of neurons and astrogliosis in the striatum, primarily the caudate nucleus. Histologically, intracellular inclusions consisting of ubiquitinated polyglutamine aggregates have been found in neurons of the striatum and other less affected areas such as neocortex.

The *HD* gene encoding the huntingtin protein was first localized to chromosome 4p16.3 in 1983 (139). The normal function of huntingtin remains an enigma; however, cloning of the normal and diseased gene revealed the mutant form of the gene contains an increased number of glutamine encoding CAG repeats in the amino terminus (139). Normal individuals contain 11 to 34 repeats, whereas affected individuals contain 40 or greater repeats (140,141). A study by Ashizawa et al. (141) provided evidence that repeat numbers correlated with age of onset and clinical symptom severity; however, the mechanism by which the expression of this mutant protein leads to cell death remains elusive.

2. Possible Mechanisms of Disease

Understanding the normal function of huntingtin may prove pivotal in understanding how the mutant form leads to the selective loss of medium spiny neurons in the striatum. In the absence of this knowledge, studies have suggested possible mechanisms by which the mutant HD gene product causes cell death and provided a basis for developing therapeutic strategies.

One proposed mechanism involves a pathway of cellular protein degradation. The ubiquitin/proteasome pathway is the major protein degradation pathway of the cell. The proteasome, a cylindrical peptidase-containing complex that cleaves ubiquitinated proteins into their amino acid constituents, is believed to be involved in the degradation of huntingtin (142,143). In Huntington's disease, ubiquitinated polyglutamine aggregates have been identified, suggesting the digested

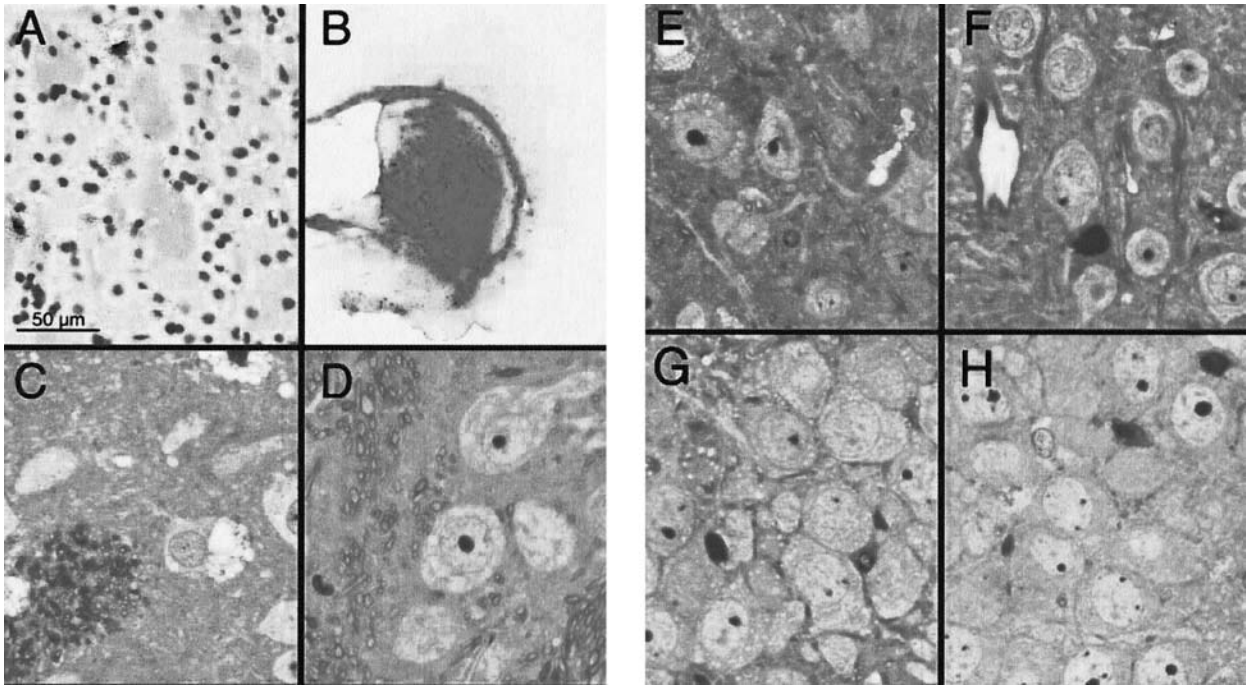

Figure 6 β-Glucuronidase expression following FIV-mediated gene transfer into the striata of MPS VIII mice and its effect on lysosomal storage. Eight-week-old MPS VII (gus^{mps}) mice were injected unilaterally into the striatum with 1×10^6 transduction units of a feline immunodeficiency virus (FIV) vector expressing β-glucuronidase (FIVβgluc). Six weeks later the animals were sacrificed and analyzed for transgene expression, β-glucuronidase enzyme activity, and lysosomal storage profiles. Transgene-positive cells were detected near the injection site as revealed by in situ RNA analyses (A). β-Glucuronidase activity in the brain of a MPS VII mouse injected with FIVβgluc was found to encompass a wide volume of the brain as determined by histological staining (red staining; B). Representative examples of lysosomal storage in the striatum (C), cortex (E), and hippocampus (G) in nontreated 8 to 12-week-old MPS VII mice are shown. Noticeable lysosomal storage is evident at this age. Analysis of age-matched, FIVβglu-treated MPS VII mice shows significant correction of the storage deficit in the contralateral striatum (D), cortex (F), and hippocampus (H). In data not shown, treated animals exhibited improved learning and memory behavior, indicating that lentivirus-based delivery of β-glucuronidase to the CNS of an animal with preestablished lysosomal storage disease can reverse the neurological deficits caused by the disease. (From Ref. 132, © 2002 National Academy of Sciences.) See the color insert for a color version of this figure.

mutant form of huntingtin creates aggregates leading to an apparent apoptotic cell death (144,145).

Huntingtin has been shown to interact with huntingtin-associated protein 1 (HAP-1) (146), huntingtin-interacting protein 1 and 2 (HIP-1, -2) (147,148) glyceraldehydes-3-phosphate dehydrogenase (GAPDH) (149), and calmodulin (150). HAP-1 binding to huntingtin is enhanced by increased glutamine repeat length (146). It is believed to be involved in vesicular membrane trafficking, but this has not been proven (151). Unlike HAP-1, HIP-1 binding to huntingtin is inversely related to the polyglutamine residue number. The loss of this interaction in a HD neuron may affect the cytoskeletal architecture given HIP-1's similarity to cytoskeletal proteins (148). HIP-2 is an ubiquitin-conjugating enzyme that may be involved in the proteasomal degradation or aggregation of mutant huntingtin (152). The glycolytic enzyme, GAPDH, binds to cleaved huntingtin fragments in vitro (149). The increased binding of GAPDH to cleaved huntingtin fragments may alter cellular energy production, leading to membrane depolarization, increased intracellular calcium, and cell death. Huntingtin can from a complex with calmodulin in a Ca^{2+}-dependent manner, but the mutant form binds independent of calcium (150). Subsequent activation of downstream targets of calmodulin, such as those activated in excitotoxic cell death, may lead to cell death. Further understanding of the interactions of huntingtin with the aforementioned proteins or other proteins will allow for targeted gene therapy. Based on our current understanding, therapies designed to block apoptosis, relieve oxidative stress and prevent the expression and accumulation of degraded mutant huntingtin may help to relieve or prevent symptoms in affected patients.

3. Potential Gene-based Therapies for HD

Yamamoto et al. (153) demonstrated that continuous expression of mutant protein is necessary to maintain intracellular

inclusions and symptoms. A therapy designed to decrease mutant protein levels by antisense therapy may prove useful. In this strategy, a viral vector expressing an antisense RNA or ribozyme (154) to huntingtin could be delivered to the striatum. Alternatively, if a technology were available to reduce the glutamine repeats and/or replace the mutant allele with a normal allele, a permanent reversal of the disease might be accomplished. The use of chimeroplasts, target-specific RNA/DNA oligonucleotides, could possibly allow correction of the genetic deficit, but this may not be technically feasible for such a large mutation (155–157).

A second approach takes advantage of the well-characterized neurotrophic factors, endogenous soluble proteins that regulate survival, growth, morphological plasticity, or synthesis of proteins for differentiated functions of neurons (157). The delivery of the neurotrophic factors GDNF, BDNF, or CNTF have shown neuroprotective effects when given prior to a quinolinic acid challenge in rodent and primate models of HD (158–160). The neuroprotective effect of lentiviral vector-mediated delivery of CNTF in the quinolinic acid model for HD is illustrated in Fig. 7. Further analysis is needed to evaluate the full potential of neurotrophic factor treatment for HD.

A third approach would be to target mechanisms of apoptotic cell death and oxidative stress. Similar to neurotrophic factors, this approach may delay the progression of the disease, but does permanently correct the genetic deficit. The antiapoptotic gene, *bcl-2*, has been shown to inhibit neuronal apoptosis both in vitro and in vivo (161–171). Delivery of the *bcl-2* gene to affected neurons may prevent or delay cell death that occurs in HD. If oxidative free radicals contribute to cell death, the expression of gene products capable of directly or indirectly lowering or removing free radicals [e.g., superoxide dismutase (SOD), catalase, glutathione reductase (GR), glutathione peroxidase (GPO), and glutathione (GSH)] might prove useful in combating neuronal loss.

HD is one of a family of trinucleotide repeat disorders, which includes spinal and bulbar muscular atrophy, spinocerebellar ataxia (types 1, 2, 3, 5, and 7), and dentatorubropallidolusian atrophy. Elucidating the mechanisms by which the mutant form of huntingtin leads to disease may aid in the development of successful gene therapies for HD and possibly other related trinucleotide repeats disorders.

E. Stroke

1. Introduction

Hypoxic injuries, such as stroke, are the genesis of substantial morbidity and mortality in neonates and older individuals. Oxygen deprivation can lead to profound effects on motor function and cognition (172), leading to severe disability and diminished quality of life. Stroke is most commonly the result of embolic obstruction that results in either reduced or complete loss of blood flow to downstream fields. Two types of cell death appear to occur following a stroke. At the ischemic core, necrosis is readily apparent and has been linked to elevated extracellular glutamate and intracellular calcium levels. Necrotic cell death involves nonspecific DNA degradation, nuclear pyknosis, diminished membrane integrity, and mitochondrial swelling. Neuronal degeneration within this area following blood vessel obstruction occurs very rapidly (minutes) following the ischemic insult, and due to this time limitation, does not represent a viable target for gene-based therapeutics. In brain areas more distal to the ischemic core, termed the prenumbra, neurons undergo a more delayed form of cell death (hours to days) that exhibits dependence6 *de novo* gene expression (173–175). This delayed neuronal death, or

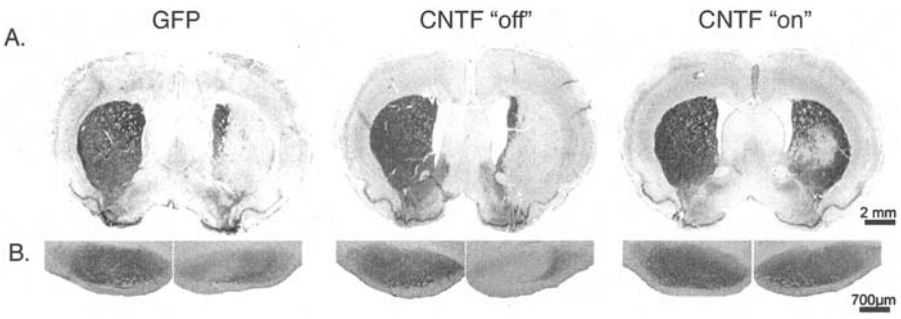

Figure 7 Use of a tetracycline-regulated lentiviral vector expressing ciliary neurotrophic factor (CNTF) in the quinolinic acid rat model of Huntington's disease has a dose-dependent neuroprotective effect. Rats received intrastriatal injections of a tetracycline-regulated lentiviral vector expressing either CNTF (TRE-CNTF) or the reporter protein GFP (TRE-GFP). The vector-injected rats were treated with saline (''off'') or doxycycline (''on'') to regulate transgene expression. Quinolinic acid was infused into the striatum of these mice and they were subsequently sacrificed and brains analyzed by immunocytochemistry for the striatal marker DARPP-32. Representative photomicrographs showing DARPP-32-immunostained striatal (A) and nigral sections (B). The quinolinic acid-induced lesion is clearly indentified by the loss of DARPP-32 staining in the GFP- and CNTF-off groups, whereas a significant protective effect is observed when CNTF expression is switched on. (From Ref. 253, © 2002 Mary Ann Liebert, Inc.)

apoptosis, is capable of producing damage equivalent to the acute necrotic lesion observed soon after severe ischemia. Cells undergoing apoptosis exhibit characteristic fingerprints, including chromosome condensation, internucleosomal DNA fragmentation, and membrane blebbing. A thorough understanding of the gene expression profiles and signaling events that occur in the prenumbra immediately following an ischemic event is likely to yield several molecular/cellular targets that are amenable to pharmacological and gene-based therapeutics.

2. Possible Mechanisms of Disease

Ischemia promotes adaptive and pathologic responses in the neuronal compartment. As illustrated in Fig. 8, extrinsic and intrinsic perturbations in the ischemic brain appear to activate a neuronal ischemic sensor, which in turn promotes adaptive and pathologic gene expression. It is the complex interplay among the numerous molecular signaling cascades and time sensitivity of the disorder that makes development of gene-based approaches for stroke both an exciting and daunting task. The ischemic sensor activates a series of transcription factors that, depending their respective stoichiometry and subcellular localization, act to initiate either an adaptive or pathologic signaling cascade. Insights into candidate gene products that confer protection against ischemic exposure can be gleaned from prior preconditioning studies (176). The gene products involved in adaptive processes include those that inactivate reactive oxygen species (ROS), and those that participate in DNA repair and cytoplasmic calcium regulation (177,178). Hypoxic insult also stimulates the secretion of factors like erythropoietin (EPO) and vascular endothelial growth factor (VEGF), which can act via a paracrine manner to effect neuroprotection (179,180). Other gene products, including heat shock protein 72 (HSP 72) and glucose transporter Glut-1, have been identified that block the initiation of pathologic gene expression (181–184). Such factors may provide sufficient protection during the early stages of cellular responses to ischemia in order to subvert potential downstream apoptotic signaling.

3. Potential Gene-based Therapies for Stroke

Many early experimental gene therapy approaches targeted either intermediate or the late stages of the apoptotic process. The commitment to apoptosis, which is believed to involve mitochondrial permeability transition, can be averted by overexpression of a subset of Bcl-2 protein family members and a neuronal apoptosis inhibitory protein (NAIP). HSV-based vectors overexpressing Bcl-2 reduces the incidence of apoptosis and improves neuronal survival both in vitro and in vivo (167,185). Adenoviral vector-mediated expression of NAIP resulted in reduced levels of activated caspase-3 and diminished neuronal degeneration following transient forebrain ischemia (186,187). Other strategies involve inhibition of cellular caspases that act during later stages of apoptosis through the use of cell-permeable peptides to block the morphologic features of apoptosis (173). In addition, vector-mediated expression of anti-inflammatory molecules (i.e., interleukin-1 receptor antagonist) has been employed to minimize poststroke inflammatory responses within the brain (188–190). However, because ischemia induces global disruptions of cellular processes upstream of mitochondrial commitment, caspase activation, and resultant inflammation, it is unclear whether these strategies can effectively interrupt the initiation of apoptosis or restore function to neurons endangered by this cellular process (191,192). It is also important to note that many of the stroke-related gene transfer approaches performed to date have been employed prior to the onset of experimental ischemia. For gene transfer to be clinically applicable for ischemic disorders, treatments must be assessed following the ischemic event (realistically, at times 1–2 postinjury) (193).

Gene-based neuroprotective approaches that employ neurotrophic and angiogenic factors have also been extensively examined. Tsai and colleagues have used AAV vectors to express GDNF in the setting of experimental stroke as an approach to minimize neuronal damage caused by transient ischemia (194). Rats receiving AAV-GDNF immediately following bilateral common carotid artery ligation and middle cerebral artery occlusion exhibited significantly reduced infarct volumes as compared with animals receiving a β-galactosidase-expressing AAV control vector (Fig. 9). Zhang et al. performed studies using adenovirus-expressed GDNF to examine the therapeutic window following transient middle cerebral artery occlusion (MCAO) in rats (193). The protective effect afforded by GDNF overexpression (i.e., reduced infarct size and inhibition of caspase-3 expression) was evident only if Ad-GDNF was administered at the time of reperfusion, but the effects of the gene transfer were minimal at 1 postreperfusion. These results underscore the importance of early postischemia interventions in minimizing neurodegeneration.

Restoration of energy stores in hypoxic neurons via overexpression of the rat glucose transporter, GLUT-1, has been an approach that has shown promise in experimental models of ischemia and brain injury. HSV vector-mediated delivery of GLUT-1 in 3 models of injury (transient focal cerebral ischemia, kainic acid, and 3-acetylpyridine) led to localized increased uptake of glucose, reduced neuron loss, blunted decline in ATP concentrations and metabolism, and decreased glutamate release and cytosolic calcium levels (183,184,195). Approaches that more directly address the detrimental cytosolic calcium excess observed following ischemia include overexpression of calcium-binding proteins. Viral vector-mediated delivery of the calcium-binding protein calbindin D28K exhibits calcium-buffering activity and is protective in conditions of hypoglycemia and experimental stroke (196–198).

During times of cellular stress, resident proteins can become misfolded, a process that can result in diminution of protein function/activity and potentially lead to intracellular aggregation [reviewed in (199)]. Stress response factors, such as heat shock proteins, have been shown to act as molecular chaperones to assist in protein folding and may represent another approach to support a cell under ischemic attack. Several reports of vector-mediated overexpression of heat shock pro-

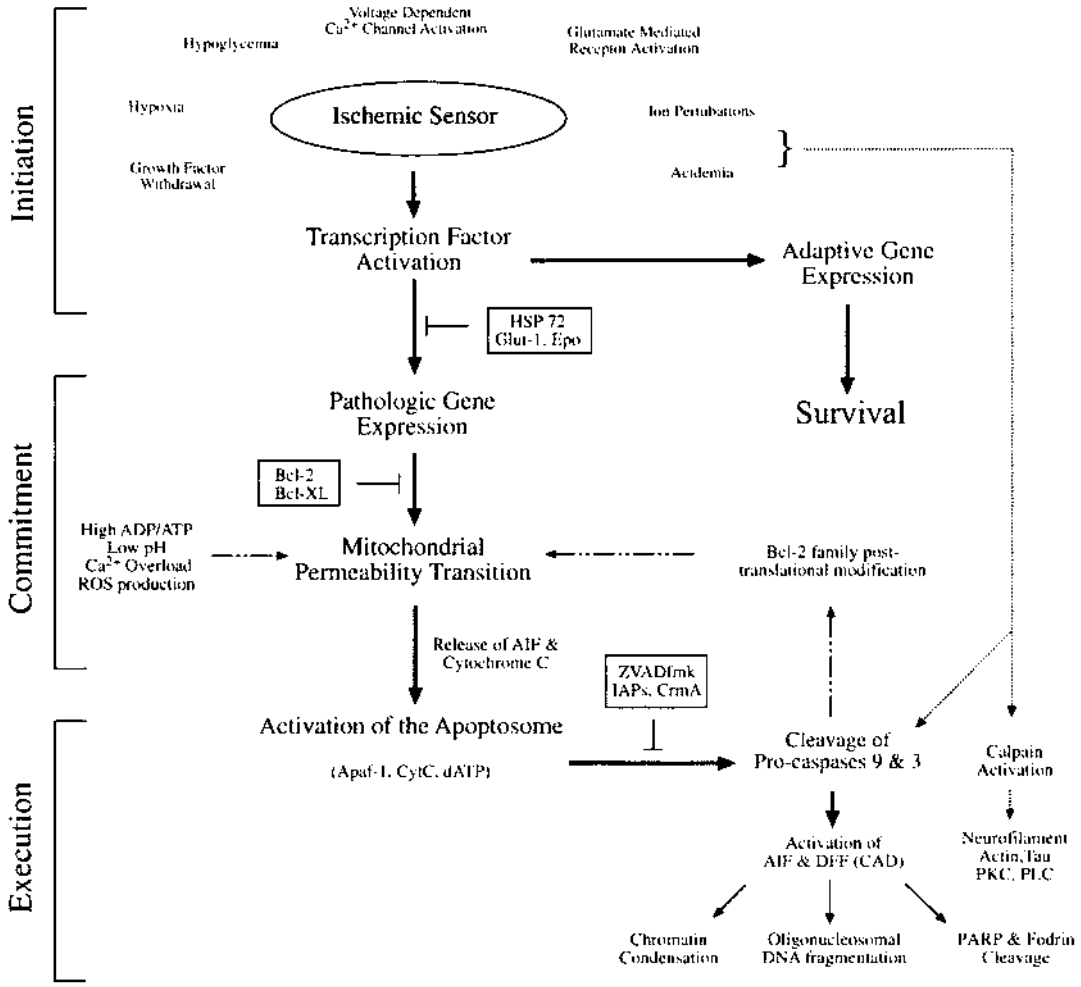

Figure 8 Ischemia promotes adaptive and pathologic responses in the neuronal compartment. Extrinsic and intrinsic perturbations in the ischemic brain activate a neuronal ischemic sensor, which in turn promotes adaptive and pathologic gene expression (solid lines). In addition, select stimuli can activate neuronal death independent of de novo gene expression (dashed lines). Specific gene products, which have demonstrated the ability to block the initiation, commitment, or execution phases of the programmed death pathway, are also included (boxed items). (From Ref. 254, © 1999 Elsevier Science B.V.)

teins (e.g., HSP72) in ischemic animal models demonstrate a neuroprotective role for these factors (200,201). HSV amplicon-mediated delivery of HSP72 to rats 30 min after MCAO resulted in higher numbers of surviving neuron numbers as compared with animals receiving a β-galactosidase-expressing amplicon (200).

In aggregate, gene transfer applications for stroke have shown preclinical promise. For such approaches to gain merit as viable treatment options in humans, major issues need to be addressed. One consideration relates to means of vector delivery. Focal administration of viral vectors following an ischemic event will likely have minimal benefit due to the large areas of the brain that are typically affected. Convection-enhanced delivery may provide the means in which to widely distribute a given therapeutic vector, but remains largely untested in ischemic paradigms (11). A second issue that is not entirely unrelated to the first concerns the window of therapeutic opportunity. As described above, a multitude of signaling events occurs immediately after ischemia that determine whether the compromised neuron follows an adaptive or a pathologic set of molecular instructions. This time window is extremely limited (1–2 poststroke), which makes the implementation of stereotactic means of gene therapy vector delivery nearly improbable. A comprehensive understanding of the molecular signals and their temporal expression profiles will likely identify targets at the earliest of times within this restricted therapeutic window. Until these gaps in disease process knowledge are filled and technical hurdles overcome,

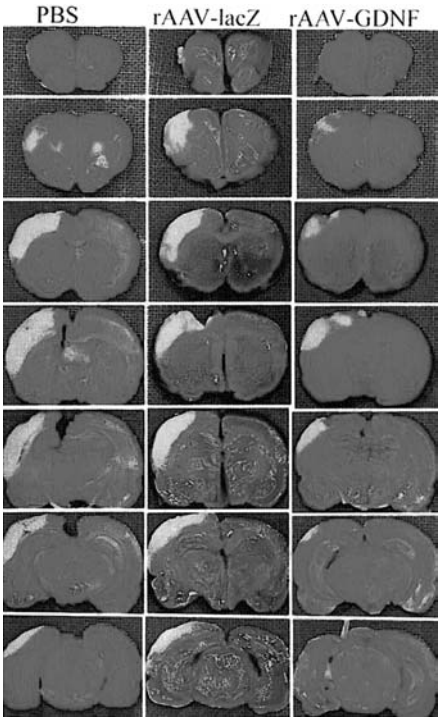

Figure 9 Injection of rAAV-GDNF markedly reduces cortical infarction induced by middle cerebral arterial ligation in rats. The right middle cerbral artery and bilateral common carotid arterial were occluded for 90 minutes. Animals received a PBS, rAAV-lacZ (10^{10} viral particles), or rAAV-GDNF (10^{10} viral particles) unilateral infusion during arterial occlusion, were sacrificed 72 hours later, and their brains were coronally sectioned (2-mm thickness) for TTC staining. White areas represent infarcted zones in the cerebral cortex. Rats receiving rAAV-GDNF exhibited a marked reduction in infarct size as compared to animals receiving the rAAV-lacZ or PBS control. clinical gene therapy interventions for stroke will remain an impractical potential alternative to pharmacologic compound-based therapeutics.

F. Epilepsy

1. Introduction

The epilepsies constitute a group of neurological disorders characterized clinically by various seizure syndromes and at the cellular level by hyperexcitability. The inherent cell biological problem is that of pathologic shifting of the normally well-regulated balance between inhibition and excitation toward the latter. The etiology of acquired epilepsy is unknown, although an emerging viewpoint is that early lifetime events, perhaps subclinical in nature, contribute to or trigger the development of the neural substrate underlying the hyperexcitable state [reviewed in (202)]. Because the processes responsible for inducing epileptogenesis are not fully elucidated, present treatment strategies are therefore directed at controlling symptoms (seizures). The seizures are the clinical manifestations of aberrant hypersynchronization of neural networks that can remain local, spread to other locations, and/or involve all cortical regions at once. Neocortical or hippocampal circuits are uniformly activated during an epileptic seizure. Synaptically connected regions may be recruited in a manner to augment or attenuate the discharge. When epileptic discharges travel unimpeded through neural networks, the network functions are subverted, temporarily rendering them incapable of executing normal tasks. With increasing duration of disease, particularly in epilepsies involving the temporal lobe, the neural substrate scars, presumably from chronic exposure to excitatory neurotransmitters (e.g., mesial temporal sclerosis).

For those epilepsies that are unresponsive to pharmacologic therapies, the only present means of relief for some individuals is neurosurgical resection. Due to the highly complex nature of the mammalian CNS and the unknown etiology of epilepsy, the execution of complicated neurosurgery to treat this debilitating disorder is approached with extreme caution. Such medically refractory and surgically difficult cases may prove to be suitable targets for gene therapy. Gene transfer would provide a means to locally alter synaptic transmission in a way as to synchronize excitatory and inhibitory signals, and in doing so, disrupt the hyperexcitable state. Of course, a number of considerations must be addressed, including the cell types to be targeted, localization of the transgene product (e.g., cell intrinsic vs. secreted), transgene expression control (e.g., constitutive vs. regulated), and effects on neighboring normal neuronal circuitry. However, in recent years, novel approaches for treating epilepsy using gene-based means have begun to exhibit promise. Two such preclinical studies are summarized below.

2. Potential Gene-based Therapies for Epilepsy

The development of animal models for epilepsy has greatly enhanced the means in which to assess the possible etiology, and in turn, new therapies for this disorder. Extant in the literature is the observation that accumulation of N-acetyl-L-aspartate (NAA) in the brain leads to induction of seizurelike syndromes. NAA is found predominantly in neurons of the CNS and has served as a useful marker of neuronal injury and/or death in several neurodegenerative diseases. Intraventricular infusions of NAA produce absencelike seizures with signature hippocampal electroencephalograms (EEGs) (spike wave like complexes) in rats (203). A deletion mutation in the aspartocyclase (ASPA) gene, which encodes for the enzyme responsible for metabolizing NAA into aspartate and acetate in glial cells, has been discovered in tremor rats, a model of human petit mal epilepsy (204). The tremor rat model represents a useful in vivo system in which to test novel antiepilepsy gene transfer approaches (205). Seki and colleagues used a

replication-defective recombinant adenoviral vector to deliver the rat ASPA gene to the tremor rat (206). Injection of the ASPA-expressing vector into the brains of 7-week-old tremor rats significantly reduced the appearance of absencelike seizures, as compared with rats receiving a β-galactosidase expressing control adenovirus vector (Fig. 10).

Another animal model that can be used to assess novel gene-based therapies for epilepsy is the protein-L-isoaspartyl methyltransferase (PIMT)-deficient mouse (207,208). PIMT is a ubiquitously expressed enzyme that repairs proteins that have undergone isomerization of aspartate residues or deamidation of asparagine residues. Failure to repair these spontaneously occurring protein alterations leads to mislocalization and diminished protein function (209). In fact, PIMT-deficient mice, which are devoid of both splice variant forms of PIMT, accumulate isoaspartate (IsoAsp) within their brains. One obvious phenotype of this deficiency is the progressive development of fatal epileptic seizures. Intraventricular delivery of both splice variants (PIMT-I and -II) via *exo-utero* means to E14.5 PIMT-deficient mice led to improved growth, diminished IsoAsp accumulation, enhanced survival times, and marked reduction in occurrence of epileptic seizures (210). Sustained therapeutic gene expression and concomitant clinical benefit was evident at times up to 7 weeks postinjection. In aggregate, the promising results garnered from these 2 epilepsy gene transfer studies evoke enthusiasm for further development of gene-based therapies for those epileptic syndromes refractory to standard symptomatic treatments.

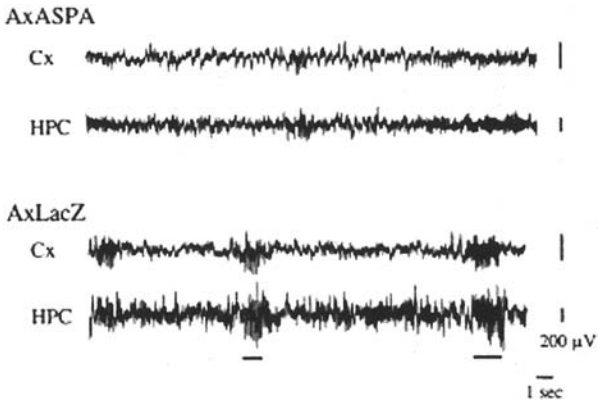

Figure 10 Electroencephalograms (EEGs) recorded from the left frontal cortex (Cx) and left hippocampus (HPC) of tremor rat 1 week after intracerebroventricular administration of an adenoviral vector expressing aspartocyclase (AxASPA) or β-galactosidase (AxLacZ). Lines under EEG represent 5–7 Hz spike-wave-like complexes that lasted for more than 1 second, considered to absence-like seizures. Delivery of AxASPA markedly diminished the occurrence of absence-like seizures in tremor rats, in constrast to animals receiving the control vector AxLacZ. G. Motor Neuron Disease

1. Introduction

The motor neuron diseases are a group of disorders characterized by predominant degeneration of the motor neurons. The most commonly recognized are familial spastic paraplegia (FSP) (upper motor neuron disease); spinal muscular atrophy (SMA) and spinobulbar muscular atrophy (SBMA, or Kennedy's disease) (lower motor neuron diseases); and amyotrophic lateral sclerosis (ALS) (combination upper and lower motor neuron disease). These disease syndromes can range in severity from debilitating (spastic paraplegia; Kennedy's disease) to lethal (some spinal muscular atrophies; amyotrophic lateral sclerosis).

The clinical features of these conditions are well known to neurologists, but the recognition of the molecular basis, and the possibility of molecular confirmation of diagnosis, has clarified the extent and relationship of some of these conditions. A genetic basis has now been identified for all these diseases. Different genetic mechanisms, including missense mutations (ALS), gene deletions or aberrant gene splicing (SMA), and trinucleotide repeat expansions (spinobulbar muscular atrophy), are responsible for the pathologic findings and clinical presentations of these motor neuron disorders. The molecular findings are of variable value as diagnostic tests. More important, it is hoped that understanding the underlying molecular basis of these conditions will ultimately allow specifically targeted treatments.

2. Models of Motor Neuron Disease

A number of mouse models of lower motor neuron degeneration or neuronopathy are currently available for experimental therapeutics. These include a number of naturally occurring mutant mice: wobbler (wr); progressive motor neuronopathy (pmn); neuromuscular degeneration (nmd); wasted (wst); motor neuron degeneration (mnd and mnd2); motor neuron disease (mneu); and muscle deficient (mdf). In all these mice, the trait is autosomal recessive, reflecting a presumed loss of function of the disease gene. To date, disease genes underlying these spontaneous mutations have not been identified (211). Within the past decade, transgenic mouse models have been created whose features closely model human motor neuron degenerative disease. These include mice with engineered abnormalities of 1 of the neurofilament subunits, and mice overexpressing mutant Cu/Zn superoxide dismutase (SOD1) that has been shown to underlie a subset of familial ALS cases (212–216). In the case of most of the transgenic mouse models, lower motor neuron pathology or degeneration is most likely the result of a gain of function related to the neurofilament or mutant SOD1. The comparable gene knockout strategies result in more subtle pathology (217,218) in the mice.

3. Potential Gene-based Therapies for Motor Neuron Disease

Putative therapeutic approaches for motor neuron disease fall into 4 major categories, based on hypothetical pathogenetic

mechanisms or cell death pathways. Evidence that excess glutamate excitotoxicity can lead to motor neuron death mediated via non-N-methyl-D-aspartate (NMDA) receptors suggests that pharmacological agents targeting the non-NMDA receptors might provide a promising strategy. Motor neuron death has been linked to excitotoxicity involving non-NMDA glutamate receptors (219–221) and related calcium-dependent pathways (222,223) in ALS and in in vitro models. These same phenomena have now been implicated in mutant SOD1-mediated motor neuron death (224,225). Related evidence supports a secondary role for voltage-gated calcium channels and downstream intracellular calcium dysregulation in motor neuron death (225). In an in vitro model, expression of the cytoplasmic calcium-binding protein calbindin-D28K was able to rescue mouse spinal motor neurons from death downstream of mutant SOD1 expression, exogenous glutamate, or paraquat (225). Studies of the efficacy of calbindin or parvalbumin in delaying onset of motor neuron degeneration, or prolonging survival of mutant-SOD1 transgenic mice are currently underway. Some beneficial effects were observed with administration of 2 antiglutamatergic agents, riluzole and gabapentin, to the transgenic mice (226). Riluzole is currently the only medication for which effect on human disease has been demonstrated (227).

Accumulated neuronal damage resulting from oxidative stress over the course of decades may be a common pathogenetic mechanism shared by neurodegenerative disorders, including ALS and PD. Oxidative damage has been documented at the molecular level (228,229). Agents that counteract oxidative stress have had mixed success in preventing motor neuron degeneration in in vitro models (225), transgenic mice, and ALS patients themselves. Some beneficial effects in transgenic mice (either delayed onset, prolonged survival, or improved function) were observed with dietary supplementation with vitamin E (226); a modified catalase, given subcutaneously (230); and treatment with trientine and ascorbate (231). N-acetyl-L-cysteine reduced lower motor neuron degeneration in wobbler (232,233). Nitric oxide synthase inhibitors failed to alter disease course in the SOD1 mutant transgenic mice (234). Collectively, these data suggest enzymes capable of reducing oxidative-free radicals (as described in above neurodegenerative disorders) may be useful in treating motor neuron diseases.

Apoptosis plays a key role in development and morphogenesis. Interplay between antiapoptotic genes such as *bcl-2*, and proapoptotic genes such as *bax* and *bad*, may determine the activation of the enzymatic cascade of caspases leading to condensation and cleavage of nuclear DNA and the hallmark death of the cell with blebbing of the membrane and cytosolic contents. Motor neurons may die by apoptosis (235,236); hence, antiapoptotic strategies have been used in in vitro and transgenic mouse models to prevent motor neuron degeneration. Delayed onset of disease was observed in double transgenic (mutant SOD1 + *bcl-2* overexpression) (237) or in transgenic mice injected intraspinally with a recombinant AAV vector encoding the antiapoptotic gene *bcl-2* (238). Some beneficial effects were also seen with the caspase inhibitor, zVAD-fmk (239). Ultimately, protection against apoptosis cannot prevent motor neuron death (240). The contribution of apoptosis to the etiology of motor neuron death is still being debated (241).

The use of neurotrophic factors has been the most aggressively pursued approach for therapy of the 1990s. Members of the nerve growth factor (NGF) family—NGF itself, NT3, NT4/5-BDNF, CNTF, LIF and GDNF, and IGF-1 (myotrophin)—have all been tested for their efficacy in supporting survival and/or regeneration of motor neurons in in vitro and mouse models. These factors may provide trophic support to the neuronal cell body, promote neurite elongation/sprouting, or reinnervation of the neuromuscular junction. Figure 11 depicts the neuroprotective effect of AAV-GDNF on motor neurons in a mouse model for ALS (242). Ad vectors have been employed to introduce CNTF, BDNF, and NT-3 in rodent models of motor neuron degeneration (234–236). Based on data from the earliest of these studies, CNTF, BDNF, GDNF, and myotrophin have all been used in some stages of clinical trials in ALS patients (243,244). In one approach, microencapsulated cells, genetically engineered to secrete CNTF, were implanted in lumbar intrathecal space (245). Results from that and others clinical trials have been discouraging (246,247). However, a promising gene therapy approach in familial ALS transgenic mice employed intramuscular grafting of myoblasts that were genetically modified to secrete the neurotrophic factor, GDNF, using a hybrid EBV/retroviral vector. The mice demonstrated reduced motor neuron loss and reduced disease progression (248).

Taken together, these studies suggest that the most effective therapies for motor neuron degeneration will include agents drawn from several of the classes described above. Further basic research addressing issues of vector, mode of delivery, and up-regulation and control of expression of the therapeutic agent (e.g., neurotrophic factor) is crucial to the design of improved gene therapy strategies for motor neuron diseases (249–251).

III. FUTURE OF GENE THERAPY AND NEUROLOGICAL DISEASES

The ability to deliver genetic material to cells of a living organism has revolutionized the conduct of biological research and created new approaches in medicine. Although in its infancy, gene therapy offers has potential advantages over traditional pharmacological therapy: a permanent correction of genetic anomaly thereby precluding the need for repetitive dosing. Neurodegenerative disorders affect millions of people, account for billions of dollars in health care costs annually, and as a group of diseases are without available curative therapy. As technology improves, this will lead to a better understanding of the underlying molecular mechanisms that constitute the pathogenesis of neurodegenerative disease. With this, the full potential of gene therapy will be realized.

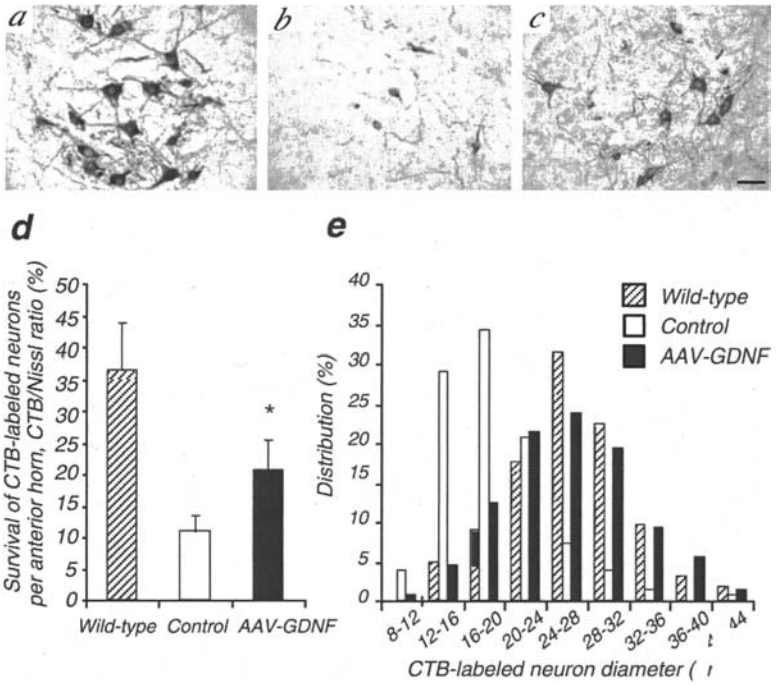

Figure 11 Delivery of AAV-GDNF exhibits neuroprotective effects on motoneurons in a mouse model of amyotrophic lateral sclerosis. Mice bearing the G93A human SOD1 mutation were injected intramuscularly at 9 weeks of age with 3×10^{10} particles of a GDNF-expressing AAV vector (AAV-GDNF) or a β-galactosidase control vector (AAV-LacZ). The illustrated photomicrographs depict the effect of GDNF on motoneurons that retained axonal projections. The neural tracer CTB was used to label motoneurons in the ventral horn at 110 days of age in wild-type (Panel A), AAV-LacZ-injected ALS mice (Panel B), and AAV-GDNF-injected ALS mice (Panel C) following intramuscular injection. AAV-GDNF vector-treated mice exhibited significantly more large CTB-labeled motoneurons than control treated ALS mice (Panel D). The value represents the CTP/Nissl ratio (average number of neurons per anterior horn). The shift in motoneuron size toward a smaller diameter was markedly retarded in AAV-GDNF vector-treated mice compared to AAV-LacZ treatment (Panel E). Scale bar, 50 μm. (From Ref. 242, © 2002 Society for Neuroscience.)

Principles of Gene Therapy for Inborn Errors of Metabolism

Jon A. Wolff and Cary O. Harding
University of Wisconsin–Madison
Madison, Wisconsin, U.S.A.

I. INTRODUCTION

A. Historical Perspective on Inborn Errors of Metabolism

Inborn errors of metabolism (IEM) have played a central role in the formulation of modern genetics. The hallmark of IEM is the accumulation of a biochemical in a bodily tissue. With the development of chemical analytical techniques, it became possible to identify and measure these biochemicals and correlate them with specific diseases (Fig. 1). Knowledge of metabolic pathways enabled enzymatic defects to be identified, which eventually led to discovery of the cognate proteins and genes.

The appreciation that inborn susceptibilities play important roles in diseases was first promulgated at the beginning of the 20th century by Alfred Garrod. He formulated the concept of an inherited metabolic disease on the basis of his studies of patients with alkaptonuria, albinism, cystinuria, and pentosuria. Cognizant of the laws of Mendel, he postulated that the relevant biochemical accumulates due to a metabolic block that is inherited in a recessive process.

The one gene–one enzyme principle developed by Beadle and Tatum provided the next conceptual framework for understanding IEM. This principle provides that metabolic processes are the result of specific enzymatic steps, which are under the control of a single gene. A mutation in a gene leads to deficiency of the enzyme that catalyzes the specific step. The molecular basis for a defective enzyme was provided by Pauling and Ingram's experiments on sickle-cell anemia, while the molecular basis for a defective gene was provided by Watson and Crick and subsequent elaboration of the central dogma. This dogma defines the flow of information as proceeding from DNA to RNA to protein. The objective of gene therapy is to modulate the flow of genetic information so as to attenuate the disease state.

B. Historical Perspective on Gene Therapy of IEM

IEM have also played a central role in the formulation of gene therapy (1). In fact, many of the first human clinical trials in gene therapy were for IEM. In the late 1960s, S. Rogers attempted to treat 3 siblings with arginase deficiency by injecting them with the Shope virus on the basis of the incorrect assumption that the virus contained an arginase gene. While being ahead of his time in anticipating the development of viral vectors, the injections had no effect on the subjects' arginine levels. In the more modern era of gene therapy, the first human trials for treating a disease involved children with severe combined immuno-deficiency (SCID) caused by a deficiency in adenosine deaminase (ADA).

In addition to human gene therapy trials, IEM have played an important role in the development of gene therapy tools (1). Cell lines deficient in hypoxanthine phosphoribosyl transferase (HPRT) and hypoxanthine/aminopterin/thymidine (HAT) selection media (developed by W. and E. Szybalski) enabled the selection for genetically modified cells that take up the HPRT gene in conjunction with other foreign genes. Similarly, cell lines deficient in thymidine kinase (TK) can be used for gene transfer selection.

With the advent of positional cloning and the human genome project, disorders are being linked to defective genes without any understanding of how metabolism has been disrupted. The current challenge will be to identify how the defective gene leads to a disturbance in development or homeostasis. Gene transfer and expression in animals and humans will provide critical tests for hypotheses of pathogenesis.

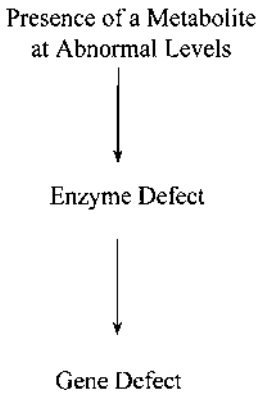

Figure 1 Flow of information in elucidating the genetic basis of metabolic disorders.

II. BASIS FOR GENE THERAPY FOR IEM

A. Types of IEM

One common type of IEM is caused by deficiency of an enzyme that catalyzes the conversion of one chemical to another (Fig. 2a). Deficiency of a specific enzyme can cause disease through 3 separate mechanisms: (1) excessive accumulation of substrate to toxic levels, (2) deficiency of an essential product, or (3) metabolism of the substrate through alternative biochemical pathways leading to toxic secondary metabolites. Examples of such IEM include phenylketonuria and methylmalonic aciduria.

IEM can also be caused by deficiency of protein that is involved in the transport of metabolite (Fig. 2b). Examples include the cystine transporter in cystinosis and the LDL (low-density lipoprotein) receptor in familial hypercholesterolemia.

Other genes relevant to IEM are required for the proper formation of organelles (Fig. 2c). Neonatal adrenoleukodystrophy and Zellweger syndrome are caused by defects in genes that are required for the proper formation of peroxisomes.

B. Different Pathogenesis Models for IEM

The pathogenesis of IEM can be explained by several models (Fig. 3). One major category includes IEM in which organ dysfunction occurs by a circulating toxic metabolite (Fig. 3a). Another major category is organ dysfunction resulting from a cell autonomous process (Fig. 3b). Although these concepts are useful in formulating gene therapy approaches, it should be appreciated that they are only models and that our understanding of the pathogenesis for many IEM is incomplete. In fact, gene therapy trials may provide decisive information concerning the mechanism by which the metabolic defect leads to the diseased state.

C. Circulating Toxic Metabolite

In this class of disorder, a metabolite accumulates in one tissue as result of an enzymatic deficiency (Fig. 3a). This leads to increased metabolite levels in the blood and toxicity in other tissues. The prototype for this type of disorder is phenylketonuria in which deficiency of hepatic phenylalanine hydroxylase leads to increased blood levels of phenylalanine and toxic effects to the developing brain. Familial hypercholesterolemia is another IEM that fits this model. Deficiency of the LDL receptor in the liver leads to increased levels of LDL and subsequent damage to the coronary arteries.

A corollary of this model is intraorgan toxicity from a metabolite that accumulates in an extracellular space within the affected tissue. It is particularly applicable to the central nervous system (CNS). Some IEM associated with neurological dysfunction may be caused by a toxic metabolite that accumulates within the brain and circulates in the cerebral spinal fluid (CSF). Gene therapy could then be predicated on providing gene expression in any cell within the brain as long as the expressed enzyme could lower levels of the toxic metabolite in the CNS. The cerebral spinal fluid could provide the conduit for such exchange.

A metabolic defect in one tissue could also harm another tissue by decreasing the circulating level of a metabolite. For example, a defect in gluconeogenesis that occurs in the liver and muscle (e.g., glycogen storage disorder) can cause hypoglycemia and damage to the brain.

D. Cell Autonomous Toxicity

In other IEM, the metabolic defect only leads to toxicity to the cell that has the metabolic deficiency (Fig. 3b). Cellular toxicity results from either increased or decreased levels of a metabolite within the affected cell. For these disorders, gene therapy would be effective only if the normal gene is targeted to the dysfunctional cell.

E. Method of Gene Correction

A variety of parameters of expression are important determinants of the ability of gene therapy to treat specific disorders. Some generalizations can be made concerning the expression requirements for IEM (Table 1). Most IEM are recessive conditions, and addition of a single gene copy is sufficient to correct the disease phenotype. In effect, gene addition converts the patient to a biochemical state analogous to that of a carrier. For those patients with single-point mutations, targeted gene correction using gene conversion or homologous recombination is a possible therapy, but gene correction is not necessary if a functional gene can be added. The obvious therapeutic gene to be added in IEM is the human gene that is defective in the disease state, but it is conceivable that a therapeutic effect could be achieved using another gene. For example, a gene from another species could metabolize a toxic metabolite by a different mechanism.

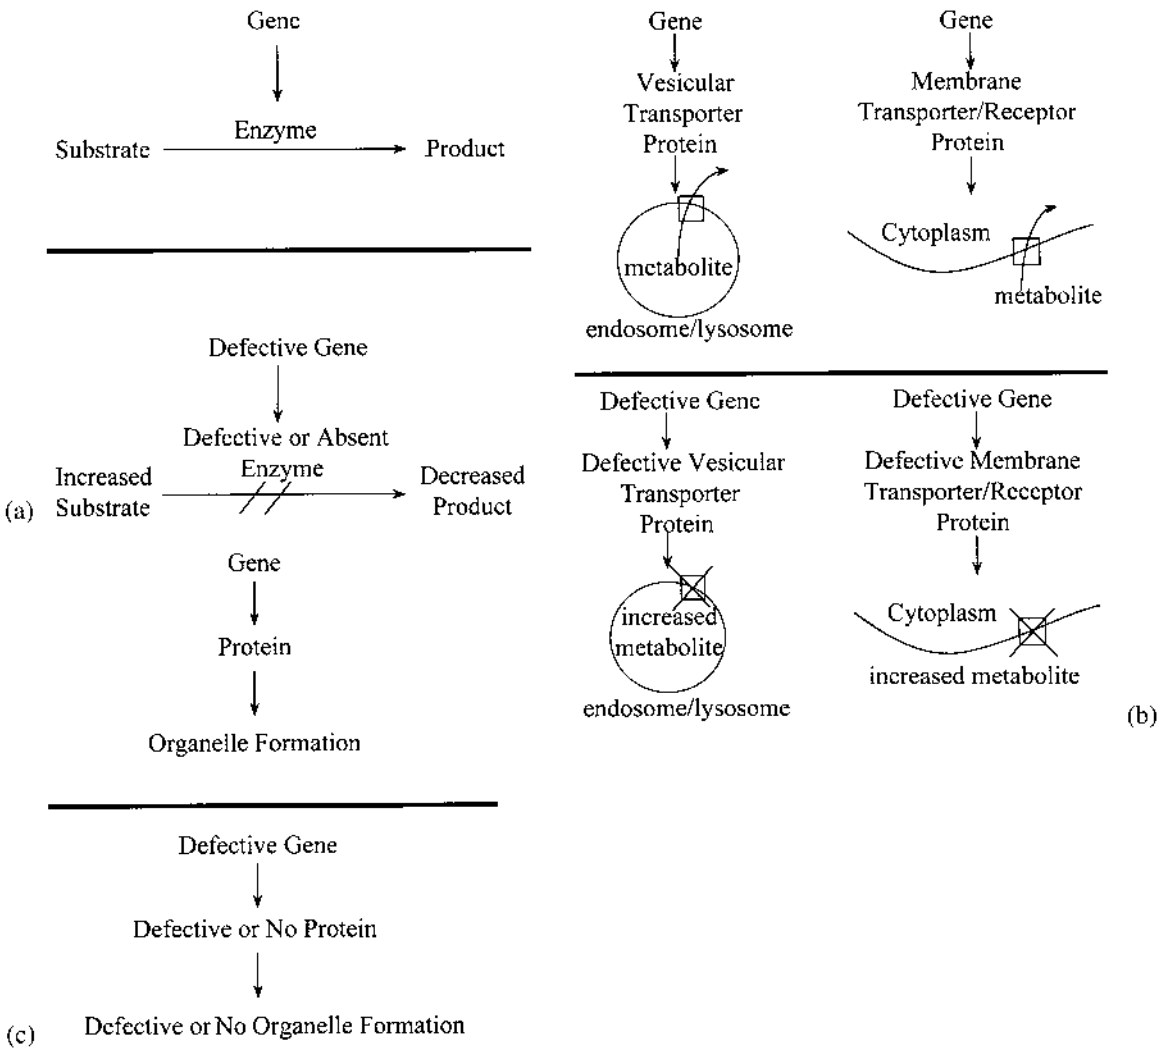

Figure 2 The types of normal functions that are disrupted in IEMs: (a) defects in enzymatic activity, (b) defects in the uptake or transport of metabolites, and (c) defects in the formation of organelles.

F. Requirements for Expression Persistence

For most IEM, gene expression does not have to be regulated and can be constant. Most genes involved in IEM are considered ''housekeeping'' genes. In contrast, in diabetes mellitus, insulin expression has to be regulated in response to blood glucose levels.

Given that IEM are chronic conditions, persistent expression is needed. It would be best if gene correction and therefore a ''cure'' could be done with 1 or few administrations. If expression cannot be persistent after 1 gene dose, then repetitive administrations are required. Repetitive administrations can be problematic for some vectors such as adenoviral vectors that induce neutralizing antibodies. Loss of expression from vectors can be a result of removal of the foreign DNA, promoter suppression, or rejection of the foreign gene product.

Immune effects can arise even if the gene product is intracellular because all parts of proteins are presented to the immune system via the MHC I complex. The important issue is whether, in the disease state, the patient expresses any residual native protein and is immunologically tolerant to the normal gene product. One measure of this is whether tissues from the patient exhibit cross-reactive material (CRM), protein that cross-reacts with antibodies against the native protein. This is best determined by performing immunoblot (Western blot) analysis. Even if protein is not present, native protein could have been produced but be unstable. Expression of the foreign gene in such a patient may not induce an immune effect because the protein is not recognized as foreign. Further experi-

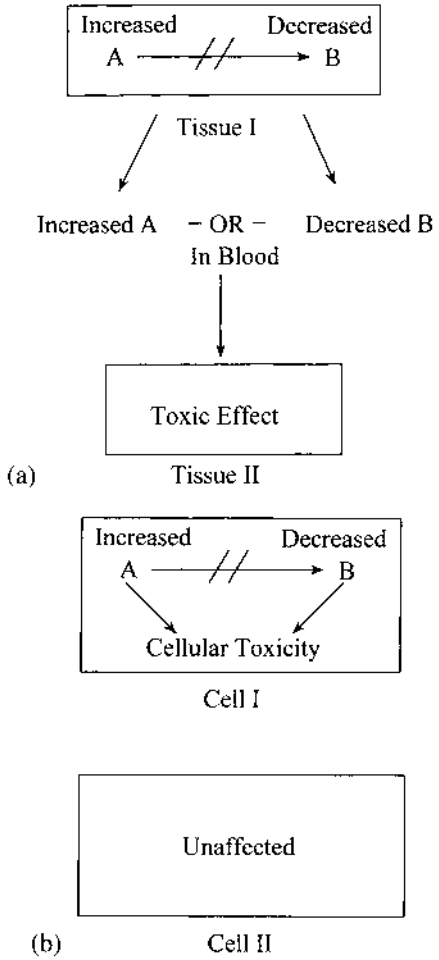

Figure 3 Two models by which IEM leads to cellular toxicity: (a) circulating toxic metabolite, and (b) cell autonomous toxicity.

Table 1 Generalizations Concerning Expression Requirements for Gene Therapy of IEM

Expression parameter	Requirement
Method of modification	Gene addition is sufficient
Therapeutic gene	Normal gene that is defective in patient
Duration	Persistent
Regulation	Not needed
Levels	>5% of normal levels
Target tissues	Liver, CNS, blood cells, muscle, heterologous expression possible in some disorders

ence is necessary to determine whether the immune system will prevent stable expression of the normal gene in patients with IEM.

G. Requirements for Expression Levels

The level of expression is a critical determinant for the success of a gene therapy. For most IEM, foreign gene expression only has to be greater than 5% of normal levels in order to attenuate the majority of the diseased state. This is based on clinical experience in which the percent of residual enzyme activity is correlated with the phenotype. In many IEM, people with more than 5% of normal enzymatic activity are free of symptoms. If enzymatic activity is between 1% and 5%, their clinical course is less severe than patients with 0% of enzymatic activity.

Although the total enzymatic activity is one measure, the percent of cells expressing the foreign gene may also be important. Overexpression in a few cells may not lead to a therapeutic effect if the expressed enzyme alone cannot completely produce the metabolic conversion. The protein deficient in the patient may be part of an enzymatic complex so that overexpression of 1 component would not necessarily lead to higher activity of the complete complex. Similarly, other enzymatic steps, cofactors, or transport of metabolites may limit the ability of the cell to perform the required metabolic conversion at a rate higher than the normal level. If so, the therapeutic gene has to be expressed in more than 5% of the target cells.

H. Target Tissues

Details of the pathogenesis for the IEM need to be understood, and the target tissue has to be tailored for each disorder. For IEM that fit the ''circulating toxic metabolite'' model, the therapeutic gene does not necessarily have to be targeted to the tissue that normally expresses the affected gene (Fig. 4). Although correction of the deficient enzymatic activity in the affected organ would be most straightforward, expression within a heterologous tissue (different from that which normally expresses the enzyme) could clear the circulating toxic metabolite and attenuate the disease state. For this approach to be effective, the enzyme must be functional within the heterologous tissue. Restrictions on enzymatic function can include requirements for protein subunits, cofactors, substrate, and clearance of product. Given the ability for several gene transfer systems (e.g., plasmid DNA, adenoviral vectors, and AAV vectors) to express foreign genes stably in muscle, it will be a useful tissue for many heterologous gene therapy approaches. Blood cells derived from genetically modified stem cells are another candidate tissue for heterologous gene expression if the problems associated with stable foreign expression are solved.

For IEM that fit the ''cell autonomous'' model, expression within the affected cell is generally required. The exception is for the lysosomal storage disorders in which the enzyme can be transferred from one cell to another.

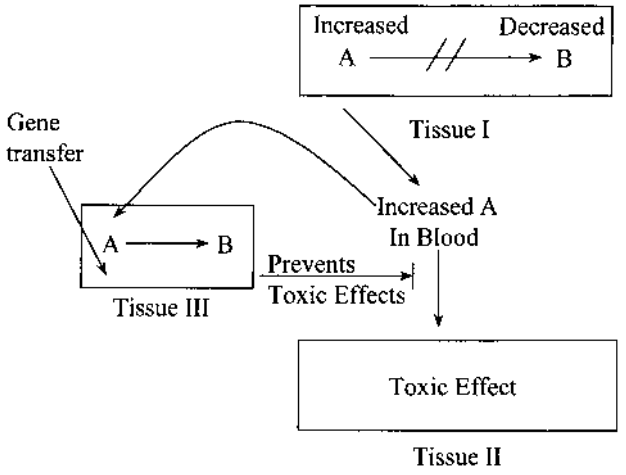

Figure 4 Heterologous tissue expression of a therapeutic gene to treat an IEM in which a circulating toxic metabolite causes the diseased state.

For IEM that affect the brain, ''global'' gene expression throughout the brain may be required. Alternatively, specific neurological symptoms could be treated by targeting specific regions of the brain. For example, in Lesch–Nyhan syndrome, choreathetoid movements could be treated by targeting the basal ganglia.

I. Mitochondrial Disorders of Oxidative Phosphorylation

Several IEM are caused by defective oxidative phosphorylation within the respiratory chain complex of mitochondria. A unique feature of mitochondria is that 13 of the more than 80 respiratory chain subunits are encoded within the mitochondrial genome. The mitochondria also contain 22 transfer RNA (tRNA) and 2 ribosomal RNA that enable protein synthesis within the mitochondria. The remaining 70 or so respiratory chain subunits are encoded within the nuclear genome. These proteins are produced within the cytoplasm and contain an amino terminus that targets their entry into the mitochondria by interacting with a number of chaperone and transport proteins.

For disorders caused by mutations in the nuclear encoded respiratory chain genes, the gene therapy approaches described above are germane. However, disorders caused by mutations in the mitochondrial genome offer additional challenges for gene therapy. One approach would be to express the deficient subunit within the nucleus, regardless of its native mitochondrial origin. The subunit could be modified to contain an amino leader sequence to enable entry into the mitochondria.

The other approach of genetically modifying the mitochondrial genome is at an early conceptual stage. Toward this end, a peptide mitochondria-targeting sequence has been covalently attached to oligonucleotide to enable mitochondrial entry. The oligonucleotide could correct a point mutation by some type of gene conversion or recombination process. Point mutations occur in mitochondrial disorders such as Leber hereditary optic atrophy (LHON), myoclonic epilepsy and ragged-red fiber disease (MERRF), and mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS). An alternative treatment approach would be the addition of functional tRNA genes to patients with mitochondrial disorders such as MERRF or MELAS that are caused by tRNA mutations. The treatment of mitochondrial DNA deletion diseases would require the delivery of larger DNA sequences (>5 kb), which would be more challenging. Deletions occur in disorders such as Kearns–Sayre syndrome. Another option would be to deliver normal mitochondria en toto.

Different mitochondria can proliferate in a tissue at different rates. This may explain why inborn and somatic (acquired) mitochondrial defects often present in later life. Any genetic modification of mitochondria must enable the corrected mitochondria to have a proliferation advantage over the abnormal mitochondria in order to achieve a permanent cure. A final challenge for mitochondrial disorders is that they often involve the nervous system, which is less accessible than other organs to therapeutic endeavors.

J. Newborn and Prenatal Screening

Gene therapy for IEM will have a significant impact on newborn screening programs and vice versa. Screening for IEM at birth enables gene therapy to be initiated prior to the onset of symptoms and any irreversible tissue damage and thereby increases the value of the gene therapy. Irreversible brain damage occurs in many IEM when a neonatal metabolic crisis is not prevented. For example, the extent of perinatal hyperammonemia in a urea cycle defect, ornithine transcarbomylase deficiency (OTC), has been directly correlated with intelligence in later life.

One criterion for the initiation of newborn screening for a particular disorder is whether an effective treatment exists. The development of effective gene therapy for a disorder could satisfy this criterion. Another criterion is the availability of a reliable, inexpensive laboratory method for disease detection.

Currently, most states in the United States and many other nations are screening for phenylketonuria and galactosemia. Screening for maple syrup urine disease or homocysteinemia is less common. Tandem mass spectroscopy procedures are being developed for analyzing blood spots in amino acids and organic acids conjugated to carnitine (acylcarnitines) in order to detect many of the disorders in amino acid and fat metabolism and organic acidurias. Such comprehensive newborn screening programs developed in conjunction with new gene therapies will have a major impact on the morbidity and mortality of IEM.

Many IEM can be reliably diagnosed in the prenatal period. As intrauterine gene therapy approaches are developed, IEM will be good candidates for such approaches. One potential

advantage of prenatal approaches may be a decreased chance of an immune recognition of the therapeutic gene product.

III. GENE THERAPY OF SPECIFIC DISORDERS

A comprehensive review of the tremendous progress in the gene therapy for IEM is beyond the scope of this review. In fact, gene therapy studies have been conducted in almost every type of IEM. Instead, specific IEM were chosen either because they illustrate the above principles or for their important historical role.

A. Aminoacidopathies

The aminoacidopathies are a heterogeneous group of recessively inherited enzyme deficiencies that are associated with the accumulation of specific amino acids in blood and other tissues. The best known and most studied aminoacidopathy is phenylketonuria (PKU) (Table 2) caused by deficiency of the liver enzyme phenylalanine hydroxylase (PAH) (Fig. 5). PAH deficiency prevents the hydroxylation of phenylalanine to tyrosine and leads to excessive accumulation of phenylalanine in the body. If PKU is left untreated in an infant, poor brain and physical growth, seizures, and mental retardation will result from increased levels of the circulating toxic metabolite phenylalanine. Other examples of aminoacidopathies include tyrosinemia, maple syrup urine disease, homocystinuria, and ornithine transcarbamoylase (OTC) deficiency (Table 2). Each of these enzyme deficiencies leads to the accumulation of a different specific substrate and causes a different symptom complex.

Contemporary therapy for these diseases is based on an understanding of the pathogenesis involved in each case, and

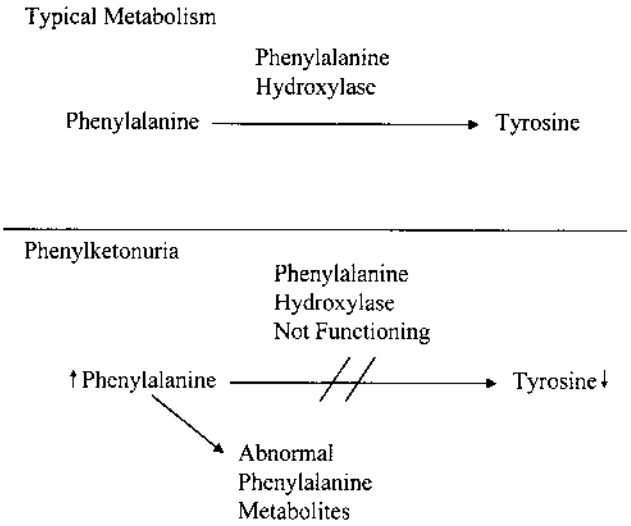

Figure 5 Pathogenesis of phenylketonuria.

the design of any gene therapy protocol must also be grounded upon a rational understanding of the specific disease pathophysiology. For example, high levels of phenylalanine in PKU are toxic to the developing brain, and reducing blood phenylalanine levels is critical to successful treatment of PKU. However, some symptoms of PKU may be caused by deficiencies of specific neurotransmitters, such as dopamine, that are synthesized from tyrosine. In tyrosinemia, elevated tyrosine levels do not appear to be directly toxic, but production of the toxic metabolite succinylacetone through an alternative biochemical pathway causes severe liver damage. So, for PKU, a successful therapy will both remove phenylalanine and restore tyrosine levels, while removal of tyrosine from individuals with tyrosinemia is less important than stopping the production of succinylacetone. These considerations must play a role in the design of any gene therapy protocol.

In many aminoacidopathies, the deficient enzyme is normally either exclusively or primarily expressed in liver; liver is the obvious target for gene transfer in these diseases (2). However, for select disorders, circulating toxic metabolites may be effectively removed from the body by enzyme expressed in a tissue other than liver. The concept of expressing in an alternative tissue a protein that is normally restricted to a specific organ is known as heterologous gene therapy. As an example, PAH expression in skeletal muscle, if supplied with the necessary cofactors, might effectively clear phenylalanine from the circulation of a person with PKU. Gene targeting to the liver may not be essential for some aminoacidopathies. For other diseases, specific pathophysiological features limit the effectiveness of a heterologous gene therapy approach. In OTC deficiency, the substrate for OTC, carbamyl phosphate, is produced only locally in the liver and does not appear in the circulation. In tyrosinemia, liver damage is mediated by local production of succinylacetone in hepatocytes; removal of succinylacetone from the circulation without preventing its production in the liver might not alter the course of tyrosinemia. If possible, disease-specific pathophysiological features and the effectiveness of any gene therapy approach should be demonstrated in an animal model of the disease, if one is available, prior to application of the method in humans. Table 2 lists animal models available for the study of some aminoacidopathies.

Gene transfer experiments to treat PKU illustrate the difficulties and complexities of gene therapy for aminoacidopathies and other liver diseases (2). The availability of a mouse model, the *Pah*^{enu2} mouse, that accurately portrays human PAH deficiency has allowed significant advances in PKU gene therapy research. Soon after cloning the PAH gene, Dr. Savio Woo and colleagues pioneered gene transfer into liver and demonstrated that PAH activity could be expressed in cultured fibroblasts or PAH-deficient hepatocytes from a PAH cDNA. This was accomplished using a variety of gene transfer vectors, including recombinant retrovirus. Scaling up to perform retroviral-mediated liver-directed gene therapy in a whole animal proved more problematic. Integration of the retroviral DNA into the target genome requires mitotic division of the target cell; the mitotic rate of hepatocytes in vivo

Table 2 Summary of Select Aminoacidopathies

Disease	Deficient enzyme	Elevated blood amino acids	Animal model?
Phenylketonuria	Phenylalanine hydroxylase (PAH)	Phenylalanine	*Pah*^{enn2} mouse
Tyrosinemia type I	Fumarylacetoacetate hydrolase (FAH)	Tyrosine	FAH knockout mouse
Ornithine transcarbamoylase deficiency	Ornithine transcarbamoylase (OTC)	Glutamine; elevated blood ammonia	Sparse fur (*spf*) mouse
Maple syrup urine disease (MSUD)	Branched-chain keto acid dehydrogenase	Leucine, valine, isoleucine	Hereford inbred calf MSUD
Homocystinuria	Cystathionine β-synthase	Homocystine	None

is estimated to be only about 1% per year in humans. So, retroviral-mediated liver-directed gene therapy requires an ex vivo approach in which part of the liver is surgically removed from an animal, the hepatocytes are cultured, allowed to divide, transfected with the recombinant retrovirus, and then the treated hepatocytes are infused back into the animal via the portal venous system. Using this approach and the β-galactosidase reporter gene, Woo and colleagues demonstrated that approximately 1% of the hepatocytes in the liver of a dog could be induced to permanently express the reporter gene. Unfortunately, successful treatment of PKU (and probably other aminoacidopathies) requires enzymatic reconstitution of at least 5% to 10% of the liver. Successful retroviral-mediated ex vivo gene therapy in the PKU mouse has not been reported. This approach has, however, been employed successfully in the treatment of murine tyrosinemia type I (3). In this mouse model, enzymatically corrected hepatocytes have a survival advantage over enzyme-deficient cells in the host; although they initially constitute only a very small fraction of the liver, retrovirus-treated enzyme-expressing hepatocytes gradually repopulate the entire liver. Recombinant retroviral-mediated gene therapy may be useful for disorders that require correction of only 1% to 2% of the liver to effect a phenotypic change or in situations where corrected cells have a competitive advantage over the native hepatocytes.

Recombinant adenoviral vectors are another promising gene delivery vehicle for in vivo application. In contrast to retroviral vectors, recombinant adenovirus can be produced and purified to higher titers and are capable of efficiently infecting nondividing cells. A recombinant adenovirus containing the PAH cDNA has been infused into the portal circulation of PKU mice (4). In this experiment, hepatic PAH activity was reconstituted to 5% to 20% of control levels. Complete normalization of plasma phenylalanine levels occurred in animals with hepatic PAH activity equivalent to at least 10% of that in control animals. However, the effect had disappeared by 3 weeks following the treatment, and no hepatic PAH activity was detected following a second treatment with the adenoviral vector. The stability of expression from adenoviral vectors administered in vivo is limited by the immune response of the host against the vector or the reporter gene product. In experimental trials of adenovirus-mediated, liver-directed gene therapy employing a variety of different therapeutic genes to treat several different animal models, gene expression has been stable for 7 to 10 days and then has decreased to undetectable levels over the next few weeks.

Further alteration of the adenoviral genome has resulted in recombinant adenovirus that is less immunogenic than first-generation adenovirus vectors. Liver OTC deficiency in the sparse fur mouse was corrected for at least 2 months following infusion of a second-generation recombinant adenovirus containing the human OTC cDNA (5). This vector is currently being used in a human clinical trial involving adult females with partial OTC deficiency. Further efforts to develop even more effective adenoviral vectors continues.

The search for the ideal liver-directed gene-transfer vector continues. Along with further modification of recombinant adenovirus vectors, the development of new viral and nonviral vectors targeted to liver has expanded the therapeutic armamentarium of the gene therapist. Early animal trials with recombinant adeno-associated virus (AAV) and lentivirus vectors have shown substantially better persistence of gene expression than with recombinant adenovirus and much higher levels of gene product than with recombinant retrovirus. Nonviral methods such as infusion of naked plasmid DNA under physical and osmotic pressure directly into the venous circulation of liver or the bile duct aim to altogether avoid difficulties with immunogenic effects of a viral delivery system. Although much further research in animal models is needed before human clinical trials should be attempted, several new gene delivery systems demonstrate the promise of physiologically significant stable gene expression in liver.

B. Organic Acidurias

Propionic aciduria and methylmalonic aciduria are 2 organic acidurias that have been well studied and are excellent candidates for gene therapy (Fig. 6). In severe cases, patients present in the neonatal period with coma, metabolic ketoacidosis, and hyperammonemia. With vigorous medical support, they can survive this initial metabolic crisis, but they then must adhere to a strict diet restricted in protein intake. Despite di-

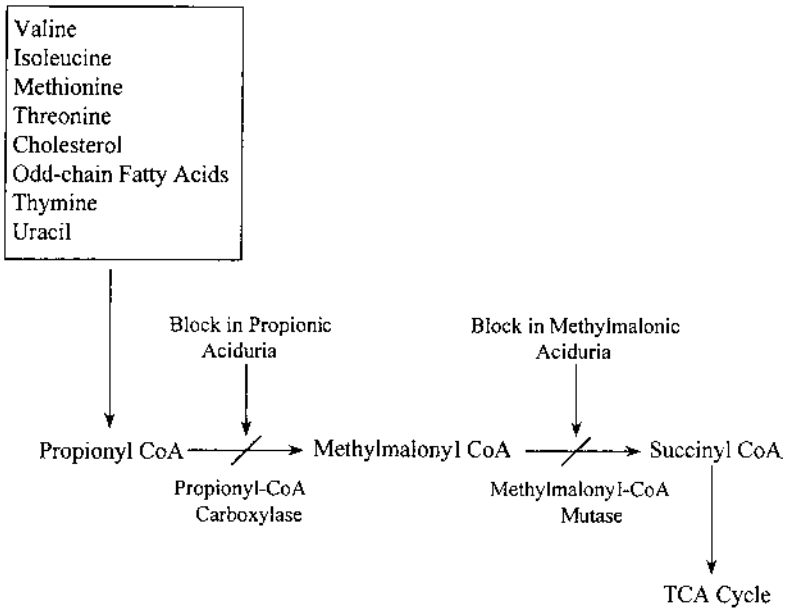

Figure 6 Enzymatic deficiencies in methylmalonic aciduria or propionic aciduria. TCA, tricarboxylic acid cycle.

etary therapy, they continue to have metabolic crises that can be life-threatening. Given the inadequacy of dietary therapy, a gene therapy approach is needed.

Both disorders are caused by enzyme deficiencies in the metabolism of 3-carbon species that are generated from the catabolism of amino acids and other metabolites (Fig. 6). Methylmalonic aciduria is caused by a deficiency of methylmalonyl-CoA carboxylase activity that is a result of a defect either in the apoenzyme or in the active form of vitamin B_{12}. Patients with the latter defect often respond well to treatment with large amounts of vitamin B_{12} and are therefore in less need of gene therapy.

The prominent target tissue for both disorders is presumed to be the liver. Hepatorenal transplantation has been successfully employed in a patient with a severe form of methylmalonic aciduria. Nonetheless, the major pathology associated with these organic acidurias is due to circulating toxic metabolites. The associated enzymes are normally expressed in many tissues including leukocytes, muscle, and fibroblasts. Therefore, these heterologous tissues should be explored in gene therapy preclinical studies. Unfortunately, animal models for these disorders do not exist at the present time.

Five percent of normal enzymatic activity in either propionic aciduria or methylmalonic aciduria is associated with a benign clinical course, indicating that this level of expression in a gene therapy should be sufficient to realize a large clinical benefit. This level of expression may have to be distributed over approximately 5% of the cells because overexpression of the relevant genes may not lead to a proportional increase in metabolic flux through the 3-carbon pathway. For example, in propionic aciduria, the propionyl-CoA carboxylase has 2 different subunits, α and β. In patients with a defect in the β subunit, overexpression would require gene transfer with both subunits. However, in patients with a defect in the α subunit, overexpression of the α subunit may be sufficient because the β subunit is produced in a 5-fold excess over that of the α subunit.

C. Lysosomal Storage Diseases

The common feature of lysosomal storage diseases is the inappropriate accumulation of normal cellular components within lysosomes. This storage of material is visible in cells by light microscopy as very large lysosomes that displace a large part of the cytoplasm. This class of disorders is caused by deficiency of specific lysosomal enzymes that are required for the degradation and recycling of glycoproteins and other cellular components. Without a specific degradative enzyme, the substrate for the reaction accumulates and cannot be removed from the lysosome. The clinical phenotype of each disease is dependent on the tissue type most affected by storage and by the accumulation rate. Physical findings that are suggestive of lysosomal storage include enlargement of the liver and spleen, anemia and thrombocytopenia due to replacement of normal bone marrow by stored material, destruction of bone, and for those enzymatic deficiencies that cause lysosomal storage in neurons, severe developmental regression, seizures, and other neurological symptoms. Not all of these problems are present in all lysosomal storage diseases; each different enzymatic deficiency presents with a specific phenotypic complex.

The challenges of gene therapy for lysosomal storage diseases are illustrated by the results of contemporary treatment

with enzyme-replacement therapy or bone marrow transplantation. A major challenge to treating a lysosomal storage disease with gene therapy (in contrast to treatment of a liver enzymopathy) is the necessity of reversing lysosomal storage in multiple separate tissues. No currently available gene transfer technique is capable of delivering DNA to multiple target tissues efficiently. However, many lines of evidence demonstrate that lysosomal enzyme proteins can be produced in isolated tissues or even purified ex vivo and effectively delivered to most target tissues. For example, glucocerebrosidase, the enzyme deficient in Gaucher's disease can be produced in vitro using standard recombinant techniques, chemically modified to facilitate lysosomal targeting, and delivered to affected organs by simple intravenous infusion. This therapy if repeated periodically dramatically reduces liver and spleen size, corrects anemia and thrombocytopenia, and possibly prevents bone deterioration, all major debilitating features of Gaucher's disease. So, at least for gene therapy of Gaucher's disease, the enzyme would not need to be locally produced in all affected tissues. The enzyme could potentially be produced in a single target tissue, secreted into the circulation, and taken up by other diseased tissues. The major limitation of this approach is the difficulty of engineering a secreted form of the enzyme that would be efficiently taken up by other cells and incorporated into lysosomes.

Alternatively, the enzyme could be transferred from the site of production to diseased tissues via circulating blood cells. Seminal experiments demonstrated that functional lysosomal enzymes may be transferred directly from a normal cell to an enzyme-deficient cell in tissue culture. Bone marrow transplantation in the treatment of lysosomal storage diseases exploits this phenomenon. Replacement of enzyme-deficient host bone marrow with enzyme-sufficient donor bone marrow yields a population of circulating blood cells of the reticuloendothelial lineage that infiltrates tissues and transfers lysosomal enzyme to the native cells. Bone marrow transplantation has been employed successfully in Gaucher's disease and in select other storage diseases that do not exhibit brain involvement. Apparently either insufficient numbers of corrected cells penetrate the central nervous system or insufficient enzyme is transferred to neurons to successfully ameliorate the neurological phenotype of many lysosomal storage disorders. Presumably, difficulties with correcting enzyme deficiency in the brain will also be a major obstacle to successful gene therapy.

Gene therapy for lysosomal storage diseases has to date focused on gene transfer into bone marrow stem cells for the purpose of supplying enzyme via circulating reticuloendothelial cells (6). Enzymatic correction of Gaucher bone marrow cells in culture has been accomplished with recombinant retroviral vectors. Similar experiments using other lysosomal enzymes in both cultured bone marrow and fibroblasts have been successful. Persistent production of enzyme in circulating blood cells has been demonstrated in rodents. Phenotypic improvement following retroviral-mediated gene transfer into bone marrow has been shown in gus^{mps}/gus^{mps} mice, a β-glucuronidase-deficient mouse model of human mucopolysaccharidosis type VII. As expected, enzymatic correction of bone marrow resulted in amelioration of the somatic symptoms but did not arrest progressive neurological deterioration in this model. However, lysosomal storage in the brain did decrease in mice that had received intracerebral β-glucuronidase-expressing fibroblast implants. Clinical trials of retroviral-mediated bone marrow stem cell-directed gene therapy are underway in humans with Gaucher's disease and in patients with Hunter's syndrome (mucopolysaccharidosis type II) who have little central nervous system involvement.

D. Lesch–Nyhan Syndrome

This X-linked syndrome is caused by a deficiency in hypoxanthine phosphoribosyl transferase (HPRT), an enzyme required for salvaging purines (Fig. 7). It is characterized clinically by increased blood and urine uric acid, mental retardation, choreoathetoid movements, and, most extraordinarily, self-mutilation. It is not understood how a deficiency in HPRT leads to these remarkable neurological sequelae. A genetic mouse model completely lacking HPRT activity does not exhibit any neurological dysfunction except when stressed with amphetamine administration or inhibition of adenine phosphoribosyl transferase (APRT) with 9-ethyladenine. The choreoathetoid movement disorder, however, is postulated to be due to dysfunction within the basal ganglion secondary to disturbed dopamine metabolism.

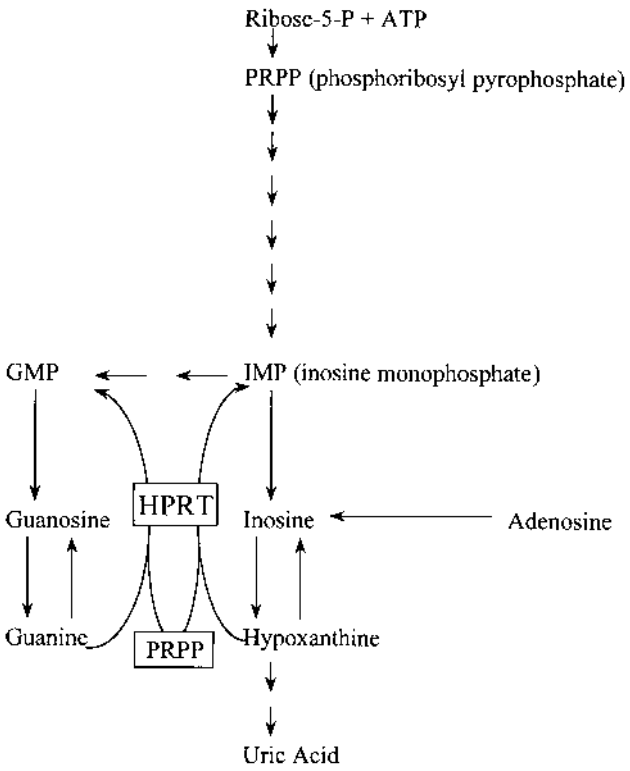

Figure 7 Enzymatic deficiency in Lesch–Nyhan syndrome.

Although the hyperuric acidemia and its sequela can be controlled with allopurinol, the absence of treatment for the neurological symptoms has prompted the search for gene therapy approaches. Historically, Lesch–Nyhan syndrome has played an important role in the development of gene therapy. One of the first demonstrations of the ability of retroviral vectors to correct a genetic mutation was done using the human HPRT gene. The first animal experiment in which a foreign gene was expressed in the brain was done by intracerebrally transplanting fibroblasts genetically modified to express the human HPRT (7). Although HPRT is expressed in all cells, its high levels in the basal ganglia suggest that this area of the brain should be targeted for gene transfer. Prevention of the mental retardation may require more global expression within the brain.

The amount of normal gene expression required to effect relief can be extrapolated from clinical experience. Although it was previously believed that the severity of the syndrome was not correlated with residual enzymatic activity, it is now realized that its severity does correlate with the amount of HPRT activity in whole cells. Patients with 1.6% to 8% of normal activity had choreoathetosis but not mental retardation or self-mutilation.

In summary, this syndrome is an example of a genetic disorder in which therapy is lacking even when so much is known about its genetic and molecular basis. The development of effective gene transfer methods into the brain may not only provide a therapy but will be quite revealing about its pathogenesis.

E. Familial Hypercholesterolemia

Gene therapy has the potential to significantly improve the clinical status of patients with familial hypercholesterolemia (FH), which is caused by a defect in the LDL receptor (LDLR) (Fig. 8). Deficiency in this receptor leads to reduced clearance of LDL by the liver and higher blood levels of LDL. In addition, affected individuals synthesize more cholesterol because the inhibitory effect of LDL on cholesterol synthesis is lost. This inhibition results from decreased HMG CoA reductase activity, the rate-limiting step in cholesterol synthesis.

Heterozygotes with LDLR deficiency occur at a frequency of 1:500 (as common as insulin-dependent diabetes mellitus), making it one of the most common genetic disorders in the United States, Europe, and Japan. Such patients have a 2-fold elevation in plasma cholesterol levels (300–600 mg/dL) and may develop coronary artery disease by the fourth decade of life. Three to 6% of survivors of myocardial infarctions are heterozygotes for FH.

Homozygotes with LDLR deficiency occur much more infrequently (1 in a million), but have much higher cholesterol levels (600–1000 mg/dL) and invariably die from coronary artery disease in their 20s. The severity of the sequelae is attenuated in the homozygotes by a few percent residual LDLR activity. Deaths were much less frequent in those homozygotes who had at least 10% of normal LDLR activity. This indicates that clinical benefit could be achieved by a gene

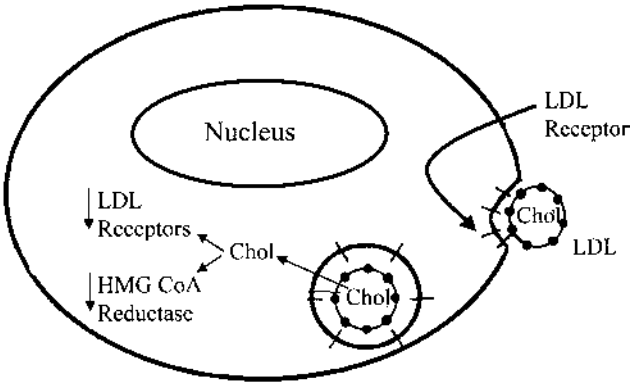

Figure 8 Pathogenesis of familial hypercholesterolemia. Chol, cholesterol; HMG, 3-hydroxymethylglutary; LDL, low-density lipoprotein.

therapy in which only a small percentage of LDLR activity is restored. Furthermore, the severity of this disorder increases the benefit-to-risk ratio of clinical trials and thereby facilitates them. A gene therapy protocol can be first tested in the homozygotes (aided by Orphan Drug Status) and then extended to the more common heterozygotes.

Liver transplantation in children has proven that correction of the LDLR defect in the liver can normalize cholesterol levels. For this reason, gene therapy techniques for FH have been directed at the hepatocyte. Based on preclinical studies in mouse and rabbit LDLR-deficient models, ex vivo gene therapy in 5 homozygous FH patients using retrovirus-mediated LDL receptor gene transfer was performed. This technically challenging protocol yielded a highly variable metabolic response with some improvement in only 1 of the patients (8). This study indicates that important modifications must be made to the ex vivo gene transfer method before gene therapy can be used as a general therapeutic procedure for such patients (9).

Given the borderline results of the human clinical trial, efforts were initiated with adenoviral vectors carrying the LDLR gene. In vivo adenovirus-mediated transfer of the LDLR was shown to be highly effective in reversing the hypercholesterolemia in LDLR knockout mice and WHHL rabbits (10). The important limitation of adenoviral-mediated gene transfer remains the transient expression in vivo after infection of somatic cells with recombinant adenovirus. Nonetheless, these studies demonstrate the proof of principle for the gene therapy of FH by the transfer of the normal LDLR gene and highlight the inadequacies of current gene transfer methods.

Current therapy for hypercholesterolemia (not limited to homozygotic FH) includes the use of HMG-CoA reductase inhibitors, which work by secondarily inducing expression of the LDLR, thereby lowering plasma LDL levels. These agents not only lower serum cholesterol, but also lower all-cause

mortality by at least 30% in men and women who have coronary disease and total cholesterol levels of 215 to 300 mg/dL. However, 2% of patients suffer liver toxicity and 0.2% develop muscle disease requiring cessation of drug administration. These drugs have to be taken once or twice every day for extended periods of time, and compliance is often difficult. A gene therapeutic agent that is administered less than every month (even by intravenous injection) would offer substantial benefit to the patient.

At high efficiencies of liver gene transfer, LDLR gene transfer into the liver could be used to prevent coronary artery disease in the general population. Taking into account all types of hypercholesterolemias, the third National Health and Nutrition Examination Survey (NHANES III) concluded that lipid-lowering therapy was required for 29% of Americans over 20 years of age (11). The Cholesterol and Recurrent Events study showed that patients with coronary artery disease but having ''normal'' LDL cholesterol levels benefited from treatment with a single statin therapy (12). The positive correlation between LDL levels and coronary artery disease is a continuum. In addition, overexpression of the normal LDL receptor in the liver of transgenic mice (4 to 5 times that of the endogenous receptor) prevented diet-induced hypercholesterolemia, suggesting that unregulated overexpression of the LDLR by liver gene therapy would be therapeutic in humans with hypercholesterolemia of various causes (13).

Many individuals develop coronary artery disease from other causes not amenable to statin therapy but that are potentially treatable by gene therapy. Liver gene therapy using the apoB mRNA editing enzyme (Apobec 1) or the VLDL receptor genes could modify LDL cholesterol levels. Other lipoprotein factors besides LDL cholesterol levels influence the onset of coronary artery disease and are amenable to modulation by liver gene transfer. Additional expression of apoA-I in the liver by foreign gene transfer could raise high-density lipoprotein levels and prevent atherosclerosis, as has been demonstrated in mouse and rabbit models. Hypertension, a predisposing factor for coronary artery disease, could be treated by delivering the kalikrein gene to the liver.

IV. SUMMARY

The foundation for treating many IEM by gene therapy has been established. It is clear that the expression of the cognate gene can correct the metabolic disturbance and the disease state in most IEM. As in other types of disorders, clinical success has been thwarted by inefficiencies in the gene delivery and expression systems. As new vectors and expression systems are developed and improved over the next few years, it is anticipated that clinical efficacy will be demonstrated for an increasing number of IEM.

Gene Therapy and HIV-1 Infection

Muhammad Mukhtar, Ralph Dornburg,† and Roger J. Pomerantz

I. INTRODUCTION

Since the discovery that acquired immunodeficiency syndrome (AIDS) is caused by a retrovirus, termed human immunodeficiency virus type I (HIV-1), enormous efforts have been undertaken to develop new pharmaceutical agents to control the spread of this epidemic disease. Such conventional drugs are specifically designed to block the action of HIV-1-specific enzymes, such as the reverse transcriptase or the protease. However, as a result of the high mutation rate of the virus, new virus variants continuously emerge that are resistant to such conventional therapies. Thus, great efforts are currently being made in many laboratories worldwide to develop alternative genetic approaches to inhibit the replication of this virus. With growing insight into the mechanism and regulation of HIV-1 replication, genetic antivirals have been developed that attack basically every step in the viral life cycle. Tissue culture cells have been transduced with genes encoding for such antivirals, and it has been shown that such transduced cells can become rather resistant to HIV-1 infection. However, although such antivirals have been proven to be very effective in vitro, their beneficiary effect in vivo is difficult to evaluate and still remains to be shown. Furthermore, the delivery of genes encoding for such genetic antivirals still constitutes one of the main problems because no efficient gene delivery tools are available at this point, which would enable the robust delivery to the actual target cell in vivo. This chapter summarizes the experimental approaches and current gene delivery techniques to inhibit HIV-1 infection.

II. HIV-1 INFECTION AND CONVENTIONAL PHARMACEUTICAL AGENTS

AIDS is caused by HIV-1. This retrovirus primarily infects and destroys cells of the human immune system, in particular, $CD4^+$ T cells and macrophages. The destruction of such cells leads to a severe immunodeficiency (e.g., the inability to fight other infectious agents or tumor cells). Thus, AIDS patients usually die from secondary infections (e.g., tuberculosis, pneumonia) or cancer (e.g., Kaposi's sarcoma). Enormous efforts have been made to study the life cycle and pathogenesis of HIV-1 in order to find potential targets to block the replication of this virus (Fig. 1). A list of potential targets and appropriate control strategies are described in Figure 2. Some viral proteins, such as the protease, reverse transcriptase, and envelope have been crystallized and their 3-dimensional structures revealed (1–6). These studies were performed to design specific compounds, which would irreversibly bind to the active sites of such enzymes, and therefore inhibit their function. Indeed, specific chemical compounds, which efficiently block the activity or function of these viral proteins are now commercially available and in use worldwide (7–11).

Studies have demonstrated that administration of a mixture of 3 antiviral compounds (called combination chemotherapy or highly active retroviral therapy, HAART) can lead to significant reduction of viral load in vivo. Using 2 reverse transcriptase and 1 protease inhibitor in treatment naive patients, the serum HIV-1 RNA levels may be reduced to an undetectable level. How long this response will last in these patients remains an open issue. Several reports have described variant strains of HIV-1, among patients receiving combination chemotherapy (12–14).

In particular, patients who have been treated with 1 antiviral inhibitor alone in the past appear to already carry a virus

† Deceased.

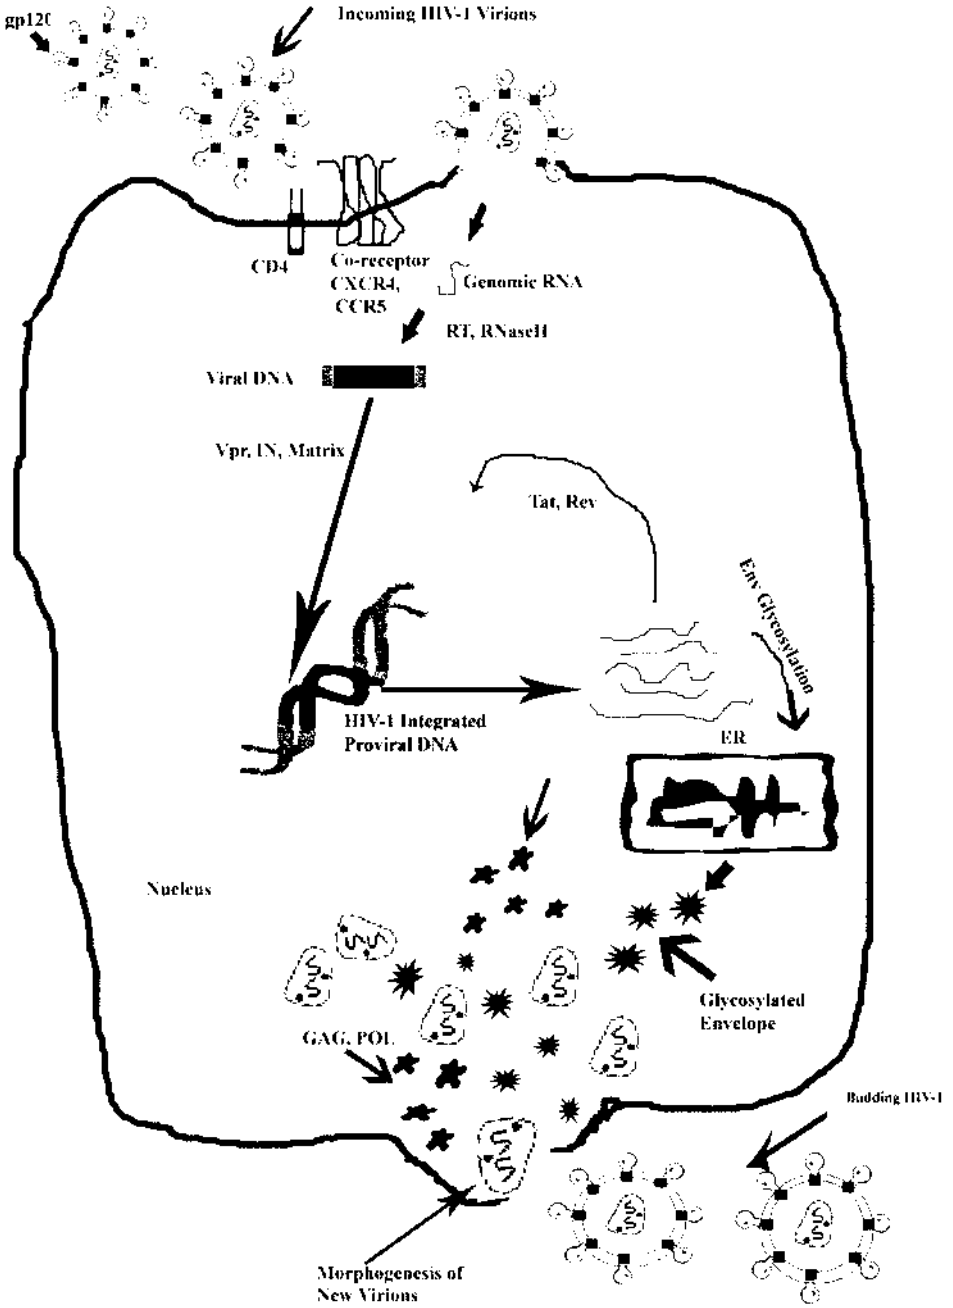

Figure 1 Life cycle of HIV-1. The life cycle of the human immunodeficiency virus type I is similar to that of all retroviruses studied. HIV-1 attaches to the target cell mainly by binding to the CD4 molecule and chemokine receptors. After fusion of the viral and cellular membranes, retroviral core particles are released into the cytoplasm. The RNA genome is converted into a double-stranded DNA by the viral reverse transcriptase (RT) and ribonuclease H (RNaseH) and actively transported into the nucleus, probably aided by the viral protein vpr. The viral DNA is integrated into the genome of the host cell by the viral integrase (IN). The integrated DNA form of the virus is called the provirus. In contrast to other retroviruses, transcription and RNA splicing of the provirus is regulated by viral accessory proteins. For example, the viral protein Tat must to bind to a specific sequence in the HIV genome (termed TAR) to enable highly efficient transcription of the provirus. Rev is required to control RNA splicing and the transport of RNAs into the cytoplasm. Finally, in the cytoplasm, virus core particles are assembled by encapsidating full-length genomic viral RNAs (recognized by specific encapsidation sequences). At the cell membrane, virus particle assembly is completed by the interaction of the core with the viral membrane proteins and new particles ''bud'' (are released) from the infected cell. For more details regarding regulatory proteins, see also Fig. 5. Env, envelope; ER, endoplasmatic reticulum.

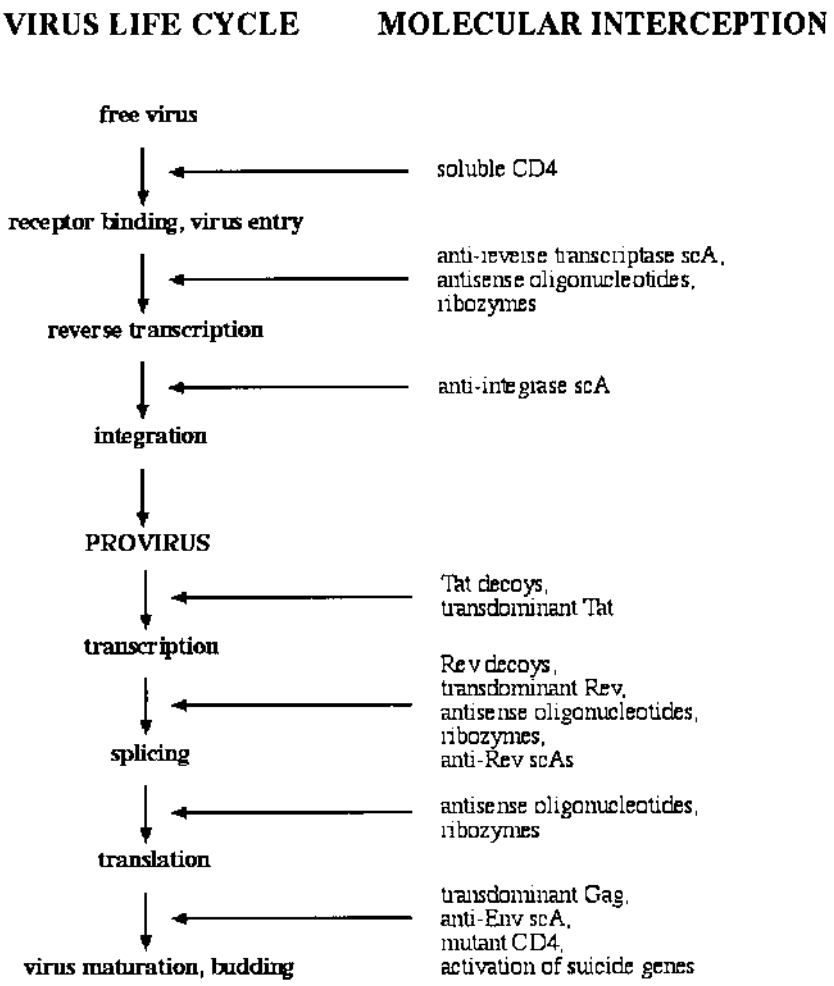

Figure 2 Overview of possible genetic targets to block HIV-1 replication. The different approaches are described in detail in the text.

strain, which is resistant to 1 of such compounds and, therefore, are partially resistant to combination therapy. Such virus strains have a higher chance to further mutate and escape the inhibitory effects of the other chemical compounds. In particular, the viral enzyme reverse transcriptase, which converts the viral RNA genome into a double-stranded DNA, does not have proofreading capabilities. On average, it inserts at least 1 incorrect nucleotide into the viral genome per replication cycle. This error rate is 1 million times higher than that of the cellular DNA polymerase I, which is the main enzyme for the replication of the eukaryotic genome. This high mutation rate explains why drug-resistant virus mutants emerge rapidly in HIV-1-infected patients (15). This high mutation rate also explains why new mutant viruses continuously arise, which are ''new'' and, therefore, not recognized and inactivated by the immune system. Consequently, in the clinically latent stage of HIV-1 infection, high virus loads persist, which consistently change their genetic outfit to escape drugs that inhibit virus replication and the immune system (16–18).

In summary, the clinical application of all drugs for the treatment of AIDS has not led to a cure of the disease and even the new combination therapy may only halt the development of AIDS in infected people temporarily, as new drug-resistant variants of the HIV-1 virus start to emerge. Thus, efforts are underway in many laboratories to develop alternative therapeutics.

III. GENETIC ''BULLETS'' TO BLOCK HIV-1 REPLICATION

The primary target cells for HIV-1 are cells of the hematopoietic system, in particular, $CD4^+$ T lymphocytes and macrophages. During HIV-1 infection, these cells are destroyed by the virus leading to immunodeficiency among infected individuals. To prevent the destruction of the cells of the immune system, many efforts are now underway to make such cells resistant to the HIV-1 virus. This approach has been termed

''intracellular immunization'' (19). In particular, the development of genetic agents, which attack the virus at several points simultaneously inside the cell and/or are independent from viral mutations, has gained great attention.

Such potential agents, also termed ''genetic antivirals'' should have 4 features, to overcome the shortcomings of conventional treatments. First, they should be directed against a highly conserved moiety in HIV-1, which is absolutely essential for virus replication eliminating the chance that new mutant variants arise, that can escape this attack. Second, they have to be highly effective, greatly reducing or, ideally, completely blocking the production of progeny virus. Third, they have to be nontoxic. A fourth criterion, which also should not be overlooked is that the antiviral agent has to be tolerated by the immune system. It would not make much sense to endow immune cells with an antiviral agent, that elicits an immune response against itself leading to the destruction of the HIV-1-resistant cell after a short period of time.

In the past few years, many strategies have been developed and proposed for clinical application to block HIV-1 replication inside the cell (see also Fig. 2). Such strategies use either antiviral RNAs or proteins. They include antisense oligonucleotides, ribozymes, RNA decoys, transdominant mutant proteins, products of toxic genes, and single-chain antigen-binding proteins (20–32). Antiviral strategies that employ RNAs have the advantage that they are less likely to be immunogenic than protein-based antiviral agents. However, protein-based systems have been engineered that use inducible promoters that only become active upon HIV-1 infection.

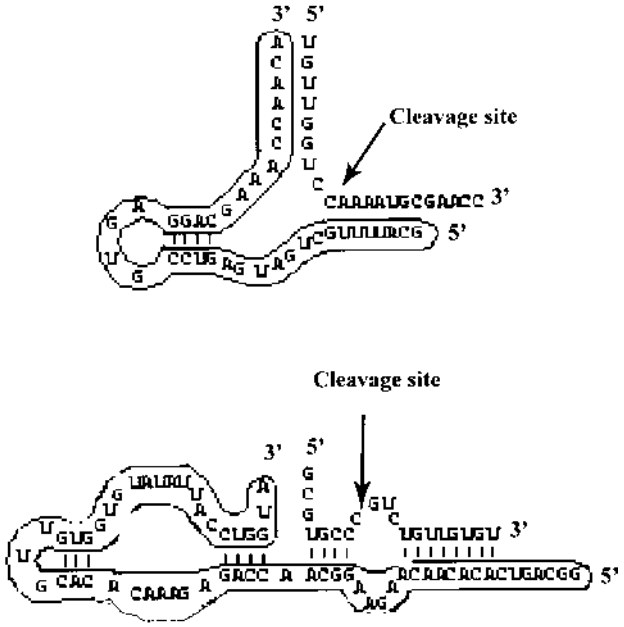

Figure 3 Schematic representation of 2 ribozymes to block HIV-1 replication. The structures shown are paired with actual HIV-I target sequences. (Top) A hammerhead ribozyme pairs specifically with a sequence in the gag region of the HIV-1 genome. (Below) A hairpin ribozyme designed to bind to and cleave the 5′ end of the viral genome, abolishing the reverse transcription and integration of progeny virus.

A. RNA-based Inhibitors of HIV-1 Replication

1. Antisense RNAs and Ribozymes

It is very well known that prokaryotes and bacteriophages express antisense RNAs, which provide regulatory control over gene expression by hybridizing to specific RNA sequences (33). In animal cells, artificial antisense oligonucleotides (RNAs or single-stranded DNAs) have been successfully used to selectively prevent expression of various genes (e.g., oncogenes, differentiation genes, viral genes, etc.) (33,34). Furthermore, the presence of double-stranded RNA inside the cell can induce the production of interferon and/or other cytokines stimulating an immune response. Indeed, it has also been reported that the expression of RNAs capable of forming a double-stranded RNA molecule with the HIV-1 RNA (antisense RNAs) can significantly reduce the expression of HIV-1 proteins, and consequently the efficiency of progeny virus production (33–38).

Ribozymes are very similar to antisense RNAs (e.g., they bind to specific RNA sequences), but they are also capable of cleaving their target at the binding site catalytically. Thus, they have the advantage that they may not need to be overexpressed to fulfil their function. Certain ribozymes (e.g., hairpin and hammerhead ribozymes, require only a GUC sequence) (Fig. 3). Thus, many sites in the HIV-I genome can be targeted. However, several questions still remain to be answered: for example, it is unclear, (a) whether efficient subcellular colocalization can be obtained, in particular, in vivo, (b) whether the target RNA will be efficiently recognized due to secondary and tertiary folding of the target RNA, or (c) whether RNA-binding proteins would prevent efficient binding. Thus, more experimentation will be necessary to address these problems (39–52). Efforts are also underway to develop multimeric/multivalent ribozymes for targeting all major clades of HIV-1, besides optimizing expression potential of these labile moieties (53–55).

2. RNA Decoys

In contrast to ribozymes and antisense RNAs, RNA decoys do not attack the viral RNAs directly. RNA decoys are mutant RNAs that resemble authentic viral RNAs and have crucial functions in the viral life cycle. They mimic such RNA structures and decoy viral and/or cellular factors required for the propagation of the virus (39,56–64). For example, HIV-1 replication largely depends on the 2 regulatory proteins Tat and Rev. These proteins bind to specific regions in the viral RNA, the transactivation response (TAR) loop and the Rev response element (RRE), respectively. Tat binding to TAR is crucial in the initiation of RNA transcription, Rev binding to RRE is essential in controlling splicing, RNA stability, and the trans-

port of the viral RNA from the nucleus to the cytoplasm. These 2 complex secondary RNA structures within the HIV-1 genome appear to be unique for the HIV-1 virus and no cellular homologous structures have been identified. Thus, such structures appear to be valuable targets for the attack with genetic antivirals.

The strategy here is to endow HIV-1 target cells with genes that overexpress short RNAs containing TAR or RRE sequences. The rationale for this is to have RNA molecules within the cells in abundance, which will capture Tat or Rev proteins, preventing the binding of such proteins to their actual targets. Based on Tat nuclear localization capabilities, recently, a chimeric small nucleolar RNA-TAR decoy that localizes to the nucleolus and nucleoli of human cells has also been described (65,66). As such it will be possible to halt early HIV-1 gene expression. Encouraging in vitro data from combination anti-HIV-1 gene therapy approaches using multiple anti-HIV-1 gene therapy moieties (i.e., antisense, decoy and trans-dominant negative mutants) supports its possible future clinical applications (67,68). Combination gene therapy is envisioned as an alternative for HIV-1 therapy due to its labile genome (69). Consequently, HIV-1 replication is markedly impaired. This strategy has the advantage over antisense RNAs and ribozymes in that mutant Tat or Rev, which will not bind to the RNA decoys will also not bind to their actual targets. Thus, the likelihood that mutant strains would arise that would bypass the RNA decoy trap is low. However, it still remains to be elucidated, whether cellular factors also bind to Tat or Rev decoys, and whether overexpression of decoy RNAs would lead to the sequestering of the resulting protein–RNA complexes in the cell.

3. Small Inhibitory RNA

RNA interference (RNAi) is a newly recognized phenomenon in the field of HIV-1 gene therapy with potential promises (70). The inhibitory mechanism involves posttranscriptional gene silencing. RNAi exploits double-stranded ribonucleic acid (dsRNA) oligonucleotides to inhibit expression of the gene with sequence similarity to the input oligonucleotide (Fig. 4). A 21–25 mer dsRNA oligonucleotide is used to interfere with the messenger RNAs (mRNAs) of a specific gene. One of the major prerequisites for achieving RNA interference is a perfect and unique match between the dsRNA oligo with mRNA that produces protein. The dsRNA binds to the target mRNA and makes it incomompetent for translation to protein. At molecular levels, a 2-step process involves editing of the dsRNA oligo by a protein complex called DICER, an RNAse-like enzyme, followed by another complex, called the RNA inhibitory silencing complex, that digests mRNA with similar sequences and hence silences that gene of interest.

There could be 3 major potential avenues for RNAi technology in HIV-1 therapeutic development. HIV-1 infection could be controlled by reducing host cellular targets such as CD4, CXCR4, and CCR5 or by silencing early HIV-1 gene products, Tat and Rev. HIV-1 integrase and gag could also be potential targets due to their crucial role in integration and morphogenesis, respectively. Several recent in vitro studies

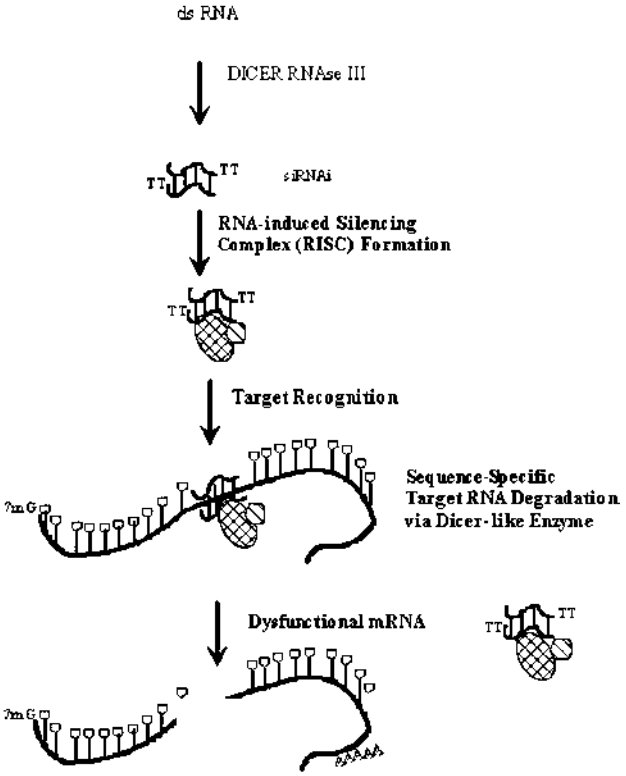

Figure 4 RNA interference model. The mechanism of action of dsRNA interference involves a key enzyme, RNAse III, commonly known as Dicer, that processes dsRNA to siRNA. Dicer generates siRNA duplexes having 5′-phosphate and free 3′-hydroxyl groups. This is followed by siRNA duplexes incorporation into siRNA-containing ribonucleoprotein complexes to generate RNA-induced silencing complexes (RISC) endonuclease. The RISC further mediates sequence-specific target RNA degradation.

targeting CD4, Tat, Rev, and Gag mRNA document the strength of this technology (71–76).

The in vitro findings of HIV-1 control by RNAi serve as a proof of principle that RNAi technology can be employed to suppress multiple steps in the HIV-1 life cycle (77). Moreover, targeting of HIV-1 coreceptors, such as CXCR4, CCR5, APJ, and a number of others, might be a promising future for this technology in HIV-1 gene therapy. An advantage of such interference would be its lowered effect on normal immune functions, one of the hurdles in conventional gene therapy.

RNAi technology will be facing several challenges before it acceptance in clinical scenarios. A major issue will be the stability of small oligos used for therapeutic purposes. In spite of such challenges, strength of this technology is the availability of data through the Human Genome Project to cross-reference redundancy of siRNAs selected for silencing purposes. Development of a vector-based strategy to target a combina-

tion of viral and cellular genes, essential for HIV-1 infection, will further add to the strength of this therapeutic intervention.

B. Protein-based Inhibitors of HIV-1 Replication

1. Transdominant Mutant Proteins

During HIV-1 replication, several regulatory proteins are essential for viral gene expression and gene regulation. Mutant forms of such proteins greatly reduce the efficiency of viral replication (78). Transdominant (TD) mutants are genetically modified viral proteins that still bind to their targets but are unable to perform their actual function. They compete with the corresponding native, wild-type protein inside the cell. The competition of several TD proteins with the wild-type counterpart has been shown to greatly reduce virus replication, especially when such TD mutants are expressed from strong promoters (the cytomegalovirus immediate early promoter, CMV-IE) (19,26,79–88).

For example, transcription from the HIV-1 long terminal repeat (LTR) promoter is dependent on the Tat protein. Mutant Tat proteins, which still bind to the nascent viral RNA, but which are unable to further trigger RNA elongation of transcription greatly reduce the production of HIV-I-RNAs and consequently the production of progeny virus. In a similar way, mutant Rev proteins interfere with regulated posttranscriptional events and also greatly reduce the efficiency of virus replication in an infected cell.

Although TD mutants have been shown to be effective in vitro, it still remains unclear how long cells endowed with such proteins will survive in vivo. An exciting area of transdominant protein research is exploring inhibitors of host proteins that interact with HIV-1 proteins. One such report using a protein that interacts with HIV-1 integrase [i.e., integrase interactor 1 also known as hSNF5] showed inhibitory effects on HIV-1 replication (89) There is a significant possibility that peptides of such proteins will be displayed via HLA leading to the destruction of the HIV-I-resistant cell by the patient's own immune system. There is, however, the potential to express such proteins from the HIV-1 LTR promoter, which only becomes activated upon HIV-1 infection. However, this would rule out that a TD Tat can be used, because TD Tat may also abolish its own expression. Even if other TD proteins are expressed from inducible promoters, it still remains unclear, whether such inducible promoters are really silent enough so that no protein is made (and no immune response) as long as there is no viral infection.

2. Toxic Genes

Another approach to reduce the production of progeny virus is to endow the target cells of HIV-1 with toxic genes, which become activated immediately after virus infection. The activation of the toxic gene leads to immediate cell death; therefore, no new progeny virus particles can be produced. Theoretically, this would lead to an overall reduction of the virus load in the patient. In vitro experiments have shown that the production of HIV-1 virus particles was indeed reduced, if target cells had been endowed with genes coding for the herpes simplex virus thymidine kinase or a mutant form of the bacterial diphtheria toxin protein. Such genes were inserted downstream of the HIV-1 LTR promoter, which only becomes activated upon HIV-1 infection, when the viral Tat protein is expressed (90–94).

Besides the question regarding the ''silence'' of the HIV-1 LTR promoter without Tat (discussed above), the main problem with this approach is the actual number of cells that carry a toxic gene present in the patient. Because the HIV-1 virus will not only infect cells that carry the toxic gene, but also many other cells of its host, this approach may only ''slow down'' virus replication for a short period of time until all cells that carry the toxic genes undergo self-destruction upon infection.

3. CD4 as Decoy

The CD4 molecule is the major receptor for the HIV-1 virus for entry into T lymphocytes. Thus, in a similar way to RNA decoys, mutant CD4, which stays inside the endoplasmatic reticulum has been shown to inactivate HIV-1 envelope maturation, preventing formation of infectious particles. In another approach, soluble CD4 has been used to block the envelope of free extracellular virus particles and to prevent binding to fresh target cells (95). However, the question remains if soluble and/or mutant CD4 in the blood of the patient will also serve as a trap for natural CD4 ligands leading to the impairment of important physiological functions (96–98).

4. Single-chain Antibodies

Single-chain antibodies (scA) have originally been developed for *Escherichia coli* expression to bypass the costly production of monoclonal antibodies in tissue culture or mice (99,100). They comprise only the variable domains of both the heavy and the light chain of an antibody. These domains are expressed from a single gene, in which the coding region for these domains are separated by a short spacer sequence coding for a peptide bridge, which connects the 2 variable domain peptides. The resulting scA [also termed single-chain variable fragment (scFv)] can bind to its antigen with similar affinity as a Fab fragment of the authentic antibody molecule.

scFvs have been developed by our group and others to combat HIV-1 replication, when expressed intracellularly (32,97,101–107). Both pre- (e.g., integrase, reverse transcriptase, matrix protein) and post- (e.g., Rev and Tat) integration sites of the viral life cycle have been targeted, with varying success (108). An HIV-1 coreceptor CXCR4 scFv has shown potent inhibitory effects on HIV-1 replication (109), and future development of CCR5 scFvs will further assist in HIV-1 control. Further studies using constructs combining multiple scFvs for potential synergistic antiviral potency are under development and should be of importance in developing robust anti-HIV-1 molecular therapeutics.

IV. GENETIC ''GUNS'' TO DELIVER GENETIC ANTIVIRALS

In all therapeutic approaches listed above, the therapeutic agent cannot be delivered directly to the cell. Instead, the

corresponding genes have to be transduced to express the therapeutic agent of interest within the target cell. Genes can be delivered using a large variety of molecular tools. Such tools range from nonviral delivery agents (liposomes or even naked DNA) to viral vectors. Because HIV-1 remains and replicates in the body of an infected person for many years, it will be essential to stably introduce therapeutic genes into the genome of target cells for either continuous expression or for availability upon demand. Thus, gene delivery tools such as naked DNA, liposomes, or adenoviruses (AV), which are highly effective for transient expression of therapeutic genes, may not be useful for gene therapy of HIV-1 infection.

Adeno-associated virus (AAV), a nonpathogenic single-stranded DNA virus of the parvovirus family, has recently gained a great deal of attention as a vector because it is not only capable of inserting its genome specifically at one site at chromosome 19 in human cells, but it is also capable of infecting nondividing cells. However, vectors derived from AAV are much less efficient and lose their ability to target chromosome 19 (110,111). Another shortcoming of AAV is the need for it to be propagated with replication-competent AV because AAV alone is replication defective. It also remains to be shown how efficiently AAV vectors transduce genes into human hematopoietic stem cells and/or mature T lymphocytes and macrophages. Because gene therapy of HIV-1 infection may also require multiple injections of the vector (in vivo gene therapy, see below) or of ex vivo manipulated cells, it also remains to be shown whether even small amounts of contaminating AV, which is used as a helper agent to grow AAV, will cause immune problems.

The most efficient tools for stable gene delivery are retroviral vectors (112–118), which stably integrate into the genome of the host cell, as this is a part of the retroviral life cycle (Fig. 1). This is why first virus-based gene delivery systems have been derived from this class of viruses, and continued development toward this class of safer vectors will lead to more suitable gene therapy system (119,120). This is also why they are being used in almost all current human gene therapy trials, including ongoing clinical AIDS trials.

Retroviral vectors are basically retroviral particles that contain a genome in which all viral protein-coding sequences have been replaced with the gene(s) of interest. As a result, such viruses cannot further replicate after 1 round of infection. Furthermore, infected cells do not express any retroviral proteins, which makes cells that carry a vector provirus (the integrated DNA form of a retrovirus) invisible to the immune system (112–118).

A. Retroviral Vectors Derived from C-Type Retroviruses

All current retroviral vectors used in clinical trials have been derived from murine leukemia virus (MLV), a C-type retroviruses with a rather simple genomic organization (Fig. 5). MLV contains only 2 gene units, which code for the inner core structure proteins and the envelope protein, respectively. It does not contain regulatory genes such as HIV-1. Thus, the construction of safe gene delivery systems is rather simple and straightforward. Such delivery systems consist of 2 components: the retroviral vector, which is a genetically modified viral genome, that contains the gene of interest replacing retroviral protein coding sequences, and a helper cell that supplies the retroviral proteins for the encapsidation of the vector genome into retroviral particles (Fig. 5). Modern helper cells contain separate plasmid constructs, which express all retroviral proteins necessary for replication. After transfection of the vector genome into such helper cells, the vector genome is encapsidated into virus particles (due to the presence of specific encapsidation sequences). Virus particles are released from the helper cell carrying a genome containing only the gene(s) of interest (Fig. 5). Thus, once established, retrovirus helper cells can produce gene transfer particles for very long time periods (e.g., several years). In the last decade, several retroviral vector systems have also been derived from other C-type chicken retroviruses (112,114,118).

B. Retroviral Vectors Derived from HIV-1

Retroviral vectors derived from MLV have been shown to be very useful to transfer genes into a large variety of human cells. However, they poorly infect human hematopoietic cells, because such cells lack the receptor, which is recognized by the MLV envelope protein. Furthermore, retroviral vectors derived from C-type retroviruses are unable to infect quiescent cells: such viruses (and their vectors) can only establish a provirus after 1 cell division, during which the nuclear membrane is temporarily dissolved. Thus, efforts are underway in many laboratories to develop retroviral vectors from lentiviruses [e.g., HIV-1 or the simian immunodeficiency virus (SIV), which are able to establish a provirus in nondividing cells (although the mechanism by which these viruses penetrate the nucleus is not fully understood)] (121). However, the fact that lentiviruses contain several regulatory proteins, which are essential for virus replication, makes the construction of lentiviral packaging cells more complicated. Furthermore, the fact that the lentiviral envelope proteins (e.g., that of HIV-1) can cause syncytia and/or that some viral regulatory proteins are toxic to the cells further hampers the development of stable packaging lines.

The ''envelope problem'' has been solved by generating packaging cells, which express the envelope protein of MLV or the envelope of vesicular stomatitis virus (VSV). Such envelope proteins are efficiently incorporated into lentiviral particles. The second and major problem for generating stable packaging lines is the toxicity of some retroviral regulatory proteins to the cell. Thus, retroviral vectors can only be generated in transient systems: 293T cells (human embryonic kidney cell line, highly susceptible for transfecting DNAs) are simultaneously transfected with all plasmids constructs to express the particle proteins and the vector genome. Figure 6 shows plasmid constructs used to make HIV-1-derived packaging cells. Vector virus can be harvested from the transfected cells for a limited time period and can be used to infect fresh target cells. Although this gene transfer system has been

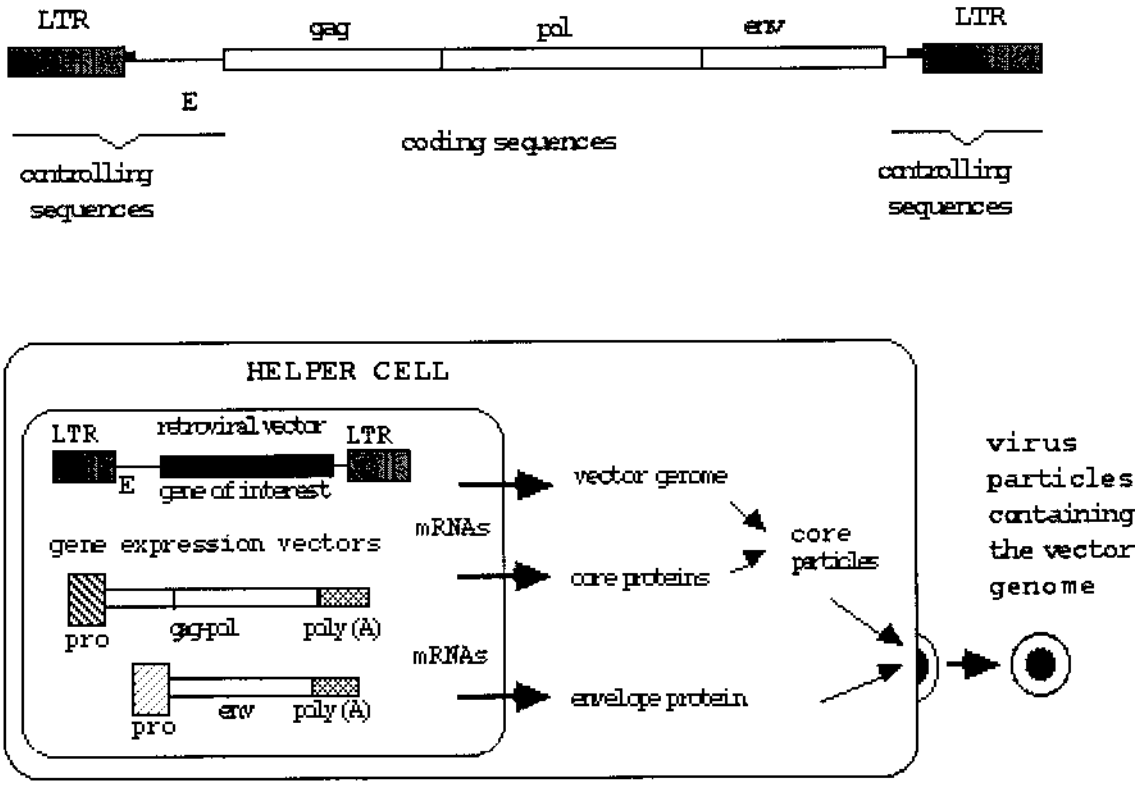

Figure 5 Retroviral helper cells derived from C-type retroviruses. A C-type retroviral provirus (the DNA intermediate of a retrovirus is shown on the top). The protein coding genes (gag-pol and env) are flanked by cis-acting or controlling sequences, which play essential roles during replication. (Below) In a retroviral helper cell, the retroviral protein coding genes, which code for all virion proteins, are expressed (ideally) from heterologous promoters (pro) and polyadenylated via a heterologous polyadenylation signal sequence [poly(A)]. To minimize reconstitution of a full-length provirus by recombination, the gag-pol and env genes are split to different gene expression vectors. In the retroviral vector, the viral protein coding sequences are completely replaced by the gene(s) of interest. Because the vector contains specific encapsidation sequences (E), the vector genome is encapsidated into retroviral vector particles, which bud from the helper cell. The virion contains all proteins necessary to reverse transcribe and integrate the vector genome into that of a newly infected target cell. However, because there are no retroviral protein coding sequences in the target cell, vector replication is limited to 1 round of infection. LTR, long terminal repeat.

shown to be functional, it is not highly efficient and better packaging cells still need to be developed. In addition, many questions regarding the safety of such vectors still need to be addressed. It is known that plasmid DNAs can recombine with each other very efficiently immediately after transfection. Thus, the question needs to be addressed, whether there is a chance that replication-competent viruses arise by recombination, which may cause a disease in gene-transduced patients.

C. Cell Type-specific Retroviral Vectors

All retroviral vectors currently used in human gene therapy trials contain the envelope protein of amphotropic (ampho) MLV or VSV. Ampho-MLV and VSV have a broad host range and can infect various tissues of many species, including humans. Thus, the use of vectors containing such envelope proteins enables the transduction into many different human tissues. However, due to this broad host range, gene transfer has to be performed ex vivo. If injected directly into the bloodstream, the chances that the vector particles would infect their actual target cells are very low. Furthermore, such vector particles may infect germ line cells (which are continuously dividing). Thus, the target cells have to be isolated and the gene transfer is being performed in tissue culture. Gene transduced cells are then selected and reintroduced into the patient.

However, this protocol has major shortcomings in regard (not only) to gene therapy of HIV-1 infection. First, it is very expensive and requires highly trained personal. Second, human cells, which are kept in tissue culture change their physiological behavior and/or take up fetal bovine proteins (a component of the tissue culture medium) and display bovine peptides via histocompatibility antigen (HLA) on the cell sur-

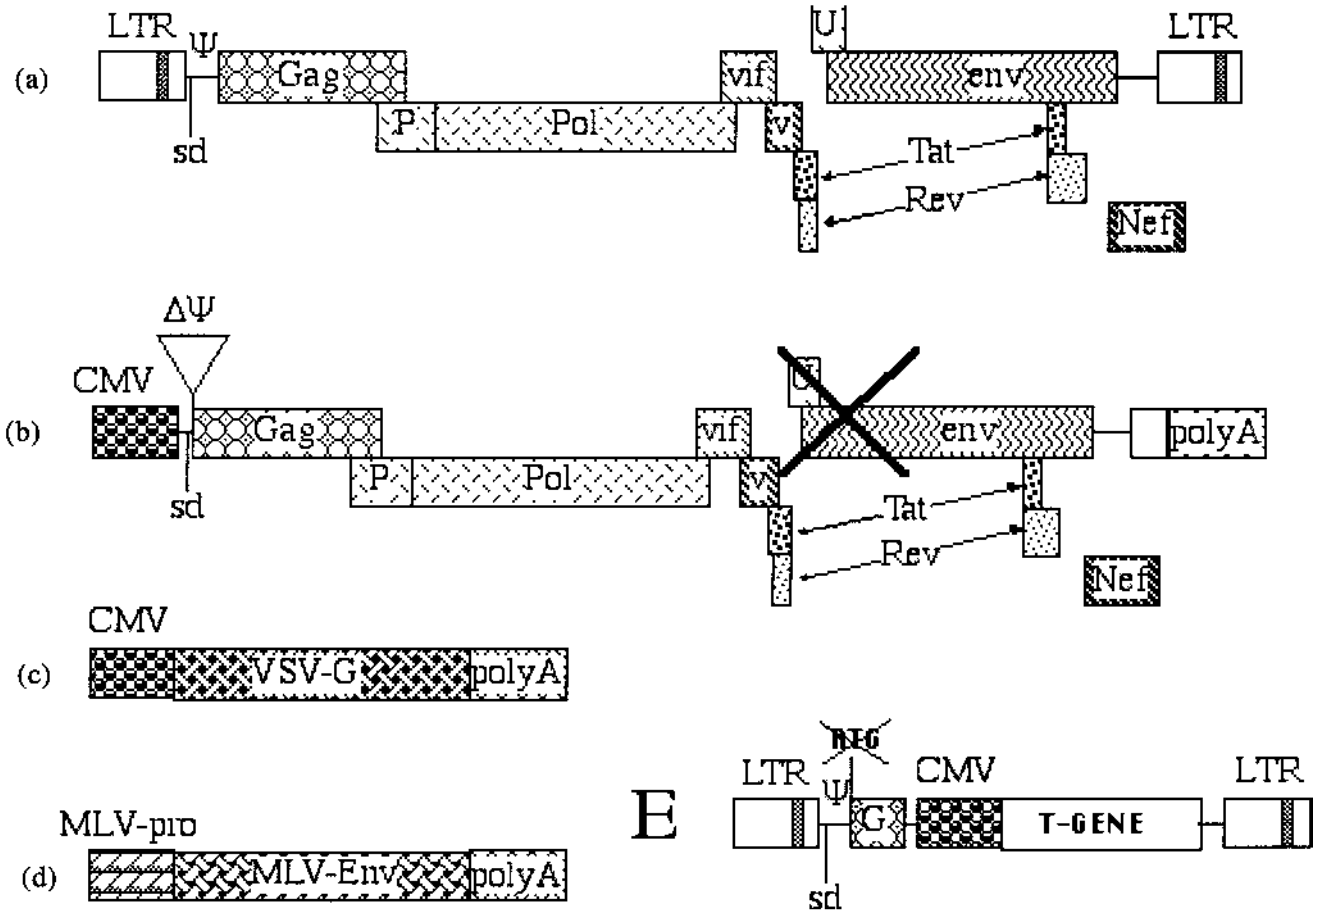

Figure 6 Retroviral packaging system derived from HIV-1. (a) A provirus of HIV-1 is shown on the top. (b–d) These show plasmid constructs to express pseudotyped HIV-1 retroviral particles, and (E) shows a plasmid construct to encapsidate and transduce genes with an HIV-1 vector (the plasmid sequences to propagate such constructs in bacteria are not shown). Besides the genes encoding for HIV-1 proteins, which form the core of the virus (e.g., Gag, structural core proteins; P, protease; Pol, reverse transcriptase and integrase) and the envelope (e.g., env, envelope protein), the HIV-1 genome also codes for several regulatory proteins, which are expressed from spliced mRNAs and have important functions in the viral life cycle. (b) plasmid construct to express the core and regulatory proteins. To avoid encapsidation and transduction of genes coding for such proteins, the following modifications have been made: the 5′ LTR promoter of the HIV-1 provirus has been replaced with the promoter of cytomegalovirus (CMV) to enable constitutive gene expression, the 3′ LTR has been partially replaced with the polyadenylation signal sequence of simian virus 40 (polyA), the encapsidation signal has been deleted ($\Delta\psi$), and the reading frame for the envelope and vpu genes have been blocked. (c) and (d) show plasmid constructs to express the envelope proteins of the vesicular stomatitis virus (VSV-G) or the envelope protein of murine leukemia virus (MLV), respectively. In the absence of HIV-1 envelope proteins, which are rather toxic to the cell, HIV-1 efficiently incorporates the envelope proteins of VSV or MLV into virions. The use of such envelopes also further reduces the risk of the reconstitution of a replication-competent HIV-1 by homologous recombination between the plasmid constructs. (E) shows a retroviral vector used to package and transduce a gene of interest (T gene) with HIV-1-derived vectors. Because the encapsidation sequence extends into the Gag region, part of the gag-gene (G) has been conserved in the vector. However, the ATG start codon has been mutated. The gene of interest is expressed from an internal promoter, because the HIV-1 LTR promoter is silent without Tat. sd, splice donor site.

face. Consequently, such cells become immunogenic and are eliminated by the immune system of the patient. To bypass such ex vivo protocols, efforts are now underway in many laboratories to develop cell type-specific gene delivery systems, which would involve injecting the gene delivery vehicle directly into the patient's bloodstream or tissue of interest. In the past few years, several attempts have been made to develop cell type-specific gene delivery tools, again with retrovirus-derived vectors leading the field.

The cell type specificity of a virus particle is determined by the nature of the retroviral envelope protein, which mediates the binding of the virus to a receptor of the target cell (122). Thus, experiments have been initiated in several laboratories to modify the envelope protein of retroviruses in order to alter the host range of the vector. One of the first attempts to specifically deliver genes into distinct target cells has been performed in the laboratory of Dr. H. Varmus. Using retroviral vectors derived from avian leukosis virus, these investigators incorporated the human CD4 molecule into virions to specifically transduce genes into HIV-1-infected cells (123). However, such particles were not infectious for unknown reasons. Recent reports indicate that MLV particles that carry CD4 can infect HIV-1-infected cells, although at very low efficiencies (124).

In another attempt to target retroviral particles to specific cells, Roux et al. have shown that human cells could be infected with eco-MLV, if they added 2 different antibodies to the virus particle solution (125,126). The antibodies were connected at their carboxy termini by streptavidine. One antibody was directed against a cell surface protein, the other antibody was directed against the retroviral envelope protein (125,126). Although this approach was not practical (infectivity was very inefficient and was performed at 4°C), these experiments showed that cells that do not have an appropriate receptor for a particular virus can be infected with that virus, if binding to the cell surface had been facilitated. These data also indicated that antibody-mediated cell targeting with retroviral vectors was possible.

To overcome the technical problems of creating an antibody bridge, it was logical to incorporate the antibody directly into the virus particle. However, complete antibodies are very bulky and are not suitable for this approach. The problem has been solved using single-chain antibody technology (127–130). Using hapten model systems, it has been shown that retroviral vectors that contained scAs fused to the envelope are competent for infection (128,129). Retroviral vector particles derived from spleen necrosis virus (SNV, an avian retrovirus) that display various scAs against human cell surface proteins are competent for infection on human cells that express the antigen recognized by the antibody (127,128,130).

Most recently, it became possible to use scA-displaying SNV to introduce genes into human T cells with the same high efficiency obtained with vectors containing wild-type envelope. In all such experiments, the wild-type envelope of SNV had to be copresent in the virus particle to enable efficient infection of human cells. However, because SNV vector particles with wild-type SNV envelope do not infect human cells at all, this requirement is not a drawback for using such vector particles for human gene therapy (131,132).

Although successful gene transfer using scA-displaying MLV vector particles has been reported from 1 laboratory (133), further experimentation in the laboratories of several other investigators revealed that MLV-derived vector particles that display various scAs are not competent for infection in human cells (125,126,134–137). The difference between MLV and SNV cell-targeting vectors is certainly based on the different features of the wild-type envelope and the mode of virus entry (138). Moreover, wild-type ampho-MLV infects human hematopoietic cells extremely poorly, most likely due to the absence of an ampho-MLV receptor on such cells (139). Thus, MLV-derived vectors are certainly not the best candidates for human gene therapy of AIDS and alternative vectors need to be developed.

D. Other New Potential Vector Systems

Most recently, other interesting attempts have been made to combat HIV-1-infected cells. Recombinant VSV has been engineered, which lacks its own glycoprotein gene. Instead, genes coding for the HIV-1 receptor CD4 and a chemokine coreceptor, CXCR4, have been inserted. The corresponding virus was able to efficiently infect HIV-1-infected cells, which display the HIV-1 glycoprotein on the cell surface. Because VSV is a virus that normally kills infected cells, the engineered virus only infects and kills HIV-1-infected cells. It has been reported that this virus indeed reduced HIV-1 replication in tissue culture cells up to 10,000-fold (140). This novel approach to combat one virus with another will certainly gain a great deal of further attention. However, it remains to be shown how effective this approach will be in vivo. Will the ''antivirus'' succeed in eliminating a large load of HIV-infected cells before it will be cleared by the immune system? On the other hand, because HIV-1 preferentially kills activated immune cells, will it destroy the immune cells that are attempting to clear the body from its own ''enemy''? How will the body tolerate a virus that does not look like one because it carries human cell surface proteins on the viral surface? The answer to these and other questions are eagerly awaited (141).

V. POTENTIAL PROBLEMS

Even if we find a gene transfer system that can transduce enough cells within the body to inhibit virus replication significantly, there are many other questions that still remain to be answered. For example, it is not clear whether a cell, which has been endowed with an HIV-1 resistance gene, will be able to fulfill its normal biological function in vivo. It has to be considered that to become resistant against HIV-1, the cells usually have to overproduce the corresponding HIV-1-resistance gene. Does this overproduction result in a loss of other functions (e.g., because the cell has to supply a significant part of its energy supply to the production of the HIV-1-resistance gene)? Will the body be able to eliminate all HIV-1-infected

cells or will the infected person become a lifelong carrier of the virus, which is still replicating in his or her body although at levels that cause no clinical symptoms due to the presence of HIV-1-resistance genes? Will the patient be capable of infecting new individuals? Finally, as genetic therapies can all be overcome with in vitro challenges of very high multiplicities of infection (MOIs) of HIV-I, will there be a difference in antiviral effects in peripheral blood vs. lymphoid tissues?

VI. ANIMAL MODELS

One of the major problems with any therapeutic agent against HIV-1 infection is the lack of an appropriate and inexpensive animal model system to test the efficiency of an antiviral agent. Because HIV-1 only causes AIDS in humans, it is difficult to test and evaluate the therapeutic effect of novel antiviral agents in vivo. Furthermore, the evaluation of the efficacy of a new drug is further complicated by the long latency period of the virus until the onset of AIDS (which can be 10 years or more). Although a virus similar to HIV-1 has been found in monkeys, the SIV results obtained with this virus do not necessarily reflect the onset of AIDS in humans caused by HIV-1. Furthermore, many antivirals that block HIV-1 are ineffective in blocking SIV. Thus, other animal model systems need to be developed to study the effect of anti-HIV-1 therapies.

Since the early 1990s, many strains of laboratory mice have been bred, which lack components of the immune system. Severe combined immunodeficient (SCID) mice are deficient in functional B and T lymphocytes. Thus, they are unable to reject allogeneic organ grafts (142–147). SCID mice have been used extensively to study human leukemia and other malignancies and for modeling human retroviral pathogenesis, including antiviral gene therapy. Furthermore, in the past few years, much progress has been made to transplant hematopoietic stem cells into SCID mice to mimic and study human hematopoiesis. It has been shown that transplantation of human hematopoietic cells into such mice can lead to the repopulation of the mouse's blood with human CD4- and CD8-positive cells. Thus, SCID mice appear also to be good candidates to develop mouse model systems for HIV-1 infection.

At present, 2 different SCID mice model systems are used to study the effect of anti-HIV-1 antiviral agents (148,149). The 2 systems are somewhat different because they represent different components of the human immune system. One is called the hu-PBL SCID model, the other is termed SCID-hu mouse.

In the hu-PBL SCID mouse system, human peripheral blood leukocytes are injected into the peritoneum of the animal. Thus, cells residing in such animals are mature $CD4^+$ and $CD8^+$ lymphocytes. The presence of activated and/or memory T cells ($CD45RO^+$ cells) has also been demonstrated. Such human cells can be recovered from various organs in the mouse (e.g., the spleen or lymph nodes). Because these animals contain human $CD4^+$ T cells, they can be infected easily with HIV-1. Even more, HIV-1 virus replicates in the animal leading to the depletion of $CD4^+$ T cells over a period of several weeks after infection. Thus, this experimental system is very valuable to test the effect of antiviral agents. For example, experiments have been performed to test the effect of monoclonal antibodies against the HIV-1 envelope protein (neutralizing the receptor-binding V3 domain). It has been shown that this antibody indeed could block the replication of the viral strain, for which the antibody was specific. This model system has also been used to test the efficiency of a vaccinia virus-derived vaccine.

In the SCID-hu mouse model system, various human fetal hematopoietic tissues (e.g., liver, lymph nodes, and/or thymus) are transplanted into the mouse (e.g., human fetal thymus and liver tissues are engrafted under the murine kidney capsule). It has been shown that normal thymopoiesis takes place for up to 1 year after implantation and human $CD4^+$ and $CD8^+$ T cells are found in the mouse blood at low levels. In contrast to the hu-PBL-SCID mouse, human cells are also found, that express the CD45RA antigen, which is considered a marker for ''naive'' T lymphocytes. Such mice can also be infected with HIV-1, although the injection of a high virus dose directly into the implant is necessary to establish an infection. However, once an infection has been established, the pathologic effects observed are similar to those observed in the thymuses of infected human adults, children, and fetuses. Moreover, a depletion of $CD4^+$/CD8-T cells is observed.

Both SCID mice model systems are very useful to study pathogenesis and the effect of anti-HIV-1 drugs and to test the effect of anti-HIV antiviral genes. However, one has to keep in mind that such model systems only represent a portion of the human immune system and HIV-1 also infects other cells in humans, such as dendrite cells, microvascular endothelial cells, and neurons in the brain. Thus, the pathogenesis observed in SCID mice certainly does not accurately reflect the pathogenesis in man. Moreover, it is not clear, whether SCID mice transplanted with human immune cells do have a functional immune system.

Recently, a group at the University of Maryland Biotechnology Institute has introduced an HIV-1 rat model (150,151). This particular transgenic animal model contains the entire genome of HIV-1, except for 2 genes involved in infectivity of the virus. These transgenic rats develop AIDS-like symptoms (i.e., weight loss, wasting syndrome, neurological complications) between 5 to 9 months. It is anticipated that HIV-1 rats will be more efficient than mouse models for molecular therapeutic studies.

VII. CLINICAL TRIALS

Recently, certain initial in vivo studies have been conducted for intracellular immunization against primate lentiviruses. A trans-dominant negative Rev protein (RevM10) has been studied in humans infected with HIV-1 by Dr. G. Nabel's group. In these initial studies, it was demonstrated that cells transduced with RevM10 had a significant longer half-life, as com-

pared with control cells, when reinfused into patients in different stages of disease. These early initial phase I trials were performed using MLVs, as well as microparticulate bombardment using a ''gene gun'' (152).

In addition, an very exciting study has been reported by R. Morgan's group in which an antisense construct to Tat and Rev genes in SIV was used to transduced T cells from rhesus macaques (153). The monkeys were then challenged with SIV intravenously. Of note, the animals with the transduced cells had significantly lower viral loads and higher CD4 counts, compared with control monkeys. Thus, this suggests, for the first time, that gene therapy against lentiviruses may have significant efficacy in vivo. Clearly, these are both preliminary studies in humans and in primates, which require more detailed evaluation. Other trials using a variety of different approaches are ongoing in initial phase I studies. According to data presented at The American Society of Gene Therapy 2002 meeting, HIV-1-infected subjects undergoing ex vivo $CD34^+$ stem cells transduction and transplantation continue to express anti-HIV-1 antisense RNA over 2 years postinfusion. This proprietary gene therapy product of Enzo Pharmaceutical is still under future development (154).

In general, gene therapy faced a major setback in 1999 due to the death of the first known gene therapy patient after receiving an experimental gene therapeutic for inherited liver disease. In the aftermath of this death, the National Institutes of Health and the Food and Drug Administration have instituted stricter guidelines for conducting and monitoring clinical trials with gene therapy (155,156).

In summary, considering all facts and problems of current gene transfer technologies, and considering our lack of knowledge regarding many functions of the immune system, how should we move forward with more phase I gene therapy trials to combat HIV-1? In spite of the lack of knowledge of many aspects of this disease, we have to remain optimistic and can only hope that one approach or the other will lead to measurable success toward the cure, or will at least significantly prolong the life expectancy of the infected person. Clearly, in addition to further exploring novel molecular therapeutics in vivo, significant attention must be placed toward answering critical basic science questions pertaining to ''intracellular immunization.''

Cutaneous Gene Therapy for Skin and Systemic Disorders

William F. Buitrago and Dennis R. Roop
Baylor College of Medicine
Houston, Texas, U.S.A.

I. INTRODUCTION

The skin serves multiple functions owing to its unique and complex structure. The skin presents remarkable advantages as a tissue for developing innovative genetic therapeutic strategies. The skin is a readily accessible organ, which facilitates gene delivery, subsequent monitoring of transgene expression, and excision of small or large areas if required (1). Epidermal keratinocytes and dermal fibroblasts can be readily expanded in culture. In addition, keratinocytes have high proliferative potential and inherent biological characteristics that allow them to synthesize mature proteins from a vast array of transgenes (2).

There have been recent advances in the molecular characterization of many skin disorders, vector design, immune modulation, regulation of gene expression, administration, and in other aspects in the field of skin gene therapy. This rapid progress has made the skin a formidable target to develop and test a variety of gene therapy approaches to both cutaneous and systemic diseases.

II. SKIN: STRUCTURE AND FUNCTION

The skin, or integument, is the most superficial and largest organ of the body. Its functions are essential for the homeostatic balance of the organism. The skin provides protection against ultraviolet (UV) light, mechanic, thermic, and chemical insults, and also prevents excessive dehydration due to its relative water impermeability (3,4). It also acts as a physical barrier against microorganisms and is involved in the coordination of multiple immune responses (5,6). The skin is the major organ involved in sensory perception. For instance, it possesses tactile, pressure, pain and temperature receptors (7,8). In humans and in many other mammals the skin is essential in thermoregulatory responses (6,9,10). For example, heat conservation is aided by the presence of hair and adipose tissue in the hypodermis, and heat loss is increased by the evaporation of water through the skin's surface and by increasing the blood flux through the rich capillary plexus of the dermis (9). The skin also plays a definite role in the body's metabolism as an important store of energy in the form of triglycerides and in the synthesis of vitamin D (6,9).

The skin presents regional variations with regards to thickness, coloration, and presence of adnexa. For instance, the skin is thicker, presents lower levels of coloration, and has no hair follicles in the palms and soles. However, the basic structure of the skin is maintained in all body areas. The external part of the skin, the epidermis, is formed by a stratified squamous epithelium, which is composed in its majority by keratinocytes. Other cell types such as melanocytes, Langerhans cells, and Merkel cells are also found in this layer. The epidermis is divided into 2 major compartments: the basal (proliferative) and suprabasal (differentiation) compartments. The suprabasal compartment is further divided into different layers based on microscopic characteristics: the spinous layer, the granular layer, and the cornified layer (Fig. 1). The basal keratinocytes are attached to the basement membrane (BM) through specialized multiprotein junctional complexes called hemidesmosomes (11). The epidermis, a tissue in constant turnover, is sustained by permanent mitotic divisions in the basal compartment where stem cells reside (12). Recent studies suggest that the skin contains 3 distinct stem cell reservoirs: the interfollicular epidermis and the anagen hair follicle ger-

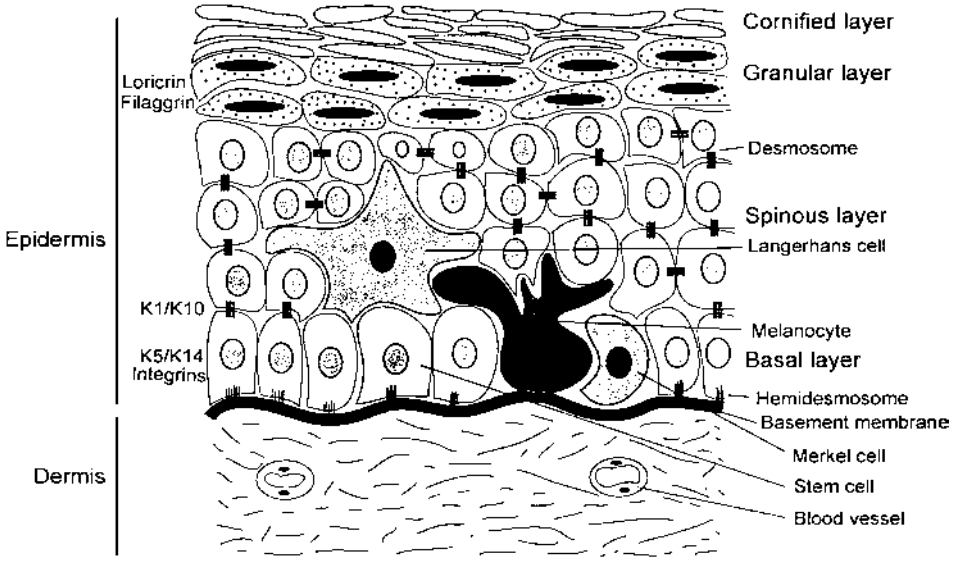

Figure 1 Schematic representation of the skin.

minal matrix where stem cells with a limited differentiation potential exist, and the upper outer root sheath (bulge), which contains potent reserve stem cells that act in the maintenance of not only the epidermis, but hair follicles and sebaceous glands (13). The cells in the basal layer undergo as series of maturational changes, and at some point, a given number move upward to the postmitotic suprabasal compartment where they undergo terminal differentiation. The basal layer is composed of a heterogeneous population of cells that can be classified according to their capacity for sustained growth into 3 subpopulations: (1). the holoclones or stem cells, which have the greatest reproductive capacity; (2). the paraclones or differentiated cells with a short replicative lifespan and limited growth capacity; and (3). the intermediate meroclones, which are the transitional stage between the holoclones and the paraclones (14). The expression of keratins, integrins, and involucrin is regulated during keratinocyte differentiation. Keratin 5 (K5), keratin 14 (K14), and integrins are expressed by basal cells, their expression is down-regulated as the cells detach from the BM and move upward to the suprabasal compartment where keratins 1 (K1) and 10 (K10) become highly expressed (15,16). Subsequently, as keratinocytes migrate toward the epidermal surface the expression of other markers, such as filagrin and loricrin, is detected (17,18). Most of the cellular organelles are degraded in the stratum granulosum, and the dead keratinocytes form the stratum corneum.

The dermis, a thick layer of fibroelastic dense connective tissue that supports and nourishes the epidermis, is composed of numerous blood and lymphatic vessels, sensory elements, and different cell types such as fibroblasts, macrophages, and lymphocytes. The hypodermis (subcutaneous layer or subcutis) is localized under the dermis, and contains adipose tissue and blood vessels. The adnexal structures such as sweat glands, sebaceous glands, and hair follicles are structures of ectodermal origin that form by invagination of the epidermic epithelium into the dermis, and sometimes the hypodermis (Fig. 1).

III. GENE DELIVERY TO THE SKIN: MAIN STRATEGIES AND GENE TRANSFER SYSTEMS

A. Main Strategies

The accessibility, visualization, and monitoring that made the skin an appealing target for genetic therapy has also allowed the development and use of strategies for gene transfer not possible in other tissues. The 2 main strategies currently used for gene delivery in skin disease models are the ex vivo and in vivo approaches.

1. The Ex Vivo Approach

In the ex vivo approach, the skin cells from the host are isolated and harvested after removal by biopsy. The cells are then grown in vitro where therapeutic gene transfer is performed. Finally, the altered cells are grafted back into the host (Fig. 2). This method offers some advantages because primary keratinocytes, including human, are receptive to gene modification, readily expanded in tissue culture under selective conditions, and easily grafted back into host (19–22, Buitrago and Roop, unpublished data). However, the ex vivo approach is disadvantageous because of its labor intensity and potential scarring.

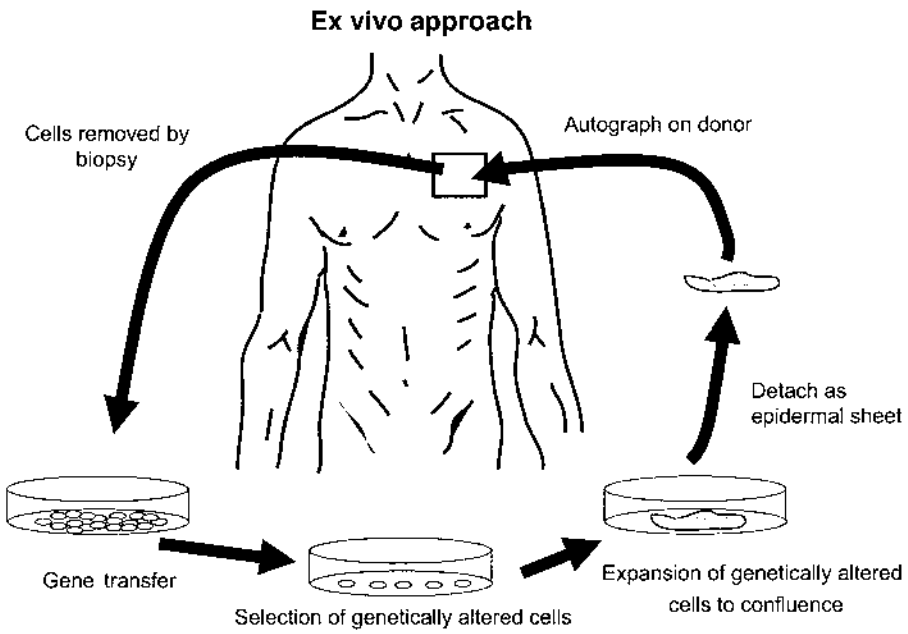

Figure 2 Ex vivo approach for cutaneous gene transfer.

2. The In Vivo Approach

In this approach, gene transfer is achieved through direct administration of genes by different modalities, such as naked DNA or in vectors of nonviral or viral origins (Fig. 3). The in vivo approach is favored over the ex vivo approach as the need for cell culture and surgery are bypassed, making it technically, clinically, and economically advantageous (19). In spite of these advantages, the direct in vivo approach is still limited by the low levels of transduction frequency for stem cells that leads to transient expression of the transferred gene.

B. Gene Transfer Systems in Cutaneous Gene Therapy

The first step in effective gene therapy is the ability to deliver the corrective gene/genetic material to the correct tissue with high efficiency. The skin can be specifically targeted by transduction in culture, intradermal injection, topical application, or other methods. A variety of specific techniques and vectors for skin gene delivery have been developed, and they can be classified in 2 large categories: viral and nonviral.

1. Viral Gene Transfer Vectors

Currently, viruses provide the most efficient means of delivering genes to target cells. Several classes of viruses have been successfully used for gene delivery and expression in the skin (Table 1). Viral vectors are efficient for gene transfer in cell culture as part of the ex vivo approach. In addition, they have also yielded positive outcomes when administered topically or by direct injection during the in vivo approach (23,24). As reviewed by Ghazizadeh and Taichman (25), there are 6 main factors to consider in a viral system for efficient gene transfer: ability for high titer generation, cargo-carrying capacity, capacity to transduce dividing and/or nondividing cells, integration properties, vector antigenicity, the ease with which clinical grade vectors can be prepared free of replication-competent virus, and the length of time of gene expression required (25). Some disadvantages should also be considered when working with viral vectors. Because the expression of the delivered genes depends heavily on the integration site, it is important to understand that all the integrative viral vectors have the limitation of their lack of true site-specific integration. Furthermore, down-regulation of the introduced genes by epigenetic mechanisms represents another significant obstacle. To overcome these obstacles, several strategies have been developed including use of insulator elements, and the bacterial tetracycline regulatory system (26–28).

a. Adenoviruses. These vectors have been widely used for skin gene transfer. Most of these vectors have been rendered replication deficient by deletion of their E1A and E1B essential genes (29,30). The development of ''gutless'' adenoviral vectors in which more viral genes are stripped has increased their cargo capacity and minimized the toxicity of viral products to target cells (31). Adenovirus vectors can carry up to 35 kb of foreign DNA, and the viral particles can be produced at high titers. They can infect a wide variety of cell types, and both replicating and nonreplicating cells. In addition, safety precedents already exist because adenovirus-based vaccines have been used in patients without any major side effect (32).

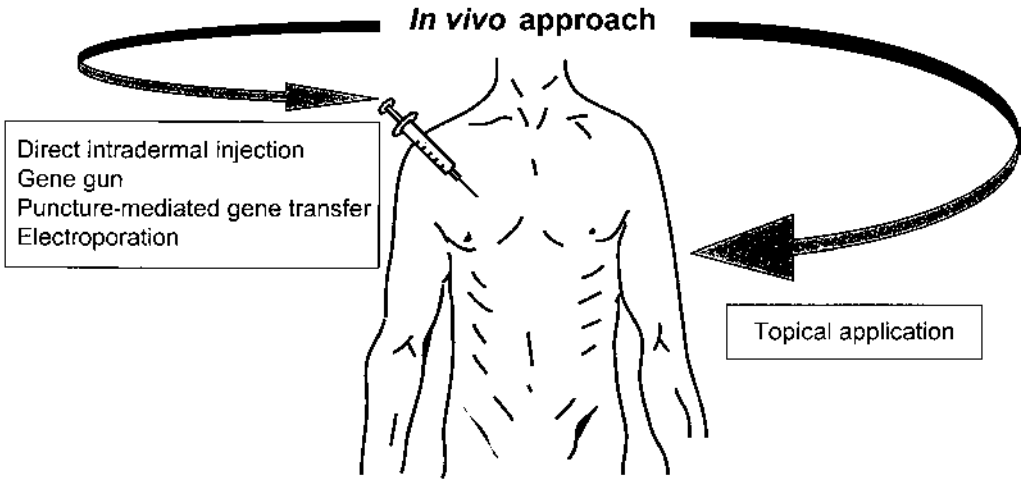

Figure 3 In vivo approach for cutaneous gene transfer.

Adenoviral transgene expression has been detected in all cell types of both dermis and epidermis when injected subcutaneously (19). However, adenoviruses are highly antigenic, and because they do not integrate into the host genome, only transient expression of the delivered gene is achieved most of the time. Therefore, adenoviral vectors are not ideal for sustained expression in a regenerating tissue such as the epidermis, making their use to correct inherited skin diseases limited. Nonetheless, it has been recently reported that recombinant adenovirus vectors carrying the xeroderma pigmentosum A (*XPA*) and C (*XPC*) genes achieved long-term expression, as well as long-term restoration of biological activity (up to 2 months) in XP-A and XP-C immortalized and primary fibroblast cell lines (33). Adenoviral vectors have been successfully used in applications such as DNA vaccination (34), anticancer therapy (35), and promotion of wound healing (36–38).

b. Adeno-associated viruses. Adeno-associated viruses (AAVs) were once considered poor vectors due to their limiting packaging size (about 4.7 kb). However, the requirement for a helper virus (adenovirus or herpesvirus) for productive infection makes them one of the safest viral vectors (39). Currently, recombinant AAVs have a high safety profile because 96% of the AAV genome has been removed. AAVs can transduce a great variety of human cell types, both in vitro and in vivo (40). AAVs can exist in both integrated and non integrated forms, and are able to transduce replicating and nonreplicating cells (25,41). AAVs do not induce a strong innate immunologic or a cytotoxic T cell response, and long-term expression of the transgene is possible (42). However, they induce an antibody response, and the transfection efficiencies are usually low (42).

c. Retroviruses. These are the most widely used viruses for gene delivery. They are capable of delivering genes to

Table 1 Viral Gene Transfer Vectors for Cutaneous Gene Therapy

Vector Type	Advantages	Disadvantages
Retroviruses	Transduce almost all dividing mammalian cells; high efficiency of transduction; long-term expression of therapeutic gene	Random integration into host genome; do not transduce non-dividing cells
Lentiviruses	Infect dividing and non-dividing cells; high efficiency of transduction; long-term expression of therapeutic gene	Random integration into host genome
Adenoviruses	Low risk of serious side effects; high cargo capacity; high titers easily achieved; no insertion into host genome; infect dividing and non-dividing cells	Highly antigenic; transient expression of therapeutic gene; does nor integrate into host genome
Adeno-associated viruses	High safety profile; transduce almost all mammalian cell types; infect dividing and non-dividing cells	Low cargo capacity; transfection efficiency usually low; insert into host DNA; induce antibody response

nearly any dividing mammalian cell type and integrate their genomes onto host cell chromosomes (43). With the introduction of pantropic envelope proteins, ''pseudotyped'' retroviruses have been used to stably deliver genes to a much broader host range, including insect cells and nonmammalian eukaryotes (44). Retroviral vectors can accommodate between 8 and 9 kb of foreign DNA, and high titer virus production is easily obtained (25). Their transduction capacity is restricted to nonproliferating cells; therefore, their use in skin gene therapy has been limited to ex vivo approaches (19 and references therein, 25).

One of the most significant advances in retroviral vector applications is the use of lentiviruses. Lentiviruses have the unique capacity to infect nondividing, as well as dividing cells (45). This is of particular importance for gene therapy approaches in which target cells are nondividing or slow dividing, such as epidermal stem cells, epidermal basal cells, or nervous tissue cells (46–49). In addition, in vivo approaches have been tested with success in both skin and nervous tissue, and stable, long-term production of proteins in a variety of model organs, such as brain, optic nerves, and skin, has been observed for genes delivered by lentiviral vectors (46–50).

2. Nonviral Gene Transfer Vectors

Although viral vectors are quite efficient for gene delivery, safety concerns have led to the development of other means for gene transfer, the nonviral vectors. The use of nonviral vectors avoids some of the problems that occur with viral vectors, such as endogenous virus recombination, potential oncogenicity, and induction of an immune response (51). Overall, nonviral vector techniques for gene transfer can be classified into 2 groups: delivery by a chemical/biochemical vector or delivery of genetic material by physical methods (51,52).

a. Chemical or Biochemical Nonviral Vectors. The advantages of chemical or biochemical nonviral vectors include their lack of immunogenicity, the absence of a theoretical size limit for the therapeutic gene, the use of one transfer agent for any desired gene, and the consequently low cost (Table 2). The 2 main nonviral vectors include cationic polymers or proteins (e.g. dendrimers, polylysine, DEAE-dextran, protamine or polyethyleneimine), and cationic lipids (51–55). These reagents can be used with naked DNA, RNA-DNA oligonucleotides, ribozymes, or other type of genetic material to increase their uptake. In addition, other means of gene delivery for cutaneous gene transfer have been explored in recent years. An engineered transposase originally isolated from fish binds to the inverted repeats of salmonoid transposons in a substrate-specific manner and mediates the precise cut-and-paste transposition in fish, as well as in mouse and human cells (56). This is an active transposon system that can be used for the introduction of a therapeutic gene. In addition, the Φ31 bacteriophage integrase (57), which is a site-specific recombinase that stably integrates large DNA molecules containing an *attB* phage attachment-site sequence into genomic ''pseudo-attp sites,'' has been recently used in studies targeting epidermal progenitor cells (58). By implementing a Φ31 integrase-based gene transfer system, Ortiz-Urda et al. were able to stably transfer the type VII collagen alpha-1 (COL7a1) cDNA into the genome of primary epidermal progenitor cells of recessive dystrophic epidermolysis bullosa (RDEB) patients and to achieve phenotypic correction in skin regenerated using these cells. Clearly, this system is advantageous because it lacks the biosafety risks of viral vectors, it is more efficient than the stable transfer achieved with plasmid-based systems, and it allows for the stable integration of large DNA sequences into chromosomal DNA.

In the mean time, antisense DNA oligonucleotides (AS-ODNs), short-length synthetic DNA molecules that hybridize with specific mRNA sequences and silence gene expression, have been used in cutaneous genetic transfer studies (59–62). RNA-DNA oligonucleotides have been used for targeted single-base gene correction through homologous recombination and mismatch DNA repair (63–66). RNA ribozymes have been used to cleave mutant target RNA and to repair mutant RNA through splicing (67–69). Finally, small interfering RNAs (siRNA) are short double-stranded RNA molecules that are capable of binding and inducing the degradation of specific mRNAs (70,71). This relatively new discovered mechanism of sequence-specific gene silencing known as RNA interference (RNAi), has been applied successfully in mammalian cells (70,71), and its potential uses in cutaneous gene therapy remain to be fully explored.

b. Physical Methods. In recent years, many physical techniques for cutaneous gene transfer have been developed (Table 3). Direct intradermal injection of naked DNA has been shown to be an efficient mechanism for gene delivery to the skin. Using this technique, gene expression has been detected in both epidermal and dermal cells (2,47,72,73). The advantages of this method are its simplicity and safety, but it is relatively inefficient and coverage area tends to be small (2,51). Therefore, additional physical methods have been tested in order to improve the efficiency of in vivo gene transfer. For example, topical application of antisense oligonucleotides and of DNA complexed with liposomes is effective in targeting the epidermal cells (74–76). The use of epidermal enzymes, depilatory creams or the stripping of the skin with tape to induce structural disruption of the stratum corneum, can potentially increase the uptake of liposomal particles or oligonucleotides (19 and references therein). Electroporation, which is the use of electrical pulse fields to increase cell permeabilization (77), has been determined to increase gene uptake and transgene expression following injection of naked DNA in numerous tissues, including the skin (48,78–82). Puncture-mediated gene transfer, a method in which a device with a constant high-frequency oscillating bundle of fine metal needles, leads to DNA transfer and subsequent detection of reporter genes in skin cells (83). Particle-mediated gene transfer or ''gene gun'' is also an effective method to deliver genetic material to skin cells, producing high transgene expression. In this method, small DNA-coated particles are accelerated into tissues and are capable of penetrating the cell in virtue of their small size; once inside the cell, the DNA dissociates and its expression ensues (51,84,85). The major

Table 2 Chemical/Biochemical Vectors for Cutaneous Gene Transfer

Vector Type	Advantages	Disadvantages
Cationic polymers/proteins Cationic lipids	Lack of immunogenicity; no theoretical size limit for cargo capacity; can be used with naked DNA, RNA-DNA oligonucleotides, ribozymes or other genetic materials; low cost	Gene transfer less efficient than viral vectors; short-lived therapeutic gene expression; long term selection usually needed
"Naked" DNA	Lack of immunogenicity; low biosafety risk	Low efficiency of gene transfer; short-lived therapeutic gene expression
ϕ 31 bacteriophage integrase Engineered transposases	Precise integration of large DNA molecules into host genome; low biosafety risk; more efficient for stable gene transfer than plasmid-based systems; no theoretical size limit for cargo capacity	Further development needed for clinical applications

limitation of the gene gun technique is the degree of penetration into tissues, but it has been demonstrated that epidermal and dermal penetration is efficient to induce high levels of transgene expression in the targeted areas (86,87). In addition, other techniques such as ultrasound and hydrodynamic injection are being developed, but their current value for gene transfer to the skin is minimal (51).

IV. CANDIDATE DISEASES FOR CUTANEOUS GENE THERAPY

Many skin diseases are characterized by single gene mutations, either dominant or recessive, and can therefore possibly be corrected by destruction of the mutant gene product or introduction of a wild-type gene product. In addition to being used to correct inherited skin diseases, the skin can be used as a delivery system to secrete various polypeptides, such as enzymes, growth factors, and cytokines, into the systemic circulation. Furthermore, taking advantage of the potent antigen-presenting dendritic cells in the epidermis (Langerhans cells) and dermis, the skin can be used as a route of immunization against tumor-associated or infectious-associated antigens.

A. Cutaneous Gene Therapy for Inherited Skin Diseases

1. Characterization of Disease Genes

The molecular basis of a number of inherited skin diseases has been elucidated in recent years. These include genetic lesions leading to skin blistering, abnormal cutaneous cornification, and predisposition for cancer. In the epidermis, mutations in the genes expressed in the basal keratinocytes usually lead to skin fragility and blistering. Examples include, K5 and K14 mutations in epidermolysis bullosa (EB) simplex (88,89), laminin 5 mutations in a subset of junctional EB (90,91), and defects in type VII collagen in dystrophic EB (92,93).

Mutations in genes expressed in the suprabasal keratinocytes lead to abnormal epidermal terminal differentiation and are often manifested as keratinization disorders known as ichthyoses, characterized by thickened and scaly skin (94). Examples include transglutaminase 1 (TGase1) mutations in lamellar ichthyosis (LI) (95), and K1 and K10 mutations in epidermolytic hyperkeratosis (EHK) (96–98). Genetic defects in genes expressed in the skin have also been linked to cancer predisposition, as in the cases of patched mutations in basal cell nevus syndrome (99,100) and mutations in XP genes in xeroderma pigmentosa (101).

Understanding of the molecular basis of disease pathogenesis provides the cornerstone in designing rational gene therapy strategies. Correction of recessive phenotypes, in principle, requires the correct expression of the wild-type gene product where it was previously absent or defective. Much progress has been made in such attempts and success has been recently achieved in model systems (20–22,102). Correction of dominant-negative phenotypes, however, presents more of a challenge. The dominant-negative gene product has to be efficiently disrupted before the normal functions of the wild-type gene product can be restored. Several strategies are under development to circumvent the negative effects of mutant gene products.

2. Establishment of Disease Models

On understanding the mechanisms of a particular skin disease, an appropriate model has to be established to test possible gene therapy strategies before they are applied to patients. Such a model can be either a human tissue/animal chimeric model or an entirely animal model.

For recessive diseases, the pathologic phenotypes develop only when both alleles are mutated or deleted from the genome. Although mutant cells retaining disease characteristics from patients can be used to test therapeutic approaches in vitro or grafted onto an animal (103), such material is often limited. The development of mouse embryonic stem (ES) cell techniques and the use of homologous recombination made it possible to obtain virtually unlimited material if a mouse model could be generated for a particular disease. The ES cell techniques and homologous recombination allow manipulation of the mouse genome in a finely controlled manner, where mutations can be made in a particular gene to observe the consequence of its alteration during development and differentiation. Mouse models for several recessive skin diseases have been made by making a null mutation in epidermal genes, such as TGase 1 gene in LI (104) and type VII collagen gene in dystrophic EB (105). These mouse models not only provided much information on the mechanisms of disease pathologic study, but are also invaluable model systems to test gene therapy approaches for these diseases.

For dominant diseases caused by haploinsufficiency, as in the case of striate palmoplantar keratoderma (106,107), introduction of a second wild-type allele for desmoplakin may eliminate the disease phenotype, as in the case for recessive diseases. For diseases caused by a dominant-negative mutation, traditional transgenic mouse models were very informative in helping us to understand the disease mechanisms. In this approach, a mutated transgene is introduced into the mouse genome, and when it is expressed at a high enough level to compete with gene products from both wild-type alleles, a phenotype is observed. Mouse models were made in this manner for epidermolysis bullosa simplex (EBS) (108) and EHK (109). However, such mouse models cannot be used to test gene therapy approaches. First, because both wild-type alleles are present, the mutant gene product has to compete with wild-type product from both alleles. Second, the transgene is integrated into the genome randomly; therefore, its expression level and consequently the severity of the phenotype are affected by the surrounding sequences. Thus, the ratio of wild-type to mutant gene product, a crucial factor in judging the success of the therapy, remains variable in these models.

We took advantage of the mouse ES cell techniques and homologous recombination, and generated several mouse models for dominant skin diseases. ''Hot spot'' mutations in the 1A region of the rod domain in K14 and K10 have been linked to EBS and EHK, respectively (110,111). Using a knock-in/replacement strategy, we replaced a wild-type K14 or K10 allele with a mutant allele containing a ''hot spot'' mutation (112,113). Heterozygous mutant mice developed phenotypes similar to EBS and EHK, respectively, as expected for the dominant mutations. These mouse models mimic the diseases at both the genetic and phenotypic level, and will be the ideal systems to test gene therapy approaches for EBS and EHK.

3. Progress in Gene Therapy of Specific Skin Disorders

a. Lamellar Ichthyosis. The autosomal recessive ichthyoses are a clinically heterogeneous family of diseases characterized by abnormal cornification, and comprise LI and congenital ichthyosiform erythroderma (114). In LI, patients are born encased in a ''collodian'' membrane that is later shed and followed by development of large, thick scales of varying degrees of erythema. Palmar and plantar hyperkeratoses are often present.

Defects in the gene encoding keratinocyte TGase 1 were identified in a number of patients with LI (95,115). TGase 1 is normally expressed in differentiated keratinocytes and catalyzes cross-linking of cornified envelope precursor molecules, such as involucrin, loricrin, and small proline-rich proteins (116,117). With loss of TGase 1 function in the formation of insoluble cornified envelope, the barrier function of the outer epidermis is disrupted (94,118). Therefore, restoration of the TGase 1 enzymatic activity may represent a possible means of correcting the LI disorder.

Correction of recessive phenotypes requires the introduction of a wild-type gene product. A high-efficiency retroviral vector containing a wild-type TGase 1 gene was used to transduce mutant keratinocytes form LI (21). More than 98% of the primary cells expressed wild-type TGase 1, as measured by the proportion of keratinocytes positive for the transferred gene compared with the total number of cells determined by propidium iodide counterstaining (21). TGase 1 enzymatic activity was restored to normal levels and was targeted to the membrane fraction. In addition, transduced keratinocytes also demonstrated restored involucrin cross-linking and normal cornification (21). When these transduced keratinocytes were grafted to immunodeficient mice, the regenerated skin displayed restored TGase 1 protein expression in vivo and was normalized at the levels of histology, clinical surface appearance, and barrier function (20). However, TGase 1 expression in the human skin graft was lost in a month because of silencing of the vector (22).

Besides transplantation of genetically modified cells, another way to deliver genes to the skin is through direct administration to the intact tissue. Choate and Khavari (119) regenerated skin from patients with LI on nude mice to examine the corrective impact of direct injection of naked plasmid DNA. Regenerated LI skin received repeated in vivo injections with a TGase 1 expression plasmid, and restoration of TGase 1 expression in the correct tissue location in the suprabasal epidermis was observed. However, unlike LI skin regenerated from keratinocytes first transduced in vitro with a retrovirus carrying TGase 1 prior to grafting, directly injected LI skin displayed a nonuniform TGase 1 expression pattern (119). In addition, direct injection failed to correct the central histologic and functional abnormalities of LI. These results show that

partial restoration of gene expression can be achieved through direct injection of naked DNA into the human skin diseased area, but underscore the need for new advances to achieve efficient and sustained plasmid-based gene delivery to the skin.

b. Junctional EB. There are 2 major forms of junctional EB, the Herlitz variant or EB letalis, and generalized atrophic benign EB (GABEB). In addition, there are several other variants (120). Both forms are transmitted in an autosomal recessive manner, and both have onset at birth and are associated with marked skin fragility and generalized blister formation. Although scarring and milia formation are usually absent in both forms of junctional EB, skin atrophy is a characteristic finding in GABEB patients who also tend to have marked dystrophic or absent nails, palmoplantar hyperkeratosis, and significant scarring alopecia of the scalp (120). A characteristic feature of Herlitz disease is the development of large, nonhealing areas of granulation tissue; common sites include the perioral and perinasal areas, trunk, and nape of the neck. In addition, extracutaneous involvement may occur in both forms of junctional EB. In Herlitz disease, findings may include oral blisters and erosions, dysplastic teeth, marked growth retardation, and severe anemia. In contrast, patients with GABEB have milder mucosal involvement (oral cavity, conjunctiva, and esophagus) and early loss of permanent teeth, but neither growth retardation nor anemia (120). Unlike dystrophic EB, musculoskeletal abnormalities are absent in both forms of junctional EB.

Junctional EB involves dissociation of the dermal-epidermal junction, which occurs beneath the basal cell layer, but above the lamina densa. On examination by electron microscopy, junctional EB is caused by dissolution of the lamina lucida. Mutations in a number of genes encoding vital structural proteins, including laminin 5 components $\alpha 3$, $\beta 3$, $\gamma 2$ (90,91), BP180 (type XVII collagen or BPAG2) (121), integrin $\beta 4$ (122), and plectin (123) have been identified in junctional EB.

Several somatic gene therapy approaches have been tested to correct the junctional EB phenotype. In one study, when keratinocytes from a patient with Herlitz junctional EB with a mutation in laminin 5 $\beta 3$ were transduced with a $\beta 3$ transgene, the transduced keratinocytes synthesized $\beta 3$ peptide that assembled with the endogenous $\alpha 3$ and $\gamma 2$. They assembled into biologically active laminin 5, which was secreted, processed, and deposited into the extracellular matrix. Reexpression of laminin 5 induced cell spreading, nucleation of semidesmosomal-like structures, and enhanced adhesion to culture substrate (124). Organotypic cultures with the transduced keratinocytes reconstituted epidermis closely adhering to the mesenchyme and presenting mature hemidesmosomes, bridging the cytoplasmic intermediate filaments of the basal cells to the anchoring filaments of the BM (124).

A mouse line with targeted disruption of laminin $\alpha 3$ (LAMA3) (laminin 5 $\alpha 3$) was recently created (125). Although the mutation in homozygous pups caused neonatal lethality, cells isolated from these pups could be used to test therapeutic approaches in vitro. In a study carried out to restore BP180 function in cultured junctional EB patient keratinocytes and skin graft through gene transduction (126), the transduced cells had normalization of their adhesion parameter. In addition, a revertant mosaicism was reported recently in a patient with GABEB, representing a ''natural gene therapy'' (127). Importantly, reversion of the affected genotype to carrier (heterozygote in a recessive disease) genotype in about 50% of the keratinocytes was sufficient for the normal functioning of the skin.

A risk for reintroducing a therapeutic wild-type protein into patients with a recessive disease is that immunologic responses may be elicited. Extra caution has to be taken to decrease such possibility.

c. Epidermolysis Bullosa Simplex. Epidermolysis bullosa (EB) is a group of hereditary mechanobullous disorders with at least 11 distinct forms, 7 of which are dominantly inherited. The EBS subtype is characterized by intraepidermal blistering, and most cases are due to dominant keratin mutations. The estimated incidence for EBS is 10 per 1 million births in the United States (128), with a considerable perinatal mortality rate because of electrolyte imbalance, marked protein loss and sepsis. The most severe form of EBS, epidermolysis bullosa herpetiformis (EB herpetiformis) or Dowling-Meara variant (EBS-DM), presents at birth with generalized blistering (129). Blisters occur characteristically in groups (herpetiform) on the trunk and extremities, including palms and soles, and usually heal without scarring. Development of hyperkeratoses starts later in childhood.

Approximately 70% of the reported mutations in EBS-DM occur at the same mutational ''hot spot,'' codon 125, an arginine located at the beginning of the rod domain of K14. On ultrastructural examination, EBS-DM cells have perinuclear aggregates of keratin filaments in the basal cells instead of keratin bundles throughout the cytoplasm in normal basal cells (128). The weakened basal cells rupture on mild mechanical trauma, and the clinical phenotype is blistering within the basal cell layer. Because K14 is only expressed in the basal keratinocytes, the suprabasal cells appear normal and undergo normal terminal differentiation.

Two mouse models were previously developed, including a transgenic model (108) and a K14 null model (130). Although both models helped us to understand the disease mechanisms, and the K14 null model also provided important insight into K15 functions, neither mimics EBS-DM at the genetic level and therefore cannot be used to test gene therapy approaches for the diseases. We recently developed a mouse model for EBS-DM, where a wild-type K14 allele was replaced with a mutant allele in the mouse germline (112). The presence of a neomycin-resistance cassette in an intron affected expression from the mutant K14 allele, and the heterozygotes had subclinical phenotypes. But homozygous pups developed extensive blisters and died shortly after birth. When the neo selection cassette was removed by Cre-mediated excision, the resulting heterozygous pups developed large blisters, as was expected for this dominant mutation. To our knowledge, this is the first mouse model that mimics EBS-DM at both the genetic and phenotypic level. Unfortunately, the pups died because of severe blistering.

To overcome such problems, we recently developed a transgenic mouse model that allows the focal deletion of geno-

mic sequence via Cre-mediated excision. A transgenic mouse line carries a Cre recombinase fused to a truncated progesterone receptor, driven by a K14 promoter (131). These mice were crossed with mice heterozygous for the mutant K14 allele with the neo cassette flanked by loxP sites, and heterozygous mutant mice carrying the transgene were obtained. On topical treatment with an antiprogestin, the neo cassette can be deleted in focal areas by activated Cre. We expect that in such areas the mutant K14 expression would be comparable with that of the wild-type K14, therefore causing blistering in the skin. We were indeed able to induce blisters using this system, and the mice remained viable (112). This transgenic mouse model is ideally suited to test gene therapy approaches for EBS-DM. In this mouse model, the mutant K14 allele can be focally activated in epidermal stem cells, and following topical administration of an inducer, blisters develop in treated areas. However, after a few weeks, blisters heal and never reappear. Some skin disorders are characterized by a mosaic pattern, with alternating stripes of affected and unaffected skin that follow the lines of Blaschko. These nonrandom patterns are believed to be caused by postzygotic mutations that occur during embryogenesis. Interestingly, a mosaic form of EBS has never been reported. It has been suggested that basal stem cells carrying a postzygotic mutation in K5 or K14 would have a selective disadvantage and be rapidly displaced by wild-type basal stem cells, which can move laterally. Using laser capture microdissection, we have shown that the induced blisters healed by migration of surrounding nonphenotypic stem cells into the wound bed. Thus, our model predicts that if EBS stem cells could be corrected, they will have a selective growth advantage when introduced into areas prone to blistering. This observation provides an explanation for the lack of mosaic forms of EBS-DM. In addition, it has important implications for gene therapy because it predicts that defective EBS stem cells will be replaced by nondefective stem cells. Another unexpected observation from this mouse model was the discovery that mice that express the mutant K14 allele at levels approximately 50% of wild-type K14 do not exhibit a skin phenotype. Previously, it had been assumed that gene therapy approaches for dominant disorders like EBS must aim to either correct the mutant allele, or completely inhibit its expression. Our model predicts that the EBS phenotype may be eliminated by overexpression of the normal K14 allele or partial suppression of the mutant K14 allele, thus increasing the ratio of wild-type to mutant protein. Technically, it is much easier to design gene therapy strategies that would achieve a partial suppression of a mutant dominant allele rather than a complete correction or suppression. Therefore, we will try to correct the EBS-DM phenotype by altering the ratio of wild-type to mutant K14 by increasing expression of wild type K14. This will be done using a viral vector expressing wild-type K14. In addition as an alternative strategy to correct the EBS-DM phenotype, we will transduce EBS-DM keratinocytes with a viral vector expressing a ribozyme designed to specifically degrade mutant K14 transcripts.

d. Epidermolytic Hyperkeratosis. This disease, also called bullous congenital ichthyosiform erythroderma, is inherited in an autosomal dominant mode, with an incidence of 1 in 200,000 to 300,000 newborns (128). Up to 50% of the reported cases arise sporadically. Affected children present at birth with erythroderma, blistering, and peeling. Erythroderma and blistering diminish during the first year of life, and hyperkeratoses develop, predominantly over the flexural areas of the extremities. On histopathologic examination, findings consist of hyperkeratosis and parakeratosis, lysis of the suprabasal keratinocytes, and perinuclear vacuolar degeneration. The basal keratinocytes appear normal but exhibit hyperproliferation (129). The transit time for keratinocytes to move from the basal layer to the stratum corneum is remarkably shortened and takes only 4 days in EHK patients instead of the normal 4 weeks (132). Mutations to K1 and K10 have been linked to EHK, and a mutational ''hot spot'' at Arg 156 in K10 has been identified in most severe cases of EHK (98,133). Three mouse models were previously generated, including 2 transgenic models (109,134) and a K10 null model (135). However, because they do not mimic EHK at the genetic level, none can be used as a model system to test gene therapy for this disease.

We recently generated a mouse model that mimics EHK at both the genetic and phenotypic levels by replacing a wild-type K10 allele with one that has a point mutation at Arg 156 (113). We will attempt correction of the phenotype by altering the ratio of wild-type to mutant K10 by increasing expression of wild-type K10. To do this, we will collect epidermal stem cells from heterozygous mutant mice, and transduce them with viral vectors (both retroviral and lentiviral vectors) to overexpress the wild-type K10 allele. In addition, we will attempt to correct the EHK phenotype by suppressing the expression of the mutant K10 allele by transducing EHK cells with a viral vector expressing a ribozyme specifically designed to cleave the mutant K10 transcripts. As opposed to EBS, in which a correction of the mutation in the basal keratins translates into a growth advantage, corrected and mutant stem cells in EHK will proliferate at similar rates because the mutant K10 is not expressed in stem cells, but only in the progeny of stem cells after they have differentiated and moved into the suprabasal layers. There is no selection against epidermal stem cells with K10 mutations, and these stem cells continue to give rise to defective differentiated progeny. It has recently been demonstrated that topical selection with colchicine can be used to select, in vivo, for human keratinocyte stem cells transduced with the multidrug-resistance gene (MDR) (136). Therefore, to efficiently amplify the corrected cell population, we will include the MDR as a selection marker in our targeting strategy to ablate defective epidermal stem cells and allow their replacement with corrected stem cells, which are expected to repopulate the epidermis.

e. X-linked Ichthyosis. X-linked ichthyosis (XLI) is caused by a deficiency in steroid sulfatase (STS), which leads to the accumulation of cholesterol sulphate and results in abnormal scaling skin (137). It is inherited in a pseudoautosomal mode, escaping X inactivation in both humans and mice. Transduction using a retroviral expression vector in vitro with

the STS gene leads to restoration of STS protein expression as well as enzymatic activity (102). In the same study, it was shown that transduced XLI keratinocytes from XLI patients regenerated epidermis histologically indistinguishable from that formed by keratinocytes from patients with normal skin, after grafting onto immunodeficient mice. In addition, the transduced XLI epidermis presented a return of barrier function parameters to normal.

f. Xeroderma Pigmentosa. These are a group of autosomal recessive disorders associated with defects in a number of DNA repair genes, and are characterized by inadequacies in DNA repair after UV injury (101,138). XP genes that are involved in a specific mechanism of DNA repair called nucleotide excision repair, fall into 7 complementation groups (XP-A to XP-G), and all have been cloned (139). Xeroderma pigmentosa (XP) patients have increased susceptibility to epidermal neoplasms, such as basal and squamous cell carcinomas, and malignant melanoma (140). XP affects both the basal and suprabasal compartments, including melanocytes. Because every cell that is unable to repair the UV-induced DNA damage should be considered a potentially tumoral cell, any treatment to be curative, must target every cell in the epidermis, including every stem cell and melanocytes. Although promising attempts to correct the genetic defects in this condition have been performed (141–143), XP represents a challenging condition for cutaneous targeted gene therapy because high-efficiency targeting of melanocytes remains to be developed.

g. Other Conditions. In addition to the dominant-negative mutations in keratins that cause various blistering diseases and hyperkeratoses, several other diseases are inherited in a dominant mode through haploinsufficiency, such as palmoplantar keratoderma that results from desmoplakin mutations (106,107). Gene therapy strategies could involve introduction of a wild-type allele, and host immunologic reactions will not be a concern in this case.

B. Cutaneous Gene Therapy for Systemic Diseases: The Skin as a Bioreactor

Epidermal keratinocytes secrete a variety of proteins such as collagen VII, laminin, proteinases, proteinase inhibitors, growth factors, and cytokines (144 and references therein). Studies using cultured human keratinocytes, grafted onto athymic mice and rats, demonstrated that keratinocytes secrete proteins that reach the systemic circulation. One of the first studies of the secretory function of keratinocytes was carried out by Lorne Taichman and colleagues. They first monitored secretion of human apolipoprotein E (apoE) in cultured human keratinocytes (145). The protein was identified as apoE on the basis of molecular weight, isoform pattern, and immunoreactivity. When they grafted human keratinocytes onto athymic mice and rats, human apoE was detected in the systemic circulation of graft-bearing animals as long as the graft remained on the animals (146). Within 24 h of graft removal, human apoE was not detected in the plasma, indicating that human apoE in the plasma resulted from continuous production of the protein by grafted human keratinocytes. These results showed that proteins as large as apoE (299 amino acids) can transverse the epidermal-dermal barrier and achieve systemic circulation.

Once it was established that epidermis-secreted proteins could reach the central circulation, genetically modified keratinocytes were used to test whether they could deliver transgene products into the bloodstream. Subsequent experiments using both in vivo and ex vivo approaches have been successful in delivering different polypeptides, such as growth hormone, erythropoietin (Epo), factor VIII and IX, leptin, and interleukin 10 (IL-10), to the circulation. In our laboratory, we have further enhanced the usefulness of the skin as a bioreactor by developing a bigenic gene switch system that allows focal induction of transgene expression via topical administration of an inducer (147). Therefore, because of its ability to deliver various polypeptides into the systemic circulation, its accessibility and abundant vascularization, added to the gene switch system development, the skin is a very attractive tissue to test gene therapy strategies for systemic conditions that respond to delivery of polypeptides into the circulation.

1. Progress in Cutaneous Gene Therapy of Specific Systemic Disorders

a. Hemophilia A. This is an X-linked inherited disease caused by deficiency of factor VIII and has an incidence of 1 in 5000 male live births (148). This condition occurs in mild, moderate, and severe forms, reflecting the mutational heterogeneity seen in the factor VIII gene, and symptoms vary from excessive bleeding only after trauma or surgery to frequent episodes of spontaneous or excessive bleeding after minor trauma, particularly into joints and muscles (148–149). In a recent study, factor VIII-deficient transgenic mice expressing human factor VIII under the control of the involucrin promoter were generated (150). Plasma factor VIII activity and correction of the phenotype were seen in this mouse model. In the same study, skin explants from these transgenic mice were grafted into factor VIII double knockouts, which showed plasma factor VIII activity of 4% to 20% normal and had improved whole blood clotting (150).

b. Leptin Deficiency. Leptin, a 16-kDa protein hormone, is involved in the regulation of body weight in mammals (151,152). It is secreted primarily by adipocytes, and it has been shown to regulate food intake and neuroendrocrine function through its action in the hypothalamus (152). In accordance with the phenotype seen in the *ob*/*ob* mice (153), it has been determined that congenital leptin deficiency is associated with early-onset obesity in humans (154). Leptin replacement therapy has provided encouraging results in clinical studies (155); however, the need for repetitive dosing has prompted an alternative approach using gene therapy to correct this condition. In a recent study, a cutaneous gene therapy approach for leptin deficiency was successful in correcting the mouse *ob*/*ob* phenotype (156). Here, immunodeficient *ob*/*ob* mice grafted with skin implants from mice overexpressing leptin, reached body weight equivalent to that of wild-type animals. In addition, immunosupressed *ob*/*ob* mice that were trans-

planted with skin grafts made of human keratinocytes transduced with a leptin cDNA-carrying retroviral vector, showed weight reduction concomitant with a decrease in blood glucose and food intake (156).

c. Anemia due to Erythropoietin Deficiency. Epo is a kidney-produced glycoprotein that regulates red cell production. It binds to its receptor found in erythroid progenitor cells, activating a signaling pathway that leads to the increase of survival of these cells by inhibiting apoptosis (157). In 1987, recombinant human Epo (rHuEpo) was approved in the United States for the treatment of anemia of end-stage renal disease (157). In addition, its therapeutic use has been extended to other conditions, such as anemia associated with Zidovudine treatment of patients with AIDS, anemia secondary to chemotherapy in the treatment of cancer, anemia of pregnancy, anemia of prematurity, myelodysplastic syndrome, and bone marrow transplantation (157 and references therein). In a recent study, a lentiviral vector encoding HuEpo was delivered by single intracutaneous injection into human skin grafts on immune-deficient mice (158). The investigators demonstrated that HuEpo was present in serum, and its levels increased in a dose-dependent fashion. In addition, the hematocrit improved within 1 month after lentiviral injection and remained stable for almost 1 year.

d. Contact Hypersensitivity. Contact hypersensitivity (CHS) responses are regulated by T cells that release cytokines and attract other inflammatory cells after reacting with antigen. IL-10 has been known to be a key regulatory cytokine in both inflammatory and immune responses. Studies have demonstrated that IL-10 is involved in the regulation of the hypersensitivity response because recombinant IL-10 (rIL-10) prevented the elicitation of CHS in previously sensitized mice (159). Meng et al. injected a DNA plasmid containing human IL-10 into the dorsal skin of hairless rats (160). They detected local expression of mRNA and protein in a dose-dependent manner. Further, they showed that the transduced keratinocytes produced and released IL-10 into the circulation by detecting it in the bloodstream, and by quantifying a reduced response to challenge in distant areas from the injection site of previously sensitized animals.

e. Growth Hormone Deficiency. Original experiments of the release of an exogenous growth hormone by transduced keratinocytes into the circulation were performed by Morgan et al. (161). Using the recently developed bigenic gene switch mouse model, we showed that after a single induction, high levels of the therapeutic protein, human growth hormone (hGH), were released from keratinocytes into the circulation (147). The serum levels of hGH were dependent on the amount of inducer applied, and repeated induction resulted in increased weight gain by transgenic vs. control mice. Furthermore, physiological levels of hGH were detected in the serum of nude mice after topical induction of small transgenic skin grafts. These results clearly demonstrate the feasibility of using the gene switch system to regulate the delivery of growth hormone into the circulation for the treatment of growth hormone deficiency.

f. Other Conditions. Additional examples of the skin as a bioreactor approach and its potential use have been performed. For example, two forms of apoE, both the endogenous human apoE and a recombinant form from a transfected vector, were detected in the serum of athymic mice bearing grafts of modified human keratinocytes (162). When human keratinocytes in culture were transduced with a retroviral vector carrying factor IX gene, they secreted active factor IX into the medium (163). When they were grafted onto nude mice, small quantities of factor IX were detected in the bloodstream (163).

C. Other Applications of Cutaneous Gene Therapy

In addition, cutaneous gene therapy has also been applied to other physiopathological processes, such as wound healing, immunoregulation, and cancer.

1. Wound Healing

The process of wound healing involves 3 stages: inflammatory reaction, formation of granulation tissue, and tissue remodeling (164). All these events are known to be regulated by different cytokines and growth factors. There are obvious advantages of gene transfer techniques for treatment of wound healing abnormalities or to enhance the wound healing rate because the epidermal barrier is defective, only limited target gene expression is needed, and the treated area is usually localized (165). Tyrone et al. successfully treated ischemic dermal ulcers in rabbits by topical application of platelet-derived growth factor (PDGF)-A or-B-DNA plasmids embedded within a collagen latice. They showed that PDGF-A and PDGF-B DNA substantially increased the formation of new granulation tissue, epithelialization, and wound closure (166). Subcutaneously injected liposomal insulin-like growth factor 1 (IGF-1) cDNA construct was shown to effectively promote reepithelialization of burn wounds, by decreasing prolonged local inflammation through modulation of the expression of pro- and anti-inflammatory cytokines (167). Intradermal injection of an AAV vector expressing human vascular endothelial growth factor A (VEGF-A) to full thickness excisional wounds in rats was found to induce new vessel formation and enhance wound healing rate (168). Similar results were obtained by Romano Di Peppe et al. using topical application of an adenovirus vector to deliver VEGF on excisional wounds of streptozotocin-induced diabetic mice (169). In other studies, liposomal keratinocyte growth factor cDNA gene delivery to acute wounds in rats, enhanced wound healing by increasing cell proliferation, reepithelialization, and neovascularization, by reducing cell apoptosis, and by activating mesenchymal cells through the induction of IGF-1 expression (170). Other groups have tested different modalities of gene transfer to skin wounds, such as the gene gun approach and the use of genetically modified cultured skin substitutes, with promising results (171,172).

2. Cutaneous Immunomodulation and Cancer Gene Therapy

Gene transfer has become a practical method to induce an immune response. The skin is rich in antigen-presenting cells that are able to initiate and control a specific immune response. It has been demonstrated that injection of naked DNA that encodes antigenic epitopes can induce specific humoral immune responses (173). The advantages of immunomodulation by genetic vaccination are evident; for example, there is no need to isolate and purify protein for vaccination, and it circumvents the use of life or attenuated viral vaccines. In addition, cutaneous transfer of plasmid DNA or mRNA allows for the concurrent delivery of genetic material encoding antigenic epitopes and immunomodulators (174,175). All these make cutaneous genetic transfer a desirable method for engineering specific immune responses. This strategy has been used to induce immune responses with different objectives, such as antitumoral immunotherapy, treatment/prevention of infections, and treatment of autoimmune diseases (175). Cutaneous gene transfer studies that induce an immune response and hold promise as plausible options in the treatment of certain malignancies are briefly presented. The gene transfer by gene gun, and subsequent expression in the skin of different the antitumoral cytokines IL-2, IL-6, and tumor necrosis factor-α and-β (TNF-α and TNF-β), led to tumor regression and/or increased survival in mice with subcutaneously implanted tumors (176). Regression of established primary and metastatic murine tumors was documented after cutaneous gene gun delivery of a plasmid carrying the mouse IL-12 (177). In the same study, the researchers were able to demonstrate that a tumor-specific immunological response had been induced in the treated mice. In a clinical trial conducted by Thurner et al., dendritic cells were isolated, propagated ex vivo, and pulsed with a Mage-3A1 peptide. Subsequently, the cells were injected subcutaneously to advanced melanoma patients; regression of some metastases was seen in 6 of 11 patients, and expansion of specific cytotoxic T cells was seen in 8 of 11 patients (178).

3. Cutaneous Gene Therapy Approaches for Melanoma and Squamous Cell Carcinoma

The incidence of malignant melanoma (MM) has been on the rise in the last years. Squamous cell carcinoma (SCC) is a common malignancy of the epidermal keratinocytes. Due to the advantages that make the skin an amenable tissue for gene transfer, MM and SCC are frequently used as models for tumor-specific gene therapy. Different strategies have been applied for both conditions. For instance, adenoviral-mediated transfer of the herpes simplex thymidine kinase ''suicide'' gene (tk) by direct intratumoral injection, followed by ganciclovir administration, was used to treat human MM established in nude mice (179). In a different study using the B16 melanoma model, a synergistic effect was observed when combination therapy by adenovirus-mediated transfer of tk and IL-2 or tk and granulocyte-macrophage colony-stimulating factor was used (180). Similar approaches have been employed in studies with SCC models (181,182). Besides gene transfer mediated by adenoviral vectors, an in vivo liposomal-mediated approach with tk and mIL-2, and a transgenic model constitutively expressing a costimulatory molecule, have been performed for treatment of SCC (19 and references therein). In addition, other genetic transfer approaches have been employed in MM models, such as genetically altered fibroblasts and the use of helper virus-dependent, HSV-1 amplicon vectors on human MM xenografts (19 and references therein, 183).

V. FUTURE PERSPECTIVES

With the identification and characterization of the genetic basis and molecular biology of inherited skin and systemic diseases, added to the multiple advantages of the skin as a target organ for gene transfer, we are in a better position in designing feasible strategies for gene therapy using cutaneous gene transfer approaches. During the last decade, we have seen the development of highly efficient cutaneous gene transfer systems, and better animal models for both inherited skin and systemic diseases. Although the general idea is to introduce wild-type gene products or destroy mutant gene products (including the mutant gene itself), the patient-specific nature of some of the diseases will still be challenging in a case-specific manner. Clearly, to apply these advances to human clinical trials, more efficient gene transfer methods with increased and prolonged levels of expression, high safety profile, low cost, and ease of administration must be developed. Nonetheless, the recent advance of model systems, epidermal stem cell techniques, and gene delivery efficiency highlight the promise for successful gene therapy of conditions using cutaneous gene transfer approaches.

Gene Therapy for Childhood Onset Blindness

Jean Bennett
University of Pennsylvania
Philadelphia, Pennsylvania, U.S.A.

I. BACKGROUND: GENE THERAPY AND LEBER CONGENITAL AMAUROSIS

In recent years, mutations in a large number of different genes have been implicated in the pathophysiology of retinal degenerative diseases (RetNet, http://www.sph.uth.tmc.edu/RetNet). Among these are mutations that lead to particularly severe early onset blinding disease. With the recent developments of methods for in vivo retinal gene delivery [reviewed by (5,7,12,15)], it has become possible to evaluate efficacy of gene therapy in animal models for particular forms of these blinding diseases. We selected a canine model for study of efficacy of gene therapy for one such disease, Leber congenital amaurosis (LCA). LCA is usually diagnosed in infancy as it severely disables its subjects, leaving them with minimal visual function and abnormal ocular movements (nystagmus). There are at least half a dozen genes that, when mutated, can lead to LCA (11,31). One of these, *RPE65*, named for the evolutionarily conserved retinal pigment epithelium (RPE)-specific 65-kDa protein that it encodes (4,28), accounts for approximately 7% to 16% of these cases (22,24,26). Mutations in *RPE65* can also lead to other severe and early onset blinding diseases, including retinitis pigmentosa (RP) (14,26,31,38).

II. RESULTS OF INITIAL STUDIES IN THE *RPE65* MUTANT DOG

A. A Canine Model for LCA: A Unique Resource

An advantage of selecting the *RPE65* gene defect for study is the availability of a large animal model for the LCA disease: the *RPE65* mutant dog. This animal suffers from an autosomal recessive inheritance of a retinal disease with severe visual deficits but a relatively slow degenerative component (2,27,41). A homozygous 4-bp deletion in the canine RPE65 coding sequence (2,39) is responsible for the phenotype in this animal. The deletion results in a frame shift leading to a premature stop codon. More than two-thirds of the wild-type polypeptide is eliminated due to this premature stop.

The exact function of the RPE65 protein is unknown, but it is known that this protein plays an important role in vitamin A metabolism (23,32,35). Without RPE65 protein, there is a deficiency of 11-cis retinal in the retina. This accounts for the abnormal qualitative and quantitative measures of visual function that are apparent early in life.

Examination of retinas of dogs who are homozygous for the defect reveals prominent RPE inclusions and slightly abnormal rod photoreceptor morphology present within the first year of life (41). There is also a lack of immunohistochemically detectable RPE65 protein (2). As the dogs age, a slowly progressive photoreceptor degeneration becomes apparent. Photoreceptor degenerative changes and loss are readily detectable in older (~5-year-old) dogs (41).

B. Proof of Principle of Gene Therapy for Retinal Degeneration

Efficacy of gene therapy for inherited retinal degeneration may be efficiently demonstrated studying animal models. Proof of principle for such treatments has been demonstrated using multiple strategies, multiple viral vectors, and several small animal models [reviewed by (5,7,12,15); also see (20,21,25,34,40)]. Successful strategies include delivery of wild-type cDNA in the case of loss-of-function disease (8,16,17,37,40), delivery of ribozymes that specifically target the mutant mRNA in the case of gain-of-function disease (19,18), delivery of neurotrophic factors (20,21,25), which

preserve the integrity of the photoreceptors, and delivery of genes with antiapoptotic function (9) in order to limit programmed cell death. Rescue has been achieved with a number of different vectors, including adenovirus, adeno-associated virus (AAV), lentivirus, and gutted adenovirus.

Clinical endpoints in many of these studies have involved electrophysiological evidence of improvement in retinal function as assessed by electroretinograms (ERGs). These can be recorded in noninvasive fashion. Because the diseases are usually bilaterally symmetrical, interpretation of results benefits from use of the contralateral eye as control. Results from retinal function testing have been supplemented with histological/immunohistochemical data obtained in terminal studies. In many of these paradigms, rescue has been detected for months after treatment. The studies involving the *RPE65* mutant dog have added additional outcome measures. These measures provide evidence that the brain of the treated animals can recognize that visual function has been restored (1).

C. Treatment Strategy Resulting in Rescue of Vision in *RPE65* Mutant Dog

The experimental objective was to deliver wildtype copies of the disease–causing gene (*RPE65*) to cell populations primarily affected by the gene mutation (i.e., the RPE). The minimum number of affected animals were used and analyses are described only for those animals in which 1 eye received an adequate control treatment. Affected dogs were identified through molecular diagnosis and by performing baseline ERGs (1).

Unilateral subretinal injections of the corrective gene (the canine RPE65-encoding cDNA) carried by AAV (AAV.RPE65) were performed, thereby exposing the diseased cells to the virus. The virus was prepared using the genome and capsid of AAV serotype 2 (AAV-2/2). Injections were performed when the animals were 4 months of age. A constitutive promoter (chicken beta actin) was used, and the amount of virus delivered was $1–5 \times 10^{10}$ infective units of AAV. Approximately 20% to 30% of the retina was exposed to virus. The contralateral eyes received control injections of intravitreal AAV.RPE65. Intravitreal delivery of AAV-2 results in gene delivery to the inner retina but not the outer retina/RPE (13).

The animals were followed over time with regular clinical evaluations/laboratory testing to evaluate local/systemic toxicity. Evaluations included fundus exams, monitering of weight gain/loss, complete blood count (CBC), and blood chemistries (including albumin, globulin, alkaline phosphatase, bilirubin, blood urea nitrogen, calcium, chloride, creatinine, gamma-glutamyl transpeptidase, glucose, phosphorus, potassium, alanine aminotransferase, and aspartate aminotransferase). In eyes that received subretinal injections, retinas reattached within 24 h. There was minimal inflammation immediately after surgery. Injected portions of the retina could be reliably identified based on ophthalmoscopically detectable pigmentary changes at the level of the RPE (1).

Animals appeared healthy and active after treatment. CBCs (total white blood cells, neutrophils, lymphocytes, monocytes, eosinophils, basophils, red blood cells, and platelets), red blood cell characteristics (hemoglobin, mean corpuscular volume, and hemoglobin levels), and blood chemistries were within normal limits throughout the course of the study (1).

Immune studies (including humoral and cell-mediated responses to the vector and/or to the transgene product) were also performed on sera and anterior chamber fluid samples. There was no evidence of cellular immune response to either AAV or the transgene product. Antibodies directed against AAV-2 capsid proteins increased after intraocular delivery of AAV in serum but not in anterior chamber fluid. Antibodies directed against transgenic protein (RPE65) increased after intraocular delivery of the AAV.RPE65 virus) in serum but not in anterior chamber fluid. Interestingly, there was evidence of preexisting anti-AAV capsid antibodies in serum samples as the baseline humoral response levels were elevated. This did not prevent transduction (1).

Visual function testing was performed 3 to 4 months after treatment and included ERGs, pupillometry, measurement of visual evoked cortical potentials (VECPs) and measures of visual behavior (1).

D. Efficacy of Gene Therapy in *RPE65* Mutant Dog

In the *RPE65* mutant dog, rod photoreceptor-specific ERG waveforms are essentially flat from birth on, even using high-intensity stimuli. Quantitative testing of retinal function using ERGs 3 to 4 months after treatment revealed waveforms similar to those present in wild-type dogs, although reduced in amplitude (1).

VECPs were recorded in order to determine whether there was evidence of cortical vision. There were definitive VECP waveforms in the *RPE65* mutant dogs after subretinal delivery of AAV.RPE65 (1).

There was evidence of visual behavior in treated *RPE65* mutant dogs soon after treatment. Those animals could navigate an obstacle course by 4 months after treatment using their experimentally treated eyes (1). The animals also demonstrated preferential gaze by the treated eye. Figure 1 illustrates this preferential gaze by showing the tracking pattern of a dog treated with the experimental reagent in the right eye. The dog follows the person walking around him with his right (treated) eye. The dog turns his head sharply, when the person is outside his right visual field, so that the person can continue to be visualized by the dog's right (seeing) eye.

III. FUTURE STUDIES

A. Challenges in Planning a Gene Therapy Clinical Trial for LCA

In the studies described above, AAV-2-mediated delivery of a wild-type version of the defective *RPE65* gene was used to provide retinal function in a canine model of severe early

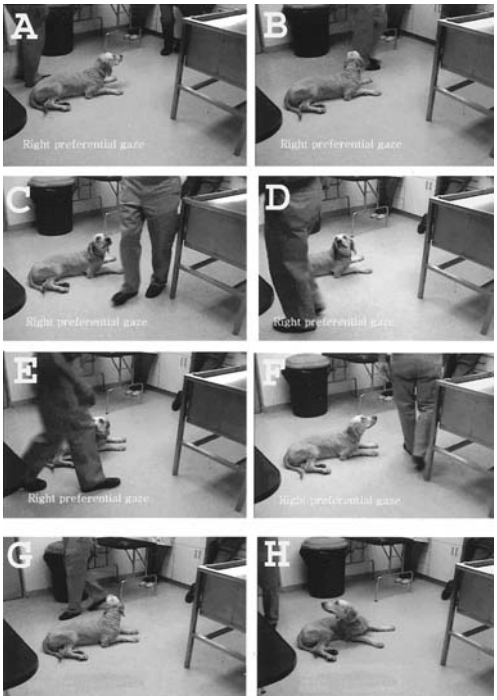

Figure 1 Frames in sequence from a video clip demonstrating right preferential gaze. Movie was filmed 9 months after subretinal delivery of AAV.RPE65 in the right eye in a mutant *RPE65* dog. The dog does not see the person when the person is behind him on his left (untreated) side (A). the dog follows the person walking around him with his right (treated) eye (B–H). When the person steps outside the visual field of the dog's right eye (H), the dog turns his head all the way to the right to visualize the person with his (seeing) eye.

onset retinal degeneration. There are many steps that must be taken before this treatment can be tested in humans with LCA. With the availability of both the canine and murine (*rpe65* knockout) (29,28) models for this disease, these steps can be taken using both animal models. The first and most important step is to establish safety of the treatment. Selection of regulatory elements that limit transgene expression to the target cells will minimize toxicity to other cells that might be exposed to the virus. Special attention must be paid to the possibility that the transgene could potentially be introduced to the brain via unwanted ganglion cell/optic nerve targeting (13).

The duration of the therapeutic effect should be characterized because LCA is a lifelong disease. The therapeutic window should be defined with respect to age of the animal/level of disease progression so that predictions can be made as to what the effects of treatment will be in younger and older humans with LCA.

The vector that provides the maximal therapeutic effect at minimum dose must then be selected. The recent demonstration that one can control cellular specificity, onset, and levels of transgene expression by packaging the AAV in capsids from AAVs of different serotypes may play a role in this process (3). Vector selection will be difficult. There is likely to be continued progress in developing viral vectors with slightly improved transduction qualities. At a certain point, a choice will have to be made: whether to select a particular vector as the candidate for formal toxicity studies (in anticipation of initiating a human clinical trial using this vector) or whether to perform additional efficacy tests on newly formulated vectors. The toxicity studies are rigorous, time-consuming, and expensive, and use a large number of animal subjects. It will be preferable not to have to repeat them using a second vector (unless the additional benefits of that vector warrant the effort). Once the ideal vector is selected, toxicity testing must be conducted to verify that the treatment does not cause any impairment to the eye or to the rest of the body. This must be performed using the same virus that is to be used in the proposed human clinical trial. Studies evaluating the possibility of readministration should also be performed with this vector in order to be able to predict whether it will be possible to treat the contralateral eyes of human patients at future timepoints.

B. Issues Regarding Future Patient Selection

While animal studies are in process, humans with LCA should be screened for their disease-causing mutations and individuals carrying homozygous/compound heterozygous *RPE65* disease-causing mutations should be identified. The typical progression pattern of the human disease (with respect to visual function measures and death of retinal cells) should be characterized. This will allow selection of the optimal noninvasive outcome measures for evaluation of effects of treatment in a human clinical trial. These outcome measures (likely measures of ERG/pupillometry response) will be quantitative and reproducible. One question that will arise is whether the first treatments, which will be phase I safety and toxicity tests, should be performed on adult vs. pediatric subjects. Also, an exit strategy should be planned if the results are unpleasant to the patient. Oliver Sacks describes, for example, the shock that a 55-year-old man had upon seeing for the first time since he was 6 years old, when he first opened his eyes after having had cataracts, present from childhood, removed (33). It should be emphasized, however, that the treatment will be deemed successful even if it is effective in a seemingly small way. If a patient can benefit from improved navigational skills that will expand his or her independence, this in itself will be a successful outcome. The ultimate goal will be, of course, to achieve vision that will allow the patient to lead as normal a life as possible.

C. Extrapolation of Success in Canine LCA Gene Therapy Studies to Other Forms of Early Onset Retinal Degeneration

A major challenge is how to extrapolate the successful treatment of the *RPE65* disease to treatment of other severe early

onset retinal degenerative diseases. One approach to meet this challenge is to identify the conditions that are responsible for the success of the *RPE65* dog study. Besides the virus delivery characteristics, there may be elements of the *RPE65*-caused disease that make it particularly amenable to treatment. Is the success due to the fact that the *RPE65* mutant retinal photoreceptors degenerate very slowly and thus there is a large therapeutic window during which the retina can be rescued? In some animal models (e.g., those with homozygous mutations in the beta subunit of rod cGMP phosphodiesterase) the degeneration is so rapid that rod photoreceptors do not even have a chance to fully differentiate before they are lost (10). In such diseases, it is likely that the treatment will have to be administered very early in life while the target cells are still viable (e.g., before postnatal day 10 in the rd1 mouse model of this disease) (8,17).

The AAV-2 vector may not have a rapid enough onset to make any impact in the disease progression of rapidly progressive degenerative diseases. One might want to employ a viral vector that results in a rapid onset of transgene expression. AAV-2 results in a slow (6–8-week) onset of transgene expression in the dog (6). In contrast, AAV-2 packaged with an AAV serotype 1 capsid (AAV-2/1) delivers transgenes that are expressed within a few days after injection in the mouse (3). If early administration with the optimal viral vector is not enough to achieve rescue, it may be possible to expand the therapeutic window by delivering the transgene at gestational timepoints. Recent progress in developing methods for in utero retinal gene transfer will expand these options (36). Finally, it will be desirable to test the rescue ability of the human *RPE65* cDNA (vs. the canine cDNA) in animal models before testing this cDNA in humans. The human *RPE65* cDNA was recently cloned and inserted into AAV vectors by N. Dejneka (personal communication; 2001) and promises to be useful in studies in both the *RPE65* mutant dog and the *rpe65-/-* mouse.

In particular diseases, there may be requirements of the disease model that will have to be met by developing alternative vectors/vector strategies. For example, one challenge is how to proceed with AAV if the cDNA and/or transgene cassette is too large to be packaged. The AAV cargo capacity is a maximum of 4.8 kb. In such a situation, one would have to consider other vectors that could carry the intact transgene cassette. Options include lentivirus, which can carry a cassette of $\sim$8 kb, and gutted adenovirus, which can carry a cassette of $>$30 kb. If one wanted to use AAV even though the transgene cassette was too large, one could harness the AAV dual vector approach and split the transgene construct into 2 complementary vectors, which would be trans-spliced in the target cell (30).

Another area that is likely to benefit from new technological developments is the ability to treat gain-of-function disease. Recent work involving gene correction strategies for both loss-of-function and gain-of-function disease and delivery of RNAi will likely be applied to animal models of early onset retinal degeneration using virus-mediated gene transfer.

IV. CONCLUSIONS

In summary, we have shown that efficacy of gene therapy for inherited retinal degeneration may be efficiently demonstrated studying animal models for the most clinically severe retinal degenerations (i.e., those that result in early onset blindness). AAV-2 was used to deliver corrective genes subretinally to a canine model of a severe retinal disease and efficacy of treatment was readily apparent. Success in this study may lead to identification of critical parameters for the success of gene therapy for early onset retinal degeneration and also to a human clinical trial designed to treat LCA.

I. IMPORTANCE OF VACCINES

A. Historical Importance of Vaccines

Vaccination is a deliberate introduction of materials in humans to elicit immune protection against diseases (1). For example, some Indian Buddhists drank snake venom to protect themselves from snake bites (1). During the 9th century in China, *The Correct Treatment of Small Pox* was written by a Buddhist nun. The manuscript recommended a mixture of ground dried smallpox scabs and herb to be blown into the nostrils of children. Even with such a long history, immunization was not widely used until Edward Jenner deliberately injected cowpox virus into humans to protect them from ravages of smallpox. Since that time, wide use of vaccines against pathogenic microorganisms has become the most important advance in the history of medicine. Vaccines have not only provided protection from smallpox, but also from poliomyelitis, measles, mumps, rubella, yellow fever, pertussis (whooping cough), hepatitis A, hepatitis B, and varicella, as well as others. These vaccines have dramatically reduced morbidity from infectious agents and have directly protected more human lives than all other avenues of modern medicine combined. Yet, as increased standards for effectiveness and safety and the increased costs of developing and manufacturing vaccines become more restrictive, the development of new vaccines has slowed. Furthermore, as new pathogens continue to emerge, it is important that novel methods for vaccine production be developed and tested to meet more demanding requirements of the 21st century.

B. Vaccine Immunology

Traditional vaccines have relied on either live-replicating or nonliving preparations of microorganisms. The injected material functions as a vaccine by generating immunity against the inoculum, and the resulting immune responses function to prevent disease. This type of induced immunity is referred to as protective immunity and results from the vaccine activating specific B and T lymphocytes, which composes the lymphocyte subsets of the white blood cells of the immune system (2).

As the major components of humoral immune response, B cells are lymphocytes that develop in the fetal liver and subsequently mature in the bone marrow. Mature B cells carry surface immunoglobulins that act as their antigen-specific receptors. They move from the bone marrow through the circulation to secondary lymphoid tissues, the lymph nodes, and the spleen, where they respond to antigenic stimuli by dividing and differentiating into plasma cells under direction of cytokines produced by T cells. When they are activated, B lymphocytes become terminally differentiated to become plasma cells, which are entirely devoted to the production of secreted antibody. Antibodies are large water-soluble serum proteins, which are induced following contact with antigen. Antibodies bind to specific antigen, which drive their expansion and either directly neutralize or inactivate them. Antibodies can also direct other cells of the immune system, such as macrophages and phagocytes, to dispose of the antigen. Furthermore, they can direct complement, highly toxic, soluble immune mediators to bind to and destroy an invading pathogen.

T cells are lymphocytes that develop in the thymus. T cells acquire their antigen receptors in the thymus and differentiate into a number of subpopulations that have separate functions and that can be recognized by their different cell surface markers. T lymphocytes develop as 1 of 2 subsets of white blood cells termed T helper cells and T cytotoxic or T killer cells in the thymus. These cells become the basis of cell-mediated immune responses and function to eradicate pathogens in different ways. T helper cells help and direct B cells to produce antibody, which target mostly extracellular pathogens. T helper cells also cooperate with cytotoxic T lymphocytes in the destruction of virally infected cells. Activated T helper cells secrete small protein messengers termed cytokines or lymphokines, which activate and expand either or both humoral and cellular immune responses. However, activated T cytotoxic cells seek out and destroy cells that have been infected with pathogens. These T killer cells bind and destroy allogeneic and virally infected cells, which display recognizable antigen-MHC class I molecules. T killer cells induce these pathogen-infected cells to die either through the release of toxic proteins such as granzyme B or through initiating apoptosis or programmed cell death in the target cells. CD8 + cells can also mobilize the immune response at the point of antigen contact through the release of beta chemokines. In addition to defense against pathogens, cytotoxic T lymphocytes (CTL) are particularly important in eradicating misbehaving host cells such as cancer cells. Humoral or cellular immunity can act independently or in concert to destroy the pathogenic organism within a vaccinated host.

C. Traditional Vaccines

In the case of live vaccines, the infectious material has been weakened or attenuated so that it no longer induces disease. In the case of the nonlive preparations, the vaccine material has been manufactured to contain killed organisms or pieces of killed organisms that cannot grow when inoculated into a host. In some instances, specific components can be purified away from other portions of the microorganism or artificially manufactured in the laboratory to function as a subunit vaccine. Both categories of vaccines are presently used throughout the world to protect individuals against specific pathogens. Each has its own general characteristics for generating immunity and exhibits properties that can be beneficial or deleterious to an individual.

Live attenuated vaccines, such as the polio and smallpox vaccines, stimulate protective immunity as they replicate in the body of an immunized host. These vaccines emulate the natural infection of pathogens and generate a broad spectrum of immune responses. Because they are a weakened form of the pathogen, no disease occurs. This category of vaccine induces broad protective immunity with induction of both antibodies and activated T cells. More specifically, because CTLs are only induced if an infectious agent or vaccine actually is produced within host cells, live attenuated vaccines are the most effective inducer of CTL. Attenuated vaccines have an additional benefit in that they provide lifelong immunity. In contrast, nonliving inactivated vaccines (including subunit preparations), such as the vaccine for hepatitis A virus, produce protective immunity that is limited to the generation of antibodies and helper T cells, but cannot induce killer T cells. Accordingly, the ability of these preparations to induce protection is limited to pathogens that can be destroyed by extracellular defenses. Unlike the live attenuated vaccines, the protective immunity induced by inactivated vaccines is normally short term and requires repeated booster injections to achieve lifetime immunity. Based on these immunological characteristics, live attenuated vaccines represent the vaccines of choice. Still, they are not without problems. For instance, there are many safety issues related to the use of live attenuated vaccines. The potential for the attenuated vaccine to mutate back to the original disease-causing organism through a process is called reversion. Attenuated vaccines may also cause disease when inoculated into persons with weak or compromised immune systems, such as cancer patients receiving chemotherapy or acquired immune deficiency syndrome (AIDS) patients, or in the elderly where the immune system deteriorates with age. Furthermore, live vaccines can infect individuals other than the inoculated individual and thus inadvertently expose a disease to a susceptible unknowing individual.

Even though inactivated vaccines are safer than their live attenuated counterparts, certain problems also exist with some inactivated vaccines. For instance, the whole organism used as the inactivated vaccine can be contaminated with components from cell culture that are not removed during the manufacturing process. This contaminated material may be important in autoimmune disease. Additional shortcomings with inactivated vaccines include contamination by components of the pathogen that are not important in the generation of protective immunity. These components may generate immune responses that are not relevant to protective immunity. Deleterious reactions, such as inflammation and allergic reactions, may also result from vaccination with the inactivated whole organism. These concerns regarding contaminants and the safety issues related to whole organism vaccines point to the use of purified subunit component vaccines.

In these subunit vaccines, only the components of the microorganism involved in conferring protective immunity are included, whereas other portions of the microorganism are removed in an extensive purification process. This increases the cost of manufacturing the vaccine to improve its safety. Subunit component vaccines have an increased specificity that can target the immune response in a very effective manner; again these vaccines elicit protective immunity by the generation of antibodies and limited T helper responses. However, if antibodies alone are insufficient to provide protective immunity against a particular pathogen, it becomes necessary to also involve the activated T lymphocyte component of the immune response. As a need for vaccines against new pathogens emerges, safe vaccines that elicit both antibodies and activated T cells will have an advantage, particularly when the requirements for protective immunity in the host are not yet unknown. It would be a distinct advantage for vaccine development to have a technology that could induce the broad

immunity normally associated with a live attenuated vaccine, while exhibiting the safety and the focus of the subunit preparations. In addition, any simplification in manufacturing and increase in stability is likely to positively impact vaccine development for the developing world.

II. DNA VACCINES

A. Concepts of DNA Vaccines

Recent work from a number of laboratories has demonstrated that the injection of a DNA plasmid containing foreign genes for proteins of a pathogen or cancer antigens directly into a host results in the subsequent expression of the foreign gene in that host and the presentation of the specific encoded proteins to the immune system (Fig. 1). DNA vaccine constructs are produced as small circular vehicles or plasmids. These plasmids are constructed with a promoter site that starts the transcription process, an antigenic DNA sequence, and a messenger RNA stop site containing the poly A tract necessary for conversion of the messenger RNA sequence into the antigen protein by the ribosomal protein manufacturing machinery (Fig. 2). The concept of genetic immunization provides that both DNA and RNA that encode specific proteins can be used to generate specific immune responses. Because DNA and RNA are both nucleic acids, the term nucleic acid vaccine has also been used to describe this process.

B. History of DNA Inoculation

The ability of genetic material to deliver genes for therapeutic purposes and its use in gene therapy has been appreciated for some time. Early experiments describing DNA inoculation into living cells were DNA transfer experiments performed by a number of investigators in the 1950s and 1960s (3–5). These reports describe the ability of DNA preparations isolated from tumors or viral infections to induce tumors or virus infection following injection into animals. Importantly, many such inoculated animals developed antibody responses to the proteins encoded within the injected DNA sequences. Over the next 20 years, a number of scattered reports focusing on gene function or gene therapy techniques provided evidence that injection of viral DNA or plasmids containing foreign gene resulted in antibody production and was related to the DNA inoculations. In 1985, Dobensky reported that plasmids containing insulin DNA sequences could produce insulin following inoculation into a living animal for some period of time. Longer-term expression of foreign genes was described in 1990 by Wolff and colleagues following plasmid inoculation in vivo (6). These 2 separate observations demonstrated that DNA in the absence of vectors could deliver proteins that might have biological relevance. Although both studies focused on the use of this technology for gene replacement strategies, other studies were already underway in several laboratories using this same technology for vaccine applications.

In 1992, Johnston and colleagues at the Southwest Foundation reported that injection of DNA encoding human growth hormone into mice resulted in transient hormone production followed by the development of antibodies in the inoculated animals specific for the human growth hormone gene (7). This important work used a ''genetic gun'' or gene gun to shoot gold particles covered with DNA through the skin layers of mice. Although these investigators were actually studying the use of this technology for a gene therapy replacement strategy, they described this development of antibody responses due to this unusual immunization procedure as genetic immunization. Simultaneously with the publication by Johnston and colleagues, a vaccine meeting held at the Cold Spring Harbor Laboratory, Long Island, New York, in September 1992, described the use of DNA immunization to generate humoral and cellular immune responses against a human pathogen, as well as protection from both tumors and viral challenges in animal systems.

Investigators from Merck and Vical reported on the development of immune responses to intramuscular injected plasmid encoding pathogen proteins. They observed that both antibody responses as well as CTL responses were induced to influenza viral gene products by this immunization technique. Furthermore, vaccinated mice were able to resist lethal viral challenge. Harriet Robinson and her colleagues at the University of Massachusetts reported on the use of the gene gun to deliver influenza virus genes in DNA plasmids, indicating that both antibody and T lymphocyte responses were produced in vaccinated mice and in chickens. In challenge studies, these responses were protective. The use of the gene gun allowed investigators to deliver very low nanogram amounts of DNA at the site of injection and still observe immune responses. David Weiner and his colleagues at the University of Pennsylvania reported the direct injection of DNA encoding the genes for the human immunodeficiency virus (HIV). Again both antibodies and T lymphocyte responses specific for the viral gene products were observed in experimental animals. As HIV does not infect mice, an in vivo mouse model was used where tumor cells, which are normally lethal to the mice, were constructed to express HIV proteins. Animals who were vaccinated with the HIV DNA vaccine were demonstrated to be immune to these HIV antigen-expressing tumor cells. Although the audience was skeptical of the ability of nonliving genetic material to produce useful immune responses, the large amount of data presented by each of these groups representing several years of successful work in diverse systems could no longer be ignored by the scientific and vaccine community. DNA vaccines were officially born.

Following these initial reports, DNA vaccination and the generation of antibody and T lymphocyte responses, as well as protective responses in a variety of animal models, have been reported in the scientific literature for many human pathogens such as hepatitis B virus, rabies virus, herpes simplex virus, hepatitis C virus, human T cell leukemia virus, human papilloma virus, and tuberculosis (8–10).

C. Potential Advantages of DNA Vaccines

As summarized in Table 1, nucleic acid immunization may afford several potential advantages over traditional vaccina-

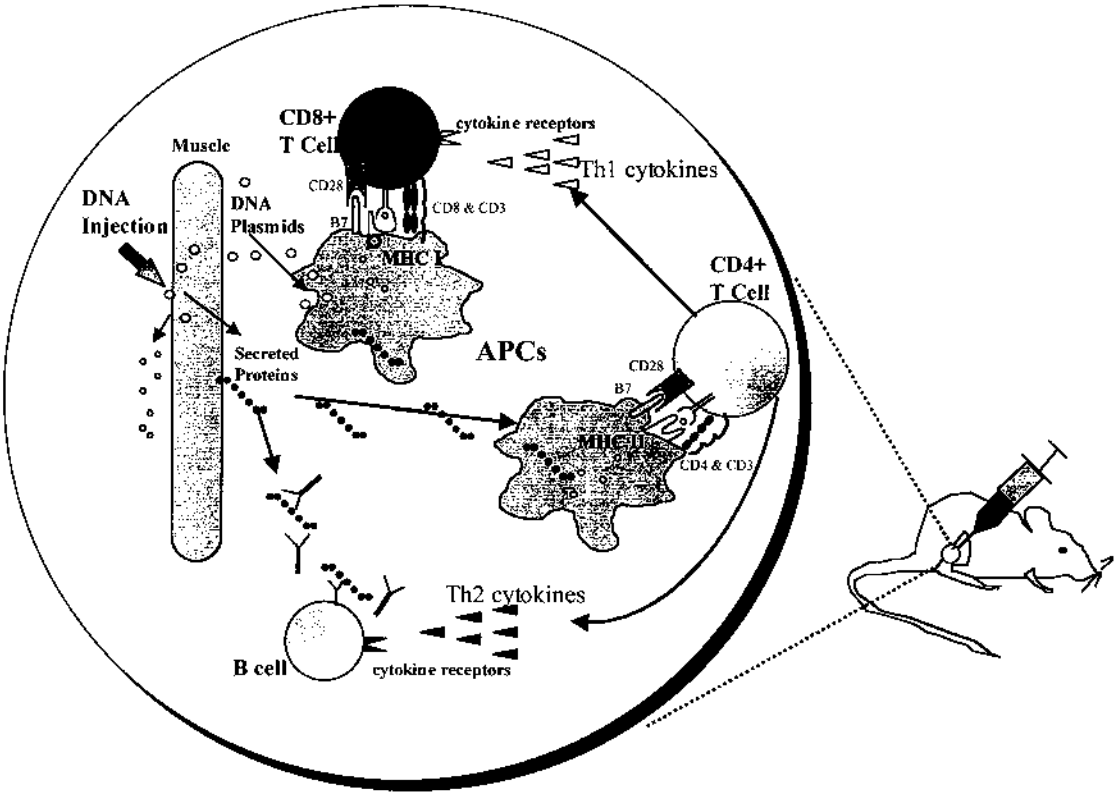

Figure 1 Induction of antigen-specific humoral and cellular immune responses following DNA immunization.

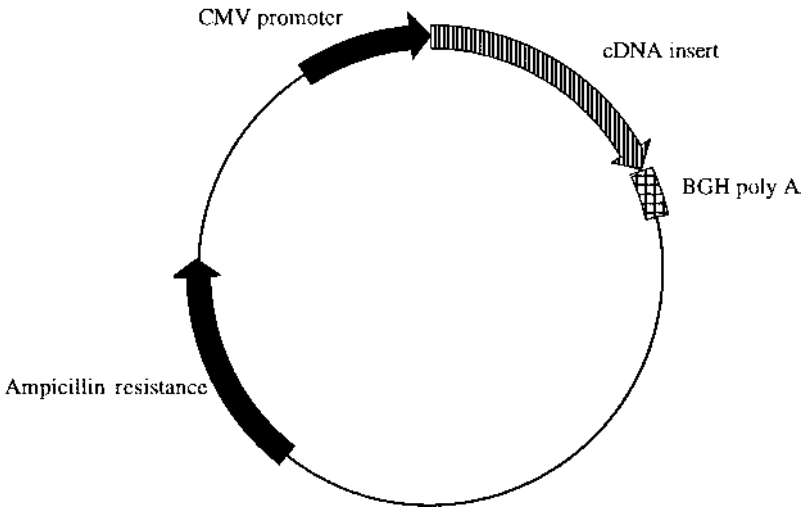

Figure 2 A diagram of a DNA vaccine construct consisting of a mammalian expression vector. The plasmids are constructed with a promoter, an antigenic DNA sequence, and a messenger RNA stop site containing the poly A tract.

Table 1 Summary of Immune Modulation by Molecular Adjuvants

	Molecular adjuvant	Immune modulation		
		Ab	Th	CTL
Proinflammatory cytokines	TNF-a	+++	++++	++++
	TNF-b	+	+	+
	IL-1a	+++	++	+/−
Th1 cytokines	IL-2	+++	++++	+
	IL-12	−	++++	++++
	IL-15	++	++	++++
	IL-18	+++	++++	++
Th2 cytokines	IL-4	++++	+	+/−
	IL-5	++++	++	+/−
	IL-10	++++	+++	+/−
Hematopoeitic cytokines	G-CSF	+	++	+
	GM-CSF	++++	++++	+
	M-CSF	++	+	++++
Chemokines	IL-8	+++	++++	+/−
	MIP-1a	++++	++	+/−
	RANTES	+	++++	++++
	MCP-1	+/−	+	++++
Costimulatory molecules	CD80	+/−	+	+/−
	CD86	+/−	++++	++++
	CD40	+/−	++++	++++
	CD40L	+/−	+	+

tion strategies, such as whole killed or live attenuated virus and recombinant protein-based vaccines, without specific shortcomings and inherent risks associated these vaccination methods. Like inactivated or subunit vaccines, DNA vaccines appear conceptually safe because they are nonreplicating and nonlive. In contrast to inactivated or subunit vaccine, DNA vaccine cassettes produce immunological responses that are more similar to live vaccine preparations. By directly introducing DNA into the host cell, the host cell is essentially directed to produce the antigenic protein, mimicking viral replication or tumor cell marker presentation in the host. Unlike a live attenuated vaccine, conceptually there is little risk from reversion to a disease-causing pathogen from the injected DNA, and there is no risk for secondary infection as the material injected is not living and not infectious. Furthermore, multicomponent DNA vaccines can be engineered to include specific immunogens, which could optimize and amplify desirable immunological responses. Perhaps this ability to target multiple antigenic components may be a particularly important characteristic of DNA vaccines because multicomponent DNA vaccines can be engineered to include specific immunogens that could optimize and amplify desirable immunological responses.

D. Mechanism of DNA Vaccines

The exact mechanism for DNA immunization has been a center of major debate (11–13), but is likely to be similar to traditional antigen presentation. In the body's immune system, cells need to process and present antigenic peptides to lymphocytes in order to stimulate antigen-specific immune response. Thus, antigen must be processed and presented to T lymphocytes by antigen-presenting cells (APCs) (14). Antigen presentation and recognition is a complex biological process that involves many interactions between antigen-presenting cells and T cells (Fig. 3). There are 4 primary components that are critical in the professional APC's ability to present the antigen to T cells and activate them for appropriate immune responses. These components are major his to compatibility complex [MHC]–antigen complexes, costimulatory molecules (primarily CD80 and CD86), intracellular adhesion molecules, and soluble cytokines. Naive T cells circulate through the body across lymph nodes and secondary lymphoid organs such as the spleen. Their migration is mediated among other factors by intercellular adhesion molecules and cytokines. As the T cells travel, they bind to and dissociate from various APCs. This action is mediated through adhesion molecules. When a naive T cell binds to an APC-expressing relevant MHC/peptide complex, the T cell expresses high levels of high-affinity IL-2 receptor. Only when this T cell receives a costimulatory signal through CD80/CD86–CD28 interaction does the T cell make soluble IL-2, which then binds to the receptors and drives the now-armed effector T cell to activate and proliferate.

Antigen is expressed at significant levels in muscle, following intramuscular inoculation of plasmid DNA (6). Using reporter gene injections in mice, various investigators have reported the detection of gene expression after intramuscular (IM) injection of DNA expression cassettes (6). Protein expression was detected in the quadriceps muscle of mice after injecting plasmid vectors encoding chloramphenicol acetyltransferase, luciferase, and β-galactosidase reporter genes into the muscle.

Muscle cells have several structural and functional features that seem to make them well suited for DNA uptake in vivo (15). Muscle consists of multinucleated contractile muscle fibers with cylindrical shape and tapered ends. These muscle fibers have mycogenic stem cells attached to them. When the muscle fibers are damaged or stressed, the stem cells are activated. The resulting myoblasts proliferate and eventually fuse to form new muscle fibers. It is believed that this continual activation and proliferation of the myoblasts allow a more opportunistic uptake of injected DNA. Because it has been shown that the uptake of the injected DNA and the subsequent production of protein occurs in muscle cells, they have been proposed as a potential site of antigen processing and presentation. However, the myocytes, which make up the muscle tissues, do not express CD80 or CD86 costimulatory molecules needed for efficient presentation, although a new study has identified an additional costimulatory molecule distinct from CD80 or CD86, which can be expressed in muscle cells (16). The question of ability of muscle cells to provide costimulatory signals drives the current debate in the literature about the mechanism of antigen presentation following intramuscular DNA immunization.

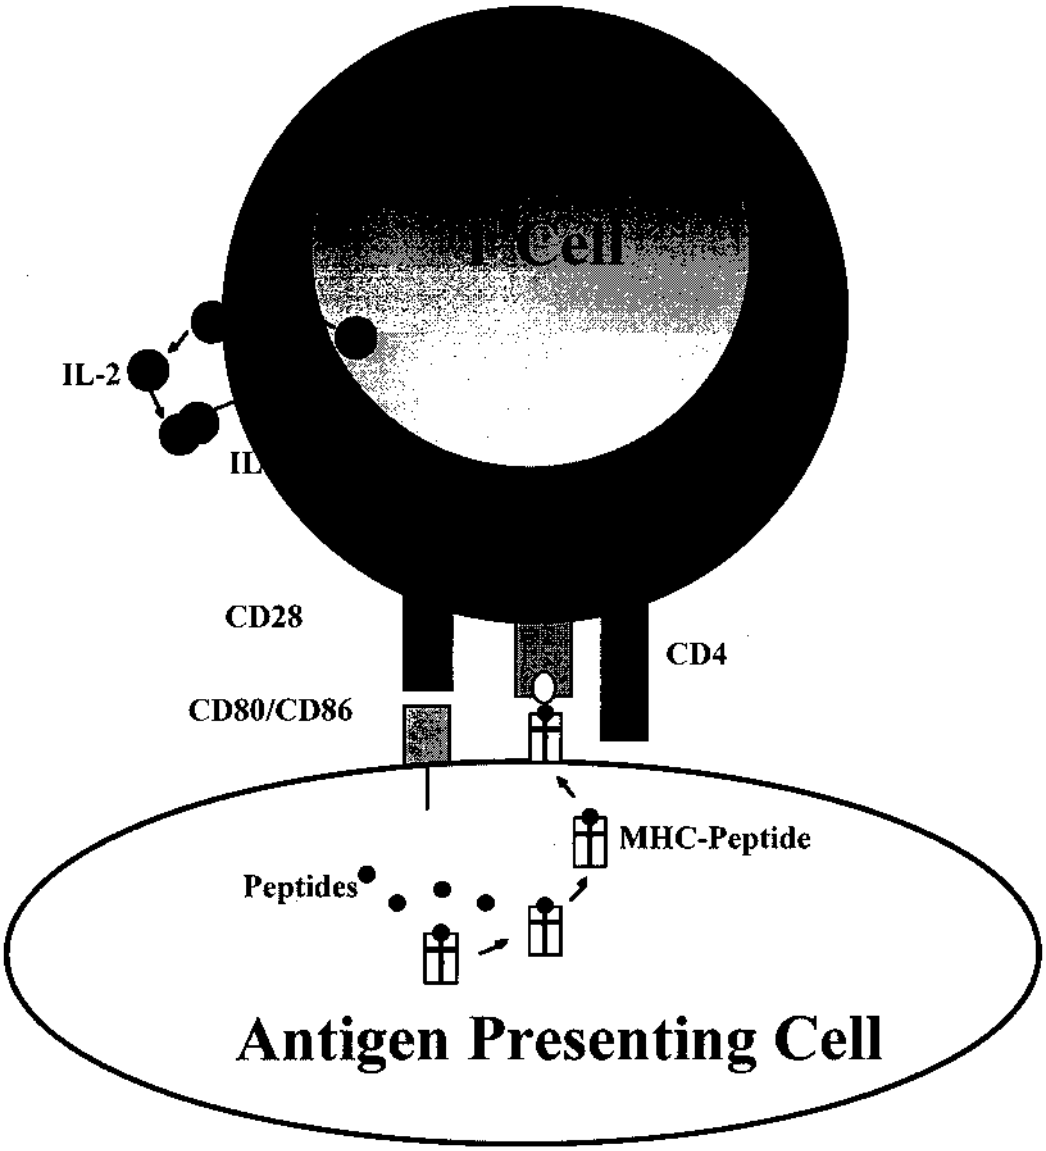

Figure 3 Effective T cell activation by APC. The interaction between antigen-MHC and T cell receptor leads to the expression of IL-2 receptor. This T cell proliferates when the second signal is provided from APC's costimulatory proteins. CD28-CD80/CD86 ligation initiates the production of IL-2 production and leads to the proliferation of activated T cell.

One potential mechanism is that the antigens produced in muscle are secreted from transfected muscle cells or released due to cell apoptosis (11,12). Such exogenous antigen could then be taken up by professional APCs in the draining lymph nodes, where the antigen is processed via the MHC class I pathway of these cells. Then, these APCs are hypothesized to present the processed peptides to T cells. Recently, there have been reports that indicate that immune system has an inherent mechanism by which exogenous antigens access MHC class I molecules. One recent report identified dendritic cells as the potent mediator of such presentation antigen derived from phagocytosed apoptotic cells (17). Immature dendritic cells engulf apoptotic cells and cross-present antigen from these sources to induce class I-restricted CTLs.

Another possible mechanism is the direct transfection of professional APCs by the injected DNA. Such a mechanism may be more probable in intradermal delivery of DNA because skin is rich in professional antigen-presenting cells, especially the dendritic cells. Condon et al. reported that through DNA immunization into skin, they were able to show expres-

sion of proteins encoded by DNA plasmids (18). However, such a mechanism is less likely within the muscle tissue, where there is significantly less presence of APCs. More recently, studies have reported that direct transfection of dendritic cells can occur following intramuscular inoculation DNA vaccine constructs, albeit at a lower level (19). Another study indicates that macrophages and dendritic cells may be a target cell for DNA transfected in vivo and that such a target might be important in driving immune responses in vivo (20). A clear understanding of the role of antigen-presenting cells in DNA vaccination could have important implications for this technology.

III. DNA VACCINES FOR INFECTIOUS DISEASES AND CANCER

A. DNA Vaccines Against HIV-1

The human immunodeficiency virus-1 (HIV-1) is a retrovirus, which preferentially infects and kills CD4+ T cells and macrophages, ultimately resulting in immune system failure and multipathogen infections. Recent breakthroughs in combination therapy using 3 or more different antiretroviral agents have generated optimism regarding the ability to control viral replication in vivo (21). However, this therapeutic regimen is costly, and it is too early to tell whether this approach can eradicate established infection (21,22). The costs and the stringent administration regimen requirements of these pharmaceutical agents make it clear that these drugs will only be effectively used in a limited part of the world population. Therefore, to address the worldwide problem of HIV-1 infection, there remains a need for a prophylactic vaccination strategy designed to control the epidemic through mass immunization campaigns (23).

One of the major obstacles in the development of a vaccine against HIV-1 is uncertainty regarding the exact immune correlates of protection (24). In studies of long-term nonprogressor groups of HIV-infected individuals, evidence supports the notion that correlates of protection against HIV-1 could be provided by humoral, cellular, or even both arms of the immune response (25,26). High levels of type-specific neutralizing antibody have been observed in protected primates in some homologous challenge models (27–31). Neutralizing antibodies are susceptible to viral deception through antigenic diversity of HIV-1 envelope, and the ability of neutralizing antibody to prevent viral pathogenesis is still under considerable investigation (32–35).

One of the hallmarks of HIV-1 disease progression is the loss of cellular immune function, and the presence of strong cellular responses in some instances can correlate with control of viral replication (9,36). In cases of acute HIV-1 infection studied by several investigators, viral clearance was associated with specific CTL activity in each case (37,38). In addition, a subset (7 of 20) of occupationally exposed health care workers who were not infected possessed transient HIV-1-specific CTL response (39). HIV-1-specific CTLs were also found in a number of chronically exposed sex workers in Gambia who continue to resist infection with HIV-1 (40). In spite of these studies supporting the role of neutralizing antibodies and CTLs in conferring immunity to infection, some vaccinated primates exhibiting both neutralizing antibody and CTL responses were not protected from subsequent viral challenge in the pathogenic SIV model (41). Recently, the important role of CD4 helper responses in the anti-HIV immune response has been highlighted (42). Such responses likely have importance for both humoral and CD8+ effector responses.

The advantages of nucleic acid immunization listed above make it well suited as a potentially useful vaccination strategy against HIV-1. Within the HIV genome, there are several potential immunological targets for DNA vaccination (Fig. 4). The HIV-1 genome is organized into 3 major structural and enzymatic genes, 2 regulatory genes, and 4 accessory genes (43). The first major gene target is *env*, which codes for the outer viral envelope proteins. HIV enters the CD4+ cells via envelope–CD4 receptor complex. Following entry of HIV viral core, synthesis of a double-stranded DNA version of the HIV genome (called DNA provirus) begins by the viral DNA polymerase, reverse transcriptase (RT). The DNA provirus is then translocated to the nucleus as part of the protein–DNA preintegration complex and is integrated into the host cell genome with the help of the viral integrase (Int) enzyme. The provirus then replicates with the host DNA each time the cell divides. The gene *gag* codes for the core protein, and *pol* codes for the enzymatic proteins RT, Int, and protease (Pro). In general, these enzymatic proteins remain somewhat conserved and preserve their catalytic functions. Accordingly, these proteins may be less divergent immune targets than envelope proteins for CTL-mediated responses (44).

The regulatory genes *tat* and *rev* affect HIV-1 gene expression. Viral transcription is increased several hundred-fold by tat transactivation (45), making it an obvious target for therapeutic intervention. The rev protein increases the release of unspliced structural RNAs from the nucleus by displacing host splicing factors that otherwise prevent RNA transport from the nucleus to the cytoplasm (46). In addition, rev is a critical component in the production of the structural proteins of HIV-1. A report of a DNA vaccine study in humans shows the immunogenicity of the *rev* gene product, again supporting its importance as a vaccine target (47). In addition, a *Tat* DNA vaccine has been reported to influence SHIV viral challenge in a macaque model system, while human immune response against HIV infection includes *Vpr* as a target (48,49). However, studies with *Vpr* as a plasmid vaccine component report that its presence can negatively influence the resulting host immune response (50,51). Therefore, this target requires more study before being included as part of a plasmid vaccine cocktail. Nonetheless, further work on these targets could be important as they and Nef are the earliest HIV antigens expressed. Targeting these antigens may give the immune system early warning of HIV challenge.

In addition to the regulatory genes, HIV-1 carries an additional set of accessory genes, *vif* (virion infectivity factor), *vpr* (viral protein r), *vpu* (viral protein u), and *nef* (negative factor), which are potential targets for DNA immunization.

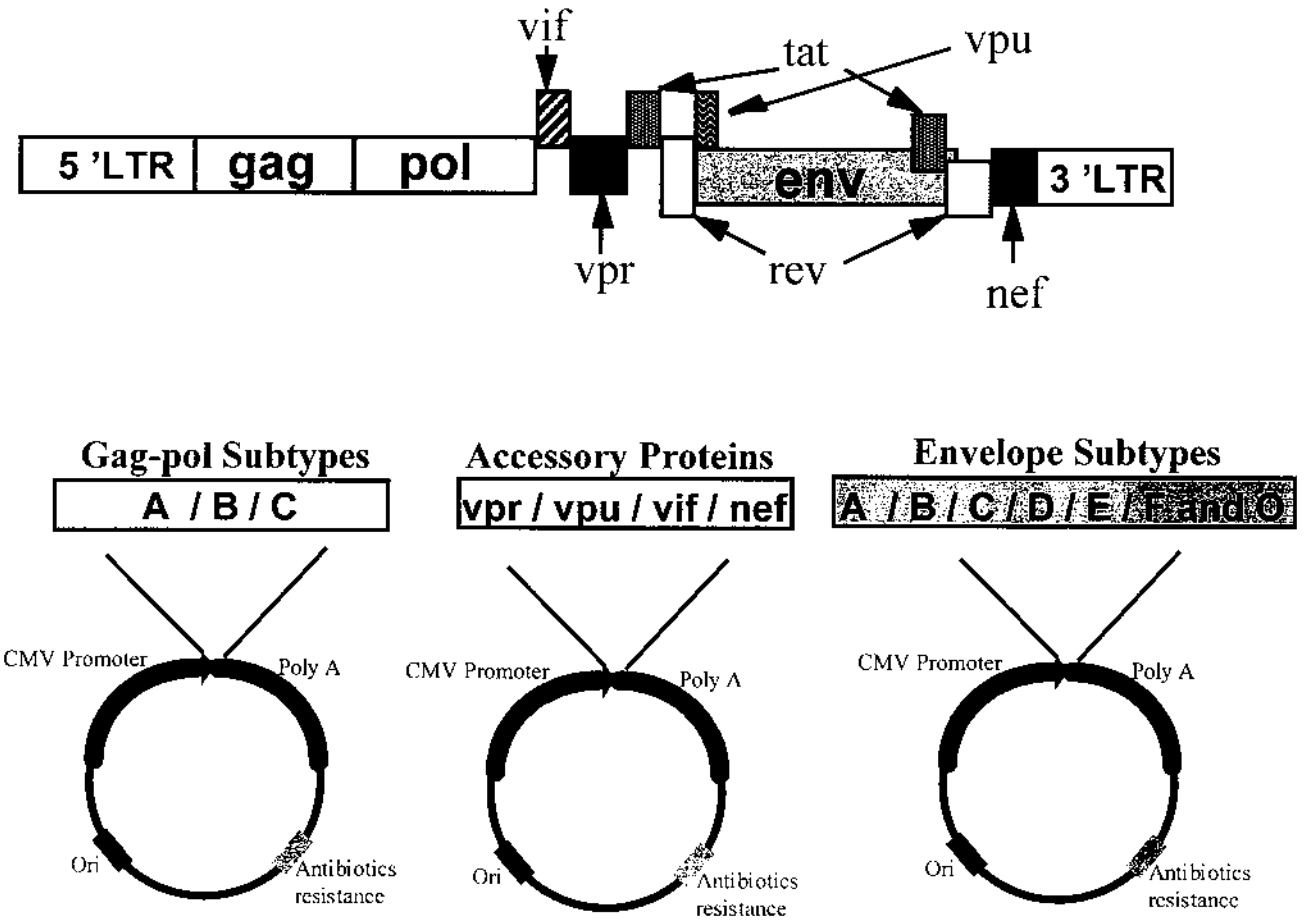

Figure 4 Potential immunological targets for DNA vaccination against HIV-1. These targets include *env*, *gag*, and *pol* genes, as well as the 4 accessory genes.

These accessory genes can be deleted from the viral genome without eliminating replication in vitro, suggesting that these gene products play a secondary rather than primary role in viral infection. The vif protein is located in the plasma membrane and may be important for production of infectious virions (52). In contrast to vif, vpu seems to facilitate the degradation of intracellular CD4 molecules (52). The vpr protein is found in the viral particle in high amounts and appears to have several biological activities, including the ability to increase viral transcription and to reactivate virus from cellular latency and arrest host cell division (53–55). Nef has never been critical for viral infection of cell lines in vitro (56), although experiments performed with the related simian immunodeficiency virus (SIV) found that rhesus macaques infected with virus having a deletion in *nef* had dramatically lower levels of viral replication (57). In addition, recent evidence suggests that *Nef* plays a crucial role in mediating bystander apoptosis through the upregulation of FasL expression on infected T cells (58). Accordingly, *Nef* expression in T cells also suppresses cell death by blocking ASK1-mediated cell death and by inducing signals that phosphorylate BAD (59,60). Developing DNA vaccine constructs directed against these accessory genes could provide additional arsenal in our battle against HIV-1.

DNA expression cassettes encoding for HIV-1 envelopes (strains HXB2, -MN, and -Z6) were among the first to be analyzed for immunogenicity (Fig. 4) (61). Initial studies demonstrated that mice immunized with envelope constructs produced antibodies specific to recombinant gp160, gp120, and gp41 proteins. The antisera neutralized HIV-1 isolates in vitro at a low level (62). Neutralization of homologous isolates has also been reported after immunization with constructs based on the HIV-1 NL4-3 isolate in the presence of relatively low antienvelope IgG titers (63). Moreover, the pM160-MN construct not only demonstrated neutralization of homologous isolates but also showed lower, yet measurable neutralization of the heterologous HIV-1 Z6 isolate (62). In addition to the humoral responses, cellular immune responses were observed from envelope inoculated mice. Induction of T helper cell

proliferative response against recombinant gp120 protein was observed (61). In addition, cytotoxic T lymphocyte responses have been observed against both targets infected with recombinant vaccinia-expressing envelope protein and targets prepared with envelope peptides (61,63,64).

In contrast to the high level of sequence divergence observed in the envelope glycoproteins of HIV-1, their *gag* and *pol* gene sequences appear to be less variable immunological targets. Thus, combining env constructs with gag/pol constructs could result in a more potent vaccination program. Expression cassettes encoding for both gag and pol elicited antigen-specific antibody, Th, and CTL responses (65). In addition to the DNA immunogen cassettes encoding env and gag/pol proteins, the DNA expression cassettes targeting nef and vif accessory proteins have been developed, and they have been shown to induce both antigen-specific humoral and cellular responses in mice (66,67).

For HIV plasmid vaccines, the issue of *rev* independence has appeared as a recent important issue. The structural genes of HIV are made as long unspliced transcripts that contain overlapping reading frames with the small regulatory genes of HIV *tat* and *rev*. These transcripts are retained in the nucleus and rapidly spliced to encode the small regulatory in the absence of *rev*, thus preventing the transport of full-length message to the ER where structural gene translation can occur. The messages are inhibited from transport to the ER by both known and cryptic *rev*-dependent sequences. In view of this, recent studies suggest that optimization of codons to the usage of highly expressed human genes, as well as deletion of residual inhibitory sequences, significantly enhanced Gag expression leading to potent augmentation of immune responses (68,69). In addition, a recent study suggested that alteration of AT-rich regions without changing the amino acid sequences can significantly enhance Gag expression through *rev*-independent mechanisms. These modifications led to enhanced Gag-specific immune responses, indicating that codon optimization may provide new avenues for enhancing vaccine potencies (70).

B. DNA Vaccines Against Other Viruses

In addition to HIV-1, there is a growing list of DNA vaccines targeted against other viral pathogens. One of its central attractions is its flexibility in modulating immune responses. As a consequence, several vaccine cocktails have been created that specifically target highly immunogenic antigens, which result in potent antiviral immune responses.

The West Nile virus (WNV) is a vectorborne pathogen that induces brain inflammation and death in endemic regions. Recently, confirmed cases of infection and death have been reported in the Mid-Atlantic region of the United States. Because there is no specific therapy for the WNV infection at this moment, there is an increasing demand for the development of vaccine strategies to prevent disease from this virus. Currently, no human or veterinary vaccine is available to prevent WNV infection, and mosquito control is the only practical strategy to combat the spread of disease. Several vaccine companies, including Acambis, Inc., and Baxter/immuno, have research and development programs on human vaccines (71). One major veterinary vaccine manufacturer (Ft. Dodge) is also developing formalin-inactivated and naked DNA vaccines.

A group from the Centers for Disease Control and Prevention has reported on the induction of protective immunity using a DNA vaccine that expressed the WNV prM and E proteins (72). In addition, as an extension of the multicomponent DNA vaccines strategy, a DNA vaccine expressing the WNV capsid (Cp) protein has been shown to induce immune responses in DNA vaccine-immunized mice (73). Collectively, these results support the potential utility of DNA vaccines as a tool for developing immunization strategies for WNV and other emerging pathogens.

Some of the earliest DNA vaccines were against influenza. In fact, the initial report by Ulmer et al. targeted the nucleoprotein as an antigen and effectively generated CTLs to achieve protection against subsequent challenge with a heterologous strain of influenza A virus (74). Protection was also achieved through immunization against the hemagglutinin antigen (75). Interestingly, cross-protection of variant viral strains was also achieved in both mice and preclinical studies (76,77).

Other exciting prospects for DNA vaccines against viruses include complete protection against measles in a macaque model. Surprisingly, protection correlated with the generation of neutralizing antibodies rather than cytotoxic T cell induction (78).

Finally with the advent of recent bioterrorism scares, much interest has focused on the development of rapid mass stocks of vaccines to immunize the general public (79). In view of this, DNA vaccines' simplicity and ease of mass production effectively overcomes such obstacles. In addition, plasmid immunization against the protective antigen and lethal factor of anthrax effectively induced complete protection in preliminary mice experiments (80,81). Similar results were also achieved against the Ebola virus in both mice and primate experiments (82). These preliminary results highlight the potential efficacy of DNA vaccines for generating mass immunizations against potential bioterroristic weapons.

C. DNA Vaccines for Cancer

Although advances in science have led to countless theories and methods designed to combat human carcinoma, the battle is far from over. Surgical excision of tumors, drug therapies, and chemotherapy have been effective in certain cases but in other situations, particularly when the tumor has begun to metastasize, effective treatment is far more difficult and far less potent. Thus, researchers are continually investigating novel and more effective treatment strategies for various forms of cancer. Research, in recent years, has turned toward the use of vaccines to treat cancer. To this end, several proteins produced by tumor cells became a target for vaccine development. These tumor-associated antigens are predominantly expressed in a tissue-specific manner and are expressed at greatly increased levels in affected cells. Besides being impor-

tant diagnostic aids, these antigens represent appropriate targets for the development of cancer vaccines (83).

Tumor-associated antigens (TAAs) are proteins produced by tumor cells that can be presented on the cell surface in the context of major histocompatibility complexes (84). Recently, these antigens have been the focus of study as a viable option for immunotherapy of various types of cancer. In this chapter, we examine the progress in the investigation of the immunological effects of 3 such TAAs, carcinoembryonic antigen (CEA), prostate-specific antigen (PSA), and human papillomavirus (HPV) type 16 E7 antigen.

D. DNA Vaccines Against Colon Cancer

Human CEA is a 180-kDa glycoprotein expressed in elevated levels in 90% of gastrointestinal malignancies, including colon, rectal, stomach, and pancreatic tumors, 70% of lung cancers, and 50% of breast cancers (84,85). CEA is also found in human fetal digestive organ tissue, hence the name carcinoembryonic antigen (86). It has been discovered that CEA is expressed in normal adult colon epithelium as well, albeit at far lower levels (87,88). Sequencing of CEA shows that it is associated with the human immunoglobulin gene superfamily and that it may be involved in the metastasizing of tumor cells (86).

The immune response to nucleic acid vaccination using a CEA DNA construct was characterized in a murine model. The CEA insert was cloned into a vector containing the cytomegalovirus (CMV) early promoter/enhancer and injected intramuscularly. CEA-specific humoral and cellular responses were detected in the immunized mice. These responses were comparable to the immune response generated by rV-CEA (87). The CEA DNA vaccine was also characterized in a canine model, where sera obtained from dogs injected intramuscularly with the construct demonstrated an increase in antibody levels (89). Cellular immune responses quantified using the lymphoblast transformation assay also revealed proliferation of CEA-specific lymphocytes. Therefore, a CEA nucleic acid vaccine was able to induce both arms of the immune responses (89). CEA DNA vaccines are currently being investigated in humans.

E. DNA Vaccines Against Prostate Cancer

Prostate cancer is the most common form of cancer and the second most common cause of cancer-related death in American men (90). The appearance of prostate cancer is much more common in men over the age of 50 (91). Three of the most widely used treatments are surgical excision of the prostate and seminal vesicles, external bean irradiation, and androgen deprivation. However, conventional therapies lose their efficacy once the tumor has metastasized, which is the case in more than half of initial diagnoses (92,93).

PSA is a serine protease and a human glandular kallikrein gene product of 240 amino acids, which is secreted by both normal and transformed epithelial cells of the prostate gland (94,95). Because cancer cells secrete much higher levels of the antigen, PSA level is a particularly reliable and effective diagnostic indicator of the presence of prostate cancer (96). PSA is also found in normal prostate epithelial tissue and its expression is highly specific (97).

The immune responses induced by a DNA vaccine encoding for human PSA has been investigated in a murine model (97). The vaccine construct was constructed by cloning a gene for PSA into expression vectors under control of a CMV promoter. Following the injection of the PSA DNA construct (pCPSA), various assays were performed to measure both the humoral and cellular immune responses of the mice. PSA-specific immune responses induced in vivo by immunization were characterized by enzyme-linked immunosorbent assay (ELISA), T helper proliferation CTL, and flow cytometry assays. Strong and persistent antibody responses were observed against PSA for at least 180 days following immunization. In addition, a significant T helper cell proliferation was observed against PSA protein. Immunization with pCPSA also induced MHC class I CD8+ T cell-restricted CTL response against tumor cell targets expressing PSA. The induction of PSA-specific humoral and cellular immune responses following injection with pCPSA was also observed in rhesus macaques (98).

F. DNA Vaccines Against Cervical Cancer

HPV 16-associated proteins, including E6 and E7, are some of the most common proteins in cervical cancers and are ubiquitiously expressed within these cells (99,100). However, DNA-based vaccine targeting these proteins seem to elicit minimal immune responses, and may necessitate potent adjuvants to provide efficacious tumor protection. Accordingly, recent studies suggest numerous targeting mechanisms (i.e., adjuvants) to enhance immunogenicity of these antigens.

Heat shock proteins (HSPs) have been found to induce tumor immunogenicity and their levels of expression are enhanced with highly immunogenic necrotic bodies (101–103). HSP–peptide complexes are also highly immunogenic and function effectively as adjuvants and cross-priming proteins (104–107). It has also been reported that the enhanced CTL responses are CD4+ independent and are limited only to antigenic peptides associated with HSPs (108–110). Importantly, evidence suggests that the HSPs may specifically target immature dendritic cells for the induction of proinflammatory reponses, further validating their potential role as vaccine adjuvants (111). In view of this, the HSP70 of mycobacterium tuberculosis was fused to the HPV-16 E7 antigen to construct a chimeric DNA vaccine. The E7-HSP70 DNA vaccine induced significantly enhanced levels of cellular responses, including a ratio of 435:14 (E7-HSP70 to E7) of E7-specific IFN-γ spot-forming CD8+ T cells via ELISPOT assays. In addition, data indicate the eradication of preexisting tumors and the resulting response was via CD4+-independent mechanisms (111). The exact mechanism of HSP-mediated peptide processing is still yet unclear, although enhanced proteasomal processing may be involved in this cross-priming maneuver (111). In a similar fashion, another member of the HSP family that has aug-

mented the potency of DNA vaccines is calreticulin (112). The idea of calreticulin as an immune modulator was based on previous findings that calreticulin in conjugation with tumor peptides stimulates potent peptide-specific CD8+ T cell responses (113). In addition, calreticulin and its fragment vasostatin operate as inhibitors of angiogensis (114,115). Accordingly, when calreticulin was fused to HPV-16 E7 antigen as a DNA vaccine, a potent antitumor effect was provoked. The resulting response was attributed to both the enhanced immunogenicity against E7 and the generation of antiangiogenesis (112).

A more recent report within the clinics also suggests that immunization through DNA can also therapeutically attenuate the growth of neoplastic cells in humans. These studies specifically encapsulated DNA plasmids encoding HLA-A2-restricted epitopes of the HPV E7 antigen within biodegradable polymer microparticles. Early work suggests no adverse side effects while enhancing immune responses when implementing this specific therapy (116). All together, these promising results emphasize the potential of DNA vaccines as therapies.

IV. INDUCTION OF IMMUNE RESPONSES IN PRIMATES

It would be desirable to evaluate in primates DNA vaccine constructs that induced high levels of immune responses in mice. Nonhuman primates represent the most relevant animal challenge model for HIV vaccine studies. Specifically, there are currently 3 different primate models for HIV vaccine studies. They include the HIV challenge model in chimpanzees and the SIV and chimeric SIV/HIV-1 (SHIV-1) challenge models in macaques. Chimpanzees can be infected by HIV isolates from humans, although they do not readily develop AIDS-like disease. However, the SIV challenge model uses the macaque SIV, which replicates to high levels and causes an AIDS-like disease in both cynomolgus and rhesus macaques. The chimeric SHIV viruses were constructed by replacing SIV envelope genes with specific HIV-1 envelope genes (117). The SHIV viruses replicate in macaques similarly to SIV and represent an infectious challenge model for HIV-1 envelope-based vaccines. Importantly, certain SHIV strains such as SHIV 89.6P are pathogenic.

DNA vaccination has been shown to induce both strain-specific neutralizing antibodies as well as antigen-specific T cell responses in both macaques and chimpanzees. The ability of DNA vaccines to provide protective immunity from viral challenge in primates has had mixed results. In a chimpanzee HIV challenge model, 2 out of 2 chimpanzees inoculated with constructs encoding for HIV envelope and gag/pol proteins from strain MN were protected from an intravenous (IV) challenge with a high dose (250 chimpanzee ID_{50}) of a heterologous stock of HIV-1 SF2 (118). In an early macaque study, 4 cynomolgus monkeys immunized with 2 different HIV-1 envelope constructs (encoding subtypes B and D) resulted in an induction of antigen-specific humoral responses, including neutralizing antibodies and cellular responses such as proliferative and cytotoxic responses (119). However, only 1 of 4 cynomolgus macaques were protected from IV challenge with 50 $TCID_{50}$ of a SHIV-1 HXB2 chimeric virus stock. More recently, 2 out of 2 rhesus monkeys primed with large doses of HIV-1 gp120 DNA vaccine constructs and boosted with gp160 protein were protected from an IV challenge with 25 $TCID_{50}$ of SHIV-1 HXB2 (120). However, protein vaccines alone can protect in this model in a type-specific fashion and protection is based on the ability of protein to boost the type-specific neutralizing antibody response. More recently, however, priming with gp160 DNA and boosting with recombinant protein did not result in protection in the identical SHIV model (121). Thus, the effectiveness of this vaccine strategy is unclear in the macaque model. Early reports have suggested that complete protection against SHIV could be achieved though when coimmunized with an IL-2-F_c fusion cytokine (183). Monkeys that were immunized with the IL-2-F_c cytokine exhibited potent CTL induction and stable CD4+ T cell counts, while minimal to no viral loads were detected (183). In addition to these DNA and protein prime/boost studies, other prime/boost strategies using DNA and recombinant viruses (e.g., recombinant poxvirus and adenovirus) are being investigated. Cellular immune responses have been reported to enhance with such prime/boost strategies (122), their effects on viral protection have been generated through the boosting with both MVA and Ad5 models (201,205).

The protective effects of DNA vaccine constructs in the SIV challenge model have been significantly less encouraging. Seven rhesus macaques were immunized with DNA vaccines encoding both envelope (4 different plasmids) and gag (1 plasmid) genes of SIV and were challenged with pathogenic SIV_{mac251} after their sixth immunization. Although vaccines induced positive responses, none of the vaccinated animals were protected from infection or disease (123).

More recently, we immunized rhesus macaques with DNA vaccine constructs encoding for HIV env/rev and SIV gag/pol proteins (124). Vaccinated animals were challenged intravenously with SHIV IIIB. Half of the animals in the vaccine group exhibited protection from infection based on sensitive limiting dilution coculture, demonstrating a dramatic effect on viral replication of the vaccines tested. The protected animals were reboosted with SIV DNA vaccines and were rechallenged intravenously with pathogenic SIV_{mac239}. All vaccinated animals were negative for viral coculture and antigenemia and remained healthy.

Whether the protection from SIV challenge is entirely due to DNA vaccines alone or due to DNA and SHIV challenge should be further studied. It is important to consider the role of SHIV challenge as a boosting agent for gag-specific cellular responses in this study. Regardless, these results demonstrate that protection from pathogenic challenge can be achieved in the absence of viral replication that reaches a threshold level of replication for effective vaccination, and these findings could be important in assessing relevant multicomponent vaccination strategies for HIV.

V. SAFETY AND EFFICACY STUDIES IN HUMANS

The ultimate goal of vaccine development is demonstrated safety and efficacy in humans. The first DNA vaccine studies to enter the clinic were DNA vaccines encoding for HIV-1 MN envelope (125). Fifteen healthy HIV-1 seropositive volunteers with greater than 500 CD4+ lymphocytes/mL were enrolled in this study. Patients in the trial received 3 injections each separated by 10 weeks with escalating dosage (3 dosage groups of 5 subjects) of envelope vaccine. Preliminary results reveal no significant clinical or laboratory adverse effects measured in all 3 dosage groups (30, 100, and 300 μg). More important, the immunized individuals developed an increase in antibody responses to envelope proteins and peptides after receiving the 100-μg dose. Some increases in cellular responses, including the lymphoproliferative and CTL responses, as well as β-chemokine expression were also observed (125).

These preliminary results demonstrate that the injection of even relatively low doses of a single immunogen DNA vaccine is capable of augmenting both existing humoral and cellular immune responses in humans. In addition to the initial human trials, phase I trials evaluating a gag/pol construct as a therapeutic vaccine as well as a prophylactic DNA vaccine study for HIV, have been undertaken. In another clinical study, the healthy volunteers who were immunized with DNA vaccines encoding for malaria proteins developed CTL responses against the target cells prepared with malaria peptides (126). Taken together, these studies are dramatically expanding our knowledge of DNA vaccines for clinical use in humans.

VI. MOLECULAR ADJUVANTS AS AN IMMUNE MODULATION STRATEGY

The primary goal of the first-generation DNA immunization studies was to demonstrate and evaluate the DNA vaccines' ability to elicit humoral and cellular responses in vivo in a safe and well-tolerated manner. As we explore the next-generation of DNA vaccines, it would be desirable to refine current DNA vaccination strategies to elicit more clinically efficacious immune responses. In this regard, the next generation nucleic acid vaccines may require better control of the magnitude and direction (humoral or cellular) of the immune responses induced. Such modulation of immune responses can be accomplished by the use of genetic adjuvants. Genetic or molecular adjuvants are different than the traditional adjuvants in that they are comprised of gene expression constructs encoding for immunologically important molecules. These molecules include cytokines, chemokines, and costimulatory molecules (9). These molecular adjuvant constructs could be coadministered along with immunogen constructs to modulate the magnitude and direction (humoral or cellular) of the immune responses induced by the vaccine cassettes themselves (Fig. 5). Such use of molecular adjuvant constructs results in concurrent kinetics of in vivo expression for both the adjuvant and antigen proteins. Perhaps this ability to engineer targeted

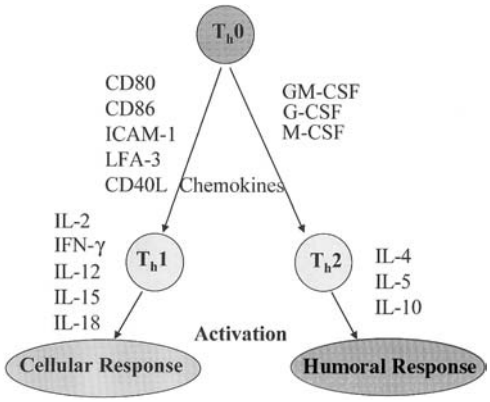

Figure 5 Cytokines, chemokines, and costimulatory molecules as immune regulators. Cytokines, chemokines, and costimulatory molecules play critical roles in the immune and inflammatory responses. Based on their specific function in the immune system, these cytokines could be further grouped as proinflammatory, Th1, and Th2 cytokines. Along with costimulatory molecules and chemokines, these cytokines also play important roles in the activation and proliferation of T and B cells.

immune responses may be a particularly important aspect of a multicomponent DNA vaccine strategy.

A. Cytokine Molecular Adjuvants

To focus the immune responses induced from DNA vaccines, we and others have investigated the codelivery of molecular adjuvants to modulate vaccine responses (65,127–135). We initially reported that coimmunization of GM-CSF cDNA with DNA vaccine constructs increases antigen-specific antibody and T helper cell proliferation responses, while coimmunization with IL-12 cDNA results in weaker antibody responses and enhanced T helper cell proliferation in mice (65,127). In addition, IL-12 coimmunization resulted in a significant enhancement of CTL responses. Importantly, we observed a significant enhancement of CTL response in vivo with the coadministration of murine IL-12 genes with 4 different HIV-1 DNA immunogens (*gag*/*pol*, *envelope*, *vif*, and *nef*), which were CD8+ T cell and MHC class I restricted. In contrast, almost no effect on CTL induction was observed with the genes for GM-CSF in these studies. Iwasaki et al. reported a similar finding using GM-CSF and IL-12 codelivery with DNA immunogen encoding for influenza NP.

More recently, we investigated the induction and regulation of immune responses from the codelivery of proinflammatory cytokines (IL-1α, TNF-α, and TNF-β), T_h1 cytokines (IL-2, IL-15, and IL-18), and T_h2 cytokines (IL-4, IL-5, and IL-10) (128). We observed that some Th1, as well as Th2, cytokine genes increased the antibody response, specifically coinjection with IL-2, IL-4, IL-5, IL-10, and IL-18, all resulted in increased levels of antibodies. We also found that coinjec-

tion with TNF-α, TNF-β, IL-2, IL-10, and IL-18 resulted in a dramatic enhancement of T helper proliferation response, while coinjection with IL-5 and IL-15 resulted in a more moderate increase in T helper proliferation. Furthermore, among all coinjection combinations, we found that only TNF-α and IL-15 coinjections resulted in a high level of CTL enhancement similar to that of IL-12 coinjection. Coinjection with TNF-β, IL-2, and IL-18 resulted in a more moderate increase in CTL response over those groups immunized with only DNA immunogen. As observed with IL-12 coinjection, the enhancement of CTL responses observed from the coinjections with TNF-α and IL-15 were restricted by MHC class I and CD8 + T cell dependent.

We also investigated whether the Th1- or Th2-type immune responses are more important for protection from HSV-2 infection (136). We codelivered DNA expression construct encoding for HSV-2 gD protein with the gene plasmids encoding for Th1-type (IL-2, IL-12, IL-15, IL-18) and Th2-type (IL-4, IL-10) cytokines in an effort to drive immunity induced by vaccination. We then analyzed the vaccine modulatory effects on resulting immune phenotype and on the mortality and morbidity of the immunized animals, following HSV lethal challenge (Fig. 6). We observed Th1 cytokine gene coadministration not only enhanced survival rate, but also reduced the frequency and severity of herpetic lesions following intravaginal HSV challenge. However, coinjection with Th2 cytokine genes increased the rate of mortality and morbidity of the challenged mice. Again, among the Th1-type cytokine genes tested, IL-12 was particularly a potent adjuvant for the gD DNA vaccination, resulting in increased survival and decreased animal morbidity.

B. Chemokine Molecular Adjuvants

Similar to cytokine gene codelivery, we found that the coimmunization with chemokine genes along with DNA immunogen constructs can modulate the direction and magnitude of induced immune responses (130). We observed that coimmunization with IL-8 and MIP-1α genes increased the antibody response in a similar manner to IL-4 or GM-CSF coimmunization. We also found that coinjection with IL-8 and RANTES resulted in a dramatic enhancement of T helper proliferation response. Among all coinjection combinations, we found that RANTES and MCP-1 coinjections resulted in a high level of CTL enhancement, almost as significant as IL-12, a potent CTL inducer for DNA vaccines. In addition, there is evidence that suggests some chemokine adjuvanted vaccines require a direct fusion of the immunogen with the chemokine. For instance, immunization against HIV gp120 with monocyte chemoattractant protein-3 (MCP-3/CCL7) or macrophage-derived chemokine (MDC/CCL22) requires the direct fusion of the 2 for effective immune response induction. Accordingly, coimmunization revealed minimal immune enhancement (137). Therefore, the use of these chemokine vaccines could be particularly important as HIV vaccine modulators of β-chemokines. In this regard, we observed that β-chemokines as vaccine adjuvants augmented β-chemokine production in a vaccine antigen-specific manner. This aspect could be especially important for a development of a vaccine that modulates the earliest aspects of the inflammatory response.

C. Costimulatory Molecule Molecular Adjuvants

Professional APCs initiate T cell activation through binding of antigenic peptide–MHC complexes to specific T cell receptor molecules. In addition, the APCs provide critical costimulatory signals to T cells, which are required for the clonal expansion and differentiation of T cells. Among different costimulatory molecules, B7 molecules (CD80 and CD86) have been

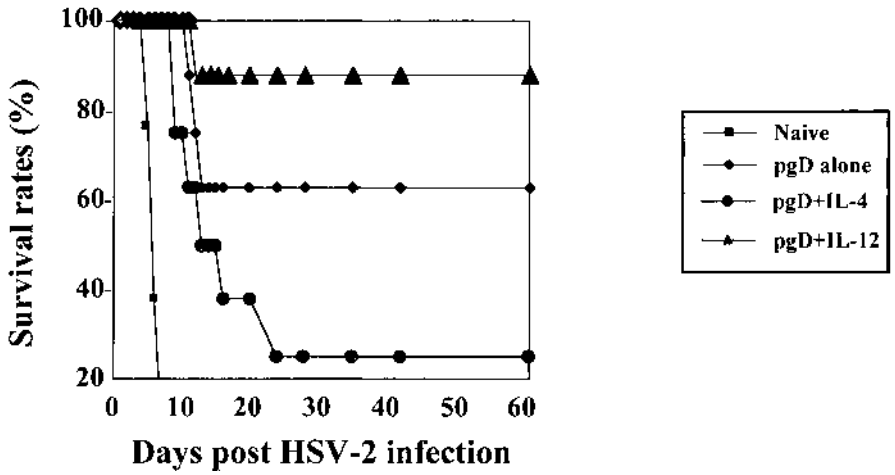

Figure 6 Protection from lethal HSV-2 challenge. Each group of mice ($n = 10$) was immunized with gD DNA vaccines (60 μg), and/or cytokine genes (40 μg) at 0 and 2 weeks. Three weeks after the second immunization, mice ($n = 8$) were challenged intravenously with 200 × LD_{50} of HSV-2 strain 186 (7×10^5 pfu).

observed to provide potent immune signals (138,139). They bind to their receptors (CD28/CTLA-4) present on T cells. The CD80 and CD86 molecules are surface glycoproteins and members of the immunoglobulin superfamily, which are expressed only on professional APCs (138–140). The blocking of this additional costimulatory signal leads to T cell anergy (141).

We reported that CD86 molecules play a prominent role in the antigen-specific induction of $CD8^+$ CTLs when delivered as vaccine adjuvants (131). Coadministration of CD86 cDNA along with DNA-encoding HIV-1 antigens intramuscularly dramatically increased antigen-specific T cell responses without a significant change to the level of the humoral response. This enhancement of CTL response was both MHC class I restricted and CD8+ T cell dependent. Similar results have been obtained by other investigators who also found that CD86, not CD80, coexpression results in the enhancement of T cell-mediated immune responses (133,134).

Accordingly, we speculated that engineering of nonprofessional APCs such as muscle cells to express CD86 costimulatory molecules could empower them to prime CTL precursors. However, the enhancement effect of CD86 codelivery could also have been mediated through the direct transfection of a small number of professional APCs residing within the muscle tissue. Subsequently, these cells could have greater expression of costimulatory molecules and could in theory become more potent. To investigate this issue, we constructed a set of bone marrow chimeric animals between normal mice and mice bearing a disrupted β_2-microglobulin (β_2m) gene (142). These bone marrow chimeras could respond and develop functional CTL responses following immunization with vaccinia virus. Next, we immunized chimeric animals with a DNA vaccine expressing HIV-1_{MN} envelope protein (pCEnv) and plasmids encoding CD80 or CD86 genes (pCD80 or pCD86). Using this model, we observed that in vivo transfection of only pCEnv and pCD86 could engineer non-bone marrow-derived cells such as muscle cells to prime and expand CTLs. This study suggests that CD86 and not CD80 plays a central role in the generation of the antigen-specific CTL responses. These results indicate that the strategy of engineering muscle cells to be more efficient APCs could be an important tool for the optimization of antigen-specific T cell-mediated immune responses in a pursuit of more rationally designed vaccines and immune therapies through the control of MHC class I restriction. This method of engineering nonhematopoietic cells to be more efficient APCs could be especially important in cases where antigen alone fails to elicit a CTL response due to poor presentation by the host APCs.

In addition to the B7 family of costimulatory molecules, the immunology of CD40 and its ligand has also been implemented to enhance vaccine potency. CD40 functions by interacting with CD40 ligand (CD40L) expressed on activated CD4+ or CD8+ T cells. The attachment of CD40L onto APCs, with or without T helper cells, has been shown to ''condition'' the APCs for antigen-specific CTL activation (143–145). In addition, their ligation has shown to enhance the expression of B7 costimulatory molecules on APCs, including dendritic cells (146–148). Therefore, the engagement of CD40 with its ligand becomes advantageous for activation of CTLs during an immune priming response. Accordingly, coimmunization of plasmids coding for β-galactosidase and CD40L has been reported to induce immune enhancement (149). Importantly, the addition induced enhancement of CTL responses without suppressing the development of antibody responses (150,151). Interestingly, coinjection of CD40L was revealed to be more effective than CD40 (152), indicating that expression of CD40L on muscle cells may also induce the ''licensing'' of APCs for the activation of CTLs. However, the possibility of direct transfection into antigen-specific infiltrating T cells cannot be eliminated, although T cells have not been yet established as an in vivo transfection target for DNA vaccines.

In light of these findings, we further investigated the strategy of engineering immune responses using additional costimulatory molecules (153). We coimmunized cDNA expression cassettes encoding intracellular adhesion molecule (ICAM)-1, lymphocyte function-associated antigen (LFA)-3, and vascular cell adhesion molecule (VCAM)-1, along with DNA immunogens, and analyzed the resulting antigen-specific immune responses. We observed that antigen-specific T cell responses can be enhanced by the coexpression of DNA immunogen and adhesion molecules ICAM-1 and LFA-3. Coexpression of ICAM-1 or LFA-3 molecules along with DNA immunogens resulted in a significant enhancement of Th cell proliferative responses. In addition, coimmunization with ICAM-1 (and more moderately with LFA-3) resulted in a dramatic enhancement of CD8-restricted CTL responses. Although VCAM-1 and ICAM-1 are similar in size, VCAM-1 coimmunization did not have any measurable effect on cell-mediated responses. Rather, these results imply that ICAM-1 and LFA-3 provide direct T cell costimulation. These observations were further supported by the finding that coinjection with ICAM-1 dramatically enhanced the level of IFN-γ and β-chemokines MIP-1α, MIP-1β, and RANTES produced by stimulated T cells. Through comparative studies, we observed that ICAM-1/LFA-1 T cell costimulatory pathways are independent of CD86/CD28 pathways, and they may synergistically expand T cell responses in vivo. Furthermore, these studies indicate that CD8+ effector T cells at the site of inflammation can regulate the level of effector function through the expression of specific chemokines and adhesion molecules (Fig. 7) (130,153). Therefore, the end-stage effector T cells in the expansion phase of an antigen-specific immune response could direct their destiny through coordinated expression and release of these molecules.

D. Cell Death to Enhance Immunogenicity

In addition to powerful signaling, dendritic cells often function as scavenger cells by engulfing and processing apoptotic bodies. For instance, immature dendritic cells phagocytose apoptotic bodies by employing the receptors alphavbeta5 integrin and CD36 (154–156). Subsequent engulfment of the apoptotic body by both immature and mature dendritic cells induces viral and tumor immunogens to activate MHC class I restricted

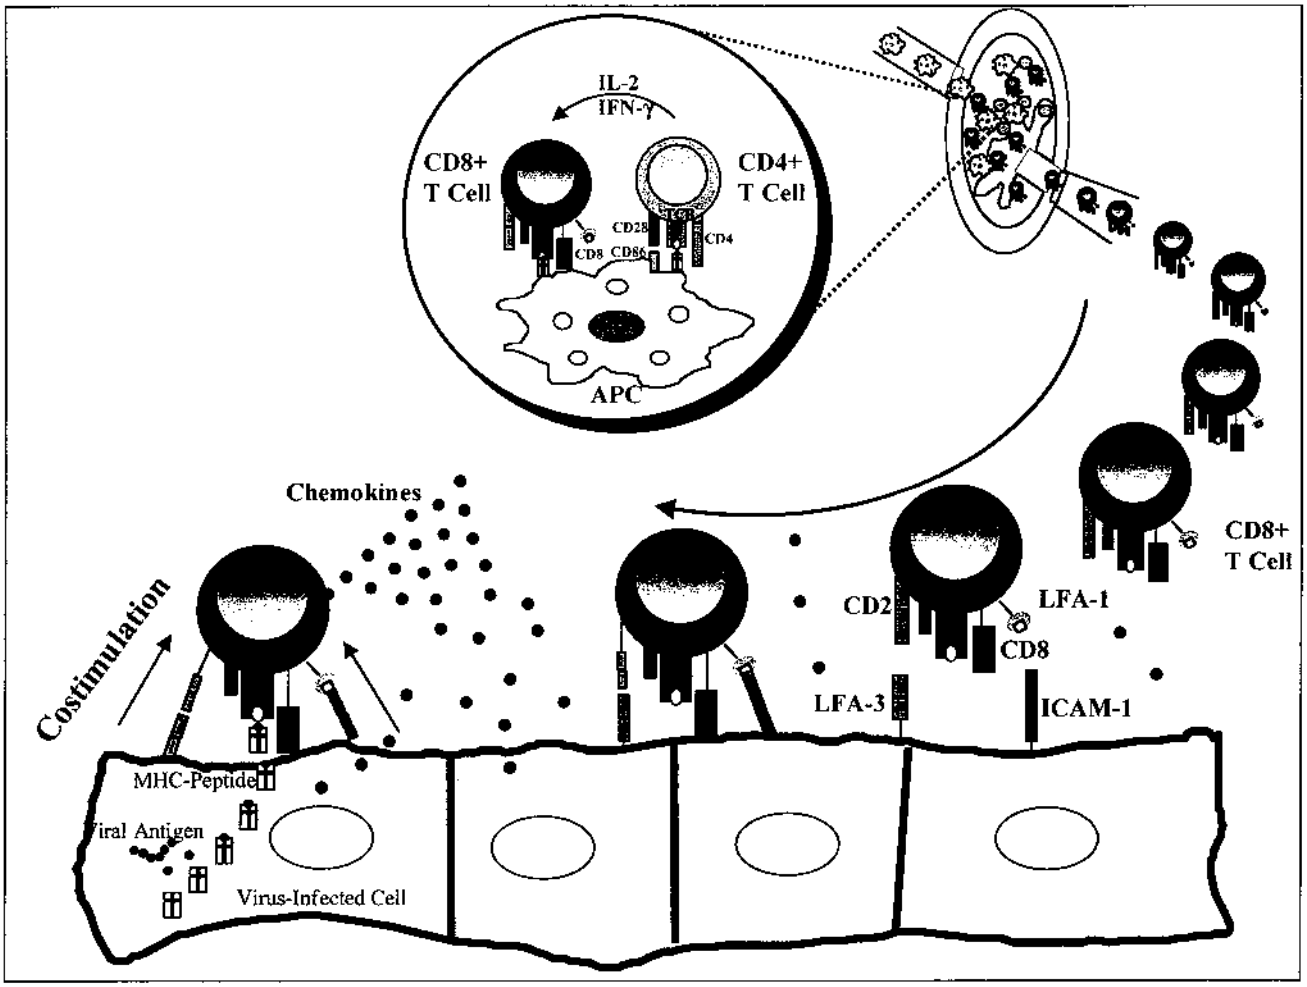

Figure 7 Regulation of CD8+ T cell expansion by adhesion molecules and chemokines in the periphery. Specific adhesion molecules and chemokines provide modulatory signals to CD8+ T cells in effector stage. This network of cytokine, chemokine, costimulatory molecules and adhesion molecules represents a coordinated regulation and maintenance of effector T cells in the periphery.

CD8+ CTLs (17,156). Interestingly, in vivo depletion of CD11c+ and CD8+ cells in mice fail to cross-prime antigens to prime naive T cells, specifying its essential role in inducing T cell activation (158). Both dendritic cells and macrophages have been shown to present apoptotic engulfed antigens, but the latter fails to activate naive T cells, which becomes a vital step in the activation of adaptive immunity (17,157). In addition, Rovere et al. and Ronchetti et al. demonstrated that there is a quantitative dependency on apoptotic bodies by dendritic cells in inducing the secretion of proinflammatory cytokines TNF-α and IL-1β both in vitro and in vivo, respectively (156,159). Hence, an optimum strategy to develop potent vaccines would necessitate the activation of dendritic cells and the packaging of immunogens in these apoptotic bodies for uptake. Appropriately, we have employed a novel strategy whereby immunogen constructs were coimmunized with the death cell receptor Fas. In theory, this model induces the expression of both the immunogen and Fas within the same muscle cells and apoptosis would materialize through the interaction of Fas with its ligand, possibly via T cell assistance. When these 2 constructs were coimmunized, there was a significant augmentation of immune responses as measured by enhanced CTLs and Th1 cytokines, including IFN-γ and IL-12 (160). In addition, implementing Fas as the apoptosis receptor may also provide a compounding effect on dendritic cell maturation, as Fas engagement possesses multiple functional roles. For instance, Fas not only contributes with the induction of cell death, but also stimulates the maturation of dendritic cells when engaged with its ligand (161). This is especially crucial, because direct in vivo transfection of dendritic cells has been proposed as a potential mechanism responsible for the induction of immune activation with respect

to DNA vaccines (18–20). More recent work by Sasaki et al. implemented mutant caspases to decrease apoptotic efficiency to aliquot ample time for immunogen expression, while still delivering apoptosis-mediated antigens to dendritic cells (162). This raises an interesting question because these mutant caspases decreased apoptotic efficiency in vitro by nearly 10-fold from the native caspase proteases (162). However, it is also currently understood that high quantities of apoptotic bodies are engulfed by scavenger macrophages and induce subsequent release of anti-inflammatory factors including IL-10, TGF-β, PGE2, and PAF (163,164). Accordingly, inflammation is observed when the clearance of apoptotic bodies becomes inefficient and results in their delayed removal from the surrounding environment (165). This results in the development of postapoptotic necrosis, which may function to deliver additional signals for proinflammatory developments and dendritic cell maturation (165,166). However, decrease in overall apoptotic quantity and potency with mutant caspases was able to provide enhanced immune response levels when compared with the more potent apoptotic signal (162). Therefore, it is also likely that delaying the expression of the apoptotic signal and/or working upstream of caspases may validate the requirement for the balance between immunogen expression vs. apoptotic stimuli (162). This reveals the necessity to delay the expression of apoptotic signals to maximize immunogen expression, while maintaining the potency of the death signal. It is also important to note that necrosis, not apoptosis, is traditionally the prime cell death mechanism by which inflammation and immune activation occurs (167). Interestingly, recent work suggests several models may be involved to induce immune activation through cell death. For instance, one model suggests that necrosis in conjunction with apoptosis delivers the maturation signal to dendritic cells (166,168). However, the role of postapoptotic necrosis as the stimulus is ruled out or insufficiently strong to deliver the maturation signal. Another model suggests that both primary necrotic and apoptotic cells are equivalent at inducing the maturation of dendritic cells and initiating immune activation (169). Therefore, either channel of cell death may be competent to stimulate the immune system for activation. Lastly, it is suggested that cell death or injury releases adjuvanting properties from the cytoplasm and is able to effectively stimulate immune activation (170). Therefore, components are actively secreted from dead cells that trigger the induction of immune responses. It is also evident that apoptosis and necrosis may function together to deliver immunogens to dendritic cells while inducing potent maturation signals (168). However, further studies are crucial to validate the precise roles that these cell death components may play in the generation of inflammatory responses with DNA immunizations.

VII. USE OF MOLECULAR ADJUVANTS IN PRIMATES

We sought to evaluate whether the enhancement of immune responses observed in mice with coimmunization with cytokine genes could also be achieved in rhesus macaques. DNA vaccines for HIV env/rev and SIV gag/pol alone were evaluated for their immunogenicity and compared with these vaccines, which also included IL-2, IFN-γ (Th1), or IL-4 (Th2) cytokine cDNA constructs (171). The cytokines dramatically enhanced seroconversion induced by the vaccines and appeared to modulate cellular responses as well, although more modestly. Vaccinated animals were challenged intravenously with SHIV IIIB. Half of the animals in the vaccine or vaccine plus Th1 cytokine groups exhibited protection from infection based on sensitive limiting dilution coculture, demonstrating a dramatic effect on viral replication of the vaccines tested. The protected animals were reboosted with SIV DNA vaccines (SIV and cytokine constructs) and were rechallenged intravenously with pathogenic SIV_{mac239}. All vaccinated animals were negative for viral coculture and antigenemia. In contrast, the control animals exhibited antigenemia by 2 weeks post challenge and exhibited greater than 10 logs of virus/10^6 cells in limiting dilution coculture (172). The control animal exhibited CD4 cell loss and developed SIV-related wasting within 14 weeks of high viral burden and subsequently failed to thrive. Vaccinated animals were virus negative and remained healthy. Although exact correlates of protection could include cellular responses, neutralizing antibody responses do not appear to correlate with control of viral replication and infection in these studies. These studies establish that multicomponent DNA vaccines can directly impact viral replication and disease in a highly pathogenic challenge system, thus potentially broadening our immunological weapons against HIV.

In an effort to enhance the clinical utility of the DNA-based PSA vaccine, we also examined the use of cytokine gene adjuvants to modulate vaccine-induced immune responses in animal models. We observed that pCPSA vaccine-induced humoral and cellular immune responses can be modulated through the coimmunization with cytokine genes in mice, and these enhancement effects on the PSA-specific cellular responses were extended in macaques. More specifically, coimmunization with IL-2 cDNA construct resulted in a significant enhancement of PSA-specific antibody responses in both mice and macaque models. In contrast, coinjection of IL-12 resulted in reduction of antibody responses in both models. In mice, the groups coimmunized with IL-2, IL-12, or IL-18 showed a dramatic increase in T helper cell proliferation over the results with pCPSA alone. These results support that further evaluation of this vaccination strategy to treat prostate cancer is warranted (173).

VIII. ADVANTAGES OF USING MOLECULAR ADJUVANTS

The overall objective of any immunization strategy is to induce specific immune responses that could protect the immunized individual from a given pathogen over his or her lifetime. One major challenge in meeting this goal is that the correlates of protection from an individual pathogen vary from

one infectious agent to the next. It would be a distinct advantage to design immunization strategies that can be ''targeted'' according to the correlates of protection known for the particular pathogen (Fig. 8). As summarized in Fig. 9, we observed that significant modulation was possible through the use of molecular adjuvants along with DNA vaccine constructs. This molecular adjuvant network underscores an important level of control in the induction of specific immune responses to tailor vaccination programs more closely to the correlates of protection, which vary from disease to disease. This type of fine control of vaccine and immune therapies was previously very difficult to obtain. Controlling the magnitude and direction of the immune response could be advantageous in a wide variety of vaccine strategies, including HIV-1. Much of the current literature supports that T cell-mediated responses are more critical for providing protective immunity against HIV infection (44,174,175). In such cases where T cell-mediated response is paramount, MCP-1, RANTES, or IL-12 genes could be chosen as the immune modulator to be codelivered with a specific DNA immunogen. However, for building vaccines to target extracellular bacteria, for example, MIP-1α, IL-4, IL-5, IL-10, or GM-CSF genes could be coinjected. In addition, in cases where both CD4+ T helper cells and antibodies play more important roles in protection, IL-2, IL-8, or GM-CSF could be codelivered. Furthermore, these genes can be combined with 1 or more additional cytokine or costimulatory genes to further control the immune responses. Additional studies in higher animal models such as the primates can further address potential risks and benefits of applying this genetic adjuvant network, ultimately leading to modulation of human diseases.

IX. RECOMBINANT PRIME/BOOST STRATEGIES IN PRIMATES

The generation of potent CTL responses through the utilization of DNA immunization has become an attractive approach against many pathogens, including HIV-1. Specifically, inefficient generation of antibodies possessing high avidity against different HIV strains have determined to be the downfall associated with humoral immune response dominant vaccines (176,177). However, an inverse correlation can be made between HIV viral load and CTL frequency, indicating its importance in both treatment and vaccine applications (174,178). In fact, virus-specific CTLs attribute significantly to the control of acute phase infection and denote the mechanism by which viral loads are controlled (179–181). Furthermore, studies on SIV infection models have also indicated that viremia of viral load could be effectively controlled by CD8+ T cells (181,182). As a result, recent applications have concentrated on maximizing the cellular arm of the immune system by generating potent CTLs to target and eliminate virally infected host cells. Previously through DNA vaccines, complete challenges were achieved against nonpathogenic AIDS viruses (118,120) and against pathogenic SHIV-89.6P (183). Collectively, DNA vaccines represent an effective means by which cellular responses can be raised against HIV. In view of this, one of the most promising DNA vaccine models is to manipulate the immune system by employing different prime/boost strategies. Moreover, studies by differing groups have garnered tremendous enhancement of CTLs by priming with DNA and boosting with attenuated viruses.

There is great intrigue with the immunology of recombinant virus boosting, as the order of application has shown to be crucial in generating potent enhancements. For instance, vaccine regimens in reverse (virus priming and DNA boosting) or merely DNA alone exhibit minimal amplification and fail to provide protective immunity against subsequent challenges (184–186). Historically, the order of application in attenuated prime/boost strategies has also exhibited similar results, as priming with a recombinant influenza virus and boosting with recombinant vaccinia resulted in enhanced CD8+ responses and protective immunity against malaria (187). It was proposed that perhaps the influences of these viruses to preferentially migrate CTLs to sites favored by the boosting virus may influence the overall potency of the vaccine (188). However, another study proposed that the immunogenicity may be correlated to the immunodominance of the boosting, as the antigen-specific memory responses from the priming may provide a greater focused isolation of the antigen of interest. Consequently, boosting with recombinant viruses concentrates the primed antigens from the recombinant and may enhance their amplification (186–188). This theory correlates with other reports, indicating that homologous prime/boosting with the same virus with heterologous antigens fails to proliferate antigen-specific CD8+ cells (189). Meanwhile, heterologous boosting with the modified vaccinia virus Ankara (MVA) and fowlpox viruses, while maintaining the same immunogen, provided significant enhancement of CTLs (190). It is also likely that the enhanced assembly of memory T cells that resulted from the primed immunization may augment the boost's proliferation by providing a larger memory T cell pool.

In addition to its efficacy, attenuated virus boosting specifically with MVA provides a resilient history for safety, as it was employed to vaccinate 120,000 humans during the smallpox eradication campaign (186,191). Furthermore, the inability of the virus to replicate in humans while maintaining efficient viral gene expression makes it a perfect component for recombinant boosting approaches (192,193). Cytokine studies of these viruses indicate an elevated degree of Th1 vs. Th2 responses, corresponding to the potent CTLs essential for an efficacious HIV-1 DNA vaccine (194,195). Further reports on the immunology of the MVA recombinant virus both in vitro and in vivo demonstrate that potent CTLs are generated as indicated by enhanced CD8+ populations and secretion of proinflammatory cytokines IL-6 and TNF-α (196–199). Consequently, the natural immune response of the virus correlates well with essential characteristics of vaccines by compounding the host's cellular responses.

To date, many different viruses have been studied to function as recombinant boosters for DNA vaccines, including the modified vaccinia Ankara, fowlpox, and the adenovirus

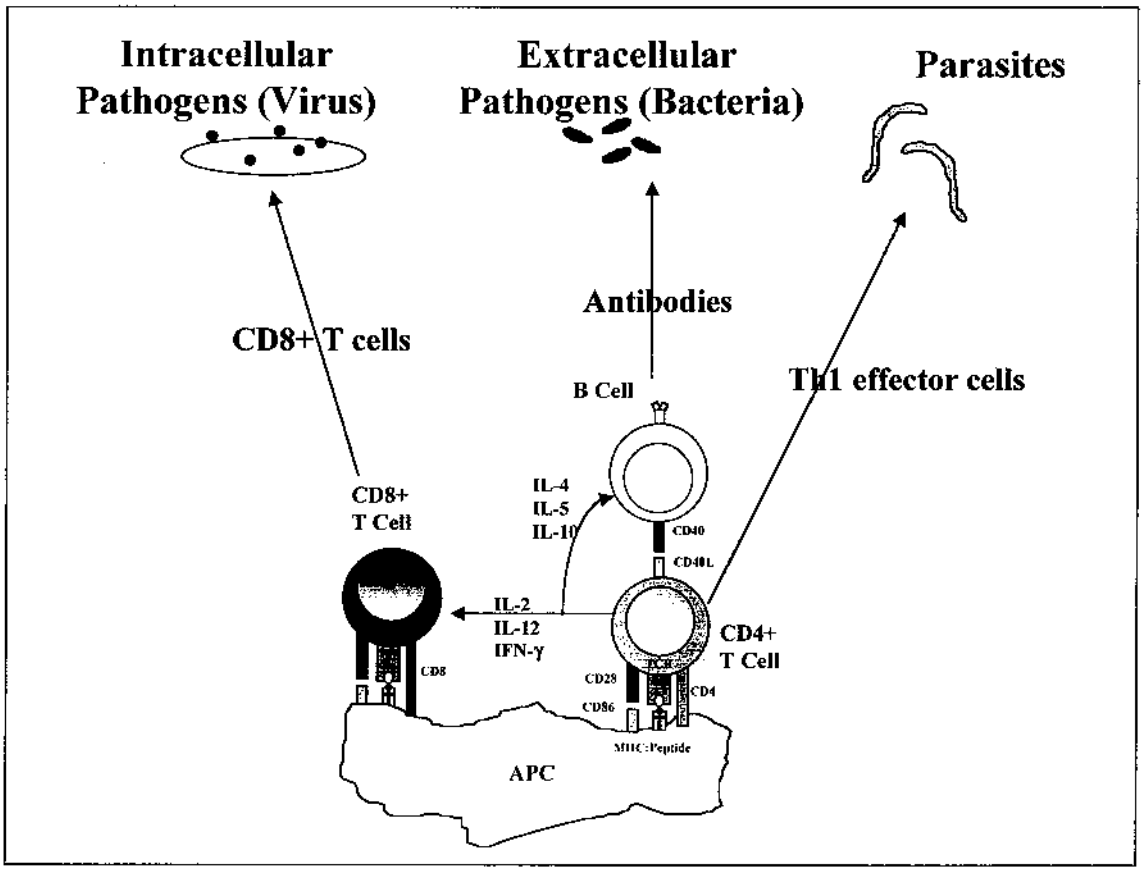

Figure 8 The potential utility of the molecular adjuvant network. Tailoring the induction of specific immune responses by vaccination programs against viral, bacterial, or parasitic diseases could be beneficial.

(200–205). Although most have reported potent CTLs and enhanced Th1-biased cytokine expression, the most promising are recent studies implementing the DNA/MVA boost scheme, as well as the DNA/Adeno5 model. The rhesus macaque from these studies garnered protective responses against subsequent pathogenic SHIV89.6P challenges by preventing clinical AIDS, while displaying low to no viral loads. The overall comparisons indicate that the most promising model is the Ad5 through survival of higher T cell counts and lower viral loads (205). However, the final judgments for these vaccines are premature until the evaluation of these models in human trials. This is especially of importance as previous challenged primates have been shown to eventually regress and develop clinical AIDS because of mutations within the gag dominant epitope (206). However, these challenges were conducted with the more pathogenic 89.6 SHIV model, and do not fully signify and mimic the in situ human HIV-1 infection setting.

X. CONCLUSION

DNA immunization holds great promise for providing safe and inexpensive vaccines for many infectious pathogens and cancer. The direct injection of foreign genes by genetic immunization has resulted in specific immune responses that exhibit characteristics of protective immunity against a number of infectious agents in a variety of animal models. For example, genetic vaccination cassettes targeting each of HIV-1's 3 major genes (env, gag, and pol), regulatory genes, and accessory genes have been developed and studied in small animals, primates, and humans. DNA vaccine constructs for cancer-targeting tumor-specific antigens have also been studied in a variety of animal models. Developing successful vaccines for HIV-1 or cancer will likely involve targeting multiple antigenic components to direct and empower the immune system. Such a collection of immunization cassettes should be capable of stimulating broad immunity against both humoral and cellular epitopes, thus giving a vaccine the maximum ability to deal with viral immune escape or tumor growth. DNA vaccines can be combined with other vaccines, including recombinant protein, poxvirus, adenovirus, and others, to further enhance initial immune responses. In addition, the potential of the molecular adjuvant coadministration to dramatically enhance and regulate the antigen-specific humoral and cellular immune responses induced by DNA immunogens represents important

Each adjuvant is plotted on the 3-dimensional axis, according to its effects on the 3 modes of immune response.

new avenues for vaccine and immune therapeutic exploration. Although further studies are warranted, these studies collectively support that optimized combinations of DNA expression cassettes coding for env, gag/pol, accessory proteins, costimulatory molecules, cytokines, chemokines, or other vaccine modulators may provide the basis for an effective vaccination strategy against infectious diseases and cancer.

Cardiovascular Gene Therapy

Pinak B. Shah, Kapildeo Lotun, and Douglas W. Losordo
St. Elizabeth's Medical Center
Boston, Massachusetts, U.S.A.

I. INTRODUCTION

Over that last quarter-century, numerous advancements have been made in the understanding of the molecular and cellular processes that lead to the development of atherosclerosis. The respective roles of the endothelium, inflammatory mediators, and thrombosis in the pathogenesis of vascular disease are beginning to be better understood. As more is learned of the initiation of atherosclerotic cardiovascular disease, new targets for systemic therapies are being discovered. Several classes of medications have been shown to be beneficial in preventing adverse cardiovascular events in patients with cardiovascular disease. These medications include platelet inhibitors (aspirin and thienopyridines), angiotensin-converting enzyme inhibitors, and 3-hydroxy-3-methylglutaryl-conenzyme A (HMG-CoA) reductase inhibitors (''statins'').

In conjunction with the improved understanding of the pathogenesis of vascular disease have been improvements in mechanical therapies for vascular disease. Surgical techniques have been perfected so that obstructed arteries can be effectively bypassed (as in coronary artery bypass grafting and lower- extremity bypass grafting), or be cleared of obstructive plaque (as in carotid endarterectomy). Revascularization strategies have since moved to less invasive endovascular techniques. Coronary arteries are routinely treated with metallic stents to improve myocardial blood flow and reduce ischemic symptoms. Stents are also routinely placed in iliac arteries for disabling claudication or critical limb ischemia, renal arteries for renovascular hypertension, and more recently, carotid arteries for the prevention of stroke. Percutaneous therapies are slowly supplanting surgical therapies as the treatment of choice for patients with cardiovascular disease, particularly in those patients with significant comorbidities limiting surgical options.

Ironically, while advancements in therapy have resulted in patients living longer with more severe cardiovascular disease, they have also resulted in a growing population of people who are no longer candidates for conventional therapies for their symptoms. These ''no-option'' patients live with severe angina, congestive heart failure, or disabling claudication/limb ischemia, and are becoming an increasingly larger part of our aging society. The fundamental problem in these patients is a deficiency in the blood supply to the myocardial and lower-extremity muscle beds due to severe, diffuse, and often totally occlusive vascular disease. The next ''holy grail'' in cardiovascular medicine is to stimulate the development of new vasculature to ischemic tissue (therapeutic angiogenesis) in order to improve blood flow, improve end-organ function, and relieve symptoms. Gene therapy may prove to be the most effective means of promoting therapeutic angiogenesis. Before reviewing gene therapy for cardiovascular disease, a description of vasculogenesis, angiogenesis, and angiogenic growth factors is warranted.

II. VASCULOGENESIS AND ANGIOGENESIS

In 1971, Folkman and colleagues published their pioneering work on growth factors, suggesting that the establishment and maintenance of a vascular supply is essential for growth of normal as well as neoplastic tissue (1). The establishment of a vascular supply occurs as a result of 2 main processes: vasculogenesis and angiogenesis. Vasculogenesis is the de novo in situ differentiation of endothelial cells (ECs) from mesodermal precursors in the embryo by association of endothelial progenitor cells (EPCs) or angioblasts and their subsequent reorganization into a primary capillary plexus 2. In contrast, angiogenesis is the formation of new blood vessels from

preexisting blood vessels. Angiogenesis is induced by the proliferation and migration of preexisting, fully differentiated ECs resident within parent vessels in response to stimuli such as hypoxia, ischemia, mechanical stretch, and inflammation (3,4). Angiogenesis can be a normal physiological process (e.g., as wound healing) or a pathological process (e.g., as in neoplasms and proliferative diabetic retinopathy).

Vasculogenesis was previously considered to be restricted to embryonic vascular development, while angiogenesis was believed to be responsible for both embryonic vascular development and postnatal neovascularization. Recent evidence, however, suggests that the basis for embryonic as well as therapeutic neovascularization likely encompasses both processes. Circulating CD34 antigen-positive EPCs were recently isolated from adult species and shown to differentiate along an endothelial cell lineage in vitro, thus constituting inferential evidence for the importance of rculating stem cells in angiogenesis (5). In addition, the demonstration that bone marrow-derived EPCs are increased in number in response to tissue ischemia, migrate and incorporate into foci of neovascularization in adult animals, and augment collateral development following *ex vivo* expansion and transplantation suggests that neovascularization in the adult involves both angiogenesis and vasculogenesis (6–8). Taiteshi-Yuyama et al. showed the potential of autologous stem cell transplantation to result in angiogenesis in patients with critical limb ischemia (9).

Arteriogenesis has been recognized as a mechanism that probably contributes to collateral vessel formation. A proportion of newly recognized medium-size arteries may be the result of proliferation of preexisting arteriolar connections into larger collateral vessels by remodeling (10). It is unknown whether such remodeling occurs as a direct result of growth factor modulation or as a flow-mediated maturation of these collateral conduits by a process of ''arteriolization'' of capillaries.

III. ANGIOGENIC GROWTH FACTORS

Although many cytokines have angiogenic activity, the best studied in animal models and clinical trials are vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF).

A. Vascular Endothelial Growth Factor

The human VEGF proteins that have been identified to date are VEGF-1, VEGF-2 or VEGF-C, VEGF-3 or VEGF-B, VEGF-D, VEGF-E, and placental growth factor. All are encoded by different genes and localized to different chromosomes but share considerable homology. There are 4 isoforms of VEGF-1 that are the result of alternate splicing and are named according to the number of amino acids: $VEGF_{121}$, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$. These isoforms of VEGF show similar angiogenic potential in animal models (11), but differ in their solubility and heparin-binding capacity, accounting for differences in target cell binding. The principal cellular target of VEGF is the EC. There are 3 known endothelial-specific fms-like tyrosine kinases: VEGFR-1 (Flt-1), VEGFR-2 (Flk-1/KDR), and VEGFR-3. Hypoxia induces the formation of VEGF by the ECs and leads to up-regulation of VEGF receptors (VEGFRs) (12). VEGFR-1 generates signals that organize the assembly of ECs into tubes and functional vessels (13). VEGFR-2 is responsible for EC proliferation and migration (14,15). VEGFR-3 (Flt-4) principally mediates lymphangiogenesis (16).

VEGF possesses several features that facilitate gene transfer. First, VEGF contains a hydrophobic leader sequence that is a secretory signal sequence that permits the protein to be secreted naturally from intact cells, thus enabling a sequence of additional paracrine effects to be activated (17). Second, its high-affinity binding sites are exclusive to ECs; therefore, the mitogenic effects of VEGF are limited to ECs. This is in contrast to acidic and basic FGF, both of which are known to be mitogenic for smooth muscle cells and fibroblasts as well as ECs (18,19). Third, VEGF possesses an autocrine loop that is shared by most angiogenic cytokines and facilitates modulation of EC behavior. When activated under hypoxic conditions, the autocrine loop serves to amplify and thereby protract the response in ECs stimulated by exogenously administered VEGF. Furthermore, factors secreted by hypoxic myocytes up-regulate VEGFR expression on ECs within the hypoxic milieu. Such localized receptor expressions may explain the finding that angiogenesis does not occur indiscriminately, but rather is relatively limited to sites of tissue ischemia. Recently, an important additional role for VEGF has been described in augmentation of circulating EPC numbers documented in mice and humans following VEGF gene transfer (20–22). These EPCs have been shown to home into areas of myocardial ischemia.

B. Fibroblast Growth Factor

FGF is a family of 9 factors, including acidic FGF (FGF-1), basic FGF (bFGF or FGF-2), and FGF 3-9. Acidic FGF and basic FGF are the most extensively characterized members of the FGF family. FGFs are nonsecreted growth factors lacking a signal peptide sequence. The extracellular release of FGF is caused by cell death or damage. It binds to tyrosine kinase receptors via cell surface heparan sulfate proteoglycans, and as result, FGF is rapidly removed from the circulation and localized to cells and extracellular matrix. Although FGFs are potent EC mitogens, they are not EC specific and also serve as ligands for other cell types, including vascular smooth muscle cells and fibroblasts. At least 4 high-affinity FGF receptors have been identified and their cDNAs have been cloned. The FGFs, like VEGF, also stimulate EC synthesis of proteases, including plasminogen activator and metalloproteinases, important for extracellular matrix digestion in the process of angiogenesis (23).

Unlike VEGF, however, the common forms of FGF (FGF-1 and -2) lack a secretory signal sequence, and therefore, clinical trials of FGF gene transfer have required either modification of the FGF gene or use of another of the FGF gene family with a signal sequence (24–26).

IV. THERAPEUTIC ANGIOGENESIS

Angiogenic cytokines may be administered as recombinant protein or as genes encoding for these proteins. Given that both protein and gene delivery approaches have been relatively well tolerated thus far in clinical trials, ongoing investigations will determine the optimal preparation and delivery strategy for therapeutic neovascularization. Protein therapy remains the more conventional approach, and some investigators have indicated that this strategy is the closest to practical use. Nevertheless, recombinant protein is usually administered systemically and several issues limit its use. First, high plasma concentrations are required to achieve adequate tissue uptake to translate into a meaningful biological effect. This leads to higher potential for adverse effects. Second, recombinant human protein is difficult to produce and the costs are prohibitive.

Gene transfer allows for the high levels of sustained gene expression without provoking adverse host reactions. The efficiency with which the transgene is introduced and expressed into the target cell and the duration of transgene expression determines the success of gene transfer strategies. Transfer vectors facilitate cellular penetration and intracellular trafficking of the transgene, and local delivery systems deliver the vector to the vicinity of the target cells.

There are two major categories of gene transfer systems: viral and nonviral. The most commonly used viral vectors for gene transfer are adenovirus and retrovirus. The nonviral methods for gene transfer include introduction of naked DNA into the target area or the transfer of genetic material via a liposomal vehicle.

Hypoxia stimulates secretion of the angiogenic cytokines and also causes an increased expression of nitric oxide (NO) and VEGF receptors. Thus, ischemic muscle represents a promising target for angiogenic growth factor therapy. Striated and cardiac muscles have been shown to take up and express naked plasmid DNA as well as transgenes incorporated into viral vectors. Moreover, previous studies have shown that the transfection efficiency of intramuscular gene transfer is augmented more than 5-fold when the injected muscle is ischemic (27,28). Viral vectors may enhance transfection efficiency and thus yield higher levels of gene expression. In vitro and in vivo models have demonstrated that low-efficiency, but site-specific transfection (successful transfection in $<1\%$ of cells) with a gene (plasmid DNA) encoding for a secreted protein (e.g., VEGF) may overcome the handicap of inefficient transfection (29,30). By secreting adequate protein locally that translates into physiologically meaningful biological effects, therapeutic effects are achieved that are not realized by transfection with genes encoding for proteins that remain intracellular (e.g., bFGF). Furthermore, unlike viral vectors, plasmid DNA does not induce inflammation.

V. CLINICAL TRIALS OF VEGF PROTEIN AND GENE THERAPY

A. Peripheral Vascular Disease

The consensus statement of the European Working Group on Critical Limb Ischemia states that no medical treatment has been shown to alter the natural history of critical limb ischemia (31). In a large proportion of patients with critical limb ischemia, the distribution and extent of the arterial occlusive disease makes percutaneous or surgical revascularization impossible. In advanced stages of disease, quality-of-life measures are comparable to those patients with terminal cancer (32). Despite appropriate medical and surgical therapy, the unrelenting course of the disease ultimately leads to amputation. Of patients undergoing 1 amputation, 10% require a second amputation (33–36).

Despite the associated morbidity and mortality associated with amputation, it is often chosen as first-line therapy. Consequently, the need for alternative treatment strategies in patients with critical limb ischemia is compelling. Significant research has focused on developing angiogenic therapies to provide novel approaches to the treatment of limb ischemia.

Preclinical studies have established proof of principle for the concept that the angiogenic activity of VEGF is sufficiently potent to achieve therapeutic benefit. After intra-arterial administration of recombinant VEGF protein, augmentation of angiographically visible collateral vessels and histologically identifiable capillaries were demonstrated in rabbits with severe, unilateral hindlimb ischemia (37). Evidence that VEGF stimulates angiogenesis in vivo had been developed in experiments performed on other animal models, including rat and rabbit cornea, the chorioallantoic membrane, and the rabbit bone graft model (18,38). Intra-arterial gene transfer of $phVEGF_{165}$ in a human patient subsequently demonstrated angiographic and histologic evidence of angiogenesis (39).

Intra-arterial delivery, however, has several inherent limitations that could undermine successful growth factor transfer for critical limb ischemia. In the case of recombinant proteins, large doses of protein are necessary to exert a treatment effect in the face of rapid degradation by circulating proteinases. With naked DNA (i.e., DNA unassociated with viral or other adjunctive vectors), cellular uptake is virtually nil when the transgene is directly injected into the arterial lumen, presumably due to prompt degradation by circulating nucleases. In addition, the diffuse distribution of neointimal thickening and/or extensive atherosclerotic disease may limit gene transfer to the smooth muscle cells of the arterial media (40).

Preclinical studies of VEGF gene therapy were therefore designed to establish the feasibility of site-specific intramuscular gene transfer of VEGF in critical limb ischemia to promote therapeutic angiogenesis. Meaningful biological outcomes were observed following VEGF gene transfer of naked DNA by direct injection into skeletal muscle of ischemic rabbit hindlimbs, as evidenced by increased hindlimb blood pressure ratio, increased Doppler-derived iliac flow, enhanced neovascularity by angiography, and increased capillary density at necropsy (28,41).

Intramuscular gene transfer of 4000 μg naked plasmid DNA-encoding VEGF ($phVEGF_{165}$) was used to successfully accomplish therapeutic angiogenesis in patients with critical limb ischemia (42). Gene expression was documented by a transient increase in serum levels of VEGF monitored by en-

zyme-linked immunosorbent assay (ELISA). Meaningful clinical and physiological benefit was demonstrated by regression of rest pain and/or improved limb integrity, increased pain-free walking time, increased ankle-brachial index (ABI), newly visible collateral vessels by digital subtraction angiography, and qualitative evidence of improved distal flow by magnetic resonance imaging.

In a subsequent clinical trial in 55 patients (ages 24–84 years, $m = 56.7$ years) with ischemic rest pain ($n = 14$) or ischemic ulcers ($n = 41$) were treated with intramuscular injections of $phVEGF_{165}$. Evidence of clinical improvement was observed in 13 of 14 (72%) patients with rest pain alone and 26 of 41 (63%) patients with ischemic ulcers over a follow-up period of 4 to 36 months. For the total cohort of 55 patients, a favorable clinical outcome was achieved in 65.5%. Multiple logistic regression analysis identified rest pain and age <50 years as significant, independent predictors of a favorable clinical outcome. Diabetes, smoking, hyperlipidemia, hypertension, and $phVEGF_{165}$ dose were not predictors of clinical outcome (43). Complications in these patients have been limited to lower-extremity edema that develops in approximately one-third of patients 44. Edema was either self-limited or required a brief course of diuretic therapy, and it resolved approximately 1 to 2 months after gene transfer.

A similar treatment strategy was used in 11 patients with Buerger's disease presenting with critical limb ischemia, 9 of which were successfully treated with intramuscular $phVEGF_{165}$ (45). These patients had resolution of nocturnal rest pain and healing of foot and/or leg ulcers. The ABI increased by greater than 0.1, and newly formed collateral vessels were seen on MRA and serial contrast angiography.

Preclinical studies from our laboratory demonstrated that VEGF-2 could promote angiogenesis in a rabbit hindlimb ischemia model and stimulate the release of NO from ECs (46). Based on these preclinical studies, a randomized, double-blind, placebo-controlled, dose-escalating trial to investigate the therapeutic potential of VEGF-2 gene transfer in patients with critical limb ischemia (CLI) was recently completed. Forty-eight patients were enrolled between 1999 and 2000. These patients had Rutherford category 4/5 limb ischemia and no revascularization options. The dose of gene used ranged between 1.0 and 4.0 mg. Patients received 8 calf injections, were followed up weekly for 12 weeks and then monthly for 3 months, and visited at 9 and 12 months. Because from this study are currently being reviewed, the results are unavailable.

Recently, Nabel et al. published preliminary results of a phase I trial to evaluate the safety of an adenoviral vector encoding $VEGF_{121}$ in patients with disabling peripheral arterial diseases. Intramuscular injections of the adenoviral vector were performed in skeletal muscle of the lower limbs at sites of desired collateral formation. There was a favorable influence on lower-extremity endothelial function and flow reserve in 5 patients treated (47).

B. Prevention of Restenosis After Peripheral Angioplasty

In the adductor canal, the superficial femoral artery (SFA) is prone to stenosis and this represents one of the most common sites of peripheral arterial obstruction. Several postulates have inadequately explained this phenomenon. Percutaneous transluminal angioplasty (PTA) has been used widely and successfully to treat atherosclerotic obstructions in the peripheral and coronary circulations. However, high rates of restenosis following angioplasty of the SFA/popliteal artery continues to be a vexing, and consequently, expensive complication of this otherwise efficacious intervention. Although immediate procedural success for percutaneous revascularization of lesions in the SFA using conventional guide wires and standard PTA is well in excess of 90%, published reports have established that restenosis may complicate the clinical course of as many as 60% of patients undergoing PTA for SFA stenosis and/or occlusion. Previous strategies to limit the development of restenosis by nonmechanical means have not proved effective. Treatment strategies aimed at specifically restoring endothelial integrity have not been previously explored for restenosis prevention. Animal studies demonstrated that administration of mitogens, such as VEGF, which promote EC migration and/or proliferation, might achieve acceleration of reendothelialization and thereby reduce intimal thickening (48–51).

We therefore designed a phase 1, single-site, dose-escalating, open-label, unblinded gene therapy trial to accelerate reendothelialization at the site of PTA-induced endothelial disruption as a novel means to inhibit restenosis following PTA. The primary objective of this study was to document the safety of percutaneous catheter-based delivery of the gene encoding VEGF in patients with claudication due to SFA obstruction.

Arterial VEGF gene transfer has thus far been performed in 30 patients, 21 males and 9 females, with a mean age of 68 years. All patients had 2 or more cardiovascular risk factors. Gene expression was documented by a rise in plasma levels of VEGF. Peak plasma levels were recorded at a mean of 12 days following gene transfer. Mean claudication time increased from 2 min at baseline to 5 min up to 18 months post gene transfer. Prior to gene transfer, all patients were classified as Rutherford class 3. At 12 to 18 months following gene transfer, 15 patients were asymptomatic and 8 patients were class 1. After an initial improvement in 2 Rutherford classes following revascularization, 6 patients returned to class 3. One patient developed critical limb ischemia and required salvage therapy with intramuscular gene transfer of naked plasmid DNA encoding VEGF.

There was a significant and sustained improvement in ABI, post gene transfer compared with baseline. Prior to gene transfer, the mean ABI was 0.70, increased to 0.92 at 18 months after gene transfer, and was sustained at 0.91 at 48 months after gene transfer. SFA stenosis in 24 patients dropped from a mean of 94% at baseline to 30% at an average of 9 months following gene transfer. These results were supported by intravascular ultrasound (IVUS) findings at the time of follow-up angiography. Six patients had evidence of restenosis at angiography performed 6 to 12 months following gene transfer. Target vessel revascularization was required in all 6 patients. Histology from 3 of 4 patients undergoing directional atherectomy at the time of repeat revascularization for restenosis demonstrated active smooth muscle cell proliferation and

high levels of proliferating cell nuclear antigen, indicating extensive proliferative activity.

Thus, in the 30 patients that have been treated with arterial VEGF gene transfer for prevention of restenosis, VEGF expression has been documented by ELISA. At 48 months' follow-up, 6 of 30 patients (20%) required target vessel revascularization for angiographic and ultrasound evidence of restenosis. When compared with historical controls, at 6 months, restenosis rate was 20% in the gene transfer group, 29% in patients undergoing brachytherapy, and 55% in patients undergoing percutaneous angioplasty alone (52). This preliminary study has suggested that gene therapy designed to accelerate reendothelialization at the site of PTA-induced endothelial disruption can be safely performed. Importantly, no evidence of accelerated atherosclerosis or an increase in the restenosis rate was observed following gene transfer.

C. Myocardial Ischemia

For patients in whom antianginal medications fail to provide sufficient symptomatic relief, other interventions such as angioplasty or bypass surgery may be required. Although both types of intervention have been shown to be effective for various types of patients, a considerable group of patients may not be candidates for either intervention due to the diffuse nature of their coronary artery disease. Moreover, there are many patients in whom recurrent narrowing and/or occlusion of bypass conduits after initially successful surgery has left the patient again symptomatic with no further option for conventional revascularization.

For the purposes of myocardial angiogenesis, $VEGF_{165}$ recombinant protein has been administered via a wide variety of routes. Phase I studies of both intracoronary and intravenous injection of $VEGF_{165}$ recombinant protein in patients with symptomatic, inoperable coronary artery disease revealed encouraging improvements in anginal status as well as both rest and stress nuclear perfusion studies (53–55).

The Vascular endothelial growth factor in Ischemia for Vascular Angiogenesis (VIVA) study was a phase 2, double-blind, placebo-controlled, multicenter, dose-escalating trial of patients with angina and viable myocardium who were not optimal candidates for percutaneous or surgical revascularization. Patients randomized to the treatment group received intracoronary injections and 3 intravenous infusions injections of VEGF-1 protein (56–59). The doses used were 17 or 50 μg/per minute via intracoronary route for 20 min and intravenously for 4 h on days 3, 6, and 9. One hundred and fifteen patients received the recombinant VEGF and 63 patients received the placebo. Patients were followed up at 60 days, 120 days, and 1 year. At 60 days, there were similar increases in exercise time for both treatment and placebo group (approximately 45 sec). Similarly, there were similar decreases in angina and quality of life, and no change in perfusion studies. At 120 days, patients who received the high dose had a decrease in angina grade and a trend to increased exercise time. At 1 year follow-up, there were no statistical difference in the clinical and measured parameters, but there was a trend toward decrease angina class in patients receiving the VEGF-1 recombinant protein. Angiographic and single positron emission computed tomography (SPECT)–Sestamibi scan did not show any significant change in any group.

The VIVA trial demonstrated that hypotension was a significant limitation in the dose of recombinant VEGF that could be administered intravasculary. This complication of recombinant VEGF therapy was also seen in animal experiments performed in our laboratory using recombinant human VEGF ($rhVEGF_{165}$). Hypotension after systemic administration of recombinant VEGF is believed to be mediated by VEGF-induced release of NO (60). Similar results were reported from other groups using intracoronary injection in the pig and dog (61,62). Other routes of administration of VEGF (intramyocardial, periadventitial, and intravenous) have shown limited efficacy (61,63,64) likely due to an inability to administer a sufficient dose of the protein.

Accordingly, it has been hypothesized that local expression of VEGF for a protracted period of 2 to 3 weeks via gene transfer might circumvent the problem of symptomatic hypotension, yet still achieve a reduction in myocardial ischemia. VEGF gene transfer for myocardial ischemia has been performed in animal models both by using adenovirus vectors as well as by the administration of naked plasmid DNA. Intramyocardial injection of adenovirus encoding $VEGF_{121}$ via thoracotomy in a pig ameroid model improved collateral perfusion and function (65,66). Intracoronary adenoviral gene delivery produced much lower gene and VEGF levels in the myocardium with poor localization (66). Pericardial delivery of adenovirus encoding $VEGF_{165}$ in a dog model did not increase collateral flow (67).

Our center initiated a phase 1, dose-escalating, open-label clinical study to determine the safety and bioactivity of direct myocardial gene transfer of $phVEGF_{165}$ as sole therapy (i.e., without angioplasty, stenting, or bypass graft surgery) for myocardial ischemia. Patients with stable exertional angina refractory to medical therapy, areas of viable but underperfused myocardium on perfusion scanning, and multivessel occlusive coronary artery disease were selected. Preliminary results of this trial suggested that safe and successful transfection could be achieved by this method with a favorable clinical effect (68,69). Thirty patients with mean age of 63 years were selected. Twenty-nine out of 30 patients had coronary artery bypass graft (CABG) surgery, and all had suffered myocardial ischemia. All received $phVEGF_{165}$ administered by direct myocardial injection in 4 aliquots of 2.0 mL via a ''minithoracotomy''; total dose 125 μg ($n = 10$), 250 μg ($n = 10$), 500 μg ($n = 10$). By using a stabilizing device that facilitates vascular anastomosis during beating heart bypass an immobile field for intramyocardial injection was ensured. Continuous transesophageal echocardiographic monitoring was performed throughout the procedure to monitor development of wall motion abnormalities associated with injections and ensure that plasmid DNA was not injected into the LV cavity (70). No perioperative complications occured. There was no evidence of myocardial damage by cardiac enzyme analysis and patients maintained left ventricular function. Gene expression was documented by a transient but significant increase in plasma levels of VEGF monitored by ELISA

assay. All patients experienced marked symptomatic improvement and/or objective evidence of improved myocardial perfusion. At 360 days, 15 of 30 patients were free of angina. Specifically, sublingual nitrate use fell from 60 per week to 3 per week at day 360, accompanied by a significant reduction in episodes of angina from 56 per week to 4 per week at day 360. Exercise time for the group at 360 days had increased by 98 sec and exercise time to angina increased by 2.5 min over baseline. There were 2 late deaths (4.5 and 28.5 months), and 1 patient underwent a cardiac transplant at 13 months (69). Evidence of reduced ischemia on SPECT–Sestamibi myocardial perfusion scanning was documented in 22 of 29 patients with a significant reduction in both stress and rest mean perfusion/hemia score at day 60. In addition, 22 of 29 patients (76%) improved by 2 Canadian Cardiovascular Society (CCS) angina classes at 12 months, and 20 of 28 patients (71%) improved by equal or more than 2 CCS classes at 2 years.

It is intriguing to note that not only defects observed in the perfusion scans with pharmacological stress, but also those observed at rest, improved post gene transfer; sequential SPECT scans recorded before and after gene transfer demonstrated partial or complete resolution of fixed defects in 4 (33%) and 5 (43%) patients, respectively, in whom defects were present on the initial rest image. This is consistent with the notion that these preexisting defects constitute foci of hibernating viable myocardium that have resumed or improved contractile activity as a result of therapeutic neovascularization (71–73). This observation was supported by the findings of electromechanical mapping used in the final 13 consecutive patients. Resting perfusion defects on the SPECT images corresponded to areas with ischemic characteristics (reduced wall motion with preserved viability) on the endocardial maps. Foci of ischemia were identified preoperatively in all patients with significant improvement in these endocardial wall motion abnormalities at 60 days post gene transfer (74). This study provides the first evidence for a favorable clinical effect of direct myocardial injection of naked plasmid DNA encoding for VEGF as the sole therapeutic intervention.

A similar favorable experience was seen in an open-label, dose-escalating, multicenter clinical trial of VEGF-2 plasmid DNA in 30 patients with end-stage coronary artery disease and refractory class III or IV angina. Twenty-four male patients and 6 female patients with a mean age of 61 were selected. All had previous CABG, and all had sustained 1 to 2 episodes of myocardial ischemia. Their medical regimen included more than 2 antianginal medications. In all patients, there were no procedural adverse events, although there was 1 death 20 h after surgery. At 12 months following gene transfer, the mean number of anginal episodes and nitrate tablets consumed per week decreased significantly. By day 90, 21 of 30 (70%) patients improved by more than 2 CCS angina classes with an additional 4 patients (25 of 29 patients or 86%) with similar improvement at 360 days. The mean duration of exercise also increased by more than 2 min (Vale, et al., 2000, unpublished data).

The other reported study of direct myocardial VEGF gene transfer was with adenoviral-assisted $VEGF_{121}$ injection to patients undergoing bypass graft surgery ($n = 15$), and as sole therapy via minithoracotomy ($n = 6$). Symptoms and exercise duration improved in both bypass surgery and sole therapy groups, but stress-induced nuclear perfusion images remained unchanged. The data in this study are consistent with the concept that adenovirus $VEGF_{121}$ appears to be well tolerated in patients with advanced coronary disease.

The recently reported Efficacy and Safety of Gene Therapy in Patients with Advanced Coronary Artery Disease and No Options for Revascularization (REVASC) trial is the largest clinical trial in humans to date evaluating the efficacy of adenovirus mediated VEGF ($AdVEGF_{121}$) gene therapy for myocardial ischemia (75). In this phase 2, randomized, multicenter trial, 67 patients were randomized to receive $AdVEGF_{121}$ administered by direct intramyocardial injections via a limited thoracotomy or to continue with optimal medical management. At 26 weeks, time to ischemia on treadmill testing was significantly increased in the $AdVEGF_{121}$ vs. the medical therapy group ($P = 0.024$). There were significant improvements in anginal status as well as in several domains of the Seattle Angina Questionnaire in the $AdVEGF_{121}$ compared with the medical therapy group as well. Although these data are encouraging, there were 4 patients in the $AdVEGF_{121}$group that suffered cardiac complications due to the thoracotomy.

Each of the aforementioned studies has 1 major limitation: the need for thoracotomy for VEGF gene transfer. Thoracotomy has a small but real complication risk that can lead to substantial morbidity, particularly in patients with significant comorbidities. Furthermore, the strategy of gene therapy alone administered via a minithoracotomy does not permit randomization against placebo (untreated controls) or clinical testing of alternative dosing regimens, including multiple treatments.

Recent studies have suggested that a less invasive approach to gene transfer using a catheter-based delivery of naked plasmid $VEGF_{165}$ and VEGF-2 is effective in the pig (76). This less invasive approach to intramyocardial gene transfer has been shown to achieve suitable gene expression (76–79). Catheter-based myocardial gene transfer is performed using a previously described navigation system and catheter mapping technology (NOGA™) integrated with an injection catheter (Biosense-Webster, Warren, NJ), the distal tip of which incorporates a 27G needle to inject plasmid into the myocardium. To determine the safety and feasibility of catheter-based gene transfer, Vale et al. used this system to deliver naked plasmid VEGF to the myocardium of normal and ischemic swine (77). Results with methylene blue suggested safe, reliable, and reproducible targeting of endocardial sites. Injection of a reporter gene (pCMV-nls*LacZ*) demonstrated peak β-galactosidase (β-gal) activity in the target area with low-level to negligible activity seen in areas remote from the injection sites, suggesting relatively localized gene transfer. β-gal activity was greater in ischemic versus nonischemic myocardium indicating enhanced gene transfer in ischemic myocardium. Similar findings were demonstrated by a study using adenoviral-assisted gene transfer of a reporter gene (80). These results established that percutaneous myocardial gene transfer could be successfully achieved in normal and ischemic myocardium in a relatively site-specific fashion without significant morbid-

ity or mortality. The mapping capabilities of the NOGA system used in this study were useful for demonstrating that gene expression could be directed to predetermined left ventricle sites. This technique clearly may be advantageous for avoiding gene transfer to sites of myocardial scar, as well as relocating the tip of the injection catheter to areas of myocardial ischemia (or hibernating myocardium) where gene transfer will be optimized.

Subsequently, we initiated a pilot study of percutaneous, catheter-based VEGF-2 DNA gene transfer or a sham procedure guided by the NOGA mapping system in 6 patients with nonrevascularizable symptomatic myocardial perfusion (81). VEGF-2-transfected patients reported significant reduction in weekly anginal episodes and nitrate tablet consumption at 12 months post gene transfer. In contrast, although blinded patients randomized to the control group reported an initial reduction in these parameters, this changed clinical profile was not sustained past 30 days, suggesting that the continued reduction in angina in the VEGF-2-treated group was not a placebo effect. The symptomatic improvement was again accompanied by objective evidence of improved myocardial perfusion by both SPECT–Sestamibi perfusion scanning and electromechanical mapping (81). Although the clinical findings of this pilot trial concerning efficacy are similarly encouraging, the number of patients and the single-blind design preclude firm conclusions in this regard.

Consequently, a multicenter randomized, double-blind, placebo-controlled trial of catheter-based VEGF-2 gene transfer was initiated and results recently published. (82). Nineteen patients with chronic myocardial ischemia not amenable to percutaneous or surgical revascularization were randomized in a double-blind fashion to receive 6 injections of placebo or phVEGF-2. It was planned that 27 patients were to be randomized to receive gene or placebo in a 2:1 ratio. However, the study was interrupted by the Food and Drug Administration after 19 patients had been enrolled. Twelve patients received the gene product and 7 patients were randomized to placebo. A total of 114 injections were delivered through a steerable deflectable 8-french catheter with a 27-gauge needle guided by LV electromechanical mapping (NOGA). Perioperatively, there were no hemodynamic alterations, sustained arrhythmias, myocardial infarction, or ventricular perforation. There was a significant improvement in the CCS angina class at endpoint analysis at 12 weeks. Other endpoint analysis studied, including change in exercise duration, functional improvement in CCS by more than 2 classes, and Seattle Angina Questionnaire data showed strong trends favoring efficacy of phVEGF-2 compared with placebo treatment.

These preliminary experiences thus suggest that it is feasible to supplement or potentially replace currently employed operative approaches with minimally invasive techniques for applications of cardiovascular gene therapy designed to target myocardial function and perfusion. Such an approach may have at least 3 advantages compared with an operative approach. First, it potentially allows more selective delivery of the transgene to targeted ischemic zones, including sites that are less accessible by a minithoracotomy. Second, because it obviates the need for general anesthesia and operative dissection through adhesions resulting from prior surgery, the transcatheter approach facilitates placebo-controlled, double-blind testing of myocardial gene therapy. Third, the intervention can be performed as an outpatient procedure and repeated, if necessary.

D. Prevention of In-Stent Restenosis

Drug-eluting stents are expected to revolutionize interventional cardiology by reducing the incidence of in-stent restenosis from 30% to nearly 10%. However, the agents that have been studied to date as candidate drug coatings delay endothelial recovery. Prior studies have suggested that acceleration of endothelial cell formation following coronary stenting may attenuate the restenosis process. VEGF is a potent stimulator of endothelial cell recovery, and it has been hypothesized that a coronary stent coated with VEGF may have beneficial effects on prevention of stent thrombosis and prevention of in-stent restenosis. This hypothesis has been tested in a randomized fashion in the rabbit model of atherosclerosis (83). Fifty-four rabbits were treated with either an uncoated coronary stent or a stent coated with phVEGF-2 plasmid. At 3 months, the rabbits treated with the gene-coated stents had significantly larger lumen cross-sectional areas and a significantly smaller percent cross-sectional narrowing. In addition, there were increased numbers of EPCs and increased EC recovery (as assessed by NO production) in the rabbits treated with the gene-coated stents. Currently, a phase 1 trial is being designed for evaluating the safety of phVEGF-2-coated stents in humans. Alternative strategies at preventing restenosis are also being evaluated, including using a specialized infiltration catheter to directly deliver plasmid VEGF into coronary plaque prior to stenting.

VI. CARDIOVASCULAR TRIALS OF FGF PROTEIN AND GENE THERAPY

A. Peripheral Vascular Disease

Several investigators have shown improvements in muscle perfusion in animal models of hindlimb ischemia using recombinant FGF (84–86). The safety of intra-arterial bFGF administration in patients with intermittent claudication was recently demonstrated (87). In this phase I, double-blind, placebo-controlled clinical trial there was improvement in calf blood flow by strain gauge plethysmography in bFGF-treated patients at 6 months compared with controls. To date, the TRAFFIC study is the only clinical trial testing the efficacy of recombinant FGF in humans with peripheral vascular disease (88). A total of 190 patients with intermittent claudication were randomized to receive placebo, a single dose of FGF-2 (30 mcg/, or 2 doses of FGF-2. There was a trend toward patients receiving FGF-2 having increases in peak walking time at 90 days (0.60 min in placebo vs. 1.77 min in single-dose FGF-2 vs. 1.54 min in double-dose FGF-2, $p = 0.075$). There was no significant difference in adverse events between the 3 groups. The authors concluded that the increase in walking

time in patients receiving FGF-provided evidence that recombinant FGF-2 resulted in angiogenesis.

The first clinical trial in human subjects with peripheral vascular disease using FGF gene therapy was conducted on 51 patients with ischemic rest pain or tissue necrosis (89). This was a phase 1 evaluation of naked plasmid DNA encoding for FGF-1 (NV1FGF) administered via intramuscular injection. These patients were deemed to have severe obstructive lower-extremity vascular disease not amenable to mechanical revascularization. Patients received either escalating single dose or escalating double dose of NV1FGF. Overall, intramuscular injection of NV1FGF was well tolerated. Although there were adverse events, none were believed to be due to NV1FGF. Measurements of serum and plasma FGF-1 were made to assess gene expression. The distribution of plasmid in the plasma was limited, presumably due to destruction by endogenous endonucleases. There was no increase in serum FGF-1 levels. In the first 15 patients with completed 6-month follow-up, there was a significant reduction in pain and ulcer size as well as an increase in transcutaneous oxygen pressure compared with pretreatment values. There was also a significant increase in the ABI in these patients. This study confirmed the safety of NV1FGF for the treatment of inoperable lower-extremity peripheral vascular disease. The encouraging clinical results, however, need to be confirmed in larger, double-blind, placebo-controlled trials.

Presently, phase 1/2 clinical trials are ongoing in Europe to evaluate the safety and potential efficacy of FGF-4 delivered via an adenovirus vector (Ad5-FGF4) for the treatment of peripheral vascular disease. These are double-blind, placebo-controlled trials that will enroll up to 130 patients at 10 sites across Europe.

B. Myocardial Ischemia

A series of animal experiments have demonstrated that intracoronary and local delivery of FGF improves myocardial perfusion and function and increases collateral flow in myocardial ischemia (90–93). Several phase 1 trials have been performed to evaluate the safety of recombinant FGF-1 and FGF-2 for therapeutic angiogenesis in patients with myocardial ischemia (94–99). Each of these small studies showed reductions in anginal status, need for antianginal medications, and improvements in nuclear perfusion scanning. These studies, however, were limited by the fact that these patients were all scheduled for CABG surgery. Therefore, any potential applicability of these approaches would be limited to patients able to undergo thoracotomy. Intravenous and intracoronary administration of recombinant FGF-2 has also been evaluated in phase I studies of patients with symptomatic coronary artery disease with mixed results (100–102). Intravenous injection of recombinant FGF-2 was associated with improvements in anginal status, exercise time, and left ventricular function. However, intracoronary administration resulted in no change in exercise time or time to ischemia. Several patients experienced persistent hypotension for up to 3 days, conduction system disturbances, thrombocytopenia, and proteinuria.

The FIRST trial was a phase 2 that randomized 337 patients with inoperable coronary artery disease to receive either placebo, or 1 of 3 doses of intracoronary recombinant FGF-2 (103). The results of this trial did not show dramatic improvements in objective endpoints in patients receiving intracoronary FGF-2. The 90-day exercise time and stress nuclear perfusion results were not significantly different between FGF-2-treated patients and placebo-treated patients. There was trend toward improved anginal status in patients receiving intracoronary FGF-2, particularly in older and more symptomatic patients.

Results of these phase 1 and 2 trials again point to the potential shortcomings of recombinant protein therapy for therapeutic angiogenesis. FGF gene therapy in animal models of coronary ischemia has shown promise for therapeutic angiogenesis. In a chronic coronary occlusion animal model, human FGF-5 carried by an adenovirus vector (Ad5-FGF5) administered by intracoronary infusion resulted in sustained production of growth factors at 12 weeks, effective development of coronary collaterals, and relief of stress-induced ischemia (25,104).

Thus far, only 1 clinical trial in humans using FGF gene therapy for myocardial ischemia has been reported. Grines et al. conducted the Angiogenic Gene Therapy (AGENT) trial in which 79 patients with chronic stable angina (CCS class II and III) were randomized to receive placebo or 1 of 5 escalating doses of Ad5-FGF4 in a double-blind fashion (105). The Ad5-FGF4 was administered by a single intracoronary injection. Overall, patients receiving Ad5-FGF4 tolerated the infusion well with few immediate adverse events. One patient developed a fever during the first day after virus transfer and 2 patients had minor, self-limited elevations of liver enzymes. There were no significant differences in adverse events in patients receiving placebo and Ad5-FGF4 at a mean of 311 days of follow-up. Overall, patients receiving Ad5-FGF4 experienced a trend toward increased exercise times at 4 weeks. The trial prespecified a subgroup analysis in the 50 patients with baseline exercise times less than 10 min. There was a significant improvement in exercise time in this more symptomatic subgroup of patients in those who received Ad5-FGF5 (1.6 min vs. 0.6 min, $P < 0.01$). These data suggest that the intracoronary infusion of Ad5-FGF4 is safe and may be effective at improving hard clinical endpoints in patients with myocardial ischemia. Interestingly, in this study, patients enrolled were not ''no-option'' patients. The effects of intracoronary Ad5-FGF5 may be more dramatic in no-option patients. The true clinical value of this approach will be evaluated in future clinical trials designed to assess hard clinical endpoints.

VII. SAFETY CONCERNS REGARDING CARDIVASCULAR GENE THERAPY

Given that the inhibition of angiogenesis may be of value in the treatment of neoplasms, concern has been raised that the administration of angiogenic growth factors could lead to development of tumors. There are neither in vitro nor in vivo

data to suggest that either VEGF or FGF increases the risk of neoplastic growth and/or shmetastases, although longer-term follow-up will be required to address this issue in clinical trials. In our own experience with 88 subjects who have undergone VEGF gene transfer for CLI, the cumulative 7-year incidence of cancer has been limited to 2 patients with bladder cancer and 1 with liver and brain metastases from unknown primary (106). It was interesting to note that in the VIVA trial that there was a greater incidence of tumors in the placebo group compared with the VEGF group. This highlights the fact that the age group receiving such therapy will develop some unrelated tumors. Due to the theoretical risk of neoplastic growth, one must be vigilant about the possibility of cancer in patients treated with these angiogenic growth factors. In addition, concerns regarding the development of angiomata were raised in studies involving mice or rats treated with transduced myoblasts or supraphysiologic doses of plasmid DNA, respectively. Importantly, no other preclinical or clinical reports, including those using adenoviral vectors, have described this complication (107,108).

It is theoretically possible that VEGF may exacerbate proliferative and/or hemorrhagic retinopathy in patients with diabetes in view of the high VEGF levels demonstrated in the ocular fluid of patients with active proliferative retinopathy leading to loss of vision (109). To date, this adverse effect of therapeutic angiogenesis has not been observed. The local delivery of naked plasmid DNA encoding for VEGF-1 or VEGF-2 to more than 100 patients (one-third with diabetes and/remote retinopathy) treated at our institution with up to 4-year follow-up did not effect the visual acuity or fundoscopic findings as evidenced by serial funduscopic examinations pre- and post gene transfer by an independent group of retinal specialists.

Experiments in transgenic mice engineered to overexpress VEGF ± angiopoietin have demonstrated lethal permeability-enhancing effects of VEGF (110). However, even though VEGF has been reported to cause local edema, which manifests as pedal edema in patients treated with VEGF for CLI, it responds well to treatment with diuretics (44). As previously described, hypotension has been observed in therapies with recombinant proteins, particularly when used systemically and in higher doses (111,112). This is believed to be due to the fact that VEGF up-regulates NO synthesis. This complication, however, has never been described following gene transfer in either animals or humans (113,114).

Moulton et al. observed that when hypercholesterolemic, apolipoprotein E- deficient mouse models were treated with inhibitors of angiogenesis (endostatin or TNP-470), there were significant regression of plaque areas and inhibition of intimal neovascularization (115). This study with several other studies raised concern regarding the potential for VEGF and other proangiogenic therapies to promote atherosclerosis (92, 116,117). However, data available from 4 separate animal studies and 2 clinical studies of human subjects fail to support the notion that accelerated atherosclerosis is a likely consequence of administering angiogenic cytokines (48–51, 118,119). The outcome is quite the opposite, in that administration of VEGF led to a statistically significant reduction in intimal thickening due to accelerated reendothelialization, thereby refuting the notion that acceleration of atherosclerosis will be a consequence of VEGF-induced stimulation of angiogenesis.

VIII. CONCLUSIONS

The preliminary effectiveness of gene therapy for therapeutic angiogenesis in patients with critical limb and chronic myocardial ischemia are both encouraging and promising. The different trials using angiogenic protein and transgenes encoding for VEGF and FGF attest to the safety and effectiveness of these strategies. The current clinical strategies employed for CLI and chronic myocardial ischemia constitute an extrapolation from initial applications of gene transfer to animal models with limb ischemia. These results, however, likely have generic implications for strategies of therapeutic neovascularization using alternative candidate genes, vectors, and delivery strategies. Preclinical data supporting the use of other VEGF-1 isoforms (120), as well as other VEGF genes (121), has been previously reported as having preclinical studies using FGF (25,122); all these are being actively studied in ongoing clinical trials. Furthermore, the relative merits of gene transfer vs. recombinant protein administration remain to be clarified.

The otherwise negative primary endpoint results of the VIVA and FIRST studies using intracoronary ± intravenous protein administration underscore the concern that the pharmacokinetics of recombinant protein administered into the vascular space may lead to inadequate local delivery of angiogenic growth factor within the ischemic myocardium. Additional investigations comparing doses of recombinant protein and routes of delivery will be required to resolve this issue. Until these studies are complete, the ideal method of achieving therapeutic angiogenesis remains unknown. In addition, results of phase 1 studies, designed by definition to assess safety, must be interpreted with caution. Typically, the number of patients enrolled in such trials is relatively small, and for those lacking a control group, a placebo effect cannot be excluded. For studies in which recombinant protein or gene is administered in conjunction with conventional revascularization, it may be difficult to determine the relative contributions of the angiogenic agent vs. bypass surgery to the symptomatic response.

It is clear, however, that site-specific VEGF gene transfer can be used to achieve physiologically meaningful therapeutic modulation of vascular disorders and specifically that IM injection of naked plasmid DNA achieves constitutive overexpression of VEGF sufficient to induce therapeutic angiogenesis in selected patients with critical limb ischemia. Of note, there was no evidence of immunological toxicity neither in our intra-arterial animal studies, nor our human clinical experience using naked plasmid DNA encoding for VEGF. Furthermore, at this early stage of clinical trials into myocardial gene therapy, it has been shown that direct myocardial gene

transfer using different doses of naked plasmid DNA encoding for $VEGF_{165}$ and VEGF-2, as well as intracoronary FGF-5 carried by an adenovirus vector, can be performed safely with augmentation of myocardial perfusion. The catheter-based delivery of plasmid DNA is an attractive and safe option. In terms of safety, no operative complications and no aggravated deterioration in eyesight due to diabetic retinopathy (123) have been observed in patients treated with $phVEGF_{165}$ gene transfer. With specific regard to mortality, it should be noted that the cumulative mortality for the 85 patients with class 3 or 4 angina undergoing operative or percutaneous naked DNA gene transfer of VEGF-1 or VEGF-2 has been 3 of 85 or 3.5% at up to 33 months follow-up. This compares favorably with an average 11% to 13% 1-year mortality for a similar group of almost 1000 patients receiving laser myocardial revascularization or continued medical therapy in 5 contemporary controlled studies (124–128). Ongoing clinical studies will determine the potential for neovascularization gene therapy to be performed by nonsurgical, catheter-based delivery, although early results are encouraging from a therapeutic standpoint.

For the most part, clinical studies of therapeutic angiogenesis have been restricted to patients with myocardial or limb ischemia who have no other options. Although this is the group to target in the near future, it is not difficult to foresee a time when a significant populations of patients who undergo bypass surgery but are not optimal candidates for that procedure may be eligible for therapeutic angiogenesis. The latter might be performed at an earlier stage of disease, and the potential for repeat treatment may translate in a greater possibility of a successful outcome.

Selectively Replicating Adenoviruses: Clinical Experience with Onyx015 and Future Directions

Leonard E. Post
Onyx Pharmaceuticals
Richmond, California, U.S.A.

I. INTRODUCTION

As reviewed elsewhere in this volume, (Chap. 2), adenoviruses have proven to be one of the most promising gene delivery vectors, at least partly because of the highly efficient mechanism for cellular entry and delivery of DNA to the nucleus. Even with this most efficient of delivery systems, however, it is unrealistic to expect that biodistribution of adenovirus will be adequate to infect a high percentage of cells within a tumor. If delivered locally, physical barriers within a tumor will inevitably prevent uniform infection of the entire tumor; if delivered via the vasculature, the most efficient delivery will be to perivascular cells. One way to address the limited number of cells that can be infected has been to use adenoviral vectors containing transgenes that can kill cells that have not received the transgene, but are nearby cells that have the ''bystander effect.'' Even with genes that have a good bystander effect, the biodistribution of intravenous adenovirus primarily to liver and the reticuloendothelial system [reviewed in (1)] implies that a small fraction of virus gets to a tumor, so that dosed vector is unlikely to deliver genes to enough cells for efficacy.

An approach to address these limitations is the construction of adenoviral vectors that replicate selectively in tumors. After infection of the cells accessible to the dosed virus, the replication of the vector produces progeny virus, which then infects more cells and spreads further in subsequent rounds of infection. If the replicating and spreading virus contains a transgene, that gene is delivered to all the infected cells. This approach is quite different from the goals of most gene therapy vector designs because the cells that support replication are killed. Although that is exactly the desired endpoint in cancer therapies, it is just the opposite from the usual goal in gene therapy, which is to leave a healthy cell containing a therapeutic gene.

For replicating vectors to be a safe way to delivery genes to tumors, there must be a basis for selectivity in that replication. A fundamental insight by McCormick (2) was that adenovirus inactivates some of the same cellular pathways for its replication as are inactivated in carcinogenesis, so the viral functions that inactivate these pathways are nonessential in tumor cells where the pathways are already inactivated. This led to the development of Onyx015, the first selectively replicating adenovirus to enter clinical development. This chapter reviews the clinical development of Onyx015. Because there are other excellent reviews on this subject (3–5), this chapter focuses on more recent results and their implications for the future of selectively replicating adenoviruses.

II. ONYX015: SELECTIVITY FOR P53-DEFICIENT CELLS

The adenovirus E1B55K protein has several functions, among them the inactivation of p53. In normal cells, this is essential for efficient replication, where the early functions of adenovirus would lead to accumulation of active p53 in the absence of the E1B55K function [reviewed in (3)]. Accumulation of active p53 would lead to cell-cycle arrest and/or apoptosis, aborting the virus infection. When the E1B55K degrades p53, the virus infection can proceed and produce progeny virus. In cancer cells with p53 mutations, the degradation of p53 is not essential and E1B55K is not essential. This insight led to the first publication of a selectively replicating adenovirus, Onyx015 (2), originally called dl1520 (6).

After the original publication there was controversy about the mechanism for Onyx015 selectivity. There were examples

of cancer cells with wild-type 53, which supported replication of Onyx015, and cancer cells with mutant p53, which did not support replication. The issue of p53 positive cell lines supporting replication of Onyx015 was settled by Reis et al. (7), showing that p14arf mutant cell lines would also support replication of Onyx015. In cells with mutant p14arf, the activation of p53 in response to adenovirus infection does not occur, allowing virus replication. Because many wild-type p53 cancer cells do contain p14arf mutations, this discovery not only clarified the p53 selectivity of Onyx015, but also established a basis for broader application of Onyx015 in tumors with mutant and wild-type p53 genes.

To address the issue of p53 mutant and p14arf mutant cell lines that do not support replication of Onyx015, one must recall that E1B55K has other functions beyond inactivation of p53. It is needed for shut-off of host protein synthesis and for efficient expression of late viral genes (8). Apparently this function of E1B55K is essential in some but not all tumor cells, and some tumor cells have a function that can complement the missing functions of E1B55K. Recent results suggest that through various physical and pharmacological manipulations, it is possible to make many tumor cells that poorly support replication of Onyx015 do so efficiently (F. McCormick, personal communication, 2003), and thereby increase the utility of Onyx015 even further.

The selectivity of Onyx015 is sufficient to result in an excellent safety record after administration to over 300 cancer patients. This clinical development history is the subject of the remainder of this chapter.

III. CLINICAL DEVELOPMENT OF ONYX015: LOCAL/REGIONAL APPLICATIONS

Because of the limitations on biodistribution of adenovirus and the need for a pioneering product like Onyx015 to proceed cautiously in early clinical development, the initial clinical trials of Onyx015 were done by direct intratumoral injection. This clinical development program has been reviewed by Kirn (4,5).

The indication most extensively explored by intratumoral delivery of Onyx015 has been head and neck cancer. These studies have been published in four papers (9–12). In these studies, electron microscopic evidence was obtained for virus replication in tumor cells, and not in normal cells. Clinical activity was demonstrated by shrinkage of tumors. However, in the monotherapy trials, the responses were generally short. This led to a trial of Onyx015 in combination with 5FU/cisplatin, a standard chemotherapy for head and neck cancer (10). Preclinical data indicate that Onyx015 plus chemotherapy would have benefit over either treatment alone (13). Because this was a single-arm trial and was conducted in a patient population where some would be expected to respond to the chemotherapy alone, definitive proof of the combination activity was not obtained from this study. However, comparison with historical results, and shrinkage of virus-injected tumors but not uninjected tumors (which were also exposed to the same systemic chemotherapy) in some patients, led to the conclusion that this trial suggested activity of the combination of Onyx015 and chemotherapy.

A study was also conducted in oral leukoplakia, a premalignant condition that can progress to squamous cell carcinoma. Mutations in p53 are often detected in these lesions (in 45% of cases), which suggested that they might be susceptible to Onyx015. In this study, Onyx015 was administered as a mouthwash, in which the patients rinsed and held the virus solution for up to 30 min. In a preliminary report (14), 4 of 19 evaluable patients achieved complete histological resolution of dysplasia, and the grade of dysplasia improved in 3 additional patients. This result is encouraging that Onyx015 may have a role in treatment of premalignant lesions before progression to malignancy.

Several other studies have given Onyx015 via intratumoral injection. Pancreatic cancer has been treated by both percutaneous injection (15) and by endoscopic ultrasound guided delivery (16). Hepatobiliary cancer patients were treated with Onyx015, with report of one partial response in a patient with cholangiocarcinoma (17). An encouraging observation in the latter study was that half (8 of 16) of the treated patients had a greater than 50% reduction in tumor markers associated with a period of radiographic stable disease. Habib et al. (18) administered dl1520 via percutaneous injection to 5 hepatocellular carcinoma patients and reported 1 partial response. Onyx015 has also been delivered via intraperitoneal injection in treatment of ovarian cancer (19).

Evidence for viral replication after intratumoral administration has been obtained in various studies by electron microscopy, in situ hybridization, and circulating viral DNA. These data across the various studies have been comprehensively reviewed by Kirn (5).

IV. INTRAVASCULAR DELIVERY OF ONYX015: HEPATIC ARTERY DELIVERY

The first intravascular treatment with Onyx015 was via catheter into the hepatic artery in a phase I/II trial design. The dosing schedule was first to give Onyx015 alone in 2 doses 1 week apart. Then starting 2 weeks later, cycles of Onyx015 plus bolus 5FU/leucovorin were given every 4 weeks.

This study involved a dose escalation, starting at 2×10^8 viral particles per dose, to a top dose of 2×10^{12} particles per dose. The phase I dose escalation portion of the trial did not find a dose-limiting toxicity, and the most common adverse events reported were fever, rigors, and fatigue (20). This was followed by the phase II portion of the trial, in which 27 patients were treated at the top dose of virus on the same schedule as the phase I portion of the study (21). This expanded group of patients also demonstrated an excellent safety profile of Onyx015, with the flulike symptoms being the most common adverse events. These symptoms were consistent with the observed elevation of the proinflammatory cytokines (tumor necrosis factor-α, interferon-γ, and IL6). The occasional observations of elevated transaminases or hyperbilirub-

inemia were either judged due to disease progression, or transient and not considered dose limiting. An independent study also administered dl1520 at a dose of 6×10^{12} viral particles per dose via the hepatic artery to 7 patients, and also concluded that the virus could be safely administered by this route (22).

An important conclusion from this study was the measurement of viral DNA circulating in plasma by quantitative polymerase chain reaction. After dosing, the circulating viral DNA had a short half-life (12 min), and was reduced below or to the level of detection by 6 h. Five patients were reported to have circulating viral DNA reappear on days 4 to 5 at levels over 10-fold above the level of detection (22). This reappearance of circulating viral DNA after complete clearance of the input dose from circulation is taken as strong evidence for virus replication. Unfortunately, the quality of available biopsy material did not allow for direct microscopic evidence of virus replication in this trial.

Because this was a single-arm trial in combination with chemotherapy, there are limitations on conclusions about efficacy. However, tumor shrinkage was reported in 3 patients who were refractory to 5FU-based chemotherapy regimens (22). Furthermore, the investigators made the intriguing observation that patients receiving doses of at least 6×10^{11} particles had a median survival of 359 days, compared with 155 days for the patients receiving lower doses (23).

With the strong evidence for viral replication and suggestion of clinical efficacy, this trial provided an important observation for the development of selectively replicating adenoviruses as cancer therapeutics: virus delivered via vasculature can infect a tumor and result in productive infection and clinical activity.

V. INTRAVENOUS DELIVERY OF ONYX015

The experience with Onyx015 has provided a number of encouraging signs that this virus can be used for local-regional treatment of cancer. Although there are significant cancers that are amenable to local therapy, a large number of cancer patients need a systemic therapy that can address metastatic disease. Intravenous delivery of adenovirus results in distribution of most of the dose to the liver and spleen (1). Because Onyx015 can replicate in the tumor cells, if a small amount of virus dose reaches a tumor it should be possible to mount an infection.

The first intravenous trial of an oncolytic adenovirus was a 10-patient study conducted with Onyx015 by Nemunaitis et al. (24). This study involved dose escalation from 2×10^{10} to 2×10^{13} viral particles per dose. The virus as administered every 3 weeks, in combination with carboplatin and paclitaxel. No dose-limiting toxicity was achieved with these doses of virus, with the most common adverse events being fever, rigors, and transient transaminitis. Nemunaitis conducted treatment of an additional 10 patients with Onyx015 in combination with CPT11 and with IL2 (25). A trial of intravenous Onyx015 monotherapy was also conducted by Hamid et al. (26) in 18 patients with metastatic colorectal cancer. Habib et al. (22) reported safe treatment of 3 patients with intravenous dl1520.

In all these reports, the dosed Onyx015 was rapidly cleared from circulation. One of the patients treated by Hamid et al. (22) died from a treatment-unrelated cause 56 h after dosing, and autopsy results demonstrated that most of the viral DNA was found in the spleen and liver. However, in several of the patients in each intravenous Onyx015 study, there was viral DNA detected in plasma at 3 days after dosing at levels above what was detected after clearance. This is suggestive of viral replication. Furthermore, Nemunaitis et al. (25) obtained electron microscopic evidence of viral replication in a tumor biopsy sample.

Safety and evidence for viral replication after intravenous administration has also been reported with 1 other selectively replicating adenovirus, CG7870 (27). This virus is selective for prostate cells because of prostate-specific promoters controlling E1A and E1B.

Although there is evidence for viral DNA replication, no objective clinical response has been reported with intravenous Onyx015. Coupled with the evidence that local Onyx015 can have clinical activity, the conclusion is that, although intravenous virus does reach the tumor and replicate, there is insufficient virus and insufficient replication to produce a clinical response. An intriguing observation by Hamid et al. (26) was that the patients with plasma viral DNA evidence of replication were the ones with very low titers of adenovirus-neutralizing antibody before dosing. This suggests strategies to blunt development of neutralizing antibodies (e.g., 28) may increase the efficiency with which intravenous Onyx015 reaches the tumor on repeated dosing. Formulation of the virus to protect it from the activity of neutralizing antibodies may also address this issue (29).

VI. SELECTIVELY REPLICATING ADENOVIRUSES AS VECTORS FOR GENE THERAPY

Important future applications of Onyx015 and other selectively replicating adenoviruses are as vectors to deliver genes to tumors. The replication and spread of Onyx015 will enable delivery of an inserted gene to more cells than the initial dose reaches. An important consideration is that there would be little benefit to using a replicating adenovirus to deliver a gene that would kill or correct a defect in an infected cell because the infected cell is destined to die from the lytic infection. The goal using the virus as a vector would be to deliver a gene with a ''bystander effect'' (i.e., ability to kill surrounding uninfected cells). This may be important if there is a subpopulation or cells in the tumor that are not susceptible to virus infection.

The first clinical example of a replicating viral vector delivering a transgene was recently published by Freytag et al. (30). These investigators constructed a derivative of dl1520 in which a fusion gene of herpes simplex virus thymidine kinase (TK) and *Escherichia coli* cytosine deaminase (CD) is

expressed from the cytomegalonirus immediate early promoter, inserted into the E1B55K region of the viral genome. The TK gene product can convert ganciclovir to its toxic phosphorylated metabolite, and CD can convert 5-fluorocytosine to the cytotoxic 5-fluorouracil. The study involved dose escalation from 10^{10} to 10^{12} viral particles given by intraprostatic injection, in 16 patients with locally recurrent prostate cancer. A 1- or 2-week course of ganciclovir plus 5FC was begun 3 days after virus injection. Prostate biopsies taken 2 weeks after virus injection showed evidence of expression of the transgene in 4 of 12 patients, and evidence of necrosis of the tumors. Encouraging was a drop in serum levels of prostate-specific antigen of at least 25% in 7 of 16 patients, and of at least 50% for at least 4 weeks in 3 of the patients. Two of the patients were free of adenocarcinoma on biopsy 1 year after treatment.

A further refinement of the use of a replicating adenovirus vector comes from insertion of the transgene under late viral transcription control (31). Late genes are expressed only after DNA replication and are not expressed efficiently by Onyx015 in normal cells. This results in selective expression of an inserted transgene in cancer cells where the virus replicates. The use of replicating viruses as vectors using this technology have been reviewed by Hermiston and Kuhn (32)

VII. PROSPECTS FOR THE FUTURE

The clinical experience with Onyx015 points to several directions for its development as a local-regional therapy. Evidence for efficacy in head and neck cancer, metatstatic colorectal cancer, and oral leukoplakia support further development. Signs of activity in other diseases such as hepatocellular carcinoma and cholangiosarcoma are also encouraging. Whether Onyx015 can be used for systemic treatment of cancer depends on finding ways to enhance the activity (either delivery of a greater fraction of virus dose to the tumor, or greater replication of the virus that is delivered to the tumor) beyond what was seen in the early intravenous trials.

Use of Onyx015/dl1520 as a vector has been shown to be feasible in both preclinical (31) and clinical (30) studies. This approach may increase the anticancer efficacy of the viruses sufficiently to give systemic efficacy.

A second-generation virus, Onyx411 (33), is selective for tumors defective in the retinoblastoma pathway. This virus has a combination of features that may improve intravenous activity, including greater replication than Onyx015 in many tumor lines, and an early and very tight block in replication in normal cells. The result is that insertion of genes into this virus under late transcriptional control is even more highly selective for tumor cells than when Onyx015 is used as a vector (34; Y. Shen, unpublished data, 2003). Although showing a promising safety and efficacy profile in mice, Onyx411 or its derivatives have not yet been tested in patients.

The scope of this chapter was to review the clinical experience with Onyx015. Readers should note that there are now a variety of creative approaches for engineering adenovirus and other viruses for selective replication in tumors. The broader field of oncolytic viruses was reviewed by Chiocca (35), and some approaches of enhancing systemic delivery of adenoviruses were reviewed by Green and Seymour (1).

With the excellent prospects for Onyx015 as a cancer therapeutic and second-generation viruses that may broaden the scope of disease treatable with oncolytic viruses, it seems highly probable that selectively replicating adenoviruses will become a new method of cancer treatment. The potential for selective amplification and expression of therapeutic genes in tumor cells makes these viruses a promising platform for cancer gene therapy.

ACKNOWLEDGMENTS

The author wants to acknowledge all the clinical investigators who have brought Onyx015 to their patients, and by doing so established selectively replicating viruses as a promising new possibility for the treatment of cancer. Particular thanks go to Scott Freeman, Tony Reid, and John Nemunaitis for many useful discussions.

Gene Therapy for the Treatment of Cancer: From Laboratory to Bedside

Raphaël F. Rousseau, Ettore Biagi, Martin Pulé, and Malcolm K. Brenner
Baylor College of Medicine
Houston, Texas, U.S.A.

I. STRATEGIES OF GENE TRANSFER FOR THE TREATMENT OF CANCER

Since the 1970s, a multidisciplinary approach combining surgery, chemotherapy, and radiation has lead to a dramatic improvement in survival for patients affected by malignant diseases. Cellular therapies, such as stem cell transplantation, have also made a significant contribution. Nonetheless, many patients are still resistant to standard therapies, which also have high and often unacceptable acute and chronic organ toxicity, with an increased risk for secondary malignancies. Therefore, new strategies are needed to improve overall survival and decrease treatment-associated morbidity.

Several approaches may be considered to incorporate gene transfer techniques in the clinical arsenal against cancer:

1. *Modification of tumor cells*, by repairing genetic defects believed to be responsible for tumoral proliferation, for example, by restoring genes controlling cellular division or that induce programmed cell death (apoptosis).
2. *Sensitization of normal tissues or tumor cells in order to modify their therapeutic index*, by introducing into the tumor cells genes encoding for an enzyme that can transform a nontoxic prodrug into an active drug, or by introducing genes into normal tissues that can protect them against the effects of antitumor toxic drugs.
3. *Modulation of tumor invasiveness*, by delivering genes that can inhibit the growth of new blood vessels to impede nutrient supply to the tumor cells (inhibition of neoangiogenesis).
4. *Enhancement of the antitumor immune response*, either by inducing the recognition of tumor cells by the host's immune system or by enhancing the cytotoxic function of immune effectors.
5. *Gene marking*. Even though gene marking is not a therapeutic intervention per se, this approach has helped investigators to understand the behavior and outcome of transduced cells once administered back to the patient. This strategy is discussed elsewhere in this book (See Chapter 44).

This chapter describes the strategies currently used in patients with cancer, with a particular emphasis on the use of gene transfer to improve the recognition of tumor cells by immune effectors.

II. MODIFICATION OF TUMOR CELLS

Progress made in the understanding of molecular aberrations has allowed a much better characterization of the different steps leading to cancer. Many of these aberrations alter key regulatory, survival, and differentiation steps of the normal cell cycle. Other aberrations lead to the production of abnormal fusion products, with subsequent gain or loss of critical functions of the cellular cycle.

In theory, gene therapy could be used to replace an inactive gene with an active one or to neutralize an abnormal function gained by a mutated gene. Inactivation of regulatory genes frequently induces tumor cell growth. For example, mutations of the p53 gene have been identified in numerous tumor models. The exact role of the wild p53 gene has not been totally identified, but its product suppresses the expression

of genes involved in cellular proliferation and may induce proapoptotic genes. Restoration of the activity of the p53 gene in p53-mutated or -deficient tumors may stop uncontrolled cell growth (1) or induce apoptosis (2). Several strategies using adenoviral (3), retroviral (4), or nonviral (5) p53 gene transfer have tested this hypothesis in preclinical tumor models (6). Clinical trials have demonstrated the potency of p53 gene transfer in hepatocellular (5), head and neck (7), and lung carcinomas (8). Objective clinical responses, including transient tumor regression, were observed in this last trial and are described elsewhere in this book (see Chapter 38). Likewise, alterations of p16 have been described in squamous head and neck carcinomas, and approaches similar to those developed for p53 mutations are underway (9).

Many other oncogenes or aberrant fusion transcripts are involved in the tumorigenic process. These oncogenes or their products are the targets of several therapeutic strategies that aim at restoring their normal function either to stop anarchic cell growth or to induce apoptosis. Oncogenes from the *ras* family (H-*ras*, N-*ras*, and K-*ras*) are activated by a simple point mutation (10). It has been possible in a lung cancer model to block the mRNA of a mutated K-ras gene and subsequently prevent the secretion of the altered protein and delay tumor cell growth in vitro and in vivo (11,12). Similar approaches have been tested to block the effects of *fos* oncogene in a murine model of mammary tumor using a retroviral vector (13). Other methods using ribozymes (14) (see Chapter 18), antisense RNA (15,16) (see Chapter 19), or intracellular antibodies (17) have shown promising results, but are too preliminary to envision clinical applications in the near future.

Numerous difficulties must be overcome before tumor correction strategies can be successful in a clinical trial. For example, first, it will be necessary to get a corrective gene into an extremely high proportion of malignant cells, although it has been suggested that there is some form of uncharacterized ''bystander'' effect on nontransduced tumor. Second, targeting metastases will usually be necessary. Third, correction of a single defect may be inadequate to actually kill the tumor cells, leaving instead a collection of ''*n*-1 cells'' (where *n* is the number of mutations required for malignancy to occur) capable of undergoing another mutation to restart the malignant process.

Hence, exploitation of the tumor correction strategy will require significant improvements in vector efficiency and targeting, and until these come to pass, the development of novel rationally targeted small molecules will likely dominate this approach.

III. SENSITIZATION OF NORMAL TISSUES OR TUMOR CELLS

A. Prodrug-metabolizing Enzyme

Introduction of a gene encoding an enzyme that metabolizes an otherwise inert molecule into a cytotoxic agent has frequently been used in tumor gene therapy. Although the herpes simplex thymidine kinase (HSV-Tk)-ganciclovir system has been most widely applied, there are more than 20 such prodrug-metabolizing enzyme (PDME) systems currently in various stages of development and/or clinical trials (18,19). For these, the concept is that the gene encoding the PDME is expressed in the cancer cell and metabolizes a small molecule to an active moiety, which then kills the tumor cell directly. The molecule may also diffuse either through intercellular gap junctions or in the extra cellular space and destroy adjacent tumor cells. In this way, transduction of even a small proportion of tumor cells can produce a large ''bystander'' effect on adjacent tumor tissue. This in turn compensates for the low efficiency of transduction achieved by currently available vectors and may help to destroy a large tumor burden.

Brain tumors were an attractive initial target for PDME gene therapy. Because the tumors seldom metastasize, the goal of the therapy is the local eradication of the tumor. Hence, the major limitation of PDME—that it requires local inoculation of a tumor with the vector encoding the gene—does not represent a major disadvantage. A number of adult studies have been performed (20) using retroviral and (more recently) adenoviral vectors (21). Twelve children with recurrent or progressive supratentorial brain tumors were enrolled, and after tumor resection, they were treated with instillation in the tumor bed of retroviral producer cells generating particles encoding HSV-Tk followed by ganciclovir administration (22). Unfortunately, disease progression was seen in 10 of 11 patients, although 1 patient remained free of progression for 18 months.

More recently, a study has been performed on patients with retinoblastoma (23,24), which is also a highly localized tumor that is conventionally treated by enucleation and/or chemoradiotherapy. Enucleation is obviously disabling and deforming, and if the tumor is bilateral it leads to blindness. The alternatives of chemotherapy and radiotherapy are less mutilating but are both associated with secondary malignancies. In a study at Baylor College of Medicine, Hurwitz and colleagues injected bilateral retinoblastomas with adenovirus (Ad) type 5 encoding the thymidine kinase gene, followed by administration of ganciclovir. Three of the first 5 patients showed substantial tumor responses with the Ad Tk and are disease free, with retained vision, at up to 1-year post therapy (25). This trial is now accruing patients with monolateral retinoblastoma.

Other suicide gene therapies are being evaluated. Among the most developed of these is the cytosine deaminase system, which converts fluorocytosine to fluorourosil (26). There are, however, concerns that this suicide system may be less potent than the Tk-ganciclovir prodrug system. Other molecules that metabolize drugs or trigger apoptotic pathways within tumor cells are also being considered. Perhaps the most important future trend is to attempt to enhance the bystander effect. At present this is mediated predominantly by transfer of the small molecule cytotoxic drug from cell to cell. However, it is apparent that at least part of the bystander effect is dependent on an immune response generated to the lysed tumor. Hence, the bystander effect in immunocompromised animals has been observed to be substantially less than in those with intact im-

mune systems. Investigators are now attempting to combine PDME genes with sequences encoding a variety of immunostimulatory molecules (see Section V.E.1), including but not limited to interleukin 2 (IL-2) IL-12, and granulocyte-macrophage colony-stimulating factor (GM-CSF) (27–31). Data from these studies are yet to be evaluated. Efforts are also being made to generate vectors, which can selectively divide in malignant cells (conditionally replication-competent vectors; see Chapters 3 and 38) and may therefore spread their encoded PDME genes throughout the tumor bed (32).

PDME has also effectively been used as a means of controlling T cell therapies. For example, graft vs. host disease (GvHD) may occur when donor T cells are given to patients after allogeneic stem cell transplantation in an effort to treat tumor relapse (graft vs. tumor effect) or posttransplant infections. Several groups have infused donor T cells transduced with the HSV-Tk gene and reported successful abrogation of GvHD after treatment with ganciclovir (33–36). More recently, efforts have been made to induce expression of the death signal Fas in donor T cells. An inducible construct is used in which Fas expression occurs only in the presence of an orally administered small molecule (rapamycin or its analogs) that dimerises 2 individually inactive components of a Fas transcriptional regulator, leading to expression of the Fas receptor and cell death on exposure to the ligand (37).

As T cell therapies for cancer become more widespread, these suicide mechanisms will become extremely important in ensuring that the regimens are acceptably safe.

B. Cytotoxic Drug-resistance Gene Transfer

The concept of dose intensification has long been current in modern oncology, including pediatric oncology. In other words, it is believed that giving more of a cytotoxic drug over a longer period will cure a higher proportion of patients. Although there are many obvious exceptions to this rule, for many pediatric malignancies it is clear that failure to tolerate chemotherapy in the intended doses correlates well with an increased risk of relapse. For that reason, there is an interest in using genes, which will protect normal tissues while leaving malignant cells vulnerable to destruction. By increasing the therapeutic index in this way, it is hoped that more drug can be administered and a higher percentage of patients cured.

There are many different candidate drug-resistance genes to be transferred, but perhaps the most widely studied is the human multidrug resistance-1 (MDR-1) gene. The gene product acts as a drug efflux pump and prevents accumulation of toxic small molecules, including a range of cytotoxic drugs such as mitoxantrone and daunorubicin. The primary toxicity of many of these cytotoxic drugs is on hematopoietic progenitor cells. Retroviral-mediated gene transfer of drug-resistance genes into hematopoietic stem cells has until recently been difficult to accomplish. The incorporation of fibronectin together with hematopoietic growth factors into the transduction regimen, together with repeated cycles of gene transfer, has allowed a significant proportion of hematopoietic cells to be protected with expression levels adequate to reduce the sensitivity of these stem cells to chemotherapeutic agents (38). Several other drug-resistance genes are currently under study and may soon join MDR-1 in clinical trial. These include the bacterial nitroreductase gene, which protects against drugs such as thiotepa, (39) and dihydrofolate reductase mutants, which protect against methotrexate/trimetrexate (40).

There are 2 major problems with using transfer of drug-resistance genes. The lack of targeting of current vectors means that they may transduce malignant cells and normal cells, and therefore increase the resistance of both to the cytotoxic drug. Moreover, although it may be possible to protect a significant proportion of marrow stem cells, secondary toxicities to other organ systems such as skin, lung, and gut will rapidly become evident as doses are escalated because these tissues are much less readily protected than hematopoietic stem cells.

IV. ANTIANGIOGENESIS GENE THERAPY

Because angiogenesis is a prerequisite for the development of metastatic disease for solid tumors, and probably also for leukemias and lymphomas, an attack on newly formed blood vessels may help to impede the spread of disease. A number of different large and small molecule inhibitors are currently under study, and some of these are suitable for a gene therapy approach (41). For example, endostatin, a 20-kd fragment of collagen XVIII can efficiently block angiogenesis, but the recombinant protein is difficult and expensive to produce and is somewhat unstable. Delivery of endostatin in murine tumor models by several different vector systems has been able to overcome this limitation and has proved extremely promising (42–44). Similarly, angiostatin, a fragment of plasminogen, also functions as a large molecule inhibitor of vessel growth and impedes metastastic tumors. This too can be transferred (e.g., by adeno-associated virus vector) to produce benefit in animal models of malignant brain tumors (45,46).

Much remains to be learned about the most appropriate route and cell of delivery of angiogenesis inhibition, but as with any protein-based therapeutic, gene transfer should allow a continual delivery of the drug rather than the peak-and-trough concentrations that result from most forms of injection, and may thereby produce a more sustained and effective response.

V. GENE MODIFICATION OF THE IMMUNE RESPONSE

Immunotherapy represents one of the most appealing of new antitumor approaches and active immunization in particular has proved to be among the most important of these new cellular strategies because of its ability to stimulate the immune system to actively recognize and kill the malignant cells. Identification of antigens expressed on tumor cells (Table 1) and the improvements made in gene transfer techniques, together with a better understanding of the molecular and cellu-

Table 1 Tumor Antigens Recognized by T Lymphocytes

Antigen	Primary tumor[a]	Normal tissues
Differentiation antigens		
Tyrosinase	Melanoma	Melanocytes
ACE	Colon, digestive tumors	Colon
Immunoglobulin (idiotype)	B lymphomas	B lymphocytes
gp100	Melanoma	Melanocytes, retina[b]
melan A/Mart 1	Melanoma	Melanocytes, retina[b]
gp75/TRP-1	Melanoma	
PSA	Prostate	Prostate
Self-antigens expressed at low levels on normal tissues		
MAGE-1	Melanoma	Testis,[b] trophoblast
MAGE-3	Melanoma	Testis[b]

ras	Colon, lung, pancreas	
MUM-1	Melanoma	
bcr/abl	Chronic myeloid leukemia	

[a] Antigen expressed in more than 25% of cases.
[b] These tissues do not express MHC class-1; therefore, antigen may not be presented.

lar mechanisms involved in the immune response against cancer, have given investigators tools to manipulate the immune system to induce an efficient immune response in the tumor-bearing host.

A. Tumor Escape

Even though many in vitro cancer gene and immunotherapy studies have been published since the early 1980s, few clinical applications have been successful. Despite impressive improvements in gene transfer technology and techniques for immune manipulation, clinical efficacy is still poor. Interest is now more focused on a better understanding of the mechanisms by which tumors can escape immunosurveillance in vivo, perhaps the greatest impediment to successful application of immunotherapy strategies. Table 2 briefly summarizes the most important ways by which tumors can evade immune surveillance.

B. Antigen Presentation Defects

An appropriate pattern of T helper and T cytotoxic cells stimulation has been proved to be essential in mounting an efficient immune response. Many tumors prevent the recruitment of T cell immune response by down-regulation of major histocompatibility (MHC) molecules or of costimulatory and adhesion molecules.

Several immunotherapy strategies have been conceived to overcome these defects. Introduction of MHC molecules into tumors was one of the first strategies adopted clinically in the 1990s. Earlier murine models had shown that an increased expression of MHC class I molecules decreased tumorigenicity, due to enhanced antigen presentation to $CD8^+$ cytotoxic T lymphocytes (CTLs) (47). Tumor immunogenicity has also been increased by gene transfer of both allogeneic MHC class I and II molecules (48–50), thus demonstrating the relevance of both CD8 cytotoxic and CD4 helper T cells in enhancing

Table 2 Mechanisms by Which Tumor Can Escape Immune Surveillance

Defects in antigen presentation
- Adhesion deficiency
- MHC molecules/pathway defects
- Defects in antigen processing/transport
- Defects in costimulatory pathways
- Antigenic variants
- Decoys

Microenvironment abnormalities
- Inhibitory cytokines/ligand
- Growth/survival factors, angiogenesis
- Immune sanctuaries (eye, testis, central nervous system)
- Establishment of latency (virus-induced tumors such as EBV, HPV, and HTLV)

T cell defects
- Absence/deletion of specific T cell precursors
- Anergy
- Down-regulation of TcR ζ chain
- Mutations in signaling pathways
- Deletion/defect in helper T cell
- Defect in establishment of T cell memory
- T cell inhibitors

systemic immunity against cancer. Increased expression of MHC molecules can also be obtained indirectly by transducing tumor cells with cytokines able to induce MHC molecule up-regulation on the cell surface: examples of cytokines with this property are interferon-γ (IFN-γ) (51,52), IL-4, and Tumor Necrosis Factor-α (TNF-α) (53).

Once the T cell receptor (TcR) has specifically interacted with the epitope, costimulatory signals induce a T cell response and prevent anergy (54). A number of such signals have been identified of which the B7 family members, such as B7.1 (CD80) and B7.2 (CD86), are among the best known. These molecules are expressed on the antigen-presenting cell (APC) surface and bind to their cognate receptor, CD28, on the responding T cell (54–56). Other costimulatory molecules, such as intercellular adhesion molecules and leukocyte function-associated antigens are also important (57). The absence of costimulatory molecules on the tumor cell surface is one of the explanations for the unresponsiveness of $CD8^+$ T cells in the tumor-bearing host. This important role of CD80/86-CD28 interaction in T cell activation made B7 genes an appealing target for gene transfer into tumor cells (58–60).

CD40 ligand (CD40L) also represents a possible candidate for gene transfer because it can enhance antigen presentation by tumor cells and induce maturation of professional APCs (61,62). This molecule (normally expressed only by activated $CD4^+$ T lymphocytes) interacts with the specific receptor CD40 and increases antigen presentation by malignant cells by up-regulating costimulatory molecules (e.g., B7-1 and B7-2), adhesion molecules (e.g., ICAM-1 and ICAM-3) and MHC molecules. CD40L also increases antigen uptake by dendritic cells (DCs) and allows them to bypass $CD4^+$ T helper cells in recruiting specific CTL (63–65). Hence, CD40L gene transfer has been widely used in multiple preclinical and several clinical studies (described later in this chapter) with promising results (66–69).

Failure to take up tumor antigens or to present them adequately on APCs (mainly DCs) is commonly observed in tumors. Many immunotherapy strategies therefore aim to increase the efficiency of antigen presentation. In this context, GM-CSF has been widely used for transducing autologous or allogeneic cancer cells and proved to be one of the most potent molecules in vivo, mainly acting as a critical factor for promoting maturation of DCs at the site of vaccine injection and thereby enhancing tumor antigen uptake and presentation (70).

C. T Cell Defects

T lymphocytes in the tumor-bearing host may be decreased in number or fail to home to tumor infiltrates. They may also be anergic and show increased apoptosis, impaired cytokine secretion, inhibition of proliferation, decreased cytotoxic capacity, defects in helper function, and absence of memory T cells. There may also be an increased production of immunosuppressive factors, such as transforming growth factor-β (TGF-β) and IL-10, originating from regulatory T cells or from the tumor itself (71–73).

Multiple strategies have been used to overcome T cell defects. Most commonly, tumor cells are transduced with genes encoding cytokines able to re-create an optimal microenvironment for T cells recruitment, activation, and expansion. Several cytokines can be used alone or in various combinations to enhance antitumor T cell-mediated immunity: recruitment of cytotoxic $CD8^+$ T cells able to recognize tumor-specific antigens is observed with IL-4 (74), whereas $CD4^+$ T cell recruitment is favored by TNF (75) and IL-7 (76,77). Expression of class I antigens is enhanced by IFN-γ (78,79), which in turn increases tumor immunogenicity. A combination of these effects may also be obtained: for example, IL-2 can recruit both cytotoxic T and natural killer (NK) cells directly (80) and can also induce release of the secondary cytokine IFN-γ (81–84). NK cells may also be important in generating an effective antitumor immune response (85). These cells exert cytotoxic activity through the granzyme-perforin system and release inflammatory cytokines (including IFN-γ, IL-5, TNF-α, and GM-CSF). NK cells, unlike T lymphocytes, recognize and destroy target cells that lack MHC antigens, so they can be effective against tumors with down-regulated surface expression of these molecules. IL-2 can also induce the generation of lymphokine-activated killer cells form both T and NK cells (80,86), which have enhanced cytolytic activity against a broad range of tumor cells and act in an MHC-unrestricted manner.

Costimulatory surface molecules such as B7.1 or CD40L may serve as accessory signals in the T cell activation process and prevent/overcome the T cell anergy induced by tumors (87,88). Finally, chemokines [such as the T cell specific lymphotactin (Lpth)] (89) may be used to attract immune-effector cells to the vaccination site, thereby enhancing the probability of adequate immune activation.

D. Microenvironment Abnormalities

Tumors can secrete substances able to induce immunosuppression. The best characterized of these are TGF-β, IL-10, and vascular endothelial growth factor (VEGF). TGF-β affects CTL function, inhibiting production of Th1 cytokines (especially IL-12), down-regulating surface expression of IL-2 receptors on T cells, inhibiting antigen presentation on MHC class II molecules and decreasing surface expression of costimulatory and adhesion molecules (71–73). As described later in this chapter, T lymphocytes can be genetically modified to express a nonfunctional TGF-β receptor and overcome the inhibitory effects of this molecule. IL-10 shares many immune-inhibitory properties with TGF-β, reducing Th1 cytokine synthesis and making tumor cells insensitive to CTL-mediated lysis. IL-10 antisense gene transduction can restore immunogenicity when tumor cells produce high amounts of IL-10 (90). VEGF serves to promote tumor angiogenesis and inhibit DC differentiation. Antisense gene transduction or gene therapy with soluble inhibitory receptors represents a promising strategy to block VEGF effects (91,92).

E. Clinical Applications of Immuno-gene Therapies

Gene transfer can be used in several ways to manipulate the immune system (Table 3). Passive immunotherapy consists of the adoptive transfer either of specific antitumor immune effectors, gene modified or not, or of specific antibodies (generated ex vivo) to the cancer patient. The use of cancer vaccines in active immunotherapy aims to induce efficient and long-lasting immune responses by direct stimulation (with gene-modified cells or cell components) of the patient immune system.

1. Gene-modified Autologous and Allogeneic Tumor Cells

Several clinical applications in humans have been reported using manipulated autologous cancer cells (93). When transduced autologous tumor cell lines cannot be obtained (because the tumor is not accessible, because the tumor cells do not grow ex vivo, or because gene delivery is difficult), an immunogenic allogeneic tumor cell line can be a valid alternative. This approach unfortunately has several limitations: (1) The tumor antigens present on the autologous tumor population may be absent in the tumor cell line; (2) the antigen may be presented on a mismatched MHC molecule and, in the absence of cross-priming of host lymphocytes, may fail to be recognized by host T and cells; (3) the tumor antigen may not contain peptides capable of being presented by host APC so an immunogenic allogeneic tumor in one individual may be nonimmunogenic in a second patient with a different human leucocyte antigen (HLA) type.

Among the many immunomodulatory gene products tested to date, vaccination with irradiated cancer cells engineered to secrete GM-CSF induced the most efficient, specific, and long-lasting immunity in several murine tumor models (70). Phase I clinical trials using autologous human genitourinary cancer cells as source of cancer cell antigens have been recently concluded (94). In the first study, renal cancer cells were removed and then genetically modified to secrete high levels of GM-CSF via ex vivo transduction with a retroviral vector. Eighteen patients with advanced renal cancer were treated. Vaccine treatment triggered an anticancer immune response manifest as conversion of delayed-type hypersensitivity (DTH) skin responses against irradiated autologous cancer cells. One patient with measurable metastases treated at the highest vaccine dose level had a partial response. The safety of GM-CSF-secreting autologous cancer cell vaccines was also shown in a phase I clinical trial for prostate cancer (8 patients treated). Cells were prepared from prostate tumors by ex vivo transduction with the same retroviral vector used for the previous study. Vaccine treatment induced anticancer immunity as assessed using DTH skin testing. Serum anticancer antibodies were detected after vaccination. An autologous GM-CSF vaccine trial was also conducted in metastatic melanoma patients (95): immunization sites were intensely infiltrated with T lymphocytes, dendritic cells, macrophages, and eosinophils in all 21 evaluable patients. Metastatic lesions resected after vaccination were densely infiltrated with T lymphocytes and plasma cells, and showed extensive tumor destruction, fibrosis, and edema in 11 of 16 patients examined. Antimelanoma cytotoxic T cells and antibody responses were associated with tumor destruction. One partial, 1 mixed, and 3 minor clinical responses were observed. Results of a phase I trial in pancreatic adenocarcinoma (in which 14 patients were enrolled) have been recently published (96). The vaccine consisted of 2 different pancreatic cell lines with a *k-ras* mutation. Patients received escalating number of vaccine cells after pancreaticoduodenectomy. Twelve patients then received adjuvant radiation and chemotherapy for 6 months. One month after completing adjuvant treatment, 6 patients still in remission received up to 3 additional monthly vaccinations. Vaccination induced increased DTH responses to autologous tumor cells in 3 patients receiving the highest dose of manipulated cells. These 3 patients remained disease free at least 25 months after diagnosis.

A third approach consists of the simultaneous administration of autologous tumor cells admixed with an allogeneic bystander GM-CSF producer cell line (97). The cell line chosen (K562) lacks HLA class I or II antigens, so reduces the probability of inducing an allogeneic T cell-mediated response. In addition, the cell line produces large amounts of GM-CSF, so that few modified cells need to be given together with autologous unmodified tumor cells. This greatly increases the feasibility of the approach for clinical application.

Table 3 Strategies in Cancer Immunotherapy

Passive immunotherapy "*adoptive immunotherapy*"	Active immunotherapy "*cancer vaccines*"
Transfer of effector cells	*In vivo immunization with*
• Sensitized ex vivo	• Purified antigen
– Pulsed APCs[a]	• Immunodominant peptide
– Transduced effectors	• "Naked" DNA encoding tumor antigen
– Restricted/nonrestricted epitopes	• Recombinant viruses encoding tumor antigen
• Expanded ex vivo	• Whole tumor cells
– Bulk	– Used as APCs
– Cloned population	– Modified to attract host APCs (cross-priming)
Transfer of specific monoclonal antibodies	*Adjuvant therapies*
– Induce ADCC[b]	– IL-2, IFN-γ: systemic administration
– Coupled with toxin or radioisotope	– IL-2, GM-CSF,[c] Lptn[d]
	– IL-12: in situ administration

[a] APC, antigen-presenting cell.
[b] ADCC, antibody-dependent cell-dependent cytotoxicity.
[c] GM-CSF, granulocyte-macrophage colony-stimulating factor.
[d] Lptn, lymphotactin.

A clinical trial at Johns Hopkins University Hospital is evaluating this approach in patients with multiple myeloma.

IL-2 has also emerged as a potential immunomodulatory molecule alone or in combination with other cytokines or chemokines, such as Lptn. Clinical trials conducted by our group at St. Jude Children's Research Hospital and Baylor College of Medicine used neuroblastoma cells transduced with adenoviral vectors so that they expressed the IL-2 gene. Both autologous and allogeneic studies were instituted. In the autologous trial, patients received up to 8 injections of their own tumor cells subcutaneously. More than half the patients produced specific antibody and a specific cytotoxic T cell response directed against the autologous neuroblasts. Of 10 patients, 5 had clinical tumor responses including 1 complete and 1 very good partial response (81). In the allogeneic study, however, the immunizing cell line induced no evident specific immunity and only 1 patient showed a partial response (82). Of note, in both studies a significant number of children showed good tumor responses on subsequent treatment with low-dose oral etoposide. This interaction between genetic immunotherapy and low-dose chemotherapy has subsequently been observed in a number of tumor vaccine studies (98,99), and likely represents a genuine interactivity between these treatment modalities that may usefully be exploited for therapeutic benefit in the future.

A subsequent clinical study in neuroblastoma was based on animal data showing that the combination of Lptn, a T cell chemokine, and IL-2, the T cell growth factor, accelerated and augmented the immune response to a tumor cell line (89). Accordingly, patients received either an autologous vaccine or an allogeneic one expressing both IL-2 and Lptn (100). In the allogeneic group, it was possible for the first time to observe specific antitumor immune responses to the immunizing cell line, and 2 patients entered complete remission, which was durable in 1 (101). In the autologous study, the clinical results did not appear to be measurably superior to IL-2 alone, but a clear bias toward a Th2 MHC-restricted immune response was observed (R. Rousseau, personal communication). Hence, in the allogeneic setting at least, there is preliminary evidence that the combination of 2 agents acting at different phases of the immune response may be superior to a single agent. If these results are confirmed, they may increase the feasibility of using allogeneic vaccines with the considerable simplification in protocol development that would result.

In hematologic malignancy, a phase I study of autologous acute myeloblastic leukemia cells engineered to secrete GM-CSF has recently commenced, and this study is now being extended to pediatric acute myeloid leukemia (102). It has also proved feasible to express costimulator molecules such as CD40, CD40L, or B7.1 on primary tumor cells surfaces. We are currently using a combination of CD40L and IL2 gene transfer into pediatric acute lymphoblastic leukemia cells in an effort to generate an antitumor immune response in patients with high-risk disease who have entered remission. To date, this study has proved to be safe and has generated antileukemia humoral and cellular Th1 immune responses (103). Because these patients are treated in remission, we do not yet know whether there has been any antileukemia activity.

Genetic modification of tumor cells appears safe and is capable of generating specific humoral and cellular antitumor cytotoxic responses. There have been at least some tumor regressions and the approach is now being evaluated in a wider range of tumors and in a larger number of patients.

2. Cancer Therapy with Gene-modified T Cells

Several studies have suggested the feasibility and apparent clinical efficacy of adoptive transfer of CTLs directed at viral or tumor antigens (104–108). By using gene-marked cells in these studies, it has not only been possible to determine the survival and homing of the infused T cells, but also to determine if they mediate adverse effects such as GvHD (109,110). Clinical studies and their results are described elsewhere in this book (see Chapter 44), and include Epstein-Barr virus (EBV)-associated post transplant lymphoproliferative disorder (PTLD) (111–114), Hodgkin's disease (115), and nasopharyngeal carcinoma (116).

a. Protecting T cells Against Tumor-induced Down Regulation. Clinical studies using CTL against EBV-related malignancies are promising and there have been tumor responses, particularly in patients with PTLD. Nonetheless, no patient with aggressive relapsed EBV^+ Hodgkin's disease has been cured using EBV-specific CTL. This may be due to a lack of specificity of the EBV-specific CTL for the immunosubdominant LMP1 and LMP2 antigens that are all present on the Hodgkin tumor cells. In addition, the tumor secretes immunosuppressive cytokines and chemokines, which affect CTL function and APC activity (117).

Gene transfer can be used to overcome both types of problems. By using dendritic cells transduced with adenoviral vectors encoding either LMP2 or a mutated LMP1, it is possible to generate CTL that have high cytolytic activity in vitro to LMP2- or LMP1-positive targets when compared with conventional EBV-CTL (118–120). Although LMP2- or LMP1-specific CTL may be more effective, there is a concern that they will remain vulnerable to the immunosuppressive cytokines secreted by the Hodgkin's Reed–Sternberg cell. The cytokine that has the most devastating effects on CTL proliferation and function is TGF-β (117,121). This cytokine is secreted by a wide variety of childhood tumors and allows the tumor to escape the immune response (122). To overcome this capacity to inhibit the EBV-CTL, our group transduced CTL from patients with relapsed EBV-positive Hodgkin's disease with a retrovirus vector expressing a dominant-negative TGF-β type II receptor (DNR). This prevents formation of the functional trimeric receptor. Cytotoxicity, proliferation, and cytokine release assays showed that exogenous TGF-β had minimal inhibitory effects on DNR-transduced CTLs (123). This combination of tumor-specific and tumor-resistant CTL may prove highly effective for therapy.

b. Chimeric T Cells for Tumor Therapy. Primary T cells genetically modified to express chimeric receptors derived from antibodies and specific for tumor or viral antigens have

considerable therapeutic potential. Chimeric T cell receptors allows the recognition specificity of T lymphocytes to extend beyond classical T cell epitopes by transducing cells with genes that encode the variable domain of a tumor-specific monoclonal antibody (MAb) single-chain fragment (ScFv) joined to a cytoplasmic signaling domain. This strategy can therefore be applied to every malignancy that expresses a tumor-associated antigen for which an MAb exists (124,125). Unlike conventional T cell receptors, these chimeric receptors will be active even if the tumor cells are MHC class I negative. Chimeric receptor-transduced T cells have numerous advantages over immunotherapies based on monoclonal antibodies or T lymphocytes alone. Because there is no need to select and expand tumor-specific antigens from scanty precursors, large populations of antigen-redirected T lymphocytes can be obtained in a matter of weeks. Moreover, chimeric T cell receptors are MHC unrestricted, so that tumor escape by down-regulation of HLA class I molecules or defects in antigen processing are bypassed. Because both $CD4^+$ and $CD8^+$ T cells can express the same chimeric receptor, the full network of T cell function is directed against tumor cells. The presence of chimeric TcR-mediated effector function may be more likely to produce tumor cell lysis than humoral immune responses alone. The perforin/granzyme killing mechanism may be effective against cells that are relatively resistant to antibody and complement, whereas cytokine secretion upon T cell activation by tumor antigen recruits additional components of the immune system, amplifying the antitumor immune response. Furthermore, unlike intact antibodies, T cells can migrate through microvascular walls, and extravasate and penetrate the core of solid tumors to exert their cytolytic activity. Finally, a single T lymphocyte can sequentially kill a multiplicity of target cells.

Human T lymphocytes genetically engineered to express these recombinant receptor genes have exhibited specific lysis via the perforin/granzyme pathways, as well as cytokine secretion upon exposure to tumor cells expressing the cognate target antigen (126). Engagement of single T cell or Fc receptor chains suffices to induce cellular activation and proliferation (127–130). Adoptively transferred chimeric receptor-transduced cells were protective in murine tumor models (126,131,132). Examples of clinical applications in treatment of tumors are given in Table 4. In particular, a high proportion of neuroblastoma tumors express tumor-associated antigens such as GD_2, L1-CAM, and N-CAM. $CD8^+$ CTL clones genetically modified to express the CE7R chimeric immunoreceptor, which consists of an extracellular L1-CAM-specific single-chain antibody, transmembrane CD4, and T cell CD3 complex zeta chain, is currently being investigated in a clinical trial (133).

However, chimeric receptor signaling produces only limited activation of the T cells, and our group is currently exploring an alternative approach to increase the in vivo functionality of the cells (134,135). We have transduced EBV-specific (not primary) T cells with GD_2-specific chimeric receptor genes. In vitro we have shown that these cells can be expanded and maintained long term in the presence of EBV-infected B cells. Although they recognize EBV-infected targets through their conventional T cell receptor and thereby become activated, they are also able to recognize and lyse tumor targets through their chimeric receptors (Fig. 1). Several cycles of virus target→tumor target→virus target can be demonstrated ex vivo, implying that EBV-specific T cells expressing chimeric antitumor receptors may represent a new source of effector cells that would persist and function long term after their transfer to cancer patients (136).

F. DC Clinical Vaccines

To overcome the antigen presentation defects in antitumor immune recognition, DCs can themselves be manipulated ex vivo and used as cancer vaccines, mainly acting by priming naive T cells (137). Several methods are now available to isolate and expand DCs from peripheral blood and bone marrow, making their use feasible in clinical trials. DCs can be induced to present tumor antigens by several strategies, including feeding with tumor cell lysates and apoptotic bodies or by using tumor-derived RNA or making DC–tumor cell hybrids. Specific tumor antigen gene transfer into DC using viral or nonviral vectors is also possible (93,138).

Several clinical studies using active immunization with DCs have been completed in patients with metastatic melanoma, metastatic renal cell carcinoma, and B cell lymphoma. Most of them have used antigen-pulsed DC (93,138), but some investigators have reported induction of immune responses using gene-modified DC (139–143)

G. Nucleic Acid Vaccines

Nucleic acid vaccines induce an immune response targeted against a protein expressed in vivo subsequent to the administration of its encoding DNA or RNA. Investigators demonstrated that the intradermal and intramuscular injections of polynucleotide products generate long-lasting T cell and humoral immunity (144).

Nucleotide-based vaccines have several advantages over proteins and peptides. They provide prolonged antigen expression that can continuously stimulate the immune system, probably through an intracellular antigenic reservoir, resistant to antibody-mediated clearance. This may favor induction of immune memory even in the absence of booster immunization. Codelivery with plasmids encoding cytokines or costimulatory molecules can further enhance the immune response (145). Moreover, nucleotide vaccination leads to antigen processing through both the endogenous and exogenous pathways, so that specific CTL and helper T cells can be recruited.

In a murine model of B cell lymphoma, mice immunized with DNA constructs encoding the idiotype had specific antibody responses and were protected against tumor challenge. Use of DNA encoding a fusion protein of idiotype and GM-CSF greatly improved vaccine efficacy (146). Improvement of vaccine efficacy was also observed when the idiotypic DNA was fused to the C fragment of tetanus toxoid (147). These preliminary results indicate that DNA may be a simple and

efficacious system of inducing immune responses against a weak tumor antigen, provided that additional stimuli are included with the DNA (e.g., GM-CSF or tetanus toxoid) (148).

H. Future Perspectives for Immunotherapy in Cancers

Tumors possess multiple and powerful strategies to escape immune surveillance and can develop new immune evasion mechanisms during disease progression. Many of these stratagems have been elucidated, and counterattack can now be planned thanks to major improvements in protein engineering, gene transfer, and cell therapy technologies. Why then have few major clinical success yet been reported? Two centuries past, in 1893, William Coley reported regression of tissue sarcoma in 10% of patients after they had been infected with live or heat-inactivated bacteria. Since then, clinical response rates after immunotherapy have not convincingly changed. Hence, our nightmare is that this is as good as it ever gets! But the reality is that, despite lack of concrete clinical progress, our increasing knowledge and skills offers a real promise of improved results in the near future. It is also clear that immunotherapy by itself is unlikely to be sufficient to eradicate tumors because human malignancies are too heterogeneous in terms of the antigens they express and their susceptibility to immune-mediate killing. Only integration with standard treatments will likely be successful. Active immunization will be used as adjuvant therapy to eradicate minimal residual disease in patients previously debulked of their tumor by surgery, chemoradiotherapy, or stem cell transplantation. Patients receiving allogeneic stem cell transplant represent an obvious paradigm. After transplantation, when a new immune system is reconstituting, cancer vaccines could induce the formation of potent and long-lasting immunity. Specific cytotoxic lymphocytes from the donor could also be expanded ex vivo in the presence of host malignant cells and administered after transplant should malignancy recur.

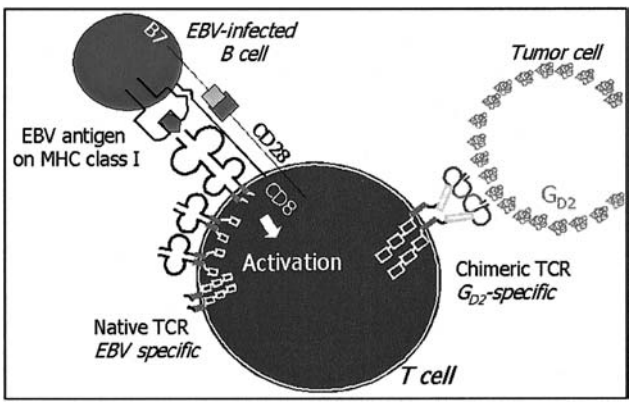

Figure 1 Chimeric anti-EBV T lymphocyte transduced with the gene encoding for the chimeric GD_2 specific-zeta chain + scFv. See the color insert for a color version of this figure.

Although no ''breakthrough'' clinical success has been reported, a better understanding of immune evasion strategies and the availability of improved technologies of immune manipulation have opened the way for real immunotherapies of cancer that should ultimately deliver on the dreams of the 19th and 20th centuries.

VI. CONCLUSION

We have far to go before gene therapy of malignancy can truly be said to have made a major impact on these diseases.

Nonetheless, over the past decade, new techniques including gene transfer and immunotherapy have produced unequivocal tumor responses even in advanced disease. Improvement of gene transfer for the treatment of cancer certainly relies on 4 major steps: (1) simplification of gene transfer protocols, still too complex to implement in a clinical environment; (2) controllable, tissue-specific regulation of transgene expression; (3) progress in the understanding of carcinogenesis mechanisms to improve therapeutic strategies; (4) improvement in the methodology of clinical trials, including optimal choice of the patient population, and monitoring of tumor and immune responses, within the tight frame of regulatory and cost-related issues. As we continue to make incremental advances in the application of these approaches, we can expect to see gene therapy increasingly supplement probably long before they can eventually supplant conventional cancer therapeutics.

I. INTRODUCTION

A. Brief History of Cancer

At one time the only treatment available for malignant tumors was surgical removal of the cancer. Surgical methods were advanced and refined in the quest to ''cure cancer,'' but radical excision alone, no matter how skillfully performed, could not provide the answer.

Armed with excised tumor tissue for study, medical science began the search for the ''magic bullet.'' Because cells proliferating out of control rapidly synthesize large amounts of DNA, radiation and chemotherapy, both inhibitors of DNA synthesis, were perfectly suited for cancer therapy. The focus was soon on finding ways to reduce the toxicity of radiation and chemotherapy by varying dosages and treatment schedules, combining chemicals, and searching for new cytotoxic chemicals. Although these tools were, and will continue to be, extraordinarily useful, DNA damaging agents alone cannot provide the ''magic bullet.''

With the discovery that the immune system recognizes tumors and often kills tumor cells naturally, the science of immunology was expected to provide ''the cure.'' Monoclonal antibody technology was a boon to cancer research, as tumor-associated proteins were zeroed in on, but hopes that these tools would provide a ''quick fix'' for cancer—that antibodies could be developed that would recognize a tumor and kill it or possibly carry toxins directly to the cell efficiently enough to cure the disease—have yet to be fully realized.

Rapid advances in genetics and molecular biology provided an even more detailed look into the machinery of the cell. Soon it became possible to identify the genes that code for proteins critical for cell function and genes that in turn regulate those genes. Once investigators were able to peer into the DNA to learn the genetic makeup of individual tumor cells, it became clear that the secret to cancer lay in the genes.

Even with the tools of molecular genetics in place, many scientists continued to denounce the theory that tumors resulted from mutations in somatic cells. Ironically, it was the discovery of a tumor virus by one scientist who initially spoke out strongly against the role of mutations in causing cancer, Peyton Rous, that eventually resulted in a universally accepted genetic paradigm that drove cancer research to where it is

today (1). Eventually, the ability to look at the genetic makeup of tumor cells provided at least one definitive answer. Cancer is caused by multiple genetic alterations in a cell that, through alterations in expression in critical genes, allow the cell to escape the natural mechanisms that prevent it from proliferating out of control.

Although highly evolved tools and techniques were necessary for cancer research to reach this point, it should not be forgotten that suspicions that we would find ourselves at this place were voiced early on. In 1914, T. Boveri suggested that a ''preponderance of the chromosomes that promote division'' might result in ''the unlimited tendency to rapid proliferation in malignant tumor cells'' (2). He continued, ''another possibility is the presence of definite chromosomes which inhibit division . . . cells of tumors with unlimited growth would arise if those 'inhibiting chromosomes' were eliminated.'' Boveri would not be at all surprised to find that replacement of tumor suppressor genes (TSG), our more elaborate term for his ''inhibiting chromosomes,'' was among the first gene therapy strategies to be successfully applied to cancer.

B. Programmed Cell Death and Cancer

An intricate web of biochemical pathways within each mammalian cell enables the cell to grow, divide, differentiate, and/or die quite independently of the organ system or of the complete organism of which it is a part. A genetically encoded developmental program, constantly tweaked by the biochemical makeup of the surrounding milleu, achieves a balance between cell proliferation and cell function consistent with the needs of the whole organism. Numerous genes are involved in an elaborate system of checks and balances that ultimately dictates, at any given time, whether a cell will proliferate or whether the cell cycle will be arrested.

During most of the lifetime of a cell, cell-cycle regulatory mechanisms restrict the cell to either G_0, where the cell is essentially at rest, or to the ''functional'' phase of the cell cycle, G_1, where genes are expressed, protein synthesis occurs, and the cell makes the proteins that are characteristic of its function. Only when appropriate is the cell released from these restrictions to progress through G_2, M, and S, the phases of the cell cycle characterized by rapid DNA synthesis and cell division. Alterations in expression of one or more critical regulatory genes, due either to inborn or acquired mutations in DNA, can upset the balance and result in blockage at a critical point in the cell cycle and/or in an inappropriate stage of differentiation.

Quite fortuitously, woven into the web of pathways is a mechanism to detect and repair defective DNA or, if repair is not possible, direct the cell to self-destruct through a process called apoptosis, or ''programmed cell death.'' Apoptosis prevents the cell from dividing and passing the genetic defect to daughter cells. Tasked with detecting damaged DNA and directing the cell to repair it or to undergo apoptosis is the TSG, p53, often referred to as ''the guardian of the genome.''

II. GENE THERAPY FOR CANCER: THE GENES AND THE DISEASES

A. Historical Perspective

The rapid development of new tools of molecular biology allowed cell biologists to examine the inner workings of cells on the DNA level and to confirm what was long suspected—that cancer is caused, in whole or in part, by genetic mutations. Following naturally from this knowledge was the desire to use the same tools to treat the disease at its core—to alter the defective DNA.

Although cancer results from genetic alterations, the array of genetic events varies widely between cancers and among patients, making it seem unlikely at first that one gene could be found that would impact a large subset of tumors. Even when a few genes were found in a large percentage of tumors, many researchers doubted that targeting a single damaged gene, when there were multiple genetic lesions present, could lead to regression of an established malignant tumor. Cancer, despite its genetic etiology, seemed an unlikely target for gene therapy.

Quite to the contrary, cancer has become the number one application of gene therapy in recent years. According to the minutes of the March 8, 2001 meeting of the Recombinant DNA Advisory Committee (RAC), 280 of the 409 clinical protocols for gene transfer therapy approved between 1989 and 2001 were for cancer.

B. The Genes

In spite of what initially appeared to be overwhelming diversity in the genetic profiles of malignant tumor cells, genetic analysis of large numbers of tumors has revealed some common patterns of mutations in 2 gene families—oncogenes (1) and tumor suppressor genes (3). Alterations in expression of genes from both families lead to disruption of normal biochemical pathways in cells—pathways governing the cell cycle, signal transduction, DNA transcription, apoptosis, cell migration, and angiogenesis—and are commonly implicated in the etiology of cancer. Although alternate pathways often exist to bypass a nonfunctional gene, the sequential acquisition of multiple random mutations eventually gives rise to cells that cannot take advantage of alternate pathways, resulting in malignant transformation.

Oncogenes are the transformed or tumorigenic versions of the proto-oncogenes that generally play prominent roles in signal transduction and transcription. Historically, these genes were relatively easy to identify for study because they stood out on genetic analysis of tumor cells as different than their normal counterparts. Tumor suppressor genes, now known to govern proliferation by regulating transcription and the cell cycle, as well as to play a major role in induction of apoptosis, were more difficult to identify as causal factors in cancer. Because the importance of TSGs to normal cell function is evident only when they are missing from the genome, more advanced gene manip-

ulation technology was required for their identification and study. The literature base on TSGs has expanded rapidly in recent years; only 10 years ago investigators, although optimistic, still spoke cautiously about how the detection of tumor suppressor genes might someday be applied to cancer. In a 1991 review article, Bishop (1) stated, ''There has been talk of restoring functional copies of tumor suppressor genes to tumors in which they are defective, but realization of this objective (if it is ever to come at all) seems many years distant.'' Instead, study of TSGs and the role their protein products play in normal cellular function has brought TSGs from the laboratory bench to the patient's bedside in a single decade.

One of the first TSGs described, *RB* (the retinoblastoma gene), has been implicated in retinoblastoma, osteosarcoma, and carcinomas of the bladder, lung, and breast. The TSG *p53* has been associated with carcinoma of the bladder, lung, and breast, along with astrocytoma and osteosarcoma. Early in the history of TSG research, particular genes were associated with Wilms tumor (*WT1*), colon carcinoma (*DCC*), and neurofibromatosis (*NF-1*). These discoveries were reviewed in depth in 1991 by Robert Weinberg (3) and by Michael Bishop (1). More recently, genes such as *PTEN* (4), *BRCA-1*, and *p16* have been recognized as TSGs, and their potential therapeutic uses are being explored.

Even with the rapid pace of developments in molecular genetics and new information about TSGs revealed daily, it is likely that we have still only scratched the surface of the base of knowledge about TSGs that will soon be available. Studies reported already though have led to the identification of genetic alterations in several TSGs, including p53, that contribute to the development of malignant tumors, and subsequently to the development and implementation of formidable therapeutic strategies.

1. Role of TSGs in Normal Cellular Function

The myriad roles TSGs play in normal cell function cannot be covered in detail in this chapter; however, a general understanding of the molecular events involved in maintaining the balance between proliferation and cell-cycle arrest is important. Briefly, expression of growth factors, oncogenes, cyclins, and cyclin-dependent kinases (CDKs) drive the cell cycle toward proliferation, while expression of TSGs and other inhibitors of CDKs induces cell-cycle arrest when appropriate.

TSGs play key roles in 2 major G_1 cell-cycle arrest pathways, the RB pathway and the P53 pathway. These tightly entwined biochemical pathways are regulated at the protein level by other TSGs and by oncogenes. In general, mammalian cell proliferation is under the control of these 2 pathways, with the Rb protein regulating maintenance of, and release from, the G_1 phase, and the p53 protein monitoring cellular stress and DNA damage, and effecting either growth arrest and repair or progression to apoptosis (5).

2. Role of TSGs in Programmed Cell Death/ Apoptosis

The importance of the tumor suppressor family of genes became evident in the early 1990s and TSGs are now acknowledged as critical elements in regulation of the cell cycle and gene transcription. One TSG, *p53*, is central to a cell's response to stress. When faced with the stress of oncogene activation, hypoxia, or DNA damage, *p53* is tasked with determining whether a cell will receive the signal to simply halt at the G1 stage of the cell cycle, will be signaled to attempt repair or, will self-destruct via apoptosis. Apoptosis plays a key role in numerous normal cellular mechanisms from embryogenesis to self-policing of DNA damage due to random mutations, ionizing radiation, and DNA damaging chemicals (6–8).

Whether a cell will be steered toward apoptosis depends on a precisely maintained balance between 2 types of signals received by a cell at any one time: proapoptotic signals vs. prosurvival signals. Although these signals determine p53's actions, expression of many of the genes that generate these critical signals is regulated by the activation status of *p53*, forming an elaborate feedback loop.

Two groups of genes are targets of p53's housekeeping duties: the ''prosurvival'' (or antiapoptotic) genes, and the ''proapoptotic'' genes. Prosurvival genes include *bcl-2*, *bcl-X2*, *bcl-w*, and *CED9*, whereas the proapoptotic genes include *bax*, *bad*, and *bid* (9). When these genes are transcribed, available transcripts of each interact with one another forming heterodimers. The relative ratio of proapoptotic to prosurvival proteins in these heterodimers determines activity of the resulting molecule, thereby determining whether the cell lives or is directed to undergo apoptosis.

3. Biochemistry of Apoptosis

Numerous genes are involved in the process of apoptosis. *Bax*, a proapoptotic gene in the *bcl-2* family, was the first gene mediator of apoptosis discovered (10). Another gene, *FAS/APO1* or the so-called ''death receptor,'' is critical for another pathway to apoptosis. Both of these pathways to apoptosis depend on p53 for induction of the caspase cascade that, in turn, is dependent on the mitochondrial enzyme cytochrome C (cytC). CytC functions as a cofactor for ATP in activation of Apaf-1, which subsequently activates caspase 9, the ''initiator'' of the caspase cascade.

Antiapoptotic (prosurvival) family members halt the caspase cascade by inhibiting the cofactor activity of cytC. For example, the p53 protein can transcriptionally induce *bax* and inhibit the activity of the prosurvival molecule bcl-2, allowing the cascade to proceed to apoptosis. Additional elegant feedback loops maintain barely detectable levels of p53 in normal, unstressed cells. Activation of p53 by stress to the cell, however, results in induction of expression of the oncogene *mdm2*. *Mdm2* encodes a protein, mdm2, which binds to and inhibits the activation of p53, closing an autoregulatory loop. Under normal, unstressed conditions, mdm2 is bound to the N-terminal transactivating domain of p53 [reviewed by (5)], prohibiting p53 activation and instead leading to rapid degradation. This precisely regulated relationship results in a very short biological half-life (20–30 min) for active p53 in the normal unstressed cell.

In the event of genotoxic stress, resulting DNA damage causes phosphorylation of serines on p53, weakening its binding to mdm2 and destabilizing the p53/mdm2 interaction. Disruption of the bond stabilizes p53, DNA-binding activity increases, and p53, through an array of downstream signals, acts to switch other genes on or off. The finely tuned sequence of biochemical events culminating in cell death requires a functional *p53* gene. Induction of apoptosis via the p53 pathway in response to random mutation, ionizing radiation, and other DNA damaging agents will not occur without *p53*.

III. REPLACEMENT OF TUMOR SUPPRESSOR GENES IN NON-SMALL CELL LUNG CANCER

A. Rationale

Targeting specific genetic lesions responsible for tumorigenesis and cancer progression is an attractive strategy for enhancing effectiveness of anticancer therapeutics as well as for reducing treatment-related toxicity. However, to be successful, a gene therapy strategy must achieve 3 goals: (1) therapeutic DNA must be successfully delivered to appropriate tissue, (2) the gene must be expressed in the appropriate target cell, and (3) expression must be subject to regulation.

Several TSGs have been successfully transferred and expressed in various tumor targets in preclinical and clinical studies. Although most cancer TSG gene therapy clinical trials to date are still in phase I, several have already provided evidence of clinical benefits to study participants and given rise to larger phase II and III trials. Several multicenter studies involving hundreds of patients are currently underway.

Some genetic alterations show up more frequently than others in tumors, but the most common damaged or missing gene discovered so far is *p53*, altered in over 50% of malignant tumors. Because inactivation of this gene through deletion or mutation correlates closely with tumorigenesis, it follows that replacement of a copy of a ''wild-type'' (wt; nonmutated) gene might restore normal regulation of proliferation. Because p53 in the normal cell is tasked with detection of damaged DNA and, when repair is not possible, induction of apoptosis, it also follows that restoring p53 has the potential to restore the normal apoptotic pathway to tumor cells. As listed in the March 8, 2001 report of the RAC, 25 protocols involving transfer of TSG DNA alone or in combination with conventional therapy were registered between 1989 and March 2001. Of these 25, 5 study protocols for *BCR-1* gene transfer in ovarian cancer were approved, along with 3 for *p16* (all prostate cancer) and 1 for transfer of the *Rb* gene. *p53* gene transfer was the most common TSG gene transfer protocol approved (16 studies), and was also being tested in the widest range of cancers: bladder (1), brain (1), breast (3), liver (1), colon (1), prostate (1), general advanced cancers (1), and lung cancer (7).

After several years of clinical trials, it now appears that the rationale for TSG gene replacement therapy in cancer is a valid concept. Because most of the TSG gene therapy clinical data to date arises from *p53* gene replacement strategies, the following discussion of the therapeutic applications of TSGs focuses on *p53*. Other TSGs, however, either alone or in combination with *p53*, also have promise as potentially beneficial therapeutic strategies.

Normally when DNA is damaged, as occurs on a regular basis by random mutation and/or by exposure to carcinogens, p53 induces G_1 arrest and directs the cell to repair the damage or to commence the pathway to apoptosis (5). Due to the critical role of p53 in the normal cell, loss of p53's cell-cycle regulatory functions, loss of the ability to self-repair damaged DNA, or unchecked expression of molecules normally regulated by the p53 protein, might make a cell more susceptible to transformation. Replacement of the *p53* gene and subsequent expression of p53 then, might be expected to restore apoptosis, increasing the sensitivity of tumor cells to conventional therapies, inducing tumor dormancy, or even preventing progression of premalignant cells to the malignant phenotype. Restoring p53 function to a cell might also suppress the tumorigenic influence of mutations in other genes critical to the functional program of the cell. Also, experimental evidence suggests a link between *p53* expression and apoptosis (11–13).

B. Preclinical Studies of p53 Gene Transfer

Preclinical studies of *p53* gene transfer into pancreatic cancer cell lines (14) and colorectal cancer cell lines (15) demonstrated suppression of cell proliferation and induction of apoptosis after transduction with *p53*. In vivo studies in a mouse xenograft tumor model also showed significant suppression of tumor growth (16). Several other lines of evidence also support the feasibility of *p53* gene replacement. For example, one study demonstrated the efficacy of *p53* adenoviral gene therapy in a mouse model of human breast cancer (17), and in another, human breast tumors were inhibited in a preclinical model of *p53* gene transfer (18).

When preclinical trials commenced, it was believed by many that the inability of a vector to transduce every cell within a tumor might limit the effectiveness of gene therapy; however, Fujiwara et al. (19) and Cusack et al. (20) demonstrated in 3-dimensional cancer cell matrices and subcutaneous xenografts that therapeutic genes were likely to spread beyond the immediate intratumoral injection site. P53 gene transfer also induced significant ''bystander'' killing in which *wt-p53* transduced cells mediated killing of surrounding cells that had not themselves been transduced possibly by mechanisms involving inhibition of angiogenesis (10,21), immune up-regulation (22–24), or secretion of soluble FAS protein (25).

Thus, despite the diversity of genetic lesions in cancer, restoration of function of a single tumor suppressor gene is sufficient to mediate tumor regression in vivo.

C. Clinical Trials of p53 Gene Transfer

In the first clinical trial of *p53* gene replacement, non-small cell lung cancer (NSCLC) patients were administered the *p53*

gene via a retroviral vector under control of the B-actin promoter (24). No vector-related toxicity was observed, and 3 of the 9 patients demonstrated evidence of antitumor activity. This was the first clinical trial to show that tumor suppressor gene replacement could mediate tumor regression in human cancer. Although this study demonstrated the feasibility and safety of gene therapy, the transduction efficiency of the retroviral vector was limiting, as is generally true of retroviral vectors. In addition, retroviruses are difficult to prepare at titers high enough to be useful in most gene therapy protocols, so subsequent trials used a more appropriate vector.

Adenoviral vectors, unlike retroviral vectors, are capable of infecting both dividing and nondividing cells and can be produced at high titers. These vectors do not integrate into the genome, however, so gene expression is transient. Although less stable expression may not be optimal in treating some diseases, transient expression is not necessarily a disadvantage in cancer therapy because prolonged expression is not required once tumor cell death has occurred.

Transfer of *p53* by an adenoviral vector Ad-p53 into lung cancer cells was demonstrated by Zhang et al. (27) and, based on these results, a phase I clinical trial with 28 NSCLC patients whose cancers had not responded to conventional treatments was initiated (28). Successful gene transfer was demonstrated in 80% of the evaluable patients, and vector-specific *p53* DNA was detected in 46%. Apoptosis was demonstrated in all but 1 of the patients expressing the gene. Most important, despite up to 6 injections per patient, there were no significant toxic effects related to transfer of the vector. In addition to demonstrating low toxicity, successful gene transfer and successful gene expression, antitumor activity was observed in 2 patients who achieved greater than a 50% reduction in tumor size. One patient remained free of tumor more than 1 year after the conclusion of therapy. Another patient experienced nearly complete regression of an upper-lobe endobronchial tumor that had resisted chemotherapy, radiotherapy, and laser treatment.

Transfer of the Adp53 construct also caused little toxicity in a phase I study of 33 patients with head and neck squamous cell carcinoma (HNSCC) (29) and, once again, significant clinical response was observed in 9 of 18 clinically evaluable patients. Interestingly, systemic Adp53 DNA was present transiently for under 48 h as demonstrated by presence in blood, urine, and sputum.

Over 200 HNSCC patients were enrolled in a phase II clinical trial of Adp53 that resulted in demonstration of complete or partial responses in approximately 10% of patients with recurrent or refractory head and neck cancer (30,31). Inclusion of those patients with prolonged inhibition of tumor growth resulted in evidence of antitumor activity in 60% patients.

Adp53's low toxicity (less than a 5% incidence of serious adverse events) suggests the potential for combining Adp53 with other anticancer treatments without significant increases in treatment-related toxicity (32).

IV. p53 GENE THERAPY IN COMBINATION WITH CONVENTIONAL DNA DAMAGING TREATMENTS

A. Rationale for Combination Therapy

Many cancer patients fail conventional therapy because their tumors are resistant to DNA damaging agents, such as chemotherapy and radiation therapy, and toxicity makes increasing doses of conventional treatments intolerable. Once apoptosis was implicated as the normal mechanism of cell destruction in response to these DNA damaging agents, it followed that a defect in the normal apoptotic pathway might confer resistance to some tumor cells. As discussed previously, p53 is the molecule that is responsible for detecting damage to DNA and directing repair or destruction through apoptosis. Interestingly, *p53* is often missing or nonfunctional in radiation- and chemotherapy-resistant tumors.

In the early 1990s, several groups (11,12,33) reported that overexpression of *p53* in cells transfected with *p53* expressing plasmids could drive cells into apoptosis or growth arrest, and also illustrated the potential for *p53* gene therapy in treating the many *p53*-deficient tumors. Subsequent preclinical studies suggested that *p53* gene replacement therapy in combination with conventional doses of radiation or chemotherapeutics may have a synergistic effect without the additional toxicity encountered with high doses of these conventional DNA damaging agents. The link between apoptosis and cell death due to DNA damaging agents was established.

B. Preclinical Studies of p53 Gene Transfer Combined with DNA Damaging Agents

Several in vitro studies (11,12,33) demonstrated that overexpression of p53 in *wt-p53* transfected cell lines could drive cells into apoptosis. Subsequent studies of apoptosis in tumor cells treated with radiation or chemotherapeutic agents, either in vitro or in animal models (4,7,34–37) also supported a link between apoptosis induction and functional p53 expression, prompting initiation of clinical trials combining Ad-p53 with the DNA damaging agent, cisplatin.

Preclinical studies of *p53* gene therapy in combination with cisplatin (38,39) showed in cultured NSCLC cells, as well as in human xenografts in nude mice, that sequential administration of cisplatin and *p53* gene therapy resulted in enhanced expression of the *p53* gene product. Pretreated cells demonstrated apoptosis in over 50% of the cells 12 h after gene transfer and in over 90% of the cells at 24 h. Cells that were not pretreated with cisplatin prior to gene transfer demonstrated only 19% and 68% apoptotic cells at 12 and 24 h, respectively. The in vivo studies demonstrated that systemic cisplatin treatment prior to *p53* gene transfer produced at least a 55% further reduction in final tumor size when compared with mice receiving gene transfer only.

Preclinical studies of *p53* gene therapy in combination with radiotherapy indicated that delivery of *p53* to *p53*-deficient

tumor cells, both in vitro and in vivo, increases their sensitivity to radiation (16). Specifically, when in vitro cultured human colorectal carcinoma cells were gamma irradiated, 55% of the tumor cells survived. Transfection of the cells with *p53* prior to irradiation, however, lowered the survival rate to 23%, and apoptosis was also increased in the pretreated cells. Furthermore, in an animal tumor model, significant tumor suppression was observed; regrowth of tumors was delayed 2 days when tumors were treated with radiation alone, and 15 days after treatment with *p53* gene transfer alone. Tumors of animals receiving the *p53* gene followed by radiation treatment, however, required 37 days to reach pretreatment size.

Other studies have generated supporting evidence for a critical link between radiation sensitivity and the ability of a cell to induce apoptosis (40–44). Data for some tumor types (i.e., epitheiod tumors) has not shown a correlation between *p53* status and radiosensitivity (45–47). However, it should be considered that when high levels of gene expression are forced with vector transduction the result may be an altered cell state quite different from cancer cells, which retain low levels of wt *p53* expression or have circumvented *p53*-mediated apoptosis during malignant progression.

C. Clinical Trials of Combination Therapy: p53 and Cisplatin

A phase I trial of *p53* in sequence with cisplatin carried out by Nemunaitis and coworkers (50) enrolled 24 patients with NSCLC previously unresponsive to conventional treatments. Patients received up to 6 monthly courses of intravenous cisplatin, each followed 3 days later with intratumoral injection of *p53*. Seventeen patients remained stable for at least 2 months, 2 achieved partial responses, and 4 continued to exhibit progressive disease. One patient was unevaluable due to progressive disease. Analysis of apoptotic activity in tumor biopsies resulted in 14% indicating no change, 7% demonstrating a decrease in apoptosis, and 79% showing an increase in number of apoptotic cells. Notably, 75% of the patients entered into the trial had previously demonstrated tumor progression on cisplatin- or carboplatin-containing regimens.

A phase II study in metastatic NSCLC evaluating patients with 2 comparable lesions was carried out by Schuler and colleagues. All patients received chemotherapy, either 3 cycles of carboplatin (AUC 6) plus paclitaxel (175 mg/m^2), or cisplatin (100 mg/m^2) plus vinorelbine (25 mg/m^2). In addition, Ad-p53 was injected directly into 1 lesion, whereas the other lesion was used as a control and was not injected. The authors hoped to demonstrate enhanced radiological response in the injected lesion compared with the noninjected lesion (49). As was observed with the Nemunaitis study (48), Ad-p53 (SCH 58500) resulted in minimal vector-related toxicity and no increase in chemotherapy-related adverse events. Although the authors concluded that Ad-p53 did not provide additional benefit to patients receiving an effective first-line chemotherapy, mean local tumor regression as measured by size was significantly greater in the Ad-p53-injected lesion compared with the control lesion with the less successful cisplatin and vinorelbine regimen. The implications of this trial are that the combination of Ad-p53 and chemotherapy agents does not significantly increase overall toxicity and confirms the observation that Ad-p53 can safely be delivered with platinum-based chemotherapy regimens.

A phase I/II clinical study of recurrent ovarian cancer patients by Buller and coworkers demonstrated safety and tolerability of single-dose and multiple-dose intraperitoneal Ad-p53 in combination with platinum-based chemotherapy (51). A long-term follow-up study (52) of these patients resulted in median survival of 12 to 13 months for individuals who received multiple-dose Ad-p53 with chemotherapy, compared with only 5 months for those treated with a single dose of Ad-p53. There were 10 long-term survivors more than 20 months after multiple-dose treatment for recurrent disease compared with only 2 long-term survivors after a single dose of Ad-p53. The authors concluded that the 12- to 13-month median survival in a heavily pretreated population with recurrent ovarian cancer compares favorably with the 16-month median survival for individuals treated with paclitaxel at the time of initial recurrence of this disease and is more than double the 5-month survival seen with palliative radiotherapy or paclitaxel failure.

D. Clinical Trials of Combination Therapy: p53 and Radiation

Preclinical studies also suggested that *p53* gene replacement might confer radiation sensitivity to some tumors (16,40,42–44) leading to the initiation of a phase II clinical trial of adenoviral-mediated *p53* gene transfer in conjunction with radiation therapy. Preliminary data from 19 patients with localized NSCLC (54) revealed a complete response in 1 patient (5%), partial response in 11 patients (58%), stable disease in 3 patients (16%), and progressive disease in 2 patients (11%). Two patients (11%) were nonevaluable due to tumor progression or early death. Examination of biopsies taken 3 months following completion of therapy revealed no viable tumor in 12 patients (63%) and viable tumor in 3 (16%). Tumors of 4 patients (21%) were not biopsied because of tumor progression, early death, or weakness. These results compared favorably with the 17% reported in studies of chemotherapy combined with radiation therapy (55).

The encouraging results of these studies of combination therapy are the basis for a currently ongoing multicenter randomized clinical trial in patients with unresectable NSCLC. This study compares a conventional therapeutic strategy (concurrent radiation and chemotherapy) with concurrent chemotherapy and radiation in conjunction with intratumoral injections of adenoviral *p53*.

V. FUTURE DIRECTIONS IN TSG GENE THERAPY

In spite of the promise apparent in these early trials, tumor suppressor gene therapy of cancer is not widely applicable in

its current form. Improvement in gene delivery systems is a critical area for future development, as systemic administration of *p53* cannot be considered using current vector systems. In addition, strategies can be developed to take advantage of bystander effects, and strategies combining TSG therapy with transfer of genes aimed at blocking angiogenesis or enhancing the immune system are also on the horizon. Ongoing exploration of TSG replacement as an adjuvant with conventional chemotherapy, radiation therapy, and surgery continues to look positive.

A. Vector Development

To date, promising approaches to gene therapy in clinical studies have used retroviral, adenoviral, and herpes vectors for gene delivery. However, due to various complications caused by injecting viral material with the genetic material, new modes of delivery using nonviral vectors and naked DNA are being explored.

Liposomes as gene delivery vehicles have shown promise for potential systemic delivery of genes to distant sites with minimal toxicity. Ramesh and coworkers demonstrated liposome-mediated gene delivery in animal studies using extruded DOTAP:Chol liposomes. Transgene expression was observed in 25% of the cells in each tumor, and significant suppression was seen in both primary and metastatic lung disease. Repeated treatments resulted in a 2.5-fold increase in gene expression and an increase in therapeutic efficacy compared with single treatments (56).

B. Tissue Targeting

A current limitation to gene therapy is the nonspecificity inherent in available gene delivery methods. So far, only tumors accessible by needle or by endoscopy are viable targets for gene therapy—tumors that are unreachable or undetectable are excluded by current gene therapy delivery methods. Thus far, recombinant adenovirus has proven the most efficient at systemic delivery of genes to less accessible tissues, such as heart and skeletal muscle. Several strategies designed to target recombinant adenoviral vectors to specific types of cells by manipulating cell surface binding properties of the viral particle have been studied.

One targeting strategy under development involves bifunctional fusion proteins consisting of an antibody fragment specific to the fiber protein of the virus and a ligand, in this case, epidermal growth factor (57). The bifunctional fusion proteins blocked normal fiber binding to the coxsackie-adenovirus receptor, with concomitant targeting of the virus to the epidermal growth factor (EGF) receptor. Addition of the fusion proteins to the adenovirus then enhanced the transduction efficiency of the epidermoid carcinoma cell line A431 16-fold at optimal conditions compared with infection with native adenovirus vector. The results of this study demonstrated blocking of the native viral tropism as well as targeting gene delivery specifically to the EGF receptor by the modified adenovirus.

C. TSG Replacement Combined with Other Gene Therapy Strategies

Although the mechanisms that *p53* and p16INK4 use to cooperate in apoptosis induction are not yet fully understood, recent reports indicated that complementary tumor suppressor genes, delivered together, might cooperate to induce apoptosis. Combinatorial introduction of the tumor suppressor gene *p16INK4* and *wt-p53* demonstrated a synergistic effect on the induction of apoptosis in HuH7 hepatocellular carcinoma cells (mutated *p53*) and LOVO colon carcinoma cells (very low expression of *wt-p53*) in vitro.

VI. FROM CLINICAL TRIALS TO STANDARD OF CARE: GENE REPLACEMENT THERAPY AND SOCIETY

Gene therapy technologies are rapidly becoming a reality with the potential to impact the general population in the forseeable future. It is, therefore, a critical time for researchers, clinicians, patients, and the public to address societal issues that could bring application of gene therapy to a grinding halt.

The first human gene transfer protocol was approved in 1988, and the number of protocols approved in subsequent years has increased dramatically—from 2 in 1990, to 43 in 1995, and then to 99 in 1999, with 70 more added in 2000. Although a majority of the trials are still at the stage of assessing toxicology and pharmacology, the number of potential applications of recombinant DNA technology to clinical medicine can only be expected to expand as successful outcomes are reported.

The transfer of recombinant DNA to humans in the last decade has raised new and complex scientific, medical, ethical, and social issues that justify enhanced oversight by regulatory agencies. Because of enhanced real and theoretical risks, gene transfer clinical trials are subject to more regulatory and advisory oversight than many experienced clinical investigators may be used to encountering. This should not be perceived as an impediment to the progress of gene therapy research, but as a method of ensuring rapid progress in the development of gene therapy strategies that reflect safe, ethical, scientifically sound, and socially responsible medicine. If gene therapy is to take its place as the standard of care for gene-based diseases as quickly as possible, clinical trials must be conducted with utmost care and integrity.

A. Public Perception of Gene Therapy

The most flawless gene therapy technologies will be of little use to a public who does not understand, and is therefore not willing to accept, its benefits. After science and medicine develop and test the tools of gene therapy, the future of gene therapy still depends on the acceptance of this new and sometimes intimidating technology by the public. Many consumers are currently wary of any type of gene manipulation, and this

aura of discomfort is likely to linger until medical science can assure them that responsible application of gene technology is a far more likely scenario than one in which the technology is allowed to extend to unethical applications. In spite of the obvious promise evident in the results of the clinical trials of TSG gene transfer described in the previous section, it is critical to recognize that there are still gaps in knowledge and technology that must be filled before the most finely tuned gene therapy strategies can emerge

The most efficient method of successfully delivering gene therapy to health care consumers will be to gain public acceptance of the technology through education in basic molecular genetics and its applications, through release of accurate information (both positive and negative) from clinical trials, and through honest discussion of the limitations, as well as the promises, of gene therapy. An official step in this direction was taken in 1974, when the RAC was formed in answer to public concerns about the safety of gene manipulation

B. Educating the Public

The day that a patient is diagnosed with terminal cancer is not the time to teach scientific literacy to the patient or his or her family members. Now is a critical time to educate the public about general genetics, and about the potential of the field of gene therapy to improve length and quality of life for all health care consumers. Only then will patients be capable of making informed decisions at diagnosis. Outreach projects such as the multimedia educational kit, ''The Human Genome Project: Exploring our Molecular Selves,'' produced in 2001 by the National Institutes of Health (NIH) and numerous cosponsors and distributed free of charge on the Internet will have an enormous impact on the public perception of the potential usefulness of gene therapy. Only education of individuals will facilitate the exchange of ideas between the public, the medical community, and governing bodies as they work together to decide how to best use this new technology in an ethical, responsible, and fair manner.

Electronic access to information on cancer clinical trials is now widely available to private physicians and potential patients through various websites. In addition, the NIH Guidelines for Research Involving Recombinant DNA Molecules: RAC Guidelines (revised January 2001) prepared by the RAC can be accessed online by physicians, scientists, patients, and the public. The RAC database listing all approved clinical trials, as well as minutes of their review meetings, are available on the NIH Office of Biomedical Affairs (OBA)/RAC website. In addition, reports of adverse effects reported to the OBA are now accessible to other investigators and the public under the Reports section of the RAC website. In addition, most cancer centers with ongoing clinical trials provide educational materials to patients and physicians.

VII. SUMMARY

Although limitations still exist to the widespread application of gene therapy to cancer, the strategy has already been shown to be applicable in several clinical situations. Contrary to initial predictions, virus-assisted gene transfer has been shown to be even more efficient in cancer cells than in normal tissue cells, and viral vectors appear to spread readily through a tumor and to cause cell death via apoptosis. Initial concerns that the diversity of genetic lesions in cancer cells would prevent the application of gene therapy to cancer appear unfounded; on the contrary, correction of a single genetic lesion has, repeatedly, yielded significant tumor regression, and successful early clinical trials of *p53* gene replacement have provided information that will be useful in the design of future gene therapy strategies.

Development of more efficient vectors, novel genes, and combined modality approaches are on the horizon and will widen the applicability of gene therapy to systemic administration. Many studies suggest great potential for combining gene therapy and pharmaceutical, immunological, and radiotherapeutic approaches to kill cells more effectively and in greater numbers. Because gene therapy targets the etiology of the disease, these strategies may someday even be applied to cancer prevention.

Unresectable tumors are a prominent problem in oncology, with proven therapies such as radiotherapy and chemotherapy controlling less than 50% of lung cancers. Clinical trials of *p53* gene replacement have provided information useful in the design of future gene therapy strategies. Direct intratumor injection has low toxicity and thus can be readily combined with existing treatments. Postinjection gene expression can be documented and occurs in the presence of an antiadenovirus immune response. Importantly, this treatment can cause tumor regression or prolonged stabilization. Novel vectors will likely allow the application of this strategy to systemic cancer treatment.

Ex Vivo Gene Therapy for Alzheimer's Disease

I. INTRODUCTION

Trophic support is essential for the normal function of the central nervous system (CNS). In addition to supporting neuronal growth, migration, and targeting during development, trophic factors appear necessary for ongoing neuronal function, cell repair, and survival. Lacking such support, the dependent cell populations may lose their functional connections, atrophy, and die. Thus, deficient trophic function could form the basis for the genesis of some neurodegenerative diseases. In addition, even in cases in which trophic loss is not the inciting event, providing ongoing trophic support may prevent the cell loss that generates a clinical disease.

II. PATHOPHYSIOLOGY OF ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is the prototypical adult neurodegenerative disease. It is the most common cause of dementia in the elderly. With advancing age, AD becomes epidemic: it doubles in prevalence every 5 years after age 60, so that by age 95, 48% of individuals are affected (1). With lifespan lengthening in many societies in the world, an increasing number of individuals will live to confront the stark reality of this disease in themselves or someone they know (2,3).

AD occurs in both sporadic and inherited forms (4). A similar disease also appears in individuals with Down syndrome (5). Clinically, AD manifests as a progressive dementia, affecting higher-order cognitive functions such as memory, attention, language, judgment, and spatial reasoning. Patients often experience depression, irritability, aggression, and delusions. With time, the disease progresses to severe impairment of cognitive function, with preservation of the primary motor and sensory pathways. Gross pathological inspection of the AD brain reveals widespread loss of brain volume. Decreased gyral bulk and commensurate sulcal widening are evident. At the microscopic level, loss of synaptic connections between cortical neurons and the subcortical cholinergic system begins early and becomes profound as the disease progresses. The cortical neurons themselves are not affected until late in the course. The pathological signature findings are neuritic plaques and neurofibrillary tangles (6). Neuritic plaques contain insoluble β-amyloid, which is known to be neurotoxic. Neurofibrillary tangles contain intermediate filaments of α-synuclein, and likely represent ''ghosts'' of degenerated neurons. A chronic inflammatory reaction occurs in AD, with infiltration of microglia and macrophages in the region of senile plaques. Regional immunohistochemical analysis of specific cell populations in AD demonstrates cell loss in a host of different cell populations. Among these diseased cell populations, loss of cholinergic activity is prominent (7). In particular, cell loss occurs in the neurons located in the basal forebrain nuclei. The degree of cholinergic cell loss correlates well with the clinical disease (8).

The underlying etiology of AD remains ill defined. One hypothesis posits that amyloid plays the major role in the disease. In familial cases, a genetic defect in the amyloid precursor protein (APP)-processing enzymes presenilin-1 and presenilin-2, or APP itself, leads to amyloid accumulation and subsequent clinical AD (9). However, a pathologically identical disease occurs in the 90% of cases that are nonfamilial without a consistent identifiable genetic defect.

III. CONVENTIONAL TREATMENTS OF AD

Each perturbation observed in AD has been considered for potential therapeutic manipulation. AD involves a combina-

tion of deranged amyloid processing and metabolism, neurotoxicity, inflammatory response, loss of synaptic connections (especially cholinergic), and secondary cell senescence and death. Accumulation of amyloid and defects in amyloid processing has proven difficult as a target for therapy. The inflammatory reaction seen in the brain and oxidative stress have led to the long-term use of nonsteroidal anti-inflammatory drugs, which have been shown in some studies to decrease the risk of AD (10). Alpha-tocopherol (vitamin E) and ascorbic acid (vitamin C) may slow the progress of the disease (11). The loss of cholinergic activity correlates well with the magnitude of the disease, but medical therapy with acetylcholine, acetylcholine precursors, or cholinergic agonists has proven impractical due to the widespread nature of the cholinergic system throughout the body and the relative impermeability of the blood–brain barrier. Cholinesterase inhibitors, which work by preventing the breakdown of acetylcholine in the synapse, have achieved moderate success in clinical trials (12). Most oral pharmacological therapy for AD uses this strategy. Examples of such medications in clinical use include tacrine, donepezil, rivastigmine, and galantamine (13). On the whole, all cholinergic medications have had only limited success.

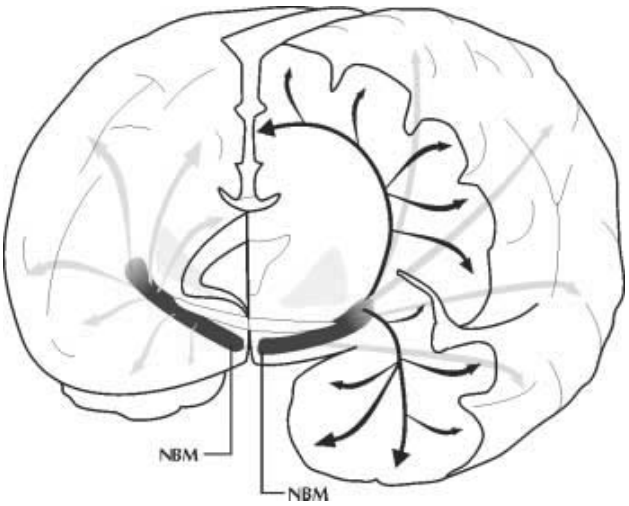

Figure 1 The diffuse connections between the NBM and the cortex are illustrated. See the color insert for a color version of this figure.

A. Trophic Factor Gene Therapy: Rationale

Optimal therapy to treat AD would be correction of the underlying defect(s) that produces the cascade of events culminating in the clinical disease. Dysfunction and death of the cholinergic cells of the basal forebrain nuclei correlate best with the clinical severity of AD. This makes therapy directed to correcting cholinergic dysfunction desirable. However, cholinergic supplementation therapies have met with limited success. An attractive approach would be the preservation and/or augmentation of the cholinergic system.

1. The Cholinergic System in AD

The classic pathological hallmarks of AD are the formation of neurofibrillary tangles and amyloid-containing neuritic plaques. These changes can occur without clinical dementia, and they are not good independent predictors of the severity of dementia. Although cell loss in AD eventually becomes widespread and involves multiple neurotransmitter populations, cholinergic cell death in particular correlates with the clinical disease and degree of synaptic loss (14). The basal forebrain nuclei are the most prominently affected. These include the nucleus basalis of Meynert (NBM), the medial septal nuclei, and the vertical limb of the diagonal band. The connections of these nuclei with the cortex are widespread (Fig. 1). Evidence of the importance of the cholinergic system in AD is supported by the observation that cholinergic antagonists can reproduce or exacerbate the symptoms of the disease, while cholinergic agonists improve the symptoms of AD (15). Clinical and experimental lesions in the cholinergic system disrupt attention and spatial memory, both of which are prominent features of AD (16–18). Importantly, damage must be widespread throughout the cholinergic system in animal models to produce such symptoms as memory deficit, suggesting that preservation of even part of the system might be enough to prevent clinical impairment (19). A number of animal models of aspects of AD exist, including injection of ibotenic acid or other toxins into the septal region and section of the fimbria/fornix. Fimbria/fornix lesions in particular disrupt the reciprocal connections between the basal forebrain cholinergic system and the hippocampus leading to substantial loss of cholinergic neurons.

a. Nerve Growth Factor. Nerve growth factor (NGF) is the prototypical member of the neurotropin family. It is a low-molecular-weight polypeptide with trophic effects for cholinergic neurons. NGF up-regulates choline acetyltransferase. The role of NGF in the support of the cholinergic system was elucidated through a series of studies that first examined the anatomical distribution of neurons that expressed NGF and NGF receptors. Later studies examined the effect of NGF on normal and injured target cells. Medial septal cholinergic neurons express both low-affinity (p75) and high-affinity (*trkA*) NGF receptors on their cell bodies and their terminals, which project to the hippocampus (20–22). The NGF that is expressed by cortical neurons binds to these receptors on cholinergic fibers and is transported retrograde to the cell bodies in the NBM (23). Fimbria/fornix lesions in both rats and monkeys that interrupt this pathway lead to the degeneration of cholinergic neurons (24,25). NGF infusion into the cerebrospinal fluid of lesioned macaques specifically prevented cholinergic neuron degeneration in the basal forebrain nuclei (26,27). NGF infusion studies in rats and subsequently in nonhuman primates showed that NGF infusion could ameliorate or even reverse age-related pathological changes. In the rat, this is associated with improved performance on tasks of spa-

tial memory (28). An alternative method of NGF delivery is the in vivo gene transfer of NGF using an adeno-associated virus (AAV) vector injected directly into the medial septal nuclei (29). This treatment reduced cell loss following a subsequent fimbria-fornix lesion when compared with placebo. Long-term transduction and cell survival (at least 6 months) of medial septal neurons transfected with AAV carrying either hBDNF or NGF is also observed (30). Last, grafting of fibroblasts modified to secrete NGF into aged rats demonstrated survival of the grafted cells, an increase in basal forebrain low-affinity NGF receptors (p75), and improvement on memory tasks (31). Neuronal rescue has also been observed in primates receiving grafts of autologous fibroblasts genetically engineered to secrete NGF (32). These studies illustrate the importance of NGF in basal forebrain cholinergic survival and function.

In addition to NGF, another trophic factor, glial cell line-derived neurotrophic factor (GDNF), also prevents cell degeneration in rats with fimbria/fornix lesions. However, it is 10 times less potent than NGF (33).

b. Trial of NGF Infusion in AD. Theoretically, infusion of a trophic factor into the cerebrospinal fluid (CSF) in the proximity of a target would appear to be a viable delivery method. This formed the basis for a clinical trial of intraventricular infusion of NGF in patients with AD (34). However, the development of wasting and painful syndromes led to cessation of the trial. The genesis of these unpleasant side effects appeared to have resulted from the circulation and action of NGF on other responsive brain targets bathed by the CSF. Animals so treated have been shown to stimulate schwann cell proliferation and migration, as well as sprouting of sensory and sympathetic neurons (35,36). These effects appear reversible with cessation of the infusion. Clinically, weight loss in animals, believed to be due to the action of NGF on the nucleus accumbens, and a pain syndrome in 3 human patients have also been seen (37–40). These observations suggest that targeted delivery of NGF for trophic factor therapy is essential.

B. Gene Therapy for AD: Gene Delivery

There are 3 major issues in the introduction of DNA for large molecules such as trophic factors to the brain. First, the CNS exists in a privileged environment that is sheltered from the rest of the body, including the immune system, by the blood–brain barrier (BBB). Second, most neurons in the adult CNS are postmitotic and therefore do not easily incorporate new DNA once introduced. Third, trophic factors need to be selectively targeted to the intended anatomical region or cell population. The BBB excludes most gene therapy vectors. Naked DNA, most viruses, and all but a few cells will not cross into the brain unassisted. Viruses that can penetrate the BBB and transduce CNS cells include herpes viruses, retroviruses, adenoviruses, and AAVs. However, these viruses lack the transduction efficiency and target selectivity for individual cell populations necessary to make them useful in the treatment of AD.

In sum, the nonselective infusion of trophic factors or their expression constructs does not offer the necessary specificity of targeting for selective therapy because the introduced factor can be distributed to other active sites to produce untoward side effects. In contrast, ex vivo gene therapy, in which cells are modified in vitro and subsequently placed precisely into their targets using stereotaxic surgery, circumvents the BBB, removes the concern about transduction efficiency, and allows for precise spatial selectivity.

C. Ex Vivo Gene Therapy: Rationale and Considerations

Ex vivo gene therapy is one form of cell-based therapy. It is similar to other cell-based treatment modalities in that all require the selection of a cell population that is immunologically compatible, nonproliferating, and robust enough to survive after implantation into specific target sites and also produce the desired effect(s) for the lifetime of the patient. Cell-based treatment strategies that have been explored for the treatment of neurodegenerative disease include (1) the supplementation of neurotransmitters that are deficient due to cell loss through the implantation of cells exhibiting the same neurotransmitter phenotype; (2) the implantation of fetal brain cells or stem cells that potentially could differentiate into region-specific cells to replace lost neurons; and (3) the prevention of progressive cell loss by providing trophic factor(s) essential to cell survival and function. The first attempt at cell implantation therapy into the CNS for neurodegenerative disease involved the grafting of a patient's own adrenal medullary cells into the caudate for the treatment of Parkinson's disease. Early enthusiastic results did not survive more rigorous scrutiny. However, this initial failure did little to dampen hopes that one day neurodegenerative diseases would be treated successfully by grafting. This approach, which is essentially a neurotransmitter replacement strategy, is inadequate for AD because of the diffuse nature of the functional connections that need to be sustained; simply applying more transmitter does not replace the lost function. Where it has been used in other diseases, supplementation therapy using neurotransmitter agonists has only been successful in addressing selective symptoms. Other strategies ultimately must address the pathophysiology more directly.

Grafting fetal human or animal brain cells represents a logical next step. This strategy has been tried both experimentally and clinically. Investigators' initial hope was that fetal cells, given their pluripotent properties, would have the ability to adapt to their new environment and automatically replace or restore failing cells. This has proved somewhat vain, but the strategy continues to hold some promise; experimental efforts to use grafted fetal/progenitor cells in this fashion continue.

The use of ex vivo modified cells to deliver trophic factors is a potentially promising cell-based strategy for the treatment of AD. In this strategy, cells in an established culture are transduced to produce a trophic factor and are then implanted at the desired site of action. Because NGF secreted by geneti-

cally engineered cells does not diffuse through the brain far from its point of release, collateral effects should be limited. Although this is an advantage from the standpoint of side effects, it comes at the cost of the risk and trouble of surgically implanting the cells precisely at every target that needs trophic support.

1. Cell Selection for Gene Therapy Grafting

Various cell types have been used as carriers for the introduction of selective genes into the brain. These include stem cells, neural progenitor cells (NPCs), and fibroblasts. Each type of cell has different advantages and liabilities in terms of host compatibility, functionality, and oncogenicity.

Stem cell lines of different ages (e.g., embryonic and fetal) and different origins (e.g., brain and blood) have been established and characterized for use in cell replacement therapy. Embryonic stem (ES) cells can potentially provide a rich source of undifferentiated cells from which cells of specific functions can be derived. These differentiated cells can then replace or augment specific cell populations in the diseased brain. The desired cells are generated from the undifferentiated cells by providing them with a series of staged signals. Dopaminergic neurons have been generated from a population of ES cells using a plasmid expressing nuclear receptor related-1 (Nurr-1) transcription factor and a 5-stage differentiation method (41). Implantation of these altered cells corrected certain neurological deficits in one model of Parkinson's disease. Such a strategy may be useful in future cellular therapy for Parkinson's disease. A similar strategy that generates NGF-secreting cells similar to those that normally provide trophic support to the basal forebrain nuclei could provide a cell source for implantation.

Immortalized NPCs represent another renewable population of cells that can be transduced ex vivo to secrete NGF. An advantage of using these cells is that large numbers can be grown and prepared, and they should adapt well to the CNS environment. In one study, NGF-secreting NPCs were implanted into the medial septum in aged, previously unoperated rats. Animals that received grafts did not undergo the age-related decline in performance on a Morris Water Maze spatial learning task that the control animals did (42). In another study, rats that received NPC grafts expressing NGF factor showed increased hippocampal CA3 cell survival and neuromotor function following experimental head trauma (43). Graft survival and cholinergic sprouting in the implantation bed have also been observed after placement of NPCs transduced with human brain-derived neurotrophic factor (hBDNF) into adult rats (44).

Last, transduced skin fibroblasts have been used as vehicles to introduce specific genes into the CNS. In this method, skin biopsies are performed and the fibroblasts are cultured. A variety of methods for transducing the fibroblasts are available. The gene of interest is encased in an appropriate vector. Possible vectors include retrovirus, lentivirus, adenovirus, AAV, or DNA constructs such as plasmid DNA or lipsome-encased DNA. The vector is introduced into the culture. The transduced cells are then isolated and expanded. The viability and reliability of transduced fibroblasts as vehicles for delivering NGF to the CNS has been demonstrated in a number of studies (45,46). Genetically modified fibroblasts grafted into the spinal cord have been shown to survive, produce NGF, and promote the growth of specific neuronal subtypes (47). In transplanted tissue, the NGF produced is released intraparenchymally and has a restricted area of action.

2. Considerations for the Application of Ex Vivo Gene Therapy to AD

Rodent and primate studies in cholinergic denervation indicate that NGF is important in rescuing cells from axotomy-induced cell death as well as potentially augmenting cholinergic function. Therefore, to evaluate the effectiveness of NGF as a therapy for AD, patients to be treated would ideally be in the early stages of the disease, so that the rate of disease progression can be assessed. Outcomes should be assessed with careful preoperative and postoperative monitoring with standard psychological batteries, AD and other dementia rating scales, and magnetic resonance imaging (MRI) of the brain.

To implement ex vivo gene therapy for AD, a population of cells needs to be genetically modified to secrete NGF. For reasons relating to their immunology, autografts of patient's skin fibroblasts appear to be the most promising vector. Animal experiments have confirmed the practicability of this strategy. The transduction of these cells can be effected by the culturing of cells harvested from patient's own skin, genetically modifying them with the application of retroviral constructs, and expanding and selecting the cell population of interest (Fig. 2). The level of trophic factor production per cell can be determined. These cells are then concentrated into a small volume for injection in a dose-specific manner.

Next, the genetically modified cells must be implanted into the NBM. To successfully introduce the cells, the exact location of the NBM must be determined and readily confirmed using radiological scanning techniques. The nucleus is situated between the anterior commissure and the base of the brain. An appreciation of its location and morphology can be achieved by examining immunostained brain sections. This anatomic knowledge can then be correlated with MRI of the appropriate sections of the brain in individual patients (Fig. 3). This then permits the determination of the coordinates of each target in the basal nucleus. The major consideration in the design of the operative procedure is the need for precise targeting of the implants while minimizing the risks of implantation. Any implantation procedure carries with it, by its necessarily invasive nature, risks of hemorrhage and infection. Stereotaxic implantation of these cells affords the most precise targeting. This involves placement of a stereotactic head frame, imaging of the brain while in the frame, determination of the coordinates for each specific target, placement of a bur hole or bur holes, and introduction of an injection catheter under precise control. Accurate graft implantation can be complicated by the potential for brain shift after the subarachnoid space is entered and CSF egress occurs. This consideration is especially germane in AD patients, who usually have substantial brain atrophy and consequent enlargement of the sub-

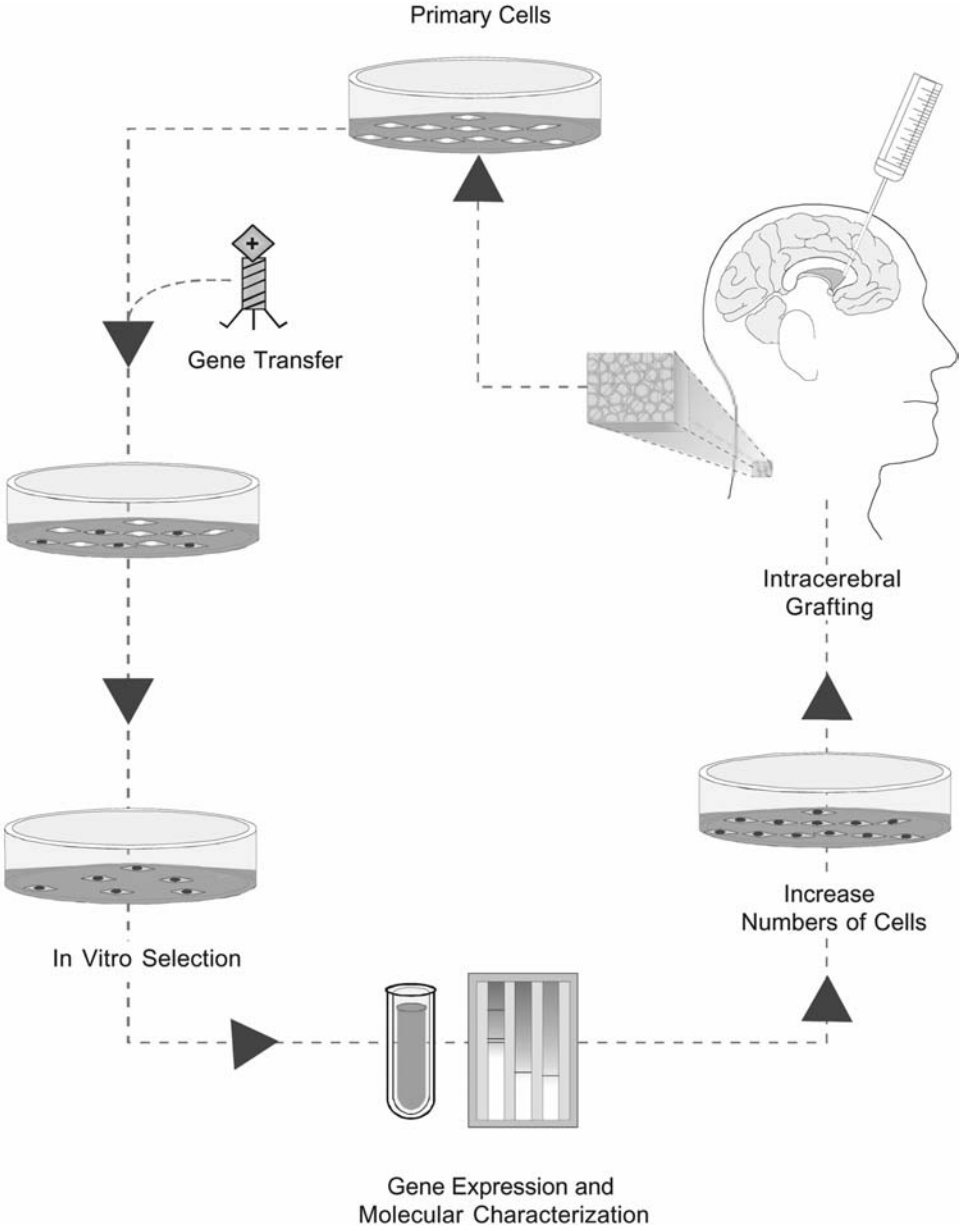

Figure 2 Schematic illustrating the basic steps in ex vivo gene therapy. See the color insert for a color version of this figure.

arachnoid space. To minimize this source of error, during surgical implantation every attempt must be made to minimize CSF egress through the bur hole. Design of the surgical procedure must also take into account the shape and orientation of the basal nucleus of Meynert. The NBM exhibits an anterior/mesial/ventral to posterior/lateral/dorsal orientation between the anterior commissure and the base of the brain. This orientation does not permit a single needle passage, depositing implanted cells along the axis of the needle, to populate the entire NBM with grafted cells. Multiple deposits therefore have to be made by passing the injection needle from the cortex to the target along multiple separate tracts. This increases the risks of hemorrhage as well as potential risk of damage to nerve fiber tracts. To decrease this risk, the planning of the operative procedure must involve planning a trajectory that does not require the needle to traverse the ventricles or any major groups of vessels. In addition, multiple injections are mandated by the fact that NGF secreted by the engineered fibroblasts exhibits limited diffusion into the surrounding brain. The entire operative procedure must also be undertaken

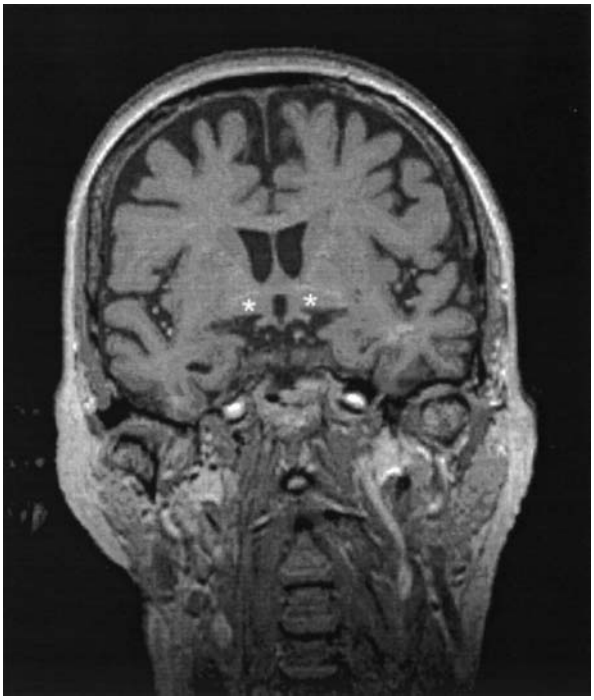

Figure 3 A coronal cut T1-weighted MRI at the level of the basal forebrain nuclei. Note the diffuse cerebral atrophy characteristic of AD. Asterisks indicate the anteriormost part of the basal forebrain nuclei. The anterior commissure is seen crossing just above the asterisks.

under deep enough anesthesia to prevent movement of the patient because trauma to the brain could occur if the head and brain move while the injection needle is inside the brain. Last, the injected cells are genetically altered and the potential for tumorigenic transformation exists. The ability to visualize the implant after injection would be essential to detect any growth of the graft. Provision for elimination of any tumor that may form (e.g., Gamma Knife radiosurgery) must be in place prior to clinical application.

These considerations must be accounted for in the design of any clinical trial of ex vivo gene therapy for AD. Such a clinical trial is currently in progress (48).

IV. FUTURE DIRECTIONS

We anticipate that in the future improved delivery techniques will make the process of factor/gene introduction safer. At present, the injection catheters are passed blindly, with a small but real risk of hemorrhage. In the near term, improved delivery will depend on further refinements in surgical instrumentation and technique and better imaging. Safety could be improved with real-time MRI and the ability to see potential hazards in the brain, such as blood vessels. The development of a readily available, renewable cell stock, preferably that does not require harvest from the individual to be transplanted, is also desirable. In vivo regulatable gene expression constructs would represent a significant advance in our ability to control the implants. Blesch et al. demonstrated the feasibility of this strategy using in vitro modulation of neurite outgrowth using rat fibroblasts transduced with a tetracycline-repressible construct secreting NGF (49). For a chronic disease such as AD, constitutive expression of NGF is probably appropriate. However, given that grafts may survive and produce NGF with variable success in different individuals, regulatable implants would allow a clinician to titrate the amount of trophic factor output to the needs of the patient.

Prospects for Clinical Application of Synthetic Gene Delivery Vectors

Nelson S. Yew and Seng H. Cheng
Genzyme Corporation
Framingham, Massachusetts, U.S.A.

I. INTRODUCTION

In many respects synthetic (''nonviral'') gene transfer vectors, comprised of either naked DNA or DNA complexed with a cationic lipid or polymer, are in a formative stage of development for use in vivo. Several diverse chemical compounds and physical methods of gene delivery are under evaluation, the mechanisms of gene transfer into different tissues are still being elucidated, and the acute and long-term toxicological consequences in vivo have not been fully characterized. Thus, it is perhaps surprising that almost one-fourth of the clinical gene therapy trials to date have used synthetic vectors, involving more than 700 patients (Fig. 1A). However, the overwhelming number of these protocols has been for the treatment of different cancers and far fewer noncancer trials have been initiated (Fig. 1B, Table 1). This chapter reviews some of the recent preclinical and clinical applications of synthetic vectors, highlighting a few disease targets that are representative of current synthetic gene delivery strategies. Included will be some discussion on the realistic prospects for synthetic vectors to be an effective therapeutic for a given disease indication and the technical challenges remaining to achieve that goal.

A. Current Status of Synthetic Vector Systems

What is the present state of synthetic gene transfer technology? Many of the originally perceived advantages of synthetic vectors are still valid, perhaps foremost being that synthetic vectors are not viruses, and as such they avoid most (but not all) of the immune complications associated with recombinant viral vectors. Although viruses have evolved over the millennia to evade host defenses, the host has likewise evolved a sophisticated system to recognize and eliminate or neutralize foreign pathogens. Because synthetic vectors presumably do not provoke specific immune responses, in theory they could be administered repeatedly, and are therefore conducive for treating diseases requiring prolonged or even lifetime correction. However, a number of overriding limitations of synthetic vectors have so far precluded capitalizing on this important feature.

One of the most significant problems continues to be the efficiency of gene transfer, and therefore the level of transgene expression that can be realized. The best synthetic vector systems express at levels that are generally 10 to 1000-fold lower than can be generated from recombinant viral vectors. This severely reduces the number of diseases for which synthetic vectors can be expected to generate therapeutic levels of a given protein. Numerous cationic liposomes, molecular conjugates, polymeric carriers, and peptides have been synthesized that mediate efficient transduction in tissue culture cells (1,2). Electroporation and ultrasound have been reported to enhance the efficiency of naked DNA transduction in skeletal muscle and other tissues (3). Novel physical methods of gene delivery have also been developed, such as catheter-mediated delivery of plasmid DNA (pDNA) to the liver and intravascular delivery into limb muscles under pressure (Fig. 2) (4–6). These techniques can generate levels of transgene expression that are significantly higher than some viral vectors such as adeno-associated virus (AAV). However, use of these methods in a clinical setting will require a further evaluation of their practicality and safety, including studies in nonhuman primates (7). At present, synthetic gene transfer efficiency remains a significant barrier to many clinical applications, but this limitation may be overcome with improved formulations and delivery methods.

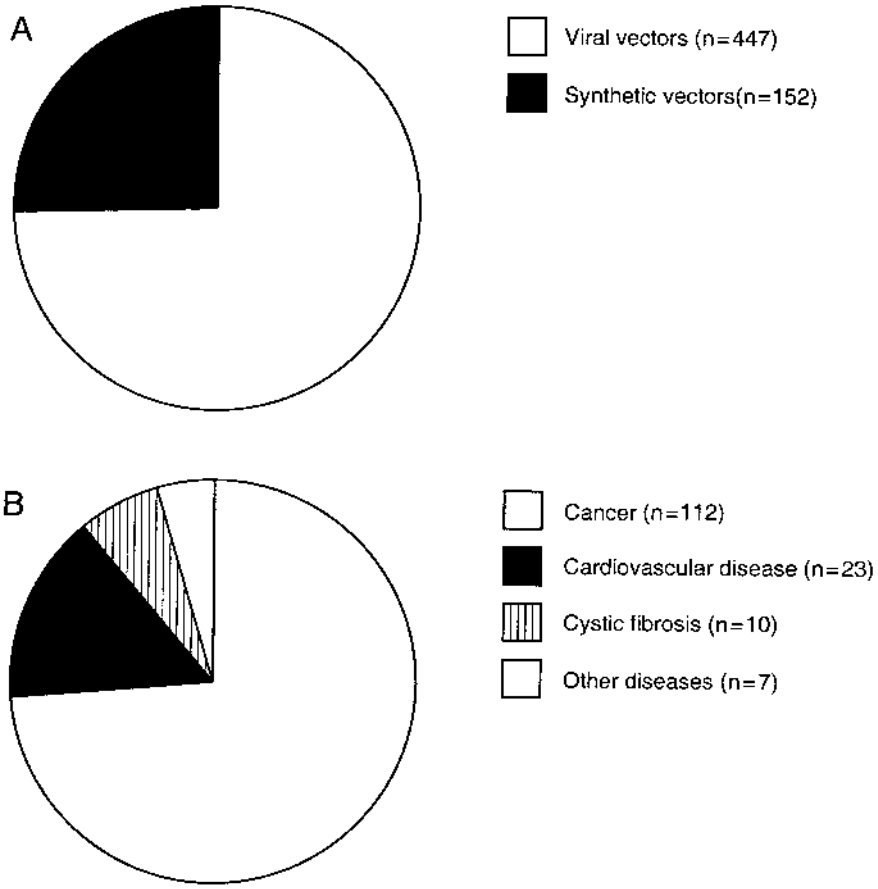

Figure 1 (A) Gene transfer vectors used in clinical trial protocols. (B) Clinical trial protocols using synthetic vectors. (Adapted from Ref. 93.)

Table 1 Clinical Trials Using Synthetic Vectors

Disease	Gene	Vector	Delivery	No. trials
Cancer	HLA-B7/β 2-microglobulin, IL-2, E1A, GM-CSF, gp100, others	Naked DNA, complex	Intratumoral, intraperitoneal, gene gun	112
Cardiovascular disease	VEGF, FGF, Del-1, others	Naked DNA, complex	Intramuscular	23
Cystic fibrosis	CFTR, AAT	Complex	Intranasal, aerosol	10
Bone disorders/fractures	Parathyroid hormone	Naked DNA	Bone implant	2
Cubital tunnel syndrome	IGF-1	Naked DNA	Intramuscular	1
Rheumatoid arthritis	HSV-TK	Naked DNA	Intraarterial	1
Hemophilia A	Factor VIII	Naked DNA	In vitro to skin fibroblasts	1
Canavan disease	Aspartoacylase	Complex	Intracranial	1
Alpha-1-antitrypsin deficiency	AAT	Complex	Intranasal	1

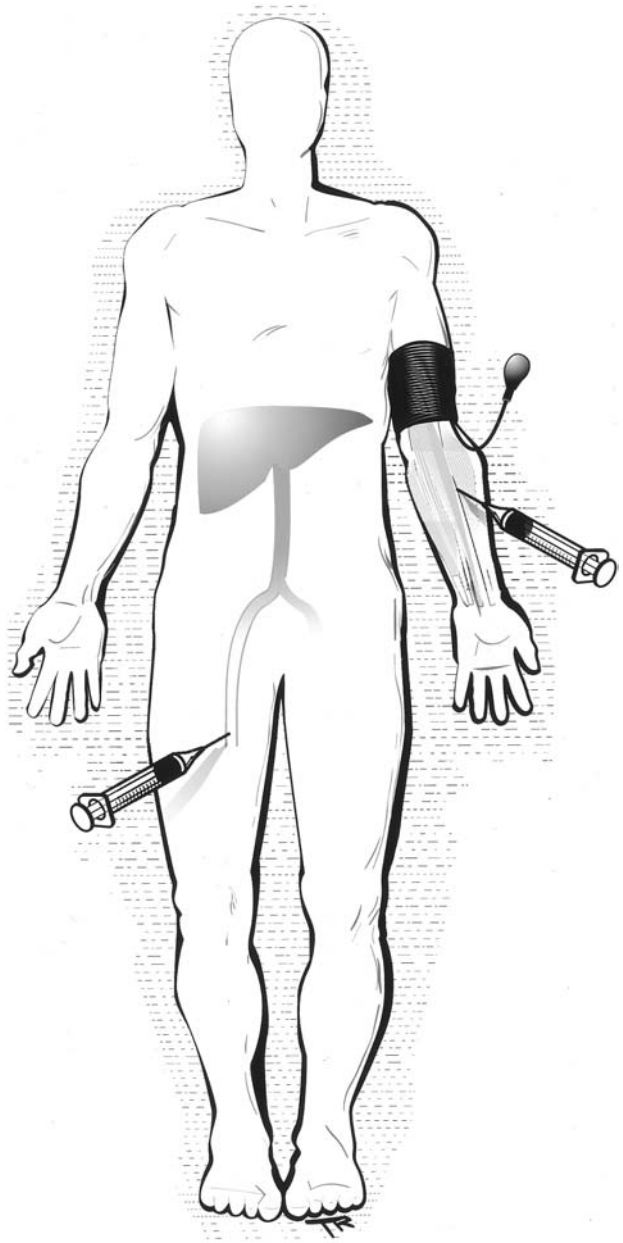

Figure 2 Two possible clinical approaches for delivering naked DNA. Depicted are intravascular delivery of DNA into skeletal muscle and catheter-mediated delivery of DNA into the liver.

Transient expression has long been another defining characteristic of synthetic vectors, which has until recently limited potential clinical applications to acute therapies. However, there are now examples of long-term expression from synthetic vectors lasting several weeks to greater than 1 year in vivo. A key aspect has been to identify promoters that remain transcriptionally active over an extended period in the major target organs, such as muscle, lung, and liver. Part of that challenge has been to identify promoters or promoter hybrids that are as transcriptionally robust as that of the widely used human cytomegalovirus (CMV) promoter, while not being prone to the known observed inactivation of CMV. Combinations of liver-specific promoter and enhancer elements have been identified that confer sustained expression in the liver with levels equivalent or superior to that of CMV (8,9). Hybrid promoters containing viral enhancer sequences linked to cellular promoters such as β-actin or ubiquitin also have been demonstrated to have significantly increased duration of expression (10,11).

Other advances in increasing the persistence of expression include the use of integrating elements to facilitate the retention of pDNA in tissues, for example, transposons (12) and phage integrases that promote integration of the vector (13,14). In addition, pDNA vectors that have been largely depleted of CpG motifs confer sustained expression through a mechanism that is presently unknown (15). Taken together, synthetic vectors are no longer limited to acute therapies and can be considered for diseases requiring long-term correction.

One of the more serious problems of synthetic vectors that are composed of a complex of DNA and a cationic liposome, polyamine, or other polycation is the acute inflammatory response observed in vivo. Intratracheal or intranasal delivery of cationic lipid–pDNA complexes induces an acute, dose-dependent inflammatory response characterized by an influx of neutrophils and the elevation of proinflammatory cytokines such as IFN-γ, TNF-α, IL-6, and IL-12 (16). Intravenous injection of complex causes a similar induction of cytokines as well as a dose-dependent activation of complement, loss of lymphocytes and platelets, and elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels indicative of liver damage (17). Injecting higher doses of complex can lead to significant morbidity. Several groups have shown that immunostimulatory CpG motifs within the pDNA vector play a significant role in the acute inflammatory and toxic response to cationic lipid–pDNA complexes (18–20). Methylation of the CpGs in the pDNA can markedly reduce cytokine induction, but interestingly cannot eliminate other toxic parameters such as lymphocyte and platelet loss or elevation of liver enzymes (21). Only synthetic pDNA vectors that have been largely depleted of CpG motifs can reduce but not totally obviate the acute toxic response (15).

B. Disease Targets for Synthetic Vectors

Given the limitations of the current technology, certain diseases are clearly more suitable for synthetic vectors than others. Cancer is highly amenable to treatment with synthetic vectors because many of the approaches involve either direct intratumoral injection or ex vivo modification of tumor cells or antigen-presenting cells, which avoids the problems associated with in vivo transduction. Diseases requiring only low levels of a secreted protein would also be favored targets given the low efficiency of gene transfer and achievable levels of expression. Such diseases also permit the muscle or lung to serve as the source of protein that can be secreted into the

circulation and distributed to other organs. Diseases that can be treated by cytokines, hormones, or growth factors therefore may be less challenging than diseases requiring correction of a protein deficiency.

II. SYNTHETIC VECTORS FOR INHERITED GENETIC DISORDERS

One class of disorders being targeted with synthetic vectors are those that are caused by a single gene mutation. Of the numerous diseases being targeted, reviewed here will be only a small representative subset that uses various vector systems and routes of delivery. In 3 of the diseases (cystic fibrosis, α-1-antitrypin deficiency, and Canavan disease), 1 or more clinical trials have already been conducted.

A. Cystic Fibrosis

Cystic fibrosis (CF) is caused by mutations in the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR), a cyclic adenosine monophosphate (AMP) activated chloride channel (22). This protein resides in the apical membrane of secretory epithelia, and in the lung is essential for maintaining proper fluid and electrolyte balance. Defects in CFTR function lead to accumulation of thickened mucus in the airway, bacterial colonization, and chronic pulmonary inflammation (23). Consequently, most CF patients die from lung failure.

Synthetic vectors have been considered appropriate for CF in part because the lung is the primary target organ, and thus the vectors can be delivered locally into the airway in the form of an aerosol without the need for targeting. Another consideration is that CF patients will have to be treated for their entire lifetimes. As such, repeat administration will be necessary, which in the absence of immunosuppression regimes is problematic for viral vectors. The interval between doses may be as often as every few months, given the normal turnover of airway cells and the increased rate of turnover in the inflamed CF lung. Preclinical studies with synthetic vectors have demonstrated correction of the CFTR-mediated chloride transport defect in vitro, and CFTR expression in the airways after aerosol delivery of cationic lipid–pDNA complexes. The levels of expression were quite low and transient, but nevertheless several groups moved forward to phase I trials in humans, primarily to assess safety.

There have been 10 clinical trials using synthetic vectors for CF (24–29). In the initial trials, cationic lipid–pDNA complex was delivered to the nasal epithelium, which served as a safe, easily accessible surrogate for the cells lining the pulmonary airway. The complex was applied using a syringe or spray, in some instances, over a period as long as 7 h (29). There was no evidence of inflammation or toxicity as a result of these treatments. Plasmid DNA and vector-specific RNA were detected in a proportion of the samples analyzed, and an increase in CFTR-mediated chloride conductance was observed in some trials, but not in others. No significant change in basal potential difference (PD), a measure of the sodium transport defect that is also present in CF patients, was observed in any of the trials. The results satisfied the primary goal of the trials showing that delivery of complex to the nose was safe.

Trials were also conducted in the lung using aerosolized cationic lipid–pDNA complex. The lung trials used a single cationic lipid (GL-67) and a CMV promoter-based plasmid that expressed wild-type CFTR. Although no changes in basal PD measurements were observed, Alton et al. (24) measured an in vivo potential difference toward normal values in 6 of 8 patients that received complex. This correction was considered statistically significant and represented a 25% restoration of chloride channel function. There was also evidence of decreased bacterial adherence on the treated airway epithelial cells.

These encouraging results were somewhat tempered by the observation of an acute inflammatory response to the administered complex, which was characterized as mild in 1 trial (24), but more severe in a second trial (26). In both, the patients developed flulike symptoms that included myalgia, headache, and fever, that began within 6 h and resolved within 24 to 48 h after treatment. This response was not observed when the same cationic lipid formulation without pDNA was aerosolized into the lungs of normal volunteers, suggesting that the complex of cationic lipid with pDNA was the causative agent (30). Unmethylated CpG motifs within the pDNA have been shown to contribute most (but likely not all) of the acute inflammation observed in mice that received complex intranasally. However, it remains to be determined whether immunostimulatory CpG motifs were the cause of the transient flulike symptoms in the human studies.

There are several challenges to be overcome before synthetic vectors can provide bonafide clinical benefit to CF patients. Many of these problems pertain to both viral and nonviral gene therapy approaches for CF (31). One barrier to gene transfer is the highly viscous mucus overlying the CF lung epithelium. Second, chronic airway infections induce inflammation, which is known to down-regulate gene expression of some promoters. Third, CFTR is not a secreted protein and will require transduction of at least 10% of the airway epithelial cells to restore normal chloride transport (32). Finally, clear and distinct measurements of clinical efficacy remain problematic (29,33).

Various strategies have been formulated to address these issues. Mucolytic agents have been shown to reduce the mucous barrier and increase gene expression (34). Promoters such as ubiquitin appear to have decreased sensitivity to inflammation and confer sustained expression in the lung (10,11). Repeated administration of a synthetic vector that has persistent expression may incrementally increase the percentage of cells transduced (Fig. 3). However, the validity of this approach must still be demonstrated and gene transfer efficiency will likely remain a significant challenge for CF therapy using synthetic vectors.

B. Alpha-1-antitrypsin Deficiency

Another lung disease that can potentially be treated with synthetic vectors is α-1-antitrypsin (AAT) deficiency. AAT defi-

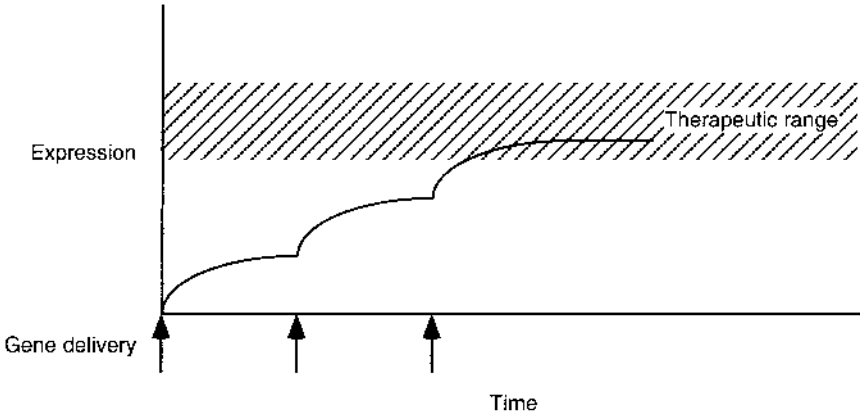

Figure 3 Theoretical strategy for achieving therapeutic levels of expression from synthetic vectors. Multiple dosing using a pDNA vector that confers sustained expression may lead to cumulative expression over time.

ciency is an autosomal recessive disorder caused by mutations in the gene encoding AAT, the principal antiprotease present in human plasma. AAT inhibits neutrophil elastase and thereby helps to protect the lung from destruction by this protease. Patients with low levels of AAT are susceptible to developing emphysema, and a subset also develops liver disease (35).

One gene therapy strategy for AAT deficiency is to transduce the liver, the normal site of AAT synthesis. The AAT is then secreted into the circulation and taken up by the lung (36). A second approach is to deliver the gene directly into the lumen of the lung, taking advantage of the ability of cationic lipid–DNA complexes to transduce the lung parenchyma. With this strategy lower but localized increases in AAT concentration may be as or more effective than elevating serum AAT levels. The levels of AAT required to be protective are not known, but in vitro studies have shown that small changes in AAT concentration can lead to relatively large alterations in neutrophil proteolytic activity (37).

A clinical trial was conducted on 5 patients with AAT deficiency (38). The cationic lipid formulation DOTMA-DOPE was complexed with a pDNA vector expressing AAT. As in the CF trials, the nose was used as a surrogate for the lung, and complex was applied to one nostril with the other nostril serving as the control. AAT levels in the nasal lavage fluid increased about 2-fold over baseline, peaking at day 5 and returning to near baseline levels by day 14. Although the peak levels of AAT reached only one-third of the normal mean, there appeared to be an anti-inflammatory effect from the treatment as evidenced by a slight but statistically significant decrease in IL-8 levels in the nasal lavage fluid. In contrast, intravenous delivery of AAT protein resulted in levels of AAT in the nasal lavage fluid within the normal range, but IL-8 levels did not decrease. These results bolster the contention that certain critical regions (e.g., the interstitial spaces between cells) are more easily accessible using localized gene transfer rather than intravenous delivery of protein (38).

If these studies are to progress to the lung, the same safety issues as in CF will need to be addressed, namely the acute inflammatory response from aerosolized cationic lipid–pDNA complex. Also as in CF, the endpoints for demonstrating clinical efficacy may be problematic. Measuring significant decreases in the rate of decline of lung function or the frequency of lung infections will require monitoring a large number of patients over a significant period of time. On the favorable side, complex can be aerosolized to reach the desired alveolar region and the levels of AAT needed to be protective may be low. This would argue for the use of a lower dose of complex that would then minimize any inflammatory response associated with the vector.

C. Lysosomal Storage Disorders

Another potential target for synthetic vectors are lysosomal storage diseases (LSDs), which comprise a group of more than 40 different disorders caused by deficiencies in different catabolic enzymes present in the lysosome that normally breakdown glycoproteins, glycolipids, and other macromolecules (39). As a result there is abnormal accumulation of intracellular storage products that, depending on the nature of the macromolecule, leads to dysfunction of 1 or more organs. LSDs are favorable targets for synthetic vectors because the threshold to correct the disease phenotype is predicted to be low, approximately 5% to 10% of normal levels based on milder forms of some LSDs. Second, a proportion of the lysosomal enzymes are secreted from the cell and are capable of being taken up by distant cells. This suggests that an organ such as the lung, liver, or skeletal muscle can be transduced to secrete a given lysosomal enzyme into the circulation that can then be distributed throughout the body.

Efforts using synthetic vectors to treat LSDs have been very preliminary to date. Marshall et al. (40) constructed pDNA vectors that express glucocerebrosidase, the enzyme that is deficient in Gaucher disease (41). The deficiency leads to an accumulation of the glycolipid glucosylceramide (GL-1) in tissue macrophages. The pDNA vector was injected hydrodynamically into the livers of a chemically induced mouse model of the disease, in which the mice transiently accumulate high levels of GL-1 within the lysosomes of their Kupffer cells. The injected mice expressed elevated levels of glucocerebrosidase in their livers and serum, and the levels of GL-1 levels were observed to decrease to baseline.

Synthetic vectors have also been used to treat a mouse model of Fabry disease, an X-linked recessive disorder caused by a deficiency of α-galactosidase A, which leads to an accumulation of the glycosphingolipid globotriaolsylceramide (GL-3) in the vascular endothelium of most tissues of the body. Fabry knockout mice have been injected intravenously with a cationic lipid complexed to a CpG-depleted pDNA vector (42). As expected, the highest level of α-galactosidase A expression was in the lung, with much lower but detectable levels in serum and the other organs. Expression persisted for approximately 2 months. During this time GL-3 levels declined gradually by 20% to 50% in the lung, liver, and heart. However, there was no reduction of GL-3 levels in the kidney, which is a critical target organ in Fabry patients.

Although GL-3 levels were only partially reduced in these studies, the results suggest that even very low but sustained expression may be sufficient to gradually deplete from the lysosome an accumulated glycolipid or glycoprotein. The transduced enzyme activity would only need to be slightly greater than the rate of accumulation of a given macromolecule. However, some of the challenges that remain include (1) the toxicity of systemically delivered complexes, (2) delivering enzyme to tissues that are difficult to reach from the circulation (e.g., bone to correct the skeletal defects in mucopolysachharidosis type VII), and (3) the need to correct both the central nervous system and visceral organs for many LSDs. Perhaps most important, the levels of expression in the lung and the amount of enzyme secreted into the circulation are at present marginally therapeutic. Improving secretion of the enzyme from the lung or targeting complexes to the liver may be beneficial. Repeat dosing may also cumulatively increase expression levels.

D. Familial Hypercholesterolemia

Synthetic vectors are being evaluated for the treatment of familial hypercholesterolemia (FH) and hyperlipidemias. FH is an autosomal dominant disorder caused by mutations in the low-density lipoprotein (LDL) receptor. Patients have persistently elevated levels of LDL in their serum, which leads to the development of atherosclerosis and coronary artery disease (43). Tomita et al. (44) injected a complex of hemagglutinating virus of Japan (HVJ) liposomes and a plasmid expressing the human LDL receptor into the hepatic portal vein of LDL receptor knockout mice. RNA was detected in the livers that peaked at days 7 to 10 after injection, but became undetectable by day 21. At day 7 there was a modest but statistically significant decrease in total cholesterol levels. Another approach being taken to treat hypercholesterolemia is to express apolipoprotein E, which is involved in removing excess lipoproteins and cholesterol from tissues. Rinaldi et al. (45) injected a plasmid that expresses apolipoprotein E (apoE) into the muscles of apoE-deficient mice. Very low levels of apoE (0.6 ng/mL) were produced in the serum, but this was sufficient to decrease serum cholesterol levels by 25% to 43%, and this reduction persisted for 16 weeks. Athanasopolulos et al. (46) also injected an apoE plasmid into apoE-deficient mice, but did not detect measurable levels of apoE in serum nor a decrease in serum cholesterol levels. Nevertheless, they did observe a retardation in the development of atherosclerotic and xanthomatous lesions.

The above results suggest that the threshold for successfully treating at least some aspects of hypercholesterolemia may be quite low, requiring expression of less than 1% of normal apoE levels to realize some benefit. This concept is supported by studies in transgenic mice expressing apoE from adrenal glands where 1% to 2% of normal serum apoE levels did not reduce hyperlipidemia but inhibited atherosclerosis (47). However, it has also been demonstrated in studies using adenoviral or AAV vectors that higher levels of expression will confer greater protection against atherosclerosis. For example, a helper-dependent adenoviral vector expressing a 1000-fold higher level of apoE in the serum than plasmid vectors inhibited the formation of atherosclerotic lesions for greater than 2 years after a single injection (48). These results suggest that higher and more sustained expression from synthetic vectors is desirable for treating FH and other hyperlipidemias.

E. Neurological Diseases—Canavan Disease

Canavan disease is an autosomal recessive disorder caused by a deficiency in the enzyme aspartoacylase, resulting in an accumulation of N-acetyl-aspartate (NAA) in the brain. The accumulation of NAA in the white matter causes spongiform degeneration of the brain, leading to severe neurological and motor impairment (49,50). Symptoms arise during infancy, and the disease is uniformly fatal.

Leone et al. (51) conducted preclinical studies in rats using LPD particles, which consist of the cationic lipid formulation DC-Chol/DOPE, the polycations poly-L-lysine or protamine sulfate, and pDNA. Intraventricular injection of LPD particles using a LacZ reporter plasmid showed (by LacZ staining) sustained expression for 10 months. Injection of LPD complex using a NAA plasmid in 2 monkeys showed no apparent toxicity, and NAA transcripts were detected by RT-PCR at 1 month.

Based on these preclinical studies, a phase I clinical study was then conducted in 2 children with Canavan disease (51). Five milliliters of LPD complex containing 400 μg of pDNA was injected into the lateral ventricle using a catheter. NAA levels were measured noninvasively and shown to be within

the normal range in the frontal and parietal, but not the occipital lobe 1 month after treatment. The levels in 2 of the lobes remained within the normal range in 1 patient for 12 months. There were some radiological, neurological, and behavioral improvements; however, it was not possible to draw firm conclusions regarding efficacy because of the small sample size and unblinded nature of the study.

Despite these early clinical efforts, application of synthetic vectors to neurological diseases will require greatly improved formulations that are optimized for gene transfer into the brain, and more extensive studies in animal models. Because of the equivocal and transient clinical results using synthetic vectors, Leone and her colleagues (52) switched to AAV vectors for their clinical trial that began in 2001.

III. SYNTHETIC VECTORS FOR ACQUIRED DISEASES

A second class of disorders being targeted with synthetic vectors are those that are not caused by a single gene mutation, but rather have a more complex etiology. Examples considered here are melanoma, myocardial ischemia, diabetes, and chronic wounds.

A. Melanoma

As seen in Table 1, by far the largest number of clinical protocols using synthetic vectors are for different cancers. This is largely a reflection of the preponderance of cancer clinical trials irrespective of the vector system used. Several different therapeutic strategies are being evaluated with synthetic vectors, including the use of antioncogenes, prodrug activating genes, tumor suppressor genes, and immunotherapeutic genes (53–56).

Several arguments can be made for using synthetic vectors for cancer. First, direct intratumoral injection is simple, minimizes systemic toxicity, and can be repeated multiple times, if needed. Second, cationic lipid–pDNA complexes that are delivered systemically or intraperitoneally are able to transduce tumors. Third, immunotherapy strategies require only relatively transient expression, sufficient to activate an immune response to the tumor. Last, immunostimulatory CpG motifs within the pDNA vector have been shown to stimulate a potent cytotoxic T lymphocyte (CTL) response, which is deleterious for most disease targets, but can be beneficial in activating an immune response to the tumor (57). In fact, several studies have shown that pDNA in the absence of expression of any cDNA is sufficient to induce tumor regression and increase survival in mouse models (58–61).

Although the preclinical and clinical studies using synthetic vectors for melanoma are too numerous and varied to be reviewed here, a few illustrative clinical trials using immunotherapy to treat melanoma can be described briefly. Advanced stages of melanoma are difficult to treat because of the development of metastatic lesions. In contrast, melanoma is characteristically highly immunogenic, and so is more responsive to immunotherapeutic approaches than many other cancers. Several groups have sought to express an allogeneic HLA-B7 molecule in a given tumor to promote a CTL response to the tumor (62). Cationic lipid–pDNA complexes were injected directly into the tumors of patients with advanced (stage IV) melanoma, with some patients receiving multiple injections at weekly intervals. Biopsies of the treated tumor were shown to contain vector-specific DNA and RNA, and enhanced tumor infiltrating lymphocyte activity was seen in most patients. In one trial, 7 of 17 patients had tumor regression of 25% or more (63). In another trial, 1 of 5 patients showed complete remission, with regression of the 2 injected nodules and distant metastatic lesions that were not injected (64).

The results of the clinical studies indicate that intratumoral injection of complex is safe and a clear clinical response was observed in some patients. However, it is at present unclear why tumor regression was seen in only a subset of the patients treated. A number of other approaches are under investigation, including the use of irradiated autologous tumor cells or dendritic cells transfected with cytokines or tumor-specific cell surface antigens (65–67). These efforts are directed toward generating a more robust immune response to the tumor and enhance response rates. Further advances in understanding tumor immunity combined with more efficient synthetic gene delivery vectors should improve the prospects for an effective immunotherapy for melanoma.

B. Myocardial Ischemia

Second to cancer indications are clinical protocols for cardiovascular disease, and most of these have used synthetic vectors to promote therapeutic angiogenesis for the treatment of cardiac ischemia. This condition, characterized by insufficient blood flow to the heart, oxygen deprivation, and inadequate removal of metabolites, is usually caused by the presence of atherosclerotic plaques in the blood vessel. Different growth factors, such as vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF-1 and FGF-2), and hepatocyte growth factor can stimulate the development of collateral vessels and improve myocardial perfusion (68).

The attractive feature of ischemia as a disease target for synthetic vectors is that these growth factors are highly potent. Expression levels can thus be relatively low and transient as well, just sufficient to promote vessel growth in the affected tissue. VEGF is also a naturally secreted protein and can be distributed to neighboring cells. In addition, the target tissue, cardiac or skeletal muscle (in the case of limb ischemia) is amenable to transduction by naked DNA.

A number of clinical trials have been performed on patients with end-stage coronary heart disease, involving injection of VEGF pDNA vectors at multiple sites into the myocardium. No adverse changes in heart function were observed as a result of the injections. Signs of clinical efficacy, such as decreased angina, were observed in many of the early trials, although interpretation was difficult in the absence of a placebo control group. A more recent randomized, double-blind, placebo-con-

trolled trial of 19 patients had results consistent with earlier trials. The patients exhibited improved exercise tolerance, had fewer episodes of angina, and required less medication (69).

The results show promise for further clinical development of synthetic vectors for ischemia. Gene transfer efficiency is low, but may be augmented using various physical methods (e.g., ultrasound, electroporation). In addition, other transgenes may be used in place of or in conjunction with VEGF to promote angiogenesis. One such transgene encodes a constitutively active hybrid transcription factor, HIF-1α/VP16 (70). HIF-1α regulates the expression of a large number of genes involved in O_2 homeostasis, including VEGF. In an acute myocardial infarction model in the rat, the combination of VEGF and HIF-1α/VP16 generated a higher capillary density than either factor alone (71).

C. Diabetes

Type I diabetes is an autoimmune disorder in which the insulin-secreting β cells of the pancreas are eventually completely destroyed. The lack of insulin results in elevated levels of glucose in the blood. Unless glucose levels are strictly controlled, patients suffer from complications such as blindness, heart and kidney disease, neuropathy, and limb ulcers.

Synthetic vectors expressing insulin have been evaluated in the streptozotocin-induced diabetic mouse model, where the goal has not been to completely restore insulin levels, but rather to provide basal levels of insulin as an adjunct to current insulin treatments. Morishita et al. (72) injected HVJ liposomes and an insulin expression plasmid to SZT-induced diabetic mice. Serum insulin levels were quite low (2 μU/mL at day 4) and persisted for only 2 weeks, although repeat injections increased the duration of expression. A number of groups have used skeletal muscle to secrete insulin by injecting naked pDNA vectors containing a furin-cleavable proinsulin cDNA, which in muscle is processed to mature insulin by endogenous furin (73–75). The peak of serum expression occurred approximately 1 week after injection and expression persisted for 4 to 6 weeks. Martinenghi et al. (76) also performed in vivo electroporation of the muscle and achieved some of the highest levels of insulin in the serum, peaking at 68 μU/mL. Furthermore, while the untreated streptozotocin-treated mice died within 3 weeks, the treated mice survived up to 10 weeks.

Clinical application of this muscle depot approach will require translation of these results into larger animal models, which may be problematic as the efficiency of transducing skeletal muscle has been observed to decrease as the size of the animal increases. Vascular delivery of pDNA under pressure may be an alternate strategy (6). A second requirement will be the need for some sort of regulated expression to avoid the toxicity of unregulated insulin levels.

D. Chronic Wounds

The treatment of chronic wounds is an attractive candidate for synthetic vectors. Problematic nonhealing wounds can be caused by burns, diabetes, pressure, vascular disease, or connective tissue disease, and represent a major clinical problem that leads to significant morbidity.

There are several arguments for using gene therapy to treat chronic wounds (77,78). The skin is readily accessible for gene delivery, and at the same time vector delivery and expression can be localized, reducing systemic toxicity (79). The effectiveness of treating lesions with growth factors has been limited by the high cost of the purified factors, the short half-lives of the proteins due to the presence of high concentrations of proteases in the wound, and the potential toxicity from the large doses required. Gene therapy could provide more constant levels of growth factor locally, the expression of which could be of relatively short duration that is sufficient for closure of the wound.

Several growth factors have been shown to promote wound healing. Those factors that have been expressed from pDNA vectors include platelet-derived growth factor, keratinocyte growth factor, insulin-like growth factor-1 (80,81), acidic fibroblast growth factor (82), epidermal growth factor, and transforming growth factor β-1. The choice of which factor to use may depend on the type of wound and the stage at which the wound is treated.

These plasmids have been delivered to the wound site by 3 principal methods. One approach is particle-mediated gene transfer involving high-velocity delivery of pDNA adhered to gold particles (83). This technique has been used to express EGF, PDGF, and TGFβ-1 in wound sites and shown to accelerate healing and increase wound tensile strength. A second approach is subcutaneous injection of liposomal–pDNA complexes. Jescke et al. (84) demonstrated that injection of a complex of DMRIE-Chol and a plasmid expressing KGF into thermally injured rats greatly improved epidermal and dermal regeneration. A third approach has been to embed pDNA within a gel or matrix (Fig. 4) (85,86). Cells are able to migrate into these matrices and take up the pDNA. For example, a pDNA expressing platelet-derived growth factor embedded in a collagen matrix has been shown to promote wound healing in a dermal ulcer model (87).

Although viral vectors such as adenovirus (88) and AAV (89) have also been evaluated, this is one application where nonviral delivery methods are prominent. Efficiency of gene delivery remains an issue, as it has been shown that administration of too high a dose of pDNA will actually inhibit the rate of wound healing (90,91). More efficient physical delivery methods, such as microseeding (92), improved liposomal formulations, and more effective polymer matrices will improve efficacy. Combinations of growth factors may be beneficial, and regulated expression systems need to be considered. Safety issues for this application seem to be minimal, and overall, clinical use of synthetic vectors for wound healing appear to be quite promising.

IV. SUMMARY

Synthetic vectors have been applied to a wide range of inherited and acquired diseases, and this review has covered only

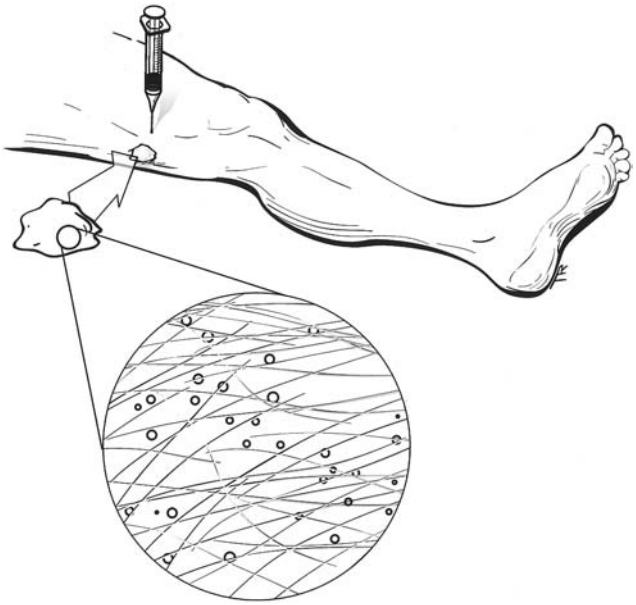

Figure 4 Synthetic gene delivery to promote wound healing. Cationic lipid–pDNA complexes can be injected subcutaneously at sites near the wound margin. Alternatively, pDNA can be embedded in a collagen or fibrin matrix. Cells migrating into the matrix take up the pDNA and express a given soluble factor.

a small list of disorders for which synthetic vectors have been used. Efficacy has been demonstrated in several animal models and clinical trials have been conducted. The preclinical and clinical results revealed genuine promise but also definite limitations that should perhaps serve as a cautionary sign for moving synthetic vectors too aggressively into clinical use.

Safety is of prime concern for any gene therapy, and although synthetic vectors are generally safe, an acute inflammatory response is observed with certain vector systems and delivery routes. Naked DNA delivery into muscle appears to present the least number of complications, with a minimal (but not totally benign) inflammatory response and little to no systemic toxicity. In contrast, cationic lipid or polycationic–pDNA complexes induce a dose-dependent toxic response when delivered by aerosol into the lung or injected systemically. The response observed in CF patients that received aerosolized complex was transient and treatable symptomatically with analgesics. However, systemically delivered complex induces a much more severe reaction, especially at higher doses, and no clinical use with this delivery route can be foreseen until this toxicity is resolved. Less toxic vectors and formulations, which include CpG-depleted vectors and smaller nonaggregating complexes, are under development. But for now, any proposed clinical application should consider the possible consequences of the innate immune reaction to current synthetic vector systems.

Gene transfer efficiency continues to be the paramount limitation of current synthetic vectors. The many published preclinical results demonstrating some degree of efficacy are generally using delivery methods or doses that would not be clinically acceptable, and most studies have been in small animals such as mice, where the levels of expression observed are often not translatable to larger animals and humans. Therefore, generating therapeutic levels of a protein to replace that which is absent in a given inherited genetic disease is probably unrealistic with the current technology. More feasible is expressing modulating proteins, such as cytokines to inhibit inflammation, tumor-specific antigens to induce an immune response, or growth factors to promote angiogenesis or cell proliferation. These approaches, as well as related strategies in which synthetic gene transfer serves as an adjunct therapy to existing therapies, may be more appropriate and have greater chances of clinical success.

Regulatory Aspects of Gene Therapy

Stephanie L. Simek and Maritza C. McIntyre
Food and Drug Administration
Rockville, Maryland, U.S.A.

I. U.S. OVERSIGHT OF GENE THERAPY

A. Food and Drug Administration Regulatory Authority

Since the beginning of recorded history, societies have been concerned about the purity of the food and drink available to the public. Regulation of food in the United States dates back to early colonial times. Federal controls over the drug supply started in 1848 when the state of California passed a pure food and drink law. In 1902, Congress made appropriations to establish food standards; in the same year, the Biologics Control Act was passed to license and regulate interstate sale of serum, vaccines, and other biologics used to prevent or treat disease in humans. The 1902 act established federal inspection of licensed facilities, prohibition of false labeling, and the concept of a dating period during which a biological product would be medically used. In 1906, the Food and Drug Act passed Congress, prohibiting interstate commerce of misbranded and adulterated foods, drinks, and drugs. In 1938, the Federal Food, Drug, and Cosmetic (FD&C) Act was enacted, making the 1906 Food and Drug Act obsolete. The FD&C Act extended controls to cosmetics and therapeutic devices, and also required predistribution clearance of new drugs based on safety. In addition, this act authorized standards of identity and quality for foods and drugs, as well as authorized factory inspections. In 1944, the Public Health Service Act (PHSA) was established and consolidated the major rule-making authority for biological products under Sections 351 and 352. The PHSA requires that the product and the establishment where the product is manufactured meet standards to ensure continued safety, purity, and potency of the biologic.

Today the primary mission of the Food and Drug Administration (FDA) is to safeguard and promote the public health by promptly and efficiently reviewing clinical research and taking appropriate action on the marketing of regulated products. This is accomplished by upholding established regulatory principles, such as quality control, sound scientific rationale, and risk–benefit assessment. During the regulatory process, it is important that these principles be applied in a way that will encourage early product development and not inhibit development of new clinical approaches. This is particularly challenging for the field of gene therapy, where some of the risks are clearly undefined, although the potential benefit of these therapies may be great. To apply these principles, the Center for Biologics Evaluation and Research (CBER) takes a comprehensive approach to the regulation of biological products. This approach involves scientific review of submissions, a strong research program to support the regulatory process, surveillance, policy development based on sound science, and compliance to ensure that the manufacture of biological products and the conduct of clinical trials are performed in accordance with the regulations and statues set forth to safeguard subjects enrolled in clinical trials.

CBER is 1 of 5 centers comprising the FDA and is responsible for the regulation of biological products. The authority to regulate biologics is mandated by both the FD&C Act and the PHSA. These acts outline binding practices for the agency and the sponsor. The FD&C Act provides the legal interpretation that a ''biologic product'' is also a ''drug,'' and section 351 of the PHSA makes provisions for the regulation of biological products through licensure of the product and the establishment in which the product is manufactured. Under the PHSA, a biologic is defined as ''a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, analogous product, or arsphenamine or derivative of arsphenamine (or any other trivalent organic arsenic compound), applicable to the prevention, treatment or cure of a disease or condition of human beings.''

Regulations pertaining to conduct of clinical investigations using biological products are outlined in title 21 of the Code of Federal Regulations (CFR). Regulations are interpretations of the laws that provide rules for daily business and are binding like laws. The regulations covered under 21 CFR 312 specify requirements necessary for submission of investigational new drug (IND) applications, whereas standards for licensure of a biological product are described under 21 CFR 610. The FDA's regulatory authority in the somatic cell and gene therapy area was established in the *Federal Register* dated October 14, 1993, entitled ''Application of Current Statutory Authorities to Human Somatic Cell Therapy Products and Gene Therapy Products.'' This document establishes that somatic cell and gene therapy products are biological products, and as such are subject to the licensing provisions of the PHSA.

Besides the statutes and regulations by which the FDA governs its day-to-day interactions with industry and academia, the agency also issues guidance documents that are not binding but rather describe CBER's policy and regulatory approach to specific product areas. Examples of documents that present recommendations, and provide relevant guidance to somatic cell and gene therapy products, are provided in section V.

B. Status of Gene Therapy in the United States

As provided in the document, ''Application of Current Statutory Authorities to Human Somatic Cell Therapy Products and Gene Therapy Products,'' human gene therapy is defined as a medical intervention based on the administration of genetic material in order to modify or manipulate the expression of a gene product or to alter the biological properties of living cells. Cells may be modified ex vivo for subsequent administration or altered in vivo by gene therapy products given directly to the subject. Examples that fall under this definition include, but are not limited to, autologous bone marrow stem cells modified with a viral vector, intramuscular injection of a plasmid DNA vector, and direct injection of a viral vector for treatment of hemophilia. Since submission of the first human gene therapy IND in 1989, 317 human gene therapy INDs have been submitted to CBER for review (through September 2002). The review of gene therapy INDs was the responsibility of the Office of Therapeutics Research and Review until September 30, 2002. Effective October 1, 2002, the review of gene therapy INDs is coordinated through the newly created Office of Cellular, Tissues, and Gene Therapies within CBER.

Currently, there are 197 active gene therapy INDs at CBER (Fig. 1). Although more than one-half of the INDs submitted have involved ex vivo modification of cells using gene therapy vectors, since 1995 the number of INDs involving direct administration of gene therapy vectors has been increasing. Currently, almost 48% of all INDs use direct vector administration. Overall, almost 90% of INDs submitted have involved expression or replacement of a gene with therapeutic intent and comprise indications as broad as cancer, HIV, cystic fibrosis, hemophilia, peripheral and arterial vascular disease, arthritis, and many rare diseases (i.e., x-linked SCID, Fanconi anemia). In approximately 26% of the INDs, nonviral plasmid vectors were used for gene delivery. Of the viral vector systems used, more than one-half of the INDs submitted have used retroviral vectors, about one-quarter adenoviral vectors, and a small number have used adeno-associated, herpes and vaccina viral vector systems.

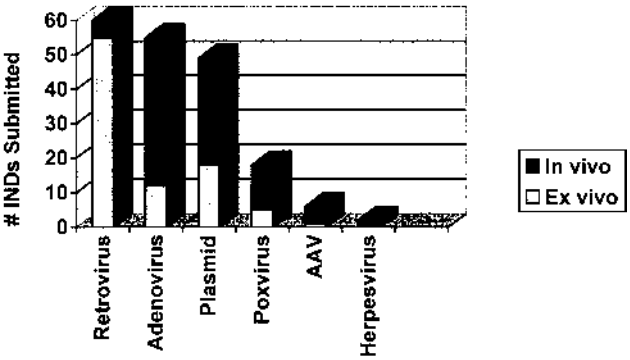

Figure 1 Schematic of currently active INDs showing the types and number of vectors being used in U.S. gene therapy clinical trials.

For the area of gene therapy, CBER has applied a unique regulatory approach that has included an element of public process that is not typically used to regulate other products at the FDA. The goal of this public interaction has been to increase the community's understanding of the CBER review process and requirements, to allow deliberation of ethical and social issues that surround the area of gene therapy, to receive input into CBER gene therapy policy development, and to provide accurate information to the public about the progress of gene therapy clinical trials. Much of this process has been facilitated by the National Institutes of Health (NIH) Office of Biotechnology Activities (OBA), through quarterly meetings of the Recombinant DNA Advisory Committee (RAC). The FDA also convenes its Biological Response Modifiers Advisory Committee to discuss relevant issues regarding the safe use of gene therapy products and conduct of clinical trails. In addition, the FDA routinely takes part in forums with industry, trade groups, academia, and the public in order to foster public understanding in the area of gene therapy, which is essential for continued progress of the field.

C. FDA/RAC Oversight

Unlike other areas under clinical investigation that are regulated by the FDA, gene therapy clinical investigations are subject to the scrutiny of 2 federal agencies within the Department of Health and Human Services, the FDA, and the NIH OBA. Oversight of human gene therapy clinical trials at the NIH involves a public process of review and discussion, conducted

by the RAC, that ensures public awareness of clinical trial registration and follow-up. The RAC meets quarterly for public discussion of proposals that are deemed novel. In contrast, FDA review of gene therapy INDs is confidential and conducted by agency reviewers on an ongoing basis.

The emphasis of the review by each group is complimentary. Both the NIH and the FDA deliberate preclinical and clinical issues; however, the RAC's responsibilities extend beyond safety and efficacy to the consideration of the ethical, legal, and social implications of such research. The FDA provides careful and thorough review of product manufacturing related to product safety, purity, potency, and identity, whereas the RAC does not consider these manufacturing issues due to the proprietary nature of such information. Currently, information regarding human gene therapy clinical trials must be submitted to both the FDA and the NIH.

1. RAC History

The RAC was established in 1975 as a result of public concern over the potential risks of the new field of recombinant DNA (rDNA) research. Scientists worldwide had voluntarily halted their research and met in Asilomar, California, to debate the future of the use of rDNA technology. The RAC evolved from these debates and met for the first time just after the Asilomar meeting. The RAC mission was to advise the NIH Director and to review in public each experiment involving recombinant DNA research. Subsequently, NIH established the OBA (previously called the Office of Recombinant DNA Activities), to provide administrative support to the RAC. Over the first few meetings, the RAC set minimum standards for biological and physical containment of rDNA molecules. This was accomplished through public debate and with input from scientists and lay representatives, including ethicists and economists. In 1976, as a result of these discussions, the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH Guidelines) were published in the *Federal Register*. The NIH Guidelines provided for submission and review of rDNA experiments by the RAC and also provided for the element of public debate of rDNA research. The NIH Guidelines are not regulations, but establish their authority through the NIH funding process. Investigators receiving NIH funding, or who are affiliated with an institution that has NIH funding, must comply with the NIH Guidelines. In addition, they ask for voluntary compliance by non–NIH-funded investigators. This process has provided a precedent for the public discussion and consideration of gene therapy clinical trials conducted today.

In 1982, in response to the report of the President's Commission entitled ''Splicing Life: Social and Ethical Issues of Genetic Engineering with Human Beings,'' the Human Gene Therapy Subcommittee (HGTS) to the RAC was established to review the application of rDNA technology to human gene therapies. The first human gene therapy protocol was approved after public discussion by this committee and separately by the FDA in 1990. Over time, as the public concern over rDNA experiments subsided and the interest in gene therapy increased, the HGTS subcommittee merged with the full RAC and the combined group discussed and approved each gene therapy protocol prior to its initiation. In 1994, an accelerated review process was adopted for certain categories of clinical trails that had been routinely reviewed by the RAC and determined not to represent significant risk to human health and the environment. Under this mechanism, such protocols were subject only to written review by several RAC members, and OBA approval, outside the quarterly meetings.

The RAC is currently comprised of 21 members from the disciplines of science, medicine, law, and ethics. They meet quarterly for the public review and discussion of novel gene therapy protocols. However, they no longer approve or disapprove protocols. Currently, their function is purely to provide a platform for public discussion of novel issues involved in gene therapy clinical trials. In addition, the RAC sponsors the Gene Therapy Policy Conferences (GTPC), which provide a mechanism for in-depth discussion of relevant gene therapy issues. For this forum, a panel of experts is convened with the goal of reaching consensus and developing guidance in a particular area. GTPC discussions have focused on topics such as genetic enhancement, use of lentiviral vectors, prenatal gene therapy, and adeno-associated virus (AAV) vectors.

2. Dual Submissions

As illustrated in Fig. 2, there is a parallel path of submissions required prior to initiation of a gene therapy clinical trial. Sponsors of a gene therapy clinical trial must submit an IND application to the CBER, FDA for review under a 30-day review cycle and may not proceed until the IND is found to be acceptable. In addition, the FDA requires that a sponsor receive the approval of the institutional review boards (IRBs) and institutional biosafety committees (IBCs) affiliated with the institutions at which the trail will be conducted. Concurrently or prior to submission of an IND to the FDA, investigators conducting the clinical trial must also submit their protocol and information specified in Appendix M of the NIH Guidelines to the NIH OBA for review by the RAC. Based on recent changes to the NIH Guidelines for Research Involving Recombinant DNA Molecules (May 2002), all investigators/sponsors who receive or who are sponsored by an entity that receives NIH support for recombinant DNA research must submit their clinical protocol to the RAC for review. Failure to follow the NIH Guidelines can result in withdrawal of NIH funding to the investigator and any supporting institutions. Although an investigator may submit the protocol to the FDA and the IRB prior to submittal to the RAC, review by the RAC is required before final IBC approval, so the committee can be informed of the RAC recommendations before making its final determination. The OBA submission must be received no less than 8 weeks prior to the next scheduled RAC meeting. A gene therapy clinical trial will be judged as exempt from, or in need of, full RAC/public discussion based on the following factors: novelty of the vector or gene delivery system, special disease concerns, unique applications of the gene therapy research or important social or ethical issues raised by the proposed research. Recommendations and comments resulting

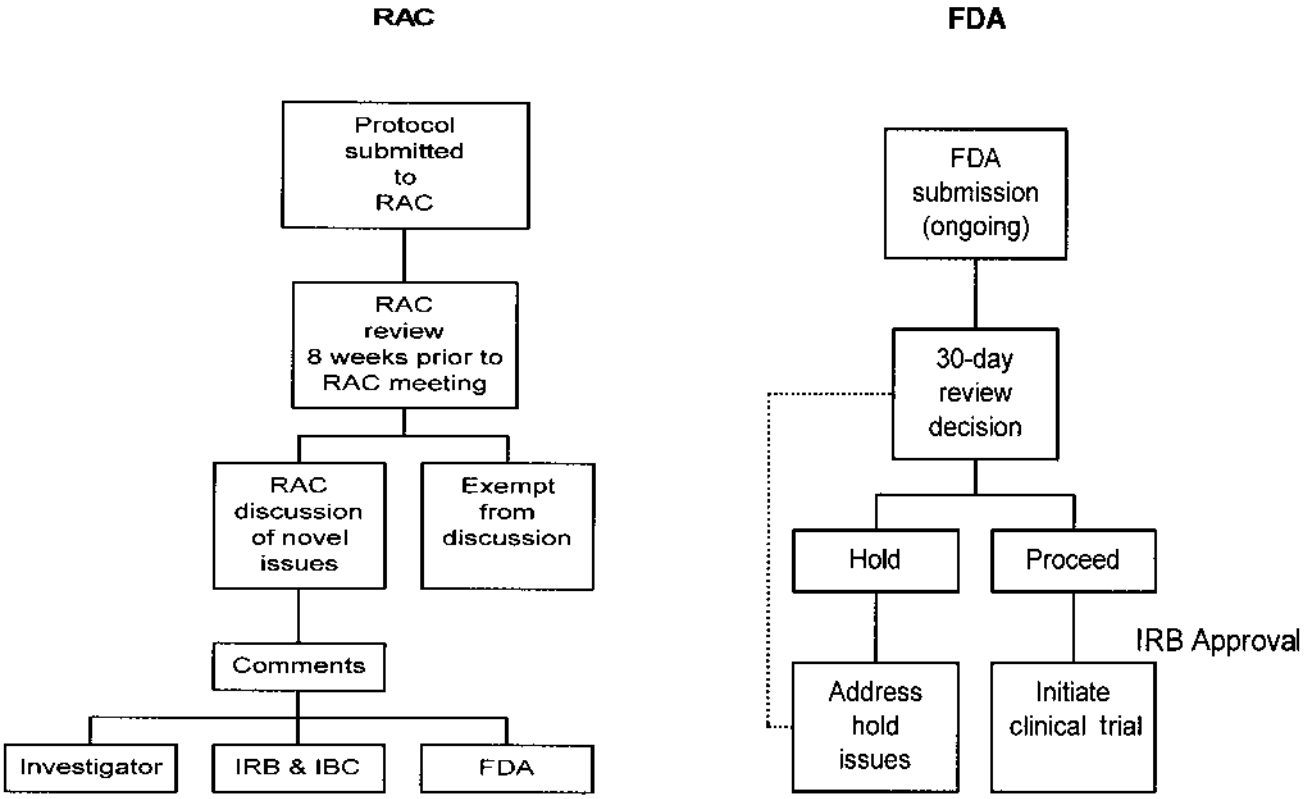

Figure 2 Overview of parallel processes for submission of documentation related to initiation of human gene therapy clinical trials to the RAC and the FDA.

from discussion at the RAC meetings are forwarded to the investigator, the IRB, IBC, and FDA.

Due to timing and regulatory requirements, there are situations where the FDA decision to allow a clinical trial to proceed must be made before public discussion can occur. In this situation the investigator/sponsor is reminded by the FDA of the need to comply with NIH Guidelines regarding DNA recombinant research and that enrollment of subjects into the clinical trial may not begin until review and, if selected, public discussion of the protocol by the RAC has taken place. In general, public discussion of gene therapy clinical trials has been highly beneficial because it allows for consideration of societal and ethical issues surrounding the field of gene therapy and ensures the continued public acceptance and progression of the field.

II. THE IND PROCESS

As mandated under section 505 of the FD&C Act and section 351 of the PHSA, it is illegal to sell or distribute any biologic unless it is licensed or under an Investigational New Drug Exemption (21 CFR 312.2). Submission of an IND to provide for this exemption allows clinical investigation of the product to proceed in order to determine safety, dosage, and effectiveness. This investigational process is usually divided into 3 phases, with each phase providing the next step in support of product licensure.

A. Definition of IND Phases

As illustrated in Fig. 3, product development begins with the pre-IND stage and progresses through the investigational or IND stage (phases I–III), where data are obtained to support product licensure. This is followed by the postlicensing stage (phase IV), during which further studies are often performed. An IND may be submitted for 1 or more phases of an investigation, although, in general, the phases of a clinical study are conducted sequentially.

A phase I trial includes the initial introduction of an investigational new drug into humans. The primary focus of a phase I study is to monitor product safety in a specific patient population, although it should be noted that assessment of product safety remains a primary issue throughout product development. Phase I studies should be designed to determine the metabolic and pharmacological actions of the drug in humans and the side effects associated with increasing doses, and, if

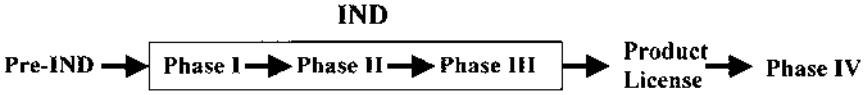

Figure 3 Phases of product development and approval.

possible, to gain early evidence of product effectiveness. During the phase I study, the investigator should focus on obtaining sufficient information about the drug's pharmacokinetics and pharmacological effects that would permit for the design of well-controlled, scientifically valid, phase II studies. In a phase I study, the product may also be assessed for structure–activity relationships, as well as the mechanism of action in humans. The total number of subjects included in a phase I gene therapy study varies but is typically between 10 and 40.

Phase II of an IND should include controlled clinical studies conducted to evaluate the effectiveness and dose ranging of the product for a particular indication in patients with the disease or condition under study. These studies should be designed to determine common short-term side effects and risks associated with the biological product. Phase II studies are typically well-controlled, closely monitored, and conducted in a relatively small number of patients, usually involving no more that several hundred patients.

Phase III studies are expanded well-controlled, randomized and, when possible, blinded studies that are performed after preliminary data for the effectiveness of the product have been obtained. These studies are intended to gather further information about product effectiveness and safety that is needed to evaluate the overall benefit–risk relationship of the product and generally serve as the pivotal efficacy study to support licensure. Phase III studies usually include from several hundred to several thousand patients, depending on the clinical indication and patient population.

Clinical evaluation of a biological product rarely ends with issuance of a biologics license. Phase IV, or the postmarketing stage, refers to the ongoing period of development after the product is licensed. Examples of postmarketing studies include clinical studies to extend claims or usage for the addition of a new patient population or indication, studies to demonstrate product comparability after manufacturing changes, and studies to validate surrogate clinical endpoints that are required in cases of expedited review and accelerated approval.

The FDA's primary objective when reviewing all phases of an IND is to assure the safety and rights of the patient, and later in phases II and III, to help assure that the validity and quality of the scientific data used to evaluate the product is adequate to assess product safety and efficacy

B. Pre-IND Phase

An IND application and the application process itself can be bewildering to novice sponsors. Therefore, before IND submission, CBER encourages an early interaction, in the form of a pre-IND meeting, to discuss preclinical animal testing, product development, and clinical trial plans. Although the central focus of the pre-IND meeting is to define what is needed to support the IND submission, another important goal is to create a dialogue between CBER and the sponsor/investigator that can be maintained throughout the process of product development. The pre-IND meeting is arranged at the request of the sponsor; however, before CBER can grant a pre-IND meeting, the sponsor will need to prepare a meeting package. Although the investigational plan does not have to be in its final form, the sponsor should be prepared to briefly describe all aspects of the proposed clinical study in the meeting package. This should encompass a description of the biological product, product manufacturing and testing schemes, established preclinical data, plans for additional preclinical studies, the proposed clinical protocol, and the general proof of concept behind the proposal. Most important, the pre-IND meeting should be used as a mechanism for focusing on unresolved issues relating to preclinical studies, clinical studies, or product development. It is recommended that questions be submitted with the pre-IND package addressing any concerns or potential problems with the investigational plan that would require guidance and/or discussion with the agency before submission of the IND. Past experience has proven that early identification and resolution of these issues will ultimately enhance and accelerate the product development process.

C. The IND Phase

Before submitting an IND, the sponsor must have generated enough preclinical data to ensure the safety of the proposed clinical trial. Preclinical data can be generated using either in vivo animal studies or in vitro studies to assess the product's activity, efficacy, pharmacology, pharmacokinetics, and toxicity. In addition, preclinical studies should be designed to identify potential target organs of toxicity and provide data to support clinical use of the product, such as safe starting dose, route of administration, and dosing regimen. Information to support the scientific rationale behind the proposal should also be provided. Issues specific for gene therapy that can be addressed with preclinical studies include biodistribution or trafficking of vectors, level and persistence of gene expression, and germline alteration. The sponsor should also have a well-developed and controlled product-manufacturing scheme, and have collected data regarding product characterization and consistency to support the manufacturing process.

This data should also be used to support proposed specifications for product quality control and release.

Once these issues have been addressed, the next step is the preparation of the IND submission. For assistance in preparation of an adequate and complete IND, the sponsor should contact the Office of Communication, Training and Manufacturers Assistance to request an IND submission package. The package contains forms to be submitted, copies of the IND regulations, informed consent and IRB regulations, information pertaining to GLP/GMP, and the essentials required for conducting adequate and well-controlled clinical trials. An IND submission package can also be obtained at the FDA website (www.fda.gov/cber/ind/ind.htm).

1. The IND Submission

The content and format of an IND submission is specified in 21 CFR under part 312.23. This part lists, in order, the items that a sponsor (person who takes responsibility for and conducts a clinical investigation) should submit in the IND (Fig. 4). The IND should be submitted to CBER in triplicate and, upon receipt the sponsor of a human gene therapy, IND will be issued an acknowledgment letter containing the date of receipt, the assigned IND number, and a reminder of their responsibility for submission to NIH OBA according to Appendix M of the NIH Guidelines. The IND receipt date begins the official review clock and the IND review will take place over the next 30 calendar days. INDs automatically become effective 30 days after receipt unless the FDA notifies the sponsor that the IND is subject to clinical hold. In the CBER, where human gene therapy INDs are reviewed, the IND review team is comprised of a product reviewer, a pharmacology/toxicology reviewer, a clinical reviewer, and a regulatory project manager who handles administrative aspects of the IND review. The product reviewer is responsible for coordinating the review team and ensuring consistency within a product area. Consult reviewers are used on an ad hoc basis, depending on the product and its application, and could come from other offices in CBER or other centers within the agency, depending on the required expertise.

At any point in the review process, a reviewer may call the sponsor to request additional information or to discuss deficiencies in the IND. After each reviewer has completed their review, the team meets to discuss the file and make a final decision on the status of the application. The IND may also be discussed at office-level meetings for further input. The review decision is communicated to the sponsor by phone within the 30-day period, and this is followed by a letter giving the details of hold issues, review comments, or requests for further information. The clinical trial may either proceed or be placed on clinical hold. Phase I INDs may be placed on clinical hold, as covered under 21 CFR 312.42(b), if human subjects are exposed to unreasonable and significant risk of illness or injury; the IND does not contain sufficient information to allow adequate assessment of the risk (21 CFR 312.23); the information in the investigators brochure is misleading, erroneous, or materially incomplete; or the clinical investigators are not qualified to conduct the study. In addition, for investigational studies of drugs intended to treat a life-threatening disease or condition that affects both men and women, phase I INDs may be placed on clinical hold if men or women of reproductive potential are excluded from the clinical trial because of reproductive risk, or the potential of reproductive risk, due to the reproductive or developmental toxicity associated with the drug. Phases II and III INDs may be put on clinical hold if any of the conditions cited above apply or if the protocol design is deficient to meet the objectives of the proposal. To proceed with the clinical study, the sponsor must correct the deficiencies identified during the review and submit the additional information or data in an amendment to the IND. Once the amendment has been submitted and reviewed by the FDA, the sponsor will be notified by phone that the clinical trial may proceed, followed by a written letter.

a. Annual Reports. An annual report describing the progress of the investigation should be submitted to the IND within 60 days of the anniversary date that the IND went into effect. 21 CFR part 312.33 should be consulted for specific details, but in general the annual report should provide information on the status of each study in progress or completed during the previous year. To this effect, the annual report should include an update on the following: the title of study(s), the number of subjects enrolled and their status, serious adverse experiences observed, summary of available study results if the study is completed, information relevant to understanding of the drug's action, results of additional preclinical studies performed during the year, manufacturing changes, and an investigational plan for the coming year. The annual report should also provide results of product characterization and lot release testing for all lots of product produced during the year under report. Annual reports for human gene therapy trials should include additional information relevant to gene therapy vectors, such as assessment of evidence of gene expression, biological activity, immune response, evidence of gonadal distribution, results from long-term patient follow-up, and status of requests for autopsy. The annual report should also contain an update on information requested in the March 6, 2000 gene therapy letter, posted on the CBER website (www.fda.gov/cber/ind/ind.htm).

2. Master File Submission

Another mechanism available for submission of information to the FDA is the Master File (MF). The procedures for submitting a MF are outlined in part 312.33 of 21 CFR. In contrast to the IND, which contains manufacturing, preclinical, and clinical information, the MF could contain product manufacturing, preclinical, clinical, or facilities information only. Submission of an MF allows the MF holder to incorporate the information by reference when the MF holder submits an IND. The MF holder may also authorize other sponsors to rely on the information to support an IND submission without disclosing the information to the sponsors. There are 4 types of Master File submissions, of which type II is the one most commonly used for biological product development. Information submitted in a type II Master File can include information on drug substance or drug product specifically regarding product

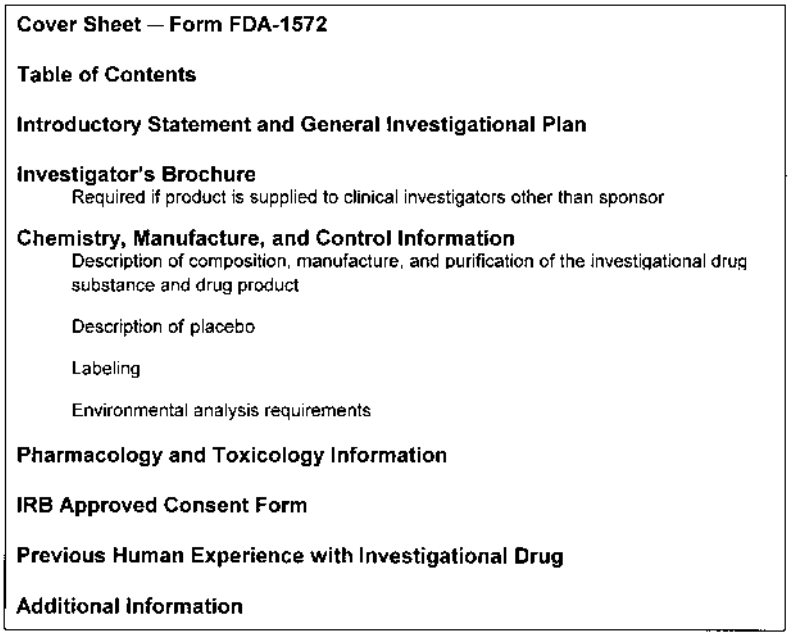

Figure 4 Content and format of the IND submission as specified in 21CFR 312.23.

manufacturing and purification schemes, SOPs, lot release protocols, tests and specifications, descriptions of tissue culture media components, and other proprietary information needed to support an IND application. When granting written permission for a cross-reference, a copy of the cross-reference letter should be filed with the MF and the IND it is supporting, and should identify by name, reference number, and volume and page number the exact information that each IND sponsor is authorized to incorporate. For example, in the case where retroviral vector supernatant is provided to an IND holder by a manufacturer and the method of manufacture is proprietary, the manufacturer could submit an MF documenting retroviral vector production and testing in support of the IND for review by CBER staff. As product lots are produced, lot release data should be submitted to the product MF as well as to the cross-referenced IND for CBER review.

MFs are often reviewed only in the context of an IND application. CBER will comment on the contents of the MF and ask for clarifying information in order to more adequately review an IND that cross-references the MF; however, a MF is neither approved or disapproved. Importantly, the MF has to contain complete information to support the decision to allow the associated IND to proceed.

III. REVIEW CONSIDERATIONS: EARLY PHASES

A. Stepwise Approach

Product characterization and quality control of gene therapy products includes issues and concerns common to most biological products, such as demonstration of safety, development of methods for assessment of potency, determination of identity and purity, and product stability. In addition, development of specifications for each parameter is an important part of product development and characterization, with specifications being established and tightened over time as data become available. Another aspect common among biologics is control and regulation of not only the product, but also each step of the manufacturing process. Adherence to this approach, which is encompassed under current good manufacturing practices (cGMPs), provides for quality and safety throughout the process and will lead to consistency of product lots.

In the area of gene therapy more than in other areas, a flexible approach to regulatory requirements has been attempted in order to find a balance between ensuring patient safety and fostering development of the field. To facilitate this process, a stepwise approach to product characterization and compliance with cGMP has been adopted. This approach involves a progressive scale of requirements for product characterization and compliance with cGMPs, which increase as the study moves from phase I toward phase III (Fig. 5). The first step in this approach is to provide preclinical toxicity data obtained from an appropriate animal model. The next step, which occurs during phase I of the clinical trial but is required throughout all product development, is the demonstration of product safety. As the clinical trail proceeds, so should the characterization of the product, such that by phase III the product is fully characterized with regards to safety, purity, identity, and potency. In addition, by phase III the product should be produced under full compliance with cGMP regulations. Requirements for licensure of a biological prod-

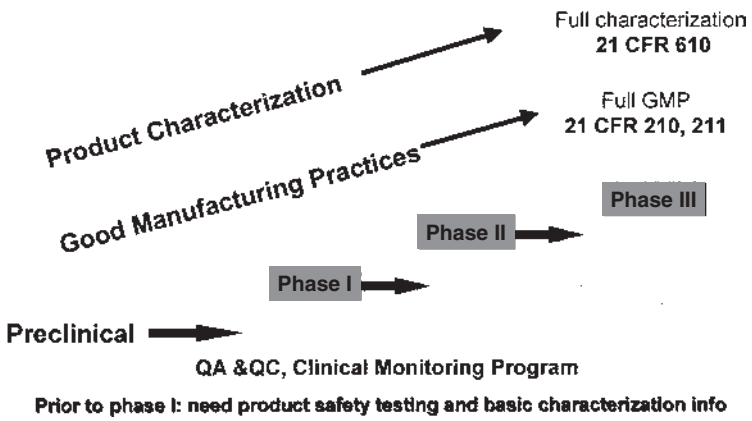

Figure 5 The stepwise approach.

uct, product standards, and cGMPs are specified in parts 610, 210, and 211 of section 21 of the CFR. The stepwise approach applies to each aspect of gene therapy product manufacture, including vector development, establishment and characterization of cell banks, product manufacture and characterization, establishment of specifications for product release, and control of reagents used during manufacture (ancillary products). It is equally important that a quality assurance/quality control (QA/QC) program, which is separate from manufacturing, be in place at the earliest phase of product manufacture. The QA/QC unit should be responsible for ensuring the quality of the product and for product release for clinical use. The role of the QA/QC unit is described in part 211 of section 21 of the CFR. Control of each aspect is important to assure product consistency and safety, and is the focus of the Chemistry, Manufacturing, and Control (CMC) review.

B. CMC Review

Each step of product development, characterization, manufacture, and control should be described in the IND under the CMC section. Sufficient information is required in this section to assure the proper identification, quality, and safety of the investigational drug. For phase I trials, data must be submitted to establish product safety. In addition, information regarding product characterization should include a description of the product's physical, chemical, or biological characteristics; the method of manufacture; analytical methods used during manufacture and testing; and initial product specifications. The emphasis of the review of an IND submission is on data; therefore, in all cases data, as opposed to conceptual information, should be provided in support of the IND. Valid scientific principles should be applied throughout product development with regard to product safety, characterization, and quality control of the manufacturing process. To ensure product quality, there should also be proper testing in place for all the components used during product manufacture. During the review process, a case-by-case approach is applied in order to ensure that requirements and recommendations are satisfied in a manner appropriate to a particular product and manufacturing method.

An early step in the development of a gene therapy product is construction of the initial gene therapy vector. The information supplied to the IND regarding the vector should include an explanation of the derivation of the vector, a description of the vector components and their sources, including the gene insert and regulatory elements, and a vector diagram. Currently, the FDA requires that all gene therapy vectors less than 40 kb be fully sequenced prior to initiation of a phase I clinical trial. A fully annotated DNA sequence and sequence analysis report should be submitted, identifying all open reading frames (expected and unexpected) and genes encoded in the vector. The report should indicate whether there is sequence alignment between the vector and the expected viral and inserted DNA sequences, as identified by a search of a relevant current database. For vectors over 40 kb, sequence analysis of the gene insert, flanking regions (at least 500 base pairs either side), and any regions of the vector that have been modified should be submitted.

In general, the next component important for the manufacture of a gene therapy product is the cell. Cells used during production of a gene therapy vector can be prokaryotic or eukaryotic. Eukaryotic cells can be either autologous or allogeneic. Information that should be submitted in the CMC section regarding the producer cells includes the cell source, collection method, whether a mobilization protocol is used, and donor testing (if applicable). If a cell bank system is used to assure consistency of production, then the next step in product development is usually the establishment of a Master Cell Bank (MCB). MCB characterization includes testing to establish the properties and stability of the cells and is performed on a one-time basis. For the IND submission, information on the history of the cell line, as well as culture and storage conditions of the MCB, should be included. Testing should be performed to establish identity, which includes cellular

phenotype and genotype, cellular isoenzyme expression, and stability. If the cell line has been engineered to express exogenous genes, then tests should be performed to establish the presence and stability of the transgene. Safety testing should be performed to demonstrate that the MCB is sterile and free of mycoplasma, endotoxin, and adventitious agents (through in vitro and in vivo assays). Depending on the origin, MCBs should be tested for species-specific pathogens. For example, if the MCB is of human origin, then testing for human pathogens such as CMV, HIV-1 & 2, HTLV-1 & 2, EBV, B19, AAV, HBV, and HCV must be performed. Analytical methods used for testing should be summarized and initial specifications for qualification of the MCB established. The MCB is the first tier of a two-tier cell bank system; the second is the Working Cell Bank (WCB), which is derived from 1 or more vials of the MCB. The amount of information needed for characterization of the WCB is generally less extensive and includes testing for sterility, mycoplasma, adventitious agents by in vitro assay, and identity. Additional information on cell banking procedures and cell bank characterization can be found in the ''Points to Consider in the Characterization of Cell Lines to Produce Biologicals'' (1993).

Depending on the gene therapy vector, the next step in gene therapy product development may be the establishment of a Master Viral Bank (MVB). MVBs are generated by infecting or transducing the specific vector into cells grown from 1 or more vials of the WCB. As with MCBs, a second tier or Master Working Viral Bank (MWVB) can also be generated. Requirements for MCB/WCB testing and characterization would also apply to testing of the MVB/MWVB, with the addition of tests for the presence of RCV related to the vector.

All procedures used during production and purification of the gene therapy vector product should be included in the CMC section of the IND submission. Safety testing and characterization of gene therapy vectors should be performed on bulk production lots, before and after purification steps, and final product after formulation and fill, as appropriate for the particular assay. Safety testing should include tests for sterility, mycoplasma, endotoxin, general safety, and RCV, as well as tests for adventitious virus by in vitro assay. Product identity for a gene therapy vector product may be established through the physical or chemical characteristics of the product using in vitro, in vivo, or, when appropriate, molecular methods, but is not absolutely required at phase I. Purity of a gene therapy vector is typically established through determination of levels of residual materials such as cellular DNA, RNA, and protein; noninfectious virus; and ancillary products. With regard to product potency, for early phase trials the level of gene expression is acceptable as a measure of potency. However, before initiation of a phase III clinical trial, a potency assay that measures the relative biological activity of the product will need to be developed and in place. A suitable potency assay should be one that is quantitative in nature, but in addition, can also include a qualitative biological assay. As with testing of the MCB and MVB, analytical methods used should be summarized in the IND and initial specifications for qualification of the gene therapy vector product established. This summary is often presented in the form of a Certificate of Analysis.

To date, approximately 48% of gene therapy clinical trials have involved the genetic modification of autologous or allogeneic cells ex vivo. This has been accomplished using viral and nonviral vectors. Information regarding the process of ex vivo modification of cells should be documented in the IND submission as follows: a description of the source of cells, results of donor screening (if applicable), method of cell collection and processing, culture conditions, and the procedure for ex vivo modification of cells. Safety testing and characterization of the ex vivo gene-modified cells should include assessment of sterility, mycoplasma, endotoxin, identity, potency, and freedom from RCV (for retrovirus vectors). Analysis of phenotypic markers and confirmation of the integrity of the genetic insert may be used to confirm cell identity. Care should also be taken to assure patient specificity for autologous products using proper labeling and tracking systems. Additional parameters to be assessed include cell viability, transduction efficiency, longevity of gene expression, and the effects of irradiation or freeze/thaw on these parameters. In addition, the vector used for ex vivo modification should be tested as described above before use in the ex vivo modification of the cell product. Analytical methods used should be summarized in the IND and initial specifications for qualification of the ex vivo modified cells established.

For gene therapy vector products and ex vivo modified cell products, a stability program that assesses product safety, activity, and integrity should be established during early phases of investigation. The objectives of stability testing during early phases are to establish that the product is stable for the duration of the clinical trial and to collect information needed to develop a final formulation and dating period. The submission to the IND should include a brief description of the proposed stability study, the test methods to be used to monitor stability, and preliminary data, if available.

The stepwise approach provides flexibility to product manufacture, characterization, and testing during early phases of product development. However, testing and assay qualification should be performed in early phases to support data collection, development of specifications, and compliance with cGMP in preparation for phase III studies.

C. Reagents

Reagent are those components that are essential for cellular growth, differentiation, selection, purification, or other critical manufacturing steps, but that are not intended to be part of the final product. Examples include fetal bovine serum, trypsin, growth factors, cytokines, monoclonal antibodies, cell separation devices, medium, and medium components. These reagents can affect the safety, potency, and purity of the final product, especially with regard to the introduction of adventitious agents. Ideally, licensed or clinical grade reagents should be used for preparation of gene therapy products; however, these are often not readily available. Recommendations for the use of reagents that are not clinical grade during early

phases of product development involve establishing a qualification program and specifications for each reagent. The qualification program should include adequate characterization, including safety testing, functional analysis, and a demonstration of purity. The purity of a given reagent need not be 100%, but the purity profile between different lots of the reagent should remain consistent. The extent of reagent testing required will depend on the point at which the reagent is used in the manufacturing process and the biological system used for production of the reagent. For example, in the case of a growth factor or cytokine, if a monoclonal antibody is used during production or purification, then the reagent will have to be tested for adventitious agents and murine retrovirus. If there are known toxicities associated with the reagent, testing for residual levels of the reagent in the final product preparation should be performed. It should be noted that the use of reagents produced under full cGMP is recommended for phase III trials.

D. Gene Therapy-specific Safety Issues

As the development of gene therapy vectors for therapeutic gene delivery broadens and moves forward, the possibility of approved therapeutic products becomes more of a reality. However, regulatory approval and use of these therapeutic products in clinical trails requires a good safety profile. The use of gene therapy vectors carries with them certain safety issues that are specific to each vector type. Concerns specific to the safe use of gene therapy vectors include the generation of replication-competent virus (RCV), vector-associated toxicity (as opposed to toxicity related to the specific transgene), and the risk of inadvertent modification of a recipient's germline. Because of their potential effect on the patient, the public health, and future generations, these issues need to be addressed during development of a gene therapy product and should be documented in the IND. Because RCV can arise from recombination events during manufacture, tests designed to detect RCV should be performed at multiple stages of manufacture and for each final lot.

Testing for replication-competent retrovirus (RCR) in the production of retroviral vectors needs to be performed at multiple points in production, including MVB, WVB, vector supernatants, end of production cells, and ex vivo modified cells. A permissive cell line such as *Mus dunni* should be used to test cells producing vector containing the amphotropic murine leukemia virus envelope. If an ecotropic packaging cell line is used, then an ecotropic retroviral assay, for detection of low-level viral contamination, will need to be performed.

Retroviral vector supernatant also must be tested by amplification on a permissive cell line such as *Mus dunni*, followed by detection in an appropriate indicator cell assay (PG-4 S+L-) . When the final product is ex vivo transduced cells, RCR testing is recommended if cells are maintained in culture for 4 or more days after transduction. If ex vivo transduced cells are cultured for less than 4 days, then archiving of cells is recommended in place of active RCR testing. Further information regarding RCR testing is contained in the CBER guidance ''Guidance for Industry: Supplemental Guidance on Testing for Replication Competent Retrovirus in Retroviral Vector Based Gene Therapy Products and During Follow-up of Patients in Clinical Trials Using Retroviral Vectors, 10/18/2000''

In studies using adenoviral vectors, MVBs and WVBs, as well as the final vector product, must be tested for replication-competent adenovirus, (RCA). The FDA recommends that the level of RCA in the final product be less than 1 in 3×10^{10} viral particles.

Adenoviral vectors pose a specific safety risk because toxicity has been observed when these vectors are administered at high doses. Current evidence suggests that a portion of the observed toxicity is due to the vector particle itself, and is not related to the actual infection of the cells by the vector. As a result, CBER requires that adenoviral vector doses be based on the actual particle count, as opposed to the infectious titer, which is commonly the unit for quantifying viruses. In addition, the agency currently asks that all sponsors of INDs using adenoviral vectors report the ratio of viral particle to infectious unit for each clinical lot of vector. The current recommended limit for this ratio is set at ≤ 30.

After the death in 1999 of a subject enrolled in an adenoviral gene therapy clinical trial, the NIH OBA established the adenoviral Safety and Toxicity Working Group, whose mission was to conduct an indepth review and evaluation of safety and toxicity data generated from adenovirus gene therapy clinical trials. One outcome of this working group was a recommendation that a qualitative and quantitative adenovirus standard be developed. In response to this recommendation, the FDA, the Williamsburg BioProcessing Foundation, and members from industry and academia formed a working group to develop and characterize an adenoviral reference material (ARM). The ARM will be used by manufacturers of adenoviral vectors to standardize viral particle and titer measurements. In addition, use of the ARM will provide a means of analyzing the safety and efficacy of adenoviral vectors produced by different manufactures and allow for comparison between different clinical trials.

Safety testing goes beyond testing of the product and should include monitoring programs for all subjects who are administered gene therapy vectors. Currently, the FDA is developing a long-term patient follow-up program that will monitor all subjects receiving gene therapy products for unanticipated adverse events that manifest themselves long after administration of the gene therapy product and after the observation period for acute toxicity, as well as product efficacy, has ended.

For in vivo administered gene therapy vectors, data must be submitted demonstrating the extent to which a vector is able to disseminate out of the injection site and distribute to the gonads. These data will provide the information required to assess the risk of inadvertent gene transfer to germ cells, which may result in genetic changes in subsequent progeny. In general, these data should be obtained during the course of product development and provided to the agency for comment and review. However, in cases where a novel vector,

route of administration, or vector delivery system is proposed, preclinical studies may be required before initiation of the phase I study. Biodistribution data may be obtained from studies in animals, from analysis of clinical samples, or from a combination of preclinical and clinical sample analyses. Clinical data should be derived from peripheral blood cells and semen samples taken during the treatment and follow-up periods for the clinical trial and from gonadal tissues obtained at autopsy from consenting patients. The agency should be updated of the status of these studies at least at the time of each annual report in order to guide further product development and track any potential adverse events. A statement explaining the risk for genetic alteration of sperm or eggs and possible outcome for a fetus and future child, which could occur as a result of study participation, should be included in the informed consent document. This statement should clearly explain the status of biodistribution studies to assess gonadal distribution for each particular clinical trial and the fact that the likelihood of an adverse outcome is currently unknown. In addition, the consent form should advise study participants to practice birth control for a suitable period of time.

IV. REVIEW CONSIDERATIONS: LATER PHASES

The previous sections have provided an overview of the review process and CBER's expectations for product development as the clinical investigation proceeds through early phases. By phase III, CBER recommends adherence to product standards and methods specified in the regulations and also that products are manufactured under full cGMP compliance. To better understand CBER's requirements for product licensure and establishment standards, a sponsor should be familiar with practices that are governed by law and specified in parts 610, 210, and 211 of section 21 of the CFR. Part 610 provides information pertaining to product release requirements and general provisions for licensure and, in some cases, will provide information on specific assay methodology; parts 210 and 211 explain the cGMPs.

Although the regulations by their nature proscribe requirements, there is a level of flexibility built into the regulations that allows for modification of required test methods or manufacturing processes. The provision for test method modification is found under 21 CFR 610.9, entitled ''Equivalent Methods and Processes.'' This provision is especially useful for gene therapy products, where conditions of the manufacturing process and many times the product itself make it difficult to perform standard assays. To apply this provision, a sponsor should provide supporting evidence for why a specific method is not ideal for the gene therapy application and present data, with appropriate controls, to demonstrate that the modified method will give equal or greater assurances of the safety, purity, potency, and effectiveness of the biological product compared with the specified method or process. Data to support the modification can be accumulated during the early IND phases and then validated in support of its use as an established method prior to licensure.

For a product to meet the requirements for licensure, it must be fully characterized prior to submission of the license application with regard to safety, purity, potency, and identity. Each of these aspects will be discussed in the context of requirements for initiation of a phase III trial and product licensure.

Demonstration of product safety requires the implementation of specific tests, which measure sterility, mycoplasma, endotoxin, and general safety of the product. Product safety also includes demonstration that the product is free from adventitious virus, which to support the phase III study and product licensure includes in vitro and in vivo adventitious virus testing of the MCB and MVB, and when appropriate testing for RCV. Testing for general safety is not as rigidly adhered to during phase I and II studies, but by phase III the required standards and methods specified in 21 CFR 610.11 should be in place. An exception is made for therapeutic DNA plasmid products (21CFR 610.10) and cellular therapy products (FR Notice, April 20, 1998), which have been exempted from this testing.

Potency is defined as the specific ability or capacity of the product to effect a given result. For phase III, tests for potency should consist of quantitative in vitro or in vivo tests. A qualitative assay may be used as an additional demonstration of product potency. A potency assay that reflects the relevant biological function of the product, as opposed to an assay that just measures the level of gene product expression, should be optimized and qualified by phase III and validated prior to licensure. A valid potency assay is essential in order to interpret clinical trail results, as well as to ensure lot to lot consistency and quality of the product after licensure.

Product identity can be demonstrated through the use of an assay or assays that are specific for each product, in a manner that will adequately identify it as the designated product and distinguish it from any other product being processed in the same facility. At phase I, a test for identity is not required but it should be in place by phase II, so that data can be collected, specifications determined, and the assay validated by licensure.

Product purity is defined as freedom from extraneous material except that which is unavoidable in the manufacturing process. Testing for purity of a gene therapy product could involve assays for residual protein, DNA, RNA, solvents used during production and purification, or ancillary products used during manufacture such as cytokines, antibodies, or serum. As with all the previously mentioned testing, a quantitative assay for purity should be in place by phase III, with development of the assay being initiated much earlier in the investigational trial.

To complete product characterization in support of phase III and product licensure, a stability testing program that includes, but is not limited to, assays that measure product integrity, potency, sterility and, in the case of an ex vivo modified product, viability is needed. A stability protocol for study of both the bulk and final drug products, as well as all MCBs

and MVBs, should be defined so that stability data generated during phase III will be appropriate to support licensure. In general, the stability program should be initiated at phase I, so that by phase II the objective of obtaining real time data to support stability of the investigational formulation can be met. For phase III, data collected should be used to support the proposed expiration dating period of the final drug product, as well as the container and closure system. In addition, stability testing of any product intermediates should be in place to support the validation of the duration and conditions of storage of the bulk product.

A. cGMP

The second element to which the stepwise approach applies is the cGMPs. cGMP is defined as a set of current, scientifically sound methods, practices or principles that are implemented and documented during product development and production to ensure consistent manufacture of safe, pure, and potent products. Some major elements of cGMP include detailed record keeping, development of written procedures or standard operating procedures institution of QC/QA programs and assays, and equipment and process validation. cGMP also requires a program be in place for the certification and training of personnel and for environmental monitoring. The approach to cGMP is also flexible at early stages of product development. cGMPs play an important role in control and regulation not only of the product, but also of all steps of the manufacturing process. Adherence to cGMPs provides for quality and safety throughout the process and will lead to reproducible and consistent performance of product lots. It should be noted that cGMPs apply to the manufacturing process and to the facilities. The differences between phase I and phase III requirements are the degree to which each element of cGMP is implemented. As product development proceeds toward phase III, so should the validation of the conditions under which the product is manufactured, controlled, and characterized. Full adherence to cGMP regulations is expected to develop as the clinical trial advances. For example, process validation, methods validation, in-process testing, and establishment of specifications should be incorporated as part of the stepwise approach to fulfilling regulatory requirements.

B. Product Comparability

Changes in the manufacturing process, equipment, or facilities often occur during product development and can result in change in the biological product itself. A manufacturer must fully describe any change to a biological product in the IND or license application, regardless of whether the change occurs prior to or after product approval. The manufacturing change should be assessed and the resulting product compared with the existing product to assure that the change does not alter the safety, purity, potency, or integrity of the final product. Determinations of product comparability may be based on a combination of in vitro or in vivo studies ranging from chemical, physical, and biological assays to assessment of pharmacokinetics and/or pharmacodynamics and toxicity in animals, to clinical testing. The type of study required would depend on the extent of the change and the phase of clinical development in which the change occurs. Product comparability should be demonstrated through side-by-side analyses of the product lots manufactured under the established procedures and qualification lots of the product manufactured by the new procedure. If a sponsor can demonstrate comparability with nonclinical data, additional clinical safety, and/or efficacy trials with the new product generally will not be needed. The FDA will determine if comparability data are sufficient to demonstrate that additional clinical studies are unnecessary. Example of changes that would require a comparability study include any change in the manufacturing scheme or site, changes to the master cell bank, modification of the vector product, a change in fermentation, isolation or purification, change in storage container, or product formulation. The final section of this chapter contains references that provide additional guidance on the demonstration of product comparability.

Immunoisolated Cells as Gene Therapy for CNS Diseases

Dwaine F. Emerich
Sertoli Technologies, Inc.
Cranston, Rhode Island, U.S.A.

I. INTRODUCTION

Degenerative central nervous system (CNS) diseases are characterized by the continuous deterioration of cognitive and motor functions leading to prolonged periods of increasing incapacity. Among the most problematic and prevalent neurological disorders are those associated with the loss of specific populations of brain neurons. Approximately 12 million people in the United States suffer from such neurological disorders resulting in public expenditures and secondary medical expenses that exceed $400 billion annually (1). Beyond monetary costs to the health care economy, however, the medical, societal, familial, and personal costs cascading from these diseases defy calculation.

Advances in molecular biology, genetic engineering, proteomics, and genomics are making available an increasing number of proteins, peptides, and other compounds with enormous treatment potential. Most of these compounds are, however, not active following systemic administration, largely because the brain uses the blood–brain barrier (BBB) to modulate the local and global exchange between the vasculature and brain parenchyma. The BBB provides an exquisite regulation of the internal chemical environment of the CNS by regulating the internal environment with a mechanism of low passive permeability, combined with a highly selective transport system between the blood and the brain (2,3). It has also been a source of frustration for researchers and clinicians searching for a means of introducing drugs to the brain.

A number of strategies have been described to circumvent the BBB. Some of the techniques currently available for delivering therapeutic molecules directly into the brain include (1) carrier- or receptor-mediated transcytosis (4,5); (2) osmotic opening (6,7); (3) direct infusion with stereotactic guidance (8–10); (4) osmotic pumps (11,12); (5) sustained-release polymer systems (13–15); (6) cell replacement/cell therapy (16–18); and, (7) direct gene therapy (19–22). A presentation outlining these techniques was recently reviewed (23). In recent years, one iteration of cell-based therapy proposes to use xenogeneic cells that are encased within a selectively permeable polymeric membrane, known as immunoisolation. Immunoisolation was originally described in 1933 by V. Bisceglie (24) with the demonstration that encapsulated xenograft cells survived beyond the limit for humoral rejection. The further application of immunoisolation for the CNS owes much of its foundation to investigators focused on peripheral diseases, particularly diabetes (25,26) and Parkinsons's disease (PD), using dopamine secreting cells (27). Immunoisolation is based on the observation that xenogeneic cells can be protected from host rejection by encapsulating, or surrounding them within an immunoisolatory, semipermeable membrane. Single cells or small clusters of cells can be enclosed within a selective, semipermeable membrane barrier which admits oxygen and required nutrients and releases bioactive cell secretions, but restricts passage of larger cytotoxic agents from the host immune defense system. The selective membrane eliminates the need for chronic immunosuppression of the host and allows the implanted cells to be obtained from nonhuman sources, thus avoiding the constraints associated with cell sourcing, which have limited the clinical application of unencapsulated cell transplantation.

In this chapter, I track the use of immunoisolated cells from the initial cell biology and encapsulation process, through several preclinical research models, and ultimately to human clinical trials (Fig. 1). The preclinical animal model data demonstrating the therapeutic potential of genetically modified, encapsulated cells for Alzheimer' disease (AD), PD, and Huntingtons's disease (HD) will be highlighted. Finally, the current state of initial clinical trials using encapsulated cells therapy is discussed.

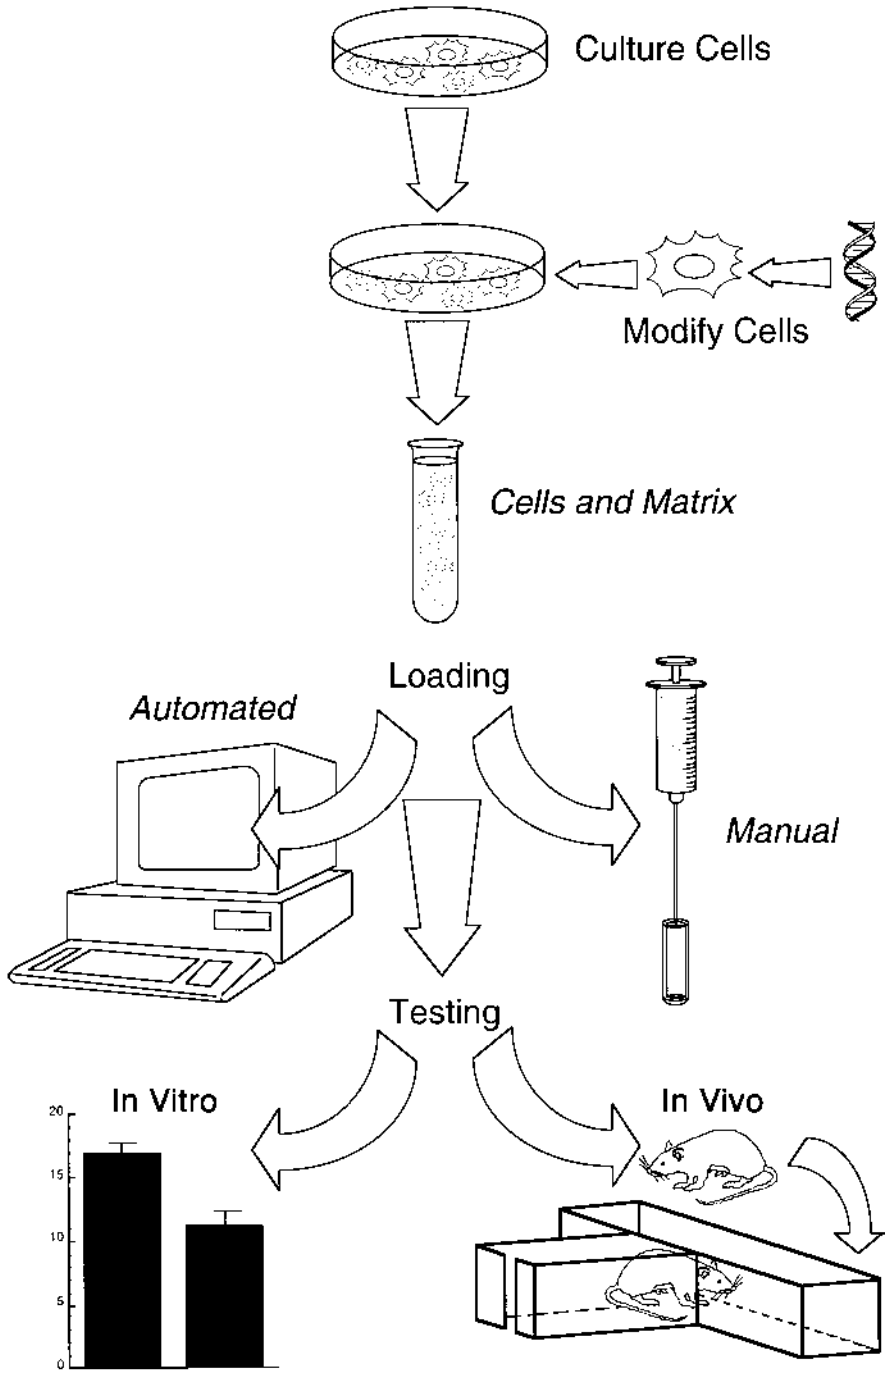

Figure 1 Flow diagram illustrating the steps involved in using genetically modified polymer encapsulated cells for CNS implantation. Cells are cultured and modified in vitro prior to either manual or automated loading into hollow fiber membranes. Following in vitro characterization, the cells are transplanted into the desired region of the brain and in vivo tests are conducted to determine the potential efficacy produced by the products secreted from the encapsulated cells.

II. CELL IMMUNOISOLATION

There are generally 2 categories for cell immunoisolation by encapsulation, micro- and macro-, each with some benefits and limitations (Table 1).

A. Microencapsulation

Microencapsulation involves surrounding cells with a thin, spherical, semipermeable polymer film. The small size, thin wall, and spherical shape of microcapsules is structurally optimal for diffusion, cell viability, and release kinetics. However, in certain types of thermoplastic-derived processing to form the microcapsule membrane around cellular clusters, cells can be exposed to organic solvents (28). Other types of microcapsules (e.g., the polyelectrolytes), although nontoxic during processing, are generally mechanically fragile and chemically unstable. For the polyelectrolytes, microcapsule membranes are formed by ionic or hydrogen bonds between 2 weak polyelectrolytes with opposite charges. Microcapsules can be prepared by gelling droplets of a polyanion/cellular suspension (e.g., alginate) in a mixing divalent cationic bath, which immobilizes the cells in a negatively charged matrix, and then coating the immobilized cells with a thin film of a polycation, such as poly(L-lysine). The poly(L-lysine)-alginate bond creates a permselective membrane whose molecular mass cutoff is on the order of 30,000 to 70,000 daltons (29). Because poly (L-lysine) is not biocompatible, a second layer of alginate is generally added to the capsule surface (Figs. 2 and 3). Polyelectrolyte-based techniques have the advantage of avoiding organic solvents and, with proper permeability control, microcapsules represent an effective configuration for cell viability and neurochemical diffusion. These types of microcapsules are, however, mechanically and chemically fragile, as well as difficult to retrieve.

B. Macroencapsulation

Macroencapsulation involves filling a hollow, usually cylindrical, selectively permeable membrane with cells, generally suspended in a matrix, and then sealing the ends to form a capsule [reviewed in (30,31)]. Polymers used for macroencapsulation are biodurable, with a thicker wall than that found in microencapsulation. Although thicker wall and larger implant diameters can enhance long-term implant stability, these features may also impair diffusion, compromise the viability of the tissue, and slow the release kinetics of desired factors. In theory, macroencapsules can be retrieved from the recipient and replaced, if necessary.

Macroencapsulation is generally achieved by filling preformed thermoplastic hollow fibers with a cell suspension. The hollow fiber is formed by pumping a solution of polymer in a water-miscible solvent through a nozzle concurrently with an aqueous solution. The polymer solution is pumped through an outer annular region of the nozzle, whereas the aqueous solution is pumped through a central bore. Upon contact with the water, the polymer precipitates and forms a cylindrical hollow fiber with a permselective inner membrane or ''skin.'' Further precipitation of the polymer occurs as the water moves through the polymer wall, forcing the organic solvent out and forming a trabecular wall structure. The hollow fiber is collected in a large aqueous water bath, where complete precipitation of the polymer and dissolution of the organic solvent occurs. The ends of the hollow fiber are then sealed to form macrocapsules. This final step is not a trivial one because reliably sealing the ends of capsules can be extremely difficult

Table 1 Advantages and Disadvantages of Unencapsulated, Micro- and Macroencapsulated Implants

Unencapsulated implants	Microencapsulation	Macroencapsulation
Advantages		
Permits anatomical integration between the host and transplanted tissue	Permits use of allo- and xenografts without immunosuppression	Permits use of allo- and xenografts without immunosuppression
Good cell viability and neurochemical diffusion	Thin wall and spherical shape are optimal for cell viability and neurochemical diffusion	Reasonable mechanical stability
		Adequate cell viability and neurochemical diffusion
		Retrievable
Disadvantages		
Likely require immunosuppression	Mechanically and chemically fragile	Dimensions (i.e., diameter and wall thickness) may limit neurochemical diffusion and cell viability
Tissue availability limited	Multiple implant sites	Multiple implant sites
Limited retrievability	Limited retrievability	May produce significant tissue damage/displacement during implantation
Societal and ethical issues		

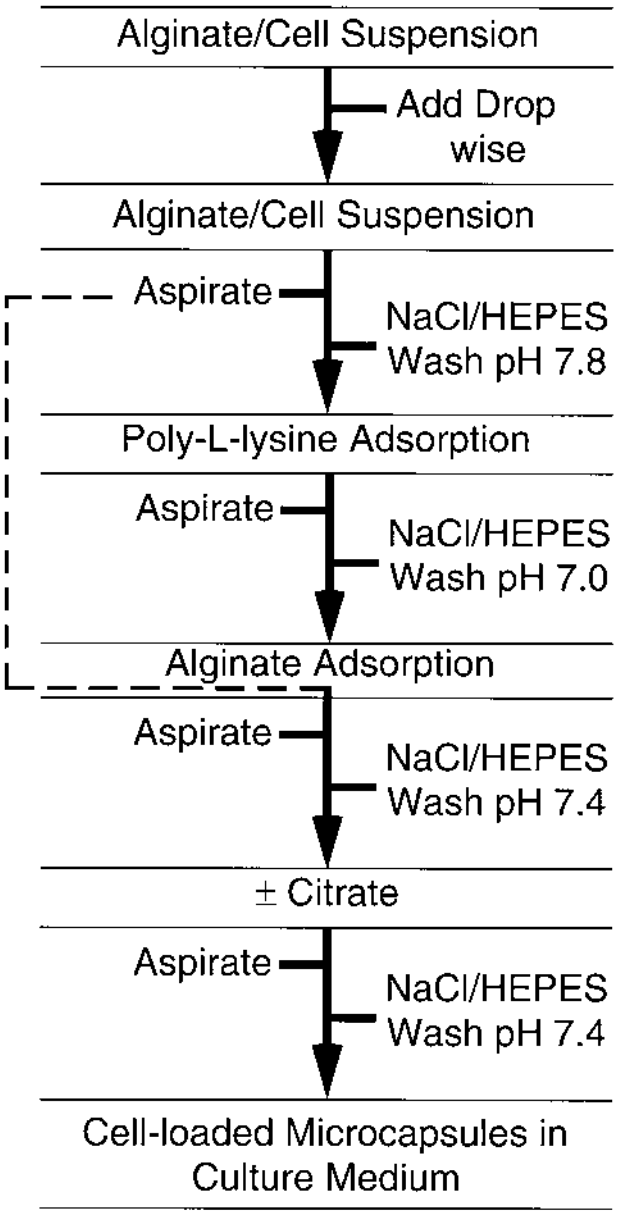

Figure 2 Flow diagram outlining the steps involved in the microencapsulation of cells. The poly(L-lysine) and alginate are sequentially adsorbed onto the alginate microspheres following immersion in a water bath.

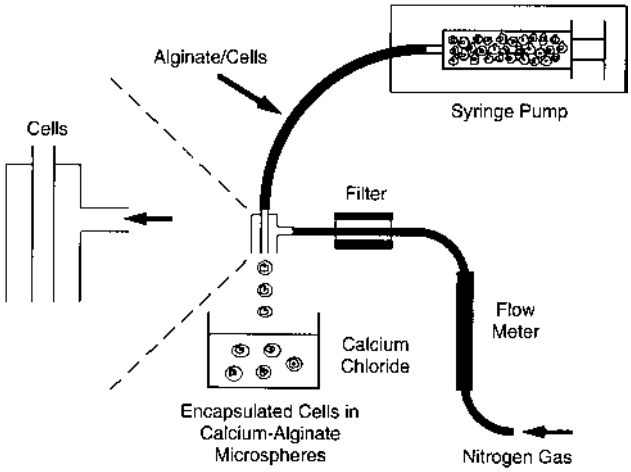

Figure 3 Schematic illustration of a syringe pump extrusion technique for encapsulating cells within alginate microcapsules. The alginate/cell suspension is extruded through the center of the annular spinneret, whereas filtered nitrogen is passed through a surrounding outer tube. In this manner, droplets are sheared off the spinneret assembly and dropped into a container of $CaCl_2$.

and provides the barrier paramount for successful immunoisolation.

A second method of macroencapsulation, called coextrusion, avoids the sealing problem by entrapping cells within the lumen of a hollow fiber during the fabrication process (32). Pinching the fiber before complete precipitation of the polymer causes fusion of the walls, providing closure of the extremities while the cells are inside. The advantages of coextrusion over loading preformed capsules are that the cells are distributed more uniformly along the entire length of the fiber and shear stresses on the cells are reduced during the loading process. In addition, the coextrusion process offers the potential for mass production of cell-loaded capsules.

Several modifications to macrocapsule configurations have been designed to provide added strength to ensure device integrity. It is important for the encapsulating membrane to exhibit enough compliance to meet the dynamics of the surrounding tissue, thus not eliciting a foreign body reaction, yet mechanically resilient to resist failure during device implantation/retrieval. Mechanical supports to provide added strength to the membrane/device are better served from within the device to therefore not impede diffusion between the encapsulating membrane and the surrounding tissue. One approach includes the addition of a cross-linked hydrogel (e.g., a 2% alginate solution) within the device. This modification was observed to enhance structural support during the implantation procedure (33). However, with time the hydrogel loses structural integrity and does not provide added strength, especially with regard to tensile strength, an important consideration for device retrieval.

The ability to retrieve devices, or remove the cellular contents from within, are important safety considerations for potential complications such as brain edema following implantation, contamination, dosing modifications, or patient request. Early designs were based on a semipermeable receptacle (16) or U-shaped configuration (32) attached to the host skull. These configurations offered the ability to empty and refill the devices, or retrieve the devices themselves, without dis-

rupting the host brain with additional neurosurgical procedures. However, devices secured to the skull could exhibit mechanical perturbations to the host tissue due to mechanical noncompliance and elicit an elevated foreign-body reaction from the host. Other configurations with internal supports have included titanium wires and braided materials to provide added tensile strength during device retrieval. Devices incorporating a titanium wire could be associated with mechanical noncompliance within the device, rendering the flexible membrane susceptible to damage. In contrast, the incorporation of braided materials within the tubular device has provided a material compliant with the membrane that enhances the tensile strength of the device.

III. CELLS AND EXTRACELLULAR MATRICES USED IN ENCAPSULATION

Cells placed within encapsulation devices generally fall into 1 of 3 categories. The first category is represented by primary postmitotic cells such as islets of Langerhans for diabetes, adrenal chromaffin cells for chronic pain, or hepatocytes for liver devices. Second, immortalized (or dividing) cells such as PC12 cells have been used to deliver dopamine for PD. The third category is typically cell lines that have been genetically engineered to secrete a bioactive substance such as baby hamster kidney (BHK) cells to secrete factors like human nerve growth factor (hNGF) for a potential therapy in AD. Dividing tissue has advantages over postmitotic tissue; it can be expanded, banked, and thus more easily tested for sterility and contaminants. However, dividing tissue is also constrained by the potential for overgrowth within the capsule environment, resulting in an accumulation of necrotic tissue that could potentially diminish the membrane's permeability characteristics, further reducing cell viability and neurochemical output.

In vivo, extracellular matrices (ECMs) provide control of cell function through the regulation of morphology, proliferation, differentiation, migration, and metastasis (34–36). Within a capsule, ECMs were originally employed simply to prevent aggregation of cells (immobilization) and resultant central necrosis, but have since been found to be beneficial to the viability and function of cells that require immobilization, as well as a scaffolding for anchorage-dependent cell lines. For example, adrenal chromaffin cells have been immobilized in alginate to prevent aggregation, which in turn reduces central necrotic cores from forming (37). The chromaffin cells appear to thrive in alginate, whereas mitotically active fibroblasts do not. In this case, the use of alginate is essential to the optimal functioning of this device because some anchorage-dependent cells such as fibroblasts or endothelial cells are present with the adrenal chromaffin cells. In the absence of alginate or similar immobilizing matrices, the fibroblasts can expand and overgrow the encapsulated milieu, resulting in a device deficient in bioactive factors produced from the chromaffin cells (38). In contrast, BHK cells, a fibroblastic cell line, prefer collagen, whereas PC12 cells exhibit a preference for distribution within precipitated chitosan, which provides a scaffolding structure on which the cells anchor (39). Inaddition, chitosan has been shown to be an effective substrate for the attachment and spreading of fibroblasts (40).

To provide a substratum designed for more specific functions, the matrix material can be manipulated chemically or mechanically, which in turn may influence cell attachment, differentiation, and/or proliferation. For example, peptides, such as arginine-glycine-aspartic acid (RGD) have been immobilized on a variety of surfaces to promote cell adhesion (41). Integrin receptors on the cell surface membrane interact with the RGD sequence, a known ligand for fibronectin receptors. Glass microbeads have been modified by attaching RGD or tyrosine-isoleucine-glycine-serine-arginine (YIGSR) motifs to provide sites for cell adhesion (41). Spherical ferromagnetic beads have been coated with specific receptor ligands to mediate cell attachment (42). With competetive binding assays and a mechanical stress testing apparatus, the endothelial cell's interaction with the ECM receptor, integrin beta-1, supported a force-dependent stiffening response, whereas nonadhesion receptors did not. A laminin-derived oligopeptide sequence, CDPG-YIGSR, has also been derivitized within an agarose hydrogel and permitted a dose-dependent increase in neurite outgrowth of neuronal cell bioassays (43). Similarly, YIGSR and isoleucine-lysine-valine-alanine-valine, both of which are found in laminin, have been immobilized on surfaces to promote neuronal cell adhesion and neurite outgrowth (44). Poly(ethylene oxide) (PEO)-star copolymers have been fabricated as a potential synthetic extracellular matrix (45). The star copolymers provide many hydroxyl groups where various synthetic oligopeptides can be attached to desired specifications.

The survival and differentiation of encapsulated cells can be influenced by the matrix interactions. A variety of matrices for use in immunoisolatory devices, such as alginate, rat tail collagen extracts, gelatin shards, porous gelatin or collagen microcarriers, carrageenan, chondroitin sulfate, fibrin, hyaluronic acid, the positively charged substrate chitosan, and an acrylamide-based thermoresponsive gel are available and were recently reviewed (46). All in all, successful cell encapsulation involves the choice of the cells to be encapsulated, the type of intracapsular matrix used, and the ability to control membrane properties such as geometry, morphology, and transport (Fig. 4). The interactions between the encapsulating membrane characteristics and the capsule core, or matrix within, should be rigorously characterized to determine the optimal configuration for each cell type.

IV. PREPARATION OF IMMUNOISOLATORY MEMBRANES

The majority of thermoplastic ultrafiltration (UF) and microfiltration (MF) membranes used to encapsulate cells are manufactured from homogenous polymer solutions by phase inversion (47). Ultrafiltration membranes have pore sizes ranging from 5 nm to 0.1 μm, while microfiltration (or microporous) membranes have pores ranging from 0.1 to 3 μm. Phase inver-

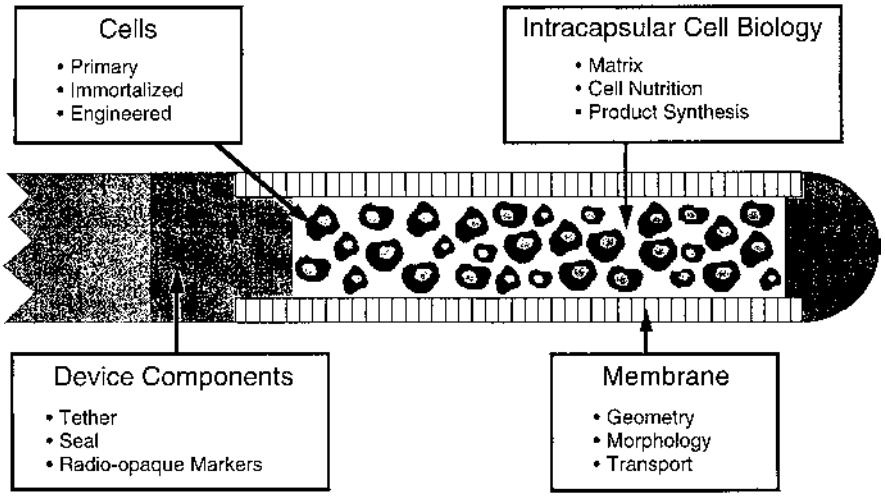

Figure 4 Diagram illustrating the different components of a macrocapsule contributing to successful implantation and cell viability. The manufacturing process involves several different aspects each with its own complexities. The initial choice of cell types includes primary, immortalized, or engineered. Intracapsular cell biology issues following encapsulation include a consideration of the need to use a compatible extracellular matrix and other considerations specific to that cell type because they impact cell nutrition and product synthesis. A series of other device-related issues include membrane geometry, morphology, and transport of molecules into and out of the device. Finally, the device must be sealed and, depending on the site of implantation, could require a tether for subsequent retrieval or the inclusion of radio-opaque markers for imaging purposes.

sion is a versatile technique that allows for the formation of membranes with a wide variety of nominal molecular weight cutoffs, permeabilities, and morphologies. The morphology and membrane properties depend on the thermodynamic parameters and kinetics of the fabrication process. In phase inversion, the polymer is first dissolved in an appropriate solvent. The solution is cast as a flat sheet or extruded as a hollow fiber. As part of the casting or extrusion procedure, the polymer solution is precipitated by a phase transition, which can be brought about by changing the temperature or solution composition. This process involves the transfer of a single-phase liquid polymer solution into a 2-phase system consisting of a polymer-rich phase that forms the membrane structure, and a second liquid polymer-poor phase that forms the membrane pores. Any polymer that will form a homogenous solution, which under certain temperatures and compositions will separate into 2 phases, can be used. Thermodynamic and kinetic parameters, such as the chemical potential of the components and the free energy of mixing of the components, determine the manner in which the phase separation takes place (48).

In cases where membrane strength limits the overall device strength, the membrane must be manufactured with certain considerations in mind, and the membrane dimensions, composition, and structure may have to be altered. Choosing a material that is inherently stronger (i.e., more ordered), or higher in molecular weight, with which to cast the membrane should increase the overall mechanical properties. UF or MF membranes can be fabricated with macrovoids within the wall or as an open-cell foam where the microvoids are interconnected. By incorporating techniques that increase the isoreticulated structure within the membrane wall, the tensile strength can be increased with similar membrane porosity, thus maintaining the same overall diffusive transport. The strength also can be improved by increasing the cross-sectional area of the membrane by thickening the walls. Decreasing the overall membrane porosity increases the overall membrane strength. An example of a macrovoid-containing structure is presented in Fig. 5.

The outer morphology of the membranes can be altered during fabrication or by a posttreatment to improve the host tissue reaction. Using various phase inversion techniques, the outer surface of the membrane can range from a selectively permeable membrane ''skin'' to a structure large enough to allow cells to enter the wall (approximately 10–20 μm in diameter). The combination of proper membrane transport and outer morphologies may also be achieved with composite membranes (49).

V. MEMBRANE TRANSPORT CHARACTERIZATION

Membrane transport is typically characterized by the capability to retain marker molecules in convective sieving experiments. Membrane transport properties have been extensively reviewed elsewhere (31,46,50).

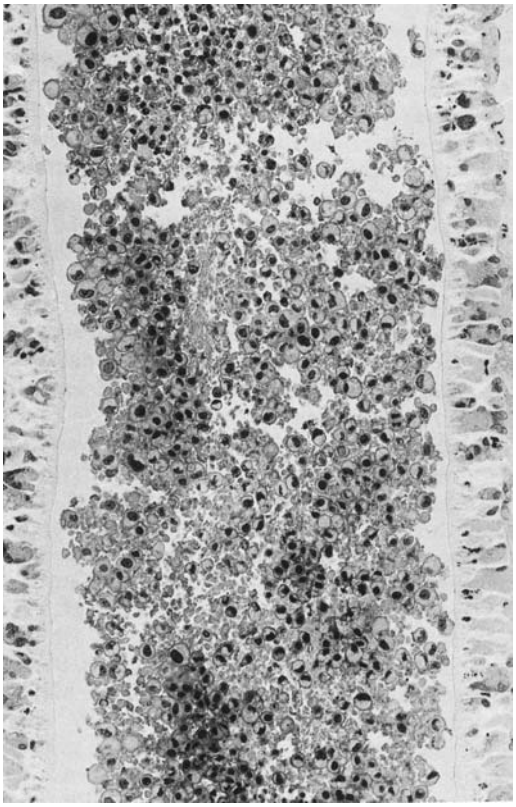

Figure 5 An example of encapsulated fibroblasts retrieved from monkey lateral ventricle illustrating many of the components listed above. Cells were modified to produce NGF and were encapsulated using Vitrogen as an extracellular matrix. Under these conditions, numerous H&E-positive cells were visible and evenly distributed within the full length of the capsule 1 month following implantation.

VI. VALIDATION OF THE CONCEPT OF IMMUNOISOLATION

A. In Vitro Studies

Two general approaches have been used to validate the premise that encapsulated cells are indeed immunoisolated. The maintenance of immunoisolation (i.e., capsule integrity) has been evaluated by several methods. Initial integrity was characterized by encapsulating a polydisperse (10^3–10^6 g/mol) dextran solution and monitoring the flux of the molecules across the semipermeable membrane over time. Similar to what has been described for assessing the molecular weight cutoff of hollow fiber membranes, a dextran rejection curve was measured from the filtrate and reservoir concentrations measured by gel permeation chromatography (50). With controlled devices that had been damaged, the large molecular weight dextran species were observed within the reservoir concentrations, while intact, integral capsules did not demonstrate these observations. In addition, capsule integrity has been evaluated in vitro on PC12 cell-loaded macrocapsules (30). This system tested the capability of the selectively permeable membrane to protect encapsulated PC12 cells against the cytotoxic killing of antibody (IgG)-mediated complement lysis. With integral cell-loaded capsules, in the presence of antibody and complement, the capsular membrane prevented antibody-mediated complement lysis (<10% cell death), while complete killing (100%) was observed in cases of damaged capsules or with PC12 cells not encapsulated.

B. In Vivo Studies

The importance of polymer capsule integrity for xenografted PC12 cell survival is illustrated in studies where unencapsulated PC12 cells, or cells encapsulated in breached (intentionally damaged) membranes, have been implanted in the brains of guinea pigs (i.e., a xenograft) (32). Intact PC12 cell-loaded capsules implanted into the guinea pig striatum showed no lymphocytic infiltration and a minimal astrocytic reaction by GFAP staining. In contrast, cell survival was poor in capsules that were intentionally damaged, with marked inflammation and heavy lymphocytic invasion into the capsule. Moreover, unencapsulated PC12 cells do not survive following implantation into either the guinea pig or the nonhuman primate striatum, whereas encapsulated PC12 cells have demonstrated viability for 6 months in nonhuman primates (51).

In addition, long-term studies were undertaken to evaluate the ability of a rat to generate antibodies against bovine adrenal chromaffin cells when implanted in the ventricular space (52). There was no evidence of elevated levels of rat antibovine adrenal chromaffin cell IgG or IgM levels in serum from rats implanted with encapsulated xenogeneic adrenal chromaffin cells for nearly 1.5 years in vivo. In contrast, a robust host immune response was induced in all animals at 5 months after implantation with unencapsulated bovine adrenal chromaffin cells.

Although these studies provide some level of comfort for the immunoisolatory nature of permselective membranes, very few studies have actually using encapsulated cells actually determined whether the procedure used formed a truly immunoisolatory membrane. Conceivably, the membranes used may have had molecular weight cutoffs sufficiently high enough to alter the function and viability of the cells.

VII. BIOCOMPATIBILITY

Transplant survival, with and without an encapsulating membrane, is mediated by many factors. The cellular/tissue reaction generated by a host in response to a foreign body, typically referred to as biocompatibility, impacts the success of the transplant. Factors that affect biocompatibility can include the method of implantation (53), the implant site (54), and implant properties, such as composition of the polymer, potential residual processing agents, surface integrity and microgeometry, and the size and shape of the implant (54). The constit-

uents of the implants should be assessed rigorously, both in vitro and in vivo, to determine the safety of the materials. For implants into the brain, the CNS tissue is not only privileged from an immunologic standpoint, but also lacks the primary reactive cells, fibroblasts, and macrophages found in peripheral locations. The brain, therefore, offers a unique environment both in terms of the inflammatory response, as well as the cellular constituents that comprise the reactive cells. Immunospecific antibodies are available to delineate the roles of the brain reactive cells, the astroctyes, and microglia, with respect to their reactivity. Nevertheless, few studies have systematically examined the reaction of host brain tissue to the presence of polymeric devices.

Early investigations used electron microscopic techniques to characterize the brain tissue reaction to plastic-embedded metal electrodes and polymer implants (55–57) reported in detail on the biocompatibility of a thermoplastic-based macrocapsule implanted into brain tissue. Necrosis of the tissue surrounding the polymer capsules implanted into the striatum of rodents was minimal, and small Nissl-positive cells were observed invading the open trabeculae in the wall of the macrocapsules. Immunospecific analysis for glial fibrillary acid protein indicated that reactive astrocytes were present 1 to 2 weeks after implantation, with the intensity of this reaction diminishing with time. By 4 weeks after implantation, there was a minimal gliotic reaction surrounding the polymer implant. No significant changes in myelin basic protein reactive oligodendroglia were observed, and neuron-specific enolase reactive neurons were readily identifiable adjacent to the implant. Subsequent studies with an immunospecific antisera against rat microglia, OX-42, has revealed a reaction and time course similar to the astrocytes. Last, electron microscopic analysis further revealed cellular and capillary invasion into the trabecular networks of the polymer walls.

The capillary invasion provides an ample supply of nutrients and oxygen in proximity to the encapsulated cells. However, because the process of angiogenesis for neovascularization typically evolves in a 4 to 7 day period (58), the encapsulated cells must endure an initial period of nutrient and oxygen deprivation. In addition, because the only means of delivery of the desired cellular products from an encapsulated cell implant is by diffusion, any reaction around the capsule might diminish the diffusion of therapeutic products from the encapsulated cells and could compromise the viability of the encapsulated tissue. These studies clearly demonstrated biocompatibility within the host nervous system, which suggests that the bidirectional transport of low molecular weight solutes across the permselective membrane can be maintained in vivo. However, these studies were undertaken with empty polymer macrocapsules (57). Cells enclosed within the capsule can impact device biocompatibility. The inclusion of primary tissues, such as bovine adrenal chromaffin cells, typically results in a host tissue interface equivalent to that observed for the empty capsules. In contrast, PC12 cell-loaded capsules can elicit a more robust host response, but additionally, have increased the level of angiogenesis adjacent to the implant. Enhancing angiogenesis has also been investigated by releasing VEGF from planar diffusion chambers to induce vascularization of the transplanted devices (59).

In an effort to further enhance the biocompatibility for cell line-containing implants, or reduce protein adsorption that may negatively impact the ability to maintain adequate long-term diffusive characteristics, several postsynthesis modifications have been attempted. Poly(acrylonitrile-co-vinyl chloride) (PAN/VC) hollow fiber membranes, which were surface modified by grafting poly(ethylene oxide) (PEO) groups, exhibited improved biocompatibility in brain tissue over the unmodified PAN/VC controls (60). Similar observations were made with PEO-modified poly(hydroxyethyl methacrylate-co-methyl methacrylate) membranes used extensively in cellular microencapsulation (28).

VIII. LONG-TERM PRODUCT SECRETION AND DELIVERY

Before patients can be routinely implanted with encapsulated cells, long-term survival (>6 months) of the encapsulated cells and continued release of the therapeutic molecule must be demonstrated. Although effective immunoisolation should result in long-term survival of encapsulated cells, surprisingly few studies have examined long-term (>3 months) implant viability. A few notable exceptions exist and provide compelling evidence about the potential for long-term survival and release of molecules from the cells. Encapsulated PC12 cells secrete high levels of catecholamines under both basal and evoked conditions, and have been evaluated as a potential means of delivering dopamine to the striatum of PD patients. Following encapsulation, PC12 cells have been maintained in vitro and in vivo for at least 6 months, while maintaining a typical morphology and clustered arrangement along the lumen of the device (32,51,61,62). The cells remain tyrosine hydroxylase (TH)-immunoreactive and can be seen in various stages of mitosis, with some necrosis in regions of high cell density. The continued presence of TH suggests that the encapsulated cells maintain the ability to synthesize and release dopamine, and indeed spontaneous and evoked release of dopamine can be detected from capsules maintained both in vitro, and following explantation from the CNS. Electron microscopy confirms the presence of numerous mitochondria, polysomes, and electron-dense secretory vesicles distributed within the cytoplasm. Both rodent microdialysis and positron emission tomography studies in primates have confirmed that encapsulated PC12 cells continue to produce L-DOPA/dopamine in situ (62,63). Other cell types, specifically bovine adrenal chromaffin cells, have been reported to survive for prolonged periods of time following encapsulation. The long-term survival of bovine adrenal chromaffin cells in macrocapsules has been characterized in spinal implants to provide a sustained source of pain-reducing neuroactive substances (64). The most convincing demonstration of long-term survival of chromaffin cells comes from a study in which intraventricular implants of encapsulated bovine chromaffin cell implants survived for nearly 1.5 years and continued to pro-

duce catecholamines and met-enkephalin (52). These results indicated the capacity for long-term survival of encapsulated xenogeneic cells implanted in the lateral ventricles of rats. Similar observations in a higher species have not been obtained.

One of the more interesting areas of research involves using both encapsulated and unencapsulated cells as biological systems for delivery of growth factors. Encapsulated cells have been used to deliver nerve growth factor (NGF), ciliary neurotrophic factor (CNTF), neurotrophin 4/5 (NT 4/5) and glial-derived neurotrophic factor (GDNF), but only the long-term effects of NGF have been examined. Polymer-encapsulated cells have been reported to survive and continue to secrete NGF for 13.5 months in normal rodents (65). Following the 13.5-month implant interval, the NGF transgene copy number, as measured with polymerase chain reaction (PCR) analyses, from the recovered NGF cells was equivalent to preimplant levels, indicating NGF gene stability. In addition, as measured by enzyme-linked immunosorbent assay (ELISA), the NGF released from encapsulated cells into the tissue culture medium was 64% higher following removal from the rat lateral ventricles after the 13.5-month interval in situ. No deleterious effects from NGF were detectable on body weight, mortality rate, motor/ambulatory function, or cognitive function as assessed with the Morris water maze and delayed matching to position in healthy young adult rats. In addition, there was no evidence that NGF from these encapsulated cells produced hyperalgesia, although tests of somatosensory thresholds did reveal effects related to the NGF delivery. Morphologic analysis of retrieved cell-loaded devices revealed abundant viable BHK-NGF cells throughout the capsule. These same animals exhibited a marked hypertrophy of cholinergic neurons within the striatum and nucleus basalis, as well as a robust sprouting of cholinergic fibers within the frontal cortex and lateral septum proximal to the implant site. Although no deleterious behavioral effects were observed, the profound anatomical changes and their relationship to functional alterations in normal and diseased brain warrant additional study.

IX. HOST-SPECIFIC EFFECTS ON OUTPUT OF ENCAPSULATED CELLS

The available data also suggest substantial variability in the in vivo performance of encapsulated cells even during the first few months. For example, there was a large range in dopamine and L-DOPA output from rodent-size devices, from 0 to more than 50 pmol/device (66). In fact, 15% of the devices from that study had no detectable output after only 4 months in vivo. Similar variability in device performance has been observed in the majority of in vivo studies. In a primate study that produced therapeutic effects in two-thirds of the MPTP monkeys implanted with PC12 cells, all 5 devices implanted in 1 monkey had virtually 0 output after explantation, whereas all 5 devices implanted in another monkey had relatively high output and all 5 devices in the third monkey had catecholamine output in the midrange (51). These results clearly demonstrate that some of the variability in device performance may be atributable to individual differences between hosts, a result consistent with that reported for NGF output from encapsulated BHK cells implanted into the lateral ventricle of rodents (67). The exact mechanism for these individual differences remains undetermined but deserves serious attention.

X. DIFFUSION OF MOLECULES FROM POLYMER DEVICES

Little work has been done to date to determine the extent of diffusion of molecules from encapsulated devices into the host tissue. Winn et al. (16) initially evaluated dopamine diffusion in a denervated striatum with acute microdialysis from a dopamine releasing polymer rod placed in a semipermeable receptacle. Morphologically, the microdialysis probes were found to be located approximately 0.5 mm from the receptacle. In addition, Tresco et al. (62) conducted a series of in vivo experiments to elucidate the relationship between diffusion of dopamine from encapsulated PC12 cells and behavioral recovery in dopamine-depleted rodents. Dopamine was detectable 200 μm from PC12 cell-loaded macrocapsules, as determined by microdialysis, in concentrations similar to those obtained in unlesioned control striatum. In contrast, the levels of dopamine in the perfusate of animals that did not exhibit behavioral recovery were undetectable.

Immunocytochemistry was used to estimate the diffusion of NGF from encapsulated cell implanted into the striatum of rats (68). One month after implantation, the diffusion of NGF was estimated to be approximately 1 mm. CNTF has also been reported to be detectable in the cerebrospinal fluid (CSF) of amyctroplate scher (ALS) patients who have received intrathecal implants of encapsulated CNTF-producing BHK cells. In contrast, CSF levels of NGF were not detectable in nonhuman primates that received intraventricular grafts of NGF-producing cells (69). At best, these data suggest that diffusion of molecules from encapsulated cells is limited. Moreover, the majority of degenerative CNS diseases will likely not be treatable by delivering drugs from the ventricular space given that diffusion of compounds in CNS tissue is generally severely limited when only governed by passive diffusion. Future work, particularly clinical considerations, must seriously consider this issue when determining the optimal numbers and spacing of polymer devices.

XI. ENCAPSULATED CELLS FOR PARKINSON'S DISEASE

A. Effects of Catecholamine-producing Cells

PD is an age-related neurodegenerative disorder characterized by hypokinesia, rigidity, and tremor. These behavioral abnormalities are mediated by a marked loss of dopaminergic neurons in the pars compacta of the substantia nigra. Pharmacological treatments are based on replacing or increasing striatal dopamine levels [e.g., L-dihydroxyphenylaline (L-DOPA) ad-

ministration]. Oral administration of L-DOPA significantly improves motor deficits in the early stages of PD. Unfortunately, this pharmacological approach has limitations. Systemic administration results in drug distribution to extrastriatal dopamine receptors, which may produce psychoses and vomiting. The therapeutic window of L-DOPA's beneficial effects becomes progressively limited as the disease continues its degenerative course. Pulsatile delivery seems to be associated with more adverse effects than continuous delivery (70). Studies using pumps to deliver dopamine continuously and directly to the striatum in both rodent and primate models of PD have reported improved motor function with few adverse effects (71–73). Several studies have detailed the effects of implanting encapsulated dopamine-producing cells into the striatum.

1. Rodent Studies

Several detailed studies have been conducted in both rodent and primate models of PD, which validate the potential of this approach. Rats with PC12 cell-loaded capsules implanted in a dopamine-depleted striatum exhibit fewer rotations after apomorphine administration than nonimplanted rats, which suggests that the devices are releasing catecholamines at levels sufficient to reduce the degree of synaptic supersensitivity that develops after dopamine-depleting lesions (Table 2). Within 2 weeks following implantation, the number of apomorphine-induced rotations is decreased by approximately 40% to 50% and remains at this level for up to 6 months (62). The specificity of the effects of PC12 cells is further supported by the observation that reductions in rotational behavioral do not occur following implants of empty polymer devices and that reductions in rotations are only evident in rats implanted in the denervated striatum and not in rats with devices implanted into the lateral ventricles (66,74). Furthermore, the behavioral effects persist only as long as the devices remain in the striatum.

Measures of drug-induced rotations provide a convenient method for assessing potential efficacy, and significant information has been acquired using this initial preclinical screen. However, relying exclusively on changes in drug-induced rotations has been criticized for the lack of clinical relevance and specificity. Accordingly, the effects of PC12 cells on a battery of nondrug-induced behaviors have been examined. Neurological testing revealed behavioral deficits in the affected forelimb analogous to the deficits exhibited in PD patients, and these deficits were significantly attenuated by oral Sinemet® (66,75). Because any transplantation procedure will be used as an adjunct to L-DOPA administration, these data provided the opportunity to investigate the effects of PC12 cells on both relevant behavioral measures and on the therapeutic window of oral Sinemet. Rats with severe unilateral dopamine depletions received striatal implants of encapsulated PC12 cells. Rats were evaluated on a series of behavioral tests over a range of doses of oral Sinemet. Results confirmed that cell-based delivery of L-DOPA and dopamine, directly to the denervated striatum, attenuated parkinsonian symptoms. The magnitude of the therapeutic effect produced by continuous, site-specific delivery of catecholamines was greater than the effect prodcued by acute, systemic oral Sinemet. The beneficial effects of oral Sinemet and striatal implants of PC12 cells were additive, but there were no adverse effects related to the implantation of the PC12 cells and these devices did not increase the adverse effects related to oral Sinemet (76). Therefore, striatal implants of catecholamine-producing devices have direct therapeutic effects, and perhaps more important, they appear to widen the therapeutic window of oral Sinemet.

Table 2 Behavioral Outcome from Encapsulated Catecholamine-secreting PC12 Cells in Models of PD

Animal model	Testing paradigm	Outcome[a]
Unilateral lesioned rats	Receptor-activated rotations	+
	T-maze alternation	+
	Somatosensory function	+
	Forelimb freezing/bracing	−
	Forelimb placing	−
	Forelimb akinesia	−
	Postural/locomotor forelimb use	−
Bilateral lesioned rats	Feeding/drinking	−
Aged rats	Activity levels	−
	Balance and coordination	+
MPTP-lesioned primates	Skilled hand use	+
	Clinical rating scale	+

[a] +, positive outcome; −, negative outcome.

In addition to motor deficits produced experimentally by depleting nigrostriatal dopamine systems in young rodents, motor deficits are also observed with increased age. Age-related deficits in motor functions include deficits in balance, coordinated movement, and generalized locomotion. Striatal dopaminergic systems appear to be involved integrally in the motor perturbations that occur during aging, and enhancement of striatal dopamine function in aged animals by induction of dopamine receptor up-regulation or administration of dopaminergic agonists can reduce age-related motor deficits. Because the motor deficits observed in aged rodents appear to be mediated partially by alterations in striatal dopamine systems, studies were conducted to evaluate the potential efficacy of striatal implants of polymer-encapsulated PC12 cells on age-related motor dysfunction in rats (77). In these studies, aged rats were significantly hypoactive relative to young animals. Moreover, compared with young rats, the aged rats (1) remain suspended from a horizontal wire for less time, (2) are unable to descend a wooden pole covered with wire mesh in a coordinated manner, (3) fall more rapidly from a rotating rod, and (4) are unable to maintain their balance on a series of wooden beams with either a square or rounded top of varying widths.

Following baseline testing, aged rats received bilateral striatal implants of empty capsules or PC12 cell-loaded capsules. Three weeks later, the aged rats that received PC12 cells showed a robust improvement in performance on the rotarod task and balance on the wooden beams. No recovery was observed in the animals receiving PC12 cell-loaded capsules on any of the other motor tasks (Table 2). Likewise, no improvement was observed on any behavioral measure in those animals receiving empty capsules.

2. Primate Studies

The studies conducted to date in the 6-OHDA rat model of PD generally support the clinical utility of encapsulated catecholamine-producing cells to restore dopamine levels within the denervated striatum. However, nonhuman primates are a more relevant model due to their size and complexity of the nervous system, which more closely approximates humans. This is especially important in neural transplantation because of the need for therapeutic agents to diffuse from the implant site through the striatal parenchyma. In terms of tissue volume, diffusion through a rat brain is easier to accomplish than adequate diffusion through the much larger human brain. The nonhuman primate model allows the assessment of therapeutic potential at this level in a way that cannot be approximated in rodents. Accordingly, the potential efficacy of encapsulated PC12 cells has been evaluated in a unilateral MPTP-lesioned primate model. Cynomolgus monkeys trained to perform a task that involved extending the arm and required fine use of the digits to pick food from small food wells were unilaterally lesioned with an injection of MPTP in the right carotid artery. The resulting MPTP-induced lesion produced a significant and stable impairment in the ability of the animals to use the contralateral limb to retrieve food rewards from the wells. The times required to empty the wells were measured for 3 months postlesion, and the monkeys were then implanted with a U-shaped device that was immediately filled with a suspension of PC12 cells (78). Following implantation of the cells, manual dexterity was improved and the time required for the monkeys to empty the tray using the impaired hand gradually decreased (Table 2). Although the PC12 cells attenuated the parkinsonian deficit in this task, some tremor remained and the animals did not recover to prelesion levels. Prior to the implantation of cells, the monkeys left arm was essentially immobile. After implantation, the monkeys could consistently move both their arm and use their fingers. When the cells were flushed out of the device, performance declined again and the time required to empty the tray increased toward preimplant levels. Together, these data indicated that encapsulated cells survived, were functional, and promoted behavioral recovery even in primate models of PD.

Similar results were obtained in a study by Kordower et al. (51), where 4 cynomolgus primates were trained on a skilled reaching task similar to that described above and then rendered hemiparkinsonian with an intracarotid injection of MPTP. Three animals received implants of encapsulated PC12 cells into both the caudate and putamen, and 1 animal received implants of empty capsules and served as a control. After a transient improvement, limb use in the control monkey dissipated and returned to post-MPTP levels of disability. Two of the 3 PC12 cell-implanted monkeys recovered performance on the task to near normal levels for up to 6.5 months post-transplantation. Capsules retrieved from the monkeys who recovered limb function contained abundant viable PC12 cells that continued to release L-DOPA and dopamine. In contrast, capsules retrieved from the monkey that did not recover contained few viable PC12 cells. Neuroanatomical and neurochemical evaluation of the implanted striatum failed to reveal any host-derived sprouting of catecholaminergic or indolaminergic fibers, which further suggested that the observed behavioral recovery was due to secretion of catecholamines from the encapsulated PC12 cells.

B. Effects of Neurotrophic Factor-producing Cells

Several recent studies have investigated the ability of encapsulated neurotrophic factor-secreting cells to exert neutotrophic effects in rodent models of PD (79–82). In an initial study (81), the ability of encapsulated GDNF-producing cells to prevent the degeneration of dopaminergic neurons was investigated in rats following transection of the medial forebrain bundle. Encapsulated cells releasing aproximately 5 ng of GDNF/day were implanted immediately rostral to the substantia nigra. One week later, the medial forebrain bundle was transected and the animals were tested for amphetamine-induced rotations for 1 week later. GDNF treatment significantly reduced the numbers of rotations in lesioned animals. GDNF treatment also attenuated the loss of neurons in the substantia nigra but had no effect on dopamine within the denervated striatum. Using the same model system, neuturin-producing cells, a homologue of GDNF, was investigated for its neurotrophic activity (82). Neurturin-treated animals had significantly more TH-positive neurons in the substantia nigra (51% compared with 16% in controls), but failed to show any behavioral improvement as measured by rotational behavior. Together, these data suggest that encapsulated cells may have a role in neurotrophic therapy for PD. However, additional studies in animal models are required to detemrine the relationship between the anatomical and behavioral consequences of cell-based delivery.

XII. ENCAPSULATED NGF-PRODUCING CELLS IN ANIMAL MODELS OF AD

AD affects approximately 5% of the population over the age of 65 and is the most prevalent form of adult onset dementia. With the increase in our aging population, the incidence of AD is expected to triple over the next 75 years. The most prominent feature of AD is a progressive deterioration of cognitive and mnemonic ability, which is at least partially related to the degeneration of basal forebrain cholinergic neurons. At present, treatments are ineffective for either slowing or preventing cholinergic neuron loss or the associated memory

deficits. Several converging lines of evidence indicate that NGF has potent target-derived trophic and tropic effects on cholinergic basal forebrain neurons (83,84).

A. Rodent Studies

Although no model faithfully recaptitulates the complex etiology and time-dependent loss of cholinergic neurons seen in AD patients, model systems have been developed to answer the specific question: Can NGF prevent the death of damaged cholinergic neurons following acute trauma? Initial studies determined whether encapsulated BHK cells modified to produce human NGF could prevent cholinergic neuron loss following aspiration of the fimbria/fornix (85) (Fig. 6). Rats received lesions of the fimbria/fornix followed by intraventricular implants of either NGF-producing or control (nontransfected) cells. Control-implanted animals had an extensive loss of ChAT-positive cholinergic neurons ipsilateral to the lesion that was prevented by NGF cell implants. Quantitation of ChAT-positive neurons for the 2 groups revealed that with the control capsules, 14% of the neurons remained viable on the lesioned side compared with the nonlesioned side, whereas with the NGF capsules, 88% of the cholinergic neurons were rescued.

One of the cardinal behavioral symptoms of AD is a progressive loss of cognitive ability. Just as no animal model faithfully mimics the complex etiology and pathophysiology of AD, comparable behavioral abnormalities are difficult to reproduce in animal models. However, the aged rodent shows a progressive degeneration of basal forebrain cholinergic neurons, together with marked cognitive impairments, which are partly reversible by administering NGF. Lindner et al. (67) trained 3-, 18-, and 24-month-old rats on a spatial learning task in a Morris water maze (Fig. 7). Cognitive function, as measured in this task, declined with age. Evidence of age-related atrophy of cholinergic neurons was observed in the striatum, medial septum, nucleus basalis, and vertical limb of the diagonal band. These anatomical changes were most severe in animals with the greatest cognitive impairments, suggesting a link between the 2 pathological processes. Following training, animals received bilateral intraventricular implants of encapsulated NGF or control cells. The 18- and 24-month old animals receiving NGF cells showed a significant improvement in cognitive function (Fig. 7). No improvements or deleterious effects were observed in the young nonimpaired animals. Anatomically, the NGF released from the encapsulated cells increased the size of the atrophied basal forebrain and striatal cholinergic neurons to the size of the neurons in the young healthy rats. Furthermore, there was no evidence that the NGF cells produced changes in mortality, body weights, somatosensory thresholds, potential hyperalgesia, or activity levels, suggesting that the levels of NGF produced were neither toxic nor harmful to the aged rats.

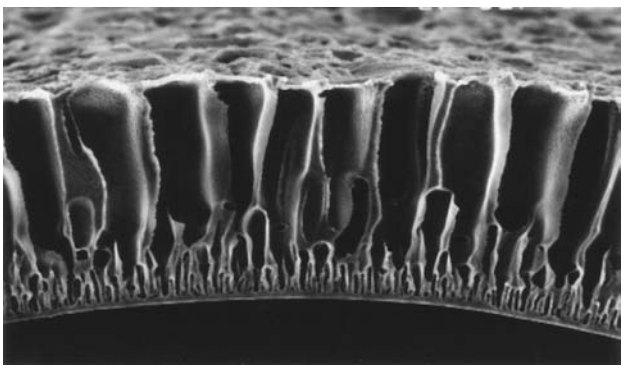

Figure 6 Scanning electron micrograph of a typical macrovoid-containing membrane used in cell encapsulation.

B. Primate Studies

Similar results were obtained in nonhuman primates (69), an essential prerequisite to human clinical trials. In these studies, cynomolgus primates received transections of the fornix followed by placement of encapsulated NGF or control cells into the lateral ventricle (Fig. 4). In the control animals, a significant reduction in the number of cholinergic neurons was observed in the medial septum and vertical limb of the diagonal band of Broca. Again, loss of cholinergic neurons was prevented by implants of NGF-secreting cells. It also appeared that cholinergic neurons within the medial septum of NGF-treated animals were larger, more intensely labeled, and elaborated more extensive proximal dendrites than those displayed by BHK-control animals (Fig. 8).

In addition to the effects on cell viability, NGF implants induced a robust sprouting of cholinergic fibers proximal to the implant site (69). All monkeys receiving NGF implants displayed dense collections of NGF receptor-immunoreative fibers throughout the entire dorsoventral extent of the lateral septum (Fig. 9). This effect was unilateral as the contralateral side displayed only a few cholinergic fibers in a manner similar to that seen in control-implanted monkeys. The cholinergic nature of this sprouting was confirmed by an identical pattern of fibers, which were both ChAT-immunoreactive and AChE-positive. These fibers ramified against the ependymal lining of the lateral ventricle adjacent to the transplant site and were particularly prominent within the dorsolateral quadrant of the septum corresponding to the normal course of the fornix. The cell sparing and sprouting results have been replicated in a group of aged nonhuman primates (86).

XIII. POLYMER-ENCAPSULATED CELLS TO DELIVER NEUROTROPHIC FACTORS IN ANIMAL MODELS OF HD

HD is an inherited, progressive neurological disorder characterized by a severe degeneration of basal ganglia neurons, particularly the intrinsic neurons of the striatum. Accompanying the pathological changes is a progressive dementia coupled

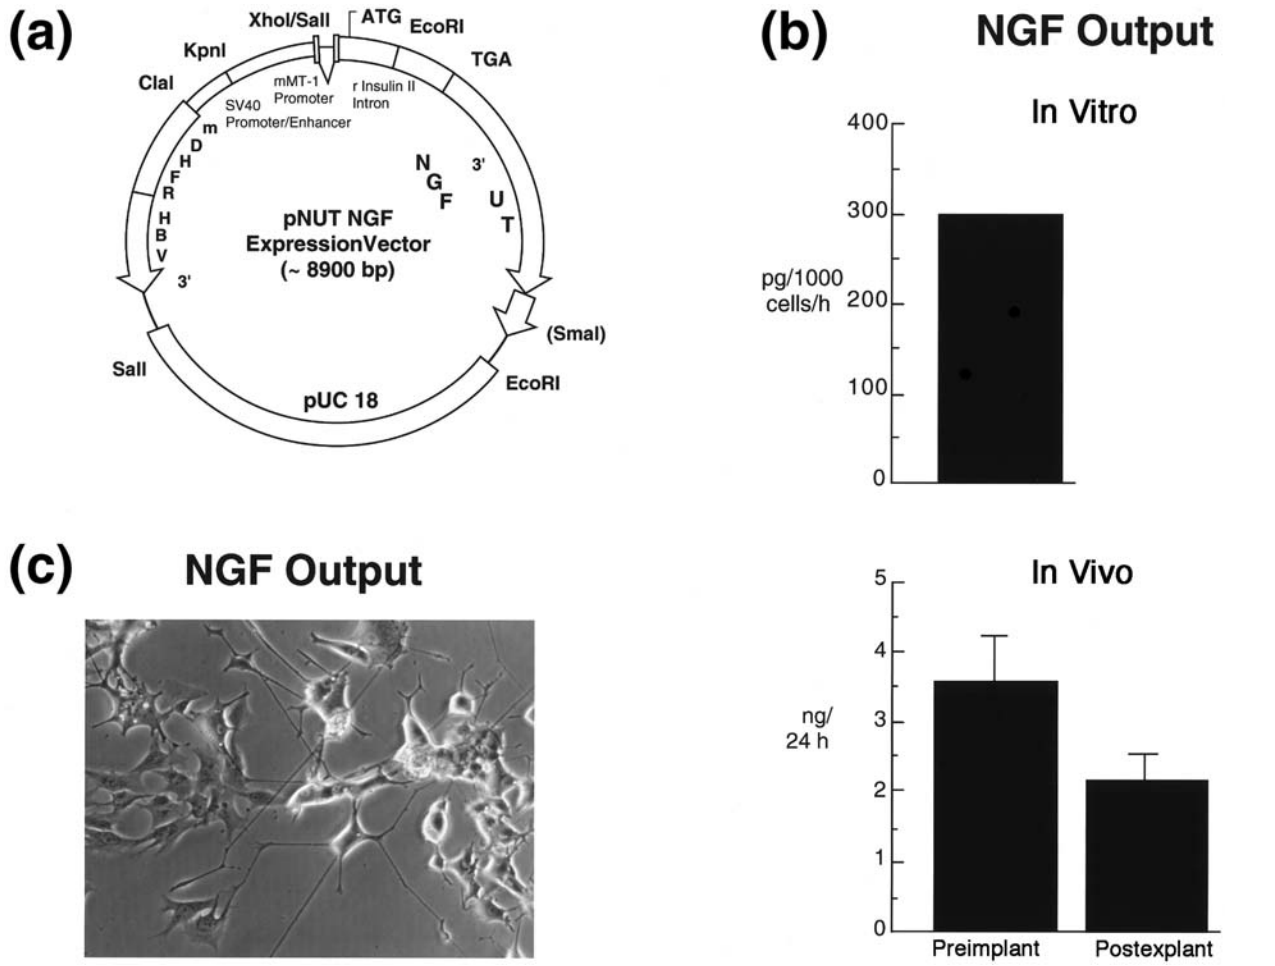

Figure 7 (a) Expression vector containing the NGF gene. (b) NGF levels, as determined by ELISA, in unencapsulated (top) and encapsulated (bottom) BHK cells. The in vivo levels were determined from devices 3 months following explant from rodent striatum. (c) The biological activity of the NGF from encapsulated BHK cells is shown in phase-contrast photomicrographs of PC12 cells that exhibit exytensive neurite processes. Original magnification, 25 um.

with uncontrollable movements and abnormal postures. From the time of onset, an intractable course of mental deterioration and progressive motor abnormalities begins with death usually occurring within 15 to 17 years. Overall, the prevalence rate of HD in the United State is approximately 50 per 1,000,000 (87). At present, there is no treatment that effectively addresses the behavioral symptoms or slows the inexorable neural degeneration in HD.

Intrastriatal injections of excitotoxins such as quinolinic acid (QA) have become a useful model of HD and can serve to evaluate novel therapeutic strategies aimed at preventing, attenuating, or reversing neuroanatomical and behavioral changes associated with HD (88–91). The use of trophic factors in a neural protection strategy may be particularly relevant for the treatment of HD. Unlike other neurodegenerative diseases, genetic screening can identify virtually all individuals at risk who will ultimately suffer from HD. This provides a unique opportunity to design treatment strategies to intervene prior to the onset of striatal degeneration. Thus, instead of replacing neuronal systems, which have already undergone extensive neuronal death, trophic factor strategies could be designed to support host systems destined to die at later time in the patient's life.

A. Rodent Studies

Infusions of trophic factors such as NGF or implants of cells genetically modified to secrete NGF have proven effective in preventing the neuropathological sequelae resulting from intrastriatal injections of excitotoxins, including QA (92–95). Emerich and colleagues (96,97) examined the ability of encapsulated trophic factor-secreting cells to affect central striatal

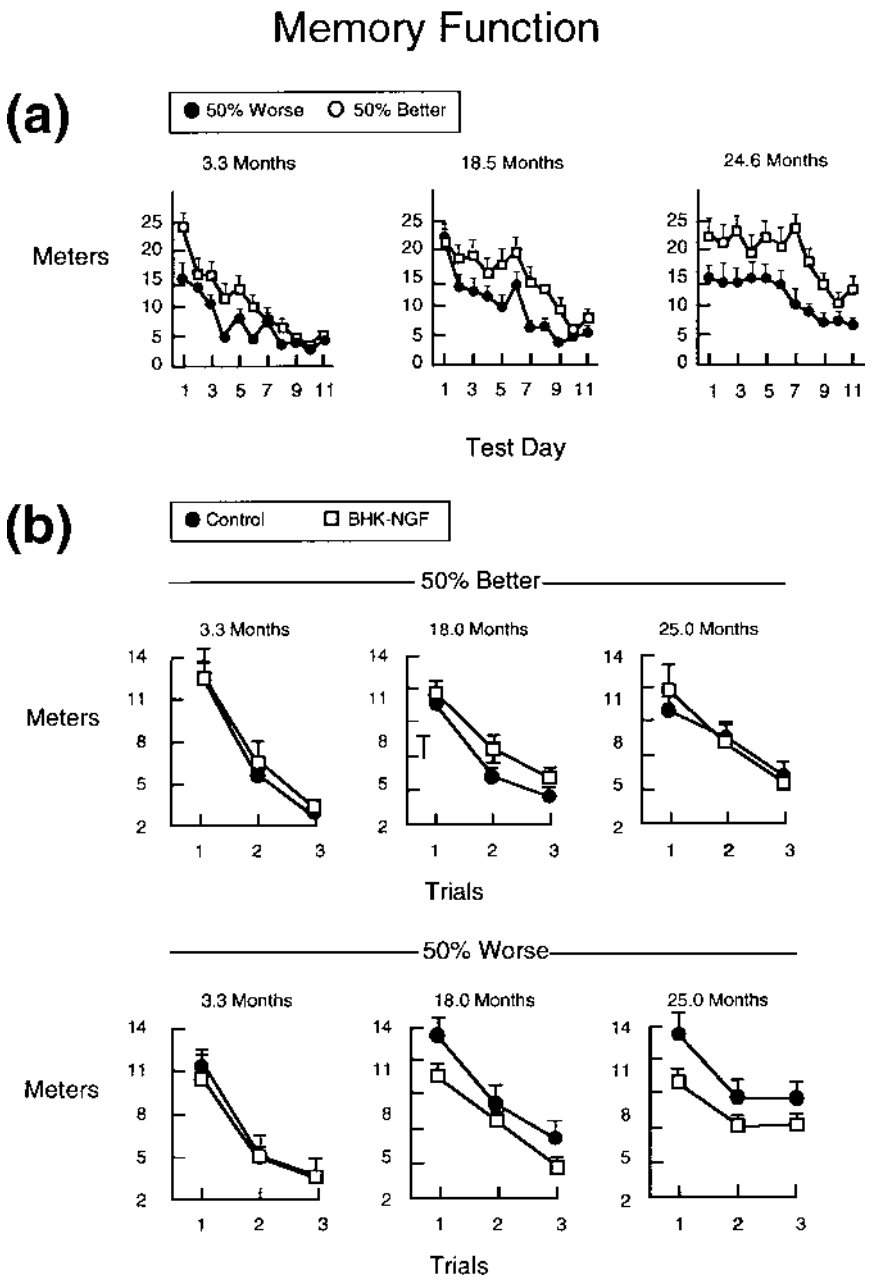

Figure 8 Cognitive function in young, middle-age, and aged rats following implantation of encapsulated NGF-producing cells into the lateral ventricles. (a) Prior to implantation, animals were divided into the 50% worse and 50% better performers in a water maze task. (b) Following implantation, NGF was found to improve performance in the middle-age and aged animals. Moreover, the improvements in cognitive performance were greatest in those animals that demonstrated the worst initial performance [see (67) for additional details].

neurons in a series of defined animal models of HD. In these experiments, rats received implants of NGF- or CNTF-producing cells into the lateral ventricles (Fig. 10). One week later, the same animals received unilateral injections of QA (225 nmol) or the saline vehicle into the ipsilateral striatum. An analysis of Nissl-stained sections demonstrated that the size of the lesion was significantly reduced in those animals receiving NGF and CNTF cells, compared with those animals receiving control implants. Moreover, both NGF and CNTF cells attenuated the extent of host neural damage produced by

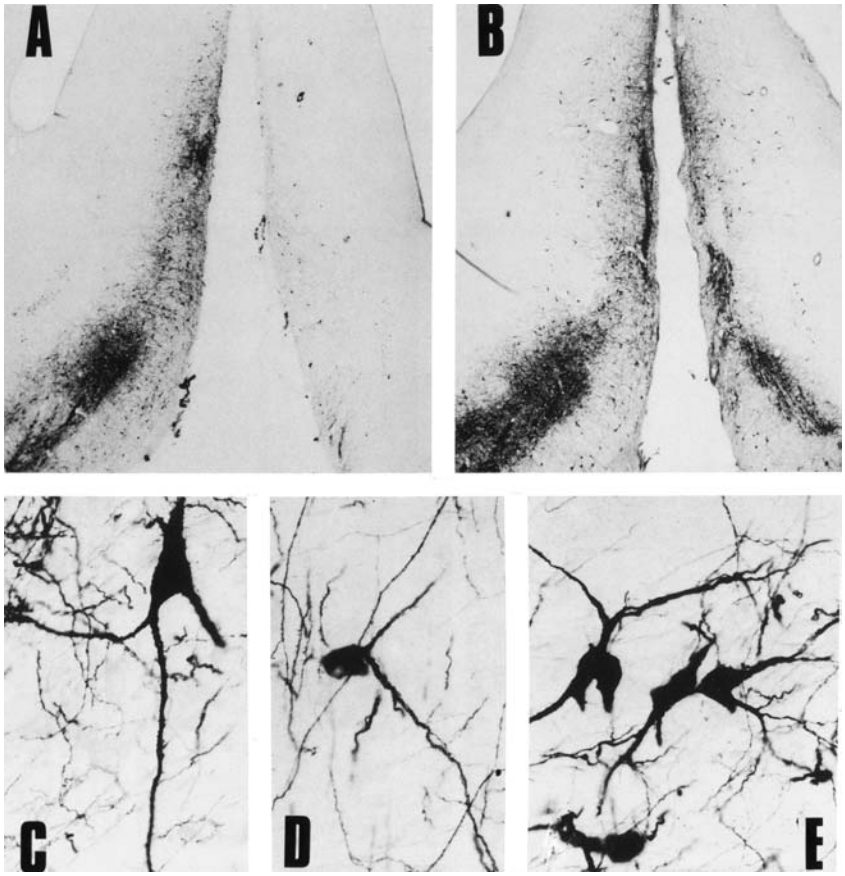

Figure 9 Photomicrographs through the septal diagonal band complex of cynomolgus monkeys. Monkeys received a fornix transection together with polymer-encapsulated implants of either BHK-control cells (A) or a BHK-NGF cells (B). Note the extensive loss of NGF receptor positive neurons ipsilateral to the lesion (right) in the control-implanted monkeys. In contrast, numerous NGF cholinergic neurons were observed in fornix-transected monkeys receiving the BHK-NGF implant. High-power photomicrographs illustrating the morphology of cholinergic neurons within the medial septum of young monkeys receiving BHK-NGF (C–E) implants. Note the enlarged perikarya and extensive neuritic arbor displayed by monkeys receiving the BHK-NGF implants [see (69) for additional details].

QA as assessed by a sparing of specific populations of striatal cells, including cholinergic, diaphorase-positive, and GABAergic neurons (Fig. 11). Neurochemical analyses have confirmed the protection of multiple striatal cell populations using this strategy (Table 3). These results suggested that implantation of polymer-encapsulated trophic factor-releasing cells can protect neurons from excitotoxin damage. Importantly, behavioral studies offer additional and compelling evidence of neuronal protection that can be produced in animal models of HD (Table 3). Trophic factor-secreting cells have provided extensive behavioral protection as measured by tests that assess both gross and subtle movement abnormalities. Moreover, these same animals show improved performance on learning and memory tasks, indicating the anatomical protection afforded by trophic factors in this model is paralleled by a robust and relevant behavioral protection (98).

B. Primate Studies

The ability of cellularly delivered trophic factors to preserve neurons within the striatum in a rodent model of HD led to similar studies in nonhuman primates, a step that is crucial to the initiation of clinical trials. A paradigm similar to the one employed in the rodent studies was used in nonhuman primates (99). Polymer capsules containing CNTF-producing cells were grafted into the striatum of rhesus monkeys. One week later, a QA injection was placed into the putamen and caudate proximal to the capsule implants. As seen in the rodent studies, the volume of striatal damage was decreased, and both GABAergic and cholinergic neurons destined to degenerate were spared in CNTF-grafted animals. Although all animals had significant lesions, there was a 3- and 7-fold increase in GABAergic neurons in the caudate and putamen, respectively,

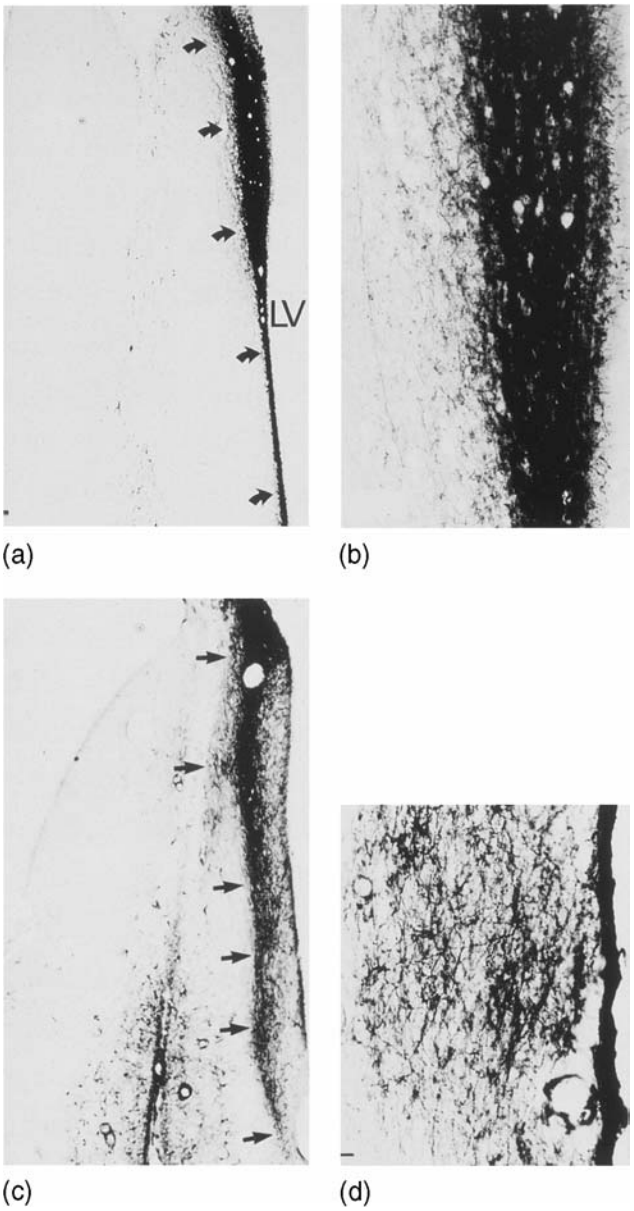

Figure 10 Sprouting of cholinergic fibers in young (a,b) and aged (c,d) NGF-treated monkeys. Low- (a,c) and high-power (b,d) photomicrographs of NGF receptor immunostained sections, illustrating a dense plexus of cholinergic fibers on the side of NGF treatment (arrows) adjacent to the lateral ventricle (LV). Scale bar in a is 1000 um for a and c; scale bar in d is 50 um for b and d.

in CNTF-grafted animals relative to controls. Similarly, there was a 2.5- and 4-fold increase in cholinergic neurons in the caudate and putamen, respectively, in CNTF-grafted animals (Fig. 12).

The ability to preserve GABAergic neurons in animals models of HD is an important, although not entirely sufficient, step to develop a useful therapeutic. If the perikarya are preserved without sustaining their innervation, then the experimental therapeutic strategy under investigation is not likely to yield significant value. The striatum is a central station in series of loop circuits that receives inputs from all the neocortex, projecting to a number of subcortical sites, and then returns information flow to the cerebral cortex. One critical part of this circuitry is the GABA-ergic projections to the globus pallidus and substantia nigra pars reticulata, the parts of the direct and indirect basal ganglia loop circuits. One approach to examining the integrity of this circuit is to use an antibody that recognizes GABA-ergic terminals (DARPP-32) to determine if the preservation of GABA-ergic somata within the striatum also results in the preservation of the axons of these neurons to critical extrastriatal sites. Using quantitative morphological assessment of DARPP-32 optical density, it has been shown that monkeys receiving QA lesions have significant reductions in DARPP-32 immunoreactivity within the globus pallidus and substantia nigra (Fig. 13). The lesion-induced decrease in GABA-ergic innervation for both of these regions was prevented in CNTF-grafted monkeys demonstrating that this treatment strategy protected GABA-ergic neurons destined to die following excitotoxic lesion, as well as sustained the normal projection systems from this critical population of neurons (99).

The intrinsic striatal cytoarchitecture can be preserved in monkeys by CNTF grafts, and once exposed to these grafts, the cells apparently maintain their projections. But are afferents to the striatum, specifically from the cerebral cortex, also influenced by these grafts? This may be particularly critical if some of the more devastating nonmotor symptoms seen in HD result from cortical changes secondary to striatal degeneration. Because layer V neurons from motor cortex send a dense projection to the postcommissural putamen, a region that was severely impacted by the QA lesion, the effects of QA lesions and CNTF implants on the number and size of cortical neurons in this region were examined. Although the QA lesion did not effect the number of neurons in this cortical area, layer V neurons were significantly reduced in cross-sectional area on the side ipsilateral to the lesion in control-grafted monkeys (Fig. 14). This atrophy of cortical neurons was virtually completely reversed by CNTF grafts (99).

A recent set of studies using CNTF-producing cells in 3NP-treated monkeys have replicated and extended these results (100). Following 10 weeks of 3NP treatment, monkeys displayed pronounced chorea and severe deficits in frontal lobe cognitive performance as assessed by the object retrieval detour test. Following implantation of CNTF-producing cells, a progressive and significant recovery of motor and cognitive recovery occurred. Histological analysis demonstrated that

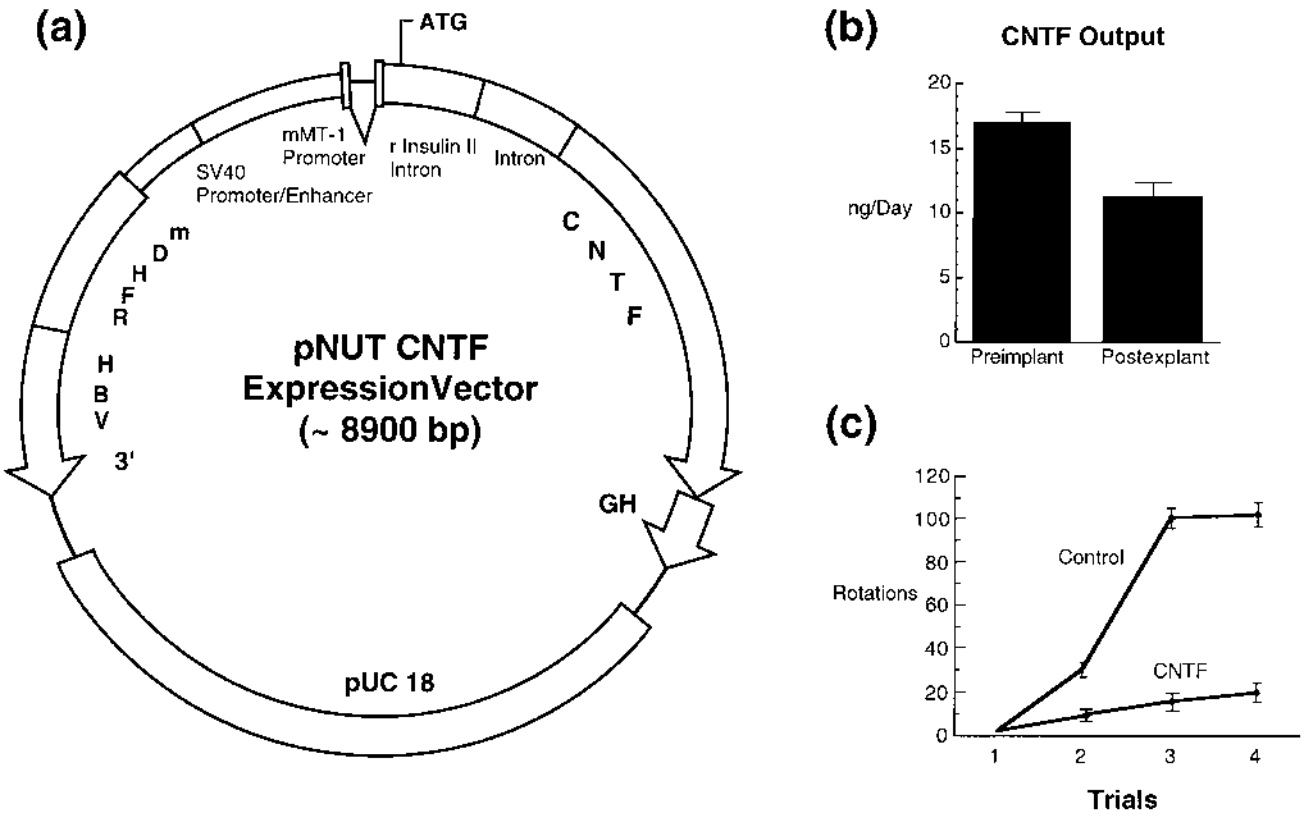

Figure 11 (a) Expression vector containing the CNTF gene. (b) CNTF levels, as determined by ELISA, in encapsulated BHK cells immediately prior to implantation (left) and immediately following retrieval from rodent lateral ventricle 70 days following implantation (right). (c) Implants of encapsulated CNTF producing cells reduce apomorphine rotations in rats after unilateral striatal injection of quinolinic acid.

CNTF was neuroprotective and spared NeuN and calbindin-positive cells in the caudate and putamen.

Although the sparing of striatal neurons and maintanence of intrinsic circuitry is impressive, the magnitude of the effect is less than that seen in rodents. In primates, robust protection is limited to the area of the capsules. However, the area of the lesion remains extensive, and it is likely that diffusion of CNTF from the capsule may not be sufficient to protect more distant striatal regions undergoing degeneration. This concept is supported by a recent experiment that examined the effects of intraventricular grafts of encapsulated CNTF grafts in the nonhuman primate model of HD (101). In contrast to when the capsules were placed directly within brain parenchyma, intraventricular placements failed to engender neuroprotection for any striatal cell types; again suggesting that diffusion is a key factor in the efficacy of this experimental therapeutic strategy. The complete lack of neuroprotection provided by intraventricular implants in primates should be considered more carefully in the current clinical trials being conducted in which encapsulated cells are being placed into the lateral ventricles of HD patients (102,103). If human trials are to yield clinically relevant positive effects, the means of CNTF delivery used in these studies needs to be improved. Whether this entails grafting more capsules, enhancing the CNTF delivery from the cells by changing the vector system or cell type employed, or changing the characteristics of the polymer membrane remains to be determined.

XIV. INITIAL CLINICAL TRIALS

A. Amyotropic Lateral Sclerosis

Neuromuscular disorders such as ALS are marked by a progressive degeneration of spinal motor neurons. The challenge for research scientists and clinicians remains to understand the etiology of this fatal disease in order to develop an effective treatment. Different families of neurotrophic factors demonstrate therapeutic potential in vitro and in animal models of motor neuron disease (104–112). The cytokine CNTF has neuroprotective effects for motor neurons in *wobbler* mice (109) and homozygote pmn (progressive motorneuropathy) mice (104,110). The delivery of CNTF to motor neurons by

Table 3 Behavioral Protection Produced by NGF and CNTF in Rodent Models of HD

[a] NE, not evaluated; +, positive outcome; −, negative outcome.

peripheral administration proved difficult due to severe systemic side effects, short half-life of CNTF, and the inability of CNTF to cross the BBB (113–115).

Continuous intrathecal delivery of CNTF proximal to the nerve roots in the spinal cord is a practical aternative that could result in less side effects and better efficacy of CNTF in ALS patients. After safety, toxicology, and preclinical evaluation, a clinical trial to establish safety has been performed in ALS patients using polymer-encapsulated cells genetically modified to secrete CNTF (116). A total of 6 ALS patients with early stage disease indicated by a forced vital capacity greater than 75% with no other major illness or treated with any investigational drugs for ALS were included. These patients were baseline tested for Tufts Quantitative Neuromuscular Evaluation, the Norris scale; blood levels of acute reactive proteins; and CNTF levels in the serum and CSF. BHK cells were encapsulated into 5 cm long by 0.6 mm diameter hollow membranes and implanted into the lumbar intrathecal space. The device included a silicone tether, which was sutured to the lumbodorsal fascia and the skin was closed over the device (Fig. 15). CNTF concentrations in the CSF were not detectable prior to implantation, but was found in all 6 patients at 3 to 4 months postimplantation. All 6 explanted devices had viable cells and CNTF secretion of approximately 0.2 to 0.9 μg/day. No CNTF was detected in the serum.

B. Chronic Pain

Numerous studies with rodent models of acute and chronic pain have suggested that adrenal chromaffin cells implanted into the intrathecal space and in the periaqueductal gray reliably produce significant analgesic effects [see (117,118) for a review]. Although the majority of these studies have used unencapsulated cells, recent studies suggested that encapsulated cell implants also produce analgesia in rats. The analgesic effects of adrenal chromaffin cells in rodent model have provided the rationale to pursue clinical trials in patients with chronic pain. Small, open-label trials demonstrated that the implantation procedure was minimally invasive and well tolerated (119,120). Neurochemical and histological studies determined that the encapsulated cells survived and were biochemically functional for up to 1 year. Because reductions in morphine intake were noted following implantation (suggesting efficacy), larger-scale, randomized studies were initiated in a collaborative study between CytoTherapeutics and Astra Pharmacueticals. Unfortunately, the trials were recently halted because the efficacy achieved did not reach a level high enough to warrant further study (121).

Interestingly, several recent reports indicate encapsulated adrenal chromaffin cell implants may not produce efficacy as originally suggested (122–125). Extensive studies in acute and chronic rodent pain models have failed to find any evidence of analgesia. This lack of effect occurred under conditions that were apparently designed to exactly reproduce previous testing procedures that did demonstrate efficacy. Among the variables examined were the location of implant (intrathecal vs. intraventricular), a wide range in cell preparation techniques, and an exhaustive battery of acute and chronic pain tests with and without nicotine stimulation. Importantly, the authors reported that systemic administration of morphine produced significant analgesia when tested in parallel in the same models. Although subtle testing differences cannot be ruled out as contributing factors in the differences between these recent and previous studies, together with the only well-controlled clinical trial conducted to date, it appears that, at the least, adrenal chromaffin cells do not produce analgesic effects as consistently as previous reported (122–124).

C. Huntington's Disease

Recently, clinical trials were initiated to determine the safety and tolerability of CNTF-producing cells implanted into the lateral ventricle of HD patients (37). Although the case for clinical evaluation is compelling, several issues are apparent with the design of the ongoing clinical trials. Although the sparing of striatal neurons and maintanence of intrinsic circuitry in monkeys is impressive, the magnitude of the effect is less than that seen in rodents. Robust protection is largely limited to the area of the capsules. However, the area of the lesion remains extensive, and it is likely that diffusion of CNTF from the capsule may not be sufficient to protect more distant striatal regions undergoing degeneration. This concept is supported by a recent experiment that examined the effects of intraventricular grafts of encapsulated CNTF grafts in the QA monkey model of HD. In contrast to when the capsules were placed directly within brain parenchyma, intraventricular placements failed to engender neuroprotection for any striatal cell types; again suggesting that diffusion is a key factor in

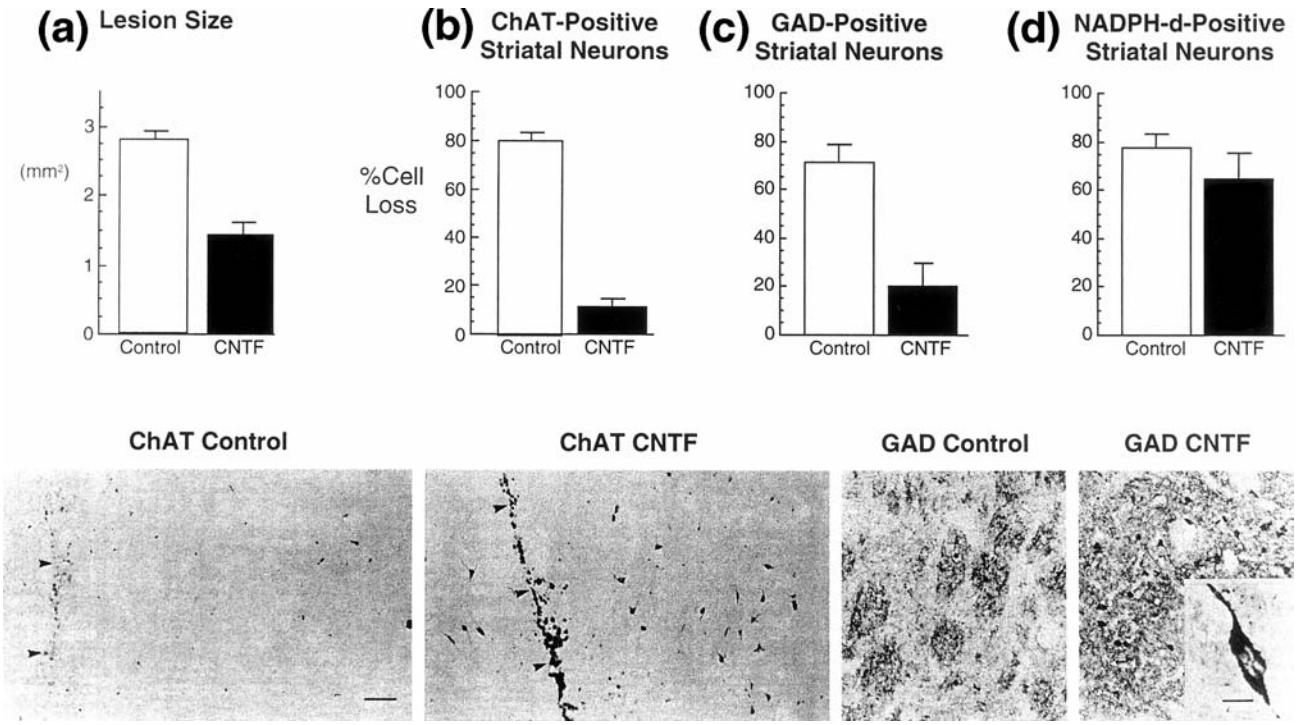

Figure 12 Lesion volume and neuronal cell counts in quinolinic acid-lesioned rats. Control-implanted animals displayed a marked lesion volume (a, determined by Nissl staining) and a significant loss of multiple types of striatal cell types, including cholinergic (b), GABAergic (c), and diaphorase-positive neurons (d). The cholinergic and GABAergic neuronal losses were largely prevented in animals receiving CNTF implants, whereas the loss of diaphorase-positive neurons was not affected. In each case, data are presented as a percent loss of neurons on the lesioned/implanted side compared with intact contralateral side. Representative photomicrographs for cholinergic and GABAergic cells are shown for both control and CNTF-implanted animals. Note the appearance of numerous healthy appearing cholinergic and GABAergic neurons in the CNTF-treated animals. Scale bar in ChAT control is 500 um for ChAT control/CNTF, and scale bar in insert is 100 um for GAD control/CNTF and 17 um for insert [see (97) for additional details].

the efficacy of this experimental therapeutic strategy (101). The complete lack of neuroprotection provided by intraventricular implants in monkeys should be considered more carefully in the ongoing clinical trials (38). If human trials are to yield clinically relevant positive effects, the means of CNTF delivery used in these studies needs to be improved. Whether this entails changing the site of implantation from the ventricle to the parenchyma, grafting more capsules, enhancing the CNTF delivery from the cells by changing the vector system or cell type employed, or changing the characteristics of the polymer membrane remains to be determined.

XV. CONCLUSIONS AND FUTURE DIRECTIONS

Since the late 1980s to early 1990s, a substantial body of data has been collected, clearly showing the promise of encapsulated cell therapy for treating a wide range of CNS disorders. Still, a number of research avenues exist that are incompletely explored and deserve attention prior to wide-scale clinical use of this technology. In some preclinical studies, the extent of diffusion from the implants appears to limit the therapeutic effectiveness of the encapsulated cells (62,68,69). Given the size of the human brain relative to the rodent and nonhuman primate brain, the potential problems related to limited tissue diffusion should be examined empirically. Studies in larger animals, such as nonhuman primates, should be conducted to include considerations of different numbers of devices and multiple reimplants distributed over long periods of time (>12 months). In this way, a reasonable assessment of the optimal spacing and distribution of multiple implants can be determined. This information could, at the same time, provide critical information regarding the relative risks of repeated tissue penetrations, tissue damage, and the potential for infection.

Encapsulation provides the opportunity to use cells from a variety of sources, including human and animal sources with and without genetic modification. In theory, the capsule should isolate the cells from the surrounding tissue. Still, if a capsule ruptures during implantation or retrieval, a deleterious

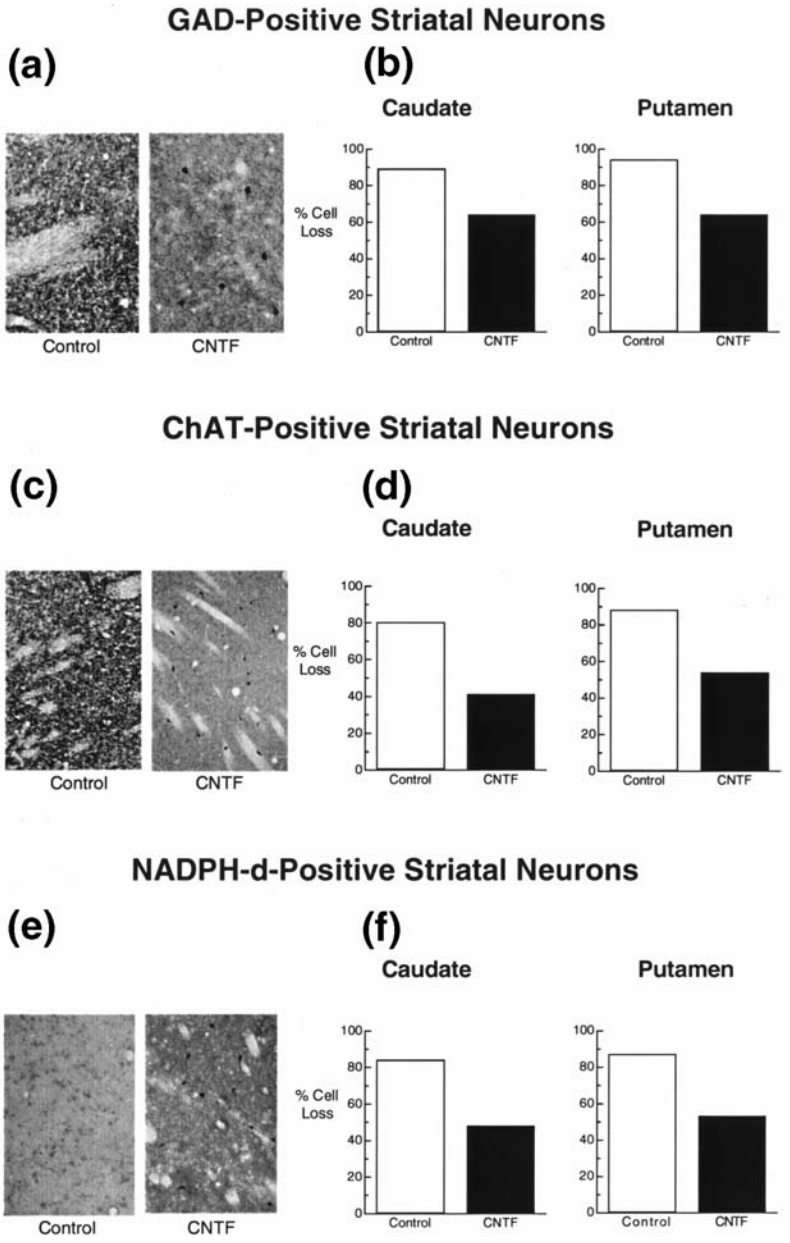

Figure 13 Neuronal cell counts in quinolinic acid-lesioned monkeys. Control-implanted animals displayed a significant loss of multiple types of striatal neurons including GABAergic (a and b), cholinergic (c and d), and diaphorase-positive neurons (e and f). Although neuronal loss was still present in animals receiving CNTF implants, it was significantly attenuated in both the caudate and putamen. In each case, data are presented as a percent of neurons on the lesioned/implanted side compared with the intact contralateral side. Representative photomicrographs for all 3 cell types are shown for both control and CNTF-implanted animals (a, GABAergic; c, cholinergic; and e, diaphorase-positive neurons) [see (99) for additional details].

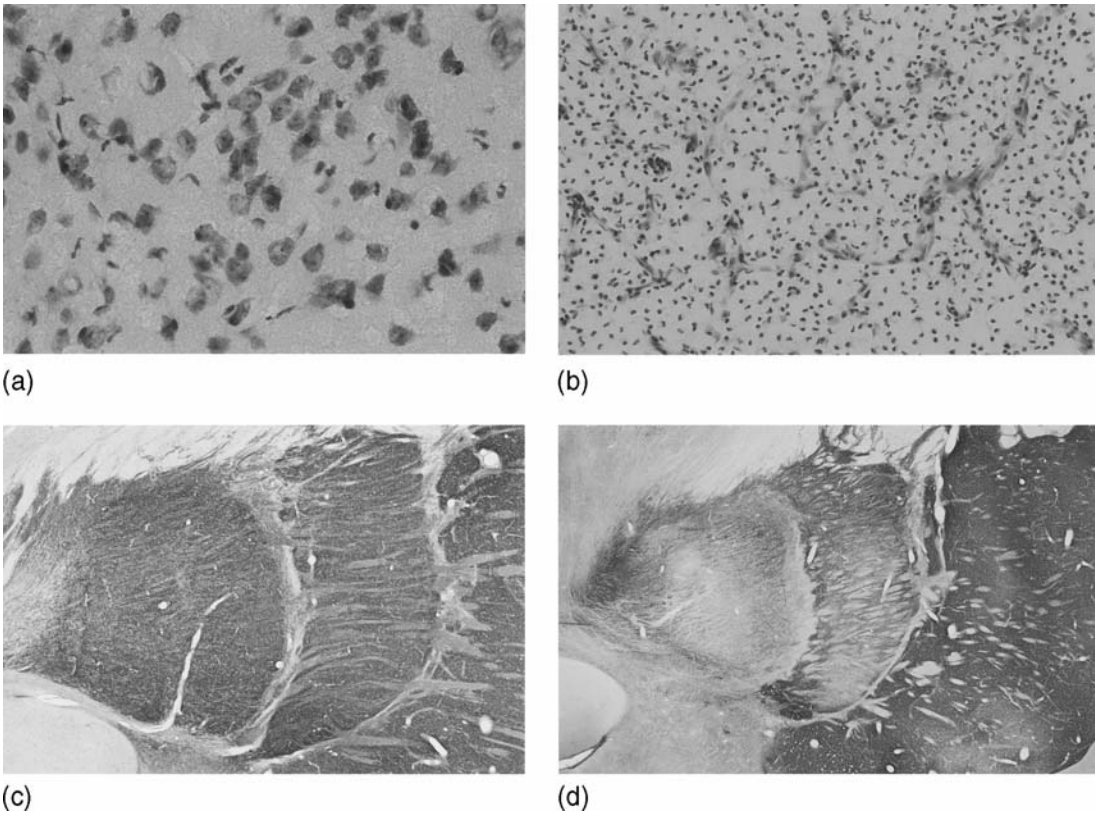

Figure 14 Photomicrographs of Nissl-stained sections through the striatum of monkeys that received quinolinic acid injections into the striatum followed by implants of encapsulated CNTF-producing (a) or control (b) BHK cells. A paucity of healthy neurons is observed in the striatum of control monkeys, which is in stark contrast to the numerous healthy appearing neurons seen in the same region of the CNTF-treated monkeys. Together with the sparing of strital neurons is a preservation of the GABE-ergic projection from the striatum to the globus pallidus. DARPP-32 immunocytochemistry revealed an intense, normal-appearing immunoreactivity within both the external and internal segments of the globus pallidus of CNTF-treated animals (c). In contrast, DARPP-32 immunoreactivity is reduced in control-implanted animals as a consequence of the lesion (d). Quantitative analysis confirmed the sparing of this projection in CNTF-treated monkeys.

host immunological response could be induced. Although the host immune system should reject any released cells following capsule damage, the potential for tumorous growth remains a safety concern. Alterations in the ability of the host immune system to reject cells following damage to implants could also change upon long-term residence of the cells within the host. To date, no studies have systematically evaluated these risks, particularly with regard to the long-term effects of encapsulated cell implants. Again, primate studies using intact and intentionally damaged devices would provide a useful starting point for evaluating these issues. These studies could use normal and immunosuppressed animals, as well as evaluate potential tumorigenicity and changes in the host immune system over short and long periods of time.

Regulation of dosage is another area that deserves attention. In its most basic iteration, varying the numbers of cells within an implant, the size of the implant, or the use of multiple implants, may permit a range of doses to be delivered. Although some long-term cell survival studies have been conducted (61–65), they have not systematically examined cell survival and output of the desired molecule over long periods of time. Rather, studies have provided a ''snapshot'' of survival and output at a single timepoint. Large, long-term, well-controlled studies need to be conducted to examine the relationship between variables that include time, cell survival, gene expression (when modified cells are used), neurochemical output, the initial numbers of cell encapsulated, and the type of semipermeable membrane and extracellular matrix used for encapsulation. Obviously, such studies are time consuming and expensive. However, without them, the conditions optimal for successful cell encapsulation will remain speculative. It should be pointed out that some efforts are ongoing in this area, and a recent study raised the interesting possibility that dose control for dividing cells could be accomplished

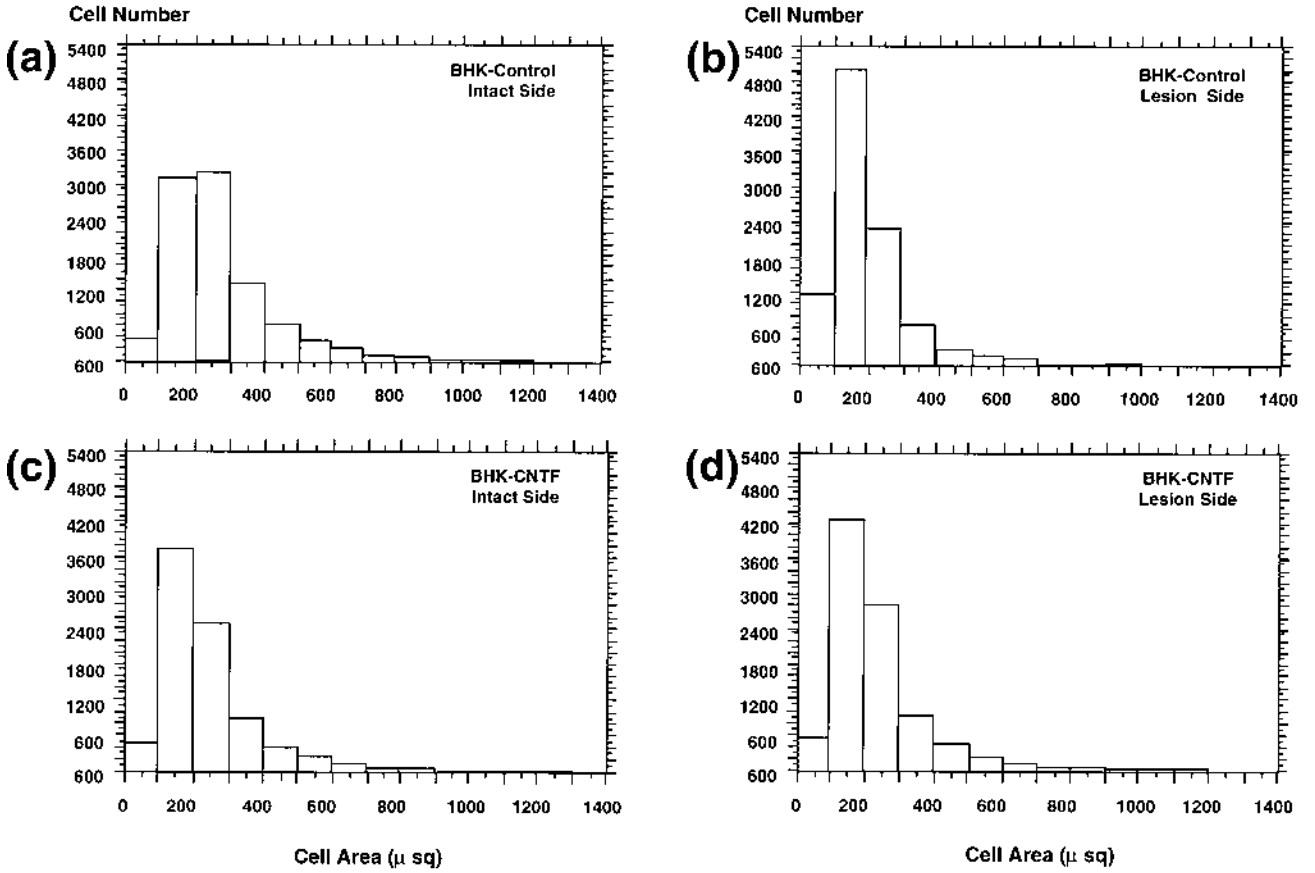

Figure 15 The cells size distribution of layer V neurons in the motor cortex of monkeys that received striatal injections of quinolinic acid followed by implants of encapsulated BHK control (a,b) or CNTF-secreting BHK cells (c,d). This figure demonstrates that CNTF-producing grafts prevented the atrophy of cortical neurons that innervate the striatum. Note that in the control animals there is an increase in the number of neurons in the 0 to 100 μm and 100 to 200 μm range and a decrease in the number of neurons in the 300 to 400 and 400 to 500 μm range ipsilateral to the lesion. This shift in cells size was not seen in those animals receiving CNTF-secreting cells.

with the use of cell-containing microcarriers in nonmitotic hydrogels (126).

Another area that has attracted little attention, concerns the variability in the in vivo performance of encapsulated cells and the possible role that the host tissue environment plays in this variability (51,66,67). As discussed earlier, it appears that at least some of the variability in device performance is attributable to differences between hosts. Although the mechanism(s) underlying these individual differences remain undetermined, several potential candidates exist, including the variations in the general health of the animals, between animal differences in immune function and undetected microbreaches in the polymer membrane prior to or during implantation. The notion that the viability of grafted cells may depend in part on host-related variability in the CNS environment has only been suggested for encapsulated cells to date. However, this emerging concept might also prove to be relevant for all CNS transplantation approaches that are cellular based. Indeed, the entire field of neural transplantation might benefit from this new perspective uncovered using encapsulated cells.

Finally, very few clinical studies have been conducted to date. Although several small safety studies have been completed, only one large, controlled clinical study has been performed using encapsulation technology. This study evaluated the use of encapsulated adrenal chromaffin cells for the treatment of pain but failed to reveal analgesia sufficient enough to continue the trials. As we have already discussed in a previous section, the selection of pain as an initial indication for detailed study might have been an unfortunate choice given that recent preclinical data using encapsulated chromaffin cells is mixed at best. The only other clinical targets under investigstion are ALS and HD, and these are apparently modest efforts. Until, larger, controlled clinical trials are conducted, the potential of this technology will not be fully realized.

In conclusion, it appears that the implantation of encapsulated cells may provide an effective means of alleviating the

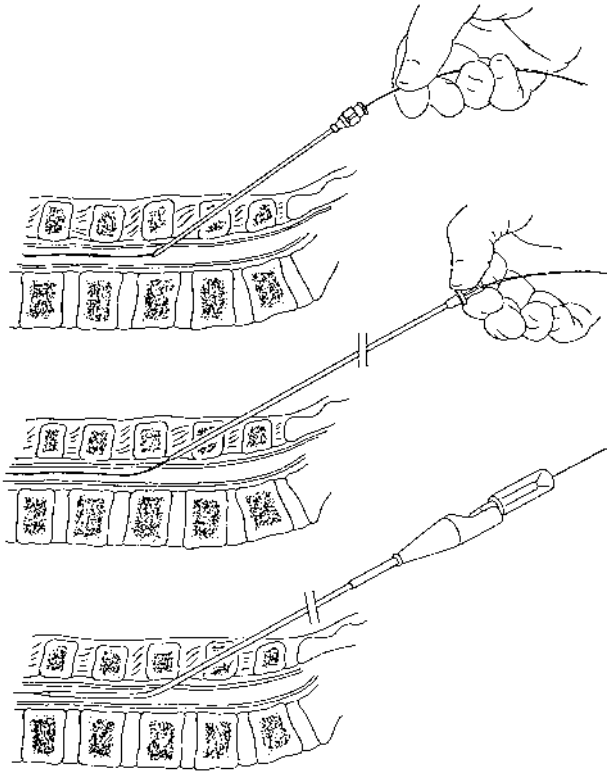

Figure 16 Under local anesthesia, a device containing CNTF-secreting cells is implanted into the lumbar subarachnoid space via a small incision over the lumbar spine. A 19-gauge Touhy needle is inserted into the subarachnoid space. A flexible tip wire is inserted, the needle withdrawn, and a dilator passed through. A smaller cannula is then inserted over the wire and the cell-containing device is guided through the subarachnoid cannula. The silicone tether is secured to the lumbar fascia and the skin is sutured closed over the entire device.

symptoms of numerous human conditions/diseases. One particularly attractive avenue of research continues to be the application of trophic factors to minimize or halt the progression of neural degeneration or promote regeneration of damaged central nerves. However, caution must be applied when considering any novel therapy for treating brain disorders, and the wide-scale use of polymer neural implants should be considered only after rigorous scientific experimentation in animal models and their demonstrated efficacy and safety in human clinical trials.

Houston, Texas, U.S.A.

I. INTRODUCTION TO HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells (HSCs) have been a focus of interest in the field of gene therapy since its inception, due to their 2 defining characteristics: their ability to differentiate into all the component cells of the hematopoietic system, and their ability to renew themselves in vivo. Genetic modification of the HSCs should result in modified cells of all lineages, including erythrocytes, platelets, myeloid cells, and lymphocytes. Due to the self-renewal properties of stem cells, genetic modification would be, at least in theory, very permanent. Despite great expectations for HSC gene therapy, clinical application has been slow primarily due to the inefficiency of gene transfer into HSCs (see Chapter 24). In addition, an inability to purify and expand these cells in vitro has hampered the development of improved transduction protocols. Finally, some of the diseases initially considered for HSC gene therapy, such as sickle-cell anemia, proved to be ambitious targets due to the complex regulation of gene expression required (see Chapter 25). Nevertheless, improvements in our understanding of the biology of HSC are being made, which will ultimately make HSC gene therapy more widely applicable, potentially even to diseases outside the hematopoietic system. In this chapter, we review the basic biology of murine and hematopoietic stem cells, explore a variety of genetic transduction strategies, and briefly review recent clinical attempts and HSC gene therapy.

II. PHENOTYPE OF HSC

A. Cell Surface Phenotype of Murine and Human HSC

The existence of the HSC was first suggested by experiments showing rescue of mice from irradiation by infusion with non-irradiated whole bone marrow (WBM) (1). Because WBM is a heterogeneous mixture of cells, identification of the cells responsible for the radiation rescue has been a focus of interest for some time. Physical properties, such as sedimentation rates, of bone marrow (BM) cell subsets were initially exploited, followed by antigenic or dye staining properties that could be identified by fluorescence-activated cell sorting (FACS).

Class I major histocompatibility antigens (MHC I) were one of the first molecules exploited for fractionating WBM (2). Depletion of activity assays, which used antibodies capable of fixing complement and directing the lysis of target cells, were employed to show that murine HSC did not express MHC I (2). In contrast, human primitive progenitors do express MHC I (3), establishing the first of many phenotypic differences between murine and human HSCs. Ultimately, it was established that that murine progenitors and HSC do not express MHC I, while human progenitors express high levels of MHC I, and human HSCs express low levels (4–7).

Cell ''panning'' has also been employed to fractionate WBM, where an antibody is fixed to the surface of a tissue culture plate and BM cells, which adhere to the antibodies, are collected and assayed for the enrichment or depletion of primitive hematopoietic potential. Cell panning helped identify c-kit (8) expression by HSCs as well as their ability to bind wheat germ agglutinin (9).

The development of flow cytometry allowed multiple antigens or fluorescent dye efflux characteristics to be used together for improved purification. A major advance was to use a cocktail of antibodies against antigens specific for the differentiated lineages to deplete the BM of the 90% differentiated cells (10). Such ''lin''—negative cells in human or mouse BM is depleted of CD4, CD8, and CD3 T cells, B cells, granulocytes, macrophages, and erythrocyte progenitors. Antibodies against human CD33 are used, as it is ex-

pressed by progenitors but not HSCs (11). Similarly, CD38 is present on human progenitors but absent from HSCs (12), so can be used for negative selection of differentiated cells.

Another major breakthrough in HSC purification entailed the use of the CD34 antigen for positive selection of human HSCs (6,13). Primate studies ushered in the use of CD34 as a tool for isolating HSCs for bone marrow transplantation (14), and CD34 became the most clinically exploited molecule expressed by HSC.

The Thy-1 antigen has also been an important tool for enrichment of murine and human HSC (15), as has been Sca-1 (for stem cell antigen) (10). Although Sca-1 is routinely used to purify murine HSCs, neither a human homolog nor function have been identified for this molecule. c-kit expression has also been used to purify both human and murine HSCs (16–20). $Lin^{Neg}c\text{-}kit^{Pos}$ murine WBM cells can repopulate mice ablated by irradiation (21).

In summary, murine and human HSCs can be selected on the basis of the expression of a number of antigens in combination: Sca-1, Thy-1 (low), $lineage^{neg}$ $c\text{-}Kit^{pos}$ in the mouse, and CD34, Thy-1 (low), $lineage^{negative}$, and $c\text{-}kit^{pos}$ in the human.

B. Markers That Change as HSCs Mature

Although CD34 clearly marks human HSCs, the most primitive murine HSCs are $CD34^{Neg}$ (22,23) and are precursors of $CD34^{Pos}$ short-term HSCs (24). When the gene for human CD34 was introduced into mice, HSCs that were negative for murine CD34 expressed the human CD34 antigen (25), suggesting that $CD34^{Pos}$ human HSCs are analogous to $CD34^{Neg}$ murine HSCs and that CD34 expression is differentially regulated in mice and humans (Fig. 1).

HSCs also vary cell surface receptor expression as they progress in the cell cycle. 5-Fluorouracil (5-FU) treatment ablates progenitors and proliferating cells in the bone marrow (26), and induces quiescent stem cells to proliferate and replenish the bone marrow. 5-FU treatment/cell-cycle induction concomitantly induces changes in several surface receptors: c-kit is down-regulated and CD34 is up-regulated on murine HSCs (24,27). Furthermore, in treated mice, both $CD34^{Pos}$ and $CD34^{Neg}$ cells are capable of long-term WBM repopulation—in untreated mice, only $CD34^{Neg}$ cells have this activity. Therefore, murine $CD34^{Pos}$ HSCs may be newly cycling HSCs.

Some cell surface markers are developmentally regulated on HSCs. AA4.1 was identified on fetal liver HSCs and HSCs isolated from embryonic yolk sac (28), but not adult HSCs. Also, Sca-1, expressed by adult HSCs, is not expressed by yolk sac HSCs (29), but is up-regulated on fetal liver HSCs (30,31). AA4.1 is expressed on 5-FU-treated HSCs, potentially correlating with their actively cycling status, as in the fetal liver (32).

C. Vital Dye Enrichments

Vital dyes have also been used alone or in combination with cell surface markers. Most WBM cells stain brightly with the DNA-binding dye Hoechst 33342, but progenitors stain dimly (33–35). Hoechst-based enrichment for stem cells was refined with the observation that with the use of 2 emission wavelengths, multiple populations could be defined. A small population can be observed on the side of the profile [the so-called side population (SP)] (Fig. 2) (36), which contains all the hematopoietic reconstituting potential of mouse bone marrow. An SP has been observed in multiple species (23) and appears to be due to a multidrug resistance (MDR)-like mediated efflux of the Hoechst dye (36). The efflux of Hoechst dye by HSCs is believed to be due to the transporter ABCG2 (37), but additional drug pumps are likely also involved. Although the natural substrate of the dye efflux is currently unknown, we hypothesize that it may be a molecule that otherwise would cause the cells to differentiate. FACS purification using the SP profile alone affords an enrichment of 1000- to 3000-fold. When used in combination with additional cell surface markers, another 15% or so of nonstem cells can be eliminated (23,36,38).

Rhodamine 123 (Rh123) is another vital dye used for HSC enrichment. Murine and human $rhodamine^{Low}$ WBM cells are enriched for HSCs (39,40). When $Hoechst^{Low}$ WBM cells were fractionated into $rhodamine^{Medium}$ and $rhodamine^{Low}$ populations (35), $Rhodamine^{Low}$ cells were shown to be more primitive (35). Rh123 binds mitochondria, and therefore Rh123 fluorescence is believed to directly reflect cellular metabolic activity (41). However, because Rh123 is also a substrate for MDR transporters, low Rh123 may simply reflect dye efflux, as is the case with Hoechst 33342.

D. Phenotype of HSC from Different Sources

HSC can be derived from other sources besides WBM, such as peripheral blood (PB), fetal cord blood (CB), fetal liver, skeletal muscle, and embryonic stem cells, with some phenotypic variations. In 1951, Brechen et. al. found mice were rescued from irradiation by parabiosis with nonirradiated partners (42), suggesting that HSCs can circulate in PB. Infusion with >5 million nonirradiated PB cells also rescued irradiated mice, showing HSCs were present in the circulation at very low frequencies (43). Human PB also contains cells with primitive hematopoietic potential (44,45), although these cells are infrequent and less potent than WBM-derived HSCs (46,47). Mobilization with GM-CSF can greatly increase the frequency of HSCs in human PB (48) and is a common strategy for enriching and purifying HSCs from PB (49).

PB-derived HSCs are phenotypically distinct from WBM HSC. Although both human WBM and PB HSCs express CD34 and are $Rhodamine^{Low}$ (50,51), mobilized PB HSCs express lower levels of c-kit than WBM HSCs (52).

HSCs are also present in newborn CB. Hematopoietic progenitors in CB have been shown to express CD34 both in vitro and in vivo (53–56). HSCs in CB are resilient to cryopreservation and extensive handling and are therefore a clinically useful source of HSCs (57,58). CB HSCs are phenotypi-

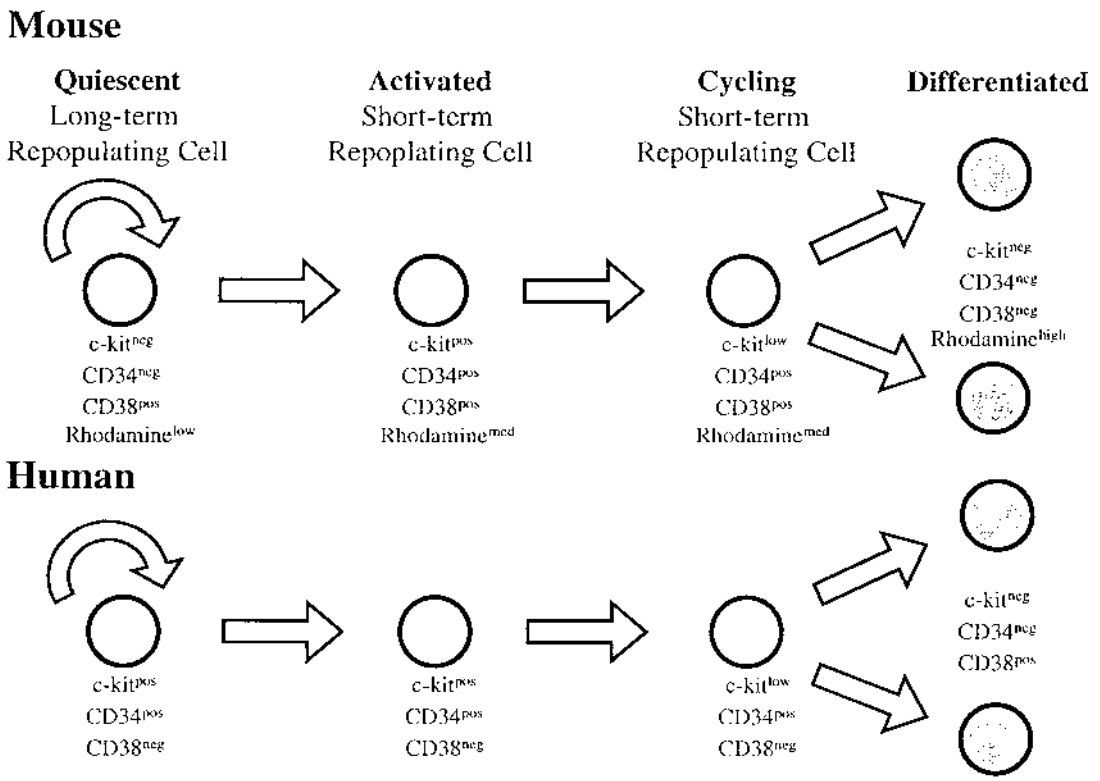

Figure 1 Progression of cell surface marker expression on maturing murine and human HSC. Summary of cell surface markers that distinguish quiescent, activated, newly cycling, and differentiating HSCs in humans and mice.

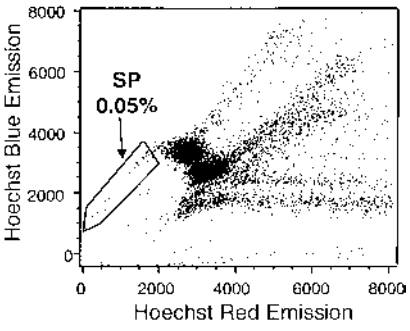

Figure 2 Representative Hoechst 33342 staining profile of murine bone marrow. When mouse bone marrow is stained with the DNA-binding dye Hoechst 33342, multiple populations are observed. All the hematopoietic reconstituting cells are found in the small population on the side, the ''side population'' or SP (boxed). See references for staining protocol.

cally similar to WBM HSCs, although there is controversy in the literature regarding their expression of CD38 (59,60).

During development, HSCs initially appear in the aortes-gonad-mesonephres (AGM). They subsequently migrate to the fetal liver and ultimately to the fetal bone marrow. As previously mentioned, AA4.1 is specifically expressed by fetal liver-derived HSCs in mice (28,31,61). HSCs isolated from the AGM and fetal liver of mice are Sca-1^{Pos}c-kit^{Pos} CD34^{Pos}Lin^{Neg}WGA^{Pos}CD43^{Pos} and Rhodamine^{Bright} (30,62). Thus, in contrast to murine WBM HSCs, embryonic HSCs take up high levels of rhodamine and express CD34, perhaps suggesting they are more activated than adult HSCs. Human fetal liver HSCs have been characterized as CD34^{Pos}CD38^{Neg} CD33^{Pos}Lin^{Neg} (63). Thus, they also differ from human WBM HSCs in their expression of CD33.

Embryonic stem (ES) cells can differentiate into hematopoietic cells. When ES cells are cultured into embryoid bodies, blood islands containing erythrocytes and macrophages spontaneously emerge (64,65). Lymphoid, myeloid, and erythroid colonies can also be found to develop (66). ES cells can be directly induced to differentiate into myeloid and B cells by eliminating M-CSF from culture medium (67). Human ES cells up-regulate CD45 expression, a hematopoietic marker,

when cultured on methylcellulose containing hematopoietic cytokines (68). ES cells isolated from rhesus monkeys develop into clusters of hematopoietic cells and up-regulate both CD34 and several hematopoietically relevant genes when cultured on S17 feeder cells along with stem cell factor, interleukin-3 (IL-3), IL-6, vascular endothelial growth factor, and G-CSF (69). In summary, ES cells can be induced to behave like HSCs in vitro under specific culture conditions, although these cultures are still not well defined.

ES cells can also function as HSC in vivo. Three-day-old blastocysts were found to rescue mice from lethal irradiation (70), and desegregated embryoid bodies were reported to moderately restore the lymphoid system of severe combined immune deficiency (SCID) mice (71). Transduction of ES cells with hematopoietic transcription factors, such as BCR/Abl and HoxB4, induced their differentiation into HSC and allowed for engraftment of the myeloid and lymphoid lineages after transplantation into irradiated mice (72,73). However, the engraftment was skewed toward the myeloid lineages. Thus, the ability to direct the differentiation of ES cells into HSCs is still limited and inefficient.

Finally, cells with HSC activity, initially believed to be trans-differentiating muscle stem cells, can also be isolated from the skeletal muscle of mice (74,75). Muscle-derived HSCs express both CD45 and Sca-1 and are therefore hematopoietic in origin (76,77). Muscle-derived HSCs have since been shown to fall into the SP compartment of skeletal muscle and be c-kit^{Dim}, relative to WBM HSCs (McKinney-Freeman, Experimental Hematology in press). Muscle-derived HSCs isolated from neonatal mice are reportedly CD45^{Neg} (78). If a nonhematopoietic HSC does exist in neonatal murine muscle, it is clear that this cell population does not persist in the adult animal (76,77) (McKinney-Freeman, Experimental Hematology in press).

III. IN VIVO AND IN VITRO ASSAYS FOR ASSESSING HSC FUNCTION

The discovery that nonirradiated WBM rescued mice from irradiation (1) established the existence of the HSCs, but was unable to measure HSC reconstituting activity because WBM is a heterogeneous mixture of HSCs and progenitors. Below is a discussion of the development of in vitro and in vivo assays for assessing and quantitating HSC function and differentiation.

A. CFU-S and CFU-C Assays

In 1961, Till and McCulloch observed macroscopic colonies of hematopoietic cells in the spleens of mice 8 days after injected with WBM (79). They dubbed the colonies ''colony forming units'' (CFU), observed that the frequency of colony formation was proportional to the number of injected cells, and concluded that spleen colony formation quantitatively reflected HSC activity. The demonstration that CFU-spleen (CFU-S) were capable of self-renewal, solidified this conclusion (80). Thus, Till and McCulloch developed the first quantitative assay of primitive hematopoietic potential.

The CFU-S assay was accepted as a method for assessing HSC potential. However, CFU-S activity was found to be sensitive to 5-FU treatment (81), with CFU-S_8 more sensitive than those appearing on days 12 to 14 (CFU-S_{12-14}) (82). HSCs are quiescent, and therefore resistant to the effects of 5-FU. It was concluded that the CFU-S assay actually measured WBM progenitor activity, with CFU-S_{12-14} reflecting the activity of more primitive progenitors than CFU-S_8, and that true HSCs may be ''pre-CFU-S'' cells (81).

In vitro assays were later developed to test the role of specific factors in hematopoiesis and evaluate the hematopoietic potential of human cells. Tightly packed, clonal colonies of differentiating cells form when WBM is overlaid on embryonic feeder cells in agar (83,84) or grown with appropriate growth factors (Fig. 3). The feeder cells supplement the agar with hematopoiesis-promoting factors, and the result is colonies of granulocytes and macrophages, called CFU-G and CFU-M, respectively (83). Primitive colonies of mixed cells derived from multipotent progenitors also form and are called CFU-GM and CFU-GEMM, for granulocyte, erythrocyte, monocyte, and macrophage (85). Erythropoietin promotes the development of erythrocytic colonies (86,87). Methylcellulose can be used as an alternative semisolid medium (88) and infusing the medium with fetal calf or human serum eliminates the need for feeder cells (85).

The in vitro CFU-culture (CFU-C) assay was initially believed to measure the activity of the same cell that forms CFU-S because erythrocytic CFU-C can form CFU-S when injected into mice (89). However, CFU-S and CFU-C activity can be separated by size and density (88) and may actually reflect the activity of distinct progenitors. Regardless, both the in vivo CFU-S and in vitro CFU-C assay measure hematopoietic progenitor activity.

The LTC-IC (long-term culture initiating cell) assay was developed to measure primitive (pre-CFU-C) human hematopoietic progenitor activity in vitro. In this assay, cells are cultured on a feeder layer of irradiated human bone marrow-derived stroma cells and then assayed for CFU-C activity 5 to 8 weeks postplating in order to extrapolate the number of LTC-IC present at initial plating (6). Figure 4 summarizes the primitive hematopoietic populations assayed by the different in vitro assays discussed above.

B. In Vivo Models

The ability of HSC to maintain lifelong hematopoiesis can only be assayed in vivo. Several animal models have been developed for assaying both murine and human HSC activity in vivo.

W/W mice have a spontaneous mutation in their c-kit receptor and die shortly after birth due to anemia and cytopenia unless rescued by transplantation with normal WBM (90). Thus, the systemic deleterious effects of lethal irradiation are avoided by using these mice as an in vivo model. W/W mice have been used to show that fetal liver contains HSCs capable of repopulating adult WBM (91).

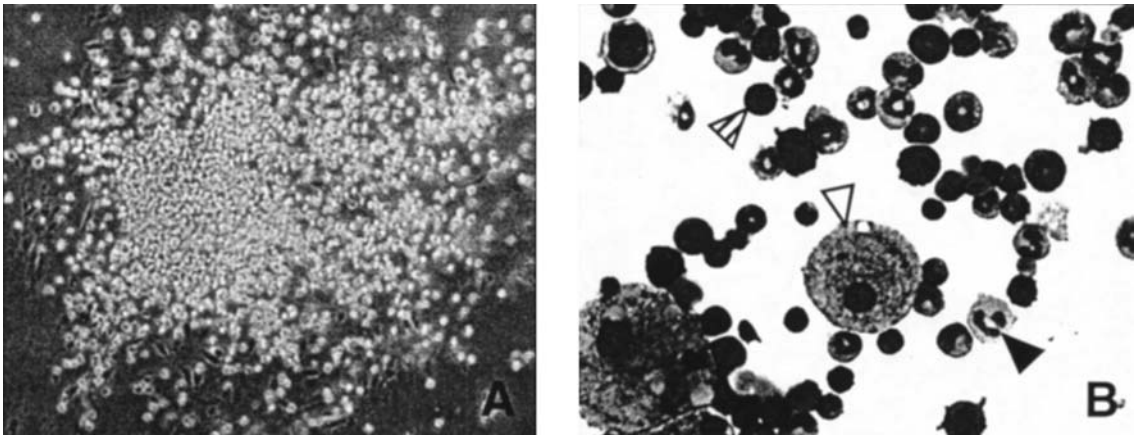

Figure 3 Representative in vitro colonies. (A) Typical appearance of a WBM-derived myeloid colony cultured for 7 days in methylcellulose supplemented with fetal calf serum and cytokines. (B) CFU types can be characterized by Wright-Geimsa stain, which allow the visualization of cytoplasmic and nuclear morphology. In this representative experiment, a mixed CFU comprising macrophages (white arrow), differentiated granulocytes (black arrow), and progenitors (striped arrows) is visualized.

To quantitatively evaluate in vivo HSC activity, donor and recipient PB reconstitution must be distinguishable because lethal irradiation does not ablate 100% of endogenous WBM. The CD45 system of congenic mice can simultaneously distinguish between donor and recipient and verify the PB identity of analyzed cells (92). CD45 is a cell surface tyrosine phosphatase exclusively expressed by nucleated hematopoietic cells (93). Monoclonal antibodies can discriminate between multiple alleles of CD45. Typically, CD45.1 WBM cells are transplanted into irradiated CD45.2 mice, and flow cytometry is used to examine recipient PB for CD45.1 positive cells. Repopulation of the different compartments of the PB can be analyzed by costaining with PB lineage markers. This model can be made semiquantitative by injecting known numbers of both a ''test'' population of CD45.1-derived cells with ''competitor'' CD45.2-derived WBM into CD45.2 recipients. The HSC activity of the test population and the competitor WBM is then compared (94).

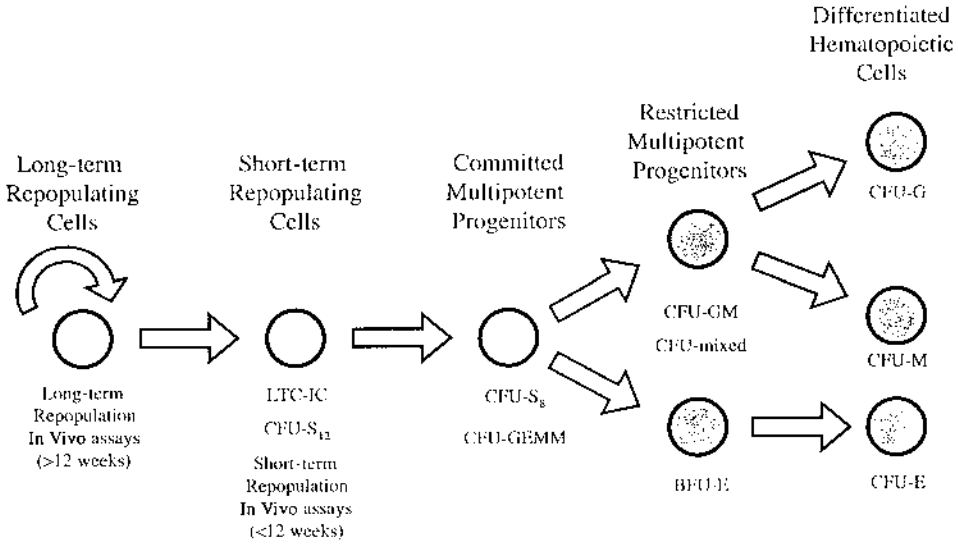

Figure 4 Summary of in vivo and in vitro primitive hematopoietic activity assays. Depicts which primitive hematopoietic stem cell and progenitor populations are assayed by various in vitro and in vivo assays.

Murine models have also been developed to examine the primitive hematopoietic potential of human WBM. In the SCID-hu model, pieces of either human fetal thymus or human fetal lymph nodes are implanted under the kidney capsule of SCID mice (95). SCID mice do not produce graft-rejecting lymphocytes and are therefore amenable to transplantation with non–self-tissues or cells. This model allowed the in vivo differentiation of human B and T cells to occur transiently (95).

Bg/nu/xid mice also do not produce graft-rejecting lymphocytes or natural killer (NK) cells (96). Transplantation of human WBM cells into sublethally irradiated bg/nu/xid mice yielded human lymphoid engraftment for 5 weeks. SCID mice injected with human growth factors and nonobese diabetes (NOD)/SCID mice (SCID mice crossed with nonobese diabetic mice that lack NK cells) can maintain higher and sustained levels of engraftment with human lymphoid cells (97,98). Also, mice transplanted with SCID WBM can support grafts of human lymphoid cells (99). Most human in vitro assays only detect myeloid differentiation because the architecture of the bone marrow and thymus, which are difficult to recreate in vitro, are required for B and T cell development. Thus, murine models of human hematopoietic differentiation are key to studying human lymphoid development in the laboratory.

Fetal sheep have also been used to assess human HSC activity in vivo. The immature immune system of the fetal sheep is tolerant to human cells transplanted in utero. Human fetal liver-derived HSC have been found to stably engraft the bone marrow and PB of primary and secondary fetal sheep recipients for >2 years posttransplant (100,101).

IV. FUNCTION OF HSC

The HSC compartment is functionally heterogeneous and varies by repopulation kinetics and persistence. In this section, we discuss the functional heterogeneity of HSC.

A. HSC Heterogeneity

Some cells capable of long-term bone marrow repopulation are unable to rescue mice from lethal irradiation (102). The ''2 waves of hematopoiesis'' theory explains this observation: bone marrow reconstitution consists of early, short-term reconstitution that rescues from irradiation and late, long-term reconstitution, which sustains the PB for an organism's lifetime (102). Long- and short-term reconstituting HSCs are phenotypically distinct: long-term HSCs are $Rhod^{Low}Mac\text{-}1^{Neg}CD4^{Neg}$, whereas short-term HSCs are $Rhod^{Med}Mac\text{-}1^{Low}CD4^{Low}$ (35,103).

Retroviruses have been used to examine the kinetics of bone marrow repopulation by HSCs. Every retrovirally infected cell is distinguishable by the unique genomic integration site of the retrovirus. The clonal nature of bone marrow-derived CFU-C in W/W mice transplanted with retrovirally transduced WBM was initially observed this way (104). Treatment of WBM with 5-FU made HSCs more prone to retroviral transduction via induction of the cell cycle (105), making it possible to observe clonal reconstitution of multiple hematopoietic tissues and verify the primitive, multipotent nature of the repopulating cell (105). Hematopoietic repopulation of PB fluctuates over time: some clones persist long term, whereas others contribute only to initial reconstitution before waning (106,107) (Fig. 5). Fluctuation lasts 4 to 6 months posttransplant and equilibrates with a few dominant HSC clones stably reconstituting the PB out to 16 months posttransplant (28). Thus, hematopoietic reconstitution is a dynamic process.

B. Self-renewal

To maintain lifelong hematopoiesis, the HSC compartment must be replenished. Self-renewal of primitive hematopoietic cells was first demonstrated when spleen colonies were shown to generate additional spleen colonies in vivo (80). Both human and murine CFU-C can be serially replated and form additional CFU-C (53,108), and bone marrow can be serially transplanted into secondary recipients without a notable loss in CFU-C potential (109). Also, a single long-term repopulating

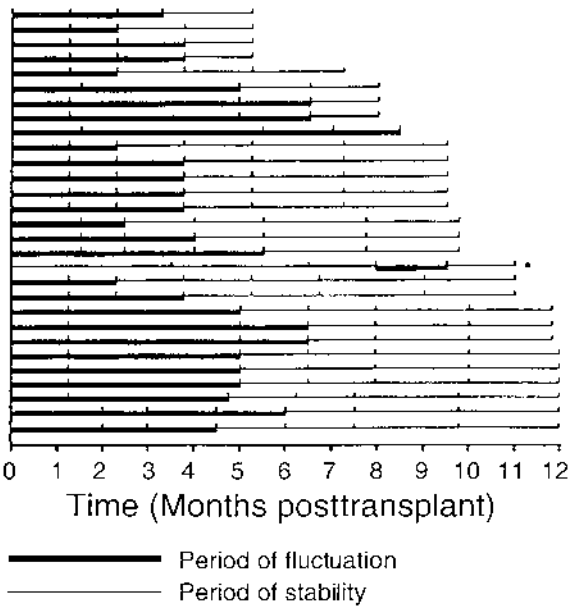

Figure 5 Clonal retroviral analysis of temporal HSC repopulation dynamics. In this experiment, retrovirally transduced HSC were transplanted into lethally irradiated mice. The contribution of clones of HSCs to peripheral blood was followed for 1 year. The thick bars represent the period posttransplant during which many HSC clones were intermittently contributing to the peripheral blood. The thin bars represent the period post transplant where a few dominant HSC clones took over the repopulation of the peripheral blood. (From Ref. 226.)

HSC can reconstitute both primary and secondary recipient mice (110).

However, the potential for self-renewal is not unlimited: serially injected CFU-S progressively lose their ability to form additional CFU-S (80). Murine bone marrow is exhausted of repopulating potential after 4 to 5 consecutive transplants (111,112), and bone marrow-derived from animals that have recovered from treatment with busulfan (an alkylating agent that ablates WBM) loses its ability to serially repopulate (113). A 7 to 8 fold loss in HSC repopulating potential after only 2 serial transplants has also been reported (114). The reduction in repopulating activity has been attributed to an exhaustion of the inherent self-renewing potential of HSCs. However, self-renewal may also be regulated by the bone marrow environment: the greatest reduction in the capacity to self-renew after serial transplantation was observed when small numbers of HSC were transplanted (115). This implies that a regulatory feedback loop may suppress self-renewal in favor of differentiation when demand is high. Also, long-term repopulating HSCs can expand 8400-fold, indicating a huge inherent potential for self-renewal. Thus, external factors must play a role in reducing HSC repopulating potential after serial transplantation (116).

C. HSCs and Aging

HSCs from old and young mice have equal repopulating potential in competitive bone marrow transplants (111). However, the HSC compartment appears, phenotypically, to increase in size in older mice, perhaps because older HSCs are more frequently in cycle than younger HSCs (117,118). Also, fetal liver-derived HSCs are reportedly 5-fold better at long-term reconstitution than bone marrow-derived HSCs (119). Thus, although in adults, old and young HSCs do not differ in activity, embryonic and adult HSCs may be functionally distinct.

HSCs from distinct strains of mice differ in their repopulating potential: C57Bl/6 HSCs outcompete DBA HSCs (120). Also, C57Bl/6-derived HSCs override DBA-derived HSCs in hematopoietic repopulation as the mice age (120). C57Bl/6 are a ''long-lived'' strain of mice relative to DBA mice, and DBA stem cells divide faster than C57Bl/6 stem cells (121). Based on these data, DBA-derived HSCs are considered to age more rapidly than C57Bl/6-derived HSCs (122). Thus, individuals with active HSCs may age more rapidly than individuals with largely quiescent HSCs. Genes regulating the cell cycle of stem cells may also regulate aging.

D. Cell-cycle Status

Most HSCs are quiescent. This is demonstrable by HSC resistance to 5-FU treatment (123–125). 5-FU or hydroxyurea (which kills all S-phase cells) treatment enriches both the engraftment potential of WBM and the frequency of bone marrow-derived CFU-S and CFU-GM (26,124–126). Ninety-nine per cent of human $CD34^{Pos}$ PB HSC are in G_0 (127) and, when mobilized human $CD34^{Pos}$ PB HSC are fractionated into G_0 and G_1 compartments, only the quiescent G_0 compartment engrafts NOD/SCID mice (128). Some studies report cell-cycle induction of HSCs diminishes their ability to repopulate WBM and form CFU-S (129–131), whereas other studies show that HSCs in both G_1-G_0 and S-G_2M have equivalent abilities to repopulate WBM (36). Follow-up reports show that, although both G_1-G_0 and S-G_2M HSCs are capable of short-term hematopoietic reconstitution, only G_1-G_0 have long-term engraftment potential (132). Thus, long-term repopulating HSCs are generally considered mitotically quiescent.

E. Homing of HSC to WBM

Injected HSCs must home to a specific niche to repopulate ablated bone marrow. Homing of HSCs is not well understood, but several factors have been implicated in this process. Selectins and integrins, adhesion molecules, and their receptors, respectively, participate in bone marrow homing of HSCs in primates and mice (133,134). Also, human HSC engraftment of NOD/SCID mice depends on the expression of CXCR4, a chemokine receptor (135). Stem cell factor is expressed in the bone marrow microenvironment, suggesting that c-kit may also regulate HSC trafficking (136).

F. HSC Genomics

Recently, global gene expression in HSCs has been examined. Gene expression in fetal liver HSCs has been examined by construction of a subtracted cDNA library (137). The HSC transcripts were analyzed for sequence homology to existing databases and an online web-accessible ''stem cell'' database published (137). Genes common to different populations of stem cells (e.g., neural stem cells, embryonic stem cells) have also been identified using subtractive hybridization (138) or Affymetrix gene chips (139,140). About 260 genes commonly expressed by HSCs, neural stem cells, and embryonic stem cells, were identified, although only about 10% of the genes reported were found by both groups. Future work must focus on identifying stem cell-specific genes crucial to stem cell identity.

V. PLASTICITY IN DIFFERENTIATION OF HSCs

Traditionally, stem cells are viewed as being restricted to differentiate into the cells of their tissue from which they were derived. However, some adult stem cells may be able to differentiate into a variety of tissue types. For example, WBM was found to contribute to the regeneration of muscle fibers in mdx mice, a murine model of muscular dystrophy (141). The HSC was later identified as the bone marrow-derived cell responsible for this myogenic activity (75). Although HSC myogenic potential is now considered extremely limited (142), these initial studies heralded a new era of research on adult stem cell ''plasticity'' in differentiation.

HSCs have since been purported to differentiate into liver, epithelium, endothelium, and cardiac muscle (143–150) (Fig. 6). However, there is some controversy regarding the prevalence as well as the existence of this phenomenon (151–154). It is likely that HSC are capable of a limited degree of trans-differentiation under specific conditions, but this must be borne out by further research.

VI. DISEASES WITH ABNORMAL HSC FUNCTION

Because HSCs give rise to all cells of the blood system, a genetic defect in HSCs will affect all the progeny cells. If the defect can be corrected in the HSC, it follows that all the progeny cells will be normal. Because HSCs can be relatively easily isolated, transduced, and reinfused, they have been believed to be an ideal candidate for gene therapy. There are a number of mouse models for human immunodeficiencies that have served as templates for gene therapy trials in humans (Table 1), and these are discussed below.

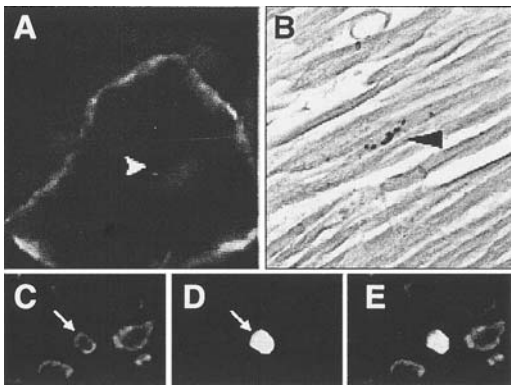

Figure 6 Examples of adult stem cell trans-differentiation. The contribution of adult stem cells to disparate tissues is typically visualized 3 ways: by transplanting male cells into female tissues and using Y-chromosome specific in situ hybridization to distinguish donor cells, by transplanting β-galactosidase positive cells and looking for the incorporation of ''blue'' cells, or by transplanting cells that express green fluorescent protein (GFP) and looking for fluorescent cells. Panel A shows the contribution of a male HSC to female dystrophic skeletal muscle (75). The red dot (white arrow) is the Y chromosome and the green staining is dystrophin, indicating that the incorporation of the HSC restored normal dystrophin expression, which is absent in these mice. Panel B shows the contribution of beta-galactosidase positive HSC to damaged cardiac muscle (145). (C–E). The white arrow in panel C is pointing out a nestin positive neuronal cell (227). Panel D reveals that this cell is derived from GFP-expressing HSC. Panel E is showing that the GFP expression and nestin staining overlap.

JAK-3 is a protein tyrosine kinase that is involved in cytokine signaling (155). It associates with the common gamma chain, which is used by the cytokines IL-2,4,7,9, and -15 (155). Lack of JAK-3 function results in low T and NK cell numbers, leading to opportunistic infections and often death (156). It is estimated that about 7% of human SCID cases are due to defective JAK-3 expression. JAK-3 null mice have a similar phenotype to humans, although they have low levels of B cells as well (157–159). One group has used retrovirus expressing JAK-3 to transduce murine HSC, which are then transplanted into JAK-3 null mice. These studies have shown that restoration of JAK-3 by this method increases the numbers of B and T cells. Most important, these mice were able to generate normal immune responses after immunization (160) and after challenge with influenza A virus (161). Because human JAK-3 deficient patients are often prone to virus infections, these studies show that the use of gene therapy of HSCs to restore JAK-3 expression may be applicable in humans.

Another immunodeficiency in which gene therapy may be useful is Wiskott-Aldrich syndrome (WAS). WAS is an X-linked disorder that is characterized by thrombocytopenia, eczema, and abnormalities in cell-mediated and antibody immune responses (162). The protein involved in this disorder is the WAS protein (WASP). Studies have shown that retroviral-mediated restoration of WASP in B cell lines, T cell lines, and primary T cells from WAS patients can partially restore normal function in these cells (163,164). Future experiments should be to transduce HSCs with the WASP protein and transplant them into WAS recipients; a murine model is available for this type of experiment.

Chronic granulomatous disease (CGD) results from a mutation in 1 of 4 proteins that make up nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. NADPH oxidase generates large amounts of superoxide in the respiratory burst. CGD patients have diminished NADPH activity; as a result, they are susceptible to bacterial and fungal infections (165). Several investigators have used mouse models for CGD to test restoration of NADPH oxidase activity by retroviral transfer of the defective protein subunit (166–169). In these studies, whole bone marrow (or bone marrow partially enriched for HSC) was transduced with a retroviral vector carrying a functional NADPH oxidase subunit gene. The cells were then transplanted into irradiated recipients that lack that gene. In all cases, NADPH oxidase activity was only partially restored, as protein levels of the expressed gene were detected at low amounts. However, this partial restoration of NADPH activity was sufficient to achieve marked improvement in defense against pathogens that would decimate mice lacking the gene entirely. One study (170) showed that retroviral transduction of a phox gene into human $CD34^+$ cells from CGD patients results in restoration of about one-half of the phox activity in these cells. Protein levels of the transduced gene were similar to those in wild-type cells.

Fanconi anemia (FA) is a disorder in which cells are hypersensitive to DNA cross-linking agents such as mitomycin C (171). The disease, which is due to mutations in the FANC-

Table 1 Animal and In Vitro Models of Gene Therapy of HSC Disorders

Deficiency	Vector	Outcome	References
JAK-3 mutations	Retrovirus	Complete correction in vivo in mouse	(160,161)
WAS	Retrovirus	Partial in vitro correction of human cells	(163,164)
CGD	Retrovirus	Partial correction in vivo in mouse, partial correction in vitro of human cells	(166–170)
Fanconi anemia	Retrovirus, AAV (in vitro)	Complete correction in vivo in mouse, complete correction in vitro with human cells	(172,173)
Sickle-cell anemia	Lentivirus	Complete correction in vivo in mouse	(174)
Beta-thalassemia	Lentivirus	Complete correction in vivo in mouse	(175)

C gene, often results in bone marrow failure and predisposition to malignancies (171). A retrovirus carrying a functional FANC-C gene was used to transduce bone marrow from FANC-C −/− mice (172). The cells were then transplanted into FANC-C −/− mice and subjected to treatment with mitomycin C. Mice receiving the corrected gene exhibited normal blood counts, whereas mice not receiving the gene exhibited decreased blood counts, leading to death. Therefore, phenotypic correction was established by retroviral transfer of the FANC-C gene. In addition, proof-of-principle studies using human $CD34^+$ cells from FA patients have demonstrated that adeno-associated virus (AAV) (173) or retroviral (173) delivery of the human FANCC gene can restore resistance to mitomycin C in vitro. Similarly, sickle-cell anemia and β-thalassemia have been corrected in mouse models by lentiviral transduction of HSCs (174,175).

In summary, gene therapy of HSCs in mouse models of human diseases has provided proof-of-principle evidence that gene therapy can be used to correct some genetic disorders, although the transition from mouse to human studies can be quite difficult. The use of mouse models for human disease does provide a template to design and test gene therapy protocols for future human trials.

A. Potential Settings to Take Advantage of Plasticity for Cell Therapies

Recent studies purporting that HSCs can differentiate to nonhematopoietic cell types have suggested that HSCs may be used as a cell-based therapy to treat disorders pertaining to nonhematopoietic cells (Table 2). The most definitive demonstration of plasticity to date is from transplantation of highly enriched HSCs into mice lacking the enzyme FAH (143). These mice are a model for hereditary tyrosinemia type I, a liver disorder in humans. Transplantation of wild-type HSCs into FAH −/− mice could reverse the lethal phenotype in some mice. The HSC compartment in bone marrow was the only fraction that had this effect. If extrapolated to humans and shown to occur at a reasonable efficiency, it is conceivable that HSCs or bone marrow transplantation could be used to treat nonhematopoietic diseases. However, as discussed above, extensive research must first be performed to confirm the phenomenon and improve the efficiency.

VII. GENE TRANSDUCTION OF HSC

HSCs give rise to all cell types of the blood and can be isolated, transduced, and reinfused back into the donor. Therefore, the correction of a genetic defect in HSC will be passed along to all its progeny, making the HSC a prime target for gene therapy. Many different viral vectors are available for use in HSCs. The selection of a proper viral vector is made based on the type of study or therapy being performed. Each viral vector has different properties, advantages, and disadvantages for use in gene therapy; these are reviewed below and in Table 3.

A. Retrovirus and Lentivirus

Stable expression of HSC can be achieved by retroviral and lentiviral transfer, which are reviewed in more detail elsewhere in this book. A main advantage of a retroviral vector is that it integrates into the chromosome of the transduced cell, resulting in stable expression. This is important for long-term expression because a nonstable vector will be lost when the HSC begins to proliferate upon activation. A main disadvantage is that the HSC must be cycling in order to be transduced with a retrovirus, and most HSCs are quiescent. Enforced cycling of HSCs leads to increased differentiation, so many HSCs are lost during retroviral transduction. These problems can be overcome by using a lentiviral vector, which can transduce nondividing cells.

Other advantages of retroviruses and lentiviruses include the ability to change the envelope of the viruses, allowing for infection of a wide variety of cell types. A disadvantage of these viruses is that stable expression may not be desired. For example, some proteins involved in differentiation need to be expressed and subsequently down-regulated to cause differentiation.

B. AAV

AAV can integrate into the genome or persist as an episome, establishing stable expression of a gene of interest, and it can

Table 2 Use of HSC for Treatment of Disorders in Nonhematopoietic Tissues

Disease	Treatment	Outcome	References
Cardiac infarct	Partially enriched HSC injected into heart or treatment with mobilizing cytokines	Partial correction of infarct	(146)
Hereditary tyrosinemia type I	Transplantation of HSC	Correction of lethal phenotype in some recipients	(143)
Acute or chronic muscle injury	Transplantation or direct injection of HSC or whole bone marrow	Few donor-derived muscle cells	(75,141,224)

infect dividing or nondividing cells. An additional benefit of AAV is that it is not toxic to cells. Disadvantages of AAV include difficulty in making high-titer, large-scale stocks free from contamination with wild-type virus (176).

AAV has been used by many groups to infect both mouse and human HSC. In mouse, AAV is believed to stably transduce HSCs (177–180). However, detailed studies looking at the efficiency of transduction of mouse HSCs have not been performed. AAV has been used far more often for transduction of human HSCs. Reports of transduction efficiency of human HSCs by AAV has ranged from 4% to 80% (181–184). The discrepancies in these studies can be partially attributed to differences in source of HSCs (bone marrow, umbilical CB, peripheral blood of mobilized patients), MOI, virus preparation, time of incubation, and the use of cytokines. The use of an AAV vector to correct a defect in human HSCs has been reported (173). This study showed in vitro correction of a phenotype of FA in $CD34^+$ cells isolated from an FA patient. It is possible that use of AAV in vivo in humans will increase as improvements in AAV production matures (176).

C. Adenovirus

Adenovirus (Ad) can transduce a wide variety of either dividing or nondividing cells. Ad can carry about 7.5 kb of transgene insert, although ''gutless'' vectors lacking Ad genes can carry over 30 kb. Other benefits of Ad include high expression levels and the ability to make large quantities of high-titer virus. Disadvantages of Ad include toxicity to transduced cells, although toxicity can be decreased by using gutless vectors. Ad expresses genes only transiently because they do not integrate into the genome. This makes adenovirus unsuitable for cases in which long-term, stable transgene expression is required.

Adenovirus has been used to transduce human HSCs. As early as 1985 (185), experimenters determined that hematopoietic cell lines could be transduced by adenovirus, and primary HSCs were shown to be transduced by Ad vectors (186). Subsequent experiments showed that Ad serotype 5 (Ad5) vectors could transduce human $CD34^+$ cells at moderate efficiencies, ranging from 5% to 45% (187–191). These studies also reported little toxicity in in vitro colony-forming ability, except at high MOI. The studies varied in MOI used, culture time, and source of HSCs. The use of cytokines during culture time to increase transduction efficiencies has yielded conflicting reports (190,192). Transduction of the more primitive $CD34^+$ $CD38^-$ cells showed transduction rates ranging from 15% to 45% (188,191). Studies using polycationic lipids to coat Ad [virus–polycation complex (VPC)] reported higher transduction efficiencies compared with virus alone (193–195). Due to the difficulties in testing human HSCs in vivo, most of these studies tested the toxicity of the virus by culturing transduced or nontransduced cells in vitro. However, one study transplanted transduced HSC into NOD/SCID animals and showed multilineage engraftment similar to nontransduced cells (195).

Most of the earlier studies used Ad5 to transduce human HSCs. However, many other serotypes exist. Thus, tests with

Table 3 Properties of Viral Vectors for Transducing HSC

	Retrovirus	Lentivirus	AAV	Adenovirus
Advantages	Stable expression	Stable expression, can infect dividing and nondividing cells	Stable expression, nontoxic, infects nondividing cells	Large insert capacity, high expression levels, high titers
Disadvantages	Infects only dividing cells	Difficulties in large-scale production, safety concerns, low expression levels	Low titers, low transduction efficiency	Transient expression, toxicity

chimeric vectors, that is, vectors constructed with parts of different serotypes, were studied. The Ad5F35 vector, consisting of the Ad5 vector with an Ad35 fiber protein, displayed highly efficient transduction of human HSCs compared with Ad5 vectors (196,197). The Ad5F50 vector also displayed greatly increased transduction efficiencies (198), up to about 90%. Ad5F11 vectors transduced about 70% of $CD34^+$ cells (199).

In contrast to the work on human HSCs, little has been reported on Ad transduction of mouse HSC heretofore. One group has shown that about 38% of a partially purified mouse HSC population can be transduced by Ad5 (200). Our group has detected about 32% transduction of highly purified mouse HSC population by Ad5. Transduced cells have normal in vitro activity. In vivo, transduced HSCs show multilineage contribution to recipients, but at a level of about half that of nontransduced cells (201).

Some groups have advocated the use of Ad to purge cancer cells from bone marrow. Such a technique would be useful for cancer patients undergoing autologous HSC transplantation to eliminate cancer cells from the autograft. Studies have shown that Ad5 infects cancer cells much more efficiently than HSCs, and can be used to selectively purge cancer cells from a bone marrow/cancer cell mixture without harming HSC activity (202–205). These reports appear to conflict with the reports cited above (206). It is probable that different experimental settings can be used to achieve either transduction of HSC or purging of cancer cells in the bone marrow environment (207). Another possibility is that Ad5 targets cancer cells more efficiently than HSC and therefore infects cancer cells at the expense of HSC in a mixed culture.

Experiments have been done on targeting the adenovirus to specific cell types in a mixture. For example, c-Kit, a cell surface receptor expressed on HSCs, is not expressed on most cell types in the bone marrow. By biotinylating Ad and SCF (the ligand for c-kit) and using avidin to attach SCF to Ad, transduction of hematopoietic cell lines was increased (208). In addition, biotinylated antibodies to c-kit could also be attached to Ad to increase transduction efficiency (208). Similarly, another study showed that by adding avidin to the Ad, and biotinylating SCF, an Ad-SCF vector could be created (209). This vector binds c-kit+ cells more efficiently, leading to more efficient transduction of human $CD34^+$ cells (209). Another group has circumvented the problems associated with biotinylating Ad chemically by developing a system in which Ad is biotinylated metabolically as it is being produced. A biotinylated anti CD71 or CD59 antibody was linked to this vector and used to greatly increase the transduction of a hematopoietic cell line (Parrot and Barry, Molecular Therapy, in press).

Hybrid vectors, which combine the favorable qualities of 2 vectors into 1 vector, are discussed in detail elsewhere in this book. For the purpose of this chapter, it is suffice to say that recent work illustrating the use of Ad for transduction of HSCs leads the way for Ad-based hybrid vectors that may allow for stable transduction of HSCs. These systems are based on an Ad vector carrying sequences from other viruses (AAV, retrovirus, or EBV) that cause stable expression of the gene of interest (210–214).

VIII. CURRENT STATUS OF GENE THERAPY FOR HUMAN HEMATOPOIETIC DISORDERS

There are many human hematopoietic disorders that could potentially be treated using gene therapy (Table 4). In most of these diseases, transplantation of bone marrow from a healthy donor could cure the patient. However, a suitable donor is not always available, and the transplantation procedure itself can be toxic. Therefore, the use of gene therapy as an alternative treatment would be a significant advance. The first disorder in which a gene therapy protocol was used in clinical trials was adenosine deaminase (ADA)-SCID, which occurs due to deficiency in ADA expression, resulting in SCID. Patients can be successfully treated by receiving exogenous ADA (PEG-ADA), but must continue this regimen for life. Early gene therapy trials used a retrovirus expressing an ADA minigene to transduce umbilical CB or bone marrow cells and/or peripheral blood lymphocytes (215–218). Although some transduced cells persisted and were functional, patients were still dependent on PEG-ADA treatment; removal of PEG-ADA resulted in a relapse into immunodeficiency.

Correction of ADA-SCID by gene therapy has now been improved with better HSC transduction and transplantation protocols (219). Two patients were reinfused with their transduced bone marrow after a nonmyeloablative conditioning regimen. Normalization of the patients' immune system in the absence of PEG-ADA was achieved and had been sustained for about 1 year at the time of the report (219).

The first successful human gene therapy trials were performed on patients with X-linked SCID (SCID-X1). SCID-X1 is caused by mutations in the common gamma chain, which is a signaling chain used by several cytokines. Lack of this chain results in drastically reduced T and NK cell development, leading to SCID. $CD34^+$ cells from SCID-X1 patients were transduced with a retrovirus carrying the common gamma chain and infused, without myeloablation, into the patients. Nearly 1 year after this, immune function was normal and

Table 4 Clinical Trials Using Gene Therapy of HSC

Disorder	Vector used	Result	References
ADA-SCID	Retrovirus	Partial correction	(216–218) (215)
SCID-X1	Retrovirus	Complete correction	(220,221)
CGD	Retrovirus	Very few cells corrected	(225)
FA	Retrovirus	Partial transient correction	(223)

patients were living normal lives at home (220,221). However, 1 of the 10 patients treated in this manner has developed a leukemia-like disease that is possibly due to integration of the retrovirus into the host chromosome (222), raising questions as to the safety of integrating viruses for gene therapy.

Retroviral transduction of HSCs has also been conducted for disorders such as CGD and FA (223). Although these studies have shown long-term expression of the defective genes, the expression level and transduction rates have been too low to show any lasting clinical benefit.

Although the successful trials with SCID-X1 and ADA-SCID patients reflect the promise of gene therapy, failures of other trials represents the obstacles needed to be overcome. One of these obstacles is the frequent problem of low expression levels of the transgene following transduction. However, as demonstrated by the mouse CGD experiments described earlier, low transgene expression may be sufficient to restore function to the affected cells. In other situations, even low levels of transgene expression may be sufficient for preferential selection of the transduced cells, bypassing the need for high transduction efficiencies and high gene expression levels. Another question is how many HSCs must be transduced in order for lasting therapeutic effect. It is likely that these questions must be empirically answered for each disorder being treated.

The possible retroviral-linked leukemia in one patient outlines another problem in gene therapy that needs to be addressed (222). Studies regarding the safety of different integrating retroviruses and the study of stable expression via nonintegrating episomes may provide more information on the plausibility of safe gene therapy treatments. Although gene therapy of HSCs has shown great promise, these questions must be answered before this type of treatment can be used on a regular basis.

Gene Marking Studies of Hematopoietic Cells

Catherine M. Bollard, Malcolm K. Brenner, and Helen E. Heslop
Baylor College of Medicine
Houston, Texas, U.S.A.

I. INTRODUCTION

The transfer of genetic material into a target cell offers a potentially powerful strategy in the treatment of a wide variety of diseases. Although gene marking does not confer therapeutic benefit, much of the biological information gained from these trials is proving to be valuable for improving the outcome of therapies such as stem cell transplantation (1,2). Gene marking can be used to track the in vivo behavior of almost any tissue (3), and the success of the strategy depends on tracking the marked cell not only for its entire lifespan, but also for the lifespan of all its progeny. The vectors used must therefore integrate into the host cell DNA and efficiently replicate with the cell. For this reason, the majority of marker studies performed to date have used murine retroviral vectors. Although these agents are able to integrate stably, they have many limitations. In particular, they are only able to integrate into dividing cells and have low transduction efficiency.

The aims of this chapter are 3-fold: (1) to identify the reasons why gene marking studies have been performed and why a continuation of this research is important to the ever-broadening field of gene transfer; (2) to discuss the vectors and marker genes employed, and the factors, which influence gene transfer efficiency and gene expression; and (3) to review the lingering concerns about the safety issues surrounding gene transfer.

II. GENE MARKING OF HEMATOPOIETIC PROGENITOR CELLS

The principle of gene marking is the transfer of a unique DNA sequence (e.g., a nonhuman gene) into a host cell (e.g., T cell, hematopoietic stem cell, etc.) allowing the gene or the gene product to be easily detected, thereby serving as a marker for these labeled cells. Detection of the marker gene may be phenotypic or genotypic. For example, the frequently used bacterial neomycin resistance (*neo*) marker gene encodes the enzyme neomycin phosphotransferase, which can inactivate neomycin or its analogs, such as G418. When cells are expressing the *neo* gene, they become resistant to G418 in culture medium and can be detected by their ability to grow in G418. The transgene can also be readily detected in these cells using the polymerase chain reaction (PCR) technique (2).

A. Gene Marking in Autologous Stem Cell Transplantation

In the first gene marking trials involving hematopoietic stem cells (HSCs), the question posed was whether relapse following autologous stem cell transplant was due to a contribution from contaminating malignant cells in the stem cell harvest (4). To answer this, a portion of the HSC product was marked at the time of harvest with a murine retroviral vector encoding the neomycin resistance gene. If the patient subsequently relapsed, it was possible to detect whether the marker gene was present in the malignant cells. Since 1991, studies have been initiated using this approach in a variety of malignancies treated by autologous HSC transplantation (4–12). As shown in Table 1, the underlying malignancies treated with marked autologous HSCs include acute myeloid leukemia (AML), chronic myeloid leukemia (CML), acute lymphoblastic leukemia (ALL), neuroblastoma, lymphoma, multiple myeloma, and breast cancer.

The initial studies evaluating this approach took place at St. Jude Children's Research Hospital (SJCRH) in pediatric patients receiving autologous bone marrow transplantation (BMT) as partial therapy for AML or neuroblastoma (4,6). In both studies, one-third of the marrow was marked in a 6-h transduction protocol in the absence of growth factors. Four

Table 1 Results of Clinical Gene Marking Studies Using Hemopoietic Progenitors as the Target Cell

Study site	Target cell	Disease	Results	References
SJCRH	Marrow mononuclear cells	Pediatric acute myeloid leukemia	Presence of marked tumor cells at relapse Persistence of marked normal cells up to 5 years	13,25
SJCRH	Marrow mononuclear cells	Neuroblastoma	Presence of marked tumor cells at relapse Persistence of marked normal cells up to 5 years	15
MD Anderson Cancer Center	Marrow mononuclear cells	CML	Presence of marked tumor cells at relapse Persistence of marked normal cells up to 1 year	16
NIH	CD34-selected blood and marrow cells	Breast cancer	Presence of marked normal cells derived from both blood and marrow	18
NIH	CD34-selected blood and marrow cells	Multiple myeloma	Presence of marked normal cells derived from both blood and marrow	18
University of Indiana	Marrow mononuclear cells	AML	No marked tumor cells at relapse No significant detection of marker gene in normal cells	17
University of Toronto	Long-term bone marrow cultures	Multiple myeloma	Persistence of marked normal cells up to 2 years	31
Karolinska Institute	CD 34-selected cells	Multiple myeloma	Low-level detection only in normal cells	12
MD Anderson Cancer Center	CD34-selected blood and marrow cells	Non-Hodgkin's lymphoma	Presence of marked cells up to 9 months No marked tumor cells in 1 patient who relapsed	80

of 12 AML patients who received marked marrow relapsed. In 3 of the 4 patients, detection of both the transferred marker and a tumor-specific marker in the same cells at relapse provided unequivocal evidence that the residual malignant cells in the marrow were a source of leukemic recurrence (13). For example, in one patient the malignant blasts had the unique phenotypic features of CD34 and CD56 coexpression and a complex t(1:8:21) translocation resulting in an AML1/ETO fusion transcript that could be identified by PCR. Malignant cells sorted by this phenotype contained both the AML1/ETO fusion transcript and the transferred neomycin gene (13). In the neuroblastoma study, (6) 5 of the 9 patients relapsed, and gene marked neuroblastoma cells, coexpressing the neuroblastoma-specific antigen GD2 together with the transferred marker gene, were detected in 4 cases (14,15). In one of these patients, marked neuroblastoma cells were detected in an extramedullary relapse in the liver (15). Similarly, marked malignant cells coexpressing the t(9;22) and *neo* transcripts were found in 2 patients with CML at relapse (16). These data show that in these 3 malignancies, marrow harvested in apparent clinical remission may contain residual tumorigenic cells that can contribute to a subsequent relapse. In contrast, marked cells have not been found in adult patients relapsing after autografts for ALL (17). However, for logistic reasons, only around 10% of the marrow was marked in this study and gene transfer to normal cells was very low. In a study at the National Institutes of Health (NIH), autologous transplantation for breast cancer used CD34 selected HSC from blood and marrow. In the 2 patients who relapsed, the marker gene was not found (18). This may reflect a lower efficiency of the marking of breast cancer cells, or the $CD34^+$ selection procedure used may have reduced contamination with malignant cells. Alternatively, relapse in breast cancer may occur predominantly from residual disease in the patient.

Therefore, as only modest levels of gene transfer into malignant progenitor cells are obtained, a definitive conclusion about the contribution of marrow-based disease to recurrence can only be drawn if a relapse is marked. Unmarked relapses might mean that marrow does not significantly contribute to recurrence or may mean that relapse is generated by only a few marrow-derived malignant cells that have escaped being marked because of the inefficiency of the transduction process.

III. THE USE OF MULTIPLE VECTORS

A. Double Gene Marking to Monitor Purging

The overall implication of the above studies is that residual malignant cells can contribute to relapse, and the outcome of HSC rescue may be improved by strategies targeted at residual malignant cells (19). One means of achieving this is purging of the transplanted marrow and gene marking techniques are useful in the evaluation of the purging technologies. In second-generation studies, 2 genetically distinct marker genes were used to compare either marrow purging vs. no purging or 2 different purging techniques (12,20,21). Two closely related vectors, G1N and LNL6, were used. These vectors differ in their 3′ noncoding sequences so primers can be designed allowing the vectors to be discriminated by virtue of the differing fragment sizes they produce after PCR amplification. In the AML study, (20) 15 patients were enrolled between September 1993 and November 1996. At least 10^8 marrow cells/kg were frozen without manipulation as a safety backup. The remaining marrow mononuclear cells were divided in half and randomized to marking with G1Na or LNL6. The aliquots were then randomly assigned to the 2 purging techniques being evaluated. Initially, the pharmacologic ''gold standard'' hydroperoxycyclophosphamide (4HC) was compared with an immunologic purge by culture with interleukin-2 (IL-2) (22). Later into the study, CD15 antibodies (instead of IL-2) were used in conjunction with 4HC (23). At the time of transplant, both aliquots were reinfused. If the patients relapsed, the premise was that detection of either marker would reveal which of the compared purging techniques had failed.

Over the 3-year period, 15 patients were treated. In 5 patients, aliquots of marrow were purged with 4HC and IL-2; in 3 patients, the marrow was purged with 4HC and CD15. PCR studies on peripheral blood granulocytes and mononuclear cells consistently showed a stronger signal from the 4HC-purged fraction than that from the IL-2-purged fraction, regardless of which vector was used for marking each aliquot. These observations suggested that the 4HC-purged fraction was making a greater contribution to hematopoietic reconstitution than the IL-2-purged fraction, thus resulting in the substitution of CD15 antibodies for IL-2. Seven patients received marrow purged with 4HC alone. This was due to either insufficient number of cells harvested or unavailability of 1 clinical grade retroviral vector. In all, 3 of the 15 patients relapsed. Two patients relapsed early at 2 and 3 months and were noninformative, as marked malignant cells were not detected. A third patient relapsed at 20 months and his blasts were also negative (24). The *neo* gene was detected in normal hematopoietic and immune system cells at a lower level than in the studies using unpurged marrow.

IV. GENE TRANSFER TO NORMAL CELLS

These marking studies also provided information on the transfer of marker genes to normal hematopoietic cells and showed that marrow autografts contribute to long-term hematopoietic reconstitution after transplant (2,19) (Table 1). Long-term transfer up to 9 years has been seen in the mature progeny of marrow precursor cells, including peripheral blood T and B cells and neutrophils (24). It was also detected in lymphoblastoid cell lines and cytotoxic T cell lines derived from these patients. However, the level of gene transfer varied and was highest in marrow clonogenic hematopoietic progenitors, where an average of 6% of myeloid colonies were G418 resistant at 3 months. The levels of transfer into marrow progenitors are higher than predicted from animal models and may be attributed to the fact that marrow was harvested during regeneration after intensive chemotherapy, when a higher than normal proportion of stem cells are in cycle (16). In the mature peripheral blood cells, the level of gene transfer was however some 5-fold lower than in the marrow progenitors with levels of 0% to 1% seen (25).

Useful information can be gained from these initial studies, leading to the development of more complex gene marking protocols (Table 1). These include (1) double gene marking to allow simultaneous study of 2 distinctly treated cell populations (e.g., of unmanipulated HSCs vs. stem cells treated with growth-stimulatory agents); and (2) the use of more purified populations of early progenitor cells to allow the ''true'' pluripotent tem cell to be identified phenotypically and to increase the efficiency of gene transfer by more precise tailoring of transduction conditions.

A. Double Gene Marking to Compare Long-term Reconstitution from Different Populations of Hematopoietic Progenitor Cells

No in vitro assay can yet assess the capacity of a cell population to produce short- and long-term repopulation of humans. The use of double gene marking with distinguishable vectors in a single patient potentially allows (1) comparison of these properties between different sources of putative stem cells, such as peripheral blood and marrow; (2) determination of the function of stem cell subpopulations (e.g., $CD34^+CD38^+$ vs. $CD34^+CD38^-$ progenitor cells); and (3) the consequences of ex vivo manipulation, such as culture of putative stem cells on stromal support or with cytokines. By using the 2 distinguishable retroviral markers, it is possible to compare quantitatively in vivo and within each patient the short- and long-term reconstituting capacity of different populations of HSC.

One aim of clinical stem cell transplantation is to minimize the period of marrow aplasia posttransplant by increasing the number of progenitor cells infused. This approach is only of value if progenitor cell manipulation does not induce loss of self-renewal capacity when the treated cells are reinfused. One strategy is to expand the progenitor cells at least 50-fold ex vivo using stimulatory cytokines (18,26) and/or stromal (24,27) components. There are however concerns that stimulatory cytokines will not only induce primitive cells to expand, but will also cause them to differentiate and lose their capacity

for self-renewal. In other words, the cytokine stimulation ex vivo may produce a faster initial engraftment but at the cost of later graft failure. Gene marking can be used not only to address concerns about the effects of growth-stimulating agents on pluripotent progenitor cells and long-term engraftment, but also to determine whether ex vivo stimulation increases gene transfer efficiency.

The NIH study by Dunbar et al. (18) compared the reconstitution of peripheral blood and bone marrow in patients receiving autologous HSC rescue for myeloma or breast cancer. They differentially marked mobilized peripheral blood and marrow $CD34^+$ cells using 2 distinguishable *neo* containing retroviral vectors and infused both populations of stem cells into the same patient. An average of 21% of colony-forming units (CFUs) were transduced using a 3-day culture in the presence of stem cell factor (SCF), IL-3 and IL-6. The level of gene transfer into committed progenitor cells post transduction was as high as 50% using this approach. However, the engraftment of the marked cells was not accelerated compared with the earlier SJCRH studies (2,13,20,28) in which growth factors were not used. In addition, although vector sequences were found in myeloid and lymphoid cells at 0.01% to 0.001% for up to 18 months, these levels were lower than the earlier SJCRH studies (29,30). These findings may reflect the different patient population both by virtue of age (adult vs. pediatric) and disease (breast cancer/myeloma vs. leukemia/neuroblastoma). Alternatively, this may indicate that that culture with growth factors commits transduced cells to differentiation, so that high-level, long-term engraftment is not obtained.

Although the study by Dunbar et al. showed low levels of gene transfer detected in vivo, the marker gene derived from peripheral blood and marrow HSC demonstrated that each can contribute to long-term recovery (18). It is of interest that the marked peripheral blood stem cells contributed to hematopoiesis earlier and for a longer period compared with the gene marked marrow cells. It is possible that this phenomenon may be related to physiological differences in these 2 populations of HSCs. This includes the ability of each HSC to contribute to hematopoiesis, the cell-cycle status of the HSC, or the susceptibilty of the HSC to retroviral transduction (27).

Another promising method by which progenitor cells may be expanded and their transducibility increased is the initiation of long-term cultures or the addition of stromal support components to culture. One group (11,31) established marrow in long-term cultures where an autologous stroma developed over the course of 3-week culture. The cultures were transduced weekly. Initially, a mean of 16% of gene marked progenitors were seen in the early posttransplant period. This level dropped to 3% by 2 years posttransplant, and only 0.01% of the circulating blood cells were marked.

Although the use of double gene markers is in its infancy, and is hampered by the complexity of the studies, the approach remains a powerful way of investigating the biology of different stem cell populations and of determining the consequences of stem cell manipulation.

B. $CD34^+$-selected HSC Transplantation

In the context of gene marking, the justification for $CD34^+$ selection is that it reduces the required volume of vector supernatant. It may also serve as a means of marrow purging in patients in whom the malignant cells are $CD34^-$ or coexpress $CD34^+$ and 1 or more lineage (lin) commitment antigens. The marking approach can be used to discover the relative ability of distinct populations of $CD34^+$ cells to produce long-lived, multilineage reconstitution following reinfusion. The strategy can also be used to determine if lineage-positive and -negative CD34 subsets make a different contribution to short- and long-term reconstitution. The potential disadvantage of selecting $CD34^+$ cells or their subsets is that immune reconstitution may be delayed because mature lymphocytes are not transferred with the graft. This delay may then increase the risks of subsequent neoplastic change if undetected replication-competent retrovirus has contaminated the vector as demonstrated in an animal study (32).

The advantages of CD34 selection may therefore be counterbalanced, at least in part, by a decrease in the margin of safety for marker studies. Nonetheless, many of the more recently approved marker studies (as shown in Table 1) use $CD34^+$ cells as the vector target (12,18,29).

V. ROLE OF MARKER STUDIES TO VALIDATE EFFORTS TO INCREASE THE LEVEL OF GENE TRANSFER TO THE HSC

A. Role of the Cell Cycle

Attempts to induce HSCs to cycle generally use various cytokines/growth factor combinations. However, it has been demonstrated that culture of human $CD34^+CD38^-$ cells in serum-free media with IL-3, IL-6 SCF, Flt-3 ligand and thrombopoietin or megakaryocyte-derived growth factor (MDGF) for 9 days can increase both the number of HSCs cycling and the length of time they can be maintained in vitro (33–35). HSCs may also be induced to cycle in vivo as a normal physiological response to hematopoietic cytoablation and/or cytokine mobilization. In the SJCRH studies in pediatric patients, (2,13,20,28) a 6-h incubation with retroviral supernatant was employed for transduction. The success of the transduction efficiency and long-term persistence of marker gene expression in these studies compared with similar studies in adults (18,31) may however be attributed to the fact that HSCs from children have an endogenously higher proliferation index. There is also evidence that treatment of animals with a combination of granulocyte-stimulating factor (G-CSF) and SCF mobilizes marrow progenitor cells that are more primitive and more readily transduced than after treatment with G-CSF alone (36).

B. Role of Stromal Support Elements

Some groups add stromal supports such as a recombinant fragment of fibronectin to bring the retroviral vector and target

cell into close apposition, thereby increasing the efficiency of progenitor cell marking (37,38). Several studies have tried to address the extent of long-term engraftment of retrovirally transduced peripheral blood progenitor cells using recombinant fibronectin (38–41). One study (41) assessed the effects of recombinant fibronectin on marrow repopulating cells and on the efficiency of gene transfer using the multidrug resistance (MDR1) gene or *neo* gene to ascertain the fate of the treated cells. In this study, one-half of the enriched $CD34^+$ cells were transduced with MDR1 and the other half with *neo*. There was low-level gene marking of granulocytes (0.01%–1%) by PCR analysis up to 6 months posttransplant. In all 6 patients, there was a higher level of engraftment of MDR1-containing cells relative to *neo*, suggesting that MDR1 overexpression was beneficial to the engraftment potential of hematopoietic cells.

A recent study (38) reported the highest level of long-term engraftment of retrovirally transduced peripheral blood stem cells (PBSCs). The 11 enrolled patients were adults (17–51 years) undergoing tandem autologous PBSC transplants for germ cell tumors. In this study, MDR1 was used as a marker gene and in the hope that it may render the HSC resistant to oral etoposide, (42) thereby allowing for further dose-intensive therapy without the delay of prolonged cytopenia post transplant. The PBSCs were mobilized using G-CSF. The initial harvest was unmanipulated and used for the initial transplant. The second collection was $CD34^+$ selected, stimulated ex vivo with cytokines (SCF,IL-6,MDGF,G-CSF), and cultured with MDR-1 retroviral vector on plates coated with recombinant fibronectin (CH-296), then cryopreserved on day 5. The median gene transfer efficiency of all colonies immediately after transduction was 14% (4%–52%). At 12 months postinfusion of the MDR1-PBSCs, 4 of the 7 evaluable patients had detectable levels (5% to 15%) of transgene-containing colonies in their bone marrow samples. This study also showed that exposure of $CD34^+$ cells to CH-296 did not adversely affect either engraftment kinetics or long-term hematopoietic function.

These studies therefore indicate the feasibility of using MDR gene transfer as a means of enriching marrow for MDR-transduced cells. It remains unclear whether the approach will be valuable for protecting and selecting other cell types following chemotherapy.

VI. GENE MARKING STUDIES OF T CELLS

A. Gene Marking of Tumor-infiltrating T Lymphocytes

The first gene marking protocol was conducted to determine the fate of lymphoid cells that infiltrate solid tumors (43). These tumor-infiltrating lymphocytes (TILs), were obtained from tumor biopsies, expanded ex vivo and then reinfused. It was therefore important to determine if these infused TILs were tumor specific and ascertain their distribution and persistence at tumor sites after infusion. Initially, studies to assess the ability of TILs to traffic to and remain at tumor sites postinfusion used TILs that were radioactively labeled with ^{111}In (44,45). However, this approach requires a high labeling to enhance the detection level and duration, resulting in potentially toxic radiation exposure to cells from the gamma radiation emitted by the isotope. In addition, the half-life of ^{111}In is only 2.8 days, and it is therefore not suitable for monitoring TILs over extended periods of time (46).

It was apparent that a need existed for an alternative labeling technique. The genetic marking of the TIL ex vivo using a *neo* encoding retroviral vector helped to answer several questions about TILs in cancer therapy. After neo-marked TILs were infused into the patient and tumor sites biopsied, it was shown that large numbers of gene-marked TILs could be safely returned to patients, and that the marker could be transiently detected in the peripheral blood by PCR analysis using *neo*-specific primers (47,48). Analysis of peripheral blood and tumor deposits for presence of the marker gene suggested that TILs could persist for up to 2 months (43). Studies in one patient showed presence of the marker gene in biopsy tissue from a tumor deposit (49). In a French study, marked TILs were detected for up to 260 days and TILs were also detected in 4 of 8 tumor biopsies after therapy (50). A subsequent double-marking study compared the survival and tracking of peripheral blood lymphocytes (PBLs) and TILs by marking with distinguishable retroviral vectors (51). Both marked PBLs and TILs could be detected in peripheral blood for 4 months, and no selective homing of TILs to tumor sites compared with unmanipulated PBL was seen (51). None of these studies therefore provided support for the theory that TILs are capable of selective homing.

B. Gene Marking to Track Adoptively Transferred Cytotoxic T Cells After Allogeneic BMT

Several studies have shown the feasibility and apparent clinical efficacy of adoptive transfer of cytotoxic T cells (CTLs) directed at viral or tumor antigens (50–59). The transfer of a marker gene has allowed monitoring of adoptive transfer approaches to determine the survival of infused T cells. In addition, the T cells can be tracked to learn if they can home to sites of disease and if they mediate adverse effects such as graft vs. host disease (GVHD). The clinical results of gene marking approaches using T cells are summarized in Table 2.

Matched unrelated-donor or mismatched family-donor bone marrow transplantation results in a high risk of GVHD due to the greater genetic disparity between donor and recipient. An effective means of reducing this risk is to T cell-deplete the donor marrow ex vivo. The disadvantage of this approach is that recipients of the T cell-depleted bone marrow have delayed immune recovery and there is an increased incidence of viral infections. One such infection is Epstein-Barr virus lymphoproliferative disease (EBV-LPD), which is due to a proliferation of EBV-infected B cells that are highly immunogenic and that are not eliminated in the immunocompromised host. This complication occurs in 5% to 30% of patients

Table 2 Published Results of T Cell Gene Marking Studies

Study site	Target cell	Disease	Results	References
NCI	Tumor-infiltrating lymphocytes	Melanoma	Short-term detection marked cells	3
SJCRH	EBV-specific cytotoxic T lymphocytes	Post T cell-depleted allogeneic bone marrow transplant	Detection of marked cells up to 6 years Expansion in response to EBV reactivation Accumulation marked cells at disease sites	53, 55, 56
SJCRH	EBV-specific cytotoxic T lymphocytes	Hodgkin's disease	Detection of marked cells up to 6 months Accumulation marked cells at disease sites	57
Centre Leon Berard, Lyon, France	Tumor-infiltrating lymphocytes	Melanoma Renal cell cancer	Detection of marked cells up to 9 months No evidence of homing	50
University of California Los Angeles	Tumor-infiltrating lymphocytes and peripheral blood lymphocytes	Melanoma Renal cell cancer	Detection of marked cells up to 4 months No evidence of homing of TIL compared with PBL	51
Fred Hutchinson Cancer Research Center	Gag-specific CD8 clones	Patients with HIV	Eradication of infused cells containing Tk or hygromycin Trafficking of neo marked cells to HIV infected lymph nodes	52, 58
NIH	$CD4^+$ T cell from syngeneic twins	Patients with HIV	Detection of marked cells up to 4 months	59

receiving T-depleted marrows from mismatch family or unrelated donors. Donor-derived EBV-specific T cells were generated by culturing donor T cells with donor-derived EBV-infected lymphoblastoid cell lines (53,55,56,60). To determine whether these cells persisted and whether they caused adverse effects, they were marked with the *neo* gene before administration. Twenty-eight patients received *neo*-marked CTLs. Infusion of virus-specific CTLs produced a virus-specific immune response as documented by a fall in EBV DNA levels (53). The gene marking component of this study allowed the demonstration of the persistence of the *neo* gene in the peripheral blood for up to 78 months after injection of gene marked cells (56). Three patients who were treated for clinically evident EBV-LPD attained prolonged remission after CTL infusion, and in situ hybridization and semiquantitative PCR showed that the gene marked CTL had selectively accumulated at disease sites (55).

C. Gene Marking of EBV-specific CTLs for Relapsed EBV-positive Hodgkin's Disease

Marking of autologous EBV-specific polyclonal CTLs has also been used in a clinical study for patients with relapsed EBV genome-positive Hodgkin's disease (57). Seven patients with multiply relapsed Hodgkin's disease have received gene marked EBV-specific CTL in a phase I dose escalation study. Gene marked CTLs were found in peripheral blood up to 9 months following infusion. One patient had erosion of tumor through the L upper lobe bronchus and died 2 months after CTL infusion. In situ PCR revealed gene marked CTLs within part of the mediastinal tumor but not at the site of L upper lobe bronchus erosion. In another patient, EBV-specific CTLs were localized to a malignant pleural effusion 3 weeks after CTL infusion as assayed by gene marking. The conclusions from this study were that marked CTLs expanded in vivo and were found to persist for up to 9 months as tracked by RT-PCR analysis (61).

D. Gene Marking of T Cells in HIV Therapy

To study the survival of normal T cells in patients with HIV, peripheral blood lymphocytes from unaffected syngeneic twins were transduced with a *neo* vector and transferred to their HIV-infected sibling (59). Marked $CD4^+$ T cells persisted in the circulation for 4 to 18 weeks after transfer in all patients, and at 6 months marked cells were found in lymphoid tissues (59). In subsequent studies, autologous HIV gag-specific $CD8^+$ CTL clones genetically marked with the LN retrovirus were infused (58). The infused CTLs were seen to accumulate adjacent to HIV-infected lymph nodes and transiently reduced the levels of circulating productively infected $CD4^+$ T cells. This decline was transient, likely due to a lack of $CD4^+$ help. However, the study did provide some rationale for pursuing this approach in conjunction with strategies to circumvent the requirement for CD4 cells.

VII. GENE MARKING OF MESENCHYMAL CELLS

Over the last few years there has been increasing interest in the use of mesenchymal cells to treat patients with genetic disorders affecting mesenchymal tissues, including bone, cartilage, and muscle. To evaluate this therapeutic option, Horwitz and colleagues infused gene marked, donor marrow-derived mesenchymal cells to treat 6 children who had undergone standard bone marrow transplantation for severe osteogenesis imperfecta (62). The marking component of this study showed that the mesenchymal cells could engraft in bone, skin, and marrow stroma (62). Of interest, the marker gene could not be detected in 1 patient likely due to an immune response directed at the *neo* gene (62).

VIII. IMPROVING MARKER STUDIES

A. Marker Gene

Most of the clinical studies reported to date have used *neo* as the reporter gene. This marker has the advantage that its safety has been widely studied in many different animal models, and it can be detected both phenotypically and genotypically. In gene marking the concern is that the activity of neomycin phosphotransferase (the product of the *neo* gene) is also likely to phosphorylate cellular proteins and may thereby modify the growth or differentiation of cells expressing the gene. In vitro, this effect has been observed in the HL60 cell line (63). There is evidence that a similar phenomenon occurs in vivo. There is the almost uniform observation that the proportion of cells positive for the neo marker gene in circulation is 0.5 to 1 log below the number of cells that are positive as determined by in vitro colony assays in the presence of the neomycin analog G418 (14). It may be that *neo* expression retards progenitor growth and differentiation in vivo, thus rapidly diminishing the numbers of *neo* progeny detectable. It is also possible that the expression of the transgene (i.e., *neo*) by the transduced cell results in an immune response that eliminates the transduced population. For some gene products, such as the hygromycin-thymidine kinase (Hy-Tk) fusion protein, the potency of this immune response is such that the response is a rapid elimination of large numbers of transduced cells in less than 48 h (52). It is as yet unclear if so potent an immune response regularly occurs after *neo* transduction, because neo-positive cells can be detected for up to 9 years after infusion and neo-marked T cells can be readily expanded in vivo by appropriate antigenic stimulation (55,56). If the discrepancy between levels of marking in CFU and mature cells is a consequence of the immunogenicity of the marker signal, then the interpretation of certain marker studies may be rendered more difficult.

Because of the limitations of the *neo* gene as a marker, several alternatives have been proposed. Amongst the most widely used in studies are GFP and cell surface markers such as the truncated (low-affinity) receptor for nerve growth factor (dLNGFR) (64–66). Unfortunately, many of these have the same limitations as neo and there is concern that some of these proteins (e.g., GFP) may prove to be significantly immunogenic in vivo (67). Moreover, aberrant expression of cell surface molecules may lead to unwanted cell trafficking or harmful intercellular contacts, even if the cell surface molecule has been modified to preclude intracellular signaling. One such concern is highlighted in a murine model using the same truncated dLNGFR marker gene that had been used in clinical studies (66). As discussed in Section IX. A, this gene was introduced by a replication-incompetent murine retroviral vector into bone marrow cells, which were then transplanted into irradiated mice. Marrow was then harvested after 28 weeks, pooled, and transplanted into secondary irradiated mice. These recipients subsequently developed hematopoietic disorders, carrying the same leukemic clone with a single vector copy integrated into the transcription factor gene Evi1 (68), and it was suggested that the capacity of dLNGFR to produce aberrant signal transduction contributed to the oncogenic events.

Because of the above concerns that marker gene may be immunogenic, may affect cell growth, and may contribute to oncogenicity, the most ideal marker may in fact be a nonexpressed sequence (62). However, until an ''empty'' retroviral vector is validated, *neo* seems to be the most appropriate marker gene presently available for clinical use.

B. The Use of Alternative Vectors

Although a detailed discussion of the pros and cons of the various vector systems available in clinical use is beyond the scope of this review, Table 3 summarizes the advantages and disadvantages of each. For gene marking studies, in which stable transduction is required and in which all daughter cells should contain equal amounts of the marker gene, integrating vectors are required. To date, this has meant using Moloney murine leukemia virus (MoMuLV) (19,21,69). The main limitation of the Moloney-based vectors is that they can only effectively transduce actively dividing cells, a major limitation when human hematopoietic stem cells are the targets because too few of these cells are in cycle at any one time.

Because of these limitations, human and feline lentiviral vectors have attracted increasing attention as gene delivery systems (70,71). Lentiviral vectors have been reported to readily transduce hemopoietic progenitor cells (72). Because they form a more stable preintegration complex than MoMuLV, they are also able to infect quiescent subsets of primitive hemopoietic stem cells, such as the $CD34^+$, $CD38^-$, or $CD38^-$ lineage negative population, where they persist and integrate once these cells enter cycle (73). HIV can also efficiently infect terminally differentiated cells such as neurons (74), and in both types of cell, high levels of gene expression have been reported. Although lentiviral vectors have clear advantages over murine retroviruses, substantial technical and safety problems remain before they can enter general clinical usage.

IX. VECTOR SAFETY CONCERNS

Adverse publicity has sensitized investigators and the public alike to the potential dangers of gene transfer vectors. Every new therapeutic agent must, of course, be carefully monitored

Table 3 Advantages and Disadvantages of Vector Systems

Vector	Advantages	Disadvantages	Current uses
Murine retrovirus	Stable integration into dividing cells Minimal immunogenicity Stable packaging system	Low titer Only integrates in dividing cells Limited insert size Risk of silencing Risk of insertional mutagenesis	Marker studies Gene therapy approaches using hemopoietic stem cells of T cells (e.g, to treat immunodeficiency syndromes) Transduction tumor cell lines
Lentivirus	Integrates into dividing cells Expressed in nondividing cells Larger insert size than murine retroviruses	No stable packaging system Complex safety issues	No approved trials as yet
Self-inactivating lentiviral vectors (SIN-Lenti)	Incapable of replication posttransfection? Increased safety Stable packaging system	? safety concerns remain	No approved trials as yet
Adenovirus	Infects wide range cell types Infects nondividing cells High titers High level of expression Accepts 12–15 kb DNA inserts	Highly immunogenic Nonintegrating	Direct in vivo applications Transduction tumor cells
Adeno-associated virus (AAV)	Integrates into dividing cells Infects wide range cell types	No stable packaging cell line Very limited insert size	Gene therapy approaches cells targeting muscle, liver, and brain
Herpesvirus	High titers Transduces some target cells at high efficiency Accepts large DNA inserts	No packaging cell lines Nonintegrating May be cytotoxic to target cell	Transduction tumor cells Neurologic disorders
Liposomes and other physical methods using plasmid DNA	Easy to prepare in quantity Virtually unlimited size Limited immunogenicity	Inefficient entry into target cell Nonintegrating	Topical applications Transduction tumor cells

for adverse effects, and gene transfer vectors are no different. Beyond these general concerns, however, there are more specific issues that must be considered. We have already alluded to concerns about recombinational events following administration of lentiviral vectors, but insertional mutagenesis is a potential consequence of any integration event, regardless of the vector used (32). Although most integration events of the vector DNA presumably harmless, there is an unknown (albeit low) risk that, in some cases, the integration event may result in activation of neighboring gene, such as an oncogene, which could result in uncontrolled cell division or ''insertional mutagenesis.'' Because tumorigenesis is believed to be a multistep phenomenon, it is likely that an additional event would be required before a vector insertion at a given locus would result in tumor formation. The Food and Drug Administration (FDA) addressed these risks nearly 10 years ago when they requested lifelong (now 15 years) follow-up of all gene therapy subjects who participated in clinical trials, including genetic analysis of any tumors that may appear.

Two recent events have refocused attention on this risk. In a murine study, marrow stem cells transduced with a murine retroviral vector encoding a marker gene (truncated dLNGFR) used in some human studies (66) caused leukemia after serial transplantation of transduced stem cells in mice (68). Although the resulting leukemia had an integration site in the Evi-1 gene, this is not usually sufficient for transformation and it is possible that the truncated NGFR served as a cofactor. In addition, a child in a clinical gene therapy trial in France for the treatment of X-linked severe combine immunodeficiency (SCID) (75,76) developed γδT cell leukemia—a serious adverse event related to the retroviral vector gene therapy. The expanded T cells were monoclonal, with overexpression of the LMO-2 gene and integration of the provirus in the promoter element of this gene, suggesting that the vector insertion may have caused dysregulation of the LMO-2 gene. In normal cells, the LMO-2 gene (present on chromosome 11) is expressed during early stages of hematopoietic differentiation and appears critical for lymphoid and myeloid cell development (77). Further, in T cell ALL, the chromosomal translocation t(11;14) results in the joining of the T cell receptor D or J segments to the LMO-2 locus. This is probably the result of aberrant RAG-mediated V(D)J recombination, thereby

highlighting the multistep nature of the leukemogenic process (77). It is currently unclear whether the selection advantage conferred by the ADA transgene contributed to this event.

A. Safety of Gene Marking

Although these 2 reports are of concern, it is important to remember that there have been no reports of malignancies related to insertional mutangenesis in patients who have received gene marked cells. Our group has followed over 75 patients who have received gene marked marrow or T cells for up to 10 years. So far, none of these patients have shown any evidence for selective expansion of marked cells. Two reasons for this are (1) gene marking occurs at a substantially lower level than gene correction. Hence fewer cells are placed at risk, and the probability of 2 or more integration events in a single cell is statistically exceedingly remote; and (2) unlike correction of a genetic defect such as X-linked SCID, gene marking does not lead to selection for transduced cells in vivo or to hyperexpansion of the ''genetically corrected'' T cell population. Even without gene transfer, such hyperexpansion of T cells can lead to lymphoproliferation and malignancy (78). This event occurred even when as few as 0.01% of stem cells or T cells were expressing the CD40L transgene. In this case, the malignant T cell did *not* contain the CD40L transgene.

Gene marking studies are used in adults and children in an effort to improve new or established therapies for immediately life-threatening illnesses for which current therapies are unsatisfactory. As importantly, marking studies help to determine whether novel therapies are contributing to any adverse events, minimizing subsequent exposure of vulnerable subjects. As discussed in previous sections, gene marking has been an invaluable tool in validating therapies that have had a real therapeutic impact (55,79), and at present we believe the proven benefits continue to exceed the potential risks.

X. CONCLUSIONS

Since the early 1990s, clinical studies using marker gene transfer have resolved many issues concerning the biology of hematopoietic cells and their progeny and have also helped to validate new treatments for viral infections and malignancy. To date, the approach has been safe, and the use of more advanced vector systems should increase the knowledge that can be obtained from this powerful tool.

Gene-based Vaccination Against Malignant Melanoma

Dirk Schadendorf
German Cancer Research Center Heidelberg, University Hospital Mannheim
Mannheim, Germany

I. INTRODUCTION

Gene therapy is an emerging field for treating diseases by using DNA as the remedy. It can be used to treat systemic diseases and various organ disorders. The goal of gene therapy is to treat a specific disease process with the protein product of the introduced gene. This protein can be either used locally or systemically (e.g., clotting factors and hormones) (1).

An essential component of the revolution in molecular biology has been the arrival of transfer methods by transfection or transduction. In principal, 3 different ways of introducing genetic material consist of (1) viral/bacterial vectors; (2) calcium phopshate, DEAE-dextran, or liposomes; and (3) physical methods such as direct injection, electroporation, or the gene gun (2). Each method has its own inherent strengths and weaknesses, and is especially suitable for a particular application.

In 1987, Sanford and coworkers invented a new addition to the armentarium of gene delivery vehicles, which was called ''biolistic method of gene transfer'' (3). Other terms include ''particle bombardment'' and ''gene gun.'' In principal, the technique implies that DNA is coated onto 1- to 5-μm heavy metal particles (usually gold or tungsten) that were accelerated in the early days using gun powder, today using helium, to sufficient velocity to penetrate the target cells. Historically, the first cells to be penetrated were plant cells (3,4). Its most notable application was the production of the first transgenic crop (i.e., the transfection of maize) (5,6).

To design potential treatment strategies for gene therapy, it is relevant to discuss 2 general approaches: the in vivo approach and the ex vivo approach of gene transfer (Fig. 1). In the in vivo approach, the desired genes are introduced directly into the target organ, whereas in the ex vivo approach, the target cells are cultured from biopsy specimens and the desired gene is inserted while these cells are being propagated in tissue culture. The genetically modified target cells are grown in culture and eventually grafted back onto the donor. Both the in vivo and the ex vivo approaches have their relative advantages and disadvantages, which reflect their potential applications. The biggest advantage of the in vivo approach is that it is simple and direct. In the case of skin, it takes advantage of its easy accessibility. The biggest disadvantage is that expression of the desired gene is usually transient because the gene is introduced locally and only into a limited number of target cells. Generally, stem cells have not been successfully targeted using in vivo approaches with the potential exception of hematopoiesis and liposomal gene transfer (7,8). However, it should be noted that transient expression of the desired gene may be adequate for a variety of applications such as genetic vaccination.

A plethora of different techniques has been developed in gene therapy to enhance the uptake of DNA (containing the gene of interest) (2). Initially, chemical DNA transfection has used calcium chloride and DEAE-dextran to transfer genetic material followed by the use of cationic lipids or liposomes. Because of the low transfection efficiency and the substantial in vivo toxicity of cationic lipids, other methods of gene transfer have increasingly been developed to insert DNA into cells. Viral gene transfer has exploited the capability of recombinant viruses such as retrovirus, adenovirus, or adeno-associated virus to infect cells and efficiently transport the genetic material containing the gene of interest into the cells. In addition, 3 physical techniques have been developed to introduce DNA into target tissues (2). These physical techniques are similar in that they can directly introduce DNA into the target organ such as skin. Consequently, these techniques will generally be used for in vivo approaches. Beside particle bombardment, direct injection using a syringe and a small needle has been

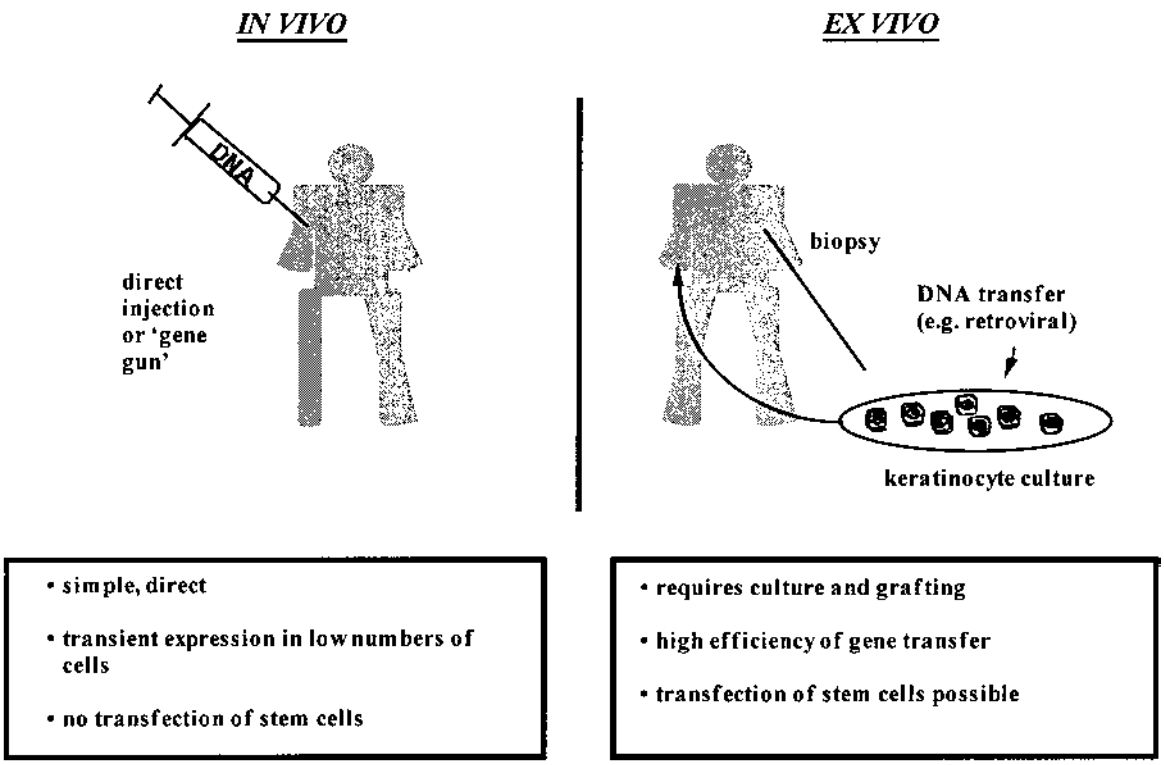

Figure 1 Schematic outline of in vivo and ex vivo gene transfer.

added as another alternative for gene transfer. Upon direct injection of DNA into skin or muscle, the DNA is taken up by the target cells and the desired genes are transiently expressed (9–12). In the case of injected muscle, the transgene can be detected for up to 1 year with some albeit low level of expression.

A variety of tissues has been successfully transfected using direct injection such as epidermis, muscle, thyroid, liver, lung, synovia, and melanoma (13–17). The exact mechanisms of how epithelial cells or muscle cells, the first tissue demonstrated to take up and express naked DNA, accomplish this is not yet clear, but there is evidence that a specialized transport process for small molecules, called potocytosis, may be involved (18,19). The existence of DNA-binding proteins on keratinocyte and muscle membranes is currently being investigated in the laboratory.

Feasibility studies have shown that plasmid DNA can also be expressed upon microinjection into the nucleus of mammalian cells (mouse fibroblast cell line LMTK$^-$), but not when injected into the cytoplasm (20). Furthermore, ultrasound has been demonstrated to allow gene transfer into mammalian cells in culture (21).

Alternative ways of introducing genetic material into the skin consist of various techniques to overcome the epidermal barrier that limits the delivery of plasmid DNA. Such methods comprise applying a pulsed electric field on topically applied plasmid DNA (22). A simpler way for gene transfer to the skin is constant puncturing using a device with oscillating fine needles (23). Topical application of plasmid DNA complexed to various cationic lipids has been demonstrated to allow gene transfer to the skin (24), although this approach has not worked for others. Topical application of plasmid DNA coding for the murine interleukin-10 gene to the scarified cornea has been shown to suppress an ongoing ocular inflammation caused by herpetic keratitis (25). The corneal route also proved effective in generating an immune response when expression plasmids coding for the herpes simplex glycoprotein B were applied (25).

The focus of this chapter is to review the progress made on genetic vaccination procedures using DNA to induce humoral and cytotoxic T cell responses.

II. BALLISTIC GENE TRANSFER

The pioneering studies by Sanford et al. demonstrated that a gene could be expressed in intact plant cells after biolistic transfer (3,4). The original gene gun as invented by Sanford and coworkers involved the placement of DNA-coated microprojectiles in an aqueous slurry on a small plastic bullet. This bullet was placed into a 22-caliber barrel in front of a gun powder cartridge. Upon firing, the cartridge propelled

a plastic bullet in the barrel until it was stopped by a solid plate. The plate had a central small hole that allowed the microprojectiles to continue their trajectory into the target tissue. Target organs or cells were placed in a chamber for bombardment. Subsequently, the gun powder device has been replaced because it created too much tissue damage and the velocity of the projectiles was not readily adjustable. Therefore, the helium device was developed as a collaboration of the Sanford and Johnston group, which used high-pressure helium that is restrained by a pierceable kapton disks. Another kapton disk, called macroprojectile, is positioned approximately 1 cm in front of the restraining membranes. The DNA-coated microprojectiles are placed in a dry state in front of this macroprojectile (Figs. 2A and B). Another centimeter in front of the macroprojectile a stopping screen is securely placed. Right in front of this stopping screen, a small orifice is put in contact with the tissue culture dish or the appropriate tissue. When the high-pressure helium gas is released by piercing the restraining membrane, a shock wave will be produced. This supersonic shock wave hits the macroprojectile, which is then launched against the stopping screen, allowing the microprojectiles to continue on into the target cells. An important technical feature is that the macroprojectiles seal off the chamber when they hit the stopping screen in order to protect the target tissue. All the single parts of the device are contained in a cylindrical chamber of the size of a soft drink can. In the chamber, where the microprojectiles are released, a vacuum is maintained in order to avoid deceleration by the air. The device is attached to a gas line and to a vacuum line, and an electric battery pack is used as power supply. This design is currently available from Biorad (PDS 1000/He; Hercules, California). Its design involves a restraining membrane that ruptures at the desired gas pressure. The distance the microprojectiles travel to the cells affects the transfection efficiency in several ways. First, especially for small particles, the velocity decreases with the travel distance. The velocity is an important variable with tissues explants, but not so with cultured cells. By placing the target cells closer to the stopping screen, the blast effect of the shock wave is increased. This effect is especially important for working with sensitive cell types. The area of bombardment increases with the distance from the stopping screen. On average, the bombarded area covers a 10-cm culture plate, when it is placed about 8 cm from the screen. The usual pressure of 25 mmHg (0.03 atm) is generally used to transfect most cultured cells. Second, studies on the plasmid delivery have determined that about 20 biologically active 6-kb plasmids can be carried on a single 0.5-mm microprojectile (26). Because commonly the microparticles are about 1 to 1.6 μm in size, considerably more copies of plasmid DNA can be loaded on 1 particle (27). However, the coating of individual particles is quite uneven. In general, tissues are bombarded with gold particles having a range of diameters from 1 to 5 μm. Tungsten particles are 3.9 μm in size. Microprojectiles are coated with DNA as described by Klein (4). Briefly, 25 μL of a gold or tungsten

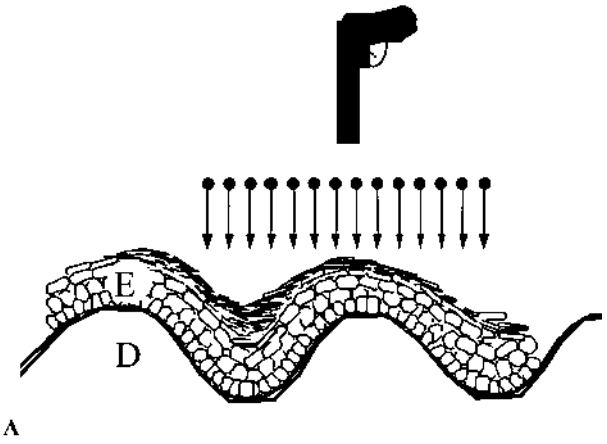

Figure 2 (A) Schematic of biolistic gene transfer. Colloidal gold particles are loaded with plasmid DNA encoding a cytokine and paramagnetic beads on the carrier disc. E, epidermis; D, dermis. (B) Detailed view of the biolistic process (see text for details). Pressure via helium gas is applied onto a burst disc causing its rupture and an acceleration of the loaded carrier disc. (C) The particle carrying disc is abruptly stopped at a stopping grid, causing a sudden release of the paramagnetic gold particles, which will subsequently hit the cells maintained in the petri culture disk at the bottom of the apparatus. Gold particles coated with paramagnetic particles and the plasmid DNA encoding human recombinant IL-7 or IL-12 will hit the tumor cells and pass the nucleus packed with chromatin. Because of the charge of the nuclear chromatin, the passing gold particles will lose most of their coated paramagnetic beads and plasmid DNA. Subsequently, cells hit are easily recovered by magnetic separation and selected for live cells, if necessary, by attachment to culture dishes. See the color insert for color version of parts (B) and (C) of this figure.

suspension are mixed with 25 μL of 2.5 M $CaCl_2$ and 5 μl of 1 M spermidine. After 10 min of incubation, the microprojectiles are pelleted and the supernatant is removed. The pellet is washed once in 70% ethanol prior to resuspension in 100% ethanol. The DNA-coated particles are spread onto macrocarrier discs and the ethanol is allowed to evaporate prior to loading the gun. Further refinement of the particle homogenicity will improve the DNA coating and will potentially lead to higher numbers of intact plasmid copies being delivered into the cells.

In the meantime, Agracetus (Madison, WI) has designed a similar device called ''Accell'' (28,29), which uses a large electrical discharge to vaporize a water droplet to create the impelling shock wave. Other adopted versions have been constructed for application in very sensitive tissues such as soft plants or seedlings as a handheld apparatus (''HandGun'' or ''Blowpipe'') (30) or airdriven (pneumatic) devices (31,32).

III. GENE TRANSFER IN MELANOMA TREATMENT

A. Clinical Background

Malignant melanoma, the most aggressive skin cancer with rapidly rising incidence over recent decades, may be curable when resected at an early stage. In its metastatic stage, melanoma is highly resistant to standard forms of therapy (e.g., surgery, chemotherapy) and causes substantial mortality (33–35).

Given the putative role of the host immune system, and particularly the cell-mediated immunity in the pathogenesis of melanoma and in containing tumor growth, many attempts have been made to amplify host antitumor immune responses, such as regional or systemic administration of a variety of biological response modifiers (e.g., BCG, immunostimulatory cytokines, IL-2, IFN-α) and the use of various vaccines consisting of intact tumor cells/cell extracts (36–39). Although these treatment modalities induced impressive tumor regression in a subset of selected patients with metastatic melanomas, overall results were disappointing. Thus, it is imperative that new approaches—therapeutically effective but low toxic—are continued to be explored.

B. Melanoma and Tumor Immunology

Melanoma is a malignant tumor of neuroectodermal origin with an increasing incidence and mortality. It needs to be detected and eliminated early because melanoma is characterized by its high resistance to conventional therapies, including surgery and chemotherapy (33,40,41). However, melanoma is supposed to be one of the most immunogenic tumors, which is demonstrated by tumor infiltrating lymphocytes (TIL) destroying melanoma cells (36,38). This may also be responsible for the occurence of spontaneous partial or complete melanoma regression and for the concomitant destruction of melanocytes in benign lesions, leading to clinical phenomena such as halo nevi, uveitis, and vitiligo in melanoma patients.

It is generally accepted that the spontaneous generation of cancer cells is a common event, and that the immune system assures a strict surveillance with the detection and elimination of these cells. To fight cancer, the idea to use the destructive power of immunologic reactions is easily visualized in autoimmune diseases and by the rejection of allografts in transplantation medicine. A number of clinical observations in human malignant melanoma suggest a particularly vigorous immune response (36,38,42). In recent years, it became more and more clear that T lymphocytes may play a critical role in antitumor immune responses and surveillance (36,43). Furthermore, CD8+ T lymphocytes derived from melanoma lesions or the peripheral blood were shown to be capable to mediate impressive tumor regressions in vivo (44,45). The availability and further characterization of such tumor-specific T cell clones in the recent years led to the identification of several melanoma-associated antigens [reviewed in (43)].

Recent progress in molecular biology (particularly recombinant DNA technology) and in gene transfer techniques have stimulated considerable interest in the development of gene therapy for treatment of cancers. One of the most popular approaches currently being developed is so-called immunogene-based therapy, which has thus far involved a large set of cloned functional genes coding for immunostimulatory cytokines and other molecules such as costimulatory molecules (B7 family), adhesion molecules (ICAM-1), chemokines, or foreign MHC antigens. Based on successful animal studies, first clinical trials of using this novel approach, particularly with cytokine gene transfer therapy to fight melanoma tumors, have been worldwide conducted over the last 6 years. Another novel approach to tumor immunotherapy is called genetic immunization, also known as DNA or polynucleotide, immunization, which takes advantage of recently cloned genes encoding melanoma-associated antigens recognized by cytotoxic T lymphocytes (CTLs). This approach aims to enhance antigen-specific immune responses of the host to their own tumors by their gene products and is still at very early clinical stage. Furthermore, first treatment approaches using oligosensenucleotides and suicide genes have been developed and are discussed. This chapter reviews these novel immunological strategies.

IV. PRECLINICAL STUDIES

A. Genetic Immunization

The promising results using ballistic transfer techniques have led to the speculation that this process of DNA transfer could be employed in the generation of antibodies and gene therapy. In this regard, DNA technology seems superior to conventional protein vaccination considering economical and logistic aspects (availability, stability, storage). The concept behind genetic immunization is a simple one: genes encoding antigens are cloned into a plasmid with an appropriate promotor, and the plasmid DNA is administrated to the vaccine recipient. The DNA is taken up by host cells and the gene is expressed. The resultant ''foreign'' protein is produced within the host cell, then processed and presented appropriately to the immune system. This may lead to the induction of a specific CTL response through the MHC class I-restricted pathway. Concurrently, proteins are released extracellularly. It is believed that this exogenously released antigen primes the induction of a humoral response, as well as a helper T lymphocyte (Th) response via MHC class II-restricted antigen presentation by antigen-presenting cells (APCs) that have taken up the foreign antigen. The mechanisms of antigen processing and presentation to T lymphocytes are only partly understood. Class I MHC molecules present on the surface of antigen-producing myocytes or keratinocytes are probably sensitized with antigenic peptides derived from the antigen that can engage the T cell receptor. Humoral immune responses may be explained following the secretion of antigen from transfected somatic cells or by the release of antigen from lytic cells (46,47). Exogenous proteins released by this fashion could be taken up and presented to CD4-positive T cells by APCs in the draining lymph nodes. The presentation of genetically produced antigens to CD8-positive CTL is less clear. Besides the scenario that transfected nonprofessional cells such as keratinocytes present the antigen directly, antigens could be taken up by APCs via phagocytosis and gain access to the MHC class I pathway leading to the induction of antigen-specific CTL-mediated immunity (48–50).

In addition to the therapeutic antigen immunstimulatory cytokines such as GM-CSF, IL-1 or IL-12 in DNA form can be used as a vaccine cocktail (51–56). At least in some cases, the coexpression of costimulatory molecules such as B7.1 has further enhanced the immune response (57). Alternatively, the immunization can be performed with the complete expression library of pathogenic organisms (58,59) leading to the expression of all proteins coded by the infectious agent's DNA independent of their immunogenicity.

Using particle bombardment, a polyclonal immune response against various pathogens such as Ebola virus (60), hepatitis B and C (61–64), herpes simplex (65,66), malaria (51,67), mycoplasma (58,68), papillomavirus (69), prions (70), rotavirus (71), and tuberculosis (72,73) has been reported. Two diseases with a major impact on socioeconomic health served as a model: influenza and HIV. Pioneering work has been performed by Johnston et al. and Liu et al., who

demonstrated protection against heterologous strains of influenza (74–79). However, therapeutic and prophylactic vaccines against HIV have represented a great challenge for researchers. Several lines of progress have been made in mice (80–85) and nonhuman primates (86–88).

Various researchers have demonstrated the dependence of the immune response from the method and route of DNA administration. More specifically, saline injections of DNA vaccines into the skin have revealed a Th1-type antibody response, whereas gene gun immunizations produced a predominantly Th2-type immune response (i.e., IgG1) (85,89,90). In addition, the nature of the antigen also seemed to influence the type of immune response (90). The elicitation of a Th1-type immune response following the biolistic approach has been achieved by codelivery of vectors expressing IL-2, IL-7, or IL-12 (85). Various other factors such as the time period between immunizations have been identified to augment the Th1-type immunity (85). Direct comparison of the epidermal vs. the intramuscular route suggested a higher rate of seroconversion and higher antibody titers following epidermal immunization (29,91). The importance of APCs for the generation of an immune response has been clearly demonstrated in chimeric mice grafted with partially MHC-matched spleen cells (49,50) and in studies where direct transfection of dendritic cells with plasmid DNA has led to an effective immunization (48). This method of generating CTLs would alleviate the need of expanding and loading dendritic cells in culture prior to reinfusion into the host. Other adjuvants such as immunstimulatory CpG motifs may offer additional benefit (92,93). Furthermore, the presence of muscle cells following intramuscular injection of plasmid DNA has not been found necessary for effective immunizations (94). In contrast, the elicitation of antibody and CTL responses was dependent on the presence of the injected skin sites for at least 48 h (94,95). Further studies have shown that injected skin, which was transplanted to naive mice up to 24 h postinjection, could elicit a primary immune response (95). Variation of the delivery concept have included biodegradable microspheres showing an enhanced immunization potential compared with naked DNA (96). Successful immunization using plasmid DNA has also been shown in the female genital tract where vaginal mucosa expressed the introduced gene producing high levels of secretory IgA antibodies that were not consistently produced by other routes (97).

This section summarizes the evolutional steps of the particle bombardment technology and attempts to present some of the experimental data that has been obtained in various cell and tissue systems. The overall importance of this relatively atraumatic technology lies in the ease of inducing an effective DNA vaccination. However, the preferential Th2-type of the immune reaction needs to be kept in mind when considering potential target diseases. Based on recent experiments where protective immunity has been achieved in various animal models, this new technology using particle bombardment can be considered a potentially useful strategy for prophylactic or therapeutic vaccination of human.

The first report of DNA immunization that serves as antigen-specific tumor vaccine was made in early 1996. Zhai et al. (98) showed that inoculation of C57BL/6 (H-2^b) mice with recombinant adenovirus (Ad2CMV)-delivered plasmid DNA coding for human gp100 tumor antigen induced both anti-gp100 antibody and CTL responses. Importantly, immunization with Ad2CMV-gp100 protected mice from subsequent challenge with murine melanoma B16 in a $CD8^+$ T cell-dependent manner, indicating that vaccination generated anti-gp100 reactive T cells that were predominantly $CD8^+$ and responsible for tumor protection. Shortly after, several studies demonstrated protective tumor immunity in the B16-C57BL/6 mouse melanoma model by human gp100 DNA inoculation (99,100), independent of the use of different gene delivery vectors such as liposome or gene gun. In most cases, tumor protection appeared to be mediated by a specific CTL response because (1) mice deficient in MHC class I but not II were not protected by DNA vaccination, and (2) adoptive transfer of lymphocytes but not serum isolated from vaccinated mice that had rejected a previous B16 challenge mediated a dose-dependent protection of nonvaccinated recipients.

One important feature of the above-cited studies is that the protective immune responses to tumor challenge was induced by using xenogeneic DNA immunization; however, it is unclear whether immune tolerance to the autoantigen can be broken by this novel vaccine. To address this point, Wagner et al. (101) constructed a murine form of gp100-encoding plasmid DNA and then administrated to DBA/2 mice (H-2^d), another animal model. They observed that intracutaneous administration of murine gp100 DNA protected more than 50% of mice against a subsequent challenge with $gp100^{high}$-expressing M3-7 melanoma cells. Depletion of CD4- and CD8-positive T lymphocytes completely abrogated the protective effect. Thus, genetic vaccination with autoantigen enables efficient induction of antigen-specific, T cell-mediated immunity resulting in antitumor reactivity in vivo.

To explore the immunotherapeutic potential of other tumor antigen-encoding genes, Steitz et al. (102) examined the effect of TRP2 DNA vaccination. They found that immunization of C57BL/6 mice with both autologous murine and xenogenic human TRP2 DNA provided significant protection against metastatic growth of B16 melanoma in lung, with the xenogene displaying more pronounced protective effect and resulting in vitiligo-like coat depigmentation as a sign of autoimmune-mediated destruction of melanocytes. Interestingly, in this study, induction of protective immunity was found associated with both TRP2-reactive antibodies and $CD8^+$ T cells.

Furthermore, immunization with recombinant adenovirus was more effective than that using gene gun. In another study by Mendiratta et al. (103), some level of protective effect of genetic immunization with murine TRP2 was also detected. In this studies, however, a combination of murine TRP2 with human gp100 genetic vaccines had a synergistic effect and caused tumor rejection in 100% of the immunized mice. This suggests that polyimmunization with a mixture of tumor differentiation antigens may be a decisive strategy for a successful therapeutic vaccination. Taken together, these preclinical

studies have shown feasibility, safety, and great potential for the use of genetic immunization against melanomas. Therefore, further studies are warranted to define factors affecting the efficacy of a genetic vaccine, such as the vector system chosen, the dose of immunization reagents, the route and/or frequency of immunizations, as well as the use of adjuvant.

B. Genetic Targeting of Melanoma Cells

Targeted vectors will be necessary for many gene therapy applications. To target retroviruses to melanomas, a single-chain variable fragment antibody (scFv) directed against the surface glycoprotein high-molecular-weight melanoma-associated antigen (HMW-MAA) was fused to to the amphotropic murine leukemia virus envelope (104). The modified viruses bound only to HMW-MAA-expressing cells. Following attachment to HMW-MAA, MMP cleavage of the envelope at the melanoma cell surface removed the scFv and an introduced proline-rich hinge, allowing infection. Complexing of targeted retroviruses special liposomes greatly increased their efficiency without affecting their target cell specificity. In a cell mixture, 40% of HMW-MAA-positive cells but less than 0.01% of HMW-MAA-negative cells were infected. The authors concluded that this approach can therefore produce efficient, targeted retroviruses suitable for in vivo gene delivery and should allow specific gene delivery to many human cell types by inclusion of different scFv and protease combinations (104).

C. Grafting Primary Human T Lymphocytes with Cancer-specific Chimeric Single-chain and 2-chain TCR

Primary human activated T lymphocytes were genetically grafted with chimeric T cell receptors (TCRs) (105). Three domain single-chain (sc-) TCRs as well as 2-chain (tc-) TCR gene constructs were derived from the MAGE-A1–specific cytotoxic human T cell (CTL) clone 82/30, and linked to the CD3-zeta signaling element. Chimeric TCR alpha and beta receptor genes were structurally designed to prevent pairing with endogenous TCR alpha and beta chains in order to prevent the generation of unpredictable immune specificities. After transduction of polyclonally activated human peripheral blood lymphocytes with retroviral vectors harboring the chimeric receptor genes, genetically engineered cells specifically recognized and responded to MAGE-A1+/HLA-A1+ cells. Importantly, each type of transduced T lymphocytes that bound specifically to peptide/MHC complexes also showed specific antitumor reactivity as well as lymphokine production. The authors concluded that genetically engineered primary human T lymphocytes expressing chimeric sc- or tc-TCR therefore hold promise for disease-specific therapies (105).

V. IMMUNOGENE-BASED THERAPY—THE CONCEPT

Cytokines exert important functions in the modulation of host immune responses and display great therapeutic potential for cancer treatment when administrated systemically at high dose. These immune modulators have certainly gained considerable attention in the development of gene-based immunotherapy. One of the first reports, from Tepper et al. (106), showed that J558L plasmocytoma cells genetically modified with IL-4 gene were rapidly rejected after inoculation in syngeneic animal host. Since then, numerous cytokines have demonstrated the ability to reduce tumorigenicity when delivered in such a mode, these include IL-1, IL-2, IL-3, IL-7, IL-12, IFN-γ, TNF-α, or GM-CSF [reviewed in (107,108]). Importantly, in many instances, cytokine gene-modified tumor cells were also capable of stimulating a systemic protective antitumor immunity because vaccination of animals with gene-modified tumor cells protected them against a subsequent challenge of parental, unmodified cells at a distant site, and in some cases, even eliminated a preexisting tumor. Protection was often associated with T cell-mediated responses, whenever analyzed. Because several studies have used poorly or nonimmunogenic tumor models, it was suggested that the protective responses elicited were solely attributed to the transduced cytokine.

The conceptional considerations of using gene transfer as a means of immune modulation include (1) gene (cytokines, chemokines) transfer into the tumor cell, resulting in sustained local release may avoid apparent systemic effects of toxicity (Fig. 3), while producing dramatic local inflammation and immune activation either by transduced cytokines/chemokines, or through second cytokine secretion from activated APC such as dendritic cell (DC) or activated $CD4^+$ T cell; and (2) introduction of genes encoding costimulatory molecules (B7 family), adhesion molecules (ICAM-1), or foreign MHC into tumor cells may render them more immunogenic in terms of immune stimulation and/or T cell activation. Two major strategies are currently being developed for gene transfer—in vivo direct introduction of gene materials into the target cells and ex vivo gene transfer into explanted cells that are then reimplanted to the patient, by virtue of recombinant viruses or via various physical methods such as gene gun or liposomes. Both approaches have been applied to cancer patients with the use of various cytokine genes or allogeneic/xenogeneic MHC class I genes.

A. Ex Vivo Cytokine Gene Transfer—Clinical Phase I/II Trials

The apparent success in animal studies has fueled considerable interest in using cytokine gene-modified cell vaccines to treat cancer patients. Various approaches were used employing autologous, allogenic, mixtures of both, and xeniogenic cell systems. Progress and problems were recently reviewed (109).

1. Cytokine Gene Transfer into Autologous Tumor Cells

We have vaccinated a total of 16 patients with advanced melanomas in 2 successive phase I trials, one using autologous IL-7-gene-transduced tumor cells in 10 patients (110) and the other using IL-12-transduced tumor cells in 6 patients (111).

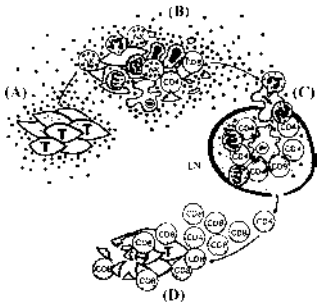

Figure 3 Rationale of cytokine gene transfer. Cytokine–gene transfer into tumor cells, causes a local secretion of cytokines (A) leading to an influx of immunological effector cells, such as T lymphocytes, NK cells, and DCs, and destruction of transduced tumor cells and inflammation (B). Destroyed tumor cells are taken up by antigen-presenting cells (APCs), which will migrate to the lymph node (LN) (C). After induction and expansion of tumor-specific T cells in the lymph node, tumor-reactive T cells of CD4- and CD8-phenotype will enter the circulation and destroy any (micro-) metastases detected at distant locations.

Immunizations were performed in weeks 1, 2, 3, and 6 by subcutaneous (s.c.) injection with total numbers of 5×10^6 to 3×10^7 modified tumor cells. In both trials, treatments were well tolerated and no major toxicity induced, except for mild fever and flulike symptoms in some patients vaccinated with IL-12-secreting tumor cells. Although no major clinical responses (complete remission: CR; and partial remission: PR) were achieved in any trial after the fourth vaccination, in IL-7-gene trial (110) 4 patients showed stable disease (SD) and 2 a mixed response (MR), whereas in IL-12 gene trial (111), 3 patients showed stabilization of the disease with 2 still alive for 10+ months. One experienced a mixed response with regression of some cutaneous metastases over 3 months. An extensive immunological evaluation was performed after the fourth vaccination. In the IL-7 gene trial, 4 patients showed increased (NK) cell activity and 7 showing an increased lymphokine activated killer (LAK) response upon vaccination (112). In 3 of 7 patients evaluated, the frequency of blood tumor-reactive CTLp increased between 2.6- and 28-fold. Of interest, all patients showing increased CTL responses were confined to clinical responders: 2 with a mixed response and 1 with a SD, implying a role of CTL in controlling tumor growth. Moreover, the magnitude of T cell responses induced was highly associated with patient's Karnofsky index and DTH reaction before vaccination, suggesting that patients with minimal tumor load or minimal residual disease may preferentially benefit from such a vaccine (110). In the IL-12 gene trial (111), vaccination induced DTH reactivity against autologous tumor cells in 2 patients, with 1 showing a heavy infiltrate of $CD4^+$ and $CD8^+$ T cells in regressing metastasis. The frequency of blood tumor-reactive CTLp was increased (up to 15-fold) in 2 patients after immunization. Furthermore, an analysis of both cohorts of patients demonstrated a significant increase of unspecfic NK and LAK activitity in patien's peripheral blood after vaccination compared with preimmunization (112).

Palmer et al. (113) conducted a phase II trial to investigate the biological effect of an autologous IL-2-secreting tumor cell vaccine introduced by retroviral gene transfer in 12 melanoma patients. Patients were treated for 1, 2, or 3 times with 10^7 modified tumor cells. No complications were observed. Three patients had stable disease for 7 to 15+ months, 1 for 17 weeks, the latter developed antitumor DTH after the first vaccination. In 4 patients, including 3 with 7 to 15+ months disease stabilization, the CTL responses to autologous tumor cells were increased upon vaccination.

Groups from Vienna, Freiburg, and Würzburg performed a phase I trial to evaluate the safety and tolerability of repeated skin injections of IL-2-transfected autologous melanoma cells into patients with advanced disease using a transferrin-mediated and adenovirus-enhanced transfection system (114). Fifteen patients received 2 to 8 skin vaccinations of either 3×10^6 (intradermal) or 1×10^7 (half intradermal, half subcutaneous) transfected melanoma cells per vaccination (secreting 140 to 17,060 biological response modifier program units of IL-$2/10^6$ cells/24 h). Overall, the vaccine was well tolerated. All patients displayed modest local reactions (erythema, induration, and pruritus) and some experienced flulike symptoms. Apart from newly appearing (4 of 14) and increasing (5 of 14) antiadenovirus and newly detectable antinuclear antibody titers (1 of 15), recipients developed de novo or exhibited increased melanoma cell-specific delayed-type hypersensitivity (DTH) reactions (8 of 15) and vitiligo (3 of 15) and showed signs of tumor regression (3 of 15). None of the patients exhibited complete or partial regressions (114).

2. Cytokine Gene Transfer into Allogeneic Tumor Cells

Obtaining sufficient number of autologous tumor cells for genetic manipulation is sometime problematic and is time consuming. Therefore, several studies have used well-characterized, allogeneic melanoma cell lines or fibroblasts as vehicles for cytokine delivery. Arienti et al. (115) and Belli et al. (116) first vaccinated 12 melanoma patients with 5 or 15×10^7 IL-2-gene-modified allogeneic melanoma cells. Three of 8 patients assessable experienced an MR. Two patients showed increased reactivity of specific CTL directed against tyrosinase and gp100 melanoma-associated antigens in postvaccination peripheral blood lymphocytes (PBL). Two additional patients showed an increased frequency of melanoma-specific CTLp in postvaccination PBL. The same group, in a subsequent study (117), tested IL-4-gene-transduced allogeneic melanoma cells in successive vaccinations in 12 melanoma patients. Both local and systemic toxicities were mild, consisting of transient fever and erythema, swelling and induration at the vaccination site. Two MR were recorded. Of 11 patients tested, antibodies and increased IFN-γ responses to allogeneic melanoma cells were documented in 2 and 7 patients, respectively, after vaccination. However, induction of a specific T

cell response to autologous tumor cells was obtained only in 1 of 6 cases studied. More recently, in a phase I/II study, Osanto et al. (118) applied an IL-2-secreting allogeneic melanoma cell line in 3 successive vaccinations (each 6×10^7 cells) to 33 melanoma patients. No major side effects were recorded. Two patients achieved complete or partial regression of subcutaneous metastases. Seven patients had protracted stabilization (4 to >46 months) of soft-tissue metastases, including 1 who developed vitiligo after vaccination. Immune responses to the vaccine could be detected in 67% of the 27 patients measured. In 2 of 5 patients, the frequency of antiautologous tumor CTLs was significantly increased by vaccination.

3. Cytokine Gene Transfer into a Mixture of Autologous and Allogeneic Tumor Cells

Differing from the above-cited studies using genetically modified tumor cells, Veelken et al. (119) in a pilot study applied IL-2-secreting allogeneic fibroblasts admixed with autologous tumor cells to 15 patients with advanced malignant tumors, including 6 melanoma patients. No major side effects were attributable to vaccines. In 2 melanoma patients, a dense infiltrate of both $CD4^+$ and $CD8^+$ T cells at vaccination sites was demonstrated. T cell lines generated from biopsies of these vaccination sites exhibited a dominant MHC class I-restricted cytotoxic activity against autologous tumor cells in vitro, and had identical V-D-J junctional sequence of TCR to that of infiltrating lymphocytes obtained from tumor sites of 1 patient. This suggests that the same CTL clone had infiltrated the tumor, circulated in the peripheral blood, and was amplified at the vaccination site (120).

At the Polish National Cancer Centers, a novel, mixed auto/allogeneic cellular melanoma vaccine modified with the IL-6 and the sIL-6R genes was designed (121). Preclinical studies in a mouse model demonstrated that the IL-6/sIL-6R-based vaccine is able to elicit efficient antitumor responses, mediated by CD8+ and NK cells, which resulted in inhibition of the tumor growth, metastases formation, and prolonged survival of the animals treated. Irradiation of vaccine cells does not only lead to their sterilization, but also causes increased secretion of exogenous IL-6 and sIL-6R. Between January 1996 and November 1999, the Polish group has vaccinated more than 100 metastatic melanoma patients (stage III and IV). Promising clinical results in 41 patients with measurable disease [22% CR (5/41) +PR (4/41), 32% SD (13/41)], and the evidence of immune responses in the vaccinated patients—including the induction of vitiligo—have prompted the group to design a prospective-randomized clinical phase III trial in stage III and IV melanoma patients, which was opened in 2000 to recruit 220 patients across Poland. The disease-free interval and 2-year overall survival will be compared with an observation arm as primary endpoints (121).

4. Cytokine Gene Transfer into Xenogeneic Tumor Cells

Based on the observation that immunodepression can be observed at the tumor site, clinical phase I clinical trials were initiated employing xenogeneic monkey fibroblasts (Vero cells) genetically engineered to produce human IL-2 (122,123). Various doses of xenogenic Vero cells were administered intratumorally in 8 patients with metastatic solid tumors. No severe adverse effect was observed. Obviously, Vero-IL-2 cells are rapidly eliminated from the organism and exogenous IL-2 mRNA could only be detected in the peripheral whole blood up to 48 h after Vero-IL-2 cell administration. A major finding of this trial concerns the 2 histological responses of 2 treated subcutaneous nodules not associated with an apparent clinical response. The relationship between local treatment and tumor regression was supported by replacement of tumor cells by inflammatory cells in regressing lesions and marked induction of T and NK cell-derived cytokines (IL-2, IL-4, IFN-γ) in posttherapeutic lesions analyzed 28 days after the start of Vero-IL-2 administration. Whether, the in vivo biological effect of immunostimulatory genes (i.e, IL-2-) may be potentiated by the xenogeneic rejection reaction needs further analysis.

B. In Vivo Cytokine Gene Transfer—The Rationale

In addition to ex vivo cytokine gene transfer, a substantial amount of work has recently focused on the direct implantation of the immunogenes in vivo. These have thus far involved the use of single cytokine or various combinations, such as cytokine/cytokine or cytokine/B7.1 costimulatory molecule. In different animal models, direct cytokine gene transfer into the tumor cells has been shown to improve the efficacy of the cytokine immunotherapy without the accompanying toxicity. Sun et al. (124) were the first to show that epidermal administration of human IL-6, TNF-α, and murine IFN-γ and IL-2 genes (by gene gun) could induce systemic antitumor effects in a renal carcinoma tumor model (Renca). Moreover, IFN-γ/IL-2 gene cotransfection resulted in eradication of preexisting tumors in 25% animals. Additional studies by Saffran et al. (125), using a murine IL-2 expression vector complexed with DMRIE/DOPE lipid, provided further evidence that intratumoral injection of IL-2 gene in Renca-bearing mice induced complete tumor regression that was mediated by $CD8^+$ T cells. Immunity was systemic, long lived, and Renca specific; further, adoptive transfer of splenocytes from treated mice protected naive mice against Renca tumor. These studies have shown an important feature for the direct in vivo gene delivery therapy: only combinations of cytokine/cytokine, cytokine/B7.1 costimulatory molecule, or cytokine/chemokine (IP-10 or MIG) could elicit a robust antitumor immunity.

1. In Vivo Cytokine Gene Transfer—Clinical Results

Results of first clinical trials at the level of feasibility studies have been appearing in the past few years, with most studies on metastatic melanomas employing the intratumoral administration of recombinant canarypox viruses—known as ALVAC—carrying cytokine genes or tumor-associated antigens (TAAs). ALVAC is an avipoxvirus derived from the licensed

Kanapox vaccine strain only capable to replicate in avian cells. IL-2-, IL-12- and GM-CSF-containing ALVAC-recombinant vaccines are currently been tested via direct intratumoral injection in clinical phase I/II studies in various European centers, including Zurich, Lausanne, and Leiden. Local inflammation, fever, cytokine serum levels, and histological infiltrate is highly dependent on inserted cytokine gene [reviewed in (126)]. In a small subset of patients, a tumor regression of injected nodules was observed without any effect on overall clinical disease progression. One of the major limitations is the strong anticanary immune response induced, which prevents repetitive administrations.

Insertion of genes or minigenes of TAAs were found to be of high scientific value in several studies. Motta and coworkers (127) have investigated the possible usefulness of ALVAC encoding the melanoma-associated Ag, Melan-A/MART-1 (MART-1). ALVAC MART-1-infected DCs were shown to express and able to process and present Melan-A/MART-1. Furthermore, infection by ALVAC induced apoptosis and cross-presentation of Ag occurred when uninfected DCs were cocultured with ALVAC MART-1-infected DCs. Uptake of apoptotic virally infected DCs by uninfected DCs, and subsequent expression of MART-1 in the latter, were verified by flow cytometry analysis, image cytometry, and confocal microscopy. Functional activity was monitored in vitro by the stimulation of a MART-1-specific cytotoxic T cell clone. The authors concluded that, overall, these data indicate that DCs infected with ALVAC may represent an efficient tool for inducing tumor-specific immunity, which can be exploited in clinical studies (127). Similarly, Chaux and colleagues (128) used a MAGE-A1-containing ALVAC construct to identify CTL epitopes by selecting naturally processed peptides. Therefore, monocyte-derived dendritic cells were infected with ALVAC containing the entire MAGE-A1 gene and were used to stimulate CD8+ T lymphocytes from the blood of individuals without cancer. Responder cell microcultures that specifically lysed autologous cells expressing MAGE-A1 were cloned using autologous stimulator cells, either transduced with a retrovirus coding for MAGE-A1 or infected with recombinant Yersinia-MAGE-A1 bacteria. The CTL clones were tested for their ability to lyse autologous cells, loaded with each a set of overlapping MAGE-A1 peptides. This strategy led to the identification of 5 new MAGE-A1 epitopes recognized by CTL clones on HLA-A3, -A28, -B53, -Cw2, and -Cw3 molecules. All these CTL clones recognized target cells expressing gene MAGE-A1 (128). A clinical evaluation of vaccination with a MAGE-1/MAGE-3 carrying ALVAC vector is presently being explored in Brussels (127).

VI. CONCLUSION AND PERSPECTIVES

Tumor immunology has made great progress in recent years. Recent animal studies have indicated that a potent protective immune response can be generated in vivo using cytokine gene-modified tumor cells. Locally secreted cytokines, such as IL-2, IL-4, IL-7, IL-12, or GM-CSF and others, from genetically modified tumor cells were shown to mediate tumor rejection and long-lived antitumor immunity. Based on these successful animal studies, various clinical protocols for the treatment of human cancer, predominantly using cytokine genemodifications, were initiated.

In summary, these clinical studies with both ex vivo and in vivo cytokine gene transfer therapy have demonstrated the feasibility, apparent safety, and low toxicity of these novel approaches. Treatment can enhance systemic antitumor cellular and/or humoral responses, or even result in objective tumor regression in a subset of patients with advanced melanoma. Because the magnitude of antitumor responses induced in patients were often correlated with a good clinical performance status, we assume these approaches would exert their most therapeutic effects in patients with low tumor loads. Nevertheless, one should keep in mind that standard therapy modalities such as chemotherapy needed decades before at least a few cancer entities could be cured. Until today, chemotherapy has not achieved a major benefit for patients with advanced malignant melanoma.
